Editor's Note

Diseases and production technologiy are often referred to by different common names in different parts of the world. The following terms have been used interchangably at the authors' discretion: pseudorabies/ Aujesky's disease, hog cholera/classical swine fever, pleurisy/pleuritis, specific pathogen free/minimal disease, and weaner pig/nursery pig.

Occasionally, outdated terms will be used when appropriate in a historical context, such as (1) mastitis-metritis-agalactia (MMA) instead of postpartum dysgalactia syndrome (PPDS) and (2) stillbirth-mummification, embryonic death-infertility (SMEDI) rather than porcine parvovirus infection.

The officially accepted name changes for bacteria have been used in the text. Some that have changed in recent years include *Actinobaculum suis* (earlier *Actinomyces suis, Eubacterium suis*, and *Corynebacterium pyogenes*) and *Brachyspira hyodysenteriae* (earlier *Serpulina hyodysenteriae* and *Treponema hyodysenteriae*).

Physical Examination, Diagnosis, and Body Systems

1 Herd Examination

Catherine E. Dewey and Barbara E. Straw

The rapid trend toward large, intensive, confinement-rearing swine production units and the emergence of herd managers with high levels of education and specialized swine experience has caused a change in the type of service required from veterinary practitioners. The hobby farmer with a few sows as a sideline enterprise may still require a veterinarian to help castrate piglets, farrow a sow, or examine a pen of ill pigs. Specialized pig farmers generally have little need for these traditional services; however, they do require the assistance of professional consultants who can help them solve complex disease, management, environmental, and production problems. Veterinarians also work with producers to ensure pork safety and the welfare of the pigs under their care.

On large swine units the veterinarian functions as part of a consulting team that may be composed of a nutritionist, engineer, marketing expert, geneticist, and accountant. Veterinarians are uniquely suited to coordinate this team, but this leadership role requires that a veterinarian must keep up-to-date with developments in a wide range of fields. The health management veterinarian must be knowledgeable enough to discuss feeding programs with a nutritionist or a ventilation problem with an engineer. The swine health management veterinarian must also be familiar with the complex biological system of a pig farm to differentiate normal and abnormal states. Finally, the swine veterinarian will use herd-based diagnostic skills to provide modern, cost-effective disease-management programs.

Often the ill-defined production problems on large swine farms are precipitated by such factors as poor housing, infectious disease, or poor management of animals or farm personnel. Educating and motivating the herdsmen rather than concentrating on disease conditions of the pig can solve many of these complex production problems. The task of helping farmers to make long-term decisions, motivating them to carry these out, and demonstrating to them the cost benefits of this advice is difficult, partly because of the long time span involved. Good record-keeping and the use of production targets are the cornerstones of such a program. Likewise, regular visits and ongoing discussions with follow-up written reports go a long way to make health management programs successful. This chapter provides an overview of the expectations of a herd health veterinarian working with a specific unit and offers charts of normal values as a reference.

THE HERD HEALTH VISIT

Understand the Producer's Goals for the Unit
The veterinarian must determine the goals of the herd's owner and manager. The recommendations for one producer who wants to eradicate disease will be different from those given to a producer who wants to develop a treatment and prevention program for the diseases in the barn.

Review Production Records
Examine monthly reproductive records for at least 12 months. Determine which parameters are below target and conduct a more thorough investigation of factors that affect these parameters. Alter target values for all parameters as the production unit changes over time. Averages for some specific parameters are listed in Table 1.1. More detail is found in Chapter 6.

Review nursery and grow/finish records for each barn filled over the past 12 months. If the unit is managed in a continuous flow basis, be sure that the values are biologically plausible. Specifically determine growth rate and compare this to the expected values in slow-, moderate-, and fast-growing pigs (Table 1.2). If the farm keeps accurate feed records, analyze the feed conversion rates and margin over feed as well. An evaluation of payment records from the packing plant will be useful to enhance the return per pig marketed.

Then determine the average and range of morbidity and mortality for each age group of pigs. Examine the causes and timing of morbidity and mortality to deter-

Table 1.1.   Country-specific sow productivity averages based on PigCHAMP records collected in 2002.

	Brazil	Canada	Mexico	Thailand	USA
Farms	119	36	78	23	105
Cull rate (%)	38.3	36.5	39.9	32.9	44.7
Death rate (%)	5.2	4.9	5.0	4.0	8.0
Nonproductive sow days	59.8	57.9	52.7	55.7	74.8
Wean-breed interval (da)	5.8	6.9	5.8	6.8	7.3
Farrowing rate (%)	81.0	79.3	82.5	81.0	71.7
Born alive/litter	10.5	10.8	10.6	9.9	10.3

Mummies/litter	0.25	0.22	0.26	0.20	0.24
Lactation length (da)	19.9	20.7	20.2	21.9	18.7

Source: Adapted from Deen and Anil (2003).

mine whether disease control programs continue to be appropriate for the unit. Identify seasonal trends in morbidity and mortality. Average nursing pig mortality rates around the world are estimated to range from 12.7 in the U.K. to 19.7% in the U.S.A. (Barnett et al. 2001). Typically, nursery barn mortality ranges from 2–5% and grower-finisher pig mortality ranges from 0.5–3%. The average sow mortality of 6% has increased over time (Abiven et al. 1998; Deen and Anil 2003). In 2002, mortality by country ranged from a low value of 3.6% in Columbia to a high of 8.0% in the United States based on PigCHAMP records (Deen and Anil 2003). There are also large farm-to-farm differences in sow mortality. In the study by Abiven et al. (1998), annual sow mortality ranged from 0–20%. See Chapter 63 for more details on sow culling and mortality.

Farms that have both stalls and pens for sow housing have a lower culling rate due to reproductive failure, lameness, age, death, and euthanasia than farms that have only pens (Paterson et al. 1997, cited by Barnett et al. 2001). Sows housed in pens for a portion of gestation are expected to have reduced farrowing time (Ferket and Hacker 1985), reduced lameness in gilts (Hale et al. 1984), and less joint damage (Fredeen and Sather 1978).

To complete the record analyses, identify problems and prioritize areas according to those with most economic concern. Make lists of short-term and long-term goals. Record questions that arise from the record analyses to be reviewed during the herd visit. Make copies of reports in either table for graph form. Produce a summary of the findings to be included in the final herd report.

Review Production Flow

Draw a detailed map of the whole production facility or system. For a farrow-to-finish facility this will be the details for one site. If the production system is multisite, include all sites in your production map. To the map add information such as number of barns, number of rooms per barn, number of pens per room, and size of each pen. Finally add the age and weight of pigs as they enter and exit the pens. The production records will provide expected values for production flow, such as number of sows, pigs weaned per litter, growth rate, and mortality rate. Using this information, determine the maximum number of pigs each pen, room, barn, and site will accommodate. Together with the facility design, determine if there is sufficient space for the anticipated production.

The pen area required per pig is determined by the maximum size and number of pigs housed in the pen (Table 1.3). If pigs are not provided adequate space, growth rate will be reduced as overcrowding begins. To enhance the use of space, some producers over stock a pen with lightweight pigs when they first arrive in a facility and then move 1/4 to 1/3 of the pigs to another pen as they grow. Another option for finisher pigs is to market the heaviest pigs at a slightly lower weight, thus alleviating the potential for overcrowding. A space savings of 3% will be gained if the first group of animals is marketed at 5 kg below the typical weight (Gonyou and Stricklin 1998). An allometric measurement of space allowance takes into consideration the floor area required by the pig over a wide range of weights. Research has shown that using the equation area = k × (body weight) 0.667, where *area* is measured in m^2 and *body weight* in kg, if the coefficient *k* is maintained at 0.33, the pigs will not be overcrowded. More detail about the impact of space on productivity is found in Chapter 64.

The area recommended for sows varies widely from 1.4 to 3.6 m^2/pig due to different housing designs and expectations determined by country (English et al. 1982; Jensen 1984; Barnett et al. 2001). When space is insufficient, sows have reduced reproductive performance and show a chronic stress response. There is a reproductive advantage to providing 3 m^2/pig over 2 m^2/pig (Jensen 1984). Outdoor housed sows will each require 1.1 m^2 (12.8 ft2) on a slab area, 0.7 m^2 (7.7 ft2) in a shed for sleeping and an additional space for cooling in a mud hole or a sprinkler area.

When pigs are housed in large groups, there is additional free space compared to housing smaller groups with the same area per pig (Barnett et al. 2001). If sows are kept in relatively small groups, they need 2.4 to 3.6

Table 1.2. Weights and daily gain by age and relative growth rate.

Age	Slow				Moderate				Ideal			
	Weight		Daily Gain in the Previous 20 Days		Weight		Daily Gain in the Previous 20 Days		Weight		Daily Gain in the Previous 20 Days

m²/pig. This is important with respect to aggression in sows. If sows are provided sufficient space, group size has little impact on aggression. However, if space is restricted, aggression increases as group size increases. Similarly, rectangular pens are essential if space is restricted; otherwise, square pens will suffice. If gilts are provided with only 1.4 m²/pig the pen must also include full stalls for feeding.

Providing individual feeding stalls within a large pen has the advantage of allowing both individualized feeding and a safe refuge for subordinate sows (Barnett et al. 2001). Partial stalls also provide similar advantages. The benefit is maximized if the sows are fed in these partial stalls. Another alternative is to build a maze or a series of partitions within the large pen to provide escape zones and sleeping areas for small social groups of sows.

Almost all sows in Europe, the U.K., North America, and Australia farrow in crates (Barnett et al. 2001). Farrowing crates are primarily used to reduce preweaning mortality rates by reducing the sow's ability to lie down quickly thereby reducing crushing. Other features include reducing the space used by the piglet, providing a creep area with supplemental heat and draft reduction and slatted floors to improve hygiene. A farrowing crate area will encompass a total width of 1.8 m and a length of 2.4 m. The slotted area of the floor of a farrowing pen should not exceed 10 mm otherwise newborn pigs will get their feet caught in the hole (English et al. 1982). The back gate of the farrowing crate should be at least 750 mm wide to enable personnel to assist the sow during farrowing (English et al. 1982). The creep area will be offset to allow 0.8 m wide on the side with the supplementary heat and 0.3 m wide on the other side for the pigs to nurse. Sow pens used for farrowing tend to be 6–10 m², whereas crates are typically 4 m².

Outdoor housing is used for one quarter of sows living in the U.K. and New Zealand, 2–4% of sows in

Denmark, 7–9% of sows in France and 5–6% of sows in Australia (Barnett et al. 2001). Welfare issues of concern for these sows include health and disease, predation, access to food and water, protection against weather extremes, mutilations, use of electric fences, paddock rotation, and stocking density. To preserve pastures, producers may use nose rings, which discourage foraging. Huts used as shelter in the cold months must provide 1.3 m²/sow so that timid sows will enter the shelter. Paddocks must provide shelter from wind and well-drained soil. In Australia, outdoor housing is limited to areas with few days over 30°C and limited rainfall. Sows housed outdoors have a higher variation in back fat, a longer outside claw length and a lower farrowing rate (Barnett et al. 2001).

Access to Feed and Water

Onto the map of the facility, insert number and type of feeders and waterers. Determine whether there are sufficient feeders and waterers for the maximum number and size of pig expected to live in the pen.

Pigs consume 10% of their own body weight in water per day, and more in hot weather. One liter of water weighs 1 kg. Therefore, a 100 kg pig will consume at least 10 liters of water per day (Table 1.4). This is important to determine access to water and for water medication. For more information on medication, see Chapter 71. Pigs drink 80% of their water in conjunction to when they feed. Also, pigs prefer to eat and drink at daybreak, and then off and on throughout the day and the evening, but spend the night sleeping. Nursery pigs eat more frequently than grower pigs, which in turn eat more frequently than finisher pigs. If water or feeder access is limited, submissive pigs will be forced to eat and drink during the night. When access to water is insufficient, there is an increase in aggression (see Chapter 64),

Table 1.4.   Recommended water requirements, water flow rate, and feeder space per pig by phase of production.

| | Water Requirements | | Feeder Space/Pig |
| | l/day | l/minute | mm (inches) |
Restricted feed			
Gestating sows	12–25	2	457–610 (18–24)
Lactating sow	10–30	2	
Boar	20	2	
Nursing	1	0.3	
Nursery	2.8	1	254 (10)
Grower	7–20	1.4	260 (10)
Finish	10–20	1.7	330 (13)
Ad libitum			
Nursery	2.8	1	60 (2.3)
Grower	7–20	1.4	65 (2.5)
Finish	10–20	1.7	76 (3)

Source: Adapted from Baxter (1984); Patience and Thacker (1989); *Swine Care Handbook,* 2003; Muirhead and Alexander (1997).

weight gain is decreased because feed intake is decreased, and there is an increase in the variation in pig body weight by age (see Chapter 66). There should be no more than 4 pigs for each feeder space in an ad libitum feed management system. One water nipple can accommodate 10 to 15 pigs. The waterers and feeders must be spaced adequately so that a pig drinking from one water nipple cannot obstruct the ability of another pig to get to a second water nipple. If water is provided in a trough, there must be 300 mm per 20 finisher pigs or 15 sows (Muirhead and Alexander 1997). Water bowls accommodate 17 to 20 pigs. Farrowing crates need to be equipped with water nipples or bowls for both the sow and the piglets.

Feeding dry sows three times per day is associated with lower sow mortality than feeding twice a day, which in turn was associated with lower mortality than feeding once a day (Abiven et al. 1998). Farms feeding dry meal or wet meal had lower mortality than those feeding pelleted ration, likely due to the decreased occurrence of torsions. Dry sows are typically fed 1.5 times their maintenance requirements which is approximately 0.6 of their ad libitum feed intake (Barnett et al. 2001).

Electronic feeders typically accommodate 40 sows per unit (Barnett et al. 2001). Provided the feeder design is appropriate to discourage vulva biting, these feeders work well in stable groups of sows. In dynamic groups, aggression may continue to be a problem because feeding order cannot be established. This may reduce reproductive performance. Group feeding sows in pens continues to provide an unfair advantage to dominant sows who gain significantly more weight during gestation than submissive sows (Bourns and Edwards 1994).

Temperature

Upper and lower critical temperature is dependent on the floor type, amount of feed provided to pigs, live weight, number of animals in the pen, drafts (or wind speed for outdoor pigs), rain, ability to gain shelter, and—for sows—stage of pregnancy (see Table 1.5). Typically, dry sows are fed 1.5 times their maintenance requirements. The lower critical limit is the temperature below which a pig will use extra feed to maintain its body temperature (Barnett et al. 2001). Pigs provided with straw in the winter months will tolerate a lower temperature. For every 5°C below the lower critical temperature, sows will need to be fed an extra 250 g feed/day. For every 1°C below the lower critical temperature for grower/finisher pigs, each pig will have to consume an extra 3.3 kg of feed to reach market weight.

Pigs held above the upper critical temperature will experience decreased feed intake. For sows, this subsequently results in lower reproductive performance and lower milk production. Boars and sows kept at 23–27°C will have reduced fertility (English et al. 1982). Pigs held above the upper critical temperature should be provided

with drip coolers for indoor pigs and wallows for outdoor pigs. If straw is provided, the upper critical temperature will be substantially lower than if pigs sleep on a concrete floor.

Ideally, sows will be kept between 21 and 22°C. Newborn pigs will have a creep area maintained at 28–30 °C. Newly weaned pigs should be kept at 26–28°C depending on their age and size at weaning. Temperature is gradually reduced each week so that they are at 22°C when they are moved to the grower barn (Curtis 1983). Grower/finisher pigs prefer to be kept in 15–20°C. It is essential that temperature does not fluctuate rapidly over time.

Begin the Herd Visit with History-Taking

Ask the manager/owner about his/her concerns. This will ensure that these problem areas are addressed during your discussion and as you walk through the barn. Follow this with a complete history-taking, including the topics covered in the following sections.

Herd Security. Were any animals brought onto the farm recently? What are the quarantine and isolation procedures for new stock? Are there one or more sources of breeding stock, nursery, or grower pigs? What steps are taken to control human and animal traffic? How are animals loaded out of the farm? Are livestock trucks clean on arrival? Take note of the biosecurity protocols used for human traffic. (See Chapter 68 for a complete description of biosecurity concerns.)

Table 1.5. Lower and upper critical temperatures (°C) by size of pig based on feeding level and flooring type.

		Maintenance Units of Feed[a]					
		1	2	3	1	2	3

[a]Feed provided at 1, 2, or 3 times maintenance.
[b]Lower critical temperature.
[c]Upper critical temperature.
NA = not available.

Genetics

What is the genetic composition of the herd? What procedures are used to guarantee that proper matings will take place? What selection criteria are used for boars, gilts, and sows? Is there a family or breed relationship between animals experiencing the disease?

Breeding Management. In units using natural mating, what is the boar-to-sow ratio? How frequently are individual boars used? Does mating occur in a pen or is hand mating used? With hand mating, what sanitary precautions are taken between boars? In units using artificial insemination, what percent of females are bred this way? Is semen purchased or collected on farm? What are the handling and storage procedures for the semen? How is estrus detection done? How frequently and at what times are sows and gilts mated? When and how is pregnancy diagnosis done? What is the conception rate for sows and gilts? What is the farrowing rate for sows and gilts? How many females return to estrus 21 days after mating and at other intervals? Have abortions been noted?

Farrowing Performance. Are sows washed prior to entering the farrowing area? Are sows induced to farrow and if so, what is the protocol? How frequently do sows require assistance to farrow? What procedure is used for cross-fostering? What are the size of litters and the total born alive, mummies, and stillbirths? What do piglets weigh at birth and weaning? What is the average and range in lactation length? How often are sows weaned?

Mortality. What is the current state of mortality on the farm? If mortality was not fully described in the records, ask questions relating to the historical pattern of mortality. What is the average and range in mortality by phase of production. Within each phase, when does the mortality occur? Is there a seasonal pattern to mortality? What are the clinical observations in pigs just before they die? What is the appearance of the dead pig? Have these types of mortalities occurred previously? What has been done, if anything, to determine the cause of these mortalities?

Medications and Immunizations. What vaccines are used routinely in the herd? What animals are vaccinated and at what time? Is there a routine worming program for sows, boars, and growing pigs? How are external parasites controlled? What medications are used in the feed? Are drugs used at a growth-promoting or therapeutic level? Is drug usage rotated? What injectable treatments are given to sick pigs? Has the producer completed and maintained a quality assurance program? Are there written standard vaccination and treatment protocols displayed as a reference for all employees?

Feed. Is feed grown on the farm or purchased? Where and how is feed mixing done? What nutrient composition is intended for each class of pig? How is feed stored and delivered to the pigs? What quantity of feed is given to limit-fed pigs, and how is the feed measured?

Disease Outbreak. What was the progression of signs within a pig? How old was the pig when signs started? How long did illness persist? Is recovery complete or is pig unthrifty? In the group affected, what is the morbidity and mortality? Has treatment been used, and to what effect? What is the course of disease within the herd? Did the disease start with an explosive outbreak or was it insidious? What animals were originally affected? What animals has disease spread to? Did the initial disease picture differ from the later signs? Is disease becoming more or less severe? Are any other animals besides pigs affected? What is the distribution of affected animals? Is disease sporadic or endemic? Are affected animals grouped by litter, pen, or building? Is one sex affected to a greater extent than the other? Were any changes in management made prior to the outbreak of the disease? Has this problem occurred before on this farm?

Disease Affecting Pigs in Litters. Are whole litters affected, or is incidence sporadic within litters? Are the biggest or smallest pigs affected? Are litters of gilts or of sows more frequently or severely affected?

"Walk Through" the Barns

It is essential to walk through the barns to observe the pigs for clinical signs of disease, abnormal behaviors, availability of space, water, and feed and also to assess the environment/ventilation. Visit all phases of production even if the producer does not have specific concerns in all areas.

Be sure to talk with all farm employees. Each person will have his/her own concerns and observations. As the veterinarian you can address these problems and encourage the employees to reach their potential. Employees will ask you to examine individual pigs showing specific clinical problems. Although swine health management deals with the group of animals, many of these individuals provide an excellent measurement of the whole. These discussions provide an opportunity to review treatment protocols and euthanasia decisions. The welfare of specific pigs and the decisions about pigs in the hospital pen will be discussed during the walkthrough. People working in the barn need to deal with individual pigs to raise the welfare in the barn.

Details of clinical examination are outlined in the systems chapters. Observe the body condition of the sows and compare this to the descriptions in Table 1.6 and Figure 1.1. Normal values for temperature, respiration, and heart rate are outlined in Table 1.7. Using Table 1.8 as a guide, determine the state of management and the health of the pigs in the farrowing room with undesirable physical problems. Discuss the treatment and

Table 1.6. Body condition evaluation.

Numerical Score	Pelvic Bones (Ilium, Ischium) Tail Head	Loin	Vertebrae	Ribs	Inches (mm) of Backfat
1	Pelvic bones very prominent. Deep cavity around the tail head.	Loin very narrow. Sharp edge on transverse spinal process. Flank very hollow.	Prominent and sharp throughout the length of the backbone.	Individual ribs very prominent.	0.5 (13) or less
2	Pelvic bones obvious but some slight cover. Cavity around tail head.	Loin narrow. Only very slight cover to edge of transverse spinal process. Flank rather hollow.	Prominent.	Rib cage less apparent. Difficult to see individual ribs.	0.6 (15)
3	Pelvic bones covered.	Edge of transverse spinal processes covered and rounded.	Visible over the shoulder. Some cover farther back.	Covered but can be felt.	0.7 (17)
4	Pelvic bones only felt with firm pressure. No cavity around tail.	Edge of transverse spinal processes felt only with firm pressure.	Felt only with firm pressure.	Rib cage not visible. Very difficult to feel any ribs.	0.8 (20)
5	Pelvic bones impossible to feel. Root of tail set deep in surrounding fat.	Impossible to feel bones. Flank full and rounded.	Impossible to feel vertebrae.	Not possible to feel ribs.	0.9 (23)
6	Pelvic bones impossible to feel. Folds of fat obscure the vulva in sows.	Thick fat cover.	Midline appears as a slight hollow between rolls of fat.	Thick fat cover.	1.0 (25)

Table 1.7. Temperature and respiration and heart rate of pigs of different ages.

Age of Pig	Rectal Temperature (Range ± 0.30°C, 0.5°F) °C	°F	Respiratory Rate (Breaths/Min)	Heart Rate (Beats/Min)
Newborn	39.0	102.2	50–60	200–250
1 hr	36.8	98.3		
12 hr	38.0	100.4		
24 hr	38.6	101.5		
Unweaned piglet	39.2	102.6		
Weaned piglet (20–40 lb) (9–18 kg)	39.3	102.7	25–40	90–100
Growing pig (60–100 lb) (27–45 kg)	39.0	102.3	30–40	80–90
Finishing pig (100–200 lb) (45–90 kg)	38.8	101.8	25–35	75–85
Sow in gestation	38.7	101.7	13–18	70–80
Sow				
24 hr prepartum	38.7	101.7	35–45	
12 hr prepartum	38.9	102.0	75–85	
6 hr prepartum	39.0	102.2	95–105	
Birth of first pig	39.4	102.9	35–45	
12 hr postpartum	39.7	103.5	20–30	
24 hr postpartum	40.0	104.0	15–22	
1 week postpartum until weaning	39.3	102.7		
1 day postweaning	38.6	101.5		
Boar	38.4	101.1	13–18	70–80

prevention of these problems with the employees responsible for that area of the production unit. Examine the nursery, grower, and finisher pigs. Specifically determine if they are managed in an all-in, all-out manner and that the room or barn is properly cleaned and disinfected between groups and allowed to dry for a few days before refilling. The pigs should not vary in body weight by age by more than 10%. There should be no indications of clinical disease, such as skin lesions, diarrhea, coughing, or sneezing. Pigs should not be exhibiting vices and should be dunging in the appropriate area. Commonly observed problems include high pig density (refer to Table 1.3); large variation in body weight; runts or poor-doing pigs; coughing, sneezing, or nasal dis-

Table 1.8. Examination of pigs in the farrowing area.

Characteristic	Desirable	Undesirable
Sows		
Physical condition		
Body condition	Normal weight.	Thin, fat, or obese.
Cleanliness	Sows have been thoroughly washed.	Sows are dirty with caked mud and manure.
Mammary glands	At least 12 prominent, evenly spaced nipples.	Inverted, juvenile, or overcrowded teats; glands hot, red, swollen, painful; abnormal milk.
Vulval discharges	Watery, clear-to-whitish fluid.	Purulent, bloody, or foul-smelling discharge.
Skin	Unblemished. Pink in unpigmented areas.	Burns from the heat lamp. Abrasions or calluses. Anemia. Hyperkeratinization.
Feet and legs	Normal stance and movement.	Splaylegged, foot lesions, difficulty getting up or lying down.
Feed		
Amount	4–6 lb (2–2.5 kg), plus 1 lb (0.5 kg) for each pig in the litter.	Less than the desired level.
Feeder condition	Clean, large capacity, and easily accessible.	Dirty, broken, containing old or moldy feed.
Water	Unlimited supply of fresh water.	Fouled water, inadequate flow or inaccessible.
Environment		
Temperature	Between 60°F and 75°F (16–24°C).	Too cold or too hot.
Floor design	Proper spacing between slats, good traction, nonabrasive.	Slippery material. Sharp edges on slats, uneven slats. Slots sized to trap teats and dewclaws.
Floor condition	Clean and dry.	Dirty, wet, cracked or broken.
Crate design	Right size for sow. Permits good exposure of underline.	Too large, allowing sows to flop over and crush pigs. Bottom bar hinders nursing.
Light	12–14 hr daily at 200 lux.	Too dark.
Baby Pigs		
Physical condition		
Birth weight	Average of 3 lb (1.3 kg) or greater.	Average is less than 3 lb (1.3 kg).
Litter sizes	Litters are matched to rearing capacity of sows.	Wide variation in litter size, with 20% or more containing 8 or fewer pigs.
Weights within the litter	Less than 1 lb (0.5 kg) difference between the largest and smallest pigs.	More than 1 lb (0.5 kg) difference between the largest and smallest pigs.
Skin	Unblemished. Pink in unpigmented areas.	Knee abrasions, facial lacerations, teat necrosis, anemia, exudative epidermitis.
Locomotion	Normal gait and anatomy.	Splayleg, swollen joints, foot lesions, lameness.
Infectious disease	None.	Diarrhea, sneezing, unthriftiness.
Teeth	Clipped on day-old pigs. Gums pink and healthy.	Teeth not clipped. Infected gums.
Tails	Clipped neatly or left long.	Clipped tails are swollen, red, or infected.
Feed		
Feed	Fresh creep feed given daily.	None or stale feed offered.
Water	Fresh water easily accessible to piglets.	None, inaccessible, or foul water.
Environment		
Temperature	Creep area provided with temperature of 85–90°F (29–32°C).	Piling or lying next to the sow. Pigs too hot and avoiding the heat lamp.
Drafts	Air evenly distributed throughout the building.	Incoming air moving directly onto litters of pigs.
Floor design	Good traction for pigs in the nursing area. Uniform spacing of slats. Nonabrasive surface.	Slippery flooring material. Slats laid so that slot length is perpendicular to the sow.
Floor condition	Clean, dry; bedded if appropriate.	Dirty, wet, cracked, broken, or exposed aggregate.
Management		
Flow	All-in/all-out animal flow.	Continuous farrowing.
Building use	All farrowings occur within a few days.	Farrowings are spread out over 1 or 2 weeks.
Farrowing schedule	Pigs weaned at the same time.	Pigs are weaned at various times and ages.
Sanitation		
Cleanliness	Excess manure and afterbirth removed daily	Accumulation of manure in the farrowing crates. Wet bedding. Poor fly control.
"Downtime"	Building is empty for a few days between farrowing batches.	New batch added the same day or the day after the previous batch was weaned.
Washing procedures	High-pressure washer is used to remove all organic material. Porous surfaces sealed or disinfected.	Manure left in cracks and corners. Accumulations of dust and cobwebs.
1.1. *Sows just after weaning. Using the criteria in Table 1.6, from left to right their body condition scores are 1, 3, 4, and 6.*

charge; anemia; skin abrasions; diarrhea; rectal prolapse or stricture; hernias; hematomas of the ears; umbilical sucking; and belly nosing. If the environment is not adequate, some problems that may be observed include bitten tails or ears, dunging in the eating or sleeping areas, pigs piling if it is too cold, or pigs panting and lying in the manure if it is too hot. Specific environmental problems include rough or abrasive floor surface or broken slats, inadequate feeder space or plugged feeders, inadequate waterers, plugged nipples, dirty water bowls, inadequate cleaning, manure in the corners of the pen and under the feeders, and cold and drafty barns.

Food Safety
Discuss the medications used in the feed and water, and as injectables to ensure these are essential (see Chapter 71 for more specifics on medications). Arrange to update the Quality Assurance program on the farm to ensure the wholesomeness of the pork being produced. Set up a drug recording and animal tracking system for the unit. Create summaries of standardized treatment plans and vaccination protocols that will be displayed in the farm office. These ensure that all employees follow the same protocols. If feed is mixed on the farm, create similar protocols for all feed that is to be manufactured.

Disease Status
The disease status of the farm can be measured by clinical signs, postmortem examination of dead pigs or those that you cull during your visit, vaccination use, slaughter-check examinations, and serological profiling. Use all or some of these to understand the diseases that are present and those that are causing problems on the farm. Postmortem evaluations must be conducted on at least three pigs during a disease outbreak to ensure that the disease process affecting the group is identified. Untreated pigs in the early phases of the disease provide ideal samples. Live animals must be submitted to diagnose enteric illness. More details about disease investigation can be found in other chapters.

Review the disease control measures being used, including vaccinations, antibiotic use, early weaning, multisite production and gilt introductions. Ensure that all vaccinations and antibiotics are essential. Alter the disease control measures if diseases are not being properly controlled.

Serial serological sampling helps determine the epidemiology of the disease within the herd. Blood samples can be taken from 10 pigs in each age category to determine when passive immunity wanes and active immunity is present, or pigs can be individually ear-tagged and then followed over time. Chapter 10 provides more detail about interpretation of tests at the pig and herd levels.

Biosecurity
Determine the biosecurity of the farm with respect to the presence of birds, rodents, and other animal species. Review the movement and access of the facility to people, trucks, incoming feed and pig movement. Identify where biosecurity can be improved, keeping in mind the realistic risks of the current biosecurity system. For detailed information on biosecurity, see Chapter 68.

Welfare
Has the producer enrolled in a welfare assurance program? If there is a formal program in your area, such as the Swine Welfare Assurance Program[SM] available, encourage the producer to participate in the program (Johnson 2004). If such a program does not exist, determine the welfare of the farm and discuss areas for improvement. The specific areas of focus in the SWAP[SM] program include herd health and nutrition, caretaker training, animal observation, body condition scoring, euthanasia, handling and movement, facilities, emergency support, and continuing assessment and education.

Goals

Set short-term goals to address the concerns of the personnel and to work on conditions of immediate economic importance. Discuss long-term goals, including the improvement of production parameters, herd disease status, and personnel issues.

Begin the collection of data for production parameters of importance. Examples include mortality tallies, movement of pigs in and out of barns, and weighing a sample of pigs in and out of the barn.

In large facilities, it is worthwhile to conduct field trials to determine the expected improvements to changes in management or disease control prior to making the change in the whole system.

Follow-up

Schedule a time for a return visit, plan what changes are to be made between now and then, identify the specific outcomes expected, and arrange for further sample collection (i.e., slaughter check or submission of dead pigs to postmortem). Provide a written report summarizing both the successes and problems observed during the review of the records and the herd visit. Outline the expected changes in the form of a checklist so that the producer can refer to these easily. Review this letter prior to the subsequent herd visit.

BLOOD SAMPLING

Blood collection in swine is difficult because of the inaccessibility of good veins and arteries. Many different techniques using various sites have been described. Some of these techniques have some role in experimental work with pigs, but if the practicing veterinarian is to sample blood of a number of pigs with some degree of speed and collect a reasonable volume, the technique of sampling from the jugular vein or the anterior vena cava must be mastered (Brown 1979; Muirhead 1981). Alternatively, some veterinarians prefer to use the orbital sinus for routine blood collection. Appropriate blood collection techniques for various sizes of pig are given in Table 1.9.

Anterior Vena Cava

Depending on the size of the pig, it is restrained either standing by means of a hog snare (Figure 1.2) or manually by holding the front legs (Figure 1.3). The position of the standing pig is important; the head should be raised, the body straight, and the front legs well back. In the standing pig, the jugular groove is traced to its caudal limit just anterior to the thoracic inlet. The needle is inserted at the caudal end of the jugular groove and directed dorsally and somewhat caudomedially along an imaginary line that passes through the top of the opposite shoulder. The location of some of the major veins are shown in Figure 1.4. When drawing blood samples from either the anterior vena cava or the jugular vein, the blood is taken from the right side, since the right vagus nerve provides less innervation to the heart and diaphragm than the left vagus. If the vagus nerve is accidentally punctured, the pig may show dyspnea, cyanosis, and convulsive struggling.

Jugular Vein

The pig is restrained in a standing position as for sampling from the anterior vena cava. The needle is inserted in the jugular groove about 5 cm cranial to the thoracic inlet. The needle is directed dorsally and slightly medially.

Ear Veins

The ear veins are raised by slapping the ear and maintained by a rubber band around the base (Figure 1.5). Venipuncture is done with a quick thrusting stab to prevent the vein from rolling away from the needle. A syringe should be used, since vacutainer collection usually results in collapse of the vein. Alternatively, the ventral ear vein may be incised with a scalpel cut made into and parallel to the vein and the blood collected in a tube as it drips from the incision.

Tail Vessels

Collection from tail vessels is possible only in mature pigs whose tails have not been docked. The tail is held vertically and the needle directed toward the point of junction of the tail with the body (Muirhead 1981).

Table 1.9.   Blood collection in swine.

Site	Type of Pig	Needle Size	Quantity	Comments
Anterior vena cava	Up to 100 lb (45 kg)	20 g. 1.5 in. (38 mm)	Unlimited	Danger of damaging the vagus nerve. Vacutainer usable.
	100–250 lb (45–133 kg)	18 g. 2.5 in. (65 mm)		
	Adult	16 g. 3.5 in. (90 mm)		
Jugular vein	Any age	20 g. 1.5 in. (38 mm)	Unlimited	More difficult to do. Vacutainer usable.
Ear veins	Adult pigs	20 g. 1 in. (25 mm); scalpel blade	1–2 mL	Possible hematoma; possible contaminated sample.
Tail	Adult pigs	20 g. 1 in. (25 mm)	5–10 mL	Requires practice. Vacutainer usable.
Orbital sinus	Up to 40 lb (18 kg)	20 g. 1 in. (25 mm)	5–10 mL	Slow. Unaesthetic. Possible postcollection orbital hemorrhage and pressure on the globe.
	40–120 lb (18–54 kg)	16 g. 1.5 in. (38 mm)		
	120 lb–adult (54+ kg)	14 g. 1.5 in. (38 mm)		
1.2. *Proper restraint for blood sampling from a standing pig. The lower circle indicates the site for sampling from the anterior vena cana; the upper circle indicates the site for sampling from the jugular vein.*

1.4. *Location of some of the major veins in the pig in relation to the skeleton.*
1.5. *Ear veins of a pig raised by rubber band placed at the base of the ear.*

1.3. *Method of restraining pigs weighing less than 20 kg for blood sampling from the anterior vena cava (circle). Location of the cephalic vein is indicated by the dashed line.*

Orbital Venous Sinus

Large pigs are restrained by snare and smaller ones held manually, with care to restrain the snout securely. A needle is placed at the medial canthus of the eye just inside the nictitating membrane and advanced medially and slightly anterioventrally until it punctures the venous sinus. Blood is allowed to drip out of the needle and is collected in an open-top tube (Huhn et al. 1969).

Cephalic Vein

Blood may be withdrawn from the cephalic vein by restraining the pig on its back with the front legs stretched backward and a little outward from the body. The vein is visible under the skin (see Figure 1.4) and is raised with digital pressure (Tumbleson et al. 1968; Sankari 1983).

Miscellaneous Methods

Cardiac puncture (Calvert et al. 1977) and femoral venipuncture techniques (Brown et al. 1978) have been described.

Indwelling Catheters

Indwelling catheters have been used for research that requires repeated blood sampling or minimal excitement of the pig. Investigators have described techniques for placing catheters in the femoral artery and vein (Weirich et al. 1970; Jackson et al. 1972), subcutaneous ab-

dominal vein and middle sacral artery (Witzel et al. 1973), ear vein (Grün et al. 1973; Brussow et al. 1981), jugular vein (Brown et al. 1973; Wingfield et al. 1974; Ford and Maurer 1978), and uterine vein (Rodriquez and Kunavongkrit 1983).

SAMPLE COLLECTION

Feces are best collected directly from the rectum by hand using a disposable glove. The sample can be kept in the glove after inversion. Urine is collected by catching a midstream sample. Females can be catheterized with the aid of an otoscope or speculum. In barrows it is not possible to exteriorize the penis because of adhesions between the penis and sheath. Procedures for tonsilar swabbing, biopsy, and scraping have been described by Mengeling et al. (1992) and Brown et al. (1995). Briefly, the pig is sedated using a drug with analgesic properties, the jaw is held open with a speculum, and one person provides illumination while another person takes the tonsilar sample. Scraping is best accomplished with a long-handled spoon that has had the bowl sharpened.

2 Immune System

James A. Roth and Eileen L. Thacker

The immune system is comprised of a variety of components that cooperate to defend the host against infectious agents. These components generally can be divided into innate (or nonspecific) immune defense mechanisms and adaptive (or acquired) immune defense mechanisms. The innate defense mechanisms are not antigen specific. They are present in a normal animal and do not require previous exposure to antigen, and they are capable of responding almost immediately to an infectious agent. The major components of the innate immune system are complement, antimicrobial peptides, phagocytic cells (macrophages, neutrophils, and eosinophils), natural killer (NK) cells, and some types of interferon. These components are very important in controlling an infection during the first few days of an initial exposure to an agent. The innate immune system controls infection until the adaptive immune system can be activated and it is important in directing the immune system to produce both antibody and cell-mediated immune responses.

B and T lymphocytes and their products are the components of the adaptive immune response system. This antigen-driven system requires 2–3 weeks to reach optimal functional capacity after the first exposure to antigen. Upon second exposure to antigen, the specific immune response system reaches optimal activity much more rapidly due to the anamnestic, or memory, response. A major mechanism by which B and T lymphocytes enhance resistance to disease is activating the innate defense mechanisms (phagocytic cells, NK cells, and complement) and increasing their efficiency.

Providing immunity at mucosal surfaces and to the newborn piglet are especially difficult challenges for the immune system and for the swine producer. The nature of these special problems are discussed as well as generalities about vaccination to improve immunity at mucosal surfaces and in newborn pigs.

If an animal is immunosuppressed due to stress, a preexisting viral infection, immunotoxicants, or nutritional factors, the innate defense mechanisms may not function optimally. In addition, an adaptive immune response may be slow to develop, and have altered to decreased efficacy and thus be inadequate to control both primary and secondary pathogens. This can result in clinical disease due to an infectious agent that would normally be controlled.

The immune system has potent mechanisms for protecting the pig from infectious and neoplastic diseases. If the immune system is overstimulated or is not appropriately regulated, it may cause hypersensitivity reactions. This can occur in response to infection, vaccination, environmental or dietary antigens, or even against normal host tissues.

PHYSIOLOGY OF THE IMMUNE SYSTEM

Innate Defense Mechanisms

Physical, Chemical, and Microbial Barriers. Physical, chemical, and microbial barriers to infection at body surfaces are a very important part of resistance to disease. These factors include the epithelial cells, bactericidal fatty acids, normal flora, the mucous layer and the flow of mucus, low pH, bile, and numerous enzymes. More detailed information on physical, chemical, and microbial barriers to infection may be found in chapters dealing with specific organ systems.

An important family of molecules that helps form a chemical barrier to limit infection at epithelial surfaces and attack invading bacteria are the antimicrobial peptides. Over 750 antimicrobial peptides have been described in eukaryotes. They are being actively investigated as an alternative to antibiotics for clinical use in antimicrobial therapy. At least 14 antimicrobial peptides have been described in the pig (Brogden et al. 2003). The antimicrobial peptides are relatively small cationic peptides, which vary in structure and antimicrobial activity. They are found predominantly at mucosal surfaces and in phagocytic cells. Some are also found in other tissues. Many have broad spectrum activity against gram-negative bacteria, gram-positive bacteria, and fungal

organisms. Some have a more limited spectrum of activity. The concentration of some of the antimicrobial peptides increases in response to inflammation or microbial infection (Brogden et al. 2003).

Complement. The complement system is an enzyme cascade system similar to the coagulation system and is composed of at least 20 serum proteins. In a cascade system the first component is activated, which in turn activates the next component, which in turn activates the next component, etc., until the reaction is completed. Since the sequential steps involve enzymes, the system is greatly amplified as it proceeds. The components of the mammalian complement system can be divided into the classical pathway, the alternative pathway, the mannan-binding (MB) pathway, the membrane attack complex, and regulatory proteins. The complement system is very important in mediating the inflammatory response and controlling bacterial infections. It also plays a prominent role in allergic and hypersensitivity reactions. The classical pathway is triggered primarily by antigen-antibody complexes consisting of IgG and IgM. The alternative pathway may also be activated by antigen-antibody complexes (IgA and IgE) and by certain bacterial products, such as endotoxin or proteases released by tissue damage. The MB pathway recognizes molecules on the surface of bacteria that differ from those present on the host cells. All three pathways end in the splitting of the third component of complement (C3) and start the formation of the membrane attack complex.

The complement system has many important biologic activities. Activation of any of the three pathways causes vasodilation and increased vascular permeability resulting in serum components (including antibody and complement) entering the tissues to help control infection. Complement components produced during activation are chemotactic and attract phagocytic cells to the site of infection. They also coat or opsonize infectious agents to increase their uptake by phagocytic cells. A very important function of the membrane attack pathway of complement is the destruction of cell membranes including some bacterial cell membranes.

The complement system is important for mediating inflammation and controlling bacterial infections. However, since it is so potent it is also capable of causing serious and even life-threatening damage if it is activated in an unregulated fashion. Therefore, there are numerous regulators of complement present in the serum. These regulators help control and stop the complement reaction once it has started.

Toll-like Receptors. Toll-like receptors (TLRs) are a key component of innate immunity (Check 2004; Cullor 1992). TLRs are a family of cell surface molecules that bind to various molecules derived from microbes, such as lipopolysaccharide, peptidoglycans, CpG rich un-methylated oligonucleotides, and double-stranded RNA. They are the primary method for early detection of and response to microbial invasion. Binding of microbial components to TLRs initiates an inflammatory response that helps activate other aspects of innate immunity and initiate the acquired immune response. Bacterial derived vaccine adjuvants enhance immune response to vaccines through binding to TLRs. At least three TLRs have been described in swine and more are likely to exist (Muneta et al. 2003; Shimosato et al. 2003).

Phagocytic Cells. Phagocytic cells are responsible for engulfing, killing, and digesting invading bacteria. They also play an important role in controlling viral and fungal infections and in killing cancer cells. There are two main types of phagocytic cells: the granulocytes or polymorphonuclear leukocytes, which include neutrophils and eosinophils, and the mononuclear phagocytes, which include the circulating monocytes in the blood and the tissue macrophages. All these cell types are phagocytic and are capable of all the reactions that are described below for neutrophils. In addition, macrophages play an important role in processing antigens and presenting them to lymphocytes to initiate and facilitate the cell-mediated and humoral immune responses.

Granulocytes. Neutrophils are produced in the bone marrow and are released into the blood. The half-life of neutrophils in the blood stream is approximately 8 hours; they then enter the tissues. In the healthy individual the neutrophils are eliminated from the intestinal tract and lungs. Neutrophils migrate into the intestinal tract rapidly in response to *Escherichia coli* infection in the pig (Sellwood et al. 1986). Neutrophils in the circulation tend to marginate in the capillaries by loosely associating with the endothelial cells. In swine, neutrophils seem to have a high affinity for margination in the capillaries of the lung (Ohgami et al. 1989).

The principal function of the neutrophil is the phagocytosis and destruction of invading microorganisms. The neutrophil is well-equipped to perform this function and has several mechanisms for destroying microorganisms. To be effective, the neutrophil must first come into the vicinity of the invading microorganism. This is achieved by the chemotactic attraction of the neutrophil to the site. Chemotactic factors may be produced directly by certain microorganisms, be generated by the cleavage of certain complement components, or be released by sensitized lymphocytes at the site of infection or inflammation. The chemotactic factors will diffuse away from the site to form a gradient. When the chemotactic factors reach a capillary they cause the endothelial cell membrane and the neutrophil membrane to increase the expression of adhesion proteins. The neutrophils then adhere to the endothelial cells and leave the capillary by diapedesis. Once in the tissues, the

neutrophils will migrate along the chemotactic factor gradient toward the source of the chemotactic factor and will thus arrive at the site of infection; they may begin to ingest the microorganisms if those agents are susceptible to phagocytic activity. Most pathogenic microorganisms must be opsonized before they can be ingested; bacteria are opsonized by the attachment of specific antibody and/or complement to their surface. The opsonization process facilitates ingestion. When a neutrophil comes into contact with an opsonized particle, it will attempt to surround the particle with pseudopodia and ingest it by the process of phagocytosis. The ingested particle will be within a membrane-bound vesicle called a *phagosome*.

The neutrophil cytoplasm contains two main types of membrane-bound lysosomes or granules: *primary* or *azurophilic granules* and *secondary* or *specific granules*. These lysosomes contain numerous hydrolytic enzymes that have been quantitated in porcine neutrophils (Chibber and Castle 1983) and at least six cationic antibacterial peptides (Brogden et al. 2003; Kokryakov et al. 1993; Shi et al. 1994; Storici et al. 1994; Zanetti et al. 1994) that are important to the bactericidal activity of the neutrophil. After a particle is ingested and is inside a phagosome, the neutrophil will "degranulate"; some of the lysosomes will fuse with the phagosome and release their contents into the phagosome with the ingested particle. The antibacterial peptides act by permeabilizing bacterial membranes. Neutrophils die after a short time at sites of inflammation. The hydrolytic enzymes are released and contribute to the inflammatory response and tissue destruction.

In addition neutrophils have potent bactericidal mechanisms that are due to the oxidative metabolism of the neutrophil. When a neutrophil is stimulated by an opsonized particle a burst of oxidative metabolism results in the production of hydrogen peroxide (H_2O_2), superoxide anion (O_2^-), the hydroxyl radical ($OH\cdot$), and perhaps singlet oxygen ($^1O_2$). All of these components can damage microbial organisms. The H_2O_2 formed after phagocytosis may also react with halide ions in a reaction catalyzed by a myeloperoxidase enzyme that is released from the primary granules. This reaction is one of the most potent bactericidal mechanisms of the neutrophil, and is also potentially fungicidal and virucidal.

Neutrophils also control certain viral infections via a mechanism referred to as antibody-dependent cell-mediated cytotoxicity (ADCC) in which antibodies form a bridge between the neutrophil and the virus-infected target cell. The neutrophil will then attempt to destroy the target cell. The mechanism of this cell destruction is not known but is thought to involve a direct membrane-to-membrane interaction. Porcine neutrophils are very active at ADCC, even in the fetus and newborn (Yang and Schultz 1986; Zarkower et al. 1982).

The eosinophil is capable of the same phagocytic and metabolic functions as the neutrophil, but to a different extent. The eosinophil is not as active as the neutrophil in destroying bacteria but is important in the host's defense against the tissue phase of certain parasitic infections. The eosinophil is geared more toward exocytosis than phagocytosis. That is, rather than ingesting and killing small particles like bacteria, it can efficiently attach to and kill migrating parasites that are too large to be ingested. Eosinophils are also important in helping to control certain types of allergic responses.

Mononuclear Phagocytes. The mononuclear phagocytic system is made up of circulating monocytes, fixed macrophages, wandering macrophages (histiocytes), and dendritic cells. Monocytes are produced in the bone marrow and released into the blood stream where they will circulate before migrating into the tissues to become macrophages and dendritic cells. The fixed macrophages are found lining the endothelium of capillaries (particularly in the lungs) and the sinuses of the spleen, bone marrow, and lymph nodes. Tissue macrophages are important for trapping and removing foreign antigens from the blood stream and lymph. Wandering macrophages are derived from blood monocytes and are found throughout the tissues of the body. In certain locations, they differentiate into specialized types of macrophages, such as the glial cells in the nervous system, Langerhans cells in the skin, and Kupffer cells in the liver. Dendritic cells are specialized cells that originate from myeloid or lymphoid precursors and assist in presenting antigens to lymphocytes, specifically T cells. Immature dendritic cells are located in the various tissues throughout the body. Upon activation, they migrate to the peripheral lymphoid organs where they mature and become important cells in the activation and differentiation of T lymphocytes (Bautista et al. 2002; Carrasco et al. 2001; Johansson et al. 2003; Summerfield et al. 2003).

Macrophages are capable of all the activities described above for neutrophils. Macrophages are said to be the second line of defense. They are slower to arrive at sites of inflammation and are not as aggressive as neutrophils in the first few minutes of contact with microorganisms. However, macrophages are capable of much more sustained activity against pathogens than are neutrophils. They are able to kill certain types of bacteria that are resistant to killing by neutrophils because of this sustained activity. This is especially true if the macrophages have been activated by cytokines secreted by T lymphocytes.

A very important function of macrophages and dendritic cells is the processing of antigen and presentation of antigen to T lymphocytes. This is an essential step in the initiation of a cell-mediated immune response and for facilitating an efficient antibody response by B lymphocytes. The interaction of macrophages and dendritic cells with antigen and T and B lymphocytes is described later.

Alveolar macrophages phagocytize inhaled particles, including low numbers of bacteria that they may encounter (Chitko-McKown et al. 1991). After ingesting the particles they leave the alveolus either through the airways, where they move up the mucociliary escalator, or by migrating out of the alveolus between alveolar epithelial cells and being carried through lymphatic drainage to local lymph nodes. There, they present the antigens they have captured to lymphocytes to initiate an immune response.

Pulmonary intravascular macrophages are found adhered to endothelial cells in the vasculature of the lung (Chitko-McKown and Blecha 1992; Winkler 1988; Winkler and Cheville 1987). They are prominent in pigs and some other species. They are believed to be important in removing infectious agents from the blood of swine. Pulmonary intravascular macrophages are primarily involved in defense against septicemia rather than protection from respiratory disease. Pulmonary intravascular macrophages that are actively clearing bacteria from the bloodstream (especially gram-negative bacteria or free endotoxin), may release cytokines and arachidonic acid metabolites, which contribute significantly to pulmonary inflammation (Bertram 1986; Crocker et al. 1981a,b).

Natural Killer Cells. Natural killer (NK) cells are lymphoid cells of the innate immune system and can kill a variety of nucleated cells without previous antigenic stimulation. NK cells in most species are also called *large granular lymphocytes* because of the presence of granules in their cytoplasm. NK cells in most species are part of the null cell population because they are distinct from B cells, T cells, and macrophages. In most species NK cells have Fc receptors for IgG and can mediate antibody-dependent cell-mediated cytotoxicity (ADCC) against most antibody-coated mammalian cells. When mediating ADCC these cells have been called killer (K) cells.

Natural killer cells in the pig differ markedly from NK cells found in other species. NK activity in swine is mediated by small granular lymphocytes that have the CD2 T cell marker (Duncan et al. 1989; Ferguson et al. 1986) and are, therefore, not null cells (Duncan et al. 1989). Swine NK cells are slower in initiating the lytic process against typical target cells (YAC-1 lymphoma or K-562 myeloid leukemia cells) than cells responsible for NK activity in other species (Ferguson et al. 1986). In swine there is evidence that the NK cell activity and the K cell activity are from two distinct populations of lymphocytes (Kim and Ichimura 1986; Yang and Schultz 1986). Swine NK cells are capable of lysing cells infected with transmissible gastroenteritis virus and pseudorabies virus (Evans and Jaso-Friedmann 1993).

The activity of NK cells in many species is increased in the presence of interferon gamma (IFN-γ) and interleukin (IL)-2. Swine NK cells have been shown to respond to an interferon inducer (poly I:C), IL-2, human interferon alpha, and human IL-1α with enhanced NK activity (Evans and Jaso-Friedmann 1993; Knoblock and Canning 1992; Lesnick and Derbyshire 1988). Therefore, NK cells are an important part of the innate defense mechanisms and also participate in a cell-mediated immune response by enhanced activity through cytokine activation.

Humoral and Cell-Mediated Immunity

Clonal Selection and Expansion. An important concept that is basic to understanding the immune response is the clonal selection process. Each mature T or B lymphocyte in the body has receptors on its surface that it uses to recognize antigens. All of the antigen receptors on one lymphocyte recognize exactly the same antigen (or small group of antigens). All of the lymphocytes that recognize exactly the same antigen make up a "clone" and they have all arisen from the same ancestor cell. There are millions of clones of T and B lymphocytes. Each clone may contain from a few hundred to a few million cells. The lymphocytes are in a resting stage as they circulate through blood, enter the lymph nodes through the postcapillary venules, percolate through the lymph nodes and reenter the bloodstream. In the lymph nodes (or other secondary lymphatic tissues) the lymphocytes come in contact with antigens that have arrived there through the afferent lymphatics and have been trapped by macrophages or dendritic cells. Each lymphocyte responds to only one specific antigen, which it recognizes through its antigen receptor. Therefore, the vast majority of lymphocytes that contact an antigen in the lymph node cannot respond to it. In an animal that never has been exposed to a particular infectious agent before, there are relatively few lymphocytes in each clone that can recognize a particular antigen. The first step, in producing an effective primary immune response is expansion of the clone of lymphocytes that recognize the antigen. The T and B lymphocytes that contact the antigen are stimulated to undergo a series of cell divisions so that within a few days there will be enough lymphocytes in the clone to mount an effective humoral and/or cell-mediated immune response. If the animal has been exposed to the antigen previously, the clone of lymphocytes has already been expanded, so fewer cycles of cell division are required to produce enough lymphocytes to mount an immune response. This can result in protection induced by vaccination or previous exposure even if there is no remaining detectable antibody. The cells present in the expanded clone are called *memory cells*. If the previous exposure has been relatively recent, there still will be circulating antibody and effector T lymphocytes, which can act immediately to control the infection.

Cellular Interactions in the Induction of the Immune Response. The induction of clonal expansion and the

immune response requires a complex interaction of macrophages, T lymphocytes, and B lymphocytes. Macrophages attempt to phagocytize and destroy infectious agents. After the infectious agent is partially degraded by the macrophage, antigenic fragments from it appear bound to MHC class II molecules on the macrophage surface where they contact T lymphocytes. Macrophages (and other specialized antigen-presenting cells) have a high density of class II MHC molecules on their surface. T helper (T_H) cells are needed to help initiate the immune response. They can only efficiently recognize foreign antigens that are on a cell surface bound to a class II MHC molecule. Cytotoxic T (T_c) cells are important for killing cells infected with intracellular pathogens and cancer cells. They can recognize only foreign antigens that have been processed intracellularly and transported to a cell surface bound to an MHC class I molecule. Therefore, T_H and T_c cells cannot respond to free soluble antigen or to whole bacteria or viruses. Because the MHC class I and class II molecules play a key role in antigen presentation to T lymphocytes, they are capable of having a significant influence on the nature of the immune response. The MHC molecules in all species are highly polymorphic or differ genetically between individuals. The MHC molecules in swine are called the *swine leukocyte antigen (SLA)* complex molecules. The type of SLA molecules that a pig inherits has some influence on their immune response to pathogens and their ability to resist some infectious diseases (Löfstedt et al. 1983; Lunney 1994).

In addition to antigen and class II MHC molecule contact, the T_H cell also requires the presence of cytokines released by the antigen presenting cell or other T cells and contact with co-stimulatory molecules on the surface of the antigen presenting cell for complete activation. Interleukin-1 (IL-1) is an important molecule released by macrophages that are processing antigen. IL-1 is a protein molecule that is a key mediator of the host response to infection through its ability to induce fever and neutrophilia, among other things. A very important function of macrophage-produced IL-1 is its action on T_H cells to cause them to secrete IL-2, which induces T cells to undergo mitosis and clonal expansion. B cells are also capable of processing antigen and presenting it to T_H cells on MHC II molecules. During secondary immune responses, B cells are thought to be the main type of antigen-presenting cell.

It has been documented that the cytokines secreted by macrophages, dendritic cells, and other T cells play a crucial role in the initiation and maintenance of immune responses against both viral and bacterial pathogens in pigs (Cho and Chae 2003; Thanawongnuwech and Thacker 2003; Thanawongnuwech et al. 2001; Zuckermann et al. 1998). Similar to other species, the CD4$^+$ T cells differentiate into T_H cells (Fischer et al. 2000). The T_H cells differentiate into two cell types known as T_H1 and T_H2 that differ in function and are differentiated only by their cytokine profile. A T_H1 cytokine profile includes the production of IL-2 and interferon gamma (IFN-γ), which activate macrophages and stimulate T_c and B cell proliferation. In contrast, T_H2 cells, which inhibit macrophage activation and promote predominantly B cell activity, produce IL-4 and IL-10. High concentrations of IL-10 are associated with the induction of T regulatory cells or T_H3 cells, which are thought to mediate a form of "tolerance" (Groux 2001). The T_H3 cells actively down-regulate pathological antigen-specific immune responses and are thought to be important in regulation of mucosal immune responses and respiratory tract homeostasis (Groux et al. 1998).

T_H cells are very important in initiating the B cell response resulting in antibody production. B cells contact antigen through immunoglobulins bound to their surface, which act as receptors. Antigens do not have to be presented on MHC class II molecules by macrophages for a B cell to recognize them. An optimal B cell response to antigen requires the help of soluble factors released by T_H cells and contact with co-stimulatory molecules on the T_H cell surface. This T_H cell help is needed for B cell mitosis and clonal expansion and for switching the class of antibody produced from IgM to IgG, IgA, or IgE.

Lymphocyte Subpopulations. Lymphocyte subpopulations are defined by the presence of certain molecules on their surface identified by a CD number that designates similar molecules in all species. CD stands for *cluster of differentiation*. More than 29 CD molecules have been identified on the surface of porcine leukocytes (Haverson et al. 2001). Over 247 CD molecules have been identified on human or mouse leukocytes, and there are probably at least that many on porcine leukocytes also.

Lymphocyte subpopulations in the blood of pigs differ markedly from other species. Young pigs have high blood lymphocyte counts compared to most other mammals (approximately 10^7/ml). Up to 50% of these lymphocytes are null cells, which lack most surface markers characteristic of B or classical T lymphocytes (Duncan et al. 1989; Hirt et al. 1990; Saalmuller and Bryant 1994). These null cells do not recirculate between the blood and lymphatic tissues, and they differ from null cells in other species in that they do not have NK cell activity. The majority of null lymphocytes are gamma delta (γδ) T cells. The T cells which predominate in the blood of man and mice and which recognize peptide antigens presented on MHC molecules are called alpha beta (αβ) T cells. Their antigen receptor is made up of an α and a β chain and they have either a CD4 or CD8 molecule to assist in their interactions with MHC molecules. The antigen receptors on γδ T cells are made up of a γ and a δ chain. The majority of porcine γδ T cells do not have CD4 or CD8 molecules associated with them because they recognize intact antigen molecules. Unlike the αβ T cells, they do not require antigen processing

and presentation on MHC molecules (Chien et al. 1996). Pigs and other ungulates have a much higher population of γδ T cells in the blood than other mammals that have been studied. γδ T cells are located predominantly along mucosal surfaces, especially as intraepithelial lymphocytes in the intestine, and are thought to be important in protecting mucosal surfaces from infection and perhaps in oral tolerance (Thielke et al. 2003). γδ T cells proliferate in the intestine and actively recirculate through the intestinal lymphatics to the blood stream and back to the gut (Thielke et al. 2003). The role of the thymus and intestinal epithelium in development of γδ T cells is not understood. A subset of circulating porcine γδ T cells can act as antigen presenting cells and present antigen to T helper cells via MHC II molecules (Takamatsu et al. 2002). Porcine γδ T cells are capable of producing gamma interferon and proliferating in response to recall antigens in vitro and can be cytotoxic (Lee et al. 2004; Takamatsu et al. 2002)**.**

Swine T lymphocytes have at least three unusual properties compared to other species (Lunney and Pescovitz 1987):

- Approximately 25% of swine peripheral blood T cells express both the CD4 and CD8 antigens on their surface. It has been suggested that many of these dual expressing T cells are memory cells; however, the functional significance of having both CD4 and CD8 on the same cells is not known (Pescovitz et al. 1994; Zuckermann and Husmann 1996). Peanut agglutinin has been shown to selectively bind to porcine memory CD4$^+$CD8$^+$ T cells and could therefore be used to isolate these cells (Hernandez et al. 2002).
- The ratio of CD4$^+$ to CD8$^+$ T cells is normally approximately 0.6 in pigs, which is reversed compared to other species. A normal ratio of CD4$^+$/CD8$^+$ in humans is 1.5–2.0.
- Resting CD8$^+$ cells in swine preferentially express class II MHC antigens. The significance of these differences between swine T lymphocytes and those of other species is not completely understood.

Lymphocyte Circulation. The lymph node structure and lymphocyte circulation are markedly different in the pig compared to man or other domestic species (Binns 1982). Recirculation of lymphocytes from blood to lymphoid tissues is very important for bringing antigen into contact with lymphocytes for recognition. Circulation of B cells, αβ T cells, macrophages, and dendritic cells through lymph nodes is also important for facilitating cellular interactions needed for the induction of the immune response as described above. Lymphocytes are produced in the bone marrow, but mature in the thymus (αβ T cells) and the secondary lymphoid tissues (B cells) in the pig. T and B lymphocytes circulate in the blood for approximately 30 minutes before entering the tissues. Porcine lymph nodes are structurally in-

verted compared to other domestic species. Lymphatics enter the node through the hilus, and the lymph passes through the node with the lymph leaving through the periphery. The lymph node has a dense medulla, which lacks sinuses and cords. The germinal centers are located in the interior of the node. Other lymphoid organs—such as the Peyer's patches, tonsils, and spleen—are similar to those found in other species (Binns et al. 1986; Pabst and Binns 1986). Lymphocytes in swine and other species enter the lymph nodes through two routes. Lymphocytes that leave the bloodstream and enter the subcutaneous tissues are carried to the lymph node in the afferent lymphatics. Lymphocytes may also directly enter the lymph node by adhering to high endothelial cells in the venules of the lymph node, and then migrating into the node. In other species, the lymphocytes exit the lymph node in the efferent lymphatics and are carried through the thoracic duct back to the circulatory system. In swine, the efferent lymph contains very few lymphocytes. The lymphocytes in the lymph node directly reenter the blood in swine (Binns et al. 1986). In addition to migrating from blood to lymphoid tissues, lymphocytes in swine migrate into most other tissues as well (Binns et al. 1986). Lymphocyte subpopulations in swine show a distinct preference for circulation to either gut-associated lymphoid tissues or surface nodes (Binns et al. 1986). For instance, mesenteric lymph node cells (both T and B lymphocytes) preferentially home to the gut (Salmon 1986). In rodents the majority of the lymphocytes found in the mammary gland also come from gut-associated lymphoid tissue, whereas in swine approximately equal numbers of lymphocytes in the mammary gland come from gut-associated lymphoid tissue and from peripheral lymph nodes. The dual origin of mammary lymphocytes in swine suggests that the local mammary immune response may not depend solely on oral immunization (Salmon 1986, 1987).

Acquired Immune Defense Mechanisms. An important component of lymphocyte activity in host defense is mediated by soluble products released by stimulated lymphocytes. T lymphocytes are the predominant population of cells that secrete a variety of cytokines as well as being cytolytic to abnormal cells. Antibodies produced by B cells are specific for the antigens to which they are induced whereas cytokines are not. The cytokines produced during an immune response play an important role in orchestrating host defense against pathogens partially through their direct activities and partially by enhancing the activity of both the innate immune system (i.e., complement, phagocytic cells, and NK cells) and the adaptive immune response by T_H cells as described earlier.

Cytotoxic T lymphocytes (T_c cells) are an important part of the cell-mediated immune response to virus infection and tumors. T_c cells have the CD8 marker on

their surface and recognize only antigen associated with MHC class I molecules on a cell surface. MHC class I molecules present peptide antigens derived from proteins synthesized within the cell, such as viral proteins. The T_C cells directly attack host cells that have foreign antigen (e.g., viral antigen) presented on MHC class I molecules on their surface. These cells do not attack free bacteria or viruses. T_C cell activity specific for hog cholera virus, African swine fever virus, and pseudorabies virus have been demonstrated in pigs that have recovered from infection (Martins et al. 1993; Pauly et al. 1995; Zuckermann et al. 1990). T_C cells kill target cells by making direct contact, releasing granzymes onto the cell surface, and inducing apoptosis (programmed cell death) in the target cells. Production of cytokines, including IL-12 and IFN-γ, by T_H1 cells are required for the activation of T_C lymphocytes and the elimination of cells infected with intracellular pathogens, especially viruses.

Immunoglobulins

Production of Immunoglobulins. B lymphocytes from clones that have never been stimulated by antigen have monomeric IgM antibody molecules on their surface that act as antigen receptors. All of the IgM molecules on one B cell are specific for the same antigen. When a B cell is stimulated by antigen and cytokines produced by T_H cells it begins to undergo mitosis. This results in the formation of many more B cells with IgM receptors that also recognize the same antigen. Some of these newly formed B cells differentiate into plasma cells that secrete IgM. As the antigen-specific IgM antibody concentration begins to increase in the blood, activated T_H cells produce the cytokines that signal the B cells to switch from IgM production to IgG, IgA, or IgE production

(Crawley and Wilkie 2003; Crawley et al. 2003). These B cells then rearrange their genetic material to produce antibody molecules with the same antigenic specificity (i.e., the same light-chain structure and variable portion of the heavy chain) but of a different antibody class (i.e., the constant heavy portion of the antibody molecule is changed). Changing the antibody class gives the antibody molecules different properties. The class of antibody that the T_H cells cause the B cells to switch to depends to a large extent upon the nature of the antigen and the location in the body where the antigen was trapped. T_H cells located in lymph nodes and the spleen tend to induce B cells to switch to IgG production. T_H cells located in Peyer's patches or under other mucosal surfaces tend to induce B cells to switch to IgA and/or IgE production, depending on the nature of the antigen and the genetic predisposition of the individual.

Antibody molecules have a variety of activities in host defense, although they alone cannot kill infectious agents. Antibody molecules can coat infectious agents to prevent them from attaching to or penetrating host cells, they can agglutinate infectious agents to reduce their infectivity, and they can directly bind to and neutralize toxins. A very important function of antibody is that it marks infectious agents for destruction by complement, phagocytic cells, and/or cytotoxic cells.

Classes of Immunoglobulins. Characteristics of the various classes of porcine immunoglobulin were thoroughly reviewed in a previous edition of this book (Porter 1986), and in a recent review article (Crawley and Wilkie 2003).

IgG is the predominant Ig class in the serum of the pig and other species. It accounts for more than 80% of the Ig in serum and colostrum (Table 2.1). The two main

Table 2.1.   Concentration of porcine immunoglobulins (mg/ml) in body fluids.

	IgG	IgG$_2$	IgM	IgA
Adult sow serum	24.3 ± 0.94	14.1 ± 0.49	2.9 ± 0.2	2.1 ± 0.2
Colostrum	61.8 ± 2.5	40.3 ± 1.6	3.2 ± 0.2	9.6 ± 0.6
Milk (24 hours)	11.8 ± 4.8	8.0 ± 3.2	1.8 ± 0.3	3.8 ± 1.0
Milk (48 hours)	8.2 ± 3.2	5.0 ± 1.8	1.8 ± 0.4	2.7 ± 0.6
Milk (3–7 days)	1.9 ± 0.6	1.3 ± 0.3	1.2 ± 0.2	3.4 ± 1.0
Milk (8–35 days)	1.40 ± 0.60	1.00 ± 0.45	0.90 ± 0.25	3.05 ± 0.74

subclasses of IgG are IgG_1 and IgG_2 (Metzger and Fougereau 1968), with IgG_1 predominating in serum and colostrum. IgG_3 and IgG_4 subclasses are found in lesser concentrations.

An 18S Ig has been described that is antigenically similar to IgG_2 and is found in low levels in normal serum and colostrum (Kim et al. 1966). Newborn piglets also possess a 5S IgG, which may not have light chains and may not be functional (Franek and Riha 1964; Stertzl et al. 1960).

IgM accounts for approximately 5–10% of the total Ig in serum and colostrum (refer to Table 2.1). The IgM is a pentamer held together by disulfide bonds and has a sedimentation coefficient of 17.8S (Porter 1969).

The porcine immune system produces far more IgA than any other class of antibody; however, most of the IgA is found on mucosal surfaces, rather than in the serum. IgA is present in swine serum as 6.4S monomers and as 9.3S dimers, which are two monomers bound together with a J chain (Halpern and Koshland 1970; Mestecky et al. 1971; Porter and Allen 1972). IgA at mucosal surfaces is mostly dimeric IgA with a J chain and associated secretory component (see the section on mucosal immunity below).

Porcine IgE has been shown to have the same physicochemical properties as in other species, including the characteristic of losing biologic activity when serum is heated to 56°C (Roe et al. 1993). A polyclonal antisera for porcine IgE inhibited a passive cutaneous anaphylaxis reaction, identified a sparse population of plasma cells in the lamina propria of the gut and mesenteric lymph nodes of parasitized pigs, and reacted with human IgE in Western blotting. Antibodies against human IgE and bovine IgE have been shown to react with a homocytotropic immunoglobulin in swine serum (Barratt 1972; Nielsen 1977).

Polyclonal and Monoclonal Antibodies. Antibody produced by an animal in response to an infection or vaccination is polyclonal and recognizes multiple antigens. Infectious agents are complex antigens with many different antigenic specificities on their surface; therefore, they stimulate many clones of B and T lymphocytes to respond. This results in a heterogenous mixture of antibodies that recognizes a wide variety of surface molecules on the microorganism. This broad spectrum of antibodies that are produced and are present in the serum are most helpful to the animal in overcoming infection. It is sometimes a disadvantage, however, if one wishes to use the serum for developing diagnostic reagents. The polyclonal antibodies produced in response to one infectious agent may cross-react with another infectious agent and thus interfere with the specificity of the assay.

Monoclonal antibodies are commonly produced in research laboratories and often overcome many of the disadvantages of polyclonal antisera for diagnostic and (less commonly) therapeutic purposes. Monoclonal antibodies are the result of expansion of one clone from a single B lymphocyte and therefore are all identical. All of the antibody molecules present in a monoclonal antibody preparation are specific for the same antigenic determinant. This helps reduce the problem of cross-reactivity between microorganisms in diagnostic tests. Monoclonal antibodies produced against a protective antigen on a microorganism could possibly be used in therapy or prevention of disease. Since they can be produced in very high concentrations and purity, a much lower volume of monoclonal antibody compared to a polyclonal antibody solution can be used to immunize animals passively. This reduces the risk of serious reaction to the passively administered antibody and its extraneous protein.

Cytokines. Cytokines are small protein or glycoprotein molecules that are secreted by cells and serve as intercellular signaling molecules. All cells of the immune system are capable of secreting and being influenced by cytokines. Cytokine secretion is usually transient and occurs in response to specific stimuli. The cytokines that are secreted may act locally if they are secreted in low concentrations, or they may have systemic effects if they are secreted in higher concentrations. A cytokine will act only on a cell that has specific receptors for it. Regulation of cytokine receptor expression is an important mechanism for controlling the response to cytokines.

Information regarding cytokine biology has increased rapidly in recent years. Most of the new information on cytokine biology was first developed in mice or humans. However, because of the economic importance of pigs, and their importance in biomedical research, considerable information has been published recently regarding porcine cytokines (Murtaugh 1994; Murtaugh and Foss 1997, 2002) . The porcine cytokines that have been studied are generally similar to their homologue in man or mice. Over 30 porcine cytokines have been described and partially characterized (Murtaugh 1994; Murtaugh and Foss 1997). A currently active field of research studies the various cytokines produced in response to disease (Darwich et al. 2003; Suradhat and Thanawongnuwech 2003; Thanawongnuwech and Thacker 2003). The information obtained from these studies helps us understand both how pathogens cause disease as well as how the immune system functions to control disease.

Cytokines can generally be categorized into four groups based on their functions (Abbas et al. 1994). One group of cytokines is important in mediating innate immunity. This includes the type I interferons (alpha and beta) and the proinflammatory cytokines that include IL-1, IL-6, and tumor necrosis factor α (TNFα). Type I interferon production occurs in response to viral infections by many cell types. Type I interferons can be detected within a few hours of viral infection and make

cells resistant to virus infection, increase NK cell activity, and increase the MHC molecule expression on cell surfaces, thus increasing antigen presentation to T cells.

The proinflammatory cytokines (IL-1, IL-6, and TNFα) are produced primarily by macrophages in response to bacterial infection and require no previous exposure. They may also be produced in response to viral, protozoal, or fungal infections, or tissue damage. The proinflammatory cytokines stimulate the liver to produce acute phase proteins and stimulate the release of amino acids from muscle tissue, and may induce cachexia or wasting in chronic infections. In addition, they induce fever, loss of appetite, and fatigue if present in high-enough concentrations. In low levels, these cytokines promote leukocyte adhesion to endothelial cells and diapedesis of leukocytes into the tissues as well as migration of macrophages and dendritic cells to the secondary lymph nodes, resulting in the activation of the adaptive immune response. Their presence in small amounts is required for an effective immune response. However, in large quantities they can induce hypovolemic shock and death.

A second group of cytokines regulate lymphocyte activation, growth, and differentiation. These are produced mainly by the T_H lymphocytes in response to antigen recognition. Four important cytokines in this group are IL-2, IL-4, IL-12 and transforming growth factor β (TGF-β). IL-2 stimulates T and B cells that have recognized antigen to proliferate. It also activates NK lymphocytes to have increased cytotoxic activity. IL-4 is important for effective IgE-mast cell-eosinophil inflammatory reactions required to control some parasites and may result in allergic symptoms to non-parasite antigens. IL-12 activates NK lymphocytes and induces CD4+ cells to differentiate into T_H1 cells and assists in the maturation of CD8+ cells into T_C cells. TGF-β is primarily a negative regulator of the immune response. It inhibits many activities of lymphocytes and may be a signal for shutting off the immune response.

A third group of cytokines are those that regulate immune-mediated inflammation. They are produced mainly by T_H and T_C cells, and their primary function is to activate or deactivate the cells of the innate immune system. Interferon-gamma (IFN-γ) causes cells to be resistant to virus infection (similar to alpha and beta interferon), and it is also a potent activator of macrophages, neutrophils, and NK cells. TNF-β often acts synergistically with IFN-γ to activate phagocytic cells. TNF-β can also activate endothelial cells resulting in diapedesis of leukocytes into sites of inflammation. IL-5 is secreted by T_H cells and acts to increase eosinophil production and to activate eosinophils resulting in an increased ability to kill parasites. IL-10, secreted by T cells and macrophages is important in suppressing macrophage function and maintaining homeostasis of the respiratory tract.

The fourth group of cytokines stimulate hemato-poiesis through the expansion and differentiation of bone marrow progenitor cells. They are called *colony stimulating factors (CSFs)*. IL-3 is a CSF that stimulates the production of all of the types of leukocytes. Granulocyte-macrophage CSF (GM-CSF) stimulates the production of granulocytes and macrophages. Granulocyte CSF (G-CSF) stimulates the production of granulocytes only. The CSFs also may enhance the antimicrobial activities of mature neutrophils and macrophages.

Mucosal Immunity

Providing immunity at mucosal surfaces is a difficult problem due to frequent exposure to infectious agents. The components of the immune system described previously may not function well in the microenvironment on the mucosal surface, and their contribution to protective immunity varies with the mucosal surface. For instance IgG, complement, and phagocytic cells function efficiently in the lower respiratory tract and in the uterus but not in the lumen of the gut.

An important component of immunity at mucosal surfaces is the secretory IgA system, which responds to antigens that enter the body through mucosal surfaces. Specialized epithelial cells called *dome cells* or *M cells* are found overlying aggregations of gut and bronchus associated lymphoid tissues. These dome cells pinocytose antigen and transport it across the epithelial layer. The antigen may then be processed by antigen-presenting cells and presented to T and B lymphocytes.

Lymphocytes in the bloodstream tend to segregate into two populations: those that circulate between the bloodstream and the systemic lymphoid tissues and those that circulate between the bloodstream and lymphoid tissues associated with mucosal surfaces. Because of the nature of the T_H cells, which home to mucosal surfaces, antigens that enter through mucosal surfaces tend to induce an IgA or IgE response. In some cases antigens that enter through the intestinal tract may induce oral tolerance, resulting in suppression of IgG antibody responses.

In the mucosal lymphoid tissues, B cells that have been stimulated by antigen and induced by T_H cells to switch to produce IgA will leave the submucosal lymphoid tissue and reenter the bloodstream. These lymphocytes will exit the bloodstream at submucosal surfaces and locate in the lamina propria where they will differentiate into plasma cells that will secrete dimeric IgA. Many of these cells will return to the same mucosal surface from which they originated, but others will be found at other mucosal surfaces throughout the body. Therefore, oral immunization can result in the migration of IgA precursor cells to the bronchi and subsequent secretion of IgA onto the bronchial mucosa. Oral immunization with live or inactivated *Actinobacillus pleuropneumoniae* has also been shown to result in the trafficking of T cells and IgG positive lymphocytes to the bronchoalveolar space and production of IgA in the

bronchoalveolar space (Delventhal et al. 1992; Hensel et al. 1994; Pabst et al. 1995). There is a special affinity for lymphocytes that have been sensitized in the gut of the sow to migrate to the mammary gland to become plasma cells and secrete IgA into the milk.

The dimeric IgA secreted by the plasma cells in the lamina propria will bind to the polyimmunoglobulin receptor on the basal membrane of mucosal epithelial cells. The dimeric IgA and polyimmunoglobulin receptor are then transported to the mucosal surface of the epithelial cell where the polyimmunoglobulin receptor is cleaved. The cleavage product is called the *secretory component* and remains bound to the dimeric IgA. The secretory component is important for protecting the IgA molecule from proteolytic enzymes and also serves to anchor the IgA into the mucous layer so that it forms a protective coating on the mucosal surface.

Secretory IgA plays an important role in immunity at mucosal surfaces by agglutinating infectious agents, preventing attachment of infectious agents to epithelial cells, and neutralizing toxins. Other components of the immune response may also be important in protection against various types of infection at mucosal surfaces. For example, neutrophils in the pig can migrate into the intestinal lumen in large numbers in response to antigen-antibody complexes. The recruitment of neutrophils into the intestinal lumen is dependent upon the presence of antibody that may be circulating IgG antibody (Bellamy and Nielsen 1974), colostral antibody (Sellwood et al. 1986), or locally induced IgA class antibody (Bhogal et al. 1987). The immigration of neutrophils into the lumen of the gut and their subsequent destruction has been shown to result in an increased concentration of lactoferrin, lysozyme, and cationic proteins. These substances may also contribute to immunity to bacterial infections in the gut.

T lymphocytes are important mediators of immunity at mucosal surfaces (Dunkley et al. 1995). This is especially true for respiratory infections caused by facultative intracellular bacterial pathogens. T lymphocytes also play a role in immunity in the intestinal tract. Pigs have high numbers of intraepithelial lymphocytes, which are predominantly $\gamma\delta$ T cells and T_C cells (Salmon 1987; Thielke et al. 2003). The T_C cells in contact with intestinal epithelial cells are likely to be important in destroying virus-infected epithelial cells. The $\gamma\delta$ T cells proliferate in the intestine and recirculate through the lymphatic and blood vessels back to the intestine. They can produce IFN-γ, be cytotoxic, and act as antigen-presenting cells through MHC II molecules (Lee et al. 2004; Takamatsu et al. 2002).

More detailed information on the various aspects of mucosal immunity may be found in chapters in this book dealing with specific organ systems or specific pathogens. The role for lymphocytes in the respiratory immune system of the pig has been reviewed (Pabst and Binns 1994).

Immunity in the Fetus and Neonate

All components of the native and acquired immune systems of the pig develop in utero and are functional at birth. However, they are generally less efficient than in the adult (Hammerberg et al. 1989). Since the normal newborn piglet has not yet been exposed to antigen, humoral and cell-mediated immune responses to infectious agents have not yet been developed. After exposure to infectious agents it will take 7–10 days for a primary antibody or cell-mediated immune response to develop. During this time resistance to infection depends upon the actions of the innate defense mechanisms and antibody, which is passively transferred from the sow to the piglet. In the pig there is virtually no transfer of antibody across the placenta. The epitheliochorial placentation of the sow has several tissue layers between maternal and fetal circulation, which prevents antibody transfer. In the sow, as in other large domestic species, passive transfer of antibody from mother to offspring occurs through the colostrum. The sow concentrates antibody in the colostrum during the last days of gestation. This antibody is largely transferred intact across the gut epithelial cells into the circulation of the newborn piglet. The passive transfer of antibody from sow to piglet in the colostrum and milk is very important for neonatal survival and is discussed in more detail below.

Innate Defense Mechanisms. The newborn piglet has low levels of hemolytic complement activity at birth. The level of hemolytic complement activity is related to the birth weight, with heavier pigs having significantly higher concentrations of complement in the serum (Rice and L'Ecuyer 1963). In colostrum-deprived pigs the hemolytic complement activity gradually increases during the first 36 days of life. Piglets allowed to suckle colostrum have higher titers of hemolytic complement than colostrum-deprived piglets during the first 3 weeks of life. This suggests that some of the complement components that are present in limiting amounts are transferred through the colostrum to the piglet (Rice and L'Ecuyer 1963).

The level of natural interferon alpha production by porcine blood mononuclear cells was shown to be low at birth and to gradually increase until adult age, with a significant increase around puberty (Nowacki et al. 1993).

Phagocytic cells are present in newborn animals but generally have reduced phagocytic activity as compared to adult animals (Osburn et al. 1982). Alveolar macrophages from 1-day-old pigs had reduced oxidative killing mechanisms compared to alveolar macrophages from adult pigs. By 7 days of age, these aspects of alveolar macrophage function had reached adult levels of activity (Zeidler and Kim 1985). Neonatal pigs have low numbers of pulmonary intravascular macrophages, which can increase up to fourteenfold by 30 days of age

(Winkler and Cheville 1987). Since phagocytes depend on complement and/or antibodies to opsonize many infectious agents, the overall efficiency of phagocytosis may be reduced due to inadequate levels of complement and antibodies. Neutrophils from fetal pigs have been shown to have antibody-dependent cell-mediated cytotoxicity activity against chicken red blood cells, which is comparable to that of adult pigs. Neutrophils from neonatal pigs have also been shown to rapidly emigrate into the lumen of the gut in response to the presence of *E. coli* and colostral antibody (Sellwood et al. 1986; Yang and Schultz 1986).

Acquired Immune Mechanisms. The percentage of CD2$^+$, CD4$^+$, and CD8$^+$ T lymphocytes increases with age over the first several weeks of life in specific pathogen-free pigs (Bianchi et al. 1992; Joling et al. 1994). The lymphocyte blastogenic responsiveness to mitogens has been shown to be low after birth and to increase by 4 weeks of age (Becker and Misfeldt 1993). The mucosal lymphoid system is also less developed at birth and matures over the next few weeks of life (Jericho 1970; Ramos et al. 1992).

Natural killer cell activity has been shown to be absent in the peripheral blood of fetal pigs and to be low in pigs of less than 2 weeks of age (Yang and Schultz 1986).

Passive Transfer in the Neonate. Pigs are born with almost no serum antibody and absorb colostrum that is enriched in IgG, IgG$_2$, and IgA as compared to the serum of sows. It has approximately the same concentration of IgM as serum (refer to Table 2.1). When the pig suckles, the colostrum is replaced with milk, which has much lower immunoglobulin content. From 3 days of age until the end of lactation, IgA is the predominant antibody found in sow milk. The percentage of immunoglobulin in the mammary gland derived from serum and locally produced in the mammary gland is different in colostrum and milk and varies with the immunoglobulin class (Table 2.2).

All three major classes of Ig (IgG, IgA, and IgM) are absorbed from the colostrum into the circulation of newborn pigs (Curtis and Bourne 1971; Porter 1969).

Table 2.2. Origin of porcine colostral and milk immunoglobulins (Stokes and Bourne 1989).

	Percent Derived from Plasma (%)	Percent Locally Synthesized (%)
Colostrum		
IgM	85	15
IgG	100	0
IgA	40	60
Milk		
IgM	10	90
IgG	30	70
IgA	10	90

IgA, however, is absorbed less efficiently than the other classes of antibody (Hill and Porter 1974; Porter 1973). This is apparently because much of the IgA in porcine colostrum is dimeric IgA lacking secretory component (Porter 1973). Neonatal colostrum-deprived piglets have been shown to express secretory component in the gut, which tends to localize in the mucus of the crypt areas (Allen and Porter 1973). Because of the affinity of the dimeric IgA and IgM for secretory component, it has been suggested that IgA and IgM are bound in association with secretory component and held in the mucus of the crypt areas and are, therefore, less efficiently absorbed from the colostrum (Butler et al. 1981). The IgA present in sow's milk throughout the suckling period may also bind to the secretory component in the crypt areas and provide relatively continuous protection against intestinal pathogens.

Intestinal absorption of immunoglobulin from the colostrum normally ceases by 24–36 hours after birth. If pigs suckle normally, the efficiency of absorption decreases with a half-life of about 3 hours (Speer et al. 1959). Lecce et al.(1961) found that the period of time that the intestine could absorb antibodies was extended up to 5 days in starved pigs, which were maintained by parental administration of nutrients. Therefore, piglets that have not had an opportunity to eat during the first 24–36 hours may still benefit from colostrum ingestion.

Neonatal pigs have been shown to absorb colostral lymphocytes from their intestinal tract into the blood stream (Tuboly et al. 1988; Williams 1993). By 24 hours cells derived from colostrum were found in the liver, lung, lymph nodes, spleen, and gastrointestinal tissue. Pigs that had absorbed the colostral lymphocytes had higher lymphocyte blastogenic responses to mitogens than control pigs. It is not clear whether the passively transferred lymphocytes also transfer clinically significant cell-mediated or antigen-specific immunity from the sow to the piglet.

HYPERSENSITIVITIES

Hypersensitivities are conditions in which there is an excessive response to an antigen to which the animal has previously been exposed. The clinical signs are due to the immune response to the antigen rather than to a direct action of the antigen or pathogens. Although hypersensitivity conditions can be divided into four types based on their mechanism of action, it is not unusual for clinical hypersensitivity conditions to involve more than one of the four types of hypersensitivity.

Type I or *immediate type* hypersensitivity involves the synthesis of specific IgE antibodies. The IgE molecules preferentially bind to Fc receptors on the surface of tissue mast cells. When the same antigen is encountered subsequently it will bind to the IgE on the mast cell surface (if there is a sufficiently high concentration of IgE specific for the antigen) and cause the mast cell to re-

lease numerous pharmacologically active substances, which are responsible for the clinical signs (e.g., histamine, serotonin, kinins, prostaglandins, and others). Type I hypersensitivities may be localized to a particular region or organ or may be systemic (anaphylaxis) (Eyre 1980). Information on naturally occurring localized type I hypersensitivities in pigs is not readily available, although it has been reproduced experimentally (Helm et al. 2003; Roe et al. 1993). Acute systemic anaphylaxis in pigs is due primarily to systemic and pulmonary hypertension, leading to dyspnea and death. In some pigs the intestinal tract may also be involved (Tizard 1987).

A *type II* hypersensitivity response (or *cytotoxic type hypersensitivity*) involves the presence of antibodies directed against cell membrane antigens. These may be normal tissue antigens in the case of autoimmune diseases or foreign antigens (e.g., drugs, viral antigens, or bacterial antigens) that have adhered to the cell surface. Type II hypersensitivities have been reported in pigs in which autoantibodies have formed against erythrocytes, thrombocytes, or neutrophils. This results in a depletion of the respective cell type and the associated clinical signs that one would expect (anemia, bleeding diathesis, or increased susceptibility to infection, respectively). These autoantibodies may arise from blood transfusions, from the use of vaccines that contain blood products, or in multiparous sows that develop antibody against the alloantigens shared by the sire and the fetus. Thrombocytopenia purpura in baby pigs due to passively transferred anti-platelet antibody seems to be rather common. Pigs appear normal at birth, and death usually occurs between 10–20 days of age. The most striking pathologic feature is the presence of hemorrhages in the subcutaneous tissues and internal organs. Castration during the period of thrombocytopenia may greatly increase the death rate.

Antibodies against erythrocytes, thrombocytes, and neutrophils may be present in the same piglet. In one report, 50% of the dams of litters affected with thrombocytopenia purpura had erythrocyte iso-antibodies in their serum (Linklater et al. 1973). Some of the anemia associated with *Mycoplasma haemosuis* (formerly *Eperythrozoon suis*) is due to the development of autoantibodies against the red blood cells induced by the organism (Messick 2004).

A *type III* hypersensitivity (or *immune-complex type hypersensitivity*) involves the presence of antigen-antibody complexes in the circulation or tissue. These immune complexes can fix complement and, therefore, may initiate an inflammatory response, attract neutrophils to the site, and damage cell membranes. The immune complex–mediated glomerulonephritis associated with chronic hog cholera virus, African swine fever virus, and possibly PCV2 infections are examples of this type of hypersensitivity. The immune complexes formed in response to these diseases may also cause polyarteritis nodosa, a systemic vasculitis. Immune complex deposition

in swine kidneys is apparently common. One study evaluated 100 kidneys collected at slaughter with no apparent macroscopic lesions. Ninety-seven of the kidneys had IgG deposits and 98 had C3 deposits as demonstrated by immunocytochemistry. The significance of these immune complex deposits in the kidney is unknown; however, the clinical diagnosis of glomerular disease in swine is rare (Shirota et al. 1986).

A *type IV* hypersensitivity (or *delayed-type hypersensitivity*) is mediated by sensitized T cells releasing cytokines. It does not involve antibody. The tuberculin skin test is a classic type IV hypersensitivity reaction. Delayed-type hypersensitivity is believed to play a role in some cases of food hypersensitivity in pigs. Very little work has been reported on other clinical conditions involving delayed-type hypersensitivity in pigs. Transfer of delayed-type hypersensitivity between genetically matched pigs by transfer of lymphocytes has been demonstrated (Binns et al. 1996).

Food hypersensitivity is thought to be responsible for some cases of post-weaning diarrhea and reduced growth performance in piglets (Stokes et al. 1987; Stokes and Bourne 1989; Li et al. 1990, 1991; Friesen et al. 1993). This apparently involves the formation of both IgG antibodies and a type IV or delayed-type hypersensitivity. Following the introduction of a new protein antigen to the diet, a small proportion (<0.002%) of that protein is absorbed intact inducing an antibody and/or cell-mediated response. Normally, a systemic antibody response (IgG) is suppressed (oral tolerance) and a local mucosal antibody response persists. The local antibody prevents further absorption of the intact protein. Oral tolerance prevents an immune response to most of the proteins that are absorbed. Therefore, following the introduction of new dietary antigen, animals may pass through a brief phase of hypersensitivity before the development of a protected state of tolerance.

In pigs that were weaned abruptly and placed on a soya-containing diet, soya protein was detected in the sera of all animals for up to 20 days postweaning. A delayed-type hypersensitivity skin test reaction to soya proteins was transiently present in the soya-fed group. The changes in gut morphology (crypt hyperplasia and villous atrophy) and the malabsorption associated with early weaning suggested that these changes occur as a result of a transient hypersensitivity to antigen in the postweaning diet. These intestinal changes can facilitate growth and disease production by *E. coli*. Feeding of large amounts of soya prior to the withdrawal of milk prevented the postweaning malabsorption and diarrhea (Stokes et al. 1987).

IMMUNODEFICIENCY AND IMMUNOSUPPRESSION

Primary or secondary immunodeficiencies increase the susceptibility of animals to disease induced by typically

low to nonpathogenic microbes. A primary immunodeficiency is defined as a disorder of the immune system with a genetic basis. A secondary immunodeficiency is a disorder in which the animal is genetically capable of normal immune function, but some secondary factor is impairing resistance to disease.

Clinical findings that are associated with immunodeficiencies include:

1. Illness from organisms of normally low pathogenicity or from an attenuated live vaccine
2. Recurrent illnesses that are unusually difficult to control
3. Failure to respond adequately to vaccination
4. Unexplained neonatal illness and death affecting more than one animal in a litter
5. A variety of disease syndromes occurring concurrently in a herd

A large number of primary immunodeficiencies have been reported in humans; however, there are no reports of primary immunodeficiencies in pigs. This is probably due to the relatively low value of the individual piglet and the expense and difficulty associated with diagnosing a primary immunodeficiency. In addition, sows and boars that produce nonvigorous litters are not kept in the breeding herd.

A common cause of secondary immunodeficiency is failure of passive transfer of adequate levels of maternal antibody through the colostrum to the piglet. This has been discussed earlier in this chapter. Other potential causes of secondary immunodeficiency (or immunosuppression) include:

1. Physical or psychological distress
2. Immunosuppressive infectious agents
3. Inadequate nutrition
4. Immunotoxic substances

Physical and Psychological Distress. There is ample evidence that both physical and psychological distress can suppress immune function in animals, leading to an increased incidence of infectious disease. Excess heat or cold, crowding, mixing, weaning, limit-feeding, shipping, noise, and restraint are stressors that are often associated with intensive animal production and have been shown to influence immune function in various species (Kelley 1985). Distress-induced alterations in immune function are mediated by interactions between the neuroendocrine and immune systems. The study of these multisystem interactions initially focused on the secretion and influence of glucocorticoids, which suppress several aspects of immune function. However, pigs are more resistant to the immunosuppressive effects of glucocorticoids compared to some other species (Flaming et al. 1994). It is now recognized that there are many mechanisms by which the neuroendocrine system can alter immune function; in addition, the immune system is capable of altering the activity of the neuroendocrine system (Breazile 1987; Dunn 1988; Kelley 1988).

Weaning is certainly a stressful event for domestic animals. Piglets are usually separated from the sow, handled, regrouped with unfamiliar pigs, and shifted from a liquid to a solid diet. Weaning at 2, 3, or 4 weeks of age (but not at 5 weeks of age) has been shown to decrease the in vivo and in vitro response of porcine lymphocytes to phytohemagglutinin (Blecha et al. 1983). This is considered to be a measure of the lymphocyte's ability to undergo clonal expansion to initiate an immune response. These same parameters were suppressed in artificially reared neonatal piglets compared to their sow-reared littermates (Blecha et al. 1986; Hennessy et al. 1987). Early weaning of pigs at 3 weeks of age suppressed the ability of mesenteric lymph node cells to produce IL-2 (Bailey et al. 1992). Weaning (at 5 weeks of age) 24 hours after the injection of sheep red blood cells (RBCs) decreased the antibody response to the sheep RBCs. Weaning 2 weeks prior to injecting the sheep RBCs did not decrease the antibody response (Blecha and Kelley 1981). However, successful vaccination strategies at the time of weaning are frequently reported in the field.

Regrouping of pigs at the time of weaning or at 2 weeks after weaning significantly increased their plasma cortisol concentration. However, there were no measurable changes in lymphocyte blastogenesis or antibody responses at the time of elevated plasma cortisol concentration (Blecha et al. 1985).

Crowding or restraint may also stress pigs sufficiently to decrease their immune responsiveness. Housing 8 pigs (11.5–18 kg) per group in pens with 0.13 m^2 of floor space per pig significantly reduced their phytohemagglutinin skin test response as compared to pigs given twice as much space (Yen and Pond 1987). When young pigs were restrained for 2 hours per day over a 3-day period, they had a significantly elevated plasma cortisol concentration, which correlated with a decrease in the size of the thymus gland and with a reduction in the phytohemagglutinin skin test response (Westly and Kelley 1984). Another report indicated that tethering of sows suppressed antibody synthesis to sheep RBCs. It also resulted in a reduction in the amount of antibodies that were transmitted through the colostrum into the blood of the piglets (Kelley 1985).

Immunosuppressive Infectious Agents. Certain infectious agents are capable of suppressing immune function, making the animal more susceptible to secondary infections. For example, infection with *Mycoplasma hyopneumoniae*, *A. pleuropneumoniae,* virulent or vaccine strains of hog cholera virus, porcine reproductive and respiratory syndrome (PRRS) virus, or pseudorabies virus increases the susceptibility of pigs to *Pasteurella multocida,* increasing the severity of pneumonia (Chung et al. 1993; Done and Paton 1995; Fuentes and Pijoan

1986, 1987; Pijoan and Ochoa 1978; Smith et al. 1973). The mechanism of the immunosuppression induced by these agents has not been completely characterized. A cytotoxin from *A. pleuropneumoniae* is toxic for alveolar macrophages (Chung et al. 1993; Dom et al. 1992; Tarigan et al. 1994). The pseudorabies virus has been shown to replicate in monocytes and alveolar macrophages and to impair their bactericidal and cytotoxic functions (Chinsakchai and Molitor 1992; Iglesias et al. 1989a, b; Iglesias et al. 1992). Porcine parvovirus replicates in alveolar macrophages, as well as lymphocytes, and has been shown to impair macrophage phagocytosis and lymphocyte blastogenesis (Harding and Molitor 1988). Swine influenza virus and PRRS virus also replicate in alveolar macrophages and PRRS virus is lytic to infected macrophages (Bautista et al. 1993; Charley 1983).

PRRS virus and porcine circovirus type 2 (PCV2) both appear to modulate the immune response at many levels. Specific details about the pathogenesis of these two viruses are covered elsewhere in this book. However, it is important to recognize that much of their impact on the swine industry is due to their ability to modulate or alter the ability of the immune system to control other pathogens. The mechanism used by these pathogens to alter the immune response is currently unknown; however, studies have demonstrated that PRRS virus induction of cytokines that induce a T_H 2-type of response, as characterized by increased IL-10 levels and decreased IFN-γ production, may play a role in the immunosuppression associated with infection (Thanawongnuwech and Thacker 2003). Thus, although neither of these viruses is classically immunosuppressive, their ability to modulate the immune system allows persistence of the viruses in the host.

In addition to modulation of the immune system by viruses, bacteria including *M. hyopneumoniae, Salmonella typhimurium,* and *S. choleraesuis* have each been shown to alter porcine neutrophil function (Coe et al. 1992; DeBey et al. 1994; Roof et al. 1992a, b) In addition, *M. hyopneumoniae* also appears to induce a preferential T_H 2 type of response that may further decrease the ability to control respiratory pathogens (Thanawongnuwech and Thacker 2003; Thanawongnuwech et al. 2000).

Nutritional Influences on Immunity. Both malnutrition and overfeeding may result in impairment of immune function and increased susceptibility to disease due to a deficiency or excess of proteins or calories, or a relative imbalance in vitamin or trace mineral content. Animals under intensive production conditions typically have a completely controlled diet. Therefore, it is very important that the diet, especially the vitamin and trace mineral content, be optimally formulated. Key vitamins and minerals for optimal immune function include vitamins A, C, E, and the B complex vitamins;

copper (Cu); zinc (Zn); magnesium (Mg); manganese (Mn); iron (Fe); and selenium (Se). The balance of these constituents is especially important since an excess or deficiency in one component may influence the availability or requirement for another (Tengerdy 1986).

It is difficult to predict the optimal diet for immune function. There is very little research data in this area for swine. The dietary requirements for optimal immune function may differ from the requirements to avoid deficiencies as judged by traditional methods. Relatively small imbalances of a particular nutrient may suppress immune function, whereas a more severe deficiency must occur before the classical clinical evidence of deficiency of that nutrient is recognized. In addition, stress or the demands of rapid growth may change dietary requirements for optimal immune function.

Dietary and injectable vitamin E and selenium have been evaluated for their influence on antibody levels in young pigs. Dietary vitamin E supplementation increased the antibody response to *E. coli* (Ellis and Vorhies 1976). Supplemental (dietary or injectable) vitamin E and/or selenium treatment in pigs beginning at 4 to 5 weeks of age increased their antibody response to sheep RBCs (Peplowski et al. 1981). Dietary vitamin E and selenium also increased the proliferation response of pig lymphocytes to phytohemagglutinin (Larsen and Tollersrud 1981).

Immunotoxic Substances. In other species, various compounds—including heavy metals, industrial chemicals, pesticides, and mycotoxins—have been shown to be immunosuppressive at very low levels. These compounds may be detrimental to the immune system and predispose animals to infectious diseases at levels that do not cause other symptoms of toxicity (Koller 1979). Very little immunotoxicology research has been conducted in swine. Aflatoxins in the feed of young pigs has been shown to impair immunity to erysipelas, to enhance the severity of clinical signs due to salmonellosis, and to enhance susceptibility to an oral inoculation with *Brachyspira hyodysenteriae* (Cysewski et al. 1978; Joens et al. 1981; Miller et al. 1978).

GENERAL PRINCIPLES OF VACCINATION

For over 100 years scientists have known that animals may develop immunity to diseases if exposed to either the killed infectious agent or a live strain of the agent that has been modified so it does not cause disease. This approach led to the development of many successful vaccines in the early 1900s. However, it soon became apparent that for certain diseases this simple approach was not effective. An animal, for example, might produce antibody in response to vaccination, but still develop the disease, demonstrating that circulating antibody alone is not protective. The challenge of developing vaccines for these diseases is to understand the basis for suc-

cessful immunity, and then to develop vaccines that induce this type of immunity. It is apparent that different diseases require different types of immunity for protection and the type of vaccine (modified live versus killed), route of administration, and type of adjuvant make a difference in the type of immune response.

General principles regarding vaccine efficacy and vaccine failure will be discussed here. It must be remembered that there are exceptions to these general principles for specific vaccines and specific diseases. Information regarding protective immunity and vaccination for specific diseases may be found in other chapters of this book.

Selective Induction of Different Types of Immunity

It is relatively easy to develop a vaccine that will induce the production of IgG and IgM antibodies in the bloodstream. However, the vaccine may not induce antibodies against the important antigens of the infectious agent, and antibodies alone do not kill infectious agents. Some disease-causing organisms are resistant to control by circulating antibodies. These organisms must be controlled by the cell-mediated immune system or the secretory IgA system. It is more difficult to develop a safe and effective vaccine that induces these types of immunity.

The nature of the vaccine and the route of administration are important for influencing the type of immunity induced. Subcutaneous or intramuscular injection of a killed vaccine will stimulate the immune system to produce both IgM and IgG. However, there is very little production of IgA to protect the mucosal surfaces. In addition, killed vaccines are generally less effective in inducing cell-mediated immunity.

Optimal induction of cell-mediated immunity generally requires a modified live vaccine capable of replicating in the animal or a killed vaccine with a highly effective adjuvant. Modified live vaccine viruses have been attenuated to be of reduced virulence. The attenuation must be shown to be stable; therefore, reversion to virulence is a rare event. New adjuvants and other novel vaccine technologies are being developed that show promise for inducing cell-mediated immunity (Roth and Henderson 2001; Spickler and Roth 2003). There are killed vaccines that have been available for many years and have been effective in controlling certain systemic-type diseases. These are generally diseases that can be controlled by the presence of IgG in the circulation. For those diseases where T cell-mediated immunity is needed for protection, it is important to characterize the response of the various T cell subsets to the vaccine antigens. Several methods exist for evaluating T cell responses to antigens in domestic species (Sandbulte and Roth 2004).

Protecting the animal from infection at mucosal surfaces such as the intestinal tract, respiratory tract, mammary glands, and reproductive tract is especially difficult for the immune system. The antibodies responsible for humoral immunity and the lymphocytes responsible for cell-mediated immunity are predominantly in the blood stream and tissues and they are typically not found on the mucosal surfaces. Therefore, although lymphocytes assist in preventing systemic invasion through the mucosal surface, they are often not very effective at controlling infection on the mucosal surface. Even in the lung and the mammary gland, where IgG and lymphocytes are found in relative abundance, they are not able to function as effectively as in the tissues. Protection on mucosal surfaces is due in large part to secretory IgA, T_C cells, and $\gamma\delta$ T cells, as discussed earlier.

The route of vaccine administration can be important when attempting to induce mucosal immunity. To induce secretory IgA production at mucosal surfaces, it is best for the vaccine to enter the body via a mucosal surface. This can be accomplished by feeding the vaccine to the animal, aerosolizing the vaccine so the animal will inhale it, or by intramammary exposure. If a sow is exposed to an infectious agent in her intestinal tract, she may respond by producing secretory IgA not only in her own intestinal tract, but also in her mammary gland. The sow passes the IgA against the infectious agent to the piglet when it suckles, thus protecting the piglet from infectious agents present in the sow's intestine. This protection will last only as long as the piglet continues to suckle. Enteric infections by many organisms are not controlled by the presence of IgG and IgM in the bloodstream or by a systemic cell-mediated immune response. If a modified live vaccine is given by injection, but goes to a mucosal surface to replicate, it may also induce a secretory IgA response. In addition, killed vaccines for some respiratory pathogens, such as *M. hyopneumoniae* and swine influenza virus, are capable of stimulating an IgA response to challenge.

Vaccination Failure. There are many reasons why animals may develop disease even though they have been vaccinated (Roth 1999). Potential reasons for vaccine failure include:

1. Insufficient time occurred after vaccination to develop immunity.
2. Something happened to the vaccine to make it ineffective.
3. The physiologic status of the animal impaired the response to the vaccine.
4. The animal was immunosuppressed at some point after vaccination.
5. The animal was exposed to an overwhelming challenge dose.
6. The duration of immunity after vaccination was not adequate.
7. Important antigenic differences exist between vaccine and field strains.

8. Interference occurs when multiple vaccines are administered concurrently.

By being aware of these factors, veterinarians and producers can help minimize the occurrence of vaccine failures.

Occurrence of Disease Shortly After Vaccination. The host requires several days after vaccination before an effective immune response will develop. If the animal encounters an infectious agent prior to or near the time of vaccination, the vaccine may not have time to induce immunity. The animal may come down with clinical disease resulting in an apparent vaccination failure. In this situation, disease symptoms will appear shortly after vaccination and may be mistakenly attributed to vaccine agent causing the disease. Modified live vaccine viruses consisting of attenuated virus may be capable of producing disease in immunosuppressed animals.

Alterations in the Vaccine. Improperly handled and administered vaccines may fail to induce the expected immune response in normal, healthy animals. Modified live bacterial and viral vaccines are effective only if the agent in the vaccine is viable and able to replicate in the vaccinated animal. Observing proper storage conditions and proper methods of administration are very important for maintaining vaccine viability. Failure to store the vaccine at refrigerator temperatures or exposure to light may inactivate the vaccine. Even when stored under appropriate conditions, the vaccine loses viability over time. Therefore, vaccines that are past their expiration date should not be used. The use of chemical disinfectants on syringes and needles can inactivate modified live vaccines if there is any residual disinfectant. The use of an improper diluent or the mixing of vaccines in a single syringe may also inactivate modified live vaccines. Diluent for lyophilized vaccines are formulated specifically for each vaccine. A diluent which is appropriate for one vaccine may inactivate a different vaccine. Some vaccines and diluents contain preservatives that may inactivate other modified live vaccines. For these reasons, multiple vaccines should not be mixed in a single syringe unless that particular combination has been adequately tested to insure there is no interference.

Host Factors Contributing to Vaccine Failure. Vaccine failures may occur because a vaccinated animal is not able to respond appropriately to the vaccine. Vaccine failure in young animals may be due to the presence of maternal antibody, which prevents adequate response to vaccination. It can also be due to immunosuppression from a variety of causes, as discussed previously.

Maternal antibodies derived from colostrum are a well-known cause of vaccine failure. These antibodies in the piglets' circulation may neutralize or remove the antigen before it can induce an immune response. Typically, virulent infectious agents are capable of breaking through maternal immunity earlier than modified live or killed vaccines. This means that even if young animals are immunized frequently, there is still often a period when they are vulnerable to infection. Vulnerability occurs between the time that young animals lose their maternal antibody and before they develop their own active immune response. This period can be shortened by the use of less-attenuated modified live vaccines or the use of killed vaccines with high antigenic mass. Overcrowding and poor sanitation exacerbate the problem of inducing immunity in young animals before they come down with clinical disease.

Because only one vaccination is commonly recommended for large domestic animals, the timing of the vaccination is important. If the vaccine is administered too soon, it may be ineffective because of the presence of maternal antibody. If the vaccine is administered after all maternal antibodies are gone from animals in the herd, there may be a prolonged period of vulnerability before they develop their own immune response. Most veterinarians and producers decide that because of time and expense considerations it is impractical to vaccinate young pigs frequently. However, frequent vaccination may be justified in cases of unusually high disease incidence.

Immunosuppression due to a variety of factors including stress, malnutrition, concurrent infection, or immaturity or senescence of the immune system may also lead to vaccination failure. If the immunosuppression occurs at the time of vaccination, the vaccine may fail to induce an adequate immune response. If the immunosuppression occurs sometime after vaccination, disease may occur due to reduced immunity in spite of an adequate response to the original vaccine. Therapy with immunosuppressive drugs (e.g., glucocorticoids) may also cause this to occur.

Another concern is that some modified live vaccines are capable of inducing disease in the immunosuppressed animal. Modified live vaccines are tested for safety in normal, healthy animals. They are not recommended for use in animals with compromised immune systems. Therefore, these vaccines should not be used in animals that are immunosuppressed for any reason. This includes animals in the first few weeks of life unless the vaccine has been specifically tested in animals this young. When it is necessary to vaccinate animals under these conditions, killed vaccines should be used.

Overwhelming Challenge Dose. Most vaccines do not produce complete immunity to disease. They provide an increased ability to resist challenge by infectious agents. If a high challenge dose of organisms is present due to overcrowding or poor sanitation, the immune system may be overwhelmed, resulting in clinical disease.

Vaccine Efficacy. Vaccines that are licensed by the United States Department of Agriculture have been tested to determine that they are safe and effective. However, "effective" is a relative term. It does not mean that the vaccine must be able to induce complete immunity under all conditions that may be found in the field. This would not be realistic since the immune system is not capable of such potent protection under adverse conditions.

To be federally licensed, the vaccine must have been tested under controlled experimental conditions. The vaccinated group must have had significantly less disease than the nonvaccinated control group. This testing is typically done on healthy, nonstressed animals under good environmental conditions and with a controlled exposure to a single infectious agent. Vaccines may be much less effective when used in animals that are under stress, incubating other infectious diseases, or exposed to a high dose of infectious agents due to overcrowding or poor sanitation.

It is important to remember that for most diseases the relationship between the infectious agent and the host is sufficiently complicated that vaccination cannot be expected to provide complete protection. The vaccine can increase the animal's resistance to disease, but this resistance can be overwhelmed if good management practices are not followed.

3 Diseases of the Digestive System

Jill R. Thomson

Diseases of the gastrointestinal tract that affect pigs between neonatal and finishing stages continue to be some of the greatest factors that limit the efficiency and profitability of pig production globally. Advances in effective disease control measures such as development of new vaccines and antimicrobial products have provided new approaches to disease control. However, this is countered by increasing awareness of other issues such as development of antimicrobial resistance, the ban or limitation of the use of antimicrobial growth promoters in some countries, and increasing public awareness and expectation of food safety—particularly in relation to salmonellosis and food residues. Salmonellae surveillance and control have become a major objective in many countries following the schemes initiated in Scandinavia. This has demanded new standards of hygiene and care involving a whole-chain approach to disease control. However, there is also increasing public concern over intensive farming systems and consumer demands for more natural and welfare-friendly methods of farming that allow pigs to express normal rooting behavior through availability of substrate. To these ends, legislation has been introduced in some countries and this is likely to increase, thus presenting new challenges for pig producers and veterinarians in relation to effective control of enteric infections. Organic product is increasing in popularity and requires alternative approaches to enteric disease prevention.

In parallel with these practical issues, there has been substantial ongoing research into the enteric physiology and immunology in the pig. This work provides the foundation for future practical advances in enteric disease control and is briefly reviewed in the following sections. Thereafter there is an overview of enteric diseases (which are covered in depth in other chapters).

ANATOMIC AND HISTOLOGIC FEATURES

The conformation and growth efficiency of the pig has changed dramatically over the years as the result of genetic selection and production of suitable hybrids. However, the gut morphology is apparently unchanged and an area of little focus or attention. The exception is the development of genotypes resistant to F18 and F4 (K88) *Escherichia coli* infections in which pigs do not possess the required receptor for these organisms to cause disease.

Gut maturation occurs rapidly after birth in response to factors such as oxygenation; enteral nutrient presentation; and hormones, particularly cortisol (Sangild 2001). Neonatal hypoxia is associated with intestinal dysfunction and an increased incidence in neonatal enterocolitis (Cohen et al. 1991; Powell et al. 1999). At birth the sudden increase in blood arterial oxygen is a vital factor in gut development. Common occurrences such as delayed parturition or congenital pneumonic infections could be initiating factors for neonatal diarrhea. After birth the small intestine undergoes a rapid growth in response to enteral presentation of nutrients (Burrin et al. 2000). This is stimulated by a wide range of factors such as hormones and growth factors (Sangild 2001). Good intake of milk in the early stages of life is important for rapid gut growth as well as promoting piglet vigor and provision of colostral immunity.

During the first 3–4 weeks of life fetal enterocytes which have high endocytotic activity are gradually replaced by adult type enterocytes devoid of such activity. The process occurs in a proximal-to-distal direction in the intestine and is an important part of intestinal maturation (Baintner 1986). Changes in enterocyte generation influence the expression of brush border enzymes. Lactose activity is high in the newborn pig and steadily decreases to become minimal after weaning, whereas sucrase and maltase activities are low in the newborn but increase after weaning (Pluske et al. 1997). Intestinal maturation can be hastened in the unweaned pig by feeding kidney bean lectin (*Phaseolus vulgaris*) (Pusztai et al. 1999; Biernat et al. 2001; Rådberg et al. 2001). This dietary means of promoting rapid gut maturation could be of value in reducing or preventing postweaning diarrhea problems in pigs in the future.

Weaning is associated with adverse effects, such as abrupt withdrawal of sow's milk, low and variable feed intake, growth stasis, and compromised integrity of the small intestinal epithelium. Changes in gut morphology at weaning include reduced villus height and increased crypt depth (Hampson 1986; Kelly et al. 1991). These adverse effects can be diet-dependent and diet-independent (McCracken et al. 1995). Villus length reduces by 30–40% at days 4 to 7 postweaning but increases back to 94% of original length at 14 days postweaning (Verdonk et al. 2001a). Additionally, a reduction in the length of microvilli occurs at 3–7 days after weaning (Cera et al. 1988). There is a significant relationship between voluntary feed intake and mucosal architecture (Makkink et al. 1994; Pluske et al. 1996b). Low feed intakes or a period of starvation postweaning reduces the villus height throughout the small intestine particularly in the proximal jejunum. To minimize the changes, diets high in milk products, cooked cereals, and low levels of antigenicity are utilized. Raw cereals have a significant adverse effect on gut mucosa as compared with cooked cereals, which are thought to improve postweaning growth (Lawlor et al. 2001). Anorexia at weaning might contribute to local inflammation in the piglet's small intestine (McCracken et al. 1999). With low nutrient intake paracellular transport is higher and this increases over the first 4 days after weaning (Verdonk et al. 2001b). Therefore it would appear that the integrity of the gut mucosa is worse in piglets with low intake levels postweaning due to higher permeability of the tight junctions between cells (paracellular transport route), but permeability of the mucosa cells is not affected. The dietary changes at weaning and the resultant villus atrophy and crypt hyperplasia leads to decreased digestive and absorptive capacities in the intestine (Pluske et al. 1997, Rådberg et al. 2001). Other factors of importance are poor feed consumption, inflammation in response to bacterial metabolites, rotavirus, and hypersensitivity to antigenic components of the diet (Kenworthy 1976; Hampson and Kidder 1986; Kelly 1990). These physiological changes can result in alterations in the number and balance of the enteric bacterial flora often allowing enteropathogenic bacteria to proliferate, resulting in serious postweaning enteropathies such as colibacillosis. The morphological and functional changes in the small intestine of the newly weaned pig have been reviewed by Pluske (2001).

Transport associated stress of pigs has been shown to lower the intestinal pH and result in increased intestinal permeability. Permeability is the highest immediately after transportation and decreases after 2–3 hours of rest (van der Meulen et al. 2001). Translocation of bacteria and/or endotoxins from the gut into the systemic circulation is possible due to increased permeability (Zucker and Krüger 1998; Berg 1999). This might explain the increase in disease problems seen after transportation (Berends et al. 1996).

PHYSIOLOGY AND NUTRITION

The intestinal mucosa receives nutrients from 2 sources—the diet (brush border membrane) and the systemic circulation (baso-lateral membrane). The gut tissues have their own particular nutrient requirements for growth and function. The gastrointestinal tissues in the young growing pig utilize nearly 50% of the dietary amino acid intake and 30–50% of the dietary lysine, leucine, and phenylalanine plus 85% of threonine (Burrin et al. 2001). A substantial proportion of the essential amino acid needs and glucose needs are derived from the arterial circulation rather than from direct dietary sources. The amino acids are utilized in many ways, such as the formation of secretary mucins (Stoll et al. 1998), biosynthesis of other amino acids (Stoll et al. 1999), glutathione (Reeds et al. 1997) and nucleic acids (Perez and Reeds 1998). Nutrient supply for the neonate is derived solely from colostrum and milk. Additionally, colostrum and milk contain a large number of biologically active peptides that have important functions in regulating growth and differentiation of intestinal tissues. Targeted expression of key genes for production of milk peptides holds potential for the future (Kelly and Coutts 1997). On low protein diets, the lysine requirements of the gut remain relatively high and are preferentially met, which limits the systemic availability of lysine for lean tissue growth (Ebner et al. 1994). Exposure to microbial antigens (both pathogenic and nonpathogenic) stimulates a proinflammatory acute-phase response (MacRae 1993; Johnson 1997), which results in the loss of dietary amino acids and reduced deposition of body protein (e.g., reduced growth rate). The use of in-feed antibiotic growth promoters enhances growth rates by limiting this process.

Dietary carbohydrates are comprised of sugars, oligosaccharides, starch, and nonstarch polysaccharides. The enzyme activity responsible for carbohydrate degradation adapts according to the age of the pig and dietary composition. In the young pig there is efficient prececal digestion of lactose during suckling, and sucrose and starch after weaning. Carbohydrates that do not get digested in the small intestine are fermented in the large intestine by a diverse population of anaerobic bacteria. These are mostly nonstarch polysaccharides (NSPs).

Increasing the amount of fermentable carbohydrates and straw in the diet increases the total gastrointestinal tract weight by approximately 8% and 7%, respectively. With fermentable carbohydrates the main weight increase occurs in the colon, whereas with straw it occurs in the stomach and colon (Rijnen et al. 2001).

Most of the starches used in pig diets are highly digestible, with up to 98% of digestion occurring in the small intestine (Glitsø et al. 1998; Bach Knudson and Canibe 2000). Nonstarch polysaccharides (fiber) are present in cereals such as barley, wheat, oats, and rye.

Although there is some digestion of NSPs in the small intestine, the major site of NSP degradation is in the large intestine. Passage of ingesta through the large intestine generally takes from 20–40 hours, allowing time for bacterial degradation. The most common bacterial isolates are *Streptococcus* sp., *Lactobacillus*, *Fusobacterium*, *Eubacterium*, *Bacteroides,* and *Peptostreptococcus* (Moore et al. 1987). Fermentation of carbohydrates and NSPs in the large intestine results in the production of short chain fatty acids, mainly acetate, proprionate and butyrate, and the gases H_2, CO_2, and CH_4. Increasing the level of NSP entering the large intestine results in higher activity of microflora (Bach Knudson et al. 1991; Jensen and Jørgensen 1994), increased production of short chain fatty acids (Giusi-Perier et al. 1989), and increased production of gases (Jensen and Jørgensen 1994). Short chain fatty acids are rapidly absorbed from the large intestine and may provide up to 24% of the maintenance energy requirements for growing pigs (Yen et al. 1991) and potentially even more for adults. The total tract digestibility of NSPs is influenced by a number of complex factors, such as the source of NSPs, the level of inclusion in the diet, the solubility, the degree of lignification, the age and weight of the animal, the transit time, and the microbial composition (Bach Knudson and Jørgensen 2001). Adult animals are more capable of degrading fiber than growing pigs due to the greater intestinal volume and slower transit times. Adaptation to dietary changes in terms of digestibility of NSP residues is considered to take 3–5 weeks (Longland et al. 1993).

In weaner pigs the use of enzyme combinations has been found to increase the apparent ileal digestibility of feeds based on hulless barley, which have high beta-glucan concentrations (Yin et al. 2001). Due to the improved apparent ileal digestibility there was also a reduction in hind gut fermentation. Similarly, the addition of certain enzymes to wheat-based diets of growing pigs has been found to have beneficial effects (Hazzledine and Partridge 1996). There is increasing interest in the role of dietary factors, especially NSP and feed processing methods in so-called nonspecific colitis of pigs (Strachan et al. 2002, Thomson et al. 2004). This condition is thought to be an important precursor to other forms of colitis in pigs although the pathogenesis of this diet-associated form of colitis is poorly understood.

IMMUNOLOGY

For the first 24–48 hours of life the pig intestine is capable of absorbing macromolecules including immunoglobulins by pinocytosis, providing the neonate with passive immunity from colostrum (Weström et al. 1984). Although this process commences prepartum, the major absorptive function occurs postnatally (Sangild et al. 1999). This is a specific maturational process that is timed to maximize immunoglobulin uptake shortly after birth. Piglets born prematurely have a lower capacity for protein absorption than piglets born at full term (Sangild et al. 1997). Therefore fetal maturity is an important factor in successful immunoglobulin uptake from the colostrum.

The intestinal immune system of the young pig is very immature and its slow development may result in increased susceptibility to disease (Stokes et al. 2001). Intestinal lymphoid tissue is present in the form of mesenteric lymph nodes, intestinal Peyer's patches, and lymphocytes distributed through the mucosal lamina propria and intraepithelial sites. In the jejunum there are between 11–26 discrete Peyer's patches containing multiple lymphoid follicles (B lymphocytes) separated by T cells. Plasma cells containing IgM, IgG, and IgA are present in the subepithelial lymphoid dome and between the follicles (Brown and Bourne 1976). The dome region contains dendritic-type cells that express high levels of MHC II antigens. Microfold cells (M cells) that are thought to absorb luminal antigens occur in the overlying lymphoepithelium (Gebert et al. 1994). In the mature pig the intestinal lamina propria is heavily populated with lymphocytes. Plasma cells and B cells predominate in the crypt area, whereas T cells are found mainly in the villi, CD8[+] cells occur in the subepithelial sites, and CD4[+] occur in association with capillary plexuses in the lamina propria (Vega-Lopez et al. 1993). The majority of intraepithelial lymphocytes express CD2, but in mature pigs a high proportion also express CD8 (Stokes et al. 2001).

Functionally the intestinal immune mechanisms play a complex role in preventing and controlling harmful intestinal infections while tolerating many dietary antigens and nonharmful antigens from the intestinal flora. The surface epithelium serves as an effective barrier, providing it remains intact. IgA antibodies play an important defensive role. Significant quantities of dietary protein are absorbed across the intestinal mucosa (Wilson et al. 1989; Telemo et al. 1991). So-called "intestinal tolerance" to dietary proteins has been demonstrated in the pig, where immune responses to the dietary proteins are regulated to prevent inflammatory reaction and tissue damage associated with foreign protein absorption (Bailey et al. 1993). The interaction between the different components of the intestinal immune system is complex, and the basis of inflammation and apoptosis versus down regulation of immune responses is the subject of ongoing research.

Development of the pig's intestinal immune system occurs in response to antigen exposure. Full development of lymphoid tissue can take 7–9 weeks and can be delayed by early weaning at 3–4 weeks of age, as carried out in most modern pig-producing countries (Vega-Lopez et al. 1995). This, among many other factors, predisposes to postweaning diarrhea associated with enterotoxigenic *E. coli* or other pathogens. There is also increasing interest in the role of glutamine in intestinal immune function. Glutamine is an important nitrogen

source for enterocytes and plays a key role in maintaining mucosal cell integrity and gut barrier function (den Hond et al. 1999). Key functions of lymphocytes are dependent on glutamine provision (Graham et al. 2000). Glutamine depletion results in immunosuppression, whereas glutamine administration has been found to have significant beneficial effects on the gut mucosal structure and intestinal immune function of piglets after weaning (Pierzynowski et al. 2001). Other studies on enhancing intestinal immune function of piglets at weaning have included feeding nucleotides for 2–4 weeks after weaning. This was found to have an immune enhancing effect on piglets through improving T-cell–mediated responses (Cameron et al. 2001). This is an important area of research because finding cost-effective methods of enhancing immune responses in the young weaner would bring significant benefits to the pig industry.

GUT FLORA

The intestinal flora of the pig is extremely complex and diverse making it difficult to study quantitatively and qualitatively. However this is an area of increasing interest in relation to maintenance of gut health and optimal function. The intestinal microflora of the large intestine has been studied and reviewed by Robinson et al. (1981, 1984).

Marked changes occur in the gut environment (for example, pH and organic acids) and microbial activity along the gastrointestinal tract of pigs (Bach Knudson et al. 1991, 1993). Differences in the diet composition can impose further changes and could affect the diversity of the gut microflora. In an experiment involving diets containing different levels of soluble and insoluble NSP, a medium to high content of NSP resulted in higher microbial diversity in the small intestine (Högberg et al. 2001). The presence of fermentable carbohydrates in the diet stimulates gut microbial activity resulting in the production of organic acids.

The potential value of prebiotics (compounds, other than dietary nutrients, that act as substrates for populations of beneficial microbial organisms in the gut) and probiotics (preparations containing beneficial bacteria) has been the subject of many studies in relation to gut health and prevention of enteric infections. Prebiotics achieve their beneficial effects in two ways. First, compounds such as fructooligosaccharides can be fermented by favorable bacteria (e.g., *Bifidobacteria* and *Lactobacilli*) giving them competitive advantage (Houdjik 1998; Nemcová et al. 1999). Second, mannose-containing compounds added to the diet result in binding with pathogenic bacteria that have mannose-specific lectins in fimbriae—for example, *E. coli* and *Salmonella*. This reduces attachment of pathogenic bacteria to receptor sites on gut mucosal cells (McDonald et al. 2002). Inulin is a natural polymer of fructose extracted from chicory that is considered to have prebiotic properties (Gibson and Roberfroid 1995; Roberfroid et al. 1998). Digestion of inulin in weaned pigs is mainly microbial and takes place in the large intestine. There, it modifies the profile of fermentation metabolites resulting in an increase in N-valerate and propionate and a decrease in acetate and ammonia (Rossi et al. 1997). Using an in vitro adhesion assay for *E. coli*, 5% inulin was found to partially inhibit adhesion of F4 positive *E. coli* to the small intestinal villi. The study also suggested that inulin might have immunomodulatory effects by boosting IgA and IgM antibodies in pigs exposed to foreign proteins (Rossi et al. 2001). In newly weaned pigs, addition of fructooligosaccharide and/or sugar beet pulp to the diet tended to increase the number of intestinal *Bifidobacterium* species and reduce the level of *E. coli,* although there was little difference in the incidence of diarrhea (Kleingebbink et al. 2001). The population of *Bifidobacterium* species is variable in piglets and constitutes less than 1% of the total bacterial population (Mikkelsen and Jensen 2001). Certain plant metabolites may interact with short chain fatty acids to create inhibitory conditions for pathogens such as *E. coli* 0157 (Duncan et al. 1998). The use of prebiotic is likely to be an area of growing scientific interest in the future.

Probiotics work on the principle of competitive exclusion of pathogenic bacteria and have been used successfully, for example, to control *Yersinia* infection in pigs (Asplund et al. 1996). Feeding probiotic bacteria, especially *Lactobacillus* species and *Bifidobacterium* species, may help with controlling enteric infections postweaning when the resident microflora are not yet stable. However, probiotics may also inhibit adherence of enteropathogenic *E. coli* and other gram-negative bacteria to enterocytes through occupying receptor sites (Spencer and Chesson 1994; Mack et al. 1999). This has potential for improved control of a wide range of enteric infections, particularly those of zoonotic importance such as *Salmonella* species and *Campylobacter* species. *Salmonella* infections in pigs are common resulting in clinical salmonellosis or subclinical disease (Lax et al. 1995). Up to 30% of finisher pigs might shed *Salmonella*, thereby presenting risk of carcass contamination at slaughter (Berends et al. 1996). *Campylobacter* is one of the most common causes of human enteric disease and has been isolated from a wide range of raw meats, including pork (Stern et al. 1985; Fricker and Park 1989; Zanetti et al. 1996). The predominant species in pigs is *Campylobacter coli* (Stern et al. 1985; Weitjnes et al. 1993, 1997; Young et al. 2000); however, some pig farms can also have a high prevalence of *Campylobacter jejuni* (Harvey et al. 1999). Contact with the sow during the suckling period results in a high prevalence of *Campylobacter* in piglets, whereas piglets removed from the sow after 24 hours and reared in isolation units have significantly less *Campylobacter* (Harvey et al. 2001).

CONTROL OF ENTERIC INFECTIONS THROUGH DIETARY INTERVENTIONS

Following the European Union ban on the use of the majority of antibiotic growth promoters, alternative measures to control the number and activity of intestinal bacteria have been explored. These include changes in management practices, feeding, hygiene, and the use of products such as probiotics, prebiotics, enzymes, herbs and plant extracts, prefermented feeds, and organic acids (Thomke and Elwinger 1998). Additionally, selective breeding for resistance; improving the pig's immune response through the use of vaccines, cytokines, and other immunomodulatory agents; organic acids; inorganic chemicals—for example, zinc oxide; and use of specific bacteriophages or bacteriocins are also possible (Hampson et al. 2001). The mechanisms by which antimicrobial agents enhance growth and feed efficiency are poorly understood (Commission on Antimicrobial Feed Additives 1997; Anderson et al. 1999). Two of the suggested mechanisms are inhibition of subclinical bacterial infection and less translocation of pathogens, and changing the small intestinal mucosal structure, mainly by increasing villus height promoting uptake of nutrients from the digesta. Finding effective non-antimicrobial alternatives requires a good understanding of the mechanisms that promote the beneficial effects in different age groups of pigs.

Dietary Fiber and Cereals

Different forms of fiber in the diet can influence the composition and metabolic activity of the large intestinal microflora in pigs (Varel et al. 1982; Varel and Pond 1985; Bach Knudson et al. 1991; Jensen and Jørgenson 1994; Reid and Hillman 1999). However, little is known about the ways in which the commensal colonic microflora interacts with pathogenic bacteria; therefore, the basis of dietary control of infectious enteric diseases is not understood. Other ways in which diet could influence pathogenic enteric infections include changing the amount or balance of substrates available for the organism at particular sites, influencing the viscosity, accessibility to receptor sites, and/or intestinal motility. For example, different cereal types and particle sizes have been shown to alter epithelial cell proliferation and lectin binding patterns of the epithelium of the large intestine of pigs (Brunsgaard 1998). The diet can also influence intestinal function. Components in boiled rice inhibit secretion in the small intestine and therefore reduce the magnitude of secretory diarrhea due to pathogens such as enterotoxigenic *E. coli* (Mathews et al. 1999).

One of the most well-recognized examples of dietary effects on enteric pathology is gastric ulceration, in which ulceration of the pars oesophagea occurs particularly in growing and finishing pigs. Such lesions can be associated with reduced growth rates (Ayles et al. 1996) but more importantly can be a cause of gastric hemorrhage and perforation leading to acute illness and death (Friendship 1999). Many studies have demonstrated a strong association between finely ground high wheat diet and gastric ulceration (Accioly et al. 1998). The role of bacteria in the pathogenesis is unclear. The spiral bacterium *Helicobacter heilmannii* has been associated with gastric ulceration in some studies (Barbosa et al. 1995, Queiroz et al. 1996), whereas in other studies, the association was weak or equivocal (Phillips 1999). Experimental inoculation of gnotobiotic pigs with *H. heilmannii* failed to produce lesions of gastric ulceration in pigs fed on a carbohydrate-enriched liquid diet (Krakowa et al. 1998). However inoculation of pigs with *Lactobacillus* sp. and *Bacillus* sp. when fed the same diet did produce ulcers, possibly due to fermentation by these bacteria in the presence of readily available dietary substrate. It is possible that production of short chain fatty acids produced through the fermentation process resulted in ulceration (Krakowa et al. 1998).

Early studies on the influence of diet in postweaning colibacillosis have shown that high concentrations of dietary protein (21%) predispose to the condition (Prohaszka and Baron 1980), whereas highly digestible milk-based weaner diets were associated with reduced postweaning diarrhea (English 1981). Conversely, inclusion of fiber sources was suggested to reduce the severity and incidence of postweaning diarrhea (Bertschinger et al. 1978, Bolduan et al. 1988). Later studies compared the effects of feeding different postweaning diets in experimental *E. coli* challenge model. Diets included a highly digestible cooked rice/animal protein diet with or without the addition of guar gum or 50% pearl barley as sources of additional soluble NSP and a commercial wheat/lupin-based diet (McDonald et al. 1997, 1999, 2001). Significantly more *E. coli* were isolated from the small intestines of piglets fed the soluble NSP supplemented diet and the wheat/lupin-based diet than the highly digestible rice/animal protein diet alone. The reason for the increased *E. coli* numbers in piglets fed the "provocative" diets is uncertain, but factors involving the amount of substrate in the small intestine, the viscosity of the ingesta, the rate of intestinal motility, and different fermentation processes within the small intestine were all potentially significant.

Most work has been done on the influence of diet on swine dysentery. Whereas a cooked rice diet was found to be protective in some studies (Siba et al. 1996) it was not in others (Kirkwood et al. 2000, Lindecrona et al. 2003). Feeding the cooked rice diet to pigs already affected with swine dysentery did not reduce the duration or severity of disease (Durmic et al. 2000). In a study of different cereal types, feeding steam-flaked maize or sorghum reduced the incidence of the disease (Pluske et al. 1996a). Soluble NSP and resistant starch were identified as important factors promoting large intestinal fermentation and bacterial colonization, whereas with the

addition of a source of mainly insoluble NSP (oat chaff) the diet remained protective (Pluske et al. 1998). Addition of enzymes to wheat-based diets or the use of heat extrusion to increase digestibility of starch in the small intestine were tested in terms of their potential protective effects in swine dysentery but neither processes prevented colonization (Durmic et al. 2000). Likewise the use of a sorghum-based diet was tested as sorghum is inherently low in soluble NSPs but this diet was not protective against swine dysentery (Durmic 2000). However, the grind size of diets was important, with significantly more pigs developing swine dysentery with coarsely ground wheat or sorghum than with these grains finely ground (Hampson et al. 2001). In porcine colonic spirochetosis, pigs on the cooked rice diet developed infection later and to a lesser extent than pigs on wheat-based diet (Hampson et al. 2000; Lindecrona et al. 2004).

Carriage of *Oesophagostomum dentatum* in pigs is enhanced by diets rich in insoluble fiber (Petkevicius et al. 1997).

Organic Acids and their Salts, Inorganic Compounds, and Fatty Acids

Alternatives to antibiotic inclusion in weaner diets have included the use of organic acids and their salts such as potassium diformate (Roth et al. 1998). Addition of 1.8% potassium diformate to a piglet starter ration decreased the counts of total anaerobic bacteria, lactic acid bacteria, yeasts, and coliforms in the digesta from the stomach, distal small intestine, cecum, and midcolon over a period of 4 weeks after weaning (Canibe et al. 2001). The apparent antimicrobial effects were attributed to the protons and anions formed from formic acid after passing through the bacterial cell wall. These have a disruptive effect on protein synthesis and inhibit bacterial enzymes, thereby reducing bacterial replication (Partenen and Mroz 1999). Other studies agree that coliform counts in the stomach and proximal colon decrease when levels of formic acid increase (Kirchgessner et al. 1992, Gabert et al. 1995), or when potassium diformate is used (Février et al. 2001). Supplementation of weaner diet with organic acids or other salts have been shown to reduce the incidence of postweaning diarrhea and improve growth performance of piglets (Sutton et al. 1991). When the coliform inhibitory effects of various organic acids were compared, the results going from most effective to least effective were benzoic, fumaric, lactic, butyric, formic, and proprionic acid.

Feed supplemented with 2500 ppm zinc oxide has been shown to reduce postweaning diarrhea and has been widely used in commercial pig production, but the mechanism of action is unclear (Holm 1998). In a study of the effects of zinc oxide on the enteric flora, no differences were recorded between the zinc oxide–supplemented group and control group, in terms of the number of coliforms, enterococci, or *Clostridium perfrin-*

gens excreted per gram of feces. However, there was an overall reduction in the diversity of the fecal coliform flora in the zinc oxide–treated pigs. In the second week postweaning zinc oxide treated pigs showed significant increases in growth rate over controls (Melin et al. 2001). However recent European Union (EU) legislation limits the maximum permissible level of zinc inclusion in pig diets to 150 ppm in EU member states (EU regulation No 1334/2003).

Fermented Liquid Feeds

Liquid feeding can improve the feed intake, growth, feed conversion, and health of weaner piglets (Brooks et al. 1996). However, steeping feed in water promotes bacterial proliferation in the feed, which reduces the quality of the feed and presents health risks. Feeding fermented liquid feed has been used as a means of controlling enteric infections through acidification. As part of the diet for newly weaned pigs, fermented liquid feed had beneficial effects on the villus height and ratio of villus height to crypt depth in the proximal jejunum (Scholten et al. 1999), as compared with the diet without fermented liquid wheat. The mechanism is uncertain but it could have been due to a lower pH, increased levels of organic acids, and an altered microbiological status. The use of fermented liquid feed in newly weaned piglets caused a significant reduction in the coliform population in the terminal ileum, cecum, and colon compared with piglets fed dried feed (Jensen and Mikkelsen 1998; Moran et al. 2001). Feed was prepared by inoculating the diet with lactic acid bacteria (*Lactobacillus plantarum)* and steeping it for 5 days at 25°C before feeding. Fermentation prevents bacterial colonization and spoilage of the liquid diet by enteropathogens and other spoilage bacteria. The fermentation temperature is important in relation to bacterial survival. *E. coli* was eliminated more effectively at 37°C than 20°C (Beal et al. 2001). There were also strain differences in terms of *E. coli* survival in fermented liquid feed, with F4 (K88) being the most resistant to killing by fermentation than others (Beal et al. 2001). The effect of temperature has implications for the management of fermented liquid feed systems. Cold-shock proteins help *E. coli* survive at lower temperature (Phadtare et al. 1999). Prefermented diets not only lower the acidity of the diet but also reduce the soluble NSP content of the diet (Hampson et al. 2001).

Piglets showed a significant preference for freshly prepared liquid feed over fermented liquid feed when given the choice (Demeckova et al. 2001). To prevent spoilage, chlorine dioxide added at 300 ppm was found to eliminate coliforms from liquid feeds for young piglets without adversely affecting palatability or growth performance (Demeckova et al. 2001). Chlorine dioxide is a strong oxidizing and phonatizing agent with broad antimicrobial spectrum, being active against bacteria and viruses (Junli et al. 1997). Addition of chlorine dioxide to freshly prepared wet feed did not signifi-

cantly alter the intake, as compared with nonsanitized freshly prepared wet feed. Chlorine dioxide is reported to kill *E. coli* through loss of permeability control of the outer bacterial cell membrane (Berg et al. 1986).

REHYDRATION OF DIARRHEIC PIGLETS

Oral rehydration fluids are used in piglets with acute diarrhea especially during outbreaks of enterotoxigenic *E. coli* (ETEC) and rotavirus infections. Studies in rats and clinical studies in children have shown that reducing the osmolality of oral rehydration solutions has beneficial effects on the course of diarrhea and the clinical outcome (Thillainayagam et al. 1998). Using an experimental pig model Kiers et al. (2001a) demonstrated that solutions with low osmolality promoted intestinal fluid absorption, although ETEC infection resulted in a decrease in net fluid absorption independent of osmolality, as compared with that of unaffected tissue.

In an experimental model mold-fermented soya bean products were found to be beneficial in maintaining fluid balance during postweaning ETEC infection through preventing fluid loss (Kiers et al. 2001b). The mechanism is uncertain. It might interfere with the attachment of *E. coli* to epithelial cells or modulate the effects of toxin in the intestine.

REGIONAL DISEASES AND PATHOLOGY OF THE DIGESTIVE SYSTEM

The Oral Cavity

There are several recognized congenital defects affecting the oral cavity. Cleft palate and palatoschisis are both multifactorial developmental abnormalities. Cleft palate in piglets has occurred with feeding poisonous plants such as poison hemlock (*Conium maculatum*) or wild tree tobacco (*Nicotiana glauca*) to sows or gilts in early pregnancy (Keeler and Crowe 1983; Panter et al. 1985). Likewise, accidental contamination of sow feed with seeds of *Crotalaria retusa* during pregnancy has resulted in palatoschisis in piglets (Hooper and Scanlan 1977). Brachygnathia superior (shortness of maxillae) is an inherited condition that is progressive and may be confused with progressive atrophic rhinitis. Hypertrophy of the tongue is a rare congenital anomaly in pigs that interfers with normal suckling behavior. Epitheliogenesis imperfecta affects gingiva and tongue and can be seen as irregular, well-demarcated red areas that are devoid of epithelial tissue.

Oral lesions arising from traumatic damage are relatively common. Gingivitis and periodontal inflammation is usually associated with poor teeth clipping technique resulting in damage to the gingival epithelium. Stomatitis and tooth root abscesses may follow. *Fusobacterium necrophorum* is a common isolate from such lesions. Pigs have a diverticulum of the pharynx in the posterior wall immediately above the esophagus. Barley awns and other fibrous materials can lodge there and penetrate the pharynx causing pharyngeal cellulitis. This is usually seen only in young pigs. Stomatitis can also be caused by irritant chemicals, such as caustic or toxic compounds, and by physical burns. Blistering and erosion of the snout epithelium can arise due to sunburn.

A number of important infectious diseases show lesions on the snout and oral tissues. These are primarily the viral vesicular diseases, including foot and mouth disease, swine vesicular disease, and vesicular stomatitis. Lesions include blanching of the epithelium, vesicles, erosions, and epithelial flaps. Sunburn and occasionally parvovirus infection can cause lesions on the snout resembling vesicular diseases. Ulcerative glossitis and stomatitis have been reported in piglets with exudative epidermitis. Piglets may also develop ulcers on the dorsum of the tongue and occasionally on the hard palate associated with *Staphylococcus hyicus* infection (Andrews 1979). Oral erosions and ulcers can also be seen in piglets with congenital swine pox. *Actinobacillus lignieresi* can cause swelling and inflammation of the tongue, with nodule and ulcer formation. Soft tissues of the pharynx and neck can also be affected. Of the parasitic infections, *Trichinella spiralis* can affect the tongue and muscles of mastication. *Gongylonema* species has been found in the mucosa of the tongue in grazing pigs where they cause mild, localized inflammation (Zinter and Migaki 1970).

The tonsils have a strategic role in immune surveillance of the oropharynx. A host of bacterial agents, including *Streptococcus suis* and Pasteurellae, are frequently carried in the tonsils. Crypt inflammation and lymphoid hyperplasia are associated with bacterial infections. Necrotizing tonsillitis occurs in Aujeszky's disease; the tonsils being the site of primary virus replication (Terpstra and Wensvoort 1988). Tonsillitis is also a feature of swine vesicular disease. Hemorrhagic necrotizing tonsillitis can occur in pigs with anthrax.

There are few reported problems concerning the salivary glands in pigs, but sialoadenitis occurs in vitamin A deficiency (Barker et al. 1993). The interlobular ducts of the salivary glands undergo squamous metaplasia leading to salivary stasis, secondary infection, and purulent inflammation. This results in pronounced swelling of salivary glands. Epithelial degeneration of salivary ducts is seen in swine vesicular disease.

The Esophagus

Conditions affecting the esophagus are uncommon but include hyperkeratosis, parakeratosis, mycotic infection, obstructions, and traumatic lesions. Hyperkeratosis and thickening of the epithelium are associated with vitamin A deficiency or chlorinated naphthalene toxicity. Parakeratosis of the esophagus occurs in pigs with cutaneous parakeratosis due to zinc deficiency. Parakeratotic thickening of the epithelium of the distal

esophagus, with basal hyperplasia of the epithelium is commonly seen in pigs with ulceration of the pars esophagea of the stomach. Reflux esophagitis is recognized in some pigs with ulceration of the pars oesophagea. The gastric secretion has corrosive effects on the squamous epithelium resulting in mucosal erosion, ulceration, and inflammation.

Mycotic esophagitis caused by *Candida albicans* can occur in suckling piglets and weaners that are immunocompromised and have been given repeated antibiotic treatment or in piglets in which the mucosal flora has been significantly disrupted for some reason.

Obstruction and/or perforation of the esophagus are associated with ingestion of large objects such as stones, potatoes, apples, or corncobs. Perforation can result from ingestion of sharp objects such as fence wire or nails. Inflammation and subsequent stricture are sequelae that affect the esophagus at the site of perforation. Such conditions lead to dysphagia and distension of the esophagus cranial to the site of obstruction or stricture. Encephalitis affecting the medulla oblongata and/or the nuclei or tracts of the cranial nerves involved in swallowing (V, IX, X, XII) also results in dysphagia. Such conditions are very rare in the pig. Nematode parasites (*Gongylonema* species) occasionally occur in the esophageal mucosa leaving serpentine-shaped tracts. However, these parasites do not appear to have any adverse effects in pigs.

The Stomach

Conditions affecting the stomach are mainly physical or functional in nature, the most important being gastroesophageal ulceration affecting the pars oesophagea. The prevalence in growing and finishing pigs varies between farms but it can be high under modern conditions of pig husbandry. The majority of lesions are subclinical, and most studies indicate that mild lesions have little impact on growth or production. Severe ulceration of the pars oesophagea is associated with clinical illness and death. Pigs become anorexic, pale, with intermittent melena, and they die suddenly due to gastric hemorrhage. In such cases, ulcers are substantial lesions. The cause is unclear, but repeated studies have shown that finely ground rations and a high wheat component in the diet are significant factors. Clinically, hemorrhage from gastric ulcers should be differentiated from other causes of melena including proliferative hemorrhagic enteropathy, swine dysentery, and intestinal torsion. This condition is described in more depth in the chapter specifically relating to gastric ulceration (Chapter 54).

Gastric overdistension can occur in adult pigs especially in sows but the cause is uncertain. It is thought to be associated with excessive intake of finely ground grain and water, resulting in excessive fermentation and gaseous distension. Gastric volvulus is thought to be due to rapid intake of large quantities of feed and water followed by physical activity in a competitive group situation. Clockwise torsion is apparently most common, although torsion can occur in either direction about the long axis of the stomach. The spleen is often involved and becomes extremely enlarged due to blood engorgement (Morin et al. 1984). The stomach becomes massively distended with gas and fluid, and intense mucosal congestion develops. This condition is rapidly fatal. Gastric foreign bodies such as stones are frequently found in stomachs of outdoor sows that are maintained on stony ground. Stone chewing is a regular activity and swallowing of the stones is thought to be accidental. Large quantities of gastric stones have been recorded in some sows, limiting the capacity of feed intake and resulting in loss of body condition.

Gastric venous infarction occurs in pigs, usually in association with severe bacterial infections or toxemia. The lesion can also be seen in classical swine fever. The mucosa in the fundic area becomes reddish black in color and caseous mucosal necrosis may be evident. Thrombosis of capillaries and venules in the mucosa and submucosa with fibrin-plugging is the cause of infarction. Multifocal areas of gastric infarction have also been recorded in cases of porcine dermatitis and nephropathy syndrome (PDNS), due to fibrinoid vasculitis of capillaries. Edema of the stomach wall is a characteristic change in edema disease caused by specific strains of *E. coli*. Edema affects the submucosa, particularly on the greater curvature of the stomach. Other conditions causing gastric edema include hypoproteinemia, arsenic toxicity, and portal hypertension. In these conditions, edematous changes are less pronounced than those of "edema disease."

Gastritis in pigs is most commonly associated with ulceration of the pars oesophagea and the inflammatory sequelae affecting tissue in the cardiac zone of the stomach, as previously mentioned. Candidiasis of the pars oesophagea may occur in association with preulcerative epithelial hyperplasia and parakeratosis. Gastritis could occur due to accidental intake of toxic compounds–such as arsenic, thallium, formalin, bronopol, and phosphatic fertilizers–and by the toxic principles in bitterweed (*Hymenoxon odorata*) or the blister beetle (*Epicanta* sp.). In commercial farming, such conditions are very rare and should be easy to exclude. Mycotic gastritis is occasionally seen in piglets, usually in association with repeated use of antibiotics. Lesions present as multifocal yellowish plaques on the gastric mucosa, with intense congestion of the peripheral gastric mucosa. Fungal hyphae colonize the mucosa and invade tissue and capillaries resulting in thrombosis. Agents are usually zygomycetes such as *Rhizopus*, *Absidia* or *Mucor* species. *Aspergillus* species involvement is rare (Mahanta and Chaudhury 1985).

Parasitic gastritis is now rare in commercial pig farms. Of the parasites that can cause gastritis, *Hyostrongylus rubidus* is of most importance because it is associated with poor growth rates or loss of body condition in

adult pigs. Other parasites that can cause mild gastritis in heavy infections include *Ascarops* sp., *Simondsia* sp., and *Physocephalus* sp. The parasite *Gnathostoma* sp. invades the mucosa and undergoes development within inflammatory cysts in the submucosa. In heavy infestations this parasite can cause thickening of the stomach wall.

The Intestinal Tract

Atresia ani is the most common congenital defect of the intestinal tract of pigs and it is believed to be hereditary (Norrish and Rennie 1968). It arises due to failure of perforation of the membrane separating endodermal hindgut from ectodermal anal membrane. Evident at birth, the defect can be corrected by minor surgery unless atresia of the rectum is also present. Persistent Meckel's diverticulum is a rare anomaly in which there is persistence of the omphalomesenteric duct. It presents as a tube of intestinal tissue similar to ileum that branches from the intestine to the umbilicus. Occasionally, it can be involved in abdominal catastrophes such as intestinal strangulation.

Intestinal displacement and obstruction is common in pigs, and a number of different conditions arise.

Rectal prolapse is relatively common in growing pigs and is associated with a number of factors resulting in an increase in intraabdominal pressure. These include persistent coughing, straining associated with enteritis and diarrhea, excessive huddling of pigs kept in cold conditions, pigs gorging on liquid feeding, and feeding of flatulent diets. Feeds high in zearalenone have also been associated with rectal prolapse. Some prolapses resolve spontaneously, but more commonly the tissue becomes traumatized or removed by penmates followed by scar formation as part of the healing process. This results in rectal stricture and progressive obstruction leading to marked distension of the colon (Figure 3.1). Such pigs fail to thrive and die unless corrective action is taken. Rectal stricture can also be a sequel to ulcerative proctitis of ischemic origin caused by *Salmonella enterica* Typhimurium infection. Occasionally, severe intestinal prolapse can accompany vaginal prolapse, via laceration to the vaginal fornix. Intestinal impaction and obstruction can occur in a variety of situations—for example, deaths have occurred in piglets maintained on wood-shavings or other fibrous materials such as peat due to impaction of the ileum or colon with such materials (Figure 3.2). On occasions, heavy infestations of *Ascaris suum* have been found to cause small intestinal impaction in piglets. Herniation of the intestine is most commonly associated with a patent umbilicus. Small lesions are of little consequence, but large pendulous lesions become traumatized, with increased risk of intestinal strangulation within the hernia, unless the defect is corrected surgically.

Torsion of the long axis of the mesentery is a common condition in pigs and leads to rapid death. The tor-

3.2. *Obstruction of the colon in a 10-day-old piglet due to impaction with wood shavings.*

sion may involve small intestine or both small and large intestine (Figure 3.3). Rotation is usually anticlockwise when viewed from the ventrocaudal aspect. Torsion is associated with pigs making sudden unpredictable movements, such as sudden deceleration combined with abrupt changes in direction, particularly when the gut is filled—for example, after feeding or drinking a large volume of water, or when the intestines are gas-filled due to pigs being on a highly fermentable ration. Once torsion occurs, pigs rapidly develop distension of the abdomen. The intestinal loops become very turgid and reddish black in color. The mesenteric vasculature is extremely engorged due to obstruction to the venous return. Other forms of intestinal catastrophe, such as volvulus of a short length of small intestine followed by strangulation of the affected portion, occur more rarely.

Many forms of inflammatory and degenerative changes can affect small and large intestine. In its simplest form, loss of surface enterocytes occurs with enteropathogenic *E. coli* and viral infections, including ro-

tavirus and coronaviruses. Fluid exudation is a consequence of this epithelial loss and results in watery diarrhea and dehydration. Villous atrophy is particularly associated with coronavirus and rotavirus infections. Intestinal erosion and necrotizing enteritis in young pigs is often associated with *C. perfringens* type C infection. *Cryptosporidium* (*C. parvum*) infection in neonatal piglets causes villous atrophy, stunting and fusion of villi, with diarrhea due to malabsorption. Intestinal ulceration is associated with salmonellosis and ulcerative typhlocolitis, with swine dysentery. So-called "button ulcers" alert concerns of classical swine fever, but they are also associated with *Salmonella choleraesuis* infection and porcine dermatitis and nephropathy syndrome (Figure 3.4). Similar lesions have also been recorded in pigs infected with bovine viral diarrhea virus (Terpstra and Wensvoort 1988). Degeneration of intestinal crypt epithelium is associated with coccidial infection and bovine viral diarrhea virus infection. In coccidiosis due to *Isospora suis* damage caused by coccidial development in the villous and crypt epithelium will result in villous atrophy, intestinal erosions, and fibrinonecrotic enteritis, mainly affecting the distal jejunum and ileum. Hyperplasia of crypt epithelium is the major feature of

Lawsonia intracellularis infection and leads to thickening of the mucosa in the ileum and/or colon (Figure 3.5). Inflammatory cell infiltration occurs in response to any cause of disruption to the epithelial barrier as well as enteropathogenic infections. Mucosal microabscesses are a feature of yersiniosis; both *Yersinia enterocolitica* and *Y. pseudotuberculosis* affect pigs.

Diseases affecting the intestinal tract are among the most important economic problems affecting pig production. The prevalence of diseases in pigs varies between countries, farming systems and units with different health status. Within farms the disease situation is dynamic and the prevalence can alter quite dramatically between batches for no apparent reason. Multiple enteric infections can occur concurrently, giving rise to complex clinical disease patterns and difficulties in arriving at successful control measures. The major diseases are mentioned only briefly here; detailed descriptions of all are given in other chapters.

In neonatal piglets, enterotoxigenic *E. coli* remains the most important disease, with *C. perfringens* type C causing problems in certain units, most notably in outdoor farming systems (Figure 3.6). Both diseases can be controlled by vaccination of breeding stock provided piglets receive adequate colostrum intake within hours of birth, prior to intestinal "closure." The availability of breeding stock that is genetically resistant to *E. coli* F4 (K88) strains heralds a new and exciting era in the control of enteric disease through genetic selection. Other infections that are commonly reported in the young unweaned pig include rotavirus and coccidiosis (*I. suis*), with cryptosporidia also being implicated in some units. It is rare for *Salmonella* infection to cause significant enteric disease in unweaned pigs though subclinical infection, and shedding can occur as a result of contact with sow feces. The viral diseases transmissible gastroenteritis (TGE) and porcine epidemic diarrhea (PED) cause severe morbidity and mortality in susceptible piglets. Vomiting and wasting disease caused by

hemagglutinating encephalomyelitis virus is associated with vomiting and wasting in suckling piglets, but it appears to have reduced in prevalence globally over the last 10–15 years. Porcine adenovirus infection is usually asymptomatic but occasionally is associated with diarrhea and vomiting, with reduced growth rates in piglets from 2–7 weeks of age. Bovine viral diarrhea virus, though a known pathogen of pigs, is rarely reported. *Clostridium difficile* is a recognized cause of necrotizing colitis in suckling piglets and it is also of zoonotic importance. However it appears to be a rare or rarely reported infection of pigs. *Strongyloides* sp. can affect pigs ranging from 10 days of age up to 3 months old. Parasites colonize the anterior half of the small intestine and cause villous atrophy and granulomatous enteritis, resulting in diarrhea and ill thrift.

A number of these preweaning infections are also capable of causing disease in young weaners. Postweaning *E. coli* continues to be a major cause of postweaning diarrhea and mortality, and diseases such as rotavirus, coccidiosis, and cryptosporidiosis can rarely affect

piglets up to 6 weeks of age. The disease patterns in units change dramatically when immunosuppression is a feature. The emergence of postweaning multisystemic wasting syndrome (PMWS), which has occurred in many countries, has dramatically altered patterns of enteric disease. The generalized lymphoid depletion that occurs in weaners with PMWS includes depletion of intestinal Peyer's patches and mesenteric lymph nodes. In units with PMWS, the age range of susceptibility to diseases such as rotavirus, cryptosporidiosis, and coccidiosis increases up to 4–6 weeks, and these enteric diseases play a significant role in the general ill-thrift problems suffered by pigs.

Diarrhea is a feature of PMWS outbreaks and in many instances no enteropathogenic agents are isolated or detected. Histologically the jejunum and ileum may show a viral-type enteropathy, primarily villous atrophy. Whether this is directly related to the disease pathogenesis or whether it is caused by one or more opportunist viruses that are unrecognized as yet remains unknown. Another equally important feature associated with PMWS is mild bacterial-type colitis. Often bacterial cultures fail to show any recognized bacterial pathogen but yield a mixed growth of commensal-type organisms. Histology of the colon shows mixed bacterial infection of crypts and surface epithelium, accompanied by crypt inflammation and goblet cell hyperplasia in chronic cases. This suggests that there is an opportunistic bacterial overgrowth or dysbacteriosis in the colon of affected pigs, possibly associated with altered enteric immune processes.

Through growing and finishing periods the most important economic-limiting diseases continue to be swine dysentery, porcine proliferative enteropathy (PPE), and porcine colonic spirochetosis. In PPE, significant progress has been made with the development of serological tests that can be used for herd profiling and more recently, development of an orally administered vaccine that has proved successful in controlling PPE in commercial units. In contrast, there are no commer-

cially available serological tests for swine dysentery or porcine colonic spirochetosis, and to date, vaccine studies have proved unsuccessful. The prevalence of *Brachyspira pilosicoli* varies between countries. This infection is becoming increasingly recognized as a cause of diarrhea and reduced growth rates. The infection may also be mild or subclinical. Mixed infections involving *Brachyspira hyodysenteriae, Brachyspira pilosicoli, L. intracellularis*, *Salmonella* sp., and *Yersinia* sp. are common in grow-finish herds with diarrhea and colitis (Figure 3.7). Achieving the correct diagnosis and finding effective control measures pose significant challenges for the swine veterinarian.

The prevalence of parasitic infections varies considerably between units. Many units have achieved total freedom of enteric parasites, such as *Ascaris suum, Oesophagostomum* sp., *Trichuris* sp., and *Hyostrongylus* sp. However "white spot liver" is commonly reported on abattoir surveys indicating that *A. suum* infection is still a notable health problem in some units (Figure 3.8). *Trichuris suis* and *Oesophagostomum* sp. can be causes of colitis that are often overlooked until nonresponse to antibiotic agents results in further investigation. Rarely, coccidiosis (*I. suis)* can cause acute enteritis and colitis in naive young adult pigs that are introduced into a heavily infected environment. Similarly, the hemorrhagic enteropathy form of PPE can cause acute hemorrhagic diarrhea and deaths in naive young adult pigs introduced into an infected environment. *Eimeria* sp. affect older pigs when exposed to yards and pasture contaminated with oocysts. Some *Eimeria* sp. are considered to be potentially pathogenic, causing villous atrophy and enteritis. *Balantidium coli* is commonly present in the large intestine of pigs. It is a commensal organism but commonly invades the mucosa if other degenerative or necrotizing lesions are present.

In addition to the common endemic diseases already mentioned, the serious epidemic diseases classical swine fever (CSF) and African swine fever (ASF) have an important enteric component. Suspected outbreaks should be reported and investigated appropriately in order to control the outbreak and limit the spread of infection. TGE and PED can cause severe diarrhea in all age groups of pigs in addition to the serious morbidity and mortality that occur in suckling piglets in particular. In Aujeszky's disease, necrotizing enteritis can affect the distal small intestine in addition to the more commonly recognized lesions of necrotizing rhinitis and tonsillitis. Control of TGE, CSF, ASF, and Aujeszky's disease by vaccination is the best method of control in some countries where disease eradication is not possible due to geographic, social, or political reasons or where there is a constant and uncontrollable threat from wildlife vectors.

The Liver
Congenital anomalies affecting the pig liver are rare. One recognized condition is a cystic anomaly affecting bile ducts. The liver is enlarged and shows numerous fluctuating cystic lesions containing bile. The enlarged liver causes abdominal distension and piglets have poor viability.

Traumatic conditions affecting the liver are important. In neonatal piglets, rupture of the liver and fatal hemorrhage is a consequence of trauma, usually inflicted accidentally by the sow. Torsion of one or more liver lobes can affect pigs of any age. It usually affects the left lateral lobe and results in infarction of the lobe. Death occurs due to shock or hepatic rupture and hemorrhage. Hepatosis dietetica is a diet-associated condition in which there is massive hepatic necrosis. Experimentally, concurrent deficiencies of sulphur-containing amino acids, tocopherols, and selenium are required for development of hepatosis dietetica. The pathogenesis is not fully understood but it is thought to be associated with formation of free radicals and their subsequent

Table 3.1. Differential diagnosis of some common enteric diseases of swine.

Cause	Age	Signs	Gross Lesions	Histological Lesions	Laboratory Confirmation—Commonly Used Methods
Escherichia coli (ETEC, EPEC)	Neonatal: 1–4 days old. Postweaning: 1–3 weeks after weaning.	Watery, yellowish diarrhea. Sudden death. Dehydration.	Fluid ingesta, small intestinal congestion, watery content. Stomach usually full of milk.	Mucosal congestion, edema. Bacterial attachment to intestinal epithelium.	Culture, serotype of isolates, PCR. Tissue IHC.
Rotavirus	1 day to 7 weeks old. Most frequent at 2–3 weeks of age.	Watery to pasty diarrhea, may be subclinical. Varying degrees of dehydration.	Fluid ingesta, pale intestines. Sparse stomach contents.	Moderate villous atrophy.	Virus detection: PAGE, PCR, ELISA detection kits. Tissue IHC.
Clostridium perfringens type C	1–14 days (rarely older).	Hemorrhagic/watery diarrhea. Sudden death.	Hemorrhagic intestines, mucosal necrosis.	Mucosal necrosis, hemorrhage. Gram-positive rods associated with lesions.	*C. perfringens* toxin ELISAs on intestinal content. Histopathology.
Cryptosporidium sp.	3 days to weaning.	Mild to moderate yellowish diarrhea. Varying degrees of dehydration.	Fluid ingesta.	None or mild villous atrophy. Cryptosporidial oocysts adjacent to surface epithelium.	Mucosal smear for cryptosporidial oocysts. Histopathology.
Isospora suis	5–21 days (occasionally older).	Watery/yellowish diarrhea. Dehydration.	Fluid ingesta, necrosis of small intestine mucosa.	Villous atrophy, fibrinonecrotic enteritis, intracellular coccidial forms.	Stained mucosal smear for coccidial oocysts. Histopathology: lesions and coccidia, identify coccidia.
Coronaviruses: TGE virus PED virus	All ages.	Watery diarrhea. Rapid dehydration. Vomiting often seen.	Thin-walled pale intestine, sparse content.	Severe villous atrophy.	Virus detection by PCR of gut content, IHC, ISH, or IF of intestinal tissue. Antibody detection by serology.
Lawsonia intracellularis	From approximately 5 weeks old to young adults.	Usually pasty to sloppy diarrhea. In PHE watery hemorrhagic (port wine colored) diarrhea, pale carcass, weakness, ataxia.	Ileitis and/or colitis. Thickened mucosa, sometimes necrotic or ulcerated. In PHE, blood clots in ileum and/or colon, carcass pale.	Crypt epithelial hyperplasia, crypt abscesses. Small curved rods in hyperplastic epithelial cells (silver stain). In PHE, blood exudation into crypts through intact epithelium.	Bacterial detection by PCR on feces or intestinal mucosa. Histopathology, IF, IHC, ISH on tissue. Antibody detection by serology.
Brachyspira hyodysenteriae	From approximately 6 weeks old to adult.	Pasty, sloppy diarrhea, may be mucohemorrhagic. Lethargy.	Typhlo-colitis, fibrinous pseudomembranes, exudation, erosions, ulceration, hemorrhage. Mucoid content in chronic cases.	Epithelial erosions, goblet-cell hyperplasia, inflammation, fibrin exudation, hyperplasia crypts with mucus. Large spirochetes present (silver stain).	Bacterial detection by PCR, culture of feces or tissue. Histopathology, IHC, ISH of tissue.
Brachyspira pilosicoli	From approximately 6 weeks to 4 months old.	Pasty, sloppy diarrhea.	Mild to moderate colitis. Lesions milder than *B. hyodysenteriae*.	Similar to *B. hyodysenteriae* but milder. End-on attachment of spirochetes to surface epithelium seen in some cases.	Bacterial detection by PCR, culture of feces or tissue. Histopathology, IHC, ISH of tissue.

(continued)

Table 3.1. Differential diagnosis of some common enteric diseases of swine (*continued*).

Cause	Age	Signs	Gross Lesions	Histological Lesions	Laboratory Confirmation— Commonly Used Methods
Salmonella sp.	All ages after weaning (rarely preweaning).	Variable, watery mucohemorrhagic. Most infections subclinical.	Fibrinous or hemorrhagic, ulcers, lesions in small and/or large intestine.	Diffuse or focal ulcers, neutrophil infiltration, fibrinous thrombi.	Bacterial detection by culture, serotype, phage type. Antibody detection by mix-ELISA.
Oesophagostomum dentatum	From weaning to adult.	Mild, sloppy diarrhea.	Erosions, edema, granulomas in cecum and proximal colon.	Granulomatous typhlocolitis with nematode parasites.	Fecal parasitology, histopathology.
Trichuris suis	From weaning to adult.	Pasty, sloppy occasionally mucohemorrhagic.	Typhlo-colitis, erosions, parasites visible to naked eye.	Erosion/ulceration and inflammation associated with nematode parasites.	Fecal parasitology, gross pathology.
Yersinia sp.	From approximately 6 weeks to 4 months old.	Pasty, sloppy diarrhea.	Mild enteritis and/or colitis.	Mild chronic, active enteritis and/or colitis, microabscesses, granulomas.	Bacterial detection by culture.

EPEC = enteropathogenic *E. coli*; ETEC = enterotoxigenic *E. coli*; IF = immunofluorescence; IHC = immunohistochemistry; ISH = in situ hybridization; PAGE = polyacrylamide gel electrophoresis; PCR = polymerase chain reaction test; PED = porcine epidemic diarrhea; PHE = proliferative hemorrhagic enteropathy; TGE = transmissible gastroenteritis.

adverse effects. It affects rapidly growing pigs and causes sudden death.

Many systemic diseases cause nonspecific changes in the liver, including congestion and inflammatory cell infiltration. Hemorrhages are a feature of septicemia, for example, salmonellosis, especially *S. choleraesuis* infection. Multifocal white nodules, so-called "paratyphoid nodules," are associated with chronic *S. choleraesuis* infection. Parasitism is undoubtedly the most common condition affecting the liver. Migrating *Ascaris suum* larvae cause mechanical damage in the form of hemorrhagic tracts that initiate intense inflammation. Reactive changes, both repair of tissue and hypersensitivity reaction to excretory and secretory products of larvae, cause eosinophil infiltration and fibrosis. "White spot" livers are an economic loss to the farmer (Figure 3.9). In heavy infestations, adult ascarids can migrate up the bile duct or pancreatic duct causing obstruction, jaundice, and cholangitis (Figure 3.10). Other parasitic infections affecting the liver include *Cysticercus tenicollis*, the metacestode of the tapeworm *Taenia hydatigena* (of dogs). Cysts can sometimes be found in the pig peritoneal cavity, often attached to the liver. Immature cysticerci migrate through the liver causing tortuous hemorrhagic tracts before emerging to encyst. *Stephanurus dentatus* infection results in migratory tracts and hepatitis. Portal phlebitis with thrombus formation in the portal vein are additional features following oral infection.

Toxicities affecting the liver can be acute or chronic in nature. Cresol toxicity is caused by exposure to tar compounds that might have been used in construction of piggery buildings, accidental environmental spillage, or "clay pigeons" used as shooting targets. Lesions include severe hepatocellular necrosis leading to sudden death. Chronic cresol toxicity results in jaundice, ascites, and anemia on account of chronic, progressive destruction of hepatic tissue. Iron toxicity occurs occasionally in neonatal piglets, with deaths occurring within 24 hours of iron-dextran administration. Toxicity is associated with marginal or deficient vitamin E and selenium status. Iron-catalyzed lipoperoxidation occurs in liver and muscle resulting in hepatic necrosis and hepatic hemorrhages. Aflatoxicosis is caused by the use of cereals contaminated with *Aspergillus* species or *Penicillium puberulum*. Lesion development is a chronic process in which there is liver hypertrophy and progressive fibrosis. The condition results in reduced growth rates and liver condemnations.

The Pancreas

There has been little focus on pancreatic conditions in pigs. Pancreatic hypoplasia is rare and associated with poor growth in individual weaner pigs. The pancreatic duct can be invaded by *Ascaris suum* in piglets with heavy infestations. This can lead to obstruction of the pancreatic duct resulting in pancreatic necrosis and acute pancreatitis.
3.9. *"White spot" liver in a 5-month-old pig, associated with* Ascaris suum *larval migration.*

3.10. Ascaris suum *in the common bile duct of a 6-week-old piglet that was heavily infested.*

4 Diseases of the Mammary Glands

Christian Klopfenstein, Chantal Farmer, and Guy-Pierre Martineau

Inadequate sow milk production leads to reduced piglet growth and, in certain cases, to increased mortality in the litter. The first section of this chapter focus on a good understanding of the normal physiologic processes involved in the initiation and maintenance of sow lactation and on how these processes relate to piglet growth and mortality. Factors affecting the milk production of sows are numerous but they can be synthesized in three major groups:

1. The number of lactocytes (or epithelial cells) producing the milk (see mammary gland)
2. The intensity of milk synthesis by lactocyte (see physiology)
3. The capacity of the other organs and systems to supply the nutrients needed by the mammary gland (see homeorhesis)

The second section of this chapter covers some strategies to increase overall milk production of sows (see manipulating milk production) and the possible etiologies of early lactational problems (see infectious and noninfectious causes of postpartum dysgalactia syndrome) as well as treatment and prevention procedures.

MILK PRODUCTION OF SOWS

Measuring Milk Production

Measuring milk production in the sow is more complicated than in other farm animals. The small teats and the large number of functional mammary glands (12–14) make hand or mechanical milking difficult. Moreover, since milk is not available continually after the colostral phase, milk ejection must be stimulated and sows would have to be milked more than 24 times a day to mimic the piglets (Hernandez et al. 1987). Consequently, sow milk production is usually estimated by taking a number of measurements during the day and extrapolating to the whole day. Seven to eight measurements over a 24-hour period are reported to provide a good estimate of daily milk production (Salmon Legagneur 1965; Mahan et al. 1971). After the colostral phase, milk letdown has to be initiated with exogenous oxytocin (see oxytocin in the treatment section).

Best results are obtained by methods using the piglets to estimate sow milk output. However, in the first part of lactation, when milk production aptitude is greater than the ingestion capacity of the piglets, these methods underestimate the milk production capacity of the mammary gland. In the second part of lactation, when milk supply is a limiting factor for piglet growth, these methods should give a good estimation of the milk production capacity of the sow.

Milking the Sow. Sows can either be hand-milked, which requires a lot of manual labor, or milked with a milking machine. The first sow milking machine was developed following the discovery of the role of oxytocin for milk ejection (Salmon Legagneur 1959). More recently, milking machines have been used to compare milk production between teats (Fraser et al. 1985) and breeds (Grun et al. 1993a). The use of a milking machine has been reported to give much more repeatable estimates of sow milk production than those obtained by hand milking (Fraser et al. 1985); yet, these are not available commercially.

Sow Weight Loss During Suckling Periods. Weighing the sow before and after a suckling period is another recognized but seldom used approach for measuring milk production. Its greatest drawback is a major lack of precision because the weight ratio between milk ejected during each nursing period and sow body weight is approximately 1:1000 (Salmon Legagneur 1956).

Weigh-Suckle-Weigh. The weigh-suckle-weigh (WSW) method has been used extensively during the past years and involves repeated weighing of piglets, preceding and following nursing, for a certain number of sucklings. Apart from the suckling periods, the piglets do not

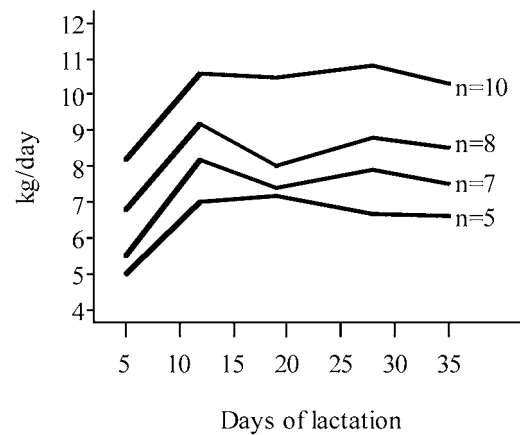
have access to the teats. The general approach is to remove the piglets from the sow 1 hour prior to the first suckling period. The following nursing periods occur at fixed intervals varying between 45 and 60 minutes, and last on average 4–5 minutes. Before each suckling period, the piglets are placed on a cold or wet surface to induce urination and defecation. The piglets can be weighed individually, as half the litter, or as a litter (Barber et al. 1955; Salmon Legagneur 1956; Mahan et al. 1971; Lewis et al. 1978; Noblet and Etienne 1989). The first two estimations should generally be discarded because of their great variability (Speer and Cox 1984). One of the main problems with this technique is to adjust for piglet urinary, fecal, and metabolic losses.

Piglet Growth. Although conceptually simple, measuring piglet growth has not generally been considered sufficiently precise for lactation studies. The first studies reported that piglet growth was a poor predictor of sow milk production ($R^2 < 0.50$) (Salmon Legagneur 1956; Lewis et al. 1978). These low predictions were likely due to the difficulty in adequately estimating sow milk production. Indeed, recent work demonstrated that milk production over different parts of lactation can be adequately predicted by using piglet growth (R^2 between 0.84 and 0.96) (Noblet and Etienne 1989). Based on these equations and other observations, a conversion efficiency of approximately 4.5 g of milk per gram of growth has been estimated (Lewis et al. 1978; Noblet and Etienne 1989).

Body Water Turnover. Milk production can also be estimated by measuring water turnover in the piglet. This method measures the dilution of endogenous water by water absorbed from nursing (MacFarlane et al. 1969). Each piglet receives a known quantity of deuterium-labeled water by parenteral injection, prior to nursing. The difference in isotope concentration preceding and following nursing represents the dilution effect of milk absorption and is directly related to sow milk production. A correlation of 0.96 was found between the estimated and the actual milk intake of artificially reared piglets using this technique (Prawirodigdo et al. 1987).

Pattern of Milk Production

Sow milk production is usually described in four phases: the colostral, ascending, plateau, and descending phases. Sows in modern production units usually do not reach the descending phase because they are weaned during the plateau phase at less than 28 days of lactation.

Typical sow milk production curves are presented in Figure 4.1 (Toner et al. 1996); they are similar to those presented by others (Noblet and Etienne 1986; Shoenherr et al. 1989; Grun et al. 1993b). In the latter publications, the end of the ascending phase was around day 14 postpartum, whereas it was reported to occur later (22–28 days) in some other publications (Elsley 1971;


4.1. *Pattern of milk production (kg/day) of first-litter sows nursing litters of different sizes (from Toner et al. 1996, reprinted with permission).*

Harkins et al. 1989). This discrepancy may be related to differences in breeds, nutrition, and parities of the sows and in the methodology used to estimate milk production.

Colostral Phase. The term *colostrum* describes the mammary secretions obtained during the few days before and/or after parturition. Colostrum usually contains more proteins, mainly immunoglobulins; less fat; and less sugar than the milk produced after initiation of lactation (Dorland 1985). Mammary secretions contain 157, 130, 9, and 6 grams of protein per liter at 0, 6, 12, and more than 12 hours after the first suckling, respectively (Klobasa et al. 1987). Consequently, the colostral phase probably ends between 12 and 24 hours after the first suckling.

Mammary secretions obtained during the first 12 hours postpartum contain large amounts of immunoglobulins (60–80 g/L) (Klobasa et al. 1987). During this short period of time, mammary secretions are continuously available to the piglets, whereas after the colostral phase, milk availability becomes cyclical (de Passillé and Rushen 1989a). Within 48–72 hours postpartum, piglets establish a teat order in which each piglet consistently sucks from one or two specific teats (Fraser 1976; de Passillé et al. 1988; Roychoudhury et al. 1995). Within 48 hours after parturition, any unsuckled mammary gland goes through involution and becomes nonfunctional (Atwood and Hartmann 1993). Consequently, daily milk production and total milk production during lactation are proportional to the number of suckled mammary glands or to the number of piglets in the litter ($R^2 > 0.95$) (Auldist et al. 1998).

Ascending Phase. The ascending phase of lactation (approximately day 0 to 10) is explained by an increase in nursing frequency as well as an increase in the volume of milk obtained at each nursing. Nursing fre-

quency doubled between day 2 and day 10 of lactation (17 vs. 35 nursings/day) (Jensen et al. 1991) and the quantity of milk obtained at each nursing is reported to increase from 29 to 53 g between the first and the third week of lactation (Campbell and Dunkin 1982).

During the ascending phase, sow milk production is adjusted to the needs of the piglets. Indeed, between days 4 and 8, litters of heavier piglets (4.45 kg at day 4) consume more milk (9.1 vs. 7.6 L/day) than litters of lighter piglets (1.92 kg) (King et al. 1997). It is well known that most piglets do not consume much creep feed before they are at least 10 days old (Aumaitre and Salmon Legagneur 1961). During the first 2 weeks of lactation, the heavier piglets at birth (1.39 kg) ingest more milk than their lighter littermates (0.89 kg); however, the milk consumption relative to body weight (g/kg of live weight) is similar for all piglets (Campbell and Dunkin 1982). The larger consumption observed among the heavier piglets was explained by a larger volume ingested at each nursing. It appears that during the ascending phase of lactation, the dynamic equilibrium state between the piglets needs and sow milk nutrient output is so well harmonized that litter size (8 vs. 11) has very little effect on piglet weight before day 7 of lactation (Klopfenstein et al. 1999) (Table 4.1).

Plateau Phase. After day 10 of lactation, milk production is maximal (Figure 4.1) (King et al. 1997); therefore, piglet growth may be inhibited by insufficient milk supply during the later part of lactation, and this inhibition will be greater with longer lactation and in larger litters (Table 4.1). The weight difference between suckling piglets supplemented or not with cow's milk between days 7 and 28 of lactation was 140 g on day 14, 756 g on day 21, and 1761 g on day 28 (Reale 1987). Supplementation with milk replacer from day 3 to weaning also in-

creased average piglet weight by 120 g on day 7, 340 g on day 14, and 910 g on day 21 (Wolter et al. 2002). It was also reported that, in a 21-day lactation, the growth limitation of suckling piglets could be more than 2 kg per pig (Harrell et al. 1993). When piglets are weaned at an early age (14–16 days), which is part of a new management procedure in the swine industry, the limiting effect is likely to be smaller.

Composition of Sow Milk

Sow milk is a complex water solution containing more than 100 different chemical components. The major components are lactose, proteins (casein, alpha-lactalbumin, beta-globulins, serum albumins, immunoglobulins G and A), lipids, lactocytes, leucocytes (neutrophils, eosinophils, lymphocytes, and macrophages), bivalent ions (calcium, phosphorus, and magnesium) and electrolytes (sodium, potassium, and chloride). The relative concentrations of these components vary according to the stage of lactation (Table 4.2). During the colostral phase protein content decreases rapidly mainly because of the fall in the concentrations of immunoglobulins.

Table 4.1. Least-square means of piglet weight (kg) at different ages from randomly chosen litters of different sizes after correction for birth weight (these litters had no mortality for the 28-day lactation period).

Litter Size	n	Age of the Piglets (Days)				
		3	7	14	21	28
8	15	1.87	2.82	4.62	6.42	8.21
9	15	1.85	2.78	4.38	6.18	7.91
10	15	1.87	2.72	4.40	6.18	7.89
11	14	1.88	2.72	4.21	5.60	7.10

Lactocytes (k¢/ml)[1,2]	152 ± 103	503 ± 315	+351	(Schollenberger et al. 1986)
Anucleate cells (k¢/ml)[1]	147 ± 160	727 ± 63	+580	(Schollenberger et al. 1986)
% de leucocytes	70	44	−26	(Schollenberger et al. 1986)

Source: adapted from Klopfenstein 2003.

[1]k¢ = 1000 cells.

[2]Somatic cells found in the first colostrum (<12 hours) contains many more cells than milk obtained at day 1–2 (>8000 k¢/ml, 98% leucocytes) (Evans et al. 1982; Magnusson et al. 1991).

[3]Leucocytes are the sum of neutrophils, eosinophils, lymphocytes, and macrophages.

Somatic Cells of Normal Milk. The somatic cell content of mammary secretions from healthy sows is much greater than that in milk of healthy cows: between 1 and 4 million cells per milliliter (M¢/ml) in sows (Evans et al. 1982; Schollenberger et al. 1986; Hurley and Grieve 1988; Magnusson et al. 1991; Drendel and Wendt 1993a; Klopfenstein 2003) compared to less than 1 million cells in cows (Paape et al. 1963). The first mammary secretions obtained at parturition contain many more somatic cells (>8 M¢/ml) than milk obtained later in lactation (Evans et al. 1982; Magnusson et al. 1991). These somatic cells are mainly composed of epithelial cells and leucocytes. The relative concentrations of the various cell types vary with the stage of lactation. In milk collected during the colostral phase, most cells are leucocytes (>98%), whereas during the rest of lactation (days 7, 14, and 28), the cells are predominantly epithelial cells (Evans et al. 1982; Schollenberger et al. 1986; Magnusson et al. 1991).

Somatic Cells of Mastitic Milk. Somatic cells content found in the milk of infected mammary glands is similar (12–35 M¢/ml) to those observed during the colostral phase or during involution (Drendel and Wendt 1993b). Somatic cells found in the milk of infected glands are mainly (>75%) leucocytes. Therefore, during sow lactation, a cellular content over 12 M¢/ml with a increased proportion of leucocytes is an indication of mammary gland alteration. However, during the colostral phase, we cannot, solely based on milk cellular content, discriminate between mammary gland infection and retarded lactogenesis (Drendel and Wendt 1993b).

MAMMARY GLAND

Anatomy
External Structure. The mammary glands of swine are located in two parallel rows along the ventral body wall, from the thoracic region to the inguinal area. In commercial breeds, their number varies generally between 12 and 18 per animal (Labroue et al. 2001) whereas pigs of the Meishan breed can have up to 22 mammary glands (personal communication, L. Maignel, Canadian Center of Swine Improvement, www.ccsi.ca). As suggested by Muirhead (1991), boars and gilts should be retained for breeding only if they have 14 well-placed normal nipples. The rows of teats should be parallel because when the teats diverge from a straight line just before and after the umbilicus, the sows have poor teat presentation therefore limiting accessibility of the teats to the piglets. Sows with poor teat presentation usually have large girth widths, which tends to spread the teat rows apart. Poor teat placement could be a major reason for failure of sows to rear 11 or 12 piglets (Muirhead 1991).

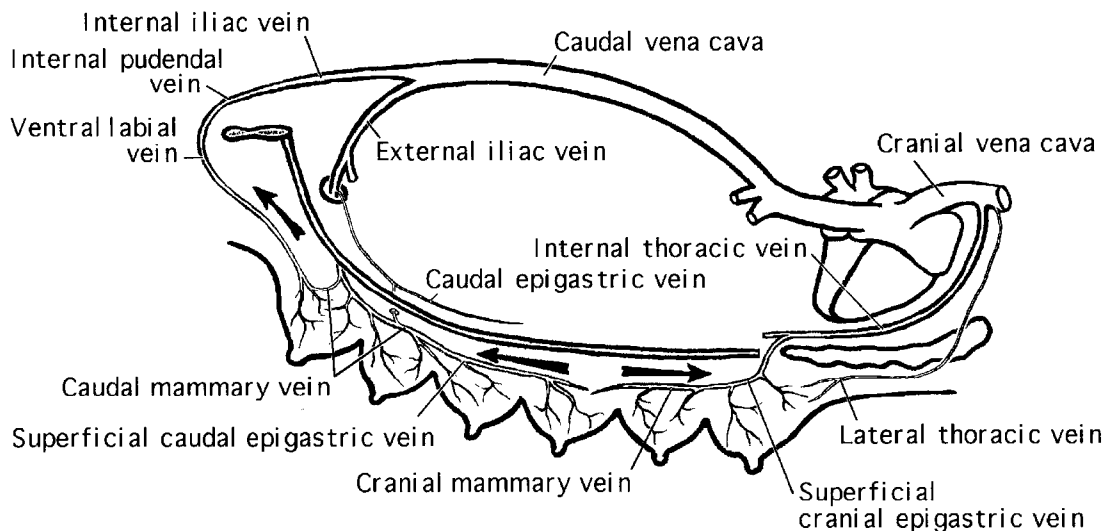
The glands are attached to the ventral body wall by adipose and connective tissue arising from the abdominal fascia. Each mammary gland normally has one teat, or nipple, with two separate teat canals. When the teat sphincter is not visible (inverted teat) it has a 50% chance of remaining blind. Functional supernumerary smaller teats can also be found. Paired vestigial nonfunctional accessory teats, not connected to glandular tissue, may also occur (Molenat and Thibeault 1977; Labroue et al. 2001).

Internal Structure. The microscopic and macroscopic anatomy of the porcine mammary gland has been described by Barone (1978), Schummer et al. (1981), and Calhoun and Stinson (1987). In the nulliparous sow, the mammary gland consists of cell buds distributed among fat and connective tissue, whereas in the lactating gland, the connective tissue is largely displaced by glandular parenchyma. The mammary glands of the lactating sow are composed of a compound tubuloalveolar tissue with the secretory units arranged in lobules. The lobules are lined by epithelial cells, generally described as lactocytes, which synthesize milk. These secreting units are connected by a nonsecreting duct system to an ostium found on the teat. There are usually two complete gland systems within each mammary gland of the pig. The glandular tissue of one system usually interdigitates with the other, although the components of the two systems are independent. Usually, each teat has two openings, one for each glandular system, but sometimes a third ostium can be seen. In these animals, one ostium ends blindly and has no glandular tissue.

The arterial, venous, and lymphatic circulation of the mammary glands in swine is provided on each side of the ventral midline by a network that extends longitudinally from the axillary to the inguinal regions (Barone 1978; Schummer et al. 1981; Lignereux et al. 1996) (Figure 4.2). Moreover, in swine there is a venous anastomosis between the right and left mammary gland of each pair of glands.

Nerve supply to the cranial mammary glands differs from that to the inguinal glands. Cranial mammary glands receive their innervation from the last eight or nine thoracic nerves while inguinal mammary glands receive their innervation mainly from the pudendal nerve (Gandhi and Getty 1969a,b; Ghoshal 1975). A more complete anatomical and histological description of the porcine mammary gland can be found in the seventh edition of *Diseases of Swine* (Smith et al. 1992).

Mammogenesis
The extent of mammary growth is largely related to the number of lactocytes present and has a determinant impact on milk capacity of the sow. Mammary growth starts at the fetal stage but occurs mainly postnatally and, to a greater extent, at the end of gestation; yet it still takes place during lactation.

The mammary glands of newborn piglets have a poorly developed duct system and are largely composed


4.2. *Mammary veins of the sow (from Dejean 1971, as modified by Lignereux et al. 1996, reprinted with permission).*

of subcutaneous stromal tissue (Hughes and Varley 1980). Accumulation of mammary tissue and mammary DNA (which is indicative of cell number) is slow until 90 days of age, at which time the rate of accretion of mammary tissue and DNA increases four- to sixfold (Sorensen et al. 2002a). By the time the gilt is mated, the mammary gland is still very small but it consists of an extensive duct system with various budlike outgrowths (Turner 1952).

In pregnant gilts, quantitative development of the mammary glands is slow in the first two-thirds of pregnancy, while almost all accumulation of mammary tissue and DNA takes place in the last third of gestation (Hacker and Hill 1972; Kensinger et al. 1982; Sorensen et al. 2002a). The mammary glands undergo major histological changes as the adipose and stromal tissues are replaced by lobuloalveolar tissue to become the milk secretory apparatus (Hacker and Hill 1972; Kensinger et al. 1982). Both histological changes and differences in DNA concentrations in mammary tissues from gilts indicate increased tissue differentiation between days 75 and 90 of gestation, with maximum cell concentrations present by day 90 (Kensinger et al. 1982).

Allometric mammary gland development occurs mainly during the last 10 days of gestation and continues during lactation (Hurley 2001). Average mammary gland wet weight of gilts was reported to remain fairly stable (approximately 100 g) up to day 110 of gestation and to increase up to 373 g by day 112 (Sorensen et al. 2002a). Average mammary weight of the suckled glands then increased linearly from 381 g on day 5 of lactation up to 593 g on day 21 (57% increase) (Kim et al. 1999). Another study showed that mammary gland wet weight increased by 70, 20, and 30% between day 113 of gestation and day 26 of lactation, for sows of parity 1, 2, and 3, respectively (Beyer et al. 1994). The increase in mammary volume during lactation is mainly the conse-

quence of mammary gland cellular hyperplasia, rather than hypertrophy, as demonstrated by DNA analysis (Kim et al. 1999).

Factors Affecting Mammary Gland Development

Hormones. Estrogens are important for mammogenesis (Kensinger et al. 1986) and the shift in the rate of mammary development occurring at approximately 90 days of age is likely linked to the onset of ovarian activity (Sorensen et al. 2002a). The finding that mammary development is enhanced with the onset of puberty in gilts corroborates this and even suggests that early onset of puberty may be beneficial for mammogenesis in swine (Farmer et al. 2004b). Prolactin was recently shown to have a great impact on the mammary development taking place before puberty. When injected to gilts for a period of 28 days, starting at 75 kg body weight, porcine prolactin stimulates mammary development through an increase in the number of milk secretory cells (Palin and Farmer 2004). The impact of such a treatment on future sow milk yield still needs to be determined.

During pregnancy, the formation of lobuloalveolar cells is related to increases in estrogen and progesterone concentrations in the maternal circulation (Ash and Heap 1975), while concentrations of prolactin remain low (Dusza and Krzymowska 1981). After day 105 of pregnancy, decreasing progesterone and increasing estrogen concentrations are related to a tremendous increase in metabolic activity of the mammary gland (Robertson and King 1974; Knight et al. 1977; Kensinger et al. 1986). The mechanism by which estrogens affect the mammary epithelium is not known; it is possible that they induce prolactin receptors in the mammary gland. There is also a positive association between prolactin levels and mammary wet weight at day 110 of gestation, which may be due to the effect of prolactin on

water movement into the gland (Kensinger et al. 1986). Prolactin was recently shown to play an essential role for mammogenesis in pregnant swine. Inhibition of prolactin in the last third of pregnancy drastically decreases mammary development in gilts (Farmer et al. 2000) and the timing of its necessary action for mammogenesis was more specifically identified as being from days 90 to 109 of gestation (Farmer and Petitclerc 2003).

Buttle (1988) reported that ovariectomy, but not removal of the corpora lutea, of gilts at day 60 of gestation delays the onset of lobuloalveolar development in the mammary glands, suggesting that the ovarian stroma or follicles produce a factor stimulating the onset of lobuloalveolar development. Later, Hurley et al. (1991) demonstrated that relaxin replacement therapy after ovariectomy restores mammary parenchymal development. Therefore relaxin plays a major role in promoting mammogenesis in gilts during the last third of pregnancy. Relaxin increases growth of parenchyma and decreases mammary fat pad while having no effect on the cellular composition of mammary parenchyma. The mechanism of action of relaxin on mammary development is unknown, yet it seems likely that it requires estrogen priming as well as interaction with other mammotropic hormones, such as prolactin (Hurley et al. 1991).

Nutrition. Feeding of gilts or sows in the two periods of rapid mammary development (i.e., from 90 days of age until puberty and during the last third of gestation) can have a major impact on the extent of this development. Sorensen et al. (2002b) suggested that a period of ad libitum feeding before puberty is needed to maximize mammary growth in gilts. In accordance, Lyvers-Peffer and Rozeboom (2001) showed that decreasing energy intake of gilts at specific periods between 9 and 25 weeks of age reduces weight of parenchymal tissue and tends to lower mammary DNA at the end of gestation. Farmer et al. (2004b) also demonstrated that a 20% feed restriction, starting at 90 days of age, decreases mammary parenchymal tissue mass by 26% at 210 days of age in gilts. On the other hand, feeding a lower protein diet (14.4% vs. 18.7% crude protein) during that same period of time does not hinder mammary development of gilts, as long as feed intakes of 2.5 and 3.3 kg/day are maintained from 90 to 150 days and from 151 to 200 days of age, respectively.

The last month of pregnancy is critical for the development of milk-secreting tissue. Various studies were conducted to examine the influence of increased energy and protein intakes in this period on mammary development; however, results are controversial. Weldon et al. (1991) reported that increased dietary protein between day 75 and 105 of gestation did not benefit mammary development. Howard et al. (1994) saw no effect of elevated energy intake and fat accretion in gestation on mammary development of pregnant gilts. Kusina et al.

(1995) also reported that even though protein intake in gestation favorably affected milk yield, this increase was not due to an improvement in mammary development. On the other hand, when manipulating the body composition of gilts by changing their protein and energy intakes during pregnancy, it was found that fat gilts produce less milk than lean gilts (7.0 vs. 9.0 L/day) at the same body weight (Head and Williams 1991). When fostering 2-week-old piglets onto gilts that were either fat or lean at the beginning of lactation, lean gilts had a much greater milk output than fat gilts, thereby suggesting that the number of secretory cells at the beginning of lactation can have a very strong effect on the amount of milk produced (Pluske et al. 1995a).

Mammary Gland Involution

Suckled mammary glands of sows undergo dramatic changes during the initial 7 days after weaning, with significant changes occurring even as early as 2 days after weaning (Ford et al. 2003). Mammary gland wet weight decreases from 485.9 g on the day of weaning (at 22 days postpartum) to 151.5 g by 7 days after weaning; mammary DNA also decreases from 838.8 mg to 278.4 mg for this same period of time. These changes in gland wet weight and DNA during the period of mammary gland involution in the sow represent losses of over two-thirds of the parenchymal mass and nearly two-thirds of the cells that were present on the day of weaning (Ford et al. 2003). Mammary gland involution in the sow is a rapid process, which is probably irreversible within 2 or 3 days postweaning, but it is a process that also occurs in early lactation. Indeed, once teat order is established, mammary glands that are not regularly suckled begin to regress through involution. This regression occurs rapidly during the first 7 to 10 days postpartum and seems to be affected by dietary nutrient levels (Kim et al. 2001). Mammary glands that are not suckled during lactation undergo no further reduction in parenchymal tissue during the first 7 days after weaning (Ford et al. 2003). It is of interest to mention that mammary glands that are suckled during lactation are larger than the nonsuckled glands at the end of involution. This may suggest more mammary tissue being available for redevelopment during the subsequent pregnancy and, therefore, greater productivity in the next lactation (Ford et al. 2003). On the other hand, a Norwegian study showed that inactive mammary glands for one or two lactation may have full milk yield in the subsequent lactation (Gut-à Porta et al. 2004).

The abrupt cessation of lactation in sows when milk production is at a maximum (3 to 4 weeks) brings about drastic changes in metabolic activity of the mammary glands and endocrine status. There is a decrease in milk lactose, a transient decrease followed by an increase in milk glucose and increases in plasma lactose and glucose (Atwood and Hartmann 1995), which is due to alterations in the status of the tight junctions between mam-

mary epithelial cells (Figure 4.3). In the week following weaning, the mammary alveoli regress (Hacker 1970) and the secretory glandular mass is replaced by adipose tissue in which a new alveolar system develops in the following pregnancy (Delouis 1986). The absence of stimulation of the mammary glands stops the regular secretion of prolactin (Benjaminsen 1981b) while the concentrations of gonadotropic hormones start to increase, allowing ovarian cycles to resume (Stevenson et al. 1981). It was recently hypothesized that estrogens could affect the mammary involution process; however, the administration of estrogens during the postweaning period did not enhance overall rate of mammary involution in sows when litters were weaned at 21 days of lactation (Ford et al. 2003).

PHYSIOLOGY OF MILK PRODUCTION

Milk Synthesis

Lactocytes are highly specialized cells that have the capacity to synthesize sugars, proteins, and lipids (Akers 2002). One gram of mammary tissue has the potential to produce 1.67 ml of milk per day (Akers 2002). Lactocytes are rich in mitochondria, rough endoplasmic reticulum (RER), and RNA (ribosomal, messenger and transport), and they have a large Golgi apparatus that allows protein and lactose synthesis (Mepham 1987). The cellular concentration of these functional organelles can be used as indicators of intensity of milk component synthesis.

Proteins. Sow milk proteins (50–70 g/L) are mainly constituted of caseins (25–30 g/L), beta-globulins (approximately 5 g/L), IgA (5 g/L), alpha-lactalbumins (approximately 3 g/L) and smaller amounts of other proteins (IgG, IgM, serum albumins, etc.) (Klobasa and Butler 1987; Dodd et al. 1994). Most of these proteins are synthesized from amino acids present in the serum and excreted from the Golgi in the alveoli with lactose, water, and electrolytes (Mepham 1983, 1987; Trottier et al. 1997). The uptake of amino acids by mammary gland tissue was recently studied and reported (Hurley et al. 2000; Jackson et al. 2000; Bryson et al. 2001).

The intensity of protein synthesis by the mammary gland is often estimated by the RNA/DNA ratio. In sows, this ratio is less than 1 at 90 days of gestation, equal to 2 at parturition, and higher than 2.5 on day 4 of lactation (Kensinger et al. 1982). These findings therefore support the idea that the intensity of protein synthesis increases between the end of gestation and parturition but also continues to change at least during the first days of lactation.

Lactose. Lactose is the most predominant molecule in milk and is synthesized in the Golgi apparatus from glucose molecules. The Golgi apparatus is a cellular component that is permeable to glucose and nonpermeable to lactose (Leong et al. 1990). This physical characteristic is one of the fundamental mechanisms allowing the creation of an osmotic gradient essential to milk secretion (Peaker 1978). In sows' milk, the concentration of lactose increases from 89 mmol/L up to 175 mmol/L between parturition and day 7 of lactation, and then remains stable up to day 28 (Klobasa et al. 1987). This supports the idea that the intensity of milk synthesis by lactocytes increases up to day 7 of lactation; however, the extent of protein and of lactose synthesis (milk volume) are not necessarily similar. Indeed, the concentration of milk protein goes down whereas that of lactose increases as lactation proceeds (Klopfenstein 2003) (Table 4.2).

Lipids. The lipids present in sow milk are mainly triglycerides (>95%) and they vary in length because they originate from three different sources: from fatty acids obtained from the digestive tract, from those obtained by tissue lipolysis, or synthesized de novo from glucose and organic acids (Mepham 1987; Migdal 1991).

Minerals. Milk contains many mineral substances (approximately 7 g/L) (Noblet and Etienne 1986). The most common minerals (5–75 mmol/L) are sodium, potassium, chloride, calcium, phosphorus, and magnesium (Park et al. 1994) (Table 4.2). Traces (<1 mmol/L) of sulfur, zinc, boron, copper, aluminum, molybdenum, and manganese can also be found (Park et al. 1994). These minerals are either free in solution or bound to proteins.

Lactogenesis

The initiation of the capacity of the mammary gland to synthesize unique milk components such as lactose, casein, and lipids is termed *lactogenesis* and is often described as a two-phase process. Lactogenesis phase I refers to preparation of the mammary tissue for the synthesis of milk components, and lactogenesis phase II, generally occurring around parturition, describes the start of important milk synthesis and secretion (Hartmann et al. 1995).

Abundant quantities of milk components appear in the alveoli between days 90 and 105 of gestation, thereby indicating the beginning of the lactogenic process (Kensinger et al. 1982). However, hardly any secretion can be obtained from the teats until parturition, and then suddenly, around the time of farrowing, copious mammary secretion can be easily extracted from the glands. This could be related to serum transudation (Figure 4.3) occurring because of the major vascular reorganization taking place at farrowing. Indeed, serum volume increases by more than 20% prior to parturition to supply the uterus (Matte and Girard 1996) and as farrowing proceeds, the excess serum needs to be eliminated and could very well be excreted through the mammary glands. At the end of gestation and during the colostral phase, the junctions between epithelial cells surrounding the alveoli are not tight and allow serum transudate
4.3. *Origins of mammary output during the colostral and lacteal phases of lactation in the sow.*

to leak from the bloodstream into the mammary secretions and milk components to leak from the mammary gland alveoli back to the bloodstream (Figure 4.3). Although serum transudation may contribute to the volume of colostrum obtained by the piglets, its contribution is most likely very short in duration.

During the colostral phase, lactose is present in high concentrations in the plasma of sows (>200 mmol/L) (Hartmann et al. 1984), and all the immunoglobulins G found in mammary secretions originate from the plasma (Bourne and Curtis 1973). On the other hand, during lactation, plasma lactose concentrations are low (<100 mmol/L) (Hartmann et al. 1984), and most of the immunoglobulins present in the mammary secretions are synthesized locally (Bourne and Curtis 1973). Similar patterns were found for the plasmatic concentrations of milk whey proteins during the colostral and lactation phases in swine (Dodd et al. 1994).

The onset of milk component synthesis is closely related to the decline in serum progesterone concentrations seen during farrowing (Robertson and King 1974; Hartmann et al. 1984). Moreover, exogenous progesterone administration during late pregnancy delays the beginning of copious milk synthesis in the sow (Whitely et al. 1990). Progesterone withdrawal is therefore considered to be the hormonal signal for the initiation of copious milk synthesis in swine. It is likely that the decrease in progesterone has the function of priming the gland, whereas withdrawal of colostrum from the glands would trigger the initiation of copious milk secretion (Hartmann et al. 1995). Prolactin is also a key hormone for the onset of lactation in sows, as in various other species (Tucker 1985). In the pregnant sow, suppression of the prepartum peak of prolactin inhibits subsequent milk production (Whitacre and Threlfall 1981; Taverne et al. 1982).

Milk Ejection

During the colostral phase, and particularly during parturition and the first hours afterward, colostrum ejection is elicited with ease. At parturition, distension of the cervix for the passage of the piglets and movements of the sow are enough to lead to colostrum ejection (Fraser 1984). Moreover, a sow can cause milk to spurt from the teats by pressing them with her back leg during an attempt to rise (Castren et al. 1989). Colostrum ejections are often as frequent as every 10–20 minutes, and the period of high intramammary pressure, permitting colostrum withdrawal, may be sustained for a minute or more. However, once 50–100 ml of colostrum have been removed, the intramammary pressure is reduced to the point that further withdrawal is more difficult (Fraser 1984).

After the colostral phase, and for the rest of lactation, milk ejection is cyclical, with approximately 24 cycles per day (Whittemore and Fraser 1974; Lewis and Hurnik 1985; Castren et al. 1993). The removal of milk from the alveoli and ductal system of the porcine mammary glands requires a neuroendocrine milk ejection reflex elicited by piglets massaging the udder (Fraser 1980). This reflex consists of an afferent neural pathway and an efferent pathway involving the release of oxytocin and the ejection of milk (Hartmann and Holmes 1989). The activation of neural receptors within the teats of the mammary gland by the nuzzling and suckling of piglets stimulates the release of oxytocin from the posterior pituitary. Oxytocin then stimulates the contraction of myoepithelial cells surrounding the alveolar lumen, thereby forcing milk through the ductal system to the teats (Ellendorf et al. 1982). The amount of oxytocin released during sucklings is not dependent on the massaging time or the number of piglets massaging the udder, but a certain amount of udder stimulation is needed to trigger oxytocin release (Algers et al. 1990). On the other hand, growth rate of piglets is not affected by the peak amplitude in intramammary pressure (Kent et al. 2003), which is linked to oxytocin levels. The increase in circulating oxytocin concentrations can occur up to 30 seconds before milk ejection (Ellendorf et al. 1982), which is very short in duration and lasts only 10–20 seconds (Fraser 1980). Whitely et al. (1985) observed acute episodic releases of relaxin in the blood of sows, both when piglets suckled and after the administration of oxytocin. These authors suggested that relaxin could oppose the action of oxytocin and/or provide a negative feedback on the hypothalamus for the suppression of oxytocin secretion.

During sow lactation not all nursings are successful. Two types of unsuccessful sucklings can be distinguished: those affecting some piglets of a litter and those affecting the whole litter. Among the latter, one must distinguish between sucklings terminated by the piglets and those terminated by the sow (Illmann and Madlafousek 1995). Unsuccessful sucklings affecting the

whole litter become more frequent after the colostral phase, both in a natural environment (Castren 1993) and in confinement (Fraser 1977). They are characterized by an absence in rise in intramammary pressure, associated with a lack of increase in plasma oxytocin (Ellendorf et al. 1982). During the first 10 days of lactation the proportion of unsuccessful sucklings is reported to be between 20% and 40% (Fraser 1977; Jensen et al. 1991). Although frequent and requiring a lot of energy from the piglets, ejection failures may be a functional part of nursing in pigs and may play a role in maintaining lactation (Algers 1993). This is supported by the fact that plasma concentrations of lactogenic hormones tend to rise after an unsuccessful nursing (Rushen et al. 1993). On the other hand, an external stress can lead to failed milk ejections; for example, placing sows in a novel environment increases the chance that the subsequent nursing attempt will fail to lead to milk ejection (Rushen et al. 1995). This stress-induced inhibition of milk ejection is not due to increased concentrations of cortisol or adrenocorticotropic hormone (ACTH) but is likely caused by an opioid-mediated inhibition of oxytocin (Rushen et al. 1995). It is of interest to note that even if it increases the chances of unsuccessful sucklings, the stress of a novel environment does not lead to a general increase in the threshold of stimulation of the mammary gland that is required for oxytocin release (Rushen et al. 1995).

Control of Milk Production

Milk Removal. Removal of milk from the mammary glands is of utmost importance in order to maintain milk secretion. Indeed, suckling and milk removal are the major stimulators of mammary growth during lactation in the sow and mammary glands that are underdeveloped at parturition can still grow rapidly in response to suckling (Hurley 2001). As milk is secreted from the mammary epithelial cells into the alveolar lumen, milk components accumulate in the lumen. One of these components is an autocrine factor, termed *feedback inhibitor of lactation* or *FIL* (Peaker and Wilde 1987), which is known to feed back and inhibit further milk secretion from alveolar epithelial cells. Indeed, milk stasis in alveolar spaces is known to be the primary stimulus for the end of lactation and involution of alveoli in swine (Boyd et al. 1995). Removal of milk therefore removes FIL and allows for continued milk secretion. Milk accumulation in the gland also causes an increase in intramammary pressure, which reduces blood flow to the tissue (Hurley 2001). Furthermore, the stimulus of suckling or massaging the mammary glands by the piglets brings about increases in circulating prolactin concentrations in the sow (Spinka et al. 1999), which is a known galactopoietic hormone (Farmer 2001). The importance of milk removal may also be shown by the fact that a drastic increase in nursing stimulus increases milk energy output (Sauber et al. 1994). Moreover, on days 7 and 8 of lacta-

tion, nursing frequency plays a crucial role in adjusting total daily milk output (Spinka et al. 1997). Piglet behavior is therefore important in modulating sow milk production, but the effect of nursing behaviors could be due either to more complete milk removal or to modified hormonal release (Ellendorf et al. 1982).

Nursing Frequency. As described earlier, the increase in nursing frequency is one of the major factors explaining the observed increasing milk production during the ascending phase of milk production. Nursing frequency is approximately 17 per day at parturition, it increases up to 35 per day at the peak of lactation (day 8 to 10), and then it tends to decrease slightly (20 to 30 per day) up to weaning (Jensen et al. 1991; Spinka et al. 1997; Puppe and Tuchscherer 2000; Farmer et al. 2001; Fisette et al. 2004; van den Brand et al. 2004). The slight decrease in nursing frequency in late lactation is indicative of a lower maternal investment.

Nursing frequency seems to be similar between day and night on day 10 of lactation, whereas it decreases during the night on day 17 (van den Brand et al. 2004). Nursing frequency also tends to be greater in sows on a low feeding level. This could easily be explained by the fact that piglets suckled by sows fed a low feeding level have a greater feeding motivation due to the lower milk yield. On the other hand, it is also possible that sows with a low feed intake terminate nursings more often due to their greater restlessness (van den Brand et al. 2004).

Hormonal Control. The activation of neural receptors within the mammary glands by the nuzzling and suckling of piglets stimulates not only the release of oxytocin from the posterior pituitary but also the release of prolactin, growth hormone (GH), ACTH, and thyroid-stimulating hormone from the anterior pituitary. Hormones from the anterior pituitary have the function of maintaining the synthesis of milk from the mammary epithelial cells (Delouis 1986).

The role of GH for milk production can be either direct or indirect (Flint 1995). Its direct role is via its implication as a regulator of nutrient partitioning for milk component synthesis. Its indirect role is via an increase in the concentrations of insulin-like growth factor I (IGF-I), which acts upon the mammary epithelial cells. When circulating levels of GH and IGF-I were reduced in lactation by immunizing sows against GH-releasing factor, milk yield (measured by the WSW method) was significantly decreased yet the growth rate of the piglets was unaltered (Armstrong et al. 1994). It was concluded that GH may have a facilitative, rather than an essential, role in support of lactation in sows.

Until recently, the role of prolactin once lactation is initiated was not clear. It was originally thought that prolactin might be important in the prefarrowing period (Smith and Wagner 1980) but was not essential for

milk synthesis in later lactation (Benjaminsen 1981a; Bevers et al. 1983; Mattioli and Seren 1985). Yet, in a recent study where the secretion of prolactin was systematically inhibited at various stages of lactation, the weight gain of piglets was suppressed in the week during which prolactin secretion was suppressed (Farmer et al. 1997). These results therefore clearly demonstrate that prolactin is essential for both the initiation and the maintenance of milk production in sows. This is in agreement with results of Plaut et al. (1989), who showed that the binding of prolactin to its receptor is a major effector of milk production in sows.

Thyroid hormones are required for various metabolic functions, such as oxygen consumption and protein synthesis by the mammary gland, that are closely related to milk production (Tucker 1985). The tripeptide thyrotropin-releasing factor (TRF) also stimulates the release of thyroid hormones and of prolactin in the circulation of sows (Dubreuil et al. 1990), which could lead to a possible involvement in the control of milk production.

HOMEORHESIS

The gestation and lactation periods are two complex physiological processes that imply dynamic changes in behavior and body composition. These dynamic changes are related to modifications in energy, protein, water, and mineral metabolisms, and they are particularly important around the time of farrowing. The dynamic equilibrium between all different characteristics needed to carry through gestation and lactation has been described by the Greek term *homeorhesis* (Bauman and Currie 1980). Although the change from gestation to lactation has an impact on almost all systems of the sow, the present chapter will cover only those that are most crucial for the initiation and maintenance of lactation.

Sow Behavior
Four behavioral changes have been observed between the end of gestation and the beginning of lactation in sows maintained under natural conditions:

1. Approximately 24 hours before parturition, the sow becomes hyperactive and leaves her group in order to build a nest.
2. On the day of parturition and the following day, the sow spends most of her time in or within a few meters of the nest, mainly resting and nursing her piglets. She leaves the nest only to drink or urinate.
3. During the next days (3–10), the sow extends her foraging excursions in time and in distance, while the piglets remain in the nest.
4. After day 10, the sow leaves the nest with her piglets, and the whole family joins the herd (Jensen 1986; Stangel and Jensen 1991; Jensen et al. 1993).

Sows maintained in farrowing crates tend to have similar behaviors (Meunier Salaun et al. 1991; Cronin et al. 1994, 1996; Klopfenstein 2003) (Figure 4.4). The day before farrowing, the number of position changes, the proportion of time spent standing and water intake increase substantially compared to the preceding days (Figure 4.4). After farrowing, sows are very lethargic (95% in lateral recumbency) in their crates and they stand up mainly for feeding. After day 3, sows gradually decrease their time in lateral recumbency to attain less than 50% at day 21.

The nursing behavior of sows changes over the lactation period and is probably related to the milk supply. During the first days after parturition, when milk production is greater than the piglets' needs, most (>85%) of the sucklings are initiated by the sow and are terminated by the piglets. After the fourth week of lactation, when the milk supply becomes limited for the needs of the piglets, most sucklings are initiated by the piglets and terminated by the sow (Jensen 1988; Jensen et al. 1991). Results during the period of midlactation are not as clear. According to the work of Boe (1991), on day 10, 80% of the sucklings are still initiated by the sow, but according to the observations of Jensen et al. (1991), this proportion might be only 55%. The sow terminates the sucklings by leaving the piglets or by rolling over on her belly and hiding her udder to limit access (de Passillé and Rushen 1989a).

Energy Metabolism
The heat excreted by each sow almost doubles between the end of gestation and the beginning of lactation (18 vs. 35 MJ per day) (Noblet and Close 1980; Noblet and Etienne 1987). This increased heat production is the consequence of the intensity of the metabolic activity necessary to sustain milk production. This extra heat production has an impact on rectal temperature and heat stress management during lactation.

Rectal Temperature. The normal rectal temperature of healthy gestating sows is reported to be between 38.3°C and 38.5°C (King et al. 1972; Elmore et al. 1979; Messias de Bragança et al. 1997; Klopfenstein et al. 1997; Klopfenstein 2003), with little variation between studies. After parturition and during lactation, the rectal temperature of sows in crates is reported to increase by 1°C (King et al. 1972; Elmore et al. 1979). Healthy lactating sows have difficulty maintaining stable rectal temperatures, values as low as 38.4°C (Cornette 1950; Ringarp 1960) and as high as 40.5°C (Messias de Bragança et al. 1997) have been reported. These wide variations are most likely the consequence of the heat stress induced by increased internal heat production and high environmental temperatures in farrowing rooms. Consequently, feed intake, room temperature, and type of housing affect the capacity of lactating sows to maintain their body temperature. Restricted-fed sows have

lower rectal temperatures than sows fed ad libitum (Moser et al. 1987; Persson et al. 1989; Messias de Bragança et al. 1997). Similarly, GH supplementation, which alters sow metabolism, increased rectal temperature (estimated weekly from days 14 to 35) from 39.1°C to 39.8°C (Toner et al. 1996).

Finally, the expected rectal temperature of lactating primiparous sows is higher than that of multiparous sows (39.6 vs. 39.3°C) (Klopfenstein 2003). This increased rectal temperature observed in lactating sows must be considered as physiological hyperthermia and should not be confused with fever. All these observations suggest that lactating sows housed in confinement are more likely to suffer from heat stress because they are fed ad libitum with high-energy diets, their environment is kept warm for the piglets, and the sows have no access to a cool floor to dissipate the excess heat.

Heat Stress. Lactating sows are extremely vulnerable to heat stress due to their large body size, high metabolic rate (Lynch 1977) and lack of functional sweat glands which prevents dissipation of heat via transpiration (Marzulli and Callahan 1957). They are often exposed to ambient temperatures higher than their upper critical temperature, being in the range of 20–25°C. High temperatures during lactation decrease sow voluntary feed intake (Messias de Bragança et al. 1997; Quiniou and Noblet 1999), increase weight loss, decrease milk production, and hence decrease litter growth rates (Messias de Bragança et al. 1997; Prunier et al. 1997), and also delay the return to estrus of weaned sows (see review by Prunier et al. 1996). Furthermore, sow mortality (and loss of litter) is also associated with high ambient temperatures (D'Allaire et al. 1996) and is largely due to cardiovascular failure.

Fever or Hyperthermia? Fever is defined as an increase in central temperature as a consequence of an increase in the thermoregulatory setpoint (Robinson 1997). Fever is the normal response to systemic infections or to the action of some pyrogenic substances (e.g., endotoxins, interleukins, etc.) (Robinson 1997). Hyperthermia on the other hand, is usually defined as the increase in body temperature observed when the heat production exceeds the heat output capacity (Robinson 1997).

In the lactating sow, there is a lot of confusion on the expected sow normal rectal temperature after farrowing. According to some authors the expected rectal temperature of the healthy lactating sow is 39.5°C (see rectal temperature); others consider that the puerperal sow with a rectal temperature higher or equal to 39.3°C is diseased (see sow rectal temperature and PPDS).

Nutrient Availability

The nutrients required by mammary tissue for milk synthesis come from the diet and from body reserves. Mammary glands are the primary users of absorbed nu-

trients in lactating sows and virtually dictate the dietary nutritional needs (Boyd et al. 1995). Indeed, it was shown that 65–70% of the total energy requirement of a lactating sow is to support milk production (Aherne and Williams 1992). Of the total uptake of plasma metabolites by mammary tissue, glucose accounts for approximately 61%, amino acids 24%, triglyceride fatty acids (TGFA) 12%, and acetate 1% (Spincer et al. 1969). Approximately 53% of the glucose taken up by the mammary gland is partitioned to lactose and 34% is oxidized. The other 13% is used for the synthesis of triglyceride-glycerol, milk fatty acids, and amino acids (Linzell et al. 1969). It is of interest to note that in the presence of both acetate and glucose, sow mammary tissue will preferentially utilize acetate for fatty acid synthesis (Bauman et al. 1970). Therefore it is conceivable that more glucose could be made available for mammary metabolism by raising TGFA levels in the diet (Boyd et al. 1995).

Mammary tissue of lactating sows is very active with respect to transport and metabolism of amino acids. Boyd et al. (1995) ranked each amino acid on the basis of relative uptake by mammary tissue. The order of amino acids was almost identical for mammary uptake and milk composition, but it was also reported that the mammary uptake of branched-chain amino acids (valine, leucine) and arginine may be greater than suggested by the milk amino acid pattern (Boyd et al. 1995; Trottier et al. 1997). Milk production is ultimately energy-dependent, so that the need in amino acid for milk synthesis depends on the amount of dietary energy available (Tokach et al. 1992), thereby reinforcing the importance of glucose sources and of a right balance of nutrients in sow feeding management.

Sow milk contains large amounts of calcium, phosphorus, and magnesium. These bivalent ions found in the milk are transferred from the digestive tract and from bone reserves. Apparent digestive bioavailability of these bivalent ions is known to be low (3–50%) (National Research Council 1998). Intestinal absorption and renal absorption of these minerals is closely regulated by a hormonal system (parathormone, calcitriol, calcitonine), whereas active absorption from the digestive tract requires the synthesis of a transport protein (Greco and Stabenfeldt 1997). After parturition, the availability of bivalent ions may affect initiation of lactation. This problem is well known in cows (Goff 2000) and is often suspected in sows.

Water Availability

Water intake patterns observed between the end of gestation and the beginning of lactation are presented in Figure 4.4. Hourly water intake increases from approximately 1 L/hour at the end of gestation to attain 2.6 L/hour 12 hours before the end of parturition (Klopfenstein 2003). Water intake can be very low in some sows during the first 24 hours following parturition (less than 10 L/day). After this period of transition, water in-

take increases gradually to attain 20 to 35 L per day during lactation. The increased water intake just prior to farrowing can be due to the occurrence of nesting behavior but is also the consequence of greater water needs. Indeed, during the hours preceding parturition, there is a rapid increase in the water content of the reproductive system to allow the process of parturition (Dobson 1988).

PIGLET GROWTH, MORTALITY, IMMUNITY, AND BEHAVIOR

The newborn piglet is totally dependent on sow's colostrum and milk as a source of protein for growth, energy to maintain body temperature, and immunoglobulins for protection against diseases. Sow milk and colostrum provide the best nutrients for the nutritional needs of the piglets. The biological value of milk protein in swine is very close to 1 (Williams 1995) and the amino acid balance in sow's milk is very similar to that in the lean tissue of pigs (King et al. 1993a).

Piglet Growth

From birth to weaning, piglets from larger litters tend to be lighter than piglets from smaller litters (Dyck and Swierstra 1987; Van der Lende and de Jager 1991; Le Dividich et al. 2004). This difference is the consequence of lower piglet birth weight and, in some cases, of lower milk supply per piglet in large litters. Average piglet birth weight is reported to decrease by approximately 30–40 g for each additional piglet in the litter (Van der Lende and de Jager 1991; Le Dividich et al. 2004). Although average piglet weight decreases with litter size, selection of hyperprolific sows over 10 years had no effect on average piglet weight (Tribout et al. 2003) because it also increased the expected weight of piglets of similar litter sizes. The expected mean birth weight of Large White piglets has not changed (1.45 kg) between 1977 and 1988 although litter size increased from 10.2 to 11.2 piglets. Interestingly, the expected average piglet birth weight for a litter size of 10.7 piglets increased from 1.37 kg to 1.46 kg over the same decade (Tribout et al. 2003).

Growth rate, usually measured as average daily gain (ADG), is related to individual piglet weight at birth (Tyler et al. 1990; Castren et al. 1991; Le Dividich et al. 2004). The expected maximal ADG of a newborn piglet weighing 1.3 kg is lower than that of a piglet with a birth weight of 2.3 kg. It is therefore necessary to take into account initial weight when comparing ADG between piglets. When piglet weights are mathematically corrected for a standard birth weight (1.4 kg), the effect of litter size is absent on day 3, is small on day 7, and becomes greater as lactation proceeds (Table 4.1). These data show that milk production becomes a limiting factor for piglet growth when the sow has attained her maximal milk production capacity (day 10 to 15).

Piglet Mortality

Although swine production is becoming more sophisticated, piglet losses between birth and weaning remain a serious problem for the industry. Preweaning mortalities are often higher than 10% of liveborn piglets and most of these occur during the first week after parturition (English and Morrison 1984; Dyck and Swierstra 1987; de Passillé and Rushen 1989b; Le Cozler et al. 2004). These losses can be explained by litter and piglet characteristics or by inadequate sow milk production.

The effect of litter size on mortality is quadratic. Piglet losses increase only in the largest litters (Guthrie et al. 1987; Fahmy and Bernard 1971; Dyck and Swierstra 1987) and are probably related to an insufficient number of functional mammary glands to supply milk for all the piglets (Chertkov 1986; Bilkei et al. 1994).

The main causes (>75%) of mortality are emaciation and piglet crushing by the sow (English and Morrison 1984; Fraser 1990; Le Cozler et al. 2004). Piglets losses due to emaciation occur mainly on days 4 and 5 after birth as a result of poor nutrition during the first days postpartum (Dyck and Swierstra 1987). Piglets crushed by the sow often had poor gains during the first postnatal days (Dyck and Swierstra 1987). Piglet mortalities are not uniformly distributed between litters. Most of them occur among a few litters (see problem litters) with poorer growth rates during the first days after birth (Pettigrew et al. 1986; Dyck and Swierstra 1987; Thompson and Fraser 1988; de Passillé and Rushen 1989a,b; Fraser and Phillips 1989; Klopfenstein et al. 1995, 1997; Klopfenstein 2003). Most of these problem litters are thought to be the consequence of some inadequate mammary function during the initiation of lactation.

Immune Protection of the Piglet

Newborn piglets rely on colostrum for passive transfer of immunity (Bourne 1976) because there is little or no placental transfer of antibodies in the pig (Rapacz and Hasler Rapacz 1982). The absorption of immunoglobulins from the sow's colostrum causes closure of the intestine for the passage of these large proteins (Klobasa et al. 1991), suggesting that absorption is possible only during the first feedings after birth. Twenty-four hours postnatally, artificially reared piglets receiving 6 hourly feedings of 25 ml of sow colostrum followed by hourly feedings of cow's milk had plasmatic immunoglobulins concentrations similar to those of naturally fed piglets (Klobasa et al. 1991). Increasing the number of hourly feedings of colostrum from 6 to 12, 18, or 24 did not increase the concentrations of plasma immunoglobulins in piglets. On the other hand, allowing the piglets to fast for periods of up to 24 hours after birth before giving them access to their first colostrum intake did not decrease serum immunoglobulins concentrations 12 and 18 hours after feeding (Klobasa et al. 1990). Therefore, closure of the gut system for the passage of immunoglobulins is dependent on the quantity of colostrum in-

gested rather than on time since birth. Six feedings of colostrum should be sufficient to give adequate immune protection to the piglets.

Passive immunity transfer from the sow to the piglet is essential for protection against diseases. The quantity of IgG ingested by each piglet is affected by birth order due to the rapid changes in colostrum composition taking place between onset of farrowing and birth of the last piglet (Klobasa et al. 2004; Le Dividich et al. 2004). Piglets dying before weaning are reported to have lower plasmatic immunoglobulin concentrations after parturition (Hendrix et al. 1978; Tyler et al. 1990); yet this association disappears when birth weight is used as a covariate (Tyler et al. 1990). Moreover, the probability of dying is not increased among last-born piglets, even though they obtain less immunoglobulins than first-born piglets (Le Dividich et al. 2004). These results, although surprising, can be explained by the fact that most mortalities are the consequence of inadequate nutrition rather than diseases.

Piglet Behavior

The nursing behavior of piglets changes over the lactation period. During the colostral phase, newborn piglets move from teat to teat in a "teat-sampling" process (Hartsock and Graves 1976), enabling them to receive a "free meal" of colostrum (de Passillé and Rushen 1989a; Fraser and Rushen 1992). Udder massaging by the piglets, although frequent during the rest of lactation, is rare during the colostral phase (Castren et al. 1989). The interval between birth and first suckling does not change greatly with birth order (Rohde Parfet and Gonyou 1988).

After the colostral phase, nursing becomes cyclical and the suckling behavior of piglets can then be characterized by four phases (Fraser 1980):

1. Piglets start by vigorously massaging the sow's udder, which is necessary for triggering the oxytocin release. During this phase, piglets often fight and are very noisy. After 1–3 minutes of udder massaging, which is one of the longest periods among mammals, the sow increases her grunting rate, which coincides with the release of oxytocin (Algers et al. 1990).
2. When piglets hear the signal, they become very quiet, keeping the teats in their mouths and waiting for their meal.
3. As soon as milk ejection occurs, the piglets drink the milk with rapid jaw movements.
4. After milk ejection, which lasts only for 10–20 seconds, the piglets continue to massage the udder for a short period of time.

No milk can be obtained by the piglets during either the pre- or postejection massaging phases. Therefore, even if piglets are often seen at the mammary gland, milk is available for only a very short period of time—less than 10 minutes per day (10–20 seconds per milk ejection, 17–30 ejections per day). Failure of milk ejection is indicated by the absence of rapid grunting from the sow and of rapid-mouth movement from the piglets as well as no change in intramammary pressure. Milk ejection failure is due to a lack of pulsatile release of oxytocin during the massaging phase (Ellendorf et al. 1982), which can be brought about by undue stress to the sow.

During the first 8 hours after birth, newborn piglets suckle an average of seven different teats and are often involved in fights (de Passillé and Rushen 1989a). The frequency of teat disputes is not affected by litter size, but piglets suckling many teats are involved in more disputes. Regardless of teat position, the piglet with a teat in its mouth at the beginning of a dispute has a higher probability of winning (de Passillé and Rushen 1989a). Within 48–72 hours postpartum, piglets establish a teat order in which each piglet consistently sucks from one or two specific teats (Roychoudhury et al. 1995). Piglets prefer the anterior teats (Vales et al. 1992), most likely because sows are more responsive to stimulation of these teats than they are to stimulation of the inguinal teats (Fraser 1976). This increased responsiveness could be due to the different nerve supply between front and rear teats (see the section on anatomy). The anatomical and physiological differences between front and rear teats could induce different milk yields. Indeed, piglets suckling the front teats were reported to be heavier at weaning than piglets suckling the caudal teats (Kornblum et al. 1993; Hoy et al. 1995).

MANIPULATING MILK PRODUCTION

Insufficient milk production to meet piglet needs usually occurs when the maximal milk production capacity is attained (7–15 days). This is usually considered a physiological limitation because it affects all sows sooner or later during lactation. Many management strategies have been studied to overcome this physiological limitation and they are discussed in this section.

Feeding Strategies

Milk production requires a great supply of substrates, which come from two sources: the lactation diet and the sow's body reserves. The relative importance of nutrient intake seems to change as lactation progresses. Body reserves might be sufficient in early lactation compared with late lactation to compensate for inadequate nutrient intake (Pettigrew 1995). Accordingly, severe restriction of feed intake during lactation has no impact on litter growth in the first week postpartum, whereas it markedly decreases litter growth during the fourth week of lactation. The size of this reduction depends on the amount of body reserves at farrowing; gilts with lower body reserves being affected most (Mullan and Williams 1989). A survey of 25,000 lactating sows (Koketsu 1994, as reported by Pettigrew 1995) showed that the impact

of lactating sows feed intake on litter weight becomes larger as lactation progresses.

The intake of protein/amino acids by lactating sows is critical for their overall lactation performance because of the great nutrient requirements to maintain milk production. Lysine is typically the first limiting amino acid for lactating sows and it was established that 26 g of dietary lysine is needed per kg of litter growth/day (Sohn and Maxwell 1999). When looking at nitrogen balance of lactating sows, Dourmad et al. (1998) demonstrated that, in order to achieve a zero protein balance, 45–55 g/day of crude lysine are required for normal- to high-yielding sows, respectively. Among the branched chain amino acids, both valine and isoleucine, but not leucine, appear to increase milk production as indicated by increased litter weight gain (Kerr 1997, as cited by Sohn et al. 1999). These amino acids can be metabolized to succinyl-CoA and can therefore potentially serve as a source of energy for the mammary gland (Sohn and Maxwell 1999). Indeed, McNamara and Pettigrew (2002) showed that sows can mobilize amino acids from muscle to support mammary growth and milk production, yet they also demonstrated that an increased energy intake can partially relieve the effects of decreased protein intake on milk production.

From various studies designed to determine the relation between milk production and dietary energy, Williams (1995) noted that each suckling piglet grows an extra 1 g/day for each MJ of metabolizable energy consumed by the sow. In recent studies, sows were fed through a stomach cannula in order to override the normal mechanisms that limit feed intake. Matzat et al. (1990) showed a linear relationship between milk output and energy intake of sows, whereas Pluske et al. (1995b) demonstrated a ceiling to milk production from gilts, whereby piglet growth did not respond beyond 75 MJ of metabolizable energy. It therefore seems that gilts and sows might partition energy differently during lactation, and this partitioning is most likely under hormonal regulation. Such a ceiling for lactational performance was also observed in first-parity sows offered increasing amounts of protein (King et al. 1993b).

When attempting to increase sow milk yield, one must keep in mind that as the milk production capacity of a sow is increased, her nutrient requirements for milk synthesis are also elevated. It is therefore important to ensure that lactational feed intake of sows is maximized and that lean-tissue gain during pregnancy is sufficient so that the sows' milk production capacity is not compromised. Various feeding management systems have been used in an attempt to increase sow feed intake. Increasing feed consumption of sows by 8% through wet-feeding had no impact on average daily gains of piglets over an 18-day lactation period (Genest and D'Allaire 1995). Similarly, the use of a bulky diet in gestation increased average lactational feed intake of sows by 8% without improving mean litter weight (Farmer et

al. 1996). Increasing daily feeding frequency from 2 to 3 (Genest and D'Allaire 1995) or 2 to 4 (Farmer et al. 1996) during lactation also had no effect on feed intake. The addition of fat to the sow's diet in order to increase energy density, and energy intake, of sows during lactation was also studied. However, it did not lead to a less-negative energy balance in the sows but resulted in fatter piglets when sows were fed at a high feeding level (van den Brand et al. 2000).

Nursing Interval

Refilling of the mammary glands with milk was reported to be almost complete within 35 minutes after a suckling bout (Spinka et al. 1997), and the frequency of gland emptying was found to play a major role in regulating milk secretion and mammary gland development (Auldist et al. 2000). These last authors increased suckling frequency via cross-suckling, using piglets from another litter, which could not be done commercially. However, it is known that sows within a farrowing room will synchronize their nursings (Wechsler and Brodmann 1996), and this is likely due to the auditory stimulus from the other animals. Experiments were therefore carried out in which the typical sow suckling grunts were recorded and played back to sows and their litters during lactation in an attempt to stimulate nursing frequency. These playbacks can indeed stimulate nursings (Stone et al. 1974). However, the results on piglet growth are variable between studies, with no effect to an 8% increase when a recording of sow suckling grunts was played at 35–42 minute intervals (Cronin et al. 2001; Fisette et al. 2004). On the other hand, playbacks at 35-minute intervals increased mammary parenchymal cell number in sows at the end of lactation (Farmer et al. 2004a). Present results suggest that use of this management practice throughout lactation is not optimal and further work is needed to establish such things as the ideal time in lactation to play these recordings, the optimal interval to be used, and whether there is a habituation effect. It is evident, however, that efforts should be made to encourage greater suckling frequency and to minimize disruption of suckling behavior in farrowing houses in order to maximize sow milk yield.

Exogenous Hormones

The important endocrine control of sow milk yield suggests that exogenous hormones could be used to stimulate milk production. Studies were therefore performed to determine the possible impacts of various peptidic hormones on sow milk yield and piglet performance. Growth hormone (GH) or GH-releasing factor (GHRF) received considerable attention since greater concentrations of GH could allow more nutrients to be utilized for milk synthesis (Farmer 1995). Early studies reported an important increase in milk yield (15–22%), leading to improved piglet growth rates (Harkins et al. 1989). But those results could not be reproduced in further trials

(Smith et al. 1991). Furthermore, Michelchen and Ender (1991) stated that the effect of GH on milk yield is not greater in sows having large litters (13 vs. 8 piglets). The effects of GH on milk composition are also contradictory, whereas reduced voluntary feed intake during lactation and greater body weight and backfat losses of sows receiving GH during lactation are consistent findings in all studies.

The decreased feed intake likely limits the lactation response to GH and leads to an increased use of body reserves to maintain milk production. The addition of 8% fat in the lactation diet could not prevent these losses of backfat in GH-treated sows (Cromvell et al. 1992). Exogenous GH may also have detrimental consequences on sow health (Smith et al. 1991; Cromvell et al. 1992), with some animals dying of bleeding stomach ulcers (Smith et al. 1991) or of apparent heat stress in the peripartal period. It is suggested that sows may be more sensitive to exogenous GH than growing pigs and that the adverse effects of GH in lactating sows may be dose-dependent (Smith et al. 1991). It is apparent that GH does play a role in the regulation of milk yield, but whether this role is an essential or a facilitative one is not known (Armstrong et al. 1994).

The secretion of GH is under the dual control of a GHRF (Guillemin et al. 1982) and a GH-inhibiting factor named somatotropin-release inhibitory factor (SRIF) (Brazeau et al. 1973). Active immunization against SRIF was used as a tool to increase concentrations of GH in sows, but the great variability in animal response to this treatment makes it an unreliable method (Farmer et al. 1990, 1991). The use of GHRF, on the other hand, consistently increases GH concentrations, with sows showing an increased responsiveness to chronic injections (Dubreuil et al. 1987). However, massive doses of GHRF (12 mg thrice daily) did not affect sow milk yield, milk composition, or piglet performance, but decreased weight, backfat thickness, and feed intake of sows on the fourth week of lactation (Farmer et al. 1992). Nevertheless, blood urea was reduced indicating that GHRF-injected sows utilized proteins more efficiently, thereby enabling them to maintain their milk production and litter performance in spite of a decreased feed intake. When combining administration of GHRF with a feeding management designed to optimize feed intake of lactating sows (Farmer et al. 1996), there was only a tendency for piglet weights to be greater. However, the increase in sow feed intake was not as large as expected and was mostly seen in early lactation. It is therefore likely that a management system having a greater effect on sow feed intake is needed for GHRF to exert its maximal effects on milk yield and piglet growth.

Daily intramuscular injections of 50 or 100 mg/sow of thyrotropin-releasing factor (TRF) increased the average daily weight gain of piglets (Wung et al. 1977), but subcutaneous injections of 9 µg/kg given twice daily during lactation had no effect on piglet growth (Dub-

reuil et al. 1990). Due to its small size, TRF can be absorbed intact by the digestive tract and when 200 mg of TRF were added daily to the feed of sows, piglet weight was increased by 0.7 and 1.1 kg on days 20 and 27 of lactation, respectively, but the weaning to estrus interval went from 4.8 to 36.9 days, making such a treatment totally inadequate for swine producers (Cabell and Esbenshade 1990).

Sows showing spontaneous lactation failure harbor abnormally low concentrations of prolactin (Whitacre and Threlfall 1981). This may explain the 8% increase in litter weight gain observed in gilts (but not sows) receiving a single injection of porcine prolactin on day 1 of lactation (Dusza et al. 1991). Two studies were carried out to determine the effects of chronic injections of prolactin from day 107 of gestation and during lactation, on milk production of sows (Crenshaw et al. 1989; King et al. 1996). Neither of these showed any effect on milk yield and it was postulated that since injections were started before there were any piglets to remove milk from the mammary glands, premature involution of the secretory units of the mammary glands might have taken place (Boyd et al. 1995). In a later study where prolactin was injected to sows from days 2 to 23 of lactation, sow and piglet performances were still unaffected (Farmer et al. 1999). These results also indicated that virtually all prolactin receptors are generally saturated in lactating sows, thereby preventing any beneficial effects of further increasing prolactin concentrations. Studies on the control of prolactin receptor numbers and affinity in lactating sows are therefore needed.

POSTPARTUM DYSGALACTIA SYNDROME

Inadequate and insufficient colostrum and milk production occurs in some sows during the puerperal period usually lasting up to 72 hours after birth of the first piglet. Historically, puerperal lactation problems have been considered to be a cause or a consequence of a pathological condition named as the mastitis-metritis and agalactia syndrome (MMA). As discussed in the first part of this chapter, poor lactation performance can also be explained by three major physiological factors:

1. Inadequate or insufficient mammary gland development
2. Inadequate or insufficient milk synthesis
3. Inadequate adaptation to lactation homeorhesis.

Therefore, postpartum sow lactation problems are more adequately described as postpartum dysgalactia syndrome (PPDS), which is preferred by the authors over the more traditionally used MMA syndrome. Indeed, the latter term has created a lot of confusion because it is assumed that all three symptoms are present in the case of early lactation problems, which is not necessarily the case.

Clinical Signs of PPDS

The primary clinical signs of a sow's inability to produce a sufficient amount of milk and colostrum are piglet growth retardation and increased mortalities. In this chapter, litters with high mortalities and low growth rates during the first days after parturition will be called problem litters. They remain a frequent observation in modern farrowing units, and veterinarians are often consulted to reduce their incidence. Unfortunately, they can be identified with certainty only when the piglets show retarded growth and high mortality, because litter characteristics at birth are poor predictors of future performances. Close observation of the piglets' behavior is one of the best methods for early detection of problem litters (Whittemore and Fraser 1974). These piglets fight more and for longer periods, lose weight, and remain close to the sow between sucklings (Algers and de Passillé 1991).

Early detection of sows with postpartum lactation problems is difficult because most of them do not show any clear clinical signs (Klopfenstein 2003). Temporal variation of sow behavior (Figure 4.4) and body condition were similar among sows nursing litters with poor (≤77 g/kg/day—problem litters) and normal (>77 g/kg/day—normal litters) growth rates between the end of parturition (time 0) and 132 h postpartum (Klopfenstein 2003). In the last study, the major differences between sows nursing problem and normal litters were related to milk composition (Table 4.3). Also, sows nursing problem litters drank less water (−0.36 L/h) and had lower skin temperature (−0.64°C) (Figure 4.4), higher serum phosphate (+0.10 mmol/L), and higher calcium (+0.05 mmol/L) concentrations at hours 36 and 60 of lactation. Rectal temperatures of sows nursing problem litters were similar to those of the others sows at the end of gestation (−96 h) and at the beginning of lactation (12 h, 36 h, 60 h) but were slightly higher at 132 h (39.6 vs. 39.4°C) postpartum. The latter study confirmed that milk production of sows nursing problem litters is different compared to the other sows but showed that there is no easy way for the farmer to identify these sows early after parturition. Moreover, in the later study, only 2 sows among the 29 sows nursing problem litters were diseased in the postpartum period. This is a good representation of what is seen in many herds. A few sows presenting PPDS are diseased but many more are apparently normal.

Prevalence of PPDS

Although PPDS is observed in some herds, there is a lot of confusion on the prevalence of postpartum lactation problems due to the subjectivity related to some of the criteria used to identify the affected sows. Indeed the most common criterion used to identify sows affected by lactation problems is based on postpartum rectal temperature. The use of the rectal temperature criteria to classify sows as diseased or normal is adding confusion to our understanding of the pathogenesis of PPDS.

Sow Rectal Temperature and PPDS

For some historical reasons, there seems to be a general consensus that postpartum rectal temperatures higher than 39.3 or 39.5°C categorize sows as being affected by PPDS (Hermansson et al. 1978b; Goransson 1989b; Persson et al. 1989; Madec and Leon 1992; Hoy 2004). However, as discussed previously, this criterion should be seriously questioned because the proposed thresholds are equal or even below the expected rectal temperature of lactating primiparous and multiparous sows (see fever or hyperthermia?).

The use of rectal temperature to classify sows as diseased or normal has led to the publication of paradoxical results. In some instances, litters from sows identified as being "severely affected by early lactation problems (MMA)" because of high rectal temperature (>39.5°C) had better growth rate and lower mortality than litters from nonaffected sows (Furniss 1987; Persson et al. 1989). Moreover, the proposed cut-off to

Table 4.3.   Temporal variation of some milk components (least square means) of sows nursing litters with slow (≤ 77 g/kg/day—Problem litters—PL) and normal (>77 g/kg/day—Normal litters—NL) growth rates between the end of parturition (time 0) and 132 hours postpartum (PP).

Milk Components	36 Hours PP		60 Hours PP		132 Hours PP	
	NL	PL	NL	PL	NL	PL
Lactose (mmol/L)	120	120	130	121*	147	141*
Sodium (mmol/L)	23	23	19	23*	16	19*

classify sows was never adjusted for parity even though the expected rectal temperature of primiparous sows is higher (approximately 0.3°C) than that of multiparous sows (Klopfenstein 2003). Accordingly, it was reported that 43% of gilts and 29% of multiparous sows have postpartum rectal temperatures higher than 39.3°C and it was assumed that all these sows were affected by MMA (Hoy 2003). The belief that higher rectal temperature identifies sows with PPDS is so generally accepted that many researchers use this criterion to identify diseased animals without estimating piglet growth and preweaning mortalities. Many published results on the MMA syndrome where piglet growth and/or litter mortality were not estimated are not included in this chapter since it is very difficult to assess whether the sows classified as "diseased" did in fact have lactation problems.

INFECTIOUS CAUSES OF PPDS

Sows with Clinical Signs of Disease

A number of postpartum lactation problems (<72 hours) are certainly the consequence of some inflammatory process related to localized or systemic infections. Localized tissue infection usually translates into measurable clinical signs such as pain, inflammation (heat), reddening and edema (Cotran et al. 1999). A localized infection can eventually affect the whole animal. Major clinical signs of a diseased sow in the postpartum period are fever (>40°C), lethargy, anorexia and eventually constipation. The main diseases affecting postpartum and lactating sows are urinary tract infections, endometritis, and mastitis. Moreover, severe milk production problems were reported with the porcine respiratory and reproduction syndrome (PRRS) (see Chapter 24). Gross and microscopic pathological evaluation of the reproductive systems of diseased and normal sows in the postpartum period suggest that endometritis is rare (Ringarp 1960; Jones 1976; Middleton-Williams et al. 1977) whereas lactation problems seem to be more frequent in sows with renal infections (Berner 1984, 1988).

Sows that were diseased in the peripartum period have increased circulating serum concentrations of acute phase proteins (haptoglobin-HPT and alpha 1-acid glycoprotein—AGP) and serum cortisol during lactation (Mirko and Bilkei 2004). The concentration of HPT was increased on days 1, 5, and 10 and normal on days 15 and 20 of lactation; AGP was normal on days 1 and 5 and increased on days 10, 15, and 20; serum cortisol concentration was elevated during the whole lactation. Litter performance of the diseased sows of the previous study was very poor (22% mortality) and is certainly related to the incapacity of these sows to produce sufficient amounts of milk.

Mastitis

Mastitis is a clear pathological entity observed in some lactating sows (Ringarp 1960; Middleton-Williams et al. 1977; Hermansson et al. 1978b; Halgaard 1983). The diseased mammary glands are warm to the touch and swollen, with a blotched appearance (Jones 1971). When many glands are involved, the sows often go off feed and have high rectal temperatures (>40°C) (Middleton-Williams et al. 1977; Halgaard 1983). The bacteria isolated from infected glands are mainly coliforms (*Escherichia coli, Klebsiella* sp, *Enterobacter* and *Citrobacter*) and bacteria of the genera *Staphylococcus* sp. and *Streptococcus* sp. (Armstrong et al. 1968; Ross et al. 1981; Persson et al. 1996).

In acute and severe mastitis, necrotic and purulent lesions are present in the mammary glands (Middleton-Williams et al. 1977), milk synthesis is altered and, when many glands are affected, piglet growth is decreased. The suppuration starting at the beginning of the infectious process can become a permanent granuloma that can be observed in culled sows. In one survey in Germany, 23% of 1000 culled sows had granulomatous lesions on some mammary glands (Bollwahn and Meermeier 1989). In another survey in Sweden, the prevalence of granulomatous mastitis in sows from different farms varied from 0 to 50% (mean 16% at weaning). Most affected sows (76%) had only one mammary gland with macroscopic lesions (Hulten et al. 2003). These data show that mastitis can affect many sows but that most of the time severe lesions are found only in a few glands.

In some studies on the importance of mastitis as a pathological entity, it is not always clear whether the sows were selected for the presence of mastitis or because the litter had retarded growth and high mortality. When sows were selected for necropsy on the basis of poor piglet performance, no macroscopic lesions consistent with mastitis were found (Nachreiner et al. 1971). Instead, mammary tissue from sows with problem litters appeared nonfunctional because it did not contain abundant quantities of milk (Martin et al. 1967; Nachreiner et al. 1971). Moreover, the higher cellular content found in the milk of sows nursing problem litters (Table 4.3) was considered to be the consequence of a concentration effect related to lower milk production rather than an indication of mastitis because the proportion of leucocytes (leucocytes/total cells) was similar in the milk of sows nursing problem and normal litters (Klopfenstein 2003). Therefore, we must consider that some problem litters are the consequence of sow mastitis but that many others are likely unrelated to it.

Endotoxemia

The absorption of endotoxins from gram-negative bacteria was proposed as an explanation for early lactation problems. Indeed, some sows (<33%) with problem litters are positive for circulating endotoxins (Morkoç et al. 1983; Pejsak and Tarasiuk 1989). Exogenous administration of gram-negative endotoxins also suppresses serum prolactin concentrations and increases sow rectal tem-

perature and respiratory rate (Nachreiner and Ginther 1974; Elmore et al. 1978; Smith and Wagner 1984, 1985b; Tarasiuk and Pejsak 1986; de Ruijter et al. 1988). However, the effects of injection of endotoxins are of short duration, with sows fully recovering within 8 hours of injection (de Ruijter et al. 1988). Even though a continuous infusion of endotoxins causes severe piglet growth retardation (Ferguson et al. 1984), a single massive dose only retards piglet growth during the 5–8 hours after the injection (Smith and Wagner 1985b). The origin of endotoxins remains unclear, but may be urinary tract inflammation, mastitis, uterine infection, or the intestine.

Sows with Subclinical Forms of Disease

Lactation problems of some sows could be the consequence of a subclinical form of the diseases aforementioned. This hypothesis is very popular because it can explain the disproportion between the number of sows showing clinical signs of disease (rare) and those nursing problem litters (more frequent). This theory is often used as a justification for the common practice of a systematic use of antibiotics and antiinflammatory drugs for the postpartum sow.

NONINFECTIOUS CAUSES FOR PPDS

Mammary Gland Development

Allometric mammary gland development occurs mainly during the last third of gestation and continues during lactation (see mammogenesis). Mammary gland development varies between sows and could certainly explain some lactation problems related to PPDS.

The number of piglets in the litter should always be adjusted to the number of functional mammary glands. Teat malformation, inverted nipples can prevent the piglets from nursing (Labroue et al. 2001). Sows with an insufficient number of functional mammary glands should be culled.

Intensity of Milk Synthesis

Concentrations of milk lactose increase during the first days of lactation (Table 4.3) and this increase is slower among sows affected by PPDS during the first 72 hours after parturition (Klopfenstein 2003). Factors explaining the slower increase in milk synthesis among sows nursing problem litters are not known but could be the consequence of retarded lactogenesis or insufficient mammary gland development at parturition.

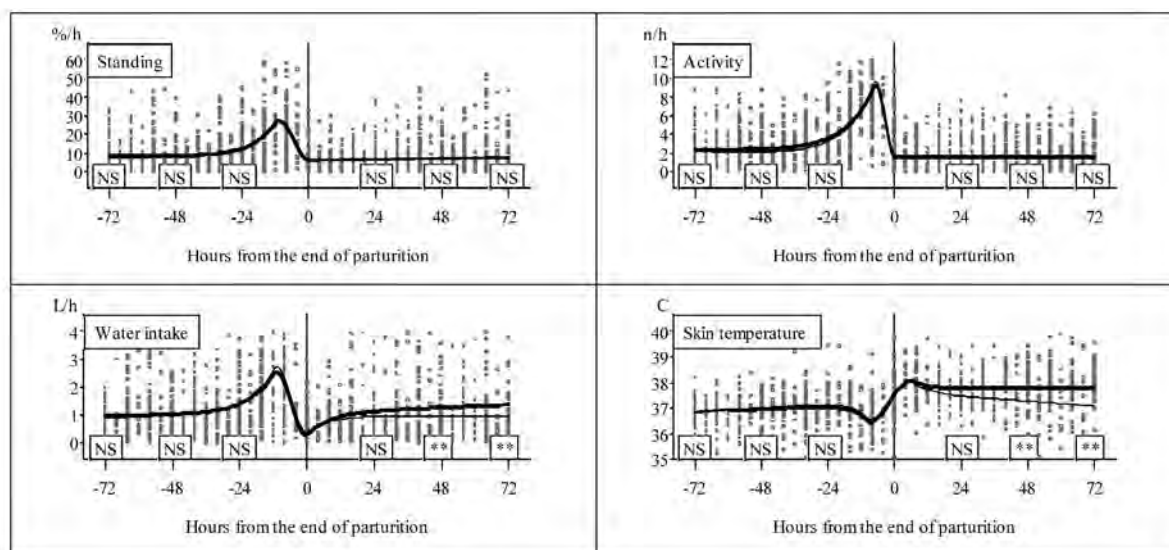
Homeorhesis

Sow Behavior. Some sows are aggressive and attempt to bite or crush their piglets soon after parturition, while others refuse mammary access to the piglets. These problems are more characteristic of first-parity sows, and chemical tranquilization is usually sufficient to cause the sow to relax and nursing to proceed normally.

Energy Balance. A recent study showed that serum concentrations of nonesterified fatty acids (NEFA) and glucose are lower in sows nursing litter with high preweaning mortalities (more than 1 piglet dying (Valros et al. 2003). This in conjunction with the well-known detrimental effects of heat stress on sow lactation performance indicates that the capacity of the sow to manage her energy balance is certainly a critical point. Problems of energy balance adjustments after parturition are well documented in cows (Drackley 1999) but have not yet been extensively studied in sows.

Water Balance. Water management around parturition can certainly explain some lactation problems related to PPDS. The shape of the temporal variation in water intake around parturition (Figure 4.4) indeed suggests that water availability prior to parturition is a critical point that needs to be considered in the farrowing room. Postpartum constipation observed in some sows affected by PPDS could be due to insufficient water intake before parturition.

Bivalent Ions Balance. Problems related to metabolic balance adjustment of bivalent ions (calcium, phosphorous and magnesium) are well-described in cows (Goff 2000) and are often suspected in sows. Hermansson et al. (1978a) reported that sows affected by agalactia problems had lower circulating calcium and magnesium concentrations. Klopfenstein (2003) observed higher serum phosphorus and calcium concentrations in sows nursing litters with lower growth rates. Moreover, DeRouchey et al. (2003) were able to increase piglet survivability up to day 10 by feeding sows a diet with a low electrolyte balance from day 109 of gestation and during lactation. This strategy is often used in dairy cows and is known for its beneficial impact on calcium and phosphorus balance in the postpartum cow. The later observations suggest that inadequate adjustment of bivalent ions balance after parturition might explain some lactation problems related to PPDS of sows.

Hormonal Balance. As early as 1967, an endocrine role in the pathogenesis of agalactia was suggested (Martin et al. 1967). Agalactic sows had smaller ovaries and thyroid glands and larger adrenal glands than control sows. In a later study, there was no difference in the size of these three glands but thyroid function was depressed in agalactic sows (Wagner 1972). More recently, it was shown that the hormonal status of first-litter sows with hypogalactia or agalactia differs from that of healthy sows. Concentrations of cortisol both before and after farrowing and prepartum levels of glucose were lower in hypogalactic sows (Samanc et al. 1992). Finally, de Passillé et al. (1993) noted a relationship between poor piglet performance and high concentrations of progesterone in the blood of sows after parturition.


4.4. *Peripartum temporal variation of some behavioral traits and skin temperature of sows nursing litters with slow (≤77 g/kg/day—thin line—Problem litters) and normal growth rates (>77 g/kg/day—thick line—Normal litters). NS = non significant difference, ** = significant difference at p <0.05. Adapted from Klopfenstein 2003.*

Feed Toxicity. Grain contamination with ergot by-products produced by *Claviceps purpurea* has been reported to cause lactation failure in sows (Penny 1970; Anderson and Werdin 1977). Ergot derivates are known to suppress prolactin release (Whitacre and Threlfall 1981; Bevers et al. 1983; Smith and Wagner 1985a), which could in turn inhibit mammary growth and lactation. Diagnosis is based on a history of grain changes and sudden appearance of a great number of affected sows with flaccid mammary glands and carpal erosions but normal rectal temperature. However this condition is rare.

TREATMENT

Every producer wants to maintain the health of the sows and prevent poor litter performance. Veterinarians are placed in a delicate situation when they are called upon to propose treatment for a poorly defined problem for which overtreatment is certainly leading to increased costs of production and unjustified medication overuse. A good strategy to reduce the consequences of PPDS should be based on three levels of intervention:

1. Defining a treatment for the truly diseased postpartum sows
2. Rapidly identifying the problem litters of sows without clinical manifestations and determining a treatment for those sows and piglets
3. Reducing the incidence of problem litters in the herd by addressing the risk factors

The Diseased Sow
The treatment of choice for the diseased sows is antibiotic and/or antiinflammatory treatment to help cure the disease. Moreover, sow treatment must also ensure adequate mammary gland function to sustain piglet growth. In the worst cases, the best strategy is to foster the piglets of the diseased sow to another healthy sow.

Systematic treatment of all sows after farrowing with an antibiotic and sometimes with nonsteroidal antiinflammatory drugs (NSAID) is a common practice in modern farrowing houses. Different strategies for the systematic administration of antibiotics were proposed:

1. Adding antibiotics to the feed from 7 days prepartum to 7 days postpartum, which could decrease piglet mortality by 43% (7.34% vs. 4.18%) and increase weaning weights by 8% (Tabjara et al. 1992)
2. Daily injections of antibiotics for the first 2 days postpartum (Rose et al. 1996)
3. In-feed medication and one injection of antibiotics on the day of parturition (Schoning and Plonait 1990)

Although all these strategies can be used when a whole herd is severely affected by PPDS, systematic treatment of all sows should be only short-term to avoid medication overuse.

Antibiotics. The selection of an antibiotic should be based on its spectrum of activity against bacterial organisms identified in postpartum diseased sows and thought to be related to PPDS. Unfortunately, identifying the most common bacterium related to the diseased sows is often difficult due to the diversity of the clinical signs.

Nonsteroidal Antiinflammatory Drug (NSAID). NSAID treatments seem to have a beneficial effect on health of affected sows. Treatment strategies usually consist of one

treatment on the day of parturition and sometimes a second treatment the next day. Drugs that have been proposed are: flunixin (2 mg/kg) (Cerne et al. 1984), tolfenamic acid (2–4 mg/kg) (Rose et al. 1996), meloxicam (0.4 mg/kg) (Hirsch et al. 2003; Hoy and Friton 2004).

Stimulating Milk Production

One of the objectives of the treatment strategy is to stimulate milk flow as rapidly as possible to minimize the consequence of PPDS. Repeated use of oxytocin is certainly the most frequent treatment administered to sows to stimulate milk production.

Oxytocin. Parenteral administration of synthetic oxytocin is a very efficient way to trigger milk ejection. The manufacturers' recommended dose for sows varies from 30 to 50 IU intramuscularly (Canadian Animal Health Institute 2001). In our experience, intramuscular injections of oxytocin do not always trigger the milk ejection process and more predictable results are obtained with intravenous injections of 10 IU. The variable response with intramuscular injections might be related to the product being deposited between muscles or in the fat pad and to the very short half-life of oxytocin. In fact, the short half-life (6–7 minutes) of oxytocin is the reason why it can be administered safely at hourly intervals for at least 6 hours (Knaggs 1967).

Although efficient and considered as safe, repeated use of oxytocin might have some detrimental effects on sows. Indeed, its use was reported to be related to poorer herd performance in some epidemiological studies (Bilkei Papp 1994; Ravel et al. 1996). Moreover, somatic cell counts in sow's milk were found to increase with oxytocin administration, and this was more apparent when oxytocin was injected intramuscularly than intravenously (Garst et al. 1999).

Prolactin Stimulators. Prolactin and prolactin-stimulators were suggested as methods to stimulate milk synthesis of sows affected with PPDS. Purified porcine prolactin is commercially available only in minute quantities. Therefore, most research on PPDS treatment with prolactin has focused on stimulating prolactin release. Administration of various phenothiazine and butyrophenone tranquilizers (e.g., chlorpromazine, acetylpromazine, haloperidol, and azaperone) significantly increases prolactin concentrations in various species; however, they have generally not been effective in stimulating prolactin release in the pig (Smith and Wagner 1985a). Thyroid-stimulating hormone was shown to be effective in increasing prolactin concentrations in swine but for such short duration (<45 minutes) that it is unlikely to be clinically useful (Smith and Wagner 1985a).

Vaccinations

Sow mammary glands initially infected with coliform bacteria do not appear to develop resistance to subsequent infections (Bertschinger and Buhlmann 1990), thereby suggesting that the development of a vaccine for the prevention of coliform mastitis is unlikely. On the other hand, vaccination against urinary tract infections at 4 and 2 weeks before parturition was reported to increase the overall lactation performance of sows (Pejsak et al. 1988).

Supportive Treatment for Piglets

Once problem litters are identified, the main objectives are to avoid piglet dehydration and provide an alternative source of energy. Observations suggest that piglets will drink appreciable amounts of tap water on the first day following birth, particularly if milk supply is limited (Fraser et al. 1988). Water intake is further increased when using a specially designed water dispenser with air bubbles (Phillips and Fraser 1991). It was speculated that under low milk intake conditions, water intake may help prevent dehydration and promote survival of the piglets. Low-birth-weight piglets suckling a sow affected with PPDS need to be transferred rapidly to another sow with good milking capacity. The lower milk production of affected sows will be less detrimental to piglets of heavy birth weight, and most of them may still reach acceptable weaning weights. Moreover, piglets can be efficiently raised with a combination of milk replacers and highly digestible adapted feed.

PREVENTION AND RISK FACTORS

One of the keys in reducing the incidence of problem litters in a herd is the identification and correction of specific risk factors. Factors related to mammary gland development, milk synthesis, and inadequate lactation homeorhesis are certainly crucial. However, because of the complexity of the underlying causes of PPDS, other specific risk factors associated with a high prevalence of problem litters have been described. These factors are not necessarily of an etiologic nature; however, the interplay between some of them will increase the incidence of PPDS. The identified risk factors are mainly related to sow body condition at farrowing, sow constipation, housing and environment.

Sow Body Condition

Maintaining optimal body condition of all sows in the herd is important to reduce the prevalence of PPDS. This is not always easy, because a small error in the amount of feed distributed over the whole gestation period can lead to overweight or underweight sows at the time of parturition (Martineau and Klopfenstein 1996). Sows maintained in pens have more variable body weights, the most aggressive often being overweight while submissive animals are underweight (Martineau 1990; Marchant 1997). Fat sows are also more likely to take longer to farrow (Bilkei 1992; Madec et al. 1992) and to have more stillborn piglets (Zaleski and Hacker 1993; Bilkei Papp 1994).

Sow Constipation

Postpartum constipation was observed in some sows nursing problem litters (Ringarp 1960; Hermansson et al. 1978b). Feeding high-fiber diets in late gestation was therefore proposed and has been widely used in order to decrease the incidence of early lactation problems (Ringarp 1960; Wallace et al. 1974). When fibers are simply added to a diet, the concentrations of the other components are decreased accordingly (Sandstedt et al. 1979; Jensen 1981; Sandstedt and Sjogren 1982; Goransson 1989a,b). As previously discussed, sow water availability is certainly a crucial factor to consider because insufficient water intake just before farrowing can certainly enhance postpartum constipation. Moreover, low postpartum water intake and low activity level of the sows were also proposed as risk factors for early lactation problems (Fraser and Phillips 1989).

Housing and Environment

Housing and general herd management can affect the prevalence of sows affected by PPDS. In one study, there were more litters with starving piglets in herds where the sows farrowed in confinement than when they farrowed on the pasture (Backstrom et al. 1982). Sows are exposed to many changes when they are moved from the gestating room to the farrowing room. Research results, however, do not suggest that these changes are harmful to sows. Indeed, allowing sows to adapt to the new environment for more than a week, rather than only a few days, before parturition was not associated with a lower prevalence of problem litters (Klopfenstein et al. 1995). Stray voltage in the farrowing unit was also suspected as a source of lactation problems (Gillepsie 1984); yet, recent research did not support this hypothesis (Robert et al. 1996). Regular washing of the farrowing unit was reported to be associated with lower preweaning mortality (Ravel et al. 1996).

Sow and piglet management around parturition, although difficult to assess, is known to be extremely important. Supervision and attendance at farrowing time is reported to decrease the number of stillborn piglets and preweaning mortality (Holyoake et al. 1995). Care must be taken to ensure that the sow and piglets are able to drink from the watering system in the farrowing room. Attention must be given to the quality of the environment. Slippery floors are one of the main causes of low activity of lactating sows and may lead to many health problems, including PPDS, and to reduced feed and water intakes. On the other hand, more interventions at farrowing are not always a good practice. Indeed, obstetric aid by either herd managers or veterinarians results in a fourfold increase in the sow's risk of acquiring early lactation problems (Jorsal 1986) and increases the incidence of postfarrowing vulvar discharges and endometritis (Bara and Cameron 1996).

Temperature control in the farrowing room is certainly a crucial factor affecting sow lactation perform-ances (see heat stress). It is essential to provide a localized warm environment for newborn piglets but the temperature requirement of the sow must also be taken into consideration since her zone of thermoneutrality is much lower than that of piglets. In modern swine units, where farrowings are managed as all-in/all-out on a room basis, it is much easier to adjust the temperature according to the physiological state of the sow and her piglets. We generally recommend that room temperature be maintained warm (20–22°C) for the 2–3 days after farrowing to favor piglet survival. However, after this crucial period, room temperature can be gradually decreased to attain 18°C or even 15°C on day 10 of lactation (Farmer et al. 1998). Indeed, when an adequate draft-free heat zone is provided for the piglets, the ambient temperature can be decreased to 15°C on day 8 of lactation with no detrimental effects on sow and litter performances. It is important that the extra heat provided is directed away from the sow and her udder and that it be rapidly removed, when not needed, to favor the sow's well-being and maximize her milk production. One must also keep in mind that position of the heat lamps has an impact on the spatial behavior of neonatal pigs (Titterington and Fraser 1975).

Others

Feeding Strategy. It was hypothesized that a reduced feed consumption in first days of lactation decreases the incidence of lactation failure. However, gradually increasing feed consumption of sows in the first week postpartum instead of feeding ad libitum within 16 hours of farrowing also showed no advantage for litter performance or occurrences of lactation failure (Moser et al. 1987).

Prostaglandins on the Farrowing Day. Prostaglandins are luteolytic agents causing a prepartum decline in progesterone and the release of relaxin from the corpora lutea. They are widely used for the induction of farrowing (Ehnvall et al. 1977), resulting in an immediate and sharp increase in prolactin concentrations lasting approximately 6 hours (Hansen 1979). In some herds with a significant percentage of gilts and sows showing PPDS, induction of parturition with the F series of prostaglandins has proven effective in reducing the incidence of PPDS (Cerne and Jochle 1981; Holtz et al. 1983), whereas it had no effect in other herds (Ehnvall et al. 1977; Hansen 1979). Prostaglandins could be effective in treating PPDS caused by retarded lactogenesis since incomplete luteolysis of corpora lutea can lead to high progesterone concentrations, which inhibit lactogenesis. Moreover, postpartum administration of prostaglandins can have a beneficial effect on uterine involution and prevention of severe clinical endometritis (Waldmann and Heide 1996).

Vitamin E. Some research has suggested a relationship between diets deficient in selenium and vitamin E, and

sow lactational problems (Trapp et al. 1970; Whitehair and Miller 1986). The exact mode of action has not been established, but these microelements may give some protection against endotoxins because they both play a role in the maintenance of cellular integrity and in leukocyte function (Elmore and Martin 1986). On the other hand, primary deficiencies are uncommon since vitamin E and selenium are generally supplemented in feed. In fact, increasing dietary levels of vitamin E from 30 to 60 IU did not decrease the prevalence of MMA diagnosed subjectively at parturition based on udder hardness and vulvar discharge (Mahan et al. 2000). In another study, injections of vitamin E (400 IU) and selenium (3 mg) to sows three times during gestation, while they were fed normal levels of these nutrients, increased the survival rate of piglets but did not affect litter weights at weaning (Chavez and Patton 1986).

5 Diseases of the Nervous and Locomotor Systems

Catherine E. Dewey

Clinical signs of lameness and neurological problems are common in swine herds. Lameness is the second most important cause of culling in breeding-stock animals and hence results in lost opportunity in reproductive performance. Preweaning and postweaning polyserositis and meningitis cause decreases in production. Although cases of nutritional deficiencies and poisonings are rare, they are nonetheless extremely important to diagnose. To diagnose a lameness or neurological problem, begin with a thorough herd evaluation followed by clinical examinations of individual animals. Determine whether the clinical signs are primarily due to the musculoskeletal system or the neurological system to narrow the list of differentials and to focus the clinical examination.

LOCOMOTOR PROBLEMS

Clinical Approach to a Lameness Problem in a Herd

The objectives of the herd examination for a lameness problem include determining the age group(s) affected, the most prominent clinical signs, and the onset and prevalence of the clinical signs. It is essential to examine the affected animals as well as their environment.

To evaluate lameness in the breeding herd, begin by examining the sows in farrowing crates and gestation stalls while they are prone. Record the number of sows that have hoof cracks, hoof wall damage, sole lesions, foot rot, long lateral toes, dewclaw damage, and soft-tissue damage. Most sows will remain prone if you handle their feet gently. Next, encourage all sows to stand. Note the number of sows with clinical lameness, the severity of the lameness, whether the clinical signs involve one or more than one leg, if it is predominantly a forelimb or hindlimb lameness, and the parity and stage of gestation of the sows affected. Palpate joints and soft tissue of the clinically affected legs and lift the leg to examine the foot to determine the primary source of the lameness. Take the sows out of the crates to observe their gait. Describe the severity of the lameness using the following terms: stiffness, weight bearing, resting the leg on the ground or carrying the leg while standing still, weight bearing or carrying the leg during ambulation, and ability to stand and walk without assistance.

Once the stalled animals are observed, examine the sows housed in pens. Note whether the lameness is associated with a specific housing type. Examine the feet of the sows that are lying down, watch the sows move about, and determine the prevalence and severity of the lameness in this group of animals. Specifically look for reluctance to move, degree of difficulty in standing, stiffness, stance with legs under the body, and weight bearing on all limbs.

Depending on the extent of the problem, you may wish to cull a representative group of sows to conduct a complete examination of all joints, feet, and vertebral column. Examine all putative causes of the lameness such as nutrition; relocation of the sows during gestation; and housing conditions, especially floors, including solid versus slatted, slipperiness, roughness, and wetness.

For growing animals, determine the range in severity of clinical signs and whether one or more legs are involved per animal. Examine animals that are acutely and chronically affected, observe their movement, palpate the joints and then each leg looking for heat, swelling, and response to pain. Examine all age groups of animals on the farm, not just those with the most severe signs. The causative factors may be in the environment of younger animals. If the producer has treated pigs, discuss the response to treatment. Finally, select a representative sample of nontreated pigs for a postmortem examination.

Preweaning Pigs

The most common conditions affecting the locomotor system of preweaning pigs will be covered in this section; others can be found in Table 5.1.

Table 5.1.   Lameness in preweaned pigs.

Cause	Clinical Signs	Epidemiology	Pathology
Abrasions of carpi and hooves	Lameness and swollen joints due to abraded skin at carpi and coronary band, and abraded horn at toe	Common, trauma to skin from concrete floors during suckling	Abraded skin
Actinobacillus suis	Listlessness, dyspnea, lameness develops later; pigs may be found dead	Acute septicemia	Petechia on kidneys, pleural effusion, pleuritis, pneumonia, purulent arthritis, omphalophlebitis
Arthritis	Reluctant to stand or move, lameness, one or more joints hot and painful, skin abrasions, poor growth	Widespread, common, sporadic with occasional outbreaks	Synovitis with excessive normal-to-purulent fluid
Hyperostosis	Distal legs thick, firm, red, taut skin; stilted gait; fatal	Rare, widespread, sporadic, inherited	Subcutaneous edema, fibrous tissue, and thickened leg bones

Splayleg.   Splayleg is a congenital abnormality causing paresis in newborn pigs. This problem of hindlimb adduction affects approximately 0.4% of live births (Ward 1978). The annual rate in pigs born to German Landrace boars between 1982 and 2000 ranged from 0.26% to 0.69% but did not decrease over time due to selection (Beissner et al. 2003). An examination of 47,323 litters born to German Landrace boars from artificial insemination units showed that the frequency of splayleg was not reduced by selection over a 14-year period (Beissner et al. 2003). The problem is widespread, common, and typically affects only 1–4 pigs per litter and just a few litters at a time. Usually individual herd prevalence is less than 1%; however, sporadic increases occur when the prevalence reaches 8% or higher (Ward and Bradley 1980).

The condition has been associated with low birth weight, slippery floors, *Fusarium* toxicity, choline or methionine deficiency in sow diets, Large White and Landrace pigs, and short gestation lengths (Ward 1978). Farrowing induction may result in a higher prevalence of splayleg especially if producers do not first determine the normal gestation length in their herd. Some studies have suggested that one cause of splayleg was a deficiency in the sow's diet of choline and methionine which are essential for normal myelin production (Cunha 1968; Kornegay and Meacham 1973). The study by Cunha (1968) did not mention the use of controls. However, others have refuted this suggestion (Dobson 1971). In clinical trials on two farms, Dobson (1971) showed that adding 3 g choline and 5 g methionine to the sows' daily ration had no effect on the occurrence of splayleg.

Although some researchers describe muscle hypoplasia as the cause of the clinical signs, myofibrillar hypoplasia is normal in all newborn pigs. At one day of age, myofibrils do not fill the muscle cells completely in splayleg or in normal pigs (Ward and Bradley 1980). Also, the vasculature, nervous supply, neuromuscular bundles, and the myelination of the intramuscular nerves are the same between healthy and affected pigs.

Clinically 3-day-old pigs show improved movement and the myofibrils increase in size, reducing the extra-myofibrillar space. By 6 days of age, the splaylegged pigs do not differ from normal pigs clinically or in the histology of the muscles. In all pigs, myofibrils and nuclei continue to increase in size.

Splayleg is caused by a reduction in the axonal diameter and myelin sheath thickness of the fibers that innervate the hindlimb adductors (Szalay et al. 2001). The pathways from the upper to the lower motor neurons, specifically the lumbar spinal motor neurons are impaired. In affected pigs, nerves at the level of L6 regions near the surface of the spinal cord are somewhat myelinated, whereas deeper areas are unmyelinated. This is particularly obvious in the ventral and lateral funiculi. These areas are responsible for innervation of the hindlimb. Myelination is required for normal impulses to be conducted along nerve fibers. The oligodendroglia form the myelin sheath as the final step in the formation and maturation of the neural pathways. Typically, the lumbar region is myelinated earlier than more rostral sections. It is not known why this problem with myelination occurs in these splaylegged pigs.

Myelin is produced by the fetus' oligodendrocytes. This production appears to occur in two phases. The first peak occurs 2 weeks prior to birth and the second 3 weeks after birth. If pigs live past the first couple of weeks, the myelin sheath is properly developed during this second phase.

Clinically pigs show extreme abduction of the limbs with an inability to stand. Splayleg affects the hindlimb adductors and in severe cases, the forelegs are also involved (Szalay et al. 2001). Clinically signs are similar in the high prevalence periods. Typically half of the affected pigs die due to starvation and overlying, because the pigs have a hard time reaching the udder, retaining hold of the nipple, competing with their littermates and moving out of the sow's lying space. Affected pigs can be kept alive if they are fed artificially, provided with supplemental colostrum and heat, assisted to nurse, cross-

fostered to reduce competition, and have their limbs taped in a natural standing pose. Pigs that live past the first week of life will recover completely.

Polyarthritis. Polyarthritis is a common problem in preweaned pigs and affects approximately 18% of litters and 3.3% of pigs after 4 days of age (Nielsen et al. 1975). Mortality due to polyarthritis is about 1.4% and is highest in the winter. Most affected pigs will die by 3 weeks of age, but 32% of the pigs do not die until 4–5 weeks of age. There is a lower incidence of polyarthritis in female pigs and in pigs from multiparous sows, small litters, closed herds, and herds that do not have their pigs' teeth clipped or tails docked (Nielsen et al. 1975; Smith and Mitchell 1976). Pigs with polyarthritis are more likely to have necrotizing gingivitis than healthy pigs. Different instruments should be used for the teeth and the tails at processing. Instruments should be disinfected between piglets, and the tail and navel sprayed with a disinfectant (Nielsen et al. 1975).

Haemolytic streptococci cause 65% of the cases but staphylococci and *Escherichia coli* are also frequent causes (Nielsen et al. 1975; Smith and Mitchell 1976). The joint lesions include increased synovial fluid, hyperemia of synovial membranes, fibrinous periarthritis, and joint swelling due to exudate and abscesses. The carpal, elbow, hock, and hip joints are most frequently affected. Often the meninges and brain are congested, and there is turbid cerebrospinal fluid, concurrent pneumonia, endocarditis, and gingivitis (Nielsen et al. 1975). The pathogenesis involves the individual pig's ability to eliminate pyogenic organisms before they multiply in the joints (Nielsen et al. 1975). Early treatment with antibiotics will reduce the duration of illness and mortality. Pigs need to be examined carefully for signs of lameness, particularly at 10 and 18 days of age (Nielsen et al. 1975).

Skin Abrasions. Skin abrasions occurring bilaterally on hindlegs and forelegs are evident within a few hours of birth. Rough floor surfaces increase the chance of skin abrasions and therefore the opportunity for the invasion of microorganisms. Although 98% of 3-day-old pigs have skin abrasions, only 11% of pigs are severely affected and most lesions heal within 2–3 weeks of life (Svendsen et al. 1979; Furniss et al. 1986). The incidence of skin abrasions is highest on old cement floors, intermediate on punch metal and new cement floors, and lowest on plastic-coated woven wire. The incidence increases if the size and shape of the slot is large compared to the piglet's foot size and in litters suckling sows with hypogalactia (Smith and Mitchell 1976). The slot width in farrowing crate floors should not exceed 10 mm.

Postweaning Lameness
Infectious Arthritis. Infectious arthritis causes slaughter condemnations equivalent to 2 whole carcasses and 49.6 partial carcasses per 10,000 pigs slaughtered (Evans and Pratt 1978). Pigs condemned due to arthritis are more likely to have erysipelas or pneumonia than pigs not condemned (Evans and Pratt 1978).

Erysipelothrix rhusiopathiae. *Erysipelothrix rhusiopathiae* affects nursery to adult pigs. It is a widespread but uncommon disease affecting up to 75% of pigs in a pen, with 10% mortality (Buddle 1987). Chronic erysipelas results in a progressively increasing lameness and weight loss over 2–3 weeks, with palpably normal joints. It causes a rheumatoid-like proliferative arthritis in the joints of the long bones, spondylitis, and spondylarthritis. The polyarthritis develops in four stages: hypertrophic villous synovitis, pannus formation and articular surface degeneration, fibrous ankylosis, and bony ankylosis. The disease may stop at one of these stages and the animal will undergo remission; otherwise the disease becomes chronic and the animal becomes unthrifty.

Clinically, the animals shift their weight from leg to leg and may have periods of remission. Early in the disease the joints are swollen, warm, and slightly painful, but in the later stages, joints become firm and nodular, with palpable periarticular enlargements and restricted joint movement (Vaughan 1969). Pigs with erysipelas prefer to lie down and have a stilted gait and poor growth rate (Grabell et al. 1962). Animals support themselves on the tips of their digits and have flexed carpi; hocks are together and feet are under the body, with the back arched. There is no palpable fluid or purulent matter in the joints.

There is moderate improvement after treatment with penicillin. Although it is difficult to isolate *E. rhusiopathiae* from chronic cases, it can be isolated from 65% of lame grower-finisher pigs and it causes large abattoir losses due to polyarthritis.

Mycoplasma hyosynoviae. *Mycoplasma hyosynoviae* is relatively rare and affects up to 10% of the animals, although in some herds 50% of the animals are involved (Buddle 1987). Clinically 3- to 6-month-old pigs experience a sudden onset of lameness over 3–10 days. The organism lives in the respiratory tract and is spread via inhalation (Burch 1986). *Mycoplasma hyosynoviae* causes severe lameness with minimal swelling of stifle, shoulder, elbow, and tarsus joints. Pigs show a shifting lameness, stiff or staggering gait, kneeling, or dog-sitting. Approximately 10–20% will become chronic and progress to recumbency. Pathologic features include fibrinous arthritis, edematous, hyperemic, hypertrophied synovial membrane, and serosanguineous synovial fluid. Treatment with either tiamulin or lincomycin at 10 mg/kg daily for 3 days reduces lameness and improves daily gain (Burch and Goodwin 1984).

Polyserositis. Polyserositis occurs most commonly in 4- to 12-week-old pigs, and more frequently in autumn

and winter than in spring and summer (Miniats et al. 1986). *Haemophilus parasuis* is isolated most frequently (36%), followed by *M. hyorhinis* (18%) and then *Streptococcus suis* and *Pasteurella multocida*. These pigs experience peracute death or lameness, inability to rise, swollen joints, and respiratory distress.

Mycoplasma hyorhinis. *Mycoplasma hyorhinis* typically affects pigs at 7 weeks of age and is associated with the decline of passive immunity (Ross and Spear 1973). This is a widespread disease but uncommon and sporadic and results in low morbidity (5–15%) and mortality (<10%) (Buddle 1987). Clinically affected animals carry affected legs because of acute, severe pain. Several joints are moderately hot and swollen, especially carpus, shoulder, tarsus, and stifle (Buddle 1987). There is also polyserositis, causing abdominal breathing and reluctance to move. Occasionally the lesions will spontaneously resolve but more typically pigs experience chronic ill thrift. The gross postmortem lesions include distension of the joint capsule, hyperemia, edema, and fibrin deposits of the synovial membrane (Roberts et al. 1963). The chronic lesions include hyperemia, hypertrophy and yellow discoloration of the synovial membrane, and bone atrophy. The tonsils and mucous membranes of the respiratory tract of sows provide the reservoir for *M. hyorhinis* (Ross and Spear 1973). Typically the organism is introduced with new breeding stock. A synergistic effect of other conditions, such as concurrent *E. coli* infections or poor management, is required to initiate clinical signs (Frus and Feenstra 1994).

***Haemophilus parasuis* (Glasser's Disease).** *Haemophilus parasuis* (Glasser's disease) causes a severe peracute and acute lameness, depression, fever, dyspnea, hot swollen joints, reluctance to stand or move, tremor, paralysis, and sudden death (Nielsen and Danielsen 1975; Smart et al. 1986; Hoefling 1994). Pigs recovering from the acute phase may have chronic arthritis. Experimentally infected pigs will be reluctant to move 36 hours post infection. By 60 hours, they have swollen joints and exhibit lateral recumbence (Vahle et al. 1997).

Haemophilus parasuis is a commensal organism living in the upper respiratory tract of pigs. It can be isolated from the nasal and oral cavities and trachea (Oliveira and Pijoan 2004). *H. parasuis* can cause acute suppurative rhinitis with loss of cilia in the nasal and tracheal mucosa (Vahle et al. 1997). This may be the portal of entry. When *H. parasuis* causes acute septicemia and sudden death, this is due to disseminated intravascular coagulation in response to the bacteria's endotoxin.

The disease is widespread and relatively common. Outbreaks occur due to regrouping pigs, at 1–2 weeks postweaning, and when naive breeding stock are moved to an endemically infected herd.

The prevalence of clinical disease due to *H. parasuis*

in nursery pigs appears to have increased since the 1980s. The change may be due to either the use of off-site early weaning facilities, porcine reproductive and respiratory syndrome virus (PRRSV), or porcine circovirus type 2 (PCV2). Maternal immunity wanes at 6 to 8 weeks of life. Most pigs have not been colonized by the *H. parasuis* bacteria before they are weaned. As maternal immunity wanes, the whole population of nursery pigs is susceptible to infection, which enables outbreaks in these nursery barns (Oliveira et al. 2001). In nurseries affected with PRRSV, pigs often exhibit polyarthritis as well as clinical signs involving other organ systems. In these herds, lameness can affect as many as 80% of the pigs and typically is the result of multiple etiologies, including *H. parasuis*, *S. suis*, *M. hyorhinis*, and *E. rhusiopathiae* (Kern 1994).

If pigs are infected with PRRSV a week before the *H. parasuis* infection, the alveolar macrophages have a marked decrease in their ability to kill the bacteria (Solano et al. 1998). In vitro research conducted by the same laboratory found different results (Segales et al. 1998). One-third of the pigs affected by postweaning multisystemic wasting syndrome in Korea were dually infected by porcine circovirus type 2 and *H. parasuis* (Kim et al. 2002).

Clinical *H. parasuis* is diagnosed by clinical signs; presence of lesions such as fibrinopurulent exudates in the peritoneal, pericardial, and pleural cavities; meningitis; arthritis; and bacterial culture of the organism (Vahle et al. 1997). The bacteria are fastidious and therefore, PCR assays may be used to improve the sensitivity of identifying the bacteria in clinical cases (Oliveira et al. 2003). However, the positive PCR test must be followed by culture for further characterization prior to implementing a control program.

Conventional pig farms typically have multiple strains of *H. parasuis* (Smart et al. 1988). The strains isolated from nasal swabs are often not the same strains isolated from systemically infected pigs from the same farm (Smart et al. 1993). A new indirect hemagglutination test used on 300 isolates from North American submissions to diagnostic laboratories showed that serovars 4, 5, 7, and 13 were the most prevalent (Tadjine et al. 2004). Oliveira et al. (2003) found serovar 4 and nontypable isolates to be the most prevalent in U.S. herds.

If treated early, affected pigs will respond to systemically administered penicillin (Desrosiers et al. 1986). Both commercially available and autogenous vaccines have been used prior to the introduction of breeding stock to reduce incidence of clinical signs (Smart et al. 1986, 1993; Miniats and Smart 1988).

Often *H. parasuis* problems in nursery and grower pigs can be controlled by the use of commercial or autogenous vaccines. However, consistent control of *H. parasuis* has been difficult because of the serovar diversity and the lack of cross protection between strains (Oliveira and Pijoan 2004).

Table 5.2. Lameness in postweaned pigs and adults.

Disease	Clinical Signs	Epidemiology	Pathology
Apophysiolysis	Gradual onset, hind feet slide forward, difficulty in standing, arched back, dog-sitting; progresses to lateral recumbency, crepitation of ischial tuberosity	May be end stage of leg weakness syndrome or may occur independently	Separation of ischial tuba
Asymmetrical hindquarter syndrome	Reduced muscle mass in hip or thigh; normal gait	Rare	Reduced muscle mass in hip or thigh
Back-muscle necrosis	Occurs in 5- to 12-month-old pigs; difficult movement due to swollen, hot, uni- or bilateral lesion of back; chronic muscle atrophy	Rare, sporadic, sudden onset; part of porcine stress syndrome	Pale, soft, exudative necrosis and hemorrhage of back muscles
Epiphysiolysis capitis femoris	Sudden onset of severe lameness in one or both hindlegs; reluctance or inability to stand, dog-sitting, squealing, crepitation and pain over hip, muscle wasting	Part of leg weakness syndrome, often seen in newly weaned gilts	Separation of femoral head at epiphyseal plate
Foot-and-mouth disease	Reluctance to stand or move; depression; fever; small vesicles on snout, coronary band, and teats and between claws; vesicle ruptures leaving hemorrhagic, granular, eroded surfaces; underrunning of hoof horn	Reportable disease; all ages, rapid spread, high morbidity, 5% mortality	Acute deaths in piglets, irregular grayish foci on myocardium
Mastitis, metritis, agalactia	Lameness, heat, front feet painful, digital pulse in fetlock region, stiff gait, reluctance to move	Widespread, common, sporadic, lameness uncommon	Laminitis
Melioidosis	Usually subclinical; occasionally acute septicemia, anorexia, nasal discharge, cough, posterior paresis, death	Zoonotic disease; uncommon, sporadic	Multiple abscesses with caseous, green, purulent matter in subcutis, lymph nodes, lung, spleen, and liver
Osteodystrophia fibrosa	Signs range from mild, shifting lameness to inability to stand; shortened, curved long bones, enlarged joints and facial bones	Absolute or relative calcium deficiency, morbidity up to 100%; secondary hyperthyroidism in grain-fed pigs due to high phosphorus and low calcium	Distorted bones; bone and marrow replaced with fibrous tissue
Trauma	Slight to severe lameness due to sprains and bruising; hoof cracks and cuts	Widespread, common, affects all ages	Referable to clinical signs

Lameness in Growing Pigs and Breeding Animals

The differential diagnosis of lameness in growing and breeding animals includes mainly foot rot, leg injuries, epiphysiolysis, apophysiolysis, osteochondrosis, arthrosis, osteomalacia, fractures, and arthritis (Penny 1979; Wells 1984) (Table 5.2). Leg weakness is a term used to describe lameness due to osteochondrosis, arthrosis, epiphysiolysis, and apophysiolysis. In several studies, osteochondrosis, which is a generalized dyschondroplasia, was found to be the most common cause of lameness in breeding-age animals (Grondalen 1974a; Reiland 1975; Hill et al. 1984; Dewey et al. 1993). The second most important cause of lameness was foot lesions, either foot rot, overgrown claws, or torn dewclaws (Dewey et al. 1993). However, outbreaks of foot problems occur

in breeding herds, where up to 100% of the sows are affected (Penny 1979).

Culling Due to Lameness. Lameness is the second most common cause of culling in breeding animals, representing 10–20% of all culled sows (Walker et al. 1966; Reiland 1975; Dagorn and Aumaitre 1978; Karlberg 1979; Friendship et al. 1986; Dewey et al. 1992). In a comparative study of Landrace sows, lameness caused the culling of 20.5% of the low-backfat line, but only 13.8% of the high-backfat line (Grondalen and Vangen 1974). Between 30% and 40% of boars at performance stations and approximately 24% of boars at artificial insemination units are culled for leg weakness; 75% of the latter are less than 18 months of age (Grondalen 1974g; Reiland 1975). Sow herds in France with a lameness prevalence of

at least 15% had higher mortality rates than herds with less lameness (Abiven et al. 1998). Lameness is frequently a cause of euthanasia in sows (D'Allaire et al. 1987). In one study, locomotor problems caused 9% of the culling and 28% of sow deaths (D'Allaire et al. 1987). Reiland (1975) examined 230 boars and sows culled for lameness and found few cases of foot rot and concluded that hoof lesions were of secondary importance in leg problems.

The culling rate due to lameness in sows varies from farm to farm, suggesting that leg weakness is a major problem on certain farms. In a survey of Ontario farms, it ranged from 0–38%, with an average of 11%, and was associated with a high culling rate for sows and high proportions of gilts to sows in the breeding herd (Dewey et al. 1992). The culling rate due to lameness in start-up herds (26% ± 13%) was higher than in established herds (8% ± 6%) (Dewey et al. 1992). Herds that are repopulating have a larger proportion of young breeding-age animals and a higher level of culling for lameness.

The housing factors associated with high levels of culling due to lameness were slatted floors for finisher pigs or sows, the use of individual sow stalls, and a high density of pigs in the finishing area. These findings suggest that a change of housing design may result in reducing the culling rate due to lameness and that attention to the way young replacement stock is housed and handled may be very important with respect to subsequent longevity and soundness. Floor type and quality, the size of the space between the slats, the width of the slat, the flooring material, and the type of ground for outdoor housed pigs all impact the prevalence and cause of lameness in pigs. Housing pigs indoors on concrete is associated with lameness in pigs (Barnett et al. 2001). Farms that have both stalls and pens for sow housing had a lower culling rate due to lameness than farms that had only pens (Paterson et al. 1997 cited by Barnett et al. 2001). However, muddy conditions and stones in the paddock cause lameness in pigs housed outdoors (Barnett et al. 2001). Sows housed in pens for a portion of gestation are expected to have reduced farrowing time (Ferket and Hacker 1985), reduced lameness in gilts (Hale et al. 1984), and less joint damage (Fredeen and Sather 1978).

Many sows culled for lameness have more than one problem causing the clinical signs. The primary cause of lameness is likely associated with genetics, predominant feed ingredients, housing type (specifically, intensive versus extensive), floor type, and drainage. Associations between the culling rate due to lameness in sows and various housing factors involving finisher pigs indicate that the environment of the young growing animal may have an effect on the skeletal system that becomes apparent only later in life. This would suggest that managers of herds with higher than acceptable levels of lameness in the sow herd should examine the flooring and housing systems used for the young replacement animals in addition to the sows' environment.

Infectious Arthritis. Infectious arthritis is generally of minor importance as a cause of sow culling and affects 2.5% of culled boars (Grondalen 1974b, e; Grondalen and Vangen 1974; Nakano et al. 1979a). In Reiland's (1975) study of animals culled for lameness, the clinical signs were due to infectious arthritis in 18% of the sows that were less than 18 months of age and in 64% of the sows that were older than 18 months. Most of these animals had spondylitis, osteomyelitis, and/or arthritis of the hock joint which were caused by *E. rhusiopathiae*, streptococci, or *Arcanobacterium pyogenes*. The chronic proliferative arthritis and discospondylitis of the vertebral column were secondary to lesions of osteochondrosis.

If osteotropic bacteria such as streptococci or *Arcanobacterium pyogenes* affect joints with a fracture or epiphysiolysis, the primary lesion cannot be determined (Reiland 1975). In suppurative infectious arthritis, if the bacteria enter the joint by direct penetration, only one joint is involved, but if the bacteria are spread from a septic focus—such as infected hoof lesions, fight wounds, skin abrasions, or uterine infections—polyarthritis ensues. The clinical signs of arthritis are heat, swelling, pain of the affected joint, refusal to bear weight on the leg, pyrexia, and anorexia (Hill et al. 1986).

Osteochondrosis. Osteochondrosis is a noninfectious, degenerative, generalized condition of cartilage. It is manifested as an abnormal differentiation of both physeal and epiphyseal cartilage with secondary bony changes (Reiland 1975; Hill et al. 1985; Palmer 1985). Osteochondrosis is the major cause of leg weakness in growing boars and sows (Grondalen 1974c, i, 1981; Reiland 1975; Nakano et al. 1979a; Palmer 1985). The incidence and severity of lesions due to osteochondrosis increase from 10 to 20 weeks of age or from 60 to 120 kg liveweight (Nakano et al. 1981b; Aherne and Brennan 1985). In animals 4–18 months of age, osteochondrosis affects the weight-bearing joints (Hill et al. 1985).

Predilection Sites. Lesions of osteochondrosis are generally found in several joints in the affected animal. The medial part of the joint is most severely affected (Grondalen 1974a; Reiland 1975; Nakano et al. 1981b). Osteochondrosis can be located in the following areas, listed in descending order of severity of lesions (Reiland 1975; Palmer 1985):

1. Articular-epiphyseal lesions: stifle, elbow, lumbar synovial intervertebral joints, hock, shoulder, and hip
2. Growth plate lesions: distal ulna, distal femur, costochondral junction, femoral head, humeral head, ischiatic tuberosity, and thoracolumbar vertebrae
3. Epiphysiolysis and apophysiolysis lesions: glenoid cavity, ischiatic tuberosity, capital femoral epiphysis, vertebral epiphyses, anconeal process, and distal ulnar epiphysis

Pathogenesis. Osteochondrosis occurs when the mechanism of endochondral bone formation is disturbed in various predilection sites, but its pathogenesis is not clear (Grondalen 1974a; Reiland 1975). It is uncertain which tissue component is abnormal and initiates the onset of the lesions: the chondrocytes, the cartilage matrix, or the blood vessels (Hill 1990). The matrix of cartilage is mainly composed of collagen fibers, water, and proteoglycans, which are protein-glycosamino-glycan (GAG) complexes that exist in free form or in aggregates bound by hyaluronic acid. Failure of endochondral ossification is associated with cell necrosis and reduced amounts of proteoglycans and collagen in the tissue. Osteochondritis dissecans and superficial fractures of the cartilage are associated with clusters of chondrocytes and a less than normal concentration of proteoglycans (Nakano et al. 1979a). More than 98% of the total GAG content of the pig's distal femoral articular cartilage is chondroitin sulfate, and its concentration decreases with increasing age from 3 days to 30 weeks (Nakano et al. 1979b). In normal animals, in the force-bearing areas of the stifle joint, the articular cartilage is thickened and contains more chondroitin sulfate and less collagen than in the non–force-bearing areas, indicating that chondroitin sulfate is used for shock absorption (Nakano et al. 1979a). As the pig grows, the joint cartilage does not mature properly, which leaves the joint surfaces prone to damage from mechanical stress.

Local overloading in the joint is a factor in the pathogenesis of osteochondrosis (Grondalen 1974b, e, i; Nakano et al. 1979a, 1981b; Reiland and Anderson 1979). The lesions may be due to a disturbance of the metaphyseal blood flow caused by a local overloading of one part of the joint (Grondalen 1974d). The mechanical stress in heavy pigs on immature cartilage causes a circulatory disturbance at the osteochondral junction, which contributes to the lesions of dyschondroplasia (Walker et al. 1966; Nakano et al. 1981b). Epiphysiolysis of the femoral head, fractures of bone trabeculae, and worn humeral head cartilage in boars may be due to overloading caused by functionally weak muscles, ligaments, cartilage, or bone or by poor conformation (Grondalen 1974b, f, i; Grondalen and Vangen 1974). This stress causes the joint cartilage to be torn or eroded, leaving exposed bone.

The growth plates that close last are most susceptible to osteochondrosis. Growth plate defects occur when the plate is displaced along the plane of the eosinophilic streaks and then bone unites the epiphysis to the metaphysis, functionally closing the plate (Palmer 1985). Premature closure of the proximal femoral growth plate will lead to a short femoral head and reduced lengthwise growth of the femur, which may cause excessive wear of the acetabular cartilage, subluxation of the femoral head, rupture of the teres ligament, or epiphysiolysis of the femoral head (Grondalen 1974a, b). Osteochondritis dissecans develops when a fissure in the subarticular cartilage extends to the articular surface, creating a flap of cartilage (Palmer 1985).

Growth Rate and Backfat. The modern domestic pig is the product of genetic selection for rapid growth, low feed consumption, long carcass length, low backfat, and high carcass yield of lean meat (Reiland 1975). Bone growth and closure of growth plates occur with age rather than with the weight of the pig or the energy content of the diet (Grondalen 1974e). Pigs reach sexual maturity at 5–6 months of age but do not have a mature skeleton until 18 months of age. Adolescence, the time period between 6 and 18 months, is when the clinical signs of osteochondrosis are seen in the pig. The prevalence of osteochondrosis is related to the pig's rate of gain and backfat thickness, which in turn are functions of both genetics and management practices (Grondalen 1974i; Reiland 1975). Rapid weight gain may increase the mechanical stress on the weight-bearing regions of immature cartilage (Aherne and Brennan 1985). If the growth rate of pigs is slowed by feeding only 50–60% of the feed recommended for their weight range, the clinical signs and the severity of the lesions of osteochondrosis are decreased (Grondalen 1974g; Reiland 1975; Nakano et al. 1979a). There is no evidence that osteochondrosis is related to nutritional excesses or deficiencies. The incidence of osteochondrosis increases with the age and the liveweight of the pig.

Genetics, Breed, and Conformation. Heredity plays a significant role in the leg weakness complex partly due to the inheritance of poor conformational features (Grondalen 1974h, i). Osteochondrotic lesions are correlated with desirable production variables (Grondalen 1974e; Reiland et al. 1978; Webb et al. 1983). The conformation of the pig's body, feet, and legs affects the incidence of osteochondrosis (Aherne and Brennan 1985). Exterior conformation traits that are associated with an increased incidence of osteochondrosis and poor locomotion are long back, narrow lumbar region, broad hams, short hindlegs, cross-legged forelegs, sloping pasterns of the forelegs, and small medial hooves on the hindlegs (Grondalen 1974a, f, g). Choosing replacement stock without these exterior conformation traits may significantly reduce culling due to leg weakness (Grondalen 1974g).

Compression, Overloading, and Physical Stress. Physical stress plays a part in the etiology of osteochondrosis, arthrosis, intervertebral disk degeneration, spondylosis, and epiphysiolysis (Grondalen 1974i; Nakano et al. 1979a). Mechanical stress on the joints leading to lesions of osteochondrosis can be caused by local overloading of cartilage or bone tissue, rapid growth rate or weight gain, poor joint stability, or weak cartilage and bone tissue (Grondalen 1974i). Joint stability is a function of musculature, ligaments, and joint shape.

Clinical Signs. Clinical osteochondrosis is a chronic, progressive, shifting lameness affecting one or more limbs in pigs from 4 to 18 months of age (Reiland 1975; Hill 1990). Affected animals will prefer to spend time lying down, will not bear weight on the affected leg(s), and will favor different legs at different times. By 18 months, the incidence of clinical osteochondrosis decreases, because either the animals have been culled or their lesions have healed (Reiland 1975). The articular cartilage is devoid of nerves, but pain is caused by an increased production of joint fluid and swelling of the joint capsule that occur secondary to the lesions of osteochondrosis (Reiland 1975; Aherne and Brennan 1985).

Animals with severe osteochondrosis or arthrosis of the elbow are often clinically sound unless the lesion is a displaced anconeal process (Grondalen 1974b; Nakano et al. 1982). Osteochondrosis of the stifle causes a severe lameness and is seen in animals less than 1 year of age (Grondalen 1974b). Young sows with a separation of the tuber ischii dog-sit with their hindlegs directed forward, and if forced to rise, they stand for only a short time (Hill et al. 1986). Severe arthrosis of the hock joint, mild arthrosis of the medial condyle of the femur, and repaired lesions of separated tuber ischii all cause little discomfort in sows (Grondalen 1974b). Osteochondrosis of the vertebrae, with or without spondylosis, results in kyphosis (Hill 1990). Proximal femoral epiphysiolysis causes an acute severe lameness, and if the lesion is bilateral, the animal is unable to rise (Hill 1990). Boars that are lame due to osteochondrosis spend a lot of time lying down, show stiffness when moving, and are unable to mount and breed (Grondalen 1974g; Reiland 1975; Nakano et al. 1981a).

Diagnosis. To diagnose osteochondrosis, first rule out all other causes of lameness. Examine suspect animals clinically and then examine a representative sample at postmortem. Sows can be followed to slaughter to examine the feet, stifle, hip and elbow joints, and cut half of the vertebral column. Proximal femoral epiphysiolysis must be differentiated from a femoral fracture, paraplegia due to a lumbosacral fracture, or a spinal canal abscess (Hill 1990). Although the definitive diagnosis of osteochondrosis is made by histologic examination of affected joints, 69% of cases can be diagnosed after clinical and gross postmortem examination (Hill et al. 1984; Dewey et al. 1993).

Gross Postmortem Lesions. Osteochondrosis is manifested as osteochondritis dissecans, epiphysiolysis, deformities of bones, and arthrosis (Palmer 1985). Affected articular cartilage may be invaginated below the level of the surrounding cartilage and may be thick and yellowish or thin and reddish (Grondalen 1974a; Reiland 1975). The border between the cartilage and bone is uneven and its surface may be wrinkled (Reiland 1975).

Joints severely affected with osteochondrosis have an increase in the amount of synovial fluid, ruptures, hemorrhages of the joint capsule and ligaments, thickened joint capsule, and villous proliferation of the synovial membrane (Grondalen 1974b; Nakano et al. 1981b).

A fissure running parallel to the joint surface separates the outer layers of cartilage from the deeper layers or may occur at the osteochondral junction (Grondalen 1974a). The fissure may extend to the articular surface, creating a cartilage flap (Grondalen 1974a; Palmer 1985). Secondary lesions include hemorrhages, connective tissue proliferation and necrosis in the subchondral bone, osteophyte production, and chip bone fractures (Grondalen 1974a; Palmer 1985). Epiphyseal separation can either be complete–as in the head of the femur and the tuber ischii–or partial–as in the distal epiphyseal plate of the ulna (Palmer 1985).

In advanced cases of osteochondrosis, the long bones of the extremities are shorter and the metaphyses are flared. The femoral and humeral heads are flattened and have short necks, and the head is lower than the major trochanter. Premature closure of the distal ulnar growth plate causes a volar deviation of the distal radius, a fractured anconeal process, and a more semicircular, semilunar notch.

Osteochondrosis of the spine occurs in the thoracolumbar region, causing the synovial joint surfaces to vary in shape and size, with the tip of the joint avulsed and connected to the rest of the joint by a fibrous tissue band. In animals older than 18 months, osteophyte production occurs and joints may become ankylosed (Reiland 1975). Intervertebral disks have a nucleus pulposus that is hemorrhagic, granular, yellowish, firm, and almost absent or changed to a homogenous, darkly colored mass. Epiphyseal separation of the tuber ischii is often associated with signs of repair and arthrosis and may cause a fracture through the primary and secondary spongiosa (Grondalen 1974b; Palmer 1985).

Histologic Lesions. Histologic lesions of osteochondrosis involving the growth cartilage of the physis and the epiphysis include foci of metaphyseal dysplasia, eosinophilic streaks, intracartilagenous cavities, and protrusions or invaginations of cartilaginous plates (Grondalen 1974e, g; Reiland 1975; Nakano et al. 1979a; Hill et al. 1984; Palmer 1985). Histologic lesions of osteochondrosis were seen in 94% of culled sows (Dewey et al. 1993).

Treatment. Pigs with a foreleg lameness due to osteochondrosis may respond to 6 weeks of rest in a pen with secure footing, sufficient room for exercise, and freedom from being mounted by other animals. Affected animals need to be rested for 6 weeks prior to being used for breeding. Boars and multiparous sows with clinical signs of the hindlegs or those with a recurring foreleg lameness should be culled. Some boars that are lame due to damaged cartilage become clinically sound when put

out on dirt lots (McPhee and Laws 1976; Fredeen and Sather 1978; Nakano et al. 1981a).

A non-steroidal anti-inflammatory drug, meloxicam, was recently approved for use in dogs and cattle and received marketing approval for pigs in Europe (Friton et al. 2003). In double blind, clinical trials, pigs affected with noninfectious causes of lameness had improved lameness scores, improved feed intake, and reduced retreatment rates 4 days after the treatment compared to pigs given a placebo.

Preventing Leg Weakness. Gilts' joints mature with age rather than with weight. Rapidly growing gilts that are fed ad libitum experience joint stress due to their weight. Overfeeding gilts results in increased leg weakness problems and increased culling due to lameness (Jorgensen and Sorensen 1998). Gilts were fed semi–ad libitum (ad libitum for two 30-minute feeding episodes per day), at the recommended Danish standard or 75% of the Danish standard. Sows in the semi–ad libitum group had higher overall leg weakness scores and tended to have weaker pasterns and long accessory digits in the forelimbs. Over the life of the sows twice as many sows were culled for leg weakness in the ad libitum–fed group compared to the other groups. The age sows were culled for lameness was younger in the ad libitum group than the other groups.

A gilt that is moved, exposed to a new floor type, mixed with a new group of animals, or trucked to a new farm will experience stress to her joints. Mating and pregnancy are also potential sources of mechanical stress. Restricted exercise in either a stall or a small pen causes lameness, leg weakness, and poor muscle development. The area per finisher pig and the number of finisher pigs per pen will affect the culling rate due to lameness in sows. Osteochondrosis is associated with rapid weight gain and mechanical stress to joints. Replacement gilts should be selected at the nursery or grower stage. By 150 days of age they should be housed with other gilts in a pen with good secure footing and 10 square feet (1.3 m^2) per animal. Their feed should be restricted and they should be bred on their second or third observed estrus.

Arthrosis. Arthrosis (arthropathy, osteoarthrosis, or osteoarthritis) is a nonspecific, degenerative condition of cartilage that develops in chronic joint disease (Palmer 1985). Lesions of osteoarthrosis include fibrillation of joint cartilage, ulceration of the articular surface, osteophyte production, and thickened synovial membrane and joint capsule (Palmer 1985). Lesions of osteochondrosis that affect the joint surface fill with fibrocartilaginous tissue, which is then replaced by osseous repair tissue (Grondalen 1974b; Nakano et al. 1979a; Palmer 1985). The incidence and severity of arthrosis increases with the increasing age of the animal (Reiland 1975). In Reiland's (1975) study of culled sows, the inci-

dence in sows less than 18 months of age was 7%, and in those older than 18 months, it was 82%. Arthrosis is usually secondary to osteochondrosis (Reiland 1975). Arthrosis of the hock is severe and the incidence is high, but it is of minor significance with respect to clinical lameness (Grondalen 1974b).

Foot Problems. Torn dewclaws, overgrown lateral digits on the hindfeet, or foot rot are either the first or second most important cause of lameness in sows (Smith and Robertson 1971; Penny 1979; Dewey et al. 1993). Dry sows that are housed on partially slatted concrete floors may have their dewclaws torn as their feet slide outward in an attempt to stand. Overgrown lateral digits are seen in animals without exercise, especially those kept on nonabrasive floors such as plastic or steel slats. These sows should have their hooves or dewclaws trimmed on a regular basis. Floors with rough edges or sharp prominences that cause abrasions and floors with poor drainage increase the incidence of foot rot.

Foot Rot. Foot rot begins as a crack in the wall of the hoof which starts at the volar surface and extends two-thirds of the way to the coronary band (Penny 1979). Secondary infection of the crack by *Fusobacterium necrophorum*, *Arcanobacterium pyogenes*, or spirochetes leads to a deep necrotic ulcer of the laminae and coronary band or a necrotic track which may reach the coronary band and form an ulcer (bush foot) or an infection of the deep flexor tendon or phalangeal bones and joints (Vaughan 1969). If the crack does not become infected, it is termed a false sand-crack and does not cause lameness (Hill et al. 1986). Clinically, foot rot causes a unilateral lameness in which the animal is reluctant to bear weight on the affected limb. This contributes to clumsiness and bad mothering in sows and impotentia coeundi in boars (Penny et al. 1963; Hill et al. 1986). Foot rot and associated foot lesions (heel, toe, and sole erosions, white line lesions, and false sand-crack) are seen in 64% of slaughter weight pigs (Penny et al. 1963). In a similar survey done by Backstrom et al. (1980), almost 50% of slaughter pigs had moderate to severe foot lesions, particularly on the pads, sole, and lateral digits.

Lesions of foot rot are commonly seen on the lateral claws of the hindlegs (Simmins and Brooks 1988). Hoof injuries often occur in the lateral claw of animals with uneven claws where the lateral claw is larger than the medial claw (Penny et al. 1963; Vaughan 1969; Grondalen 1974a; Penny 1979). The uneven claw may also cause the animal to stand and walk with an abnormal gait (Penny 1979). Crated animals have fewer hoof lesions than penned animals (Bane et al. 1980). There was a positive, significant, linear relationship between the gross postmortem scores for the foot lesions and the clinical grade and the parity of the sow. The older sows suffered from foot trouble more frequently than the younger sows (Dewey et al. 1993).

Fractures. Fractures occur when animals struggle to free a limb from between slats or under feed troughs or pen rails or when they fall on slippery concrete or during transport (Vaughan 1969; Hill et al. 1986). Clinically there is a sudden onset of severe lameness in one leg, the animal carries the leg, and there is crepitation and pain on palpation (Buddle 1987). The condition is widespread but rare.

Floors

Lameness is associated with many factors and cannot usually be blamed on only one factor. Housing appeared to be an important factor influencing the level of lameness that an individual herd experienced. Floor types affect the incidence of foot and limb disorders (Elliot and Doige 1973; Perrin et al. 1978; Newton et al. 1980; MAFF 1981; Nakano et al. 1981a; Hani and Troxler 1984). A survey of Pig Health Scheme Herds showed that 44% of farms with slatted floors had pigs with injuries, whereas only 28% of farms with solid floors had pigs with injuries caused by flooring (MAFF 1981). Good perforated floors require a durable, low-cost, nonslip, nonabrasive surface and acceptable levels of cleanliness and ease of cleaning (Smith and Mitchell 1976). In sows, lameness is influenced by the floor types used for sows and gilts as well as those used during their rearing period. Concrete floors cause more foot and leg problems than earthen floors or deep straw bedding, and injuries occur more frequently on perforated floors (Nakano et al. 1981b). Perforated floors such as partially slatted or fully slatted concrete or metal slats cause more lameness than solid concrete floors. In the farrowing crates, plastic and steel slats cause more lameness than solid floors. The best floor type for the development of feet and legs is a solid floor with bedding.

It is difficult to obtain the correct balance between nonslipperiness and nonabrasiveness with solid concrete floors. Rough floors are created by using sand of the wrong particle size or by allowing the surface to be broken down by wear or by organic acid in the urine. Poorly laid concrete floors cause abrasions to areas such as the spine of the scapula, the hooves, and the soles. Slippery concrete causes ataxia and tendon swelling, and newly laid concrete causes lameness due to its slippery qualities as well as its surface chemicals. Wet concrete pens cause cracked and bruised soles, which can lead to secondary infections (Penny 1979; MAFF 1981). Substandard concrete may be improved by using bedding, laying a new concrete floor, or coating the concrete with chlorinated rubber, epoxy resin, or polyurethane paints (MAFF 1981).

The floor types associated with culling rates for lameness in sows include steel or plastic slats in the farrowing crates, partially slatted concrete floors and fully slatted concrete floors for sow pens, partially slatted sow stalls with metal slats, and partially slatted concrete floors used for the finisher pigs. The edges of concrete slats are often too rough and the slats may be placed too far apart, causing abrasions of the coronary band and the accessory digits. Plastic slats are too slippery and cause the sow's feet to be overgrown, leading to secondary damage to the accessory digits (MAFF 1981). Foot pad lesions and hoof cracks are positively correlated with hoof and sole length. The hoof length and sole length are the longest on plastic slats, followed by aluminum, steel, and concrete.

Rough concrete floors, sharp-edged concrete slats, and slats of other materials often result in severe foot injuries, which can lead to changes in the way the pig walks. An altered gait may change the joint congruence, causing overloading in the joint and subsequent cartilage damage (Aherne and Brennan 1985). Also, both insecure footing and foot lesions increase the mechanical stress to joints, which in turn increases the incidence of leg weakness (Nakano et al. 1981b). There is an increase in leg weakness on perforated floors (Nakano et al. 1981b; Dewey 1988). Raising pigs on deep straw bedding rather than partially slatted concrete floors decreases the incidence of gait abnormalities and claw injuries and may decrease the incidence of clinical osteochondrosis (Hani and Troxler 1984; Dewey 1988).

There are unique sources of injury related to estrus detection and mating. Specifically, introducing a boar to non-estrus females increases the injury rate. Conducting estrus detection and mating in a specific mating pen reduces the cull rate for injuries. Farms that house sows in stalls for the first 3 weeks postweaning have a lower cull rate than farms that have only pens for sow housing. The prevalence of injuries including those causing lameness is higher in facilities where pigs are fearful of humans (Barnett et al. 2001).

Breeding pens that are too small, have right-angled corners or slippery floors increase the chance for injuries and lameness in boars and sows (Barnett et al. 2001). Dry, nonslip floors in large octagonally shaped pens used only for breeding are preferable (Hemsworth et al. 1989).

Exercise

Pigs given exercise and pigs penned with other animals have significantly better gait scores and less lameness and posterior paresis than pigs denied exercise or individually housed (Elliot and Doige 1973; Grondalen 1974a; Fredeen and Sather 1978). Inactive individually housed animals have a reduction in cortical bone mass and have muscular weakness. Pigs that are exercised have increased muscle strength and are more agile, allowing them surer movement on slippery floors (Elliot and Doige 1973; Grondalen 1974a, g, i). This may be one of the reasons that gilts and sows in loose housing systems are less prone to culling for leg weakness problems. The duration of confinement is correlated positively to the degree of joint damage (Grondalen 1974i; Fredeen and Sather 1978; Hani and Troxler 1984). Boars given exercise have fewer conformational abnormalities such as

bowlegs, flexion of the carpus, and sickle hocks than boars that are confined (Perrin and Bowland 1977). Perrin et al. (1978) found that floor type did not influence the degree of joint lesions, but Fredeen and Sather (1978) stated that floor and housing type in the nursing period may increase the piglets' susceptibility to joint damage after weaning.

Diet Causing Locomotor or Neurologic Problems

Diets in modern pig production are typically made of locally grown grains supplemented with a protein source, vitamins, and minerals. Deficient soil or mixing errors in feed manufacture can result in nutritional deficiencies or toxicities (Silvertsen et al. 1992) (Table 5.3).

Table 5.3. Lameness and neurological entities caused by nutritional deficiencies.

Deficiency	Clinical Signs	Epidemiology	Pathology
Copper	Incoordination, paresis, posterior paralysis, excessive flexion of hocks and forelegs, recumbency, occasionally sudden death	Rare: unsupplemented diets, deficient soil	Aortic rupture in sudden deaths
Manganese	Newborns: weak at birth, head tilt, incoordination and poor balance, inability to suckle	Rare: progeny of manganese-deficient sows	
	Growers: shifting lameness, dog-sitting, short bowed legs, thick hocks, weak joints	Rare: progeny of manganese-deficient sows	
	Sows: stillbirths, irregular estrous cycle, return to estrus, dysgalactia	Rare: progeny of manganese-deficient sows	
Niacin	Ataxia, quadriplegia, posterior paralysis, anorexia, reduced growth rate, diarrhea, anemia, dermatitis, alopecia	Unsupplemented corn diets low in tryptophan	Thickened mucosa of colon and cecum
Pantothenic acid	Goose-stepping gait, incoordination, dermatitis with periocular exudate and alopecia, diarrhea	Rare: nonbalanced diets of waste products or corn	Congestion, edema, reddened colon
Selenium (vitamin E and selenium, white muscle)	Affects all ages, especially 30–60 kg: sudden death, ataxia, stiff staggering gait, weakness, paralysis, depression, anorexia, recumbency	Less common, found in selenium-deficient area	Pale areas in muscles, petechiae and white streaks in cardiac muscle, subcutaneous edema
Vitamin A	Newborns: stillbirth, micro- or anophthalmia, cleft palate, edema, high morbidity and mortality	Uncommon	Hydrocephalus, small cranium, herniation of spinal cord in lumbar region, thick epithelial surfaces
	Nursery pigs: progressive neurological dysfunction, incoordination, swaying gait, restlessness, dog-sitting, posterior paralysis, lordosis, blindness, reduced growth	Uncommon	Hydrocephalus, small cranium, herniation of spinal cord in lumbar region, thick epithelial surfaces
Vitamin D	Nursery pigs: enlarged joints and costochondral junctions, decreased average daily gain, stiff gait, lameness	Rare: high morbidity, low mortality	Thick, soft bone cortices, uneven epiphyseal cartilage
Water (salt poisoning)	Peracute: tremors, prostration, running movements, death	Widespread, uncommon, water deprivation, then drinking excessively	Edema of meninges, flattened cerebral cortex, hyperemia, erosions of stomach mucosa
	Acute: repeated seizures at 3–7 minute intervals, twitching face and ears, dog-sitting, head up and back, falling over, violent paddling, salivation then recovery and walking away, apparent blindness, wandering aimlessly	Widespread, uncommon, water deprivation, then drinking excessively	Edema of meninges, flattened cerebral cortex, hyperemia, erosions of stomach mucosa

Biotin.   Biotin (vitamin H) is a B vitamin. The bioavail-ability of biotin in pig feed varies with the major ingredients of the feed (Brooks 1982). Corn is a good natural source of biotin (Bane et al. 1980; Hamilton and Veum 1984), but diets based on cereals such as barley that are low in available biotin may not provide sufficient biotin for horn integrity (Simmins and Brooks 1988). This makes the hoof wall prone to trauma on hard floor surfaces (Bane et al. 1980).

The response of sows with foot lesions to the addition of biotin in the feed is variable because although some may be biotin deficient, there are many causes of foot lesions (Penny et al. 1980; Grandhi and Strain 1980; Brooks 1982; Bryant et al. 1985). Biotin deficiency causes foot lesions due to soft hooves (Penny et al. 1980). Biotin supplementation of feed, 1160 μg/kg during gestation and 2320 μg/kg during lactation compared to 160 μg/kg, decreases the rate of claw lesions in gilts. However, it does not heal lesions in parity 2 and 3 sows with lesions prior to supplementation (Penny et al. 1980). Biotin may also be administered via injection at 250 μg/kg body weight in pregnant animals or 150 μg/kg in lactating animals (Brooks et al. 1977). Supplementary d-biotin at 1 mg/kg feed increases the compressive strength and the hardness of the sidewall regions of the pig's hoof and decreases the hardness of the heel bulb (Webb et al. 1984). The heel bulb acts as a cushion, absorbing energy on contact and spreading the weight of the pig over the area of the foot. Biotin supplementation may reduce the likelihood of injury to the foot and allow an increase of 8% in the floor slot-to-slat ratio from 61% to 69% for 100 kg pigs (Webb et al. 1984). As a preventive measure, pigs weighing 25 kg and more may be given biotin supplementation (Simmins and Brooks 1988).

Osteoporosis.   Osteoporosis is caused by an excess resorption of bone and results in endosteal thinning of the trabeculae and cortices (Spencer 1979). In mid-to-late lactation or the early postweaning period, osteoporosis occurs as the sows' bones decalcify to mobilize calcium for milk production. The periosteal surface has a slightly increased mineralization rate. These sows may develop fractures of their vertebrae, femurs, and phalanges. Clinically this occurs as lameness, or "downer" sow syndrome, late in lactation or when the sow is mounted by the boar or another sow. Typically the syndrome occurs late in the first or second lactation or during the postweaning period (Gayle and Schwartz 1980).

The diagnosis is made by identifying thinned cortices. The specific gravity of the bone will be less than 1.018, whereas the specific gravity is 1.022 or more in normal sows (Spencer 1979). A cross section of the sixth rib shows a cortex to total area ratio of less than 0.2 (normal sows have a ratio greater than 0.3). Serum calcium and phosphorus will be within normal levels (Gayle and Schwartz 1980).

Osteoporosis is caused by inadequate levels of dietary calcium, phosphorus, or vitamin D. Recommended daily intake levels for lactating and gestating sows are as follows: calcium, 37.5 g and 10 g; phosphorus, 25 g and 10 g; and vitamin D, 660 IU per kg of feed (Gayle and Schwartz 1980). Reduced exercise from prolonged periods in crates may predispose sows to osteoporosis (Spencer 1979) because of changes in pH and oxygen tension in the bones (Gayle and Schwartz 1980). Demineralization occurs due to the higher levels of parathyroid hormone (PTH) in lactating sows. PTH controls renal synthesis of the active form of vitamin D_3, which is responsible for trabecular bone mobilization. Exertion or slipping of these sows may cause spontaneous fractures of their pelvic bones, femurs, or lumbosacral vertebrae, leading to various degrees of stiffness, lameness, or posterior paralysis (Hill et al. 1986). Fractures in old sows, especially those of the glenoid surface, may be caused by a bone weakened by osteochondrosis (Reiland 1975). Prevention includes adequate dietary vitamins and minerals, lactation limited to 4 weeks, and breeding gilts after 7 months of age (Gayle and Schwartz 1980).

Poisoning

Poisonings occur when pigs consume products in their surroundings, such as rodent bait or excess amounts of compounds normally found in swine feeds (Table 5.4).

Arsanilic Acid.   Arsanilic acid is fed to pigs either to promote growth or to treat swine dysentery. Overdoses of arsanilic acid decrease growth rate and cause head tremor, progressive blindness, ataxia, and paresis. Pigs remain bright, alert, and even euphoric. The onset of neurological signs begins 4–6 days after ingesting high levels (1000–2000 g/ton) of arsanilic acid, but at lower levels (600 g/ton) the onset of clinical signs is much slower and growth rate is not depressed. If the drug is removed, the symptoms stop progressing and may regress (Hardin et al. 1968). Other clinical signs are seen in pigs poisoned with 3-nitro-4-hydroxy phenyl arsonic acid (Rice et al. 1980). Symptoms are not visible until the pigs are moved or exercised. After exercise there is trembling of the muscles of the shoulders, hams, and backs followed by violent tremors, incoordination, and extreme agitation and screaming. The seizure lasts for 1 minute, after which the animal lies down and the trembling ceases. Diagnosis is confirmed by identifying arsenicals in the urine. On postmortem examination, the bladder is distended, and there is degeneration of the optic nerves, optic tracts, and peripheral nerves (Hardin et al. 1968).

Insecticide.   Organophosphate and organochlorine poisoning occurs in pigs due to inadvertent mixing or spilling of insecticides used for rootworm control in corn crops (Frank et al. 1991). Most pigs (70%) consuming contaminated feed die within hours of ingesting

Table 5.4.   Lameness and neurological entities caused by ingested poisons.

Poison	Clinical Signs	Epidemiology	Pathology
Furazolidone	Ataxia, paresis, convulsions, inappetence, vomiting, feed refusal	Rare: overdose of drug concentrate	Hemorrhage, thrombocytopenia
Hygromycin B	Loss of balance, ototoxicity causing ataxia, cataracts causing blindness	Problem if fed continuously; prevent with a schedule of 2 months on, 2 months off	Cataracts
Lead	Salivation, diarrhea, anorexia, hypersensitivity, squealing, tremors, ataxia, enlarged joints, blindness, convulsions, death	Rare: oil used to treat mange	Gastrointestinal reddening
Mercury	Unaware of surroundings, dysphagia, chewing, incoordination, wandering, blindness, loud vocalizations, paresis, tremor, lateral recumbency, paddling, coma, death	Rare: alkylmercurial compounds used as fungicides in grain	Cerebral atrophy, enlarged pale kidney cortex, pale shrunken liver, necrotizing suppurative pharyngitis, focal erosive gastritis
Nitrite	Sudden death without struggling, tremors, weakness, ataxia, recumbency, convulsions, dyspnea, cyanosis, tachycardia, brown mucous membranes	Rare: consumption of preformed nitrite (microbial action on nitrates in whey)	Dark brown blood; endocardial hemorrhage
Phosphorus	Vomiting (smells like garlic), diarrhea with or without blood, abdominal pain, jaundice. Gastrointestinal signs followed by convulsions, coma, death	Rare: consumption of rodent bait	Jaundice, carcass smells like garlic, enlarged mottled liver, catarrhal inflammation of GI tract
Sodium monofluoracetate	Intermittent paddling, tonic-clonic convulsions, persistent vomiting	Rare: consumption of rodent bait	
Vitamin A	Weak hind end, knuckling of pasterns, bowed legs, reluctance to stand, standing with legs under body and back arched, development of short legs, swollen nonpainful joints due to premature closure of epiphyseal plates; thin cortices, slow growth, hyperesthesia, red skin	Rare: oversupplementation (young pigs fed >200,000 μg/kg within 14 days)	Short diaphysis; rotated and enlarged epiphyses of leg bones; pitted articular surfaces; congenital defects of heart, eye, rectovaginal area
Zinc	Enlarged shoulder joints, stiff gait, anorexia, reduced growth rate, rough coat	Rare: dairy products stored in galvanized containers and then fed to pigs	Hemorrhage into joint cavities, arthritis of head of humerus, red mucosa in GI tract

these products. Organophosphates cause pulmonary edema, myocardial hemorrhage, and cholinesterase inhibition, which results in cholinesterase levels of zero in whole blood of affected animals. These chemicals do not persist in the affected animal, so the meat is not hazardous to the consumer. Organochlorines cause convulsions. Although animals recover once the contaminated food is removed, these chemicals persist in meat and milk; therefore, it may not be possible to return the animal to the food chain (Frank et al. 1991). Chemical analysis of the feed is used for the definitive diagnosis. The best preventive measure is to store the chemicals separately from the swine feeds.

Selenium. Selenium is an essential nutrient and is required at 0.3 ppm for growing pigs; however, at more than 4 ppm it becomes toxic (Stowe et al. 1992; Stowe and Herdt 1992). Affected pigs have a decreased feed intake and an incoordinated gait and then become paraplegic or quadriplegic due to segmental spinal cord lesions. They remain bright and alert and occasionally show muscle fasciculation and occasional vomiting. With severe poisonings pigs are in lateral recumbency, show flaccid paralysis, and lose sensation to the skin (Buddle 1987). The diagnosis can be made from a history of feed-mixing error by measuring the selenium levels in the blood, or by identifying spinal cord lesions that include bilaterally symmetrical focal malacia of the gray matter of the ventral horns, a mottled liver, dehydrated carcass, and visceral edema. Once the toxic feed is removed, the majority of pigs will recover but will have a stiff gait and icterus.

Table 5.5. Lameness and neurological entities caused by inhaled toxins.

Poison	Clinical Signs	Epidemiology	Pathology
Carbon dioxide	Anxiety, staggering, coma, death at >400,000 ppm, increased respiratory rate and depth at >50,000 ppm	Rare: inadequate ventilation in winter	Dark colored blood and tissues
Carbon monoxide	Lethargy, incoordination, coma, death due to hypoxia, increased stillbirths and neonatal death, abortion storm	Rare: malfunction of fossil-fuel or gas heaters and poor ventilation	Cherry red blood, bronchodilation
Hydrogen sulfide	Sudden death if >400 ppm; listlessness, incoordination, spasms, coma, respiratory depression, cyanosis	Rare: poor ventilation after agitation of effluent; dangerous for humans, rotten egg smell	Cyanosis, pulmonary edema, congestion, emphysema

***Cassia* sp.** *Cassia* plant species seeds in grain sorghum cause decreased appetite, incoordination, ataxia, staggering, decreased weight gain, and increased mortality in grower pigs (Flory et al. 1992). A similar syndrome is found in chickens, where the plant causes muscle atrophy and pallor.

Inhaled Toxins. Pigs are susceptible to inhaled toxins due to the confinement housing systems. These toxins are described in Table 5.5.

PRIMARY NEUROLOGIC DYSFUNCTION

Clinical Examination

The purpose of the neurological examination is to determine the extent of the neurologic deficits and the location of the lesion. The neurological examination begins with a complete physical examination of the animal(s) involved. Specific history questions include previous illness, behavioral changes, seizures, head tilt, circling, and presence of pain or paresis. After observing the pig in its pen, move the pig into the alleyway, out of its normal surroundings. Allow the pig to become familiar with the area so that you can fully appreciate its behavior. Watch carefully for visual difficulties, proprioceptive loss on slippery floors, purposeful movements, mental status, gait, posture, and evidence of trauma (Kornegay and Seim 1996). Serial examinations are performed to determine the static nature of the clinical signs. Observations may be recorded using the examination form shown in Figure 5.1. Evaluation of cerebral spinal fluid may help differentiate neurologic problems with similar clinical signs (Ebeid et al. 1997).

Specific terminology is used in neurologic examinations to denote loss of function. Plegia and paralysis describe complete loss of sensory and motor function of an extremity. Paresis is partial loss of sensation and complete or partial loss of motor function. Tetraparesis refers to all four limbs, paraparesis to both pelvic limbs, hemiparesis to the front and the hindlimb on one side, and monoparesis to a single limb.

Posture is evaluated in a resting standing position and then after moving the pig into a prone position to determine whether it can regain a normal posture. The clinical signs and their referent lesions are as follows: vestibular abnormalities causing a continuous head tilt; spinal cord lesions, an abnormal truncal posture; proprioceptive deficits, an improper positioning of legs; flaccidity referring to decreased muscle tone, whereas spasticity is an increased muscle tone. Palpate the muscles carefully and systematically, comparing one side to the other. Specifically look for size, tone, strength, normal contour, repetition, and normal motion.

A normal gait requires the neurologic organization of the brain, spinal cord, and peripheral nerves. Proprioceptive abnormalities, which can be caused by a lesion at any level, are seen as knuckling, misplacement of a foot, or scuffing of the hoof. Proprioceptive positioning is tested by flexing the claw so the dorsal position is on the floor and watching how quickly the foot returns to normal positioning. A worn dorsal hoof wall and skin abrasions may signify chronic problems. Paresis, a disruption of the voluntary motor pathways, involves the cerebral cortex, brain stem, and the peripheral nerves. Ataxia is a lack of coordination and usually involves the cerebellum, vestibular system, or spinal cord. Purposeful movement is a conscious attempt to move the animals' legs. Weakly ambulatory or nonambulatory animals drag their legs. In these animals, watch hip movement and pushing with their feet; support the animal with the tail. Lack of purposeful movement suggests severe but possibly reversible spinal cord injury.

Examination of thoracic limbs in lightweight animals can be accomplished by supporting the full weight of the hind end of the animal and allowing the animal to walk forward on one (hopping) or both forelegs (wheelbarrowing). Slow initiation of movement refers to lesions in the cervical spinal cord, brain stem, or cerebral cortex. Exaggerated movements indicate cervical spinal cord, lower brain stem, or cerebellar lesions. The hopping test with poor initiation suggests proprioceptive deficits, but poor movement is due to motor deficits. In the extensor

postural thrust, the thorax is supported and the animal is lowered to the floor so that one can watch for caudal, symmetric walking movements of the hindlegs. Hemi-walking and hemi-standing are performed by supporting the forelimbs and hindlimbs of one side of the body and watching for lateral walking movements. These two tests are evaluated the same way as the wheelbarrow test.

There are two placing tests: tactile placing without vision, where the animal's eyes are covered, and visual placing, where the pig can see the surface it is approaching. Lift the animal and touch the forelegs at or below the carpus to a table; the pig should immediately place the feet on the table or with visual placing should anticipate by reaching for the table. Visual placing requires intact visual pathways to the cerebral cortex and to the motor cortex and motor pathways to the peripheral nerves. Normal tactile placing with abnormal visual placing suggests a sight disorder. The opposite suggests a sensory pathway lesion. Cortical lesions produce a contralateral (opposite) abnormality, but a lesion below the midbrain produces same-side (ipsilateral) deficit.

Spinal Cord Lesions

Vaughan (1969) suggests that the most common cause of posterior paralysis in pigs of all ages is compression of the spinal cord by an abscess that occurs secondary to an infection in the intervertebral disks, vertebral bodies, or paravertebral tissues. Clinical signs begin with incoordination of the hindquarters, which rapidly progresses to flaccid paraplegia, pyrexia, and local swelling of the tissues over the abscess (Vaughan 1969; Buddle 1987). Pigs continue to eat and drink and appear alert. The occurrence is widespread and sporadic, and morbidity is low. Diagnoses are made by identifying the abscess

in the spinal canal. In adult animals the most likely causes are an excess load on the disks causing premature disk degeneration or primary osteochondrosis of the vertebrae (Grondalen 1974b). In growing animals spinal cord abscesses are secondary to tail biting. The animals require euthanasia.

To identify a spinal cord lesion, attempt to localize the pain to an extremity or the cervical, thoracolumbar, or lumbosacral areas. Determine whether the pain or paresis is acute or chronic, progressive or static, persistent or intermittent, sharp or dull. The type of pain and paresis can be used to determine whether the spinal injury is extradural, intradural but extramedullary, or intramedullary. Extradural lesions, such as intervertebral disk extrusion, discospondylitis, or vertebral osteomyelitis, present with acute persistent and progressive pain and paresis. Intradural-extramedullary lesions cause chronic dull pain with a slowly progressive paresis. Intramedullary lesions, such as a vascular insult, cause acute sudden but short-lived pain and acute persistent paresis that is not progressive.

Spinal or myotactic reflexes test the sensory and motor components of the reflex arc and the descending motor pathways. It is easier to localize spinal reflexes to the hindlimbs than to the thoracic limbs (Table 5.6). The spinal reflex response can be normal, absent, or depressed, indicating a lower motor neuron (LMN) problem, or exaggerated, indicating an upper motor neuron (UMN) problem. The descending pathways from the brain and spinal cord normally inhibit the reflex, and thus, a UMN problem results in an exaggerated response.

Additional indications of LMN problems include poor strength, flaccid muscle tone, muscle fasciculation, early neurogenic muscle atrophy, and easy bladder expression. UMN problems are associated with variable but strong reflex strength, spastic muscle tone, late disuse muscle atrophy, clonus, difficult bladder expression, and absent root signature. Clonus is sustained quivering

of the muscles after the reflex response, which is palpable but not visual.

The perineal or anal sphincter reflex is tested by stimulating the perineum with forceps (Kornegay and Seim 1996). Contraction of the anal sphincter suggests function of the sacral spinal cord and pudendal nerve. The urinary bladder is innervated by both autonomic (hypogastric and pelvic) and somatic (pudendal) nerves. Spastic bladder outflow and difficult expression (UMN) occur with lesions above S2–S3, whereas lack of sphincter tone and easily expressed bladder occur with lesions of S2–S3 (LMN). Unconscious tail wagging may occur with urination or the anal sphincter reflex and can occur with complete transection of the sacral spinal cord.

The crossed extensor reflex is elicited by pinching the coronary band on the down limb when the pig is in lateral recumbency. Use a gentle stimulus or the animal will attempt to stand. The extension of the upper limb corresponds to a UMN lesion affecting the descending inhibitory pathway of the spinal cord. Panniculus reflex (cutaneous trunci reflex) is the twitching of the cutaneous trunci muscle on both sides of the dorsal midline at the point and cranial to the point of stimulation. Begin testing at the fifth lumbar vertebra and continue cranially. No response will occur one to two segments caudal to the spinal cord lesion.

Deep pain perception tests the functional integrity of the spinal cord. It is the most important prognostic test but should be applied at the end of the physical examination to get reliable responses to the prior tests. Apply painful stimuli to each limb and the tail. The pig will vocalize, look, or attempt to move away. The withdrawal of the limb is not a behavioral response. Spinal cord injuries result in sequential losses of function as follows: first, proprioception, then voluntary motor function, superficial pain sensation, and finally deep pain sensation. The return of function follows the reverse order. The amount of spinal cord compression will be determined by the measurable functional loss. Loss of deep pain sensation indicates a poor prognosis.

Hyperpathia is a behavioral response (vocalization, turning to look, or moving away from examiner) elicited by applying pressure to the spinous processes or paraspinal muscles of the thoracic and lumbar region or the transverse processes of the cervical region. Pain perception occurs at the level of the spinal cord injury. The sensory-level response also helps determine the location of the lesion. Pinpricks are applied to the back from the seventh lumbar vertebra cranially. The part of the back between where the normal behavioral response and the depressed response is observed is two segments caudal to the level of the injury. Lesions can be localized to specific spinal nerves using referent clinical signs and corresponding vertebral bodies (refer to Table 5.6).

Once the location of the lesion has been identified, the signalment, history, and physical examination can be used to determine a list of differential diagnoses (refer to

Table 5.6. Localization of spinal cord lesion by vertebrae site and neurologic response.

Site and Vertebra Number	Spinal Cord Segments	Neurologic Response[a]
Craniocervical: C1–C4	C1–C5	UMN to the forelimbs UMN to the hindlimbs
Caudocervical: C5–T1	C6–T2	LMN to the forelimbs UMN to the hindlimbs
Thoracolumbar: T2–L3	T3–L3	Normal forelimbs UMN hindlimbs
Lumbosacral: L4–L6	L4–S3	Normal forelimbs LMN hindlimbs
Sacral: L5	S1–S3	Normal forelimbs Normal hindlimbs LMN tail and anus

[a]UMN, upper motor neuron problem; LMN, lower motor neuron problem.

Figure 5.1). General diagnostic categories can be determined using the history of pain or paresis. Infarctions of the spinal cord and fractures of vertebrae cause acute/static pain/paresis. Degenerative, inflammatory, traumatic, or pressure necrosis, such as a spinal cord abscess, causes acute progressive signs. Degenerative or inflammatory processes cause chronic/progressive clinical signs.

Cerebral Cortex and Forebrain

Diseases affecting the cerebral cortex or thalamus (forebrain) cause an altered mental attitude, seizures, blindness with a pupillary light reflex, circling (ipsilateral), compulsive walking, and head pressing (Kornegay and Seim 1996). The four levels of altered mental attitude are

- Depression or a decreased responsiveness
- Stupor, which is unresponsive but arousable
- Coma, which is unresponsive and not arousable
- Mania or delirium with excessive motor activity

Stupor and coma are caused by a problem with the cerebral cortex or the reticular activating system of the brain stem. Mania is due to diseases of the cerebral cortex, particularly the limbic system. Depression may be due to any systemic disease and may not involve the brain. Some causes of abnormal neurological function are listed in Table 5.7; others are described in more detail in this section.

Table 5.7. Diseases causing neurological symptoms in postweaned pigs.

Disease	Clinical Signs	Epidemiology	Pathology
Botulism	Progressive, flaccid paralysis; weakness; incoordination; staggering; recumbency; vomiting; pupillary dilation; deep, labored breathing; salivation; involuntary urination and defecation; death 1–6 days after onset	Rare, sporadic: feeding decomposing food such as garbage or dead fish	No gross lesions
Cerebrospinal angiopathy	Blindness, head tilt, circling	5 weeks postweaning, may be a sequel to edema disease	No gross lesions
Edema disease (enterotoxemic colibacillosis)	Sudden death of best pigs; acute disease; depression, head pressing, difficulty standing, swaying hind end, knuckle over on front end, tremor, paddling, clonic convulsions, flaccid paralysis; characteristic subcutaneous edema of eyelids, conjunctiva, forehead, and throat; residual incoordination	Sporadic, uncommon, outbreaks 2 weeks postweaning, low morbidity, high case fatality rate, caused by specific serotypes of *E. coli*	Subcutaneous edema of eyelids, forehead, throat, ventral abdomen, hocks, elbows, stomach
Hog cholera (swine fever)	Severe systemic illness, depression, fever, anorexia, conjunctivitis, death, weak staggering gait, reddening of skin, watery diarrhea, convulsions and death after 1–3 weeks	Exotic to North America; mortality up to 90%, low-virulence strain mortality 1–60%; spreads easily; only affects pigs	Petechiae of kidneys, larynx, bladder, mucous membranes; infarcts in spleen; hemorrhage of lymph nodes
Listeriosis	Trembling, incoordination, stilted gait on forelegs, posterior paralysis; neonates with septicemia, sudden death	Widespread, rare; organism in soil	Congested lymph nodes, yellow fluid in body cavities, red liver with necrotic foci
Rabies	Sudden onset; progressive disease of incoordination, dullness, prostration, and death within 3 days; alternating periods of pronounced irritation: twitching, snout rubbing, chewing, swallowing, salivating, and recumbency; attacking other pigs or humans; apparent thirst but swallowing difficult; pushing forward and circling in kneeling position	Rare: reportable, zoonotic disease	No gross lesions; submit brain for diagnosis
Stachybotryotoxicosis	Dermatitis of snout, teats of suckling pigs, nasal exudate, depression, vomiting, tremors, anemia, sudden death, abortion	Toxin of *Stachybotrys atra* from hay or straw that depresses erythropoiesis and is epithelionecrotic	

Hydrocephalus. Hydrocephalus is an accumulation of cerebrospinal fluid (CSF) within the brain. It may be congenital or acquired—secondary to encephalitis or meningoencephalitis. Congenital hydrocephalus may be caused by vitamin A deficiency (refer to Table 5.3) or a lethal defect that is inherited as an autosomal recessive trait in Durocs (O'Hara and Shortridge 1966). Clinical signs vary from compulsive walking, head pressing, blindness, and seizures to a more mild form indicated by strabismus and stunted growth. Animals with a primary encephalitis will have signs of multifocal brain involvement.

Hypoglycemia. Hypoglycemia is a common problem in weak newborn pigs who do not nurse regularly. Early clinical signs include tachycardia, tremor, nervousness, vocalization, and irritability. As the hypoglycemia progresses, hypothermia, visual disturbances, mental dullness, confusion, depression, and seizures occur. Other causes of neurologic abnormalities in the newborn pig include congenital tremor and hypoxia (Table 5.8).

Encephalitis. Encephalitis, an inflammation of the brain, causes central vestibular disease.

Teschen Disease. Teschen disease virus causes polioencephalomyelitis, which results in mild fever and depression followed by ataxia and then nervous excitement, including muscle tremor, nystagmus, opisthotonos, and tonic-clonic convulsions (Mills and Nielsen 1968). All ages of pigs are affected and morbidity is up to 50%, with a high mortality in affected pigs.

Talfan Disease. Talfan disease is caused by the enterovirus. It is a widespread virus but clinical signs are uncommon; there is low morbidity and a moderate case fatality rate (Buddle 1987). It affects pigs under 10 weeks of age with fever, hyperesthesia, mild ataxia, and flaccid paralysis (Mills and Nielsen 1968). Affected pigs recover slowly and have a residual reduced growth rate. Both Teschen and Talfan diseases are seen in European countries and affect naive herds.

Eastern Equine Encephalomyelitis. Eastern equine encephalomyelitis virus (EEEV) causes incoordination, depression, seizures, and death in pigs of less than 2 weeks of age (Elvinger et al. 1994). Pathologic lesions include focal necrosis of the cerebral cortex and multifocal my-

Table 5.8. Neurological problems in preweaned pigs.

Cause	Clinical Signs	Epidemiology	Pathology
Congenital tremor	Varies from fine muscle tremor to whole-body shaking to severe muscle spasms causing the pigs to jump or dance; signs are present at birth, increase in severity with stimulation, decrease during sleep, and decrease progressively with age	Widespread, uncommon: depending on cause, may affect most pigs in most litters for 2–3 months or sporadically affect a few pigs in a few litters	
Type A I	Most litters, >40% pigs, high mortality	Hog cholera	Small cerebellum
Type A II	Most litters, >40% pigs, low mortality	Unknown virus	Unknown
Type A III	Few litters, 25% pigs, high mortality, male Landrace	Genetic recessive, Landrace	Small spinal cord
Type A IV	Few litters, 25% pigs, high mortality, defective vision, all Saddlebacks	Genetic recessive, Saddleback	Small spinal cord
Type A V	Most litters, >90% pigs, high mortality, any breed	Trichlorfon toxicity	Small cerebellum
Type B	Variable clinical signs	Unknown cause	Small cerebellum
Hypoglycemia	Hungry squealing pigs, progress to inappetence, huddling, lethargy, shivering, weak squealing when moved, coma, convulsions, death	Common: caused by starvation, sporadic among litters, affects smallest pigs or whole litter if chilled at birth; factors: hypoxia, temperature, teat access, litter size, available milk, housing, and disease	Thin pig with empty stomach
Hypoxia/anoxia	Postpartum central nervous system depression, inability to suck, walking backward or in circles, dog-sitting, reluctance to compete, weak, increased mortality due to starvation, hypothermia, overlying, disease	Common and widespread: associated with dystocia, old, fat, or thin sows, umbilical cord rupture, last pigs in large litter, heat stress, carbon monoxide poisoning	Meconium on pig's body, in mouth and trachea; hemorrhages and edema of thorax, heart, and thymus

ocardial necrosis. Diagnosis is made after a history of mosquito swarming and positive serum virus neutralization tests for EEEV.

Japanese Encephalitis Flavivirus. Japanese encephalitis flavivirus (JEV) is reported to cause encephalitis in pigs occasionally (Yamada et al. 2004). The virus is amplified in the pig and then transmitted via mosquitoes to other species. Researchers observed a nonsuppurative meningoencephalitis in pigs clinically affected by a wasting syndrome thought to be caused by JEV. Subsequently, when researchers injected JEV into SPF, 3-week-old pigs the pigs developed a fever (40–41°C), depression, and hindlimb tremor (Yamada et al. 2004). The JEV caused nonsuppurative encephalitis, neuronal necrosis, neurophagia, glial nodules, and perivascular cuffing. This neurotropism may be age dependent.

Blue Eye Disease. Blue eye disease caused by the pig paramyxovirus causes central nervous system damage and mortality in nursing pigs (Ramirez-Herrera et al. 2001). Morbidity and mortality due to the virus range from 20% to 90% and from 40% to 100%, respectively. Clinically affected pigs show cutaneous hyperexcitability, incoordination, hindlimb paralysis and convulsions. The CNS lesions include focal and diffuse gliosis, perivascular cuffing, glial and neural necrosis, and meningitis. Pigs injected intramusculary with live virus develop protective immunity. However, the infected nerves near the injection site have a decreased inner fiber diameter and myelin sheath disaggregation. The virus appears to reach the CNS in a retrograde fashion.

Porcine Circovirus Type 2 (PCV2). An outbreak of sudden death and acute nervous signs including paddling, tremors, and lateral recumbency occurred in all ages of pigs in one Canadian herd in 2004 (Youssef et al. 2004). PCV2 was identified by immunohistochemistry in the foci of inflammation of the brain and spinal cord in 7 of 10 pigs submitted to the diagnostic laboratory. However, the brain did not test positive for PCV2 by PCR. The tentative diagnosis was viral encephalomyelitis with a secondary bacterial infection due to *S. suis* (2 piglets), *S. equisimilis* (1 piglet) or *Actinobacillus pleuropneumoniae* (1 sow).

Hepatic Encephalopathy. Hepatic encephalopathy may have multifocal lesions in the central nervous system (CNS), but the clinical signs are primarily due to forebrain involvement. Hepatic encephalopathy occurs when neurotoxic substances build up in the bloodstream due to dysfunction of the liver. Clinical signs include blindness, ataxia, head pressing, seizures, and aggression. There will also be signs referable to liver disease, such as anorexia, weight loss, and diarrhea.

Cerebellum

The cerebellum controls unconscious proprioception; hence, dysfunction is seen clinically as truncal ataxia, broad-based stance, dysmetria (either hypermetria or hypometria), and an intention tremor (Kornegay and Seim 1996). Intention tremor is the involuntary trembling caused by intentional movement. Dysmetria is the improper measuring of distance in muscular acts, either overstepping (hypermetria) or underreaching (hypometria).

Cerebellar Hypoplasia. Cerebellar hypoplasia causes pigs to sit with their forelimbs extended or to assume a tripod sitting position. The clinical signs are nonprogressive and other CNS signs are not present.

Vestibular Disease

Vestibular disease is seen clinically as a head tilt involving a deviation of the head from a horizontal plane, or nystagmus, which is an involuntary oscillation of the eyes. Peripheral lesions are not associated with the ascending or descending tracts, so there is no paresis or conscious proprioceptive deficit, animals are not depressed, and nystagmus is always rotatory or horizontal with the fast phase opposite the head tilt and does not vary with head tilt. However, central lesions frequently cause depression, tetraparesis, and nystagmus that varies with head position and may cause other cranial nerve deficits. Most lesions cause ipsilateral clinical signs but the paradoxical vestibular disease causes contralateral signs.

Otitis Media. Otitis media (peripheral vestibular disease) is usually due to progressive external otitis (Kornegay and Seim 1996). The external ear is inflamed and contains debris, and the pig may be sensitive to manipulation of the ear. Vestibular disease causes a head tilt toward the affected side, horizontal nystagmus, and ataxia, which may include circling or falling. The animals remain bright and the appetite is normal (Buddle 1987). The condition is widespread but uncommon and sporadic. Treatment involves parenteral antibiotics and treatment of the primary external otitis.

Otitis media and interna may be common sequelae to *S. suis* infections. Most pigs (20) in a group of 28 diagnosed with meningitis due *S. suis* had either otitis media or interna (Madsen et al. 2001). Exudative otitis interna with a positive immunohistochemistry test for *S. suis* was found in 71% of the pigs. The scala tympani was affected in all of the pigs. Most of these pigs also had a perineuritis along the vestibulocochlear nerve. This nerve is likely a conduit to the CNS infection. Half of the pigs with both ears available for observation were affected bilaterally. This otitis interna can develop by the meningogenic and tympanogenic routes. A chronic, suppurative, otitis media was diagnosed in 34% of the pigs. Pigs recovering from *S. suis* meningitis may have residual

hearing and vestibular dysfunction due to chronic otitis interna.

Neuromuscular Diseases

Neuromuscular diseases diffusely involve muscles, neuromuscular junctions, peripheral nerves, or neurons. Clinically, neuromuscular diseases cause diffuse LMN dysfunction, including tetraparesis, hypo- or areflexia, a decrease in muscle tone, and, after a week, neurogenic muscle atrophy. Myopathies can be either inflammatory, infectious, immune-mediated, degenerative, acquired, or inherited.

Congenital Tremor. Congenital tremors (CT) (myoclonia congenita, trembles, jumpy pig disease) is a congenital abnormality caused by hypomyelination or demyelination of the brain and spinal cord. Unlike in splaylegged pigs where the deficit in myelin formation specifically affects the motor system, with CT there is an overall reduction of myelin in the spinal cord (Lamar and Van Sickle 1975).

Affected animals have a generalized tremor involving the entire body, especially the head and limbs (O'Hara and Shortridge 1966; Done 1968; Patterson and Done 1977; Edmonds et al. 1985). The tremor increases in intensity when the pigs are aroused and subsides when the pigs are sleeping (Done 1968). Pigs affected by CT have clonic contractions of the skeletal muscles. Posterior paresis and splayed hindlegs may occur with the tremor. The tremor can be distinguished from the primary head tremor due to cerebellar disease because the tremor becomes less pronounced at rest and more pronounced during excitement. The tremor is due to excessive irritability of the spinal reflexes.

In the Netherlands, CT affects 0.2% of pigs (Smidt 1972). An examination of 47,323 litters born to German Landrace boars from artificial insemination units showed that the frequency of congenital tremor was reduced by selection over a 14-year period (Beissner et al. 2003). The annual rate ranged from 0.23% to 0.01% but was 0.02% in 2000.

There are six categories of CT, which can be inherited or caused by viruses or toxins (refer to Table 5.8). These categories also differ by pathological lesion and prevalence within a herd. Types A and B are distinguished by morphologic changes. Type AI, caused by either the wild type or vaccine hog cholera virus produces hypoplasia, dysgenesis and cortical dysplasia of the cerebellum. The spinal cord is small and has half the normal compliment of myelin (Done 1976a). Both AI and AII produce a smaller white and gray matter areas in cross sections of the spinal cord (Done et al. 1984, 1986). In Type AII, there is significant demyelination, reduced spinal cord lipid content, and depressed and aberrant cerebroside synthesis. Type AIII causes a deficiency of oligodendrocytes with concomitant hypoplasia of the cord and reduced lipid and cellular content. Piglets in-

fected by the PR virus and born with CT have demyelination of the cerebellum. Type AV is caused by the ingestion of an antiparasitic drug, Neguvon (metrifonate, trichlorfon) by pregnant sows (Berge et al. 1987). This leads to cerebral, cerebellar, and spinal cord hypoplasia and demyelination and a decrease in the activity of neurotransmitter synthesizing enzymes.

Type AII is transmissible and is the most common form in North America. Typically other CNS functions, such as vision, reflexes, and pain, are normal; however, type AIV causes defective vision (Done 1968).

Hines and Lukert (1994) reproduced CT by inoculating sows with tissue culture fluid from the kidneys of affected pigs. They believed the piglets were infected with porcine circovirus and that this virus caused the deficient myelin. The four sows remained healthy but produced piglets with varying degrees of trembling. In the United States, PCV2 was believed to be associated with CT type AII in four Midwestern farms (Stevenson et al. 2001). The porcine circoviruses isolated from pigs with either clinical congenital tremors type AII or postweaning multisystemic wasting syndrome (PMWS) were examined to determine their genetic similarities (Choi et al. 2002). The samples each came from a different farm. The genomes of the viruses taken from CT and PMWS had 99% sequence identity with one another. Congenital tremors can also be caused by PCV1. This virus shares only 72% nucleotide sequence identity with the PCV2 that causes CT. PCV requires cell division. It is hypothesized that PCV can infect nervous tissues in the fetus only when neural cell division is occurring.

Clinical signs in affected pigs occur within hours of birth. The tremor may be fine or gross, producing twitching of the muscles of the neck and limbs that decreases when the pig is at rest and stops when the pig is sleeping. Pigs with fine tremor continue to walk and nurse. However, gross tremors will affect the ability of the pig to walk, nurse, and compete with littermates. Pigs born with CT may also exhibit splayleg. Mortality in these pigs is caused by starvation, hypothermia or crushing. In animals that survive, the severity of the tremors decrease over time and are usually resolved by 4 weeks of age. Gilt litters are more frequently affected than those of older sows because the females develop immunity to the infectious agents over time. Start-up gilt herds may experience an outbreak of the disease lasting 18 weeks.

Treatment for CT is aimed at reducing mortality. Affected pigs are to be provided with additional heat and assisted to feed. Control of CT depends on identifying and addressing the cause. For types AIII and AIV, eliminating genetic carriers from the herd is important. No affected pigs should be kept for breeding. For AV, trichlorfon is to be avoided in sows. All other types of CT will depend on disease control programs. This may include exposing open sows to the affected piglets so that transfer of infectious agents will occur. The herd is to be

considered infectious until there has been a 4-month period with no affected litters (Done 1976b).

A tremor similar to congenital tremor is seen in 3- to 6-month-old pigs (Gedde-Dahl and Standal 1970). Clinically the pigs have a tremor of the head and shoulder that varies in intensity but subsides when the pigs lie down. The problem clusters by litter and occurs more frequently in females. It is associated with high growth rates, lean carcasses, and pale-colored meat.

Seizures

Seizures are involuntary, paroxysmal brain disturbances clinically appearing as uncontrolled muscle activity (Kornegay and Seim 1996). Generalized seizures originate within the cerebral cortex, thalamus, or brain stem and are associated with symmetrical clinical dysfunction. Focal seizures lead to clinical signs that help localize the lesion. Temporolimbic seizures cause behavioral changes such as aggression or biting at the air. Focal motor seizures appear as tonic movements contralateral to the lesion and then within seconds spread to a generalized seizure. Seizures can be caused by encephalitis, neoplasia, or hydrocephalus. Most of the lesions are progressive and usually increase in frequency and severity. Toxins, such as organophosphate and chlorinated hydrocarbons, and internal toxicities, such as hepatic encephalopathy and hypoglycemia, can cause seizures.

Bacterial Meningitis. Bacterial meningitis may cause focal or diffuse CNS problems, which are progressive unless the affected pigs are treated. The problem is widespread, common but sporadic, with a low morbidity and high mortality. It can be associated with overcrowding and inadequate cleaning. Often the first symptom is sudden death. Affected pigs show depression, incoordination, hyperesthesia, tremor, circling, paresis, opisthotonos, recumbency, paddling, nystagmus, convulsions, and death. Postmortem lesions include congestion, edema, and purulent discharge of meninges.

Streptococcus suis. *Streptococcus suis* type 2 is one of the most common causes of meningitis. Additionally, this bacteria causes arthritis, septicemia with sudden death, endocarditis, polyserositis, and pneumonia in pigs (Reams et al. 1994; Madsen et al. 2002b). Of 42 pigs in one study, 27 had meningitis, 19 had polyserositis, 9 had polyarthritis, and 2 had endocarditis (Madsen et al. 2002b). Other lesions included hepatomegaly (17), bronchopneumonia (14), exudative otitis media (12) pleuritis (9), and pericarditis (4).

Clinically the animals exhibit depression, fever, anorexia, incoordination, paralysis, paddling, opisthotonos, tetanic spasms, and death (Buddle 1987). Infection with *S. suis* is widespread and common, often occurs 2 weeks after moving pigs, and is associated with overcrowding and poor ventilation. Affected pigs are

typically in the nursery phase but may range in age from 1 to 22 weeks (Madsen et al. 2002b).

Piglets acquire *S. suis* infection during farrowing from contact with the sow, her feces, and the environment (Gottschalk and Segura 2000). The pharyngeal and palatine tonsils, infected in 52% of the pigs, were the main portals of entry for the bacteria and then the bacteria appeared to spread via the lymph system because they were cultured from the lymph nodes of the upper respiratory tract (Madsen et al. 2002b). In pigs infected experimentally via aerosol, *S. suis* was isolated from the palatine and/or nasalpharyngeal tonsils of all pigs (Madsen et al. 2002a). In systemically infected pigs, the bacterium was also found in the mandibular lymph node. This suggests lymphogenous spread. Additionally, spread of *S. suis* appears to occur hematogenously from the palatine tonsils and intracellularly with the bacteria crossing the blood brain barrier. Bacteria can be found intracellularly in alveolar macrophages and tracheobronchial lymph nodes. The bacteria appear to invade the epithelium of the tonsils. Using porcine brain microvascular endothelial cells researchers have shown that *S. suis* can invade the cells that are component parts of the blood brain barrier (Vanier et al. 2004). This may explain the pathogenesis of meningitis. Interestingly, 7 hours after antibiotic treatment, intracellular viable *S. suis* were still found in porcine brain microvascular endothelial cells (Vanier et al. 2004).

S. suis diagnosis is enhanced by using bacterial culture in combination with immunohistochemistry (Madsen et al. 2002b). Culture rate is highest from the lateral cerebral ventricles or other parts of the brain. Half of the pigs are systemically infected with *S. suis*. The most prominent serotype of *S. suis* diagnosed from clinical cases changes by geographic region and time (Gottschalk and Segura 2000). In Canada, serotype 2 is diagnosed only 15% of the time, whereas in France it is the primary isolate 70% of the time. In Europe, serotypes 9 and 1 are most prominent after serotype 2 (Wisselink et al. 2002). Serotype 14 in the UK and serotypes 1/2 and 5 in Canada appear to be prominent causes of disease.

Effective vaccines against *S. suis* have not been produced because of the variation within and between serotypes and lack of knowledge of the virulence factors (Wisselink et al. 2002). Several types of vaccines have been used, but results have been inconsistent (Smith et al. 1999; Wisselink et al. 2002). (For more information, see Chapter 47.)

There is a high case fatality rate, but if treated early, pigs can recover with no residual clinical signs. Pigs should be removed from the group, put in a warm, dry environment, fed and watered by hand, and treated parenterally for 3–5 days. Of 689 isolates of *S. suis* from diagnostic laboratories and abattoirs in Japan, all were susceptible to amoxicillin and sulfamethoxazole plus trimethoprim (Kataoka et al. 2000). Most were suscepti-

Table 5.9. Infectious diseases causing neurological problems in preweaned pigs.

Disease	Clinical Signs	Epidemiology	Pathology
Bacterial meningitis	Sudden death, depression, fever, incoordination, hyperesthesia, tremor, circling, paresis, opisthotonos, recumbency, paddling, clonic convulsions	Sporadic but common, low morbidity, high case fatality, secondary to stresses such as overcrowding, continual-flow production, omphalitis	Congestion, edema, purulent exudate in meninges
Hemagglutinating encephalomyelitis (HEV)	4- to 7-day-old pigs, sudden-onset anorexia, depression, hyperesthesia, trembling, incoordination, progressive posterior paralysis, paddling, convulsions, coma and death within 10 days (vomiting, constipation, emaciation)	Virus widespread, rapid spread leads to herd immunity, 2–3 week outbreak, mortality 50–100% in affected litters	Pneumonia, conjunctivitis, corneal opacity
Tetanus	Ataxia progressing to stiff gait, muscle rigidity, erect ears, straight tail, lateral recumbency, opisthotonos, legs extended backward, death; loud noises cause tetanic spasms	Rare, associated with castration	No gross lesions
Toxoplasmosis	Neonates: diarrhea, dyspnea, cough, tremor, weakness, staggering, increased mortality; survivors exhibit ataxia and blindness	Infection might be common in certain areas, but symptoms are rare, associated with cats.	Serofibrinous exudate in cavities; small gray nodules in lungs, liver, spleen, lymph nodes, and fetal membranes; ulcers in small intestine
	Sows: stillbirths, fetal death, prolonged gestation	Infection might be common in certain areas, but symptoms are rare, associated with cats.	Serofibrinous exudate in cavities; small gray nodules in lungs, liver, spleen, lymph nodes, and fetal membranes; ulcers in small intestine

ble to penicillin G, ampicillin, and amoxicillin. Trimethoprim and sulfonamides penetrate the blood-CSF barrier. Penicillin, ampicillin, and cephalosporin will also penetrate the barrier in the presence of meningitis. Other infectious causes of neurologic problems in preweaned pigs are described in Table 5.9.

REPRODUCTIVE ANATOMY IN THE SOW

Development of the Ovaries and Uterus

Early studies indicated that embryonic gonad in the pig embryo is recognizable at 24–36 days postcoitum (PC) (Christenson et al. 1985). The ovaries of the fetal gilt develop from stromal tissue of the genital ridge and primordial germ cells that migrate to the genital ridge from the embryonic yolk sac. At approximately 31–32 days PC, the fetal gonad in female pigs is differentiated to an ovary with egg nests, which are clusters of primary oocytes within the stromal tissue. Meiosis is common in most ovaries by 50 days PC All germ cells are in egg nests until 60 days PC, at which time primordial follicles are observed (Oxender et al. 1979). Primordial follicles account for the majority of ovarian follicles from 95 days PC to 90 days after birth. Egg nests can still be seen in the gilt's ovaries at birth, and formation of follicles continues during the first few weeks after birth (Morbeck et al. 1992). Primary follicles first appear in the ovaries at 70 days PC and secondary follicles are observed about the time of birth. Tertiary (antral) follicles are rarely observed in pigs younger than 60 days of age; however, one or more tertiary follicles are observed in ovaries from pigs at 60–90 days of age (Oxender et al. 1979). As demonstrated by Greenwald (1978), the number of tertiary follicles peaks at 130 days of age, but most of them (67%) are atretic.

Perhaps the most appropriate summary of prepubertal development includes the following stages: the first stage of development from birth to 70 days, 70 days to 140 days, a variable time of resting stage from 20 weeks until puberty, and the changes associated with puberty (Dyck and Swierstra 1983). The first stage is typified by linear growth proportional to the age of the gilt. The second period commences with the appearance of tertiary follicles and an increase in ovarian and uterine weight relative to body weight. The third period or resting stage is characterized by minimal changes in ovarian follicles, ovarian weight, and uterine weight. Finally, the female pig undergoes significant physiological changes, such as preovulatory growth of follicles and increased oviduct and uterine weight, as the gilt approaches puberty.

Female differentiation of the genital ducts in pigs is comparable to most mammals. The cranial part of the Mullerian duct develops into the oviduct and the middle part develops into the uterus. The caudal part of the Mullerian duct and the urogenital sinus contribute to the vagina and vestibule. During the period from birth to 70 days of age, the uterine wall and endometrium increase in thickness, and the uterine glands commence differentiation. At birth, the uterus comprises three layers (luminal epithelium, stroma, and myometrium) with little organization. The change in the uterine wall thickness is attributed to the profound increase in the development of uterine glands and glandular epithelium and the organization of the myometrium into two layers. Furthermore, folding of endometrium also takes place during this period. It is generally accepted that uterine development during the first 2 months after birth does not require stimulation by ovarian steroids. Nevertheless, development can be altered by treatment of the neonatal gilt with estrogen (Bartol et al. 1993). At approximately 70 to 80 days, uterine growth accelerates. This accelerated growth continues until puberty when there is an abrupt increase in the size of the entire female reproductive tract. It is important to note that morphologic development of the uterine glands, endometrium, and myometrium essentially is complete by approximately 120 days of age even though puberty seldom occurs prior to 150 days.

Rearing Influences on Ovarian and Uterine Function

Numerous studies were conducted to examine the influence of rearing environment on the onset of puberty in

female pigs. Most reports focused on advancing the onset of puberty or, conversely, identifying factors that delay puberty. Growth rate and nutrition, genetics, boar exposure, management stimuli, social environment, and climatic environment clearly have the potential to influence the onset of puberty. With some notable exceptions, the studies infer that ovarian and/or uterine function was altered, based on the subsequent reproductive performance, i.e., litter size.

If one considers the three stages of prepubertal development prior to the onset of puberty, it should not be surprising that rearing conditions during the first few weeks after birth can have a permanent effect on the reproductive capacity of the mature gilt and sow. For example, litter size during the suckling period can influence the reproductive traits of pigs. Nelson and Robison (1976) used cross-fostering to rear full-sib gilts in litters of 6 or 14 until weaning at 8 weeks of age. Beyond 8 weeks, gilts were co-mingled and provided access to feed and water ad libitum. Age at puberty did not differ, but ovulation rate, number of embryos in first pregnancy, and number of pigs born alive in the first litter were greater in gilts reared in small than in those reared in large litters (Nelson and Robison 1976; van der Steen 1985). In addition, the administration of low levels of estrogen to gilts from birth to 13 days of age reduced the number of viable conceptuses and lowered embryonic survival, effects attributable to a dysfunctional uterus (Bartol et al. 1993).

Studies that examined the influence of rearing or social environment on puberty have provided controversial results. The number of gilts per pen and stocking density were shown to stimulate, impair, or have no effect on sexual maturation. However, rearing environment cannot be ignored—particularly, its effects on subsequent reproductive performance. This was exemplified when gilts between 2 (30 kg body weight (BW)) and 6 months (100 kg BW) of age were reared as full-sib gilts in low- or high-density pens (Kuhlers et al. 1985). There were no differences in growth rates; however, gilts reared in low-density pens had heavier pituitary glands, adrenal glands, brains, uteri and ovaries at 100 kg and delivered larger litters at first farrowing (Rahe et al. 1987).

Replacement gilts should receive optimal care during the entire prepubertal period, beginning at birth. Replacement gilts should be reared in smaller-sized litters and provided with an environment that encourages above average rate of gain. Replacement gilts should be reared in pens with lower densities.

Follicle Growth

Ovarian follicles undergo a gradual maturation in prenatal pigs during the later stages of gestation and the first few postnatal months. In fact, primordial and primary follicles comprise about 80% of ovarian structures in the pig at birth, but the ovary is unresponsive to gonadotropins as assessed by stimulation of follicle growth (Christenson et al. 1985). Tertiary follicles, capable of endocrine function are observed in the ovaries of gilts between 60–90 days after birth (Dyck and Swierstra 1983). These ovaries are responsive to gonadotropins with increased steroidogenesis and ovulation.

Activation and growth of primordial follicles occur continuously throughout the gilt or sow's life. Continual activation and growth are necessary because follicular development from the primordial stage to the ovulatory stage requires between 80 to 100 days (Morbeck et al. 1992). This 3-month development period is noteworthy and may provide an explanation, at least in part, of how certain factors influence follicle development and ovulation. For example, follicle growth was initiated 3 months prior to a gilt reaching puberty at 180 days of age. Similarly, a follicle that ovulates in a sow after weaning started to grow during the early to mid-trimester of preceding pregnancy.

The prolonged period of follicle growth has significant implications in reproductive management. Perhaps the best example of how management factors alter follicle growth is related to feed intake during lactation. It previously was demonstrated that feed restriction during lactation has detrimental effects on the postweaning performance of sows (Koketsu et al. 1996). Feed restriction during lactation increased weaning-to-estrus interval, impaired early follicle development, and decreased ovulation rate (Miller et al. 1996; Zak et al. 1997). Presumably, changes in metabolism affect follicular development and growth.

In fact, there is considerable evidence that nutritional and metabolic control of follicular growth is mediated by metabolic hormones and growth factors, particularly insulin-like growth factor I (IGF-I) and its binding proteins (IGFBPs) (Cox 1997). During the estrous cycle, the ovulatory population of follicles increases growth between about day 14 and day 16. Between day 16 and estrus, follicular atresia is the fate of approximately 50% of medium-sized follicles. The precise mechanisms that determine whether a follicle grows to an ovulatory diameter or undergoes atresia remain poorly understood; however, follicular atresia is considered a balance between "survival" and atretogenic factors. Factors that favor follicle survival include epidermal growth factor, nerve growth factor, IGF-I, gonadotropins, activin and estrogen, while atretogenic factors include testosterone, gonadotropin releasing hormone (GnRH), and interleukins (Hsueh et al. 1994). It is evident that follicular growth and development is a complex system involving numerous factors and hormones. In addition, the influences of nutritional and metabolic factors on the hypothalamus-hypophyseal-ovarian axis and gonadotropin release must also be considered as important factors in follicular growth (Kemp et al. 1995).

REPRODUCTIVE ENDOCRINOLOGY IN THE SOW

Endocrinology of Puberty

During the prenatal period, luteinizing hormone (LH) and follicle stimulating hormone (FSH) concentrations are low or undetectable before day 80 of gestation, and then acutely increase during the last weeks of gestation (Elsaesser et al. 1976; Colenbrander et al. 1982a). Similarly, estrogen concentrations are low at days 50–60 PC and increase significantly by day 75 (Ford et al. 1979). After birth, blood concentrations of steroids of placental origin decrease rapidly (Elsaesser and Foxcroft 1978). There is negligible secretion of estrogen by the ovary for 2–3 months after birth, and progesterone levels are low from birth to first ovulation (Esbenshade et al. 1982; Karlbom et al. 1982).

After birth, patterns of LH and FSH diverge. Serum concentrations of LH are highest around the time of birth and then decrease gradually, reaching a nadir during the second month of life (Camous et al. 1985; Grieger et al. 1986). In contrast, concentrations of FSH increase from the time of farrowing, plateau at approximately 8 weeks of age, and then gradually decline. A further reduction of FSH occurs near the end of the prepubertal period, coincident with growth of estrogen-secreting follicles.

Although spontaneous steroidogenesis appears to be minimal until just before puberty, the porcine ovary evidently is able to respond to gonadotropins. Using hourly injections of GnRH to stimulate LH release, Pressing et al. (1992) effectively mimicked a high-frequency pattern of LH secretion in gilts at 70, 100, 150, and 190 days of age. Follicular growth and ovulation was stimulated in all gilts 100 days of age or older and some gilts at 70 days of age. Consequently, it is apparent that the integration of the pituitary-ovarian axis is complete in the gilt between 70 and 100 days of age and that spontaneous activation of this axis requires a central signal for onset of puberty.

As puberty approaches, there is an increased pulsatile release of gonadotropins that stimulates the progressive development of ovarian follicles. The gonadotropins act to promote follicular development and consequently steroidogenesis. As the follicles develop, there is increased secretion of estrogen (Esbenshade et al. 1982; Karlbom et al. 1982; Camous et al. 1985). Estrogen peaks immediately prior to the pubertal estrus, which coincides with an increase in LH secretion, characterized by a change in pulse frequency and amplitude and the preovulatory surge of LH (Elsaesser and Foxcroft 1978; Lutz et al. 1984).

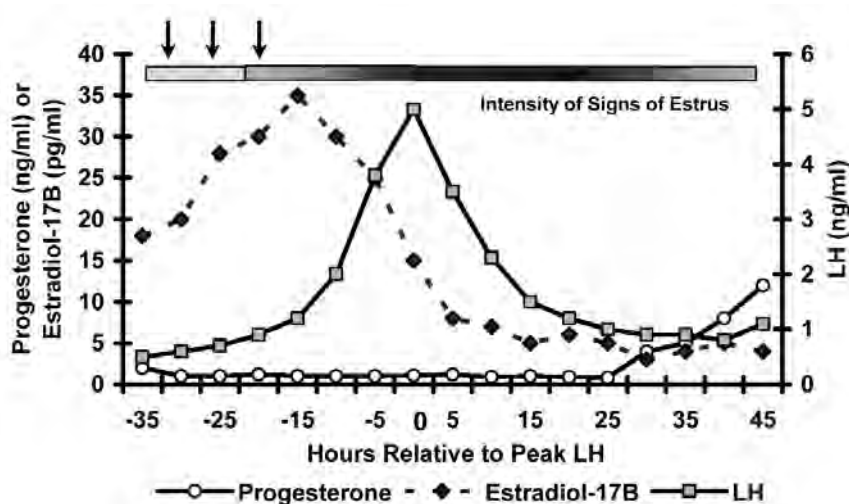
Endocrinology of the Estrous Cycle

Ovarian follicles, which are destined to ovulate, grow from approximately 4–5 mm in diameter on day 15 (day 0 = first day of standing estrus) of the estrous cycle to an ovulatory diameter of 8–12 mm (Figures 6.1A and 6.1B). The follicular phase begins when the corpora lutea (CL) regress and is associated with high-frequency, low-amplitude pulses of LH. The higher frequency pulses of LH contribute to maturation of the developing follicles, and there is an associated increase in estradiol and inhibin from these follicles. Estradiol and inhibin suppress FSH. Elevated estradiol acts at the hypothalamus to elicit a prolonged release of GnRH, which triggers the LH surge. In addition, estradiol contributes to estrous behavior and morphological changes in the reproductive tract. The LH surge is necessary to induce ovulation with the subsequent release of ova. Onset of estrus usually coincides with the preovulatory LH surge, and females may be sexually receptive for 1 to 3 days (Figure 6.2). As a general rule, female pigs ovulate at approximately two-thirds of the way through estrus (Soede et al. 1995).

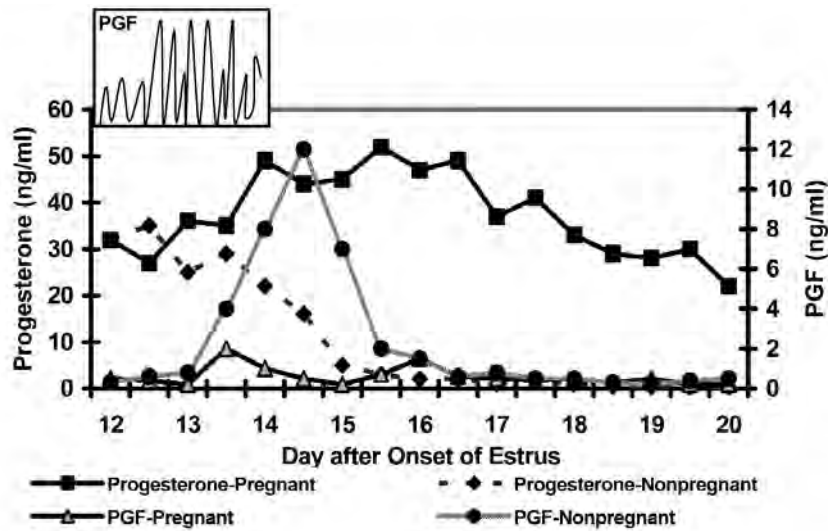
The follicular phase ends at the LH surge, because LH triggers biochemical changes in follicles, leading to a decrease in estradiol and inhibin and an increase in progesterone. After estrus, estradiol, inhibin, and progesterone are low and this leads to a postestrual surge of FSH. This postestrual surge of FSH may be important for promoting growth of follicles to develop for the next follicular phase. Following ovulation, collapsed follicles are 4–5 mm in diameter. Blood rapidly fills the central cavity of the follicles. These blood-filled structures are referred to as corpora hemorrhagica (CH; Figure 6.1C). Luteinization of the follicular remnants results in the formation of multiple CL. Luteinization is a rapid process and the early CL is capable of producing progesterone within a few hours after ovulation. The CL production of progesterone increases by 2–4 days after estrus and continues to increase until a maximum is achieved during mid-diestrus. By day 5–6, the CL have reached their mature diameter of 9–11 mm and the central cavities are completely replaced by luteal tissue (Figure 6.1D). Female pigs are not sexually receptive during these periods of progesterone production.

Failure to initiate pregnancy results in regression of the CL, a decline in serum progesterone concentrations and a return to estrus. Degeneration of the CL typically commences at approximately days 13–15, coinciding with increased concentrations of the luteolysin, prostaglandin-$F_{2\alpha}$ ($PGF_{2\alpha}$). Follicular recruitment begins on days 13–15 and follicles continue to enlarge concomitant with regression of the CL (Figure 6.1A). It is common to observe small follicles of less than 5 mm in the absence of CL in anestrous sows (Figure 6.1E).

Endocrinology of Pregnancy and Parturition

The CL lifespan is extended throughout pregnancy (Figure 6.1F) due to the maternal recognition of pregnancy (days 10–14 after ovulation and successful mating). Both maternal and conceptus factors play important roles in maternal recognition of pregnancy;
6.1. *Porcine ovaries. A) New follicles (arrow) commencing to develop among corpora lutea. The ovary was collected at approximately day 15–16 of the estrous cycle. B) Large, preovulatory follicles. C) Corpora hemorrhagica (CH). The CH form shortly after ovulation. D) Mature corpora lutea. The ovary was collected during diestrus. E) Ovary collected from an anestrous sow. Note the small follicles (<5 mm; arrow) and the absence of corpora lutea. F) Mature corpora lutea. The ovary was collected from a pregnant sow during midgestation.*


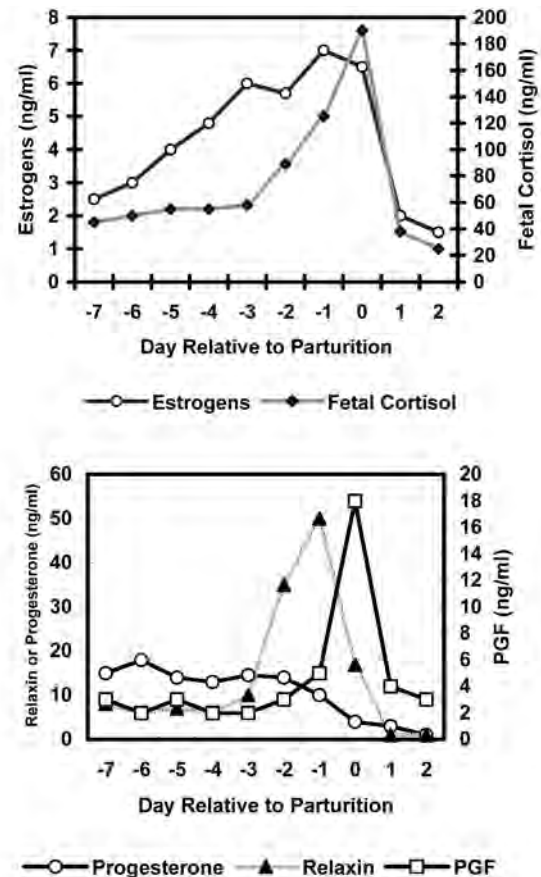
6.2. *Endocrine changes during the periestrous period relative to the peak LH concentrations. Peak LH concentrations typically coincide with the onset of standing estrus. The arrows indicate the period of proestrus, and the bar shows the intensity of signs indicative of estrus.*

however, estrogen, secreted by the conceptuses, may be considered the primary factor that triggers a series of events to maintain the CL of pregnancy. Maternal recognition of pregnancy occurs when developing conceptuses exert an effect that prevents luteolysis (Bazer 1989). In a nonpregnant pig, the uterine endometrium secretes $PGF_{2\alpha}$ in an endocrine fashion, resulting in an increase in the amount of $PGF_{2\alpha}$ reaching the ovary via the utero-ovarian vein and the uterine artery (Figure 6.3). In a pregnant pig, $PGF_{2\alpha}$ is secreted in an exocrine fashion into the uterine lumen rather than into the utero-ovarian vein. The transition from endocrine to exocrine secretion between day 10 and 12 of pregnancy coincides with the initiation of estrogen secretion by the pig conceptuses (Fisher et al. 1985). In addition, pregnant animals show an increase in secretion of PGE_2, a luteotropic prostaglandin produced by the endometrium or conceptuses. This shifts the ratio of luteotropic to luteolytic prostaglandins in a favorable direction for maintenance of CL function. Furthermore, maternal


6.3. *Changes in daily concentrations of progesterone and PGF in the utero-ovarian vein of pregnant and nonpregnant gilts (Adapted from Moeljono et al. 1977). The insert illustrates the "pulsatile" nature of the PGF release that is observed if frequent blood samples are collected.*

and conceptus-derived steroid hormones, growth factors, and cytokines, as well as integrins and their ligands, have interrelated roles in mediating adhesion between the conceptus and maternal uterine epithelium (Jaeger et al. 2001). These complex interactions between the conceptus and the uterus are critical to successful implantation in pigs.

Progesterone is required throughout pregnancy in the pig, and the primary source of progesterone is the CL. One corpus luteum is enough to maintain pregnancy, provided that the reduction in CL is done in a stepwise manner (Thomford et al. 1984). Ovariectomy, enucleation of CL or treatment with a luteolytic prostaglandin all cause abortion. The CL are autonomous for the first 2 weeks after estrus and thereafter require only basal LH support to continue to secrete progesterone (First and Bazer 1983). Progesterone concentrations in blood increase to peak values by day 12 after mating and remain elevated, thereby causing myometrial quiescence (Anderson 1987). Hypophyseal luteotropic support is required during most of pregnancy to sustain CL function. Plasma concentrations of estrone sulfate show a transient increase during the fourth week of pregnancy because of production of estrogens by the feto-placental unit. Estrogens then decline until about day 80 when unconjugated estrogens and estradiol-17β increase to peak values just prior to parturition.

As term approaches, a series of endocrine events (Figure 6.4), presumably initiated by the fetal pigs, lead to parturition. Fetuses initiate parturition through fetal pituitary release of adrenocorticotropic hormone (ACTH), which stimulates production of glucocorticoids by the fetal adrenal. Cortisol stimulates increased release of $PGF_{2\alpha}$ from the gravid uterus, which promotes luteolysis and thereby decreases concentrations of progesterone. This facilitates an increased frequency of uter-


6.4. *Endocrine changes associated with parturition in the female pig (adapted from First and Bosc 1979). Note that the decline in progesterone concentrations is not complete until 1–2 days after parturition.*

ine contractions and the initiation of parturition (First et al. 1982; First and Bazer 1983). The elevated $PGF_{2\alpha}$ concentrations also promote the release of relaxin from the CL and oxytocin from the neurohypophysis.

Relaxin and oxytocin are required for the relaxation of the cervix and promotion of myometrial activity, respectively.

Pseudopregnancy

Pseudopregnancy occurs when CL are maintained beyond the expected time of luteolysis in the absence of viable fetuses. Short pseudopregnancy has been defined as an interestrus interval of at least 3 days beyond normal for a gilt or sow with a minimum duration of at least 23 days (Pusateri et al. 1996). Long pseudopregnancy has been defined as an interestrus interval of more than 50 days. The extended interestrus interval is associated with an extension of luteal function because luteolysis is delayed.

Pseudopregnancy can be induced by treating gilts or sows with estrogen beginning on day 11 or 12 of an estrous cycle. Short-term treatment with estradiol (i.e., treatment on day 11 and 12) will induce short pseudopregnancy in most animals, but longer-term treatment (treatment for 8–9 days beginning on day 11 or 12) is required to induce consistent long pseudopregnancy. Gilts that consume moldy corn contaminated with *Fusarium roseum* that produces zearalenone may show either short or long pseudopregnancy.

Endocrinology of Lactation

Sows experience three reproductive phases after farrowing, namely, the hypergonadotropic phase, the transition phase, and the normalization phase (Britt 1996a). After parturition, the CL regress to form corpora albicantia (CA). The CA gradually regress during lactation and are less than 2 mm in diameter at the time of weaning. During the last few days of pregnancy, follicles develop on the ovary. These follicles initially are present in the first 1 or 2 days of lactation. This hypergonadotropic phase is associated with elevated LH and FSH concentrations, declining estrogens and progesterone (Sesti and Britt 1994) and large, preovulatory sized follicles. Due to suckling-induced inhibition of GnRH secretion and decreased LH and FSH, the large follicles regress within a few days after farrowing. Low levels of gonadotropins, minimal ovarian activity, and low concentrations of estradiol and progesterone characterize the transition phase from day 3 to 14 (Cox et al. 1988; Sesti and Britt 1994). Normalization occurs beyond day 14 when there is an increase in LH and FSH, number of medium and preovulatory sized follicles, and estradiol (Sesti and Britt 1993). Although suckling suppresses estrus by preventing release of GnRH from the hypothalamus, hourly pulses of GnRH will induce estrus and ovulation within 7 days. This attests to the central role the GnRH plays in regulating follicular growth and estrous cycles in both gilts and sows (Cox and Britt 1982).

The uterus is enlarged after farrowing, but involution during this period is rapid with remarkable decreases in weight and length in 2 to 3 days. During the transition phase, the uterus continues to undergo involution, with weight and length reaching a stable plateau by approximately day 14 (Varley 1982).

MANAGEMENT OF REPRODUCTIVE PROCESSES: DETECTION OF ESTRUS

Proestrual Changes

Estrus is the period of sexual receptivity during which sows and gilts display a characteristic pattern of both anatomical changes and behaviors culminating in the immobilization response or standing reflex. The first signs of approaching estrus are increased activity and vocalizations. Sows housed in crates commonly move backward and forward or from side to side within the crate and often attempt to nibble or nose females in adjacent crates. Sometimes these sows will paw at the front door of the crate and chant to animals in adjacent crates. In pens, characteristic activities include sniffing, nuzzling the rear and fore flanks, and attempting to mount or ride other females. Sows attempting to mount or actually riding other females may be either in estrus or approaching estrus.

Reddening and swelling of the vulva usually accompany or occur shortly after the increased activity. The change in size and color of the vulva is the result of an increase in blood flow and retention of fluids. As a result, the external lips of the vulva often are pushed outward exposing a portion of its highly vascular inner lining. Due to these changes, the opening to the vagina often appears to increase in size. In females that are not in heat, the external lips of the vulva are curled inward and block the opening to the vagina giving it a small, puckered appearance. The size and color change of the vulva are greatest just prior to when females will exhibit the immobilization reflex. Reddening and swelling of the vulva often do not appear to occur in older parity sows because the change in color and size are masked by the loose, flabby skin around the vulva caused by repeated deliveries.

The presence of a sticky discharge and enlargement of the clitoris usually occur immediately before and during the standing reflex. When females are in heat, the clitoris is engorged with blood, which causes it to protrude outward and have a bright red color. When females are not in heat, the clitoris is flat and has a pale, light pink color. To observe the clitoris, it is necessary to pull the external lips of the vulva apart and outward. This exposes the internal fold where the lips join and the clitoris is located. Mucus obtained from the inside lining of the vulva from sows that are not in heat has a slimy or slick feel. Just prior to the initiation of the standing reflex, the consistency of the mucus changes and becomes tacky or sticky. Assessment of the consistency of the mucus commonly is referred to as the "thumb check." The thumb check is performed by wiping the inside lining of the vulva with the thumb to ob-

tain a sample of mucus. Then, the thumb and first finger are pressed together and slowly pulled apart. The sample is considered sticky or tacky if small strands of mucus remain connected to both the thumb and pointer as they are drawn apart. In most cases, an engorged clitoris and sticky mucus are good indications that the female is in or within a few hours of exhibiting standing heat.

Standing Reflex

The standing reflex is the most common behavior associated with sexual receptivity and serves as the reference point upon which most breeding regimens are based. Duration of the standing reflex has been reported to be between 46 and 53 hours for sows and 36 and 48 hours for gilts (Signoret et al. 1972; Kemp and Soede 1996). The variation associated with these estimates is considerable, indicating that expression of the standing reflex is influenced by a number of environmental factors (Hemsworth and Barnett 1990). The successful expression and identification of the standing reflex depends upon interactions between internal and external stimuli. High concentrations of estradiol produced by preovulatory follicles are the internal stimuli, while pheromones produced by the boar serve as the external cues. Elevated estradiol levels invoke changes in the central nervous system that gives the female the ability to exhibit the standing reflex. However, it is the presence of the male pheromone, 5-alpha androsterone, that is believed to be the catalyst for the immobilization response (Hughes et al. 1990). Female pheromones may also be involved because the presence of estrual sows has been shown to stimulate and synchronize estrous behaviors in weaned sows and peripubertal gilts (Pearce and Pearce 1992).

The immobilization response requires a tremendous expenditure of energy because it involves the isometric contraction of most of the pig's skeletal muscle. This is why sows exhibiting the standing reflex often appear to quiver or tremble. Most females are only able to maintain this immobilized state for 15–30 minutes before muscles become fatigued (Levis and Hemsworth 1995). When this happens, females enter a period of refractoriness during which they are not able to exhibit a normal standing reflex. This phenomenon is called *habituation* and commonly occurs in situations where sows have continual, fence-line contact with boars. Habituation can be prevented and the standing reflex enhanced by providing short, daily periods of boar exposure or by physical separation of as little as 1 meter (Hemsworth and Barnett 1990).

Pheromones produced by boars are the most potent and effective inducer of the standing reflex in receptive females. Running a boar in front of sows in crates while a breeding technician applies back pressure is a common and effective method of estrous detection. Sows in heat will move forward and assume the standing reflex as the boar moves in front of the crate. When back pressure is applied, females that are truly in heat will actu-

ally push back—a natural response for a sow that is preparing to be mounted by the boar. Sows in crates are probably not in estrus if they try to move away from back pressure, even though they might show some other signs of estrus. In pens, sows will move to the front of the pen as the boar passes. If back pressure is applied and the sow is in heat, then she will exhibit the standing reflex. If back pressure is applied and the sow is not in heat, then she usually will run away from the back pressure. Estrous females housed in pens will sometimes attempt to follow the movement of a boar as he passes in front of their pen. This is due to the fact that sexually receptive females seek out males more so than males finding sows that are in heat.

Ovulatory Dynamics in Relation to Estrus

In general, ovulation in pigs begins 36–44 hours after the onset of estrus and lasts 1–3 hours. Most follicles (68–95%) appear to ovulate over a short period of time, while a minority ovulates over a longer interval. Nevertheless, onset and duration of ovulation are extremely variable within and among herds (Flowers and Esbenshade 1993). For example, in the study of Weitze and co-workers (1992), average duration from the onset of estrus to ovulation was 44.4 hours; but the means for animals in the first and fourth quartiles were 26.2 and 57.9 hours, respectively—a difference of 30 hours. Using real-time ultrasonography, Kemp and Soede (1996) demonstrated that most of the variation associated with the time of ovulation was due to differences in the duration of estrus.

They concluded that ovulation occurs when estrus is about 70% completed; thus, for a gilt that exhibits the standing reflex for 1 day, ovulation would be expected to begin about 17 hours after the onset of estrus, but for one that exhibits a 2-day estrus, ovulation would not begin until 34 hours after onset of estrus.

INSEMINATION

Timing and Frequency

From a physiological perspective, successful breeding regimens consistently create a situation in which an adequate number of viable spermatozoa are present in the oviduct prior to ovulation (Dziuk and Polge 1965). Thus, insemination must be coordinated with ovulation. This is usually accomplished by adjustment of the timing and frequency of matings based on the onset of estrus. However, relationships between ovulation and onset of estrus vary considerably within and among herds (Flowers and Esbenshade 1993). Consequently, reproductive performance could differ considerably among herds using identical mating regimens.

Kemp and Soede (1996) conducted a comprehensive evaluation of the relationship between timing of insemination relative to ovulation and fertility. Time of ovulation was monitored by realtime ultrasonography.

Results indicated that if a mating occurred 0–24 hours prior to ovulation, then fertilization rates were greater than 90%. The insemination dose used in the study was 3 billion spermatozoa that were 24 ± 6 hours old at artificial insemination (AI). Thus it appears that the minimum requirement for the timing and frequency of AI is one mating each day of estrus. Based on this information, one might question the importance of multiple matings within a 24-hour period. Although it is possible that two matings during the 24-hour period before ovulation might result in an improvement in fertilization rates, the 90% in the study of Kemp and Soede (1996) is generally accepted as being close to the maximal rate normally achieved in swine (Polge 1978).

Insemination Dose

Two aspects of insemination dose that affect fertility are the total number of viable spermatozoa and the total volume inseminated. The volume of the insemination dose is an important stimulus for activation of uterine smooth muscle activity, which is responsible for movement of spermatozoa from the site of deposition (cervix) to the site of fertilization (oviduct). Volumes of at least 60–80 ml appear to be required for optimal sperm transport (Baker et al. 1968). A positive relationship exists between number of sperm cells inseminated and number that enter the oviduct when insemination doses are between 1 and 8 billion (Baker et al. 1968). However, the effects of oviductal sperm numbers on litter size and farrowing rate have not been clearly established. Insemination doses between 2 and 5 billion spermatozoa are generally considered sufficient to ensure adequate fertility (Weitze 1991).

Breeding Technician

The technical competence of breeding technicians and reproductive performance within a herd often are assumed to be positively correlated; as the skill level increases, so do farrowing rates and litter size. Documentation that this assumption is true has been provided by two types of studies. In a survey of swine farms experiencing suboptimal reproduction in the southeastern United States, it was estimated that the main problem on 30% of these farms was associated with the skill level of the breeding technicians (Flowers 1996a). Poor detection of estrus was found to be the predominant problem rather than poor insemination or semen handling techniques. It is not appropriate to use these data from a retrospective study as evidence for a cause and effect relationship; however, a prospective study characterized AI breeding technicians within a single commercial swine operation (Flowers 1996a, b). In that study, matings administered by technicians occurred simultaneously within the same production environment. Thus observed differences were due to the influence of the breeding technician and not other confounding factors. Data from this study demonstrated two important con-

cepts: breeding technicians had a large influence on farrowing rates and litter size, and performance of breeding technicians did not remain constant over time. There was a 1036-pig difference in total pigs produced between the best and worst technicians based on 220 sows bred over 13 weeks. If this trend continued for an entire year in this herd, then there would be approximately a 4000-pig difference between the best and worst technician. Farrowing rates of sows supervised by 5 out of 6 technicians exhibited significant fluctuations during the 13-week study. These changes over time could be explained by environmental or animal factors that influenced the entire herd because farrowing rates for some individuals decreased and for others increased. Based on the magnitude of these changes, the ability to monitor reproductive performance of sows on a breeding technician basis would be of great value. However, to accomplish this, record keeping programs must include breeding technician as an independent variable and matings for a given female must be administered by the same individual.

CONTROL OF REPRODUCTIVE PROCESSES

Control of the onset of estrus has been approached along two lines: the induction of ovulation in acyclic, anovulatory females and the regulation of the luteal phase of the estrous cycle in cyclic, ovulatory pigs. The latter approach has utilized suppression of ovarian activity via the administration of oral-active progesterone or synthetic progestins. Presently, the most common exogenous hormone combination for induction of follicle growth and ovulation in acyclic females is a combination of 400 IU of equine chorionic gonadotropin (eCG) and 200 IU of human chorionic gonadotropin (hCG).

Induction and Synchronization of First Estrus in Gilts

To induce puberty successfully in a group of gilts, it is important to know the pubertal status of the group and the usual age of onset of puberty under the conditions on the specific farm. Gilts that are within approximately 1–2 months of natural onset of puberty will respond to treatment with gonadotropins by expressing estrus and continuing to cycle. If gilts are too young, they may express estrus, but then return to an anestrous state. If gilts have already cycled, they usually will not respond to gonadotropin treatment by showing estrus.

Puberty can be induced in gilts by treatment with a single injection of 400 IU of eCG and 200 IU of hCG. Gilts usually show estrus 3–6 days after treatment (Britt et al. 1989). The percentage of gilts that show estrus in a group may vary considerably, but most gilts ovulate even if they do not show estrus (Tilton et al. 1995). The response rate is enhanced if gilts are given daily boar stimulation by direct physical contact beginning at the time of treatment. Gilts respond best if they are held on the finishing floor until the time of injection and are

moved and injected on the same day. Failure to respond to this combination may be associated with treating gilts that have already reached puberty.

Synchronization of Second Estrus in Gilts

One can theoretically resynchronize second estrus in treated gilts by giving a luteolytic dose of $PGF_{2\alpha}$ approximately 18 days after the injection of 400 IU of eCG and 200 IU of hCG (Britt 1996b). Pig CL do not undergo luteolysis in response to a single standard luteolytic dose of $PGF_{2\alpha}$ during the first 12 days of the estrous cycle, but beyond the 12th day $PGF_{2\alpha}$ will induce luteolysis. If most gilts in a group are between day 12 and 17 of an estrous cycle, one should be able to synchronize estrus by giving a single injection of $PGF_{2\alpha}$. Most gilts should be beyond day 12 of an estrous cycle 18 days after injection of gonadotropins. If these gilts are given a luteolytic dose of $PGF_{2\alpha}$, their second estrus should be more synchronous than if they remained untreated.

Synchronization of Estrus in Pregnant Gilts

The porcine CL remain unresponsive to the acute administration of $PGF_{2\alpha}$ or its analogs until days 12 to 14 after ovulation. As the porcine CL typically commence natural regression due to endogenous prostaglandins at days 14–17, there is only a transient period when a single treatment with exogenous prostaglandins hastens the onset of estrus. Repeated $PGF_{2\alpha}$ injections between days 5 and 10 will reduce the duration of the estrous cycle; however, the labor and cost preclude this technique from practical application.

In contrast to the relative unresponsiveness of the CL to $PGF_{2\alpha}$ during diestrus, $PGF_{2\alpha}$ is effective for inducing luteolysis, abortion, and prompt return to estrus in pregnant (and pseudopregnant) gilts beyond the second week of pregnancy (Pressing et al. 1987). One method for synchronization is to penmate gilts for 3 weeks and then, treat with $PGF_{2\alpha}$ 2 weeks later (Britt 1996b). This technique is effective, but ages at first farrowing and nonproductive sow days are increased.

Synchronization of Estrus with Progestin

Cyclic gilts can be synchronized by administering a progestin for 14–18 days (Britt 1996b). The progestin inhibits follicular maturation and estrus while permitting the CL to regress naturally. When the progestin is withdrawn, follicles mature and estrus occurs beginning about 3 days later. Several studies demonstrated that feeding altrenogest at the rate of 15–20 mg per day was effective for synchronizing estrus, and subsequent litter size was normal or slightly increased (Davis et al. 1985). Treated gilts exhibit estrus 4–9 days after completion of a 14-day treatment period. The product is administered on an individual gilt basis by top-dressing the animal's daily feed allowance. It is critical that each gilt receives the recommended 15 mg each day, because underfeeding may lead to cystic ovarian degeneration.

Induction of Ovulation in Early Lactation in Sows

Initial studies demonstrated that ovulation was induced in about 75% of sows by giving hCG on the day of farrowing (Britt et al. 1997). These sows form CL that eventually regress spontaneously. If CL were induced by treatment with hCG on the day of farrowing, weaning could occur any time before day 21 but the sow would not be expected to be in heat until day 21 or slightly after. Furthermore, $PGF_{2\alpha}$ could be given after day 14–16 to induce premature luteolysis, and the sow should be in heat 3–5 days later. Despite initial success with this method of synchronization, subsequent reports indicated that the method did not have sufficient reliability for commercial sow farms (Kirkwood et al. 1999).

Induction of Estrus in Weaned Sows

Anestrus after weaning is more likely to occur during the summer and fall and is more common in primiparous than multiparous sows (Britt 1986). Incidence of anestrus can be reduced substantially by treating with gonadotropin at weaning (Bates et al. 1991); therefore, an effective strategy during periods when anestrus is likely to occur at a high rate is to treat sows at weaning with a combination of eCG and hCG. An alternative strategy to treatment of all sows in a group at weaning is selectively to treat those that have not returned to estrus by 7 days after weaning (Britt 1996a); however, there is little experimental evidence supporting the use of gonadotropins for this purpose (Tubbs et al. 1996).

Induction of Parturition

To synchronize farrowing, $PGF_{2\alpha}$ or an analog, is used to induce parturition (Table 6.1). Induction of farrowing creates an opportunity for producers to supervise parturition, reduce stillbirth rates, facilitate cross-fostering of piglets and to decrease variability of piglet weaning ages and lactation lengths. Exogenous $PGF_{2\alpha}$ typically is administered to sows after day 112 of gestation. Prostaglandin-induced farrowing prior to day 110 severely compromises piglet survivability. Some producers prefer to restrict prostaglandin injections to sows that exceed a 114-day or 115-day gestation. Other producers treat all sows with prostaglandin at a specific day (day 112 to 114) of gestation.

The duration of parturition, piglet viability and sow performance during lactation are similar following prostaglandin-induced farrowings and natural delivery (Einarsson et al. 1981; Dial et al. 1987). Prior to implementing an induction program and achieving favorable results, producers need accurate records regarding gestation length and a commitment to supervise farrowings and assist deliveries. The mean interval from $PGF_{2\alpha}$ injection to the onset of parturition was 29.5 hours with a range of 24–32 hours and considerable variation (Pressing 1992), which emphasizes the potential differences in response from farm to farm and from study to

Table 6.1.   Interval between oxytocin (OT) injection and onset of farrowing in sows treated with prostaglandin (PGF$_{2\alpha}$ 10 mg) on different days of gestation (adapted from Dial et al. 1987). The OT was given 20 hours after the PGF$_{2\alpha}$ injection. Numbers of interventions required during farrowing also are shown. Data are expressed as means ± SEM.

	Interval (h) from OT Injection to Farrowing				Interventions per Sow Days 112–114
	Gestation Day of PGF$_{2\alpha}$ Treatment				
OT Dose (Units)	112	113	114	112–114	
0	11.7 ± 2.8	9.2 ± 1.5	4.3 ± 0.7	8.5 ± 1.2	0.2 ± 0.1
5	14.0 ± 2.3	7.8 ± 2.2	4.3 ± 1.5	8.5 ± 1.5	0.5 ± 0.3
10	11.4 ± 4.1	8.3 ± 2.6	6.7 ± 2.0	8.4 ± 1.5	1.2 ± 0.5
20	11.4 ± 3.2	7.7 ± 2.1	8.0 ± 3.7	9.0 ± 1.5	0.5 ± 0.3
30	4.8 ± 1.4	4.6 ± 1.8	3.5 ± 1.8	4.4 ± 1.1	1.9 ± 0.6

study. The interval from injection to parturition tends to be less with cloprostenol, a PGF$_{2\alpha}$ analog (Pressing 1992); however, in some countries, only the natural prostaglandin is approved for use in swine. The side effects of prostaglandin-induced farrowing include hyperpnea, and increased salivation, urination, and defecation within minutes after injection. Nest-building, rooting, pawing, and bar biting are often evident but subside within 2 hours.

Initial investigations used intramuscular injections of either PGF$_{2\alpha}$ (10 mg) or cloprostenol (175 μg). Subsequent studies demonstrated that the dose could be reduced to 5 mg and 87.5 μg, respectively, with vulvomucosal injections (Friendship et al. 1990). The interval from injection to parturition was similar to the intramuscular injection; however, the undesirable side effects were reduced.

Prostaglandin and Oxytocin Combination.   It was proposed that an injection of oxytocin at 20–24 hours after the initial prostaglandin injection would improve synchrony of farrowing during working hours. Treatment with 20–30 IU of oxytocin induced earlier parturition in a larger proportion of sows than 5–10 IU of oxytocin (Table 6.1). The high doses were associated with frequent interruptions of piglet deliveries and dystocia (Dial et al. 1987). With 5–10 IU of oxytocin, few complications occurred during delivery; however, less than 90% of treated animals were induced to farrow during the working day. Thus the low doses of oxytocin cause few problems with parturition; yet they fail to improve the synchrony of parturition, which in turn diminishes the opportunity for supervised farrowings. Clinical reports indicate that vulvomucosal injection of 5 IU of oxytocin is sufficient to induce farrowing without complications.

Other Products.   Carazolol, epostane, and clenbuterol were shown to be efficacious in the control of parturition. None of these agents are licensed for use in swine in the U.S. Carazolol, a ß$_{1,2}$-adrenergic blocking agent,

when used in combination with prostaglandins, improved synchronization of farrowing. Carazolol (3 mg/sow), given 20 hours after prostaglandin administration, induced labor within 3 hours, shortened the duration of parturition and did not create adverse side effects (Holtz et al. 1990). This agent also may be used alone (1 mg/100 kg body weight) at the onset of labor to reduce the duration of parturition (Bostedt and Rudloff 1983).

Epostane, a competitive inhibitor of 3ß-hydroxysteroid dehydrogenase, was shown to decrease peripheral levels of progesterone and induce sows to farrow (Martin et al. 1987). The interval from oral administration of 5 and 10 mg/kg body weight to the birth of the first piglet was 31 and 33 hours, respectively. There were no adverse effects reported with epostane-induced farrowings.

Tocolytic agents are used to inhibit rather than hasten the onset of labor. The tocolytic effects of clenbuterol result from its ß$_2$-adrenergic properties. Intravenous or intramuscular administration of clenbuterol (150 μg/sow) during the onset of labor, but before delivery of the first pig, delayed parturition by 15 hours (Zerobin and Kundig 1980). The use of clenbuterol after delivery of one to three piglets interrupted parturition for 3 hours. Detrimental effects were not observed with this dose of clenbuterol; however, repeated, higher doses (300 μg every 6 hours) increased stillbirth rate.

Induction of Abortion

Prostaglandins are effective abortifacients (≥12–14 days after mating) in sows and most sows return to a fertile estrus following the termination of pregnancy (Guthrie and Polge 1978; Pressing et al. 1987). In addition, administration of exogenous PGF$_{2\alpha}$ is luteolytic in pseudopregnant pigs (Smith et al. 1992) and will induce parturition in sows that are carrying mummified fetuses (Hermansson et al. 1981). Both PGF$_{2\alpha}$ (10–15 mg) and cloprostenol (175–500 μg), given once or twice at a 24-hour interval, effectively terminate pregnancy and pseudopregnancy.

PREGNANCY DETECTION

Most pork producers consider pregnancy detection essential to the reproductive efficiency of the sow herd. An ideal pregnancy detection method would have 100% sensitivity and specificity. Testing would take a few seconds per animal and the method would be simple enough that training would be minimal. This "ideal" method would predict pregnancy status prior to the return to estrus at 17–24 days postmating (Almond and Dial 1987). Because an ideal technique is not available, producers rely on one or more techniques for pregnancy diagnosis.

Detection of Estrus

The most common pregnancy detection technique is based on the premise that nonpregnant sows will return to estrus within 17–24 days after breeding. Detection of estrus is improved if the sow's behavior is observed in the presence of a boar, particularly when there is physical contact between the boar and female. The overall accuracy of this technique ranged from 39% (Bosc et al. 1975) to 98% (Almond and Dial 1986). Field reports indicate that most producers identify approximately 50% of nonconceiving sows using this technique. False-positive diagnoses occur when sows are persistently anestrus due to cystic ovarian degeneration (COD), acyclic ovaries, or becoming pseudopregnant. Management factors that interfere with the detection of estrus include housing submissive sows in groups with dominant sows, attempting to detect estrous females in large groups, and assessing estrus without using boar exposure.

Hormone Concentrations

Serum concentrations of progesterone and estrone sulfate were used as indicators of pregnancy. Hormone concentrations are dynamic and collection of samples is restricted to discrete periods during pregnancy.

Progesterone. Regression of the CL typically commences prior to day 15 of the estrous cycle. Following maternal recognition of pregnancy, serum progesterone concentrations are usually greater than 5 ng/ml throughout pregnancy. Thus, serum concentrations of progesterone are high in pregnant sows and gilts during the expected time of return to estrus and low (<5 ng/ml) in sows and gilts that failed to conceive (Ellendorf et al. 1976). The interestrus interval of sows of varying parities ranges from 17 to 24 days, with a mean of 20 to 21 days (Andersson and Einarsson 1980). Therefore, the optimal time to obtain blood samples for progesterone determinations is from 17 to 20 days after mating (Almond and Dial 1987). Using serum progesterone concentrations for pregnancy diagnosis, a sensitivity of more than 97% was achieved, but specificity ranged from 60 to 90% (Larsson et al. 1975; Almond and Dial 1986). False-positive tests occur in animals with delayed or irregular

returns to estrus, pseudopregnancies, and COD. False-negative tests may result from laboratory error since it is assumed that ≥ 5 ng progesterone/ml serum are required for pregnancy maintenance in swine (Ellicott and Dziuk 1973).

Commercial enzyme-linked immunosorbent assays are available for on farm applications, which reduce the need of laboratory-based radioimmunoassays (Glossop et al. 1989). The necessity of collecting blood is a significant limitation of this method; however, enzyme immunoreactive assays (Sanders et al. 1994) and radioimmunoassays were developed for assessing fecal progesterone concentrations. Despite potential applications for these fecal tests, their utility has yet to be determined on commercial farms.

Estrone Sulfate. A high proportion of fetal estrogens is secreted from the uterus into the maternal circulation as estrone sulfate (Robertson et al. 1985). Serum estrone sulfate concentrations cannot be reliably determined until peak levels are reached between 25 and 30 days of gestation (Robertson et al. 1978). At 35 to 45 days, the concentrations decrease to a nadir (Guthrie and Deaver 1979), with a second increase commencing at 70 to 80 days.

Serum estrone sulfate concentrations of >0.5 ng/ml are indicative of pregnancy, whereas <0.5 ng/ml are suggestive of nonpregnant status (Cunningham 1982; Almond and Dial 1986). Using estrone sulfate as a pregnancy test, >97% sensitivity and >88% specificity were obtained when samples were collected between 25 and 30 days of pregnancy (Almond and Dial 1986). False-negative results were obtained in sows or gilts with a delayed rise in estrone sulfate concentrations (Cunningham et al. 1983) or when sows and gilts have less than four pigs in a litter (Almond and Dial 1986). Urinary concentrations of estrone conjugates also were used to predict pregnancy and to diagnose fertility problems (Seren et al. 1983); however, this technique was not developed for commercial application. Quantitative commercial assay kits for the determination of estrone sulfate concentrations in serum or feces from swine are not available. The need to collect blood samples limits the practical application of this technique.

Prostaglandin-F$_{2\alpha}$. The prostaglandin pregnancy test was based on the principles that if serum concentrations of PGF$_{2\alpha}$ are low (<200 pg/ml) or undetectable between days 13 and 15 after mating, the sow can be assumed to be pregnant. The prostaglandin pregnancy test had approximately 90% sensitivity and 70% specificity (Bosc et al. 1975). This method can be conducted during early pregnancy, but it is unreliable for detecting open animals and requires extensive laboratory procedures.

Rectal Palpation

Pregnancy diagnosis by rectal palpation of the sow is practical and highly accurate (Cameron 1977). Sows are

examined while standing in gestation crates or pens or while tethered. This technique is based on examination of the cervix and uterus, together with palpation of the middle uterine artery to assess size, degree of tone, and type of pulse. The pelvic canal and rectum are often too small for the procedure to be used on gilts or low parity sows. Despite the potential application of this technique, it has not gained popularity in North America.

Ultrasound Techniques

Doppler Ultrasound. Doppler instruments detect fetal heartbeats or the pulsation of arteries. Approximately 50–100 pulses/minute are detected in the uterine artery, while 150–250 pulses/minute are evident in the umbilical arteries (Swensson 1978). The abdominal probe is positioned on the flank of the animal, lateral to the nipples, and aimed at the sow's pelvis area. The ultrasound waves are emitted and received by transducers and are converted to audible signals. The rectal probe functions similarly, with the exception of the positioning of the transducer. Sensitivity (>85%) and specificity (>95%) did not differ between the rectal and abdominal probes (McCaughey and Rea 1979; Almond and Dial 1986). Optimal results were obtained at 29–34 days (Almond et al. 1985). False-positive results may occur when sows are tested during proestrus or estrus or when animals have active endometritis. False-negative diagnoses occur when examinations are conducted in a noisy environment or if feces become packed around the rectal probe.

Amplitude-Depth (A-mode or Pulse Echo) Ultrasound. Amplitude-depth instruments use ultrasound waves to detect the fluid-filled uterus (Lindahl et al. 1975). From approximately 30 days until 75 days after breeding, the overall accuracy in the determination of pregnancy was commonly >95% (Holtz 1982; Almond et al. 1985). False-negative and uncertain determinations increase from 75 days until farrowing, due to changes in the allantoic fluids and fetal growth. The sensitivity and specificity vary between the different models of amplitude depth instruments (Almond and Dial 1986). Detection of a fluid-filled urinary bladder, pyometra or endometrial edema yields a false-positive test. False-negative results were noted when animals were examined before 28 days of gestation or after day 80 (Holtz 1982).

Real-Time Ultrasonography. Results of initial studies clearly indicated that real-time ultrasonography (RTU) possessed potential for early and accurate pregnancy diagnosis in sows and gilts (Inaba et al. 1983; Jackson 1986). The transducer of RTU probe is placed against the flank of the animal, and the positioning is similar to other pregnancy detection devices. The probe is directed toward the back of the animal, allowing the ultrasound waves to pass through the uterus before returning back to the transducer. Pregnancy is based on the detection
6.5. *These figures illustrate the images observed with real-time ultrasound (linear, 5 mHz probe) at day 21 in a nonpregnant sow (A) and at days 21 (B), 23 (C), and 35 (D) of pregnancy. The circular, black structures, shown with white arrows, are cross-sections of the fluid-filled uterus. A fetus (arrowhead) is evident in the day 35 image.*

of distinct, fluid-filled vesicles in the reproductive tract (Figure 6.5).

For various reasons, such as the purchase price of an instrument, producers and veterinarians were reluctant to use RTU in commercial sow farms. However, the trend to larger sow farms and the decrease in purchase price created opportunities for RTU as a routine pregnancy detection method. On day 21 of gestation, the overall accuracy was 90% and 96% for the 3.5 and 5 mHz probes, respectively (Armstrong et al. 1997). The 5 mHz probe had a greater specificity than the 3.5 mHz probe. It also was evident that technician, day of gestation, instrument, and probe (3.5 vs. 5 mHz and linear vs. sector) influenced the accuracy of RTU. These sources of variation have much less impact when RTU is used at day 28, rather than day 21.

Conclusions. Amplitude depth (a-mode) and doppler instruments typically are used after 30 days postmating and require multiple tests to improve accuracy. Both instruments are inexpensive and neither requires extensive training; however, numerous causes of false-

positive and false-negative tests exist with either instrument. Tests for serum progesterone or estrone sulfate require blood samples at specific days of pregnancy. To eliminate blood collection, assay procedures were developed to determine progesterone concentrations in fresh fecal samples. ELISA tests for progesterone concentrations diminished the need for extensive laboratory facilities; however, few producers can justify the time to collect and process samples, and the complexity of these tests preclude their routine use on commercial farms. Rectal palpation is inexpensive, but offers few other advantages over a-mode or doppler instruments, and has not gained popularity in the U.S..

Presently, detection of nonconceiving sows that return to estrus and ultrasound are the most widely used techniques for pregnancy diagnosis. Despite routine use of these traditional methods, many sows either fail to farrow after being considered pregnant or return to estrus at irregular times during a presumed pregnancy. Success of a pregnancy detection program originates from the personnel implementing the program. The most promising technique is RTU; however, cost of the instrument and other factors might interfere with its widespread acceptance by commercial pig producers.

PROBLEMS AT FARROWING

Dystocia

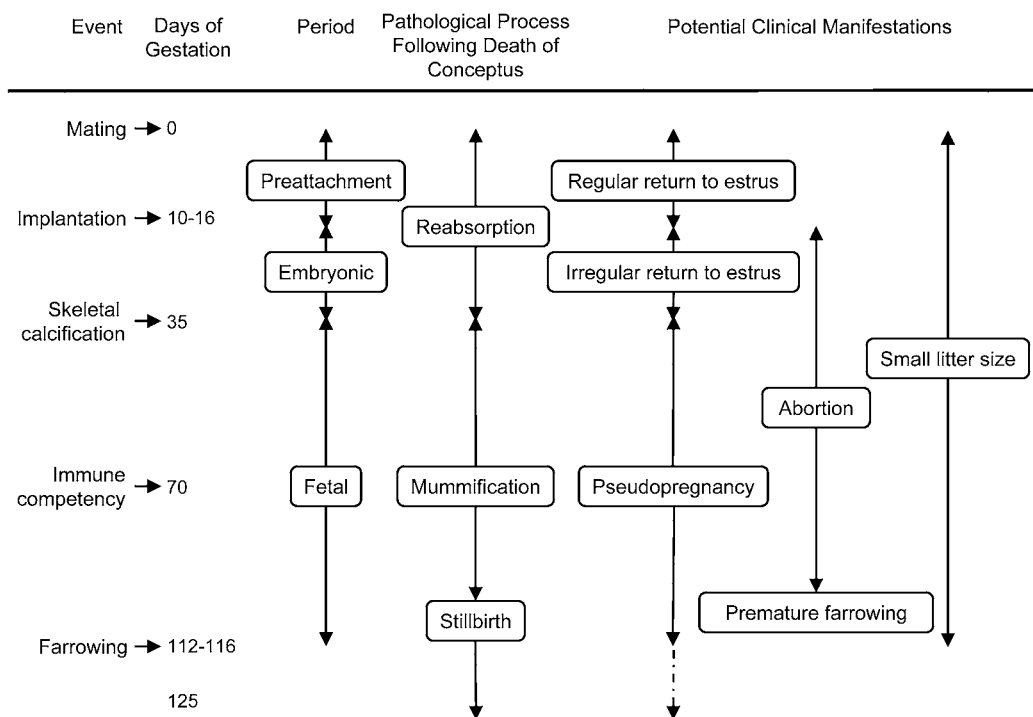
Dystocia along with several other problems that can lead to difficult farrowing (e.g., downer sow) are relatively frequent in sows. Knowledge of the normal process of parturition is essential to determine when there is a need to intervene. Swelling of the vulval lips occurs about 4 days prepartum. The mammary glands become more turbid and tense during the last 2 days before farrowing, with the mammary secretion being serous 48 hours prior to parturition and becoming milky within 24 hours of farrowing. Restlessness and nesting behavior usually start in the 24 hours prefarrowing but recede in the last hour before the first piglet. Intermittent abdominal straining occurs before the birth of the first piglet, but straining is usually mild thereafter except at the moment of expulsion. Farrowing is expected within 20 minutes when a viscid, blood-tinged secretion often containing meconium is observed at the vulva. Duration of parturition is usually less than 3 hours but ranges from 30 minutes to more than 10 hours, with an interval between the birth of piglets averaging 15–20 minutes. Fetal membranes are expulsed in general 4 hours after the birth of the last piglet, from 20 minutes to $12^1/_2$ hours.

Signs of dystocia are anorexia, blood-tinged vulvar discharges, meconium without straining, straining without delivery of piglets, cessation of labor after straining, and the delivery of one or more piglets, exhaustion of the sow, and foul-smelling and discolored vulvar discharge. Primary uterine inertia associated with a decreased contractile activity of the myometrium is uncommon in sows, whereas secondary uterine inertia is much more frequent and results from uterine and maternal exhaustion associated with fetal malpresentation or maternal obstruction. The causes of dystocia are classified into two categories, maternal and fetal dystocia, depending on the origin. Arthur et al. (1989) have reported the following causes of dystocia: uterine inertia without significant cause (37%), breech presentation (14.5%), obstruction of the birth canal (13%), simultaneous presentation of two fetuses (10%), downward deviation of the uterus (9%), and oversized fetuses (4%). In modern sow herds, dystocia may also occur as a result of the use of prostaglandin and oxytocin to induce or control farrowing.

To correct dystocia, farm personnel must act in a timely fashion, since delayed or premature pharmacological or manual intervention may result in piglet death, decreased piglet viability, localized or systemic infections in the sow, or death of the sow. A 20% stillbirth rate is often associated with dystocia. To optimize the success of intervention, sows should be observed at 30-minute intervals once parturition has commenced. At each observation the number of piglets born and the time can be recorded to better assess the interval between the birth of piglets.

Correction of dystocia is achieved by manual examination of the vagina and cervix and removal of the obstruction or malpresented fetuses. Strict hygiene is required and the use of obstetrical gloves and lubricant is recommended. Manual extraction is usually the safest technique to extract fetuses. Caution must be exercised when using forceps, blunt hooks, or cable snares, due to the risk of trauma to the sow's reproductive tract. After removal of the malpresented pigs, the birth canal should be reexamined prior to the administration of oxytocin. High doses (>20 IU) of oxytocin may create a refractory period (3 hours) in which endogenous and exogenous oxytocin fails to stimulate contractions (Einarsson et al. 1975). Injectable antibiotics are warranted if sufficient contamination occurs. Intrauterine infusions of antibiotics or iodine solutions are usually not effective in promoting uterine involution or preventing uterine infections.

Injuries Incidental to Parturition

Hemorrhage may occur postpartum as a result of uterine, vaginal, or vulvar lacerations. Lacerations of the vagina and vulva can be sutured externally, whereas severe uterine lacerations or uterine ruptures are difficult to repair without conducting a laparotomy. The economics of this latter procedure must therefore be considered. Oxytocin treatment promotes uterine contractions and may be beneficial with minor uterine lacerations. Hematomas of the vulva are resolved as the blood and the fluid are resorbed; however, sharp projec-


6.6. *Pathological reactions to disease agents according to the stage of reproductive cycle and the associated clinical manifestations.*

tions in farrowing crates increase the danger of lacerating the hematomas.

Vaginal and Uterine Prolapse

Prolapse is often seen shortly before, during or up to several days after farrowing. Factors that have been reported to increase the risk of vaginal or uterine prolapse in sows are genetics, housing, physical trauma to the genital tract following parturition, older parity, and nutrition. The procedures for correction of uterine prolapse are described in Chapter 70.

REPRODUCTIVE FAILURE

Pathological Processes

Diseases can exert their effect on the reproductive system through the general systemic effect on the dam or by infection of the conceptuses or the genital tract. The pathological reactions to disease agents depend on the type of agent and on the stage of reproductive cycle of the animal. The clinical manifestations will vary accordingly, as exemplified in Figure 6.6.

Death of the embryos before implantation, which occurs between 10 to 16 days postcoitus, results in reabsorption of conceptuses and a regular return to estrus for the sow. Four embryos are required at nidation for pregnancy to be initiated otherwise the sow will resume her cyclicity and a regular return to estrus will be observed (Dziuk 1985). Embryos are also reabsorbed when death occurs between 14 to 35 days of gestation. The sow will

have an irregular return to estrus if most of the conceptuses die or will farrow a small litter when only a proportion of embryos dies. The fetal period in swine begins at the onset of skeletal calcification at around 35 days of gestation and continues to parturition. Death of the fetus is followed by mummification or by stillbirth when it occurs in late gestation. Mummies are fetuses that have died in utero and have begun to decompose. Stillbirth results from the expulsion of dead fetus at an age when they could normally survive without undue assistance. Survival before day 109 of gestational age is limited because lung maturation has not been completed by this age. Stillborn pigs die either prepartum or intrapartum and are grossly normal at birth. In a large proportion of the deaths classified as intrapartum, the pigs were actually alive at birth. In true stillborn pigs, lungs will not float when immersed in water.

A combination of mummies and stillborn pigs of variable size is observed when fetuses die at different times of gestation. This is often the consequence of a progressive intrauterine spread of an infectious agent, such as porcine parvovirus. Sows with mummies and stillborn pigs may farrow at the expected time or experience pseudopregnancy when all conceptuses die if they fail to return to normal ovarian cyclicity due to the persistence of the pregnancy CL.

Abortion results from the termination of the pregnancy control mechanisms with subsequent expulsion of all conceptuses. Aborted sows return to estrus within 5–10 days or experience a prolonged anestrus. Abortion

may occur from day 14 throughout gestation and is associated with maternal or embryonic/fetal failure. In abortion due to maternal failure fetuses are generally all of the same age. Fetal age beyond 35 days can be estimated using the crown-rump length in the following formula, where *X* is the crown-rump length in cm (Ullrey et al. 1965):

Fetal age in days = 21.07 + 3.11X

Premature farrowing is associated with a high proportion of stillborn and low viability piglets.

Failure to conceive or to initiate and maintain a pregnancy will be expressed as regular or irregular return to estrus, abortion, or pseudopregnancy, all of which may manifest as a lower farrowing rate at the herd level. The specific problems need to be characterized because influencing factors might be different accordingly. Thus it is essential to have an efficient pregnancy detection program to determine as quickly and accurately as possible the reproductive status of the sows.

Several etiologic agents have been associated with abortion, mummification, stillbirth, birth of weak piglets, and decreased farrowing rate.

Infectious Agents

Bacterial reproductive pathogens that can exert an effect on the reproductive tract of pigs include *Brucella suis*, *Leptospira* sp., and *Chlamydia* sp. Mummification is generally not a feature of reproductive bacterial diseases. *Brucella suis* is a primary agent causing abortion at any time of gestation and birth of weak piglets. Early abortions are probably a reflection of exposure via the genital tract at breeding. *Brucella suis* causes severe placentitis and genital infection.

Late-term abortions observed with several serovars of *Leptospira interrogans* result from transplacental infection of fetuses following leptospiremia. Aborted pigs are usually all of the same age although horizontal transmission in utero has been suggested (Fennestad and Borg-Petersen 1966). Some fetuses may be born alive but weak; others are stillborn. Gross lesions in aborted fetuses are usually nonspecific. Histological examination may reveal several spirochetes in the placenta and fetal tissues, namely kidneys. The pathogenesis of infection by *Leptospira* serovar *bratislava* seems to be different. This leptospire causes uterine infection and thus is associated with low conception rate and return to estrus. It is hypothesized that abortion caused by this pathogen is a consequence of transplacental infection by leptospires present in the genital tract rather than following leptospiremia (Ellis et al. 1986). Sow infertility is a common feature in infection by *Leptospira* serovar *bratislava* (Van Til and Dohoo 1991).

Although *Chlamydia* sp. have been associated with late-term abortion and birth of dead or weak pigs, clinically inapparent infection is much more common (Eggemann et al. 2000; Vanrompay et al. 2004).

The role of eperythrozoonosis (*Mycoplasma suis* or *haemosuis*) in reproductive disease is controversial. Some authors have reported anestrus, irregular estrous cycles, abortion, small litters, and stillbirth in seropositive herds (Sisk et al. 1980; Brownback 1981), whereas others did not observe any difference in reproductive parameters between infected and noninfected sows (Zinn et al. 1983).

Several other bacterial diseases—erysipelas, listeriosis, infection with *Actinobacillus pleuropneumoniae*, *Actinobacillus suis*, *Haemophilus parasuis*, and *Lawsonia intracellularis*—induce abortion either through the general effect of fever or by infecting the conceptus. Conceptuses are usually all of the same age and do not show significant lesions. Localized bacterial infection of the genital tract may also interfere with fertilization and viability of gametes, often resulting in regular return to estrus. Several bacterial species have been isolated from infected uteri (see section on vulvar discharge).

Porcine parvovirus is ubiquitous, and infection is enzootic in most swine herds. Outbreaks may occasionally be observed in newly populated herds with several naive animals. Parvovirus has a direct effect on the conceptus by damaging the placenta and a variety of tissues. Tranplacental infection occurs with further intrauterine spread of the virus. Porcine parvovirus infection is characterized by mummified fetuses of different ages, increased returns to estrus, and small litter size, but abortion is unlikely (Mengeling et al. 2000).

The porcine reproductive and respiratory syndrome (PRRS) virus causes abortion at any time of the gestation period, although transplacental infection was initially reported to occur more frequently in the last trimester, resulting in late-term abortions and premature farrowings. Despite lesions observed in the uterus, the precise mechanisms of abortion are still unclear. It may result from the effects of acute illness and fever and from infection of fetuses. It is also suggested that fetuses may die from hypoxia due to arteritis in the umbilical vessels (Lager and Halbur 1996). A combination of mummies, stillborn, and weak piglets is characteristic of PRRS virus infection. They usually occur sequentially within a herd according to the time of infection of the dams.

Exposure to pseudorabies virus during pregnancy may result in reproductive failure. The virus crosses the placenta and infects and kills embryos and fetuses. It also induces infection with lesions in uterus, placenta, and ovaries (Bolin et al. 1985). Lesions in fetuses are characterized by multiple necrotic foci in various tissues, including liver, spleen, lung, and tonsils.

Enteroviruses once were considered to be major causes of reproductive failure. They were attributed to the SMEDI syndrome (stillbirth, mummification, embryonic death, and infertility). Parvovirus had later been identified as the main etiologic agent for this syndrome.

The pathogenesis of reproductive failure following infection by encephalomyocarditis virus is not well un-

derstood. Transmission is believed to be transplacental, but pathogenic variability in fetuses has been observed with different isolates and could explain the variability of clinical signs (Kim et al. 1989).

More recently, porcine circovirus type 2, the etiologic agent of postweaning multisystemic wasting syndrome (PMWS), has been associated with late-term abortions and increased stillbirth rate (West et al. 1999).

Swine influenza virus causes abortion, stillbirth, and weak pigs at birth due to fever through a systemic effect on the dam (Vannier 1999). However, it has also been isolated from aborted fetuses, suggesting that the virus could cross the placenta and act as a specific agent causing reproductive problems. However, at present, data are inconsistent to conclude on transplacental infection (Yoon and Janke 2002).

Cytomegalovirus infection, responsible for inclusion body rhinitis, may also manifest itself in some herds as reproductive disorders with embryonic death, mummies of variable age, stillbirth, and weak pigs with high neonatal mortality (Orr et al. 1988). Other viral diseases associated with reproductive failure include blue eye disease, bovine viral diarrhea disease, border disease, transmissible gastroenteritis virus, Japanese B encephalitis, and African and classical swine fever. Abortion, although occurring occasionally, does not seem to be a common feature in blue eye disease, bovine viral diarrhea disease, and border disease (Stephano et al. 1988) and has not been observed with Japanese B encephalitis (Joo and Chu 1999). Reovirus has been isolated from mummies, stillbirths, and aborted fetuses but its role in swine reproductive disease is unclear (Paul and Stevenson 1999).

Menangle virus has been associated with return to estrus, pseudopregnancy, mummification, stillbirth, and congenital deformities but not with abortion (Love et al. 2001). This disease has been observed in only a large farrow-to-finish herd in Australia. The probable source of the infection was a colony of fruit bats that was near the farm. The reproductive problems observed were compatible with transplacental infection, with spreading from fetus to fetus as with porcine parvovirus. Nipah virus causes outbreaks of neurological and respiratory signs. This condition was first seen in late 1998 on several swine farms in Malaysia. Abortion was observed in some sows and was probably due to an acute febrile illness (Singh and Jamaluddin 2002).

Toxoplasma gondii may infect fetuses transplacentally and cause stillbirth and weak piglets at birth. Abortion is uncommon with toxoplasmosis. Abortion and mummies associated with fungal infections, namely *Aspergillus* sp., have been reported but are rare.

Noninfectious Factors

Compared to several other species, the CL in swine are essential for maintenance of pregnancy throughout gestation. Consequently the administration of $PGF_{2\alpha}$ dur-

ing gestation will cause pregnancy cessation with subsequent expulsion and death of the conceptuses. Abortion has been observed following procaine penicillin G injection in pregnant sows. It was hypothesized that the sudden release of toxic amounts of procaine was responsible for the clinical signs, such as fever, vomiting, and shivering (Embrechts 1982). Sows and gilts given feed containing sulfadimethoxine and ormetoprim late in gestation had increased duration of gestation and numbers of stillbirths and weak newborn pigs (Blackwell et al. 1989).

Consumption of grains containing the estrogenic mycotoxin, zearalenone, may result in irregular return to estrus, small litter size, and increased stillbirth rates. Estrogens are luteotropic in swine; therefore, zearalenone will induce anestrus and pseudopregnancy rather than abortion. In prepubertal gilts it will cause swelling of the vulva and prolapse. Fumonisin, a mycotoxin produced by fungi *Fusarium* sp., may produce pulmonary edema. Hence, sows consuming high levels of fumonisin will abort shortly after due to fetal anoxia. Sows fed ergot alkaloids during gestation had piglets with low birth weight and low survival rate, but rarely aborted.

The gestation length influences stillbirth; long gestational period (>117 days) and early induction of parturition (<112 days) are both associated with an increased number of stillborn pigs. Intrapartum deaths of piglets also increase with the duration of farrowing, litter size, and advanced parity of the sow.

High ambient temperature before implantation has been completed, i.e., before day 16, has a detrimental effect on conception rate and early embryonic survival. Also, elevated temperature during the peripartum period may lead to an increase in stillbirth and sow mortality. An increased prevalence of abortion is also observed in early fall and has been attributed to insufficient levels of progesterone and thin sows kept in cold environment. High levels of carbon monoxide in underventilated farrowing facilities may cause an increased stillbirth rate.

Diets deficient in vitamin A, zinc, copper, and iodine during gestation were all reported to increase the incidence of stillbirth.

VULVAR DISCHARGE

Individual cases of vulvar discharge rarely represent a major concern. In contrast, if 5–10% or more of a breeding group show discharges, the problem needs attention. Some vulvar discharges are indicative of normal physiological events, whereas others are pathological and may interfere with fertility and conception. Abnormal discharges originate from either the urinary or the reproductive tract. The diagnostic challenge is to differentiate normal from abnormal discharge and to determine the origin. In that, characterization of the

type of discharge and its timing in relation to the estrous cycle will help (Dial and MacLachlan 1988a).

Normal Vulvar Discharges

It is normal to observe discharges following farrowing. They represent the sow's attempts to clear placental remnants and debris from the uterus and usually disappear within 2 days of farrowing. A mucopurulent vulvar discharge is also often seen in pregnant sows during the last 2–3 weeks of gestation. This discharge is associated with mucus production and cellular changes in the vulvovaginal membranes.

Periestrous discharges are considered normal. The high estrogen concentrations result in an increased uterine perfusion and tissue permeability and enhanced leukocyte migration into the uterus. The uterine contractions during proestrus and estrus contribute to physical clearance of uterine contents (De Winter et al. 1996). The discharges contain mucus, vaginal epithelial cells, semen, white blood cells, occasional red blood cells, or any combination of these cells. The quantity of these "normal" discharges is variable.

Abnormal Vulvar Discharges

The presence of fresh blood is common on the vulva of sows or gilts. Vulvar lacerations result from biting by sows (particularly in pen housing), trauma, or the boar. Careful hand-mating or AI procedures reduce the likelihood of breeding-inflicted vulvar lesions.

The presence of a purulent vulvar discharge at 14–20 days (>10 days) after breeding or estrus typically is indicative of metritis or endometritis. The causative agent or agents likely enter the uterus during estrus, either by passive ascension or by active introduction by the boar during mating. Nonspecific endometritis results from infection by bacteria not considered as specific pathogens of the reproductive tract. Several bacterial species have been isolated from these infected uteri, including *Escherichia coli, Streptococcus* sp., *Staphylococcus* sp., *Arcanobacterium pyogenes, Proteus, Klebsiella,* and a variety of others.

Sows inseminated late during estrus, often the third AI, are more susceptible to discharge problems (De Winter et al. 1992). During early metestrus, the protective mechanisms of high estrogen concentrations have dissipated, thereby rendering the animal susceptible to uterine infections. Furthermore, there is a strong correlation between serum progesterone concentrations and the development of endometritis (De Winter et al. 1996). If animals are inseminated as progesterone concentrations begin to increase after ovulation, there is a greater possibility of inducing endometritis. Therefore, some multiple-AI schemes may contribute to problems with endometritis.

Vulvar discharges are often seen in bred or virgin animals on farms with large numbers of replacement gilts, following a startup or repopulation (MacLachlan and Dial 1987). They may be observed after transport and prior to exposure to a boar. Some animals have normal physiological periestrous discharges; however, it is not uncommon to observe isolated cases of virgin animals with endometritis. The causes of discharges in virgin animals remain unclear. In some cases vaginitis is secondary to vulvar biting in the finishing house. Another theory is that many gilts attain puberty prior to transport, and infection of the uterus occurs while the animals are in gilt finishing facilities. Consequently, a discharge is observed 5–8 days prior to their second estrus.

Endometritis also occurs following parturition as a result of dystocia, traumatic injury, abortion, and unhygienic manipulations. The likelihood of subsequent infertility is greater in sows that have a prolonged vulvar discharge following parturition, e.g., more than 6 days (Waller et al. 2002). Pyometra, an acute or chronic suppurative inflammation of the uterus with accumulation of large quantities of pus, is rare in sows.

A purulent vulvar discharge with or without blood may be observed in cases of cystitis/pyelonephritis and should be differentiated from that originating from the genital tract. The discharge usually contains mucus, is associated with urination, especially at the end of the stream, and is not related to the estrous cycle. To confirm urinary tract infections, urinalyses are performed on samples from affected animals, or collection and examination of urinary bladders and kidneys are performed at slaughter. For further details see Chapter 9.

Managing the Discharging Sow

Most discharging sows return to estrus shortly after the initial appearance of the discharge. Attempts to breed these animals at this time are usually futile. One approach is to allow the animals to recycle one more time, if economics and animal flow permit it. Clinical reports have revealed that when sows failed to discharge a second time and were then mated, their conception rates were similar to those of repeat breeders. The other option is to cull any animal with a discharge. Hygiene and management procedures around farrowing, mating, and artificial insemination should be evaluated.

Numerous treatment protocols have been attempted to resolve problems of discharging sows, but their success remains dubious. Medicated feed or injectable antibiotics are common treatments. Precise pathogens involved and their sensitivity to antibiotics are rarely known, so it is often difficult to assess the effectiveness of these treatments (Dial and MacLachlan 1988b).

Some producers infuse the boar's prepuce with extralabel, antibiotic preparations, and systemic antibiotic treatment has been attempted; however, it is unknown whether effective antibiotic concentrations are achieved in the boar's reproductive tract. The prepuce of a boar is rapidly reinfected, and thus, infusion of the prepuce offers only short-term therapy.

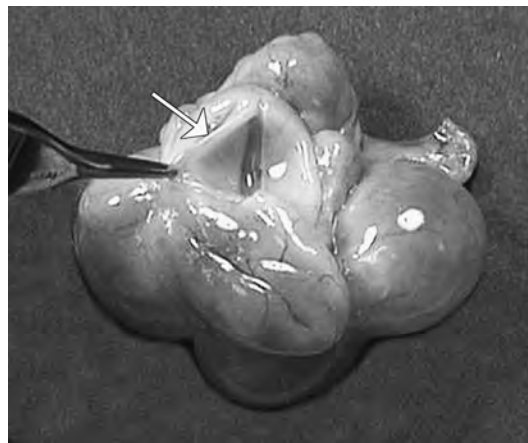
OVARIAN CYSTS

Slaughterhouse surveys have demonstrated that 5–10% of sows culled for reproductive problems are affected with cystic ovaries, varying from 1.7–24% (Ryan and Raeside 1991). On several farms on which ultrasonography was used, the incidence of ovarian cysts varied from 0–8% among nonpregnant animals (Gherpelli and Tarocco 1996; Castagna et al. 2004). Multiple large, multiple small, and single cysts occur in the ovaries of sows. They vary in size, from 1–8 cm, and in the extent of luteinization, and may regress spontaneously (Figure 6.7) (Ebbert and Bostedt 1993; Ebbert et al. 1993; Gherpelli and Tarocco 1996; Martinat-Botté et al. 1998). Luteinized cysts are more frequently observed than follicular cysts (Zannoni et al. 2003). In general, sows with ovarian cysts have a greater return to estrus rate than normal sows, 34% vs. 7.7% (Castagna et al. 2004). However, the behavioral and physiological events differ between animals affected with each type of cyst. Most of the multiple large cysts have some luteinized tissue and produce sufficient progesterone to inhibit estrous cyclicity; consequently, such affected sows may be intermittently or permanently anestrous. In contrast, multiple small cysts often produce estrogen, and sows may have irregular estrous cycles or exhibit nymphomania. Anestrus is more frequently observed in sows with a large number of cysts (>10/animal) compared to those with a smaller number, 75% vs. 53% (Ebbert and Bostedt 1993). Single ovarian cysts rarely affect fertility or the estrous cycle of sows.

An impairment or relative deficiency of the preovulatory LH surge is responsible for the failure of ovulation of one or more follicles at estrus, which leads to cystic ovary. Increased incidences of ovarian cysts have been associated with stress, zearalenone toxicity, or corticosteroid and hormonal treatment administered over an extended period, or at an improper phase of the reproductive cycle (Guthrie and Polge 1976; Meredith 1979; Varley 1991; Gherpelli and Tarocco 1996). Sows with cystic ovaries are more frequently observed when lactation length is shorter than 14 days and weaning-to-estrus interval shorter than 3 days (Castagna et al. 2004).

The diagnosis of cystic ovaries generally relies on ultrasonography (Martinat-Botté et al. 1998; Kauffold et al. 2004). Because serum concentrations of progesterone, estradiol, LH, and cortisol are similar in sows affected with ovarian cysts and in diestrous sows, serum hormone concentrations have limited diagnostic value (Almond and Richards 1991).

CONGENITAL DEFECTS AND NEOPLASIA

Defects of the female genital system are common and include cysts of the mesosalpinx; duplication of the vagina; cervix or uterine horns; segmental or complete


6.7. *Porcine cystic ovary. The cystic structures are fluid filled. The thickened cyst walls (arrow) contain luteinized tissue. The sow failed to exhibit estrus.*

aplasia of the uterus, cervix, vagina, and vulva; and intersexuality. The aplasias, hypoplasias, and duplications appear to have genetic components that can be expressed in varying degrees in different individuals (Wrathall 1975) and may contribute to infertility and perhaps dystocia. Other defects of the female genital system include persistence of the hymen, ovarian aplasia, other ovarian defects, and hypoplasia or malformation of the nipples (Done 1980; Clayton et al. 1981). The incidence of these conditions is low, and in most instances the cause is unknown or suspected to be heritable.

Intersexuality is occasionally observed in pigs. True intersexes, or hermaphrodites, have both testicular and ovarian tissues, whereas pseudohermaphrodites have gonads of one sex and other genital organs of the opposite sex. Pseudohermaphrodites are further subclassified into male or female on the basis of the gonadal tissue. The external genitalia of intersex pigs are usually female in type. In most instances the vulva appears normal, with a variable enlargement of the clitoris, but in some the clitoris is greatly enlarged and the vulva is underdeveloped or prepucelike. Some affected individuals show male behavior, while others show estrus and even become pregnant (Hulland 1964; O'Reilly 1979). Estrus, ovulation, and pregnancy are possible in true hermaphrodites. Reports of female pseudohermaphrodites in pigs are rare. Genetic analyses suggest that pig intersexuality is controlled multigenically.

Neoplasms of the genitalia in sows have not been studied intensively. Investigations of genital tracts at slaughter reveal a low prevalence of neoplasis. The most commonly observed neoplasms were leiomyoma, fibroma, cyst-adenoma, fibroleiomyoma, and carcinoma (Anderson and Sandison 1969; Werdin and Wold 1976; Akkermans and van Beusekom 1984).

INADEQUATE REPRODUCTIVE PERFORMANCE

Reproduction is an extremely complex process and involves many highly specific biological functions. Many factors—such as diet, housing, social surroundings, temperature, disease, and management—influence reproductive performances (Foxcroft and Aherne 2002). There are five major causes of reproductive failure: hormonal imbalances, mating behavior, diseases, structural defects, and management (Leif and Thomson 2002).

Because many of the elements involved in reproduction are interrelated, one problem may give rise to others. Generally by studying records and carrying out clinical observations and pathological tests it is possible to determine precisely where reproductive failure has occurred (Dial 1990). Such failures can be grouped into six categories related to stages in the reproductive cycle: anestrus, estrus and ova production, fertilization, implantation, and maturation. In general, the primary causes of reproductive failure can be identified and corrected; however, the causes of infertility cannot be determined and corrective action taken without collecting reliable information and using it in a meaningful way (Muirhead and Alexander 1997). This information allows us to understand the interrelationships of reproductive failure as related to nonreproductive factors that evade females to express their biological potential.

Definition of Most Commonly Used Parameters of Performance

During the last 15 years, the financial advantage of volume selling and buying has led to an irreversible evolution toward increasingly larger herd sizes. In a climate of increased competition for more discerning markets, the independent producer has been faced with the challenge of either becoming efficient or running the risk of no longer being competitive and no longer having a product desired by the global marketplace. A necessary prelude to being competitive in swine production in general, and in particular in the reproductive area, is a reliable record system that allows producers to monitor both biological and financial performance and to troubleshoot production and financial problems (Dial 1990).

In order to understand and interpret records it is important to have universally accepted definitions for an analyzed parameter so the calculations involved in its computation can be understood. The following is a list of the most common parameters used when troubleshooting reproductive performance:

Adjusted farrowing rate: 100 × total number of females farrowed ÷ (total number of females bred − total number of females removed due to nonreproductive causes) in a specified period of time.

Average parity: average parity of all the females in the breeding herd, including gilts that are part of the inventory.

Conception rate: 100 × (total number of females that conceived between 18–24 days after the first mating ÷ total number of bred females) in a specified period of time.

Farrowing interval: the period of time between two consecutive farrowings of a specified female. On a herd basis this term is the average of the farrowing intervals of a specified group of females in a specific period of time.

Farrowing rate: 100 × (total number of females farrowed ÷ total number of females bred) in a specified period of time.

Gilt pool: group of females that have not been mated but are considered as replacements for the breeding herd.

Irregular return to estrus: the irregular occurrence of estrus from one period to the next. An interestrus interval of more than 24 days.

Litters/crate/year: total number of litters weaned in a year ÷ total number of crates in the farrowing area.

Litters/productive sow/year: average number of litters that a productive female farrows in a year.

Litters/sow/year: average number of litters that a female in inventory farrows in a year when nonproductive days are taken into account.

$$\frac{365 \text{ days} - \text{average nonproductive days/female/year}}{(\text{gestation} + \text{lactation length in days})}$$

Mummies: fetal tissues after bodily fluids have been removed and only the nonabsorbable remains, including calcified skeleton. Mummification normally occurs after 35 days of gestation.

Nonproductive days: number of days when a female is not gestating or lactating. In economical terms nonproductive days include all the days that a female is generating expenses and not income.

Percent repeats: number of females included in a group that have returned to estrus after having been mated.

Pigs/crate/year: number of pigs weaned in a year ÷ total number of crates in the farrowing area.

Pigs weaned/sow/year: total number of pigs that a female in inventory weans in a year.

Regular return to estrus: interestrus interval of 18–24 days.

Stillborn pigs: pigs that die shortly before or during farrowing.

Total number of pigs/litter: Total number of pigs born alive + total number of stillborn pigs + total number of mummies in a litter.

Wean to estrus interval: interval between a weaning and the following estrus.

Targets

Numerous systems are currently available commercially for assessing the biological performance of the breeding herd. Although varying considerably in data entry, report format, and report content, all of the systems provide summaries of breeding, farrowing, and weaning information (Dial 1990). Most provide either time-related or group reports for information relating to fertility, lactation performance, interval from entry or weaning to mating, and piglet survival until weaning. Targets and level at which a corrective intervention should be performed (interference levels) should be included in these production reports (Table 6.2). The value of these parameters should be changed regularly as the herd performances change.

Interrelationships Between Performance Parameters

There are numerous risk factors or differential diagnoses for the different types of reproductive failure. Many can be incriminated or ruled out through examination of records. In fact, although a diagnostic examination of environment, facilities, management, disease status, and nutrition may suggest one or several of them as a cause of reproductive failure, the diagnosis typically must be corroborated through the record analysis. For example, suboptimal total pigs born/litter may involve parity distribution, lactation length, weaning-to-estrus interval, season and ambient temperature, systemic reproductive disease, genetics, nutrition, and breeding management. Both record analysis and flow diagrams are extremely helpful to identify risk factors and explanation of reduced reproductive performance.

Pigs Weaned/Sow/Year. When the productivity of the breeding herd is suboptimal the most widely used measure of the overall biological performance of the breeding herd is pigs weaned/sow/year (Polson et al. 1990a). The two components of pigs weaned/sow/year are litters farrowed/inventoried sow/year and pigs weaned/litter farrowed (Figure 6.8).

Table 6.2. Targets for the reproductive performance of the breeding herd

	Target	Interference Level
Breeding and Gestation		
Age at first service (days of age)	220–240	<220 or >260
Repeat matings (%)	10	>15
Multiple matings (%)	90	<85
Weaning to service interval (days)	4–7	>7
Farrowing rate (%)	≥85	<80%
Regular returns (%)	<6	>8
Irregular returns (%)	<3	>5
Negative pregnancy test (%)	<3	>5
Abortions (%)	<2	>4
Failure to farrow (%)	<1	>3
Adjusted farrowing rate (%)	≥90	≤88
Farrowing		
Total pigs born/litter	≥11.5	<11
Pigs born alive/litter	≥10.5	<10
% stillbirths	<7	>10
% mummies	<3	>5

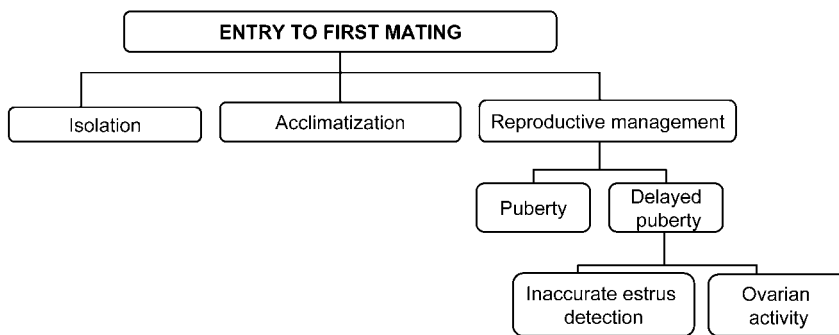
6.9. *Interrelationship between factors influencing nonproductive days.*

The interrelationship between pigs weaned/sow/year shows that litters/female/year greatly influences this interrelationship; however gestation and lactation length cannot be easily reduced or influenced. Therefore improvements in nonproductive days will by far increase pigs weaned/sow/year (Polson et al. 1990b).


Nonproductive Days. Nonproductive days and lactation length are the major factors influencing litters/sow/year. Nonproductive days are influenced largely by time from introduction into the herd or weaning until first mating; time from mating until detection of non-pregnancy status; and time from mating, entry, or weaning until female is culled or dies. Nonproductive days not only must be calculated, but also must be broken down into its different components (Figure 6.9). The risk factors for those elements also must be detailed. Nonproductive days often go unrecognized; however, they are very significant in reducing the productivity of the breeding herd.

Data analysis shows that, in general, the interval from introduction to mating and the interval between the time a female is detected nonpregnant and remating are the most biologically meaningful components of nonproductive days. In order to understand the impact of nonproductive days on the breeding herd performance we can equate 1 nonproductive day to 0.05 pig/sow/year (20 pigs weaned per female per year/365 days). Consequently a decrease of 10 nonproductive days will result in at least 0.5 extra pig/sow/year.

Entry to First Mating Interval. Improved gilt pool management is required to ensure that availability of gilts for service does not limit the ability of herds to achieve their breeding targets. Generally the problem is solved by introducing two or three times as many gilts as required. Gilts must be acclimatized before entering into a herd. This acclimatization allows the gilts to adjust to feed, housing, and management system. Most importantly, it helps to prevent new diseases from entering the recipient herd and to establish procedures that result in a common immune status between the incoming pigs and the receiving herd, without creating infection that perturbs the balance of infectious agents in the receptor herd (Batista 2000). Since the emergence of PRRS, the number of gilts introduced and the period of acclimatization, in general, have increased (Batista et al. 2002). This increase, both in days and inventory, has negatively affected nonproductive days, therefore decreasing the output of the breeding herd. Gilt acclimatization is divided into three periods, as shown in Figure 6.10.

The component that influences this interrelationship the least is isolation. In general a period of 21–30 days is advised (Kuster et al. 2000). Today many different methods of gilt acclimatization are recommended—i.e., introduction of gilts at 5, 30, or 60 kg, followed by a period of time that can range between 4–10 weeks following exposure to different pathogens and or vaccination programs (Batista et al. 2002). Therefore, acclimatization is the most significant component of nonproductive days in the entry to service interval. Finally, the entry to service interval is negatively influenced by delayed puberty. Presently, the relationship between growth performance and age at puberty is well understood. In gilts exposed to boar stimulation from 140 days of age, the minimum age at puberty was around 160 days; this could be achieved at body weights of around 90 kg if gilts were fed appropriately (Beltranena et al.

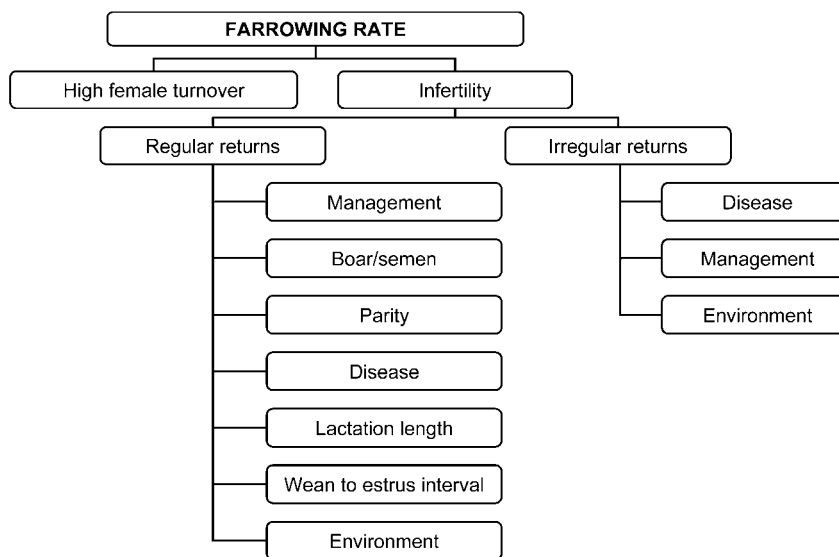
6.10. *Components of interval from entry to first mating and its impact on nonproductive days.*

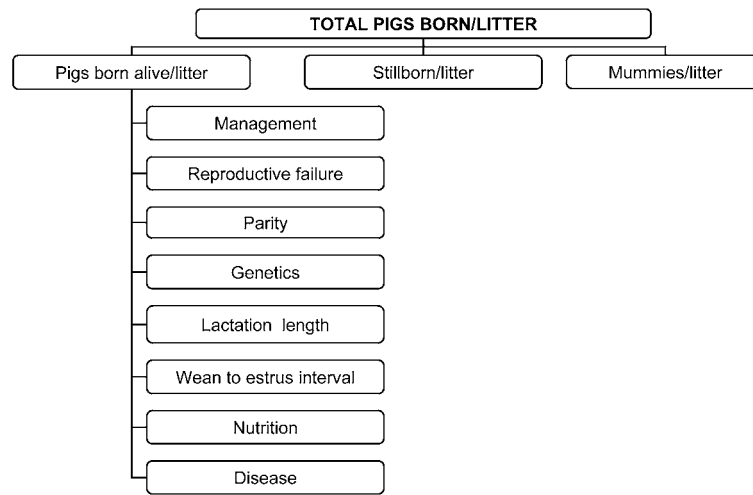
1991). Therefore management of the gilt pool plays a very important role in the decrease of nonproductive days in this area.

Farrowing Rate. The factors that cause a sow to fail to conceive are often different than those causing a sow to fail to maintain pregnancy. For example, the number of matings per estrous period affects conception but not pregnancy; in comparison, season primarily influences the capacity of the sow to maintain pregnancy. In order to troubleshoot fertility problems we need to determine whether the returns are regular or irregular. The interrelationship between the different factors affecting farrowing rate are shown in Figure 6.11.

Litter Size. In general, many of the factors influencing fertility have similar effects on total pigs born/litter. Therefore, improvements in fertility appear to be related to an increase in fecundity. When litter size is compromised it is important to review several factors. Classical examples of these interrelationships are litter size by parity, the effect of season and temperature at service

and prior to implantation, the influence of matings per estrous period and timing of matings relative to onset of estrus, the relationship between lactation feed intake and subsequent litter size, etc. (Dial et al. 1992). The main causes for a reduced litter size are presented in Figure 6.12.

Wean to Estrus Interval. Variability in the wean to estrus interval (WEI) is a major problem in the breeding herd management. Delays of the onset of estrus increase nonproductive days. Variation in WEI makes it difficult to meet breeding targets and to concentrate breeding management. Data show that WEI increased rapidly as lactation length was reduced below 17 days, but WEI was relatively unaffected by lactation lengths of 17 to 30 days (Xue et al. 1993). These data also emphasized that the percentage of sows bred by 6 days after weaning was significantly reduced for lactation lengths of 20 days or less. However, ovulation rate and fertilization rate did not appear to be affected by lactation length (Varley 1982). An inadequate nutrient and energy intake will also result in extended wean to estrus interval, lower


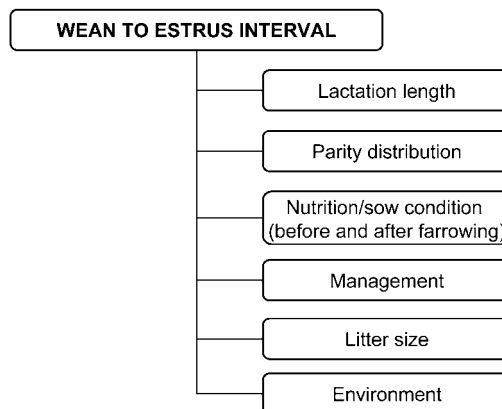
6.11. *Interrelationship between the different factors affecting farrowing rate.*


6.12. *Interrelationship between the different factors affecting total pigs born/litter.*

percentage of sows in estrus within 7 days of weaning, reduced pregnancy rate, and reduced embryo survival (Aherne et al. 1999; Quesnel et al. 1998). The factors that affect the extent of WEI are shown in Figure 6.13.

In conclusion, troubleshooting suboptimal reproductive performance requires a structured record analysis in conjunction with the use of flow diagrams that indicate the different factors and their level of importance in contributing to suboptimal reproductive performance. An organized system is less time-consuming, more inclusive, and efficient. This system should also allow validatation of progress and assessment of response to management changes in order to obtain maximal reproductive efficiency of the breeding herd.

REPRODUCTIVE DEVELOPMENT, ANATOMY, AND FUNCTION IN THE BOAR

Development of the male reproductive tract commonly is divided into three distinct periods: early fetal, perinatal, and pubertal. The onset of the early fetal period begins around day 20 postcoitum (PC) with formation of the testicles and ends around day 90 of gestation with the descent of the testicles into the scrotum. The perinatal period encompasses the period of time from just prior to birth through the first month of life. This developmental period is characterized by an increase in the testis-to-body-weight ratio due to Leydig cell differentiation and proliferation. It also has been hypothesized that a large portion of the basis for future spermatogenic capacity of boars is established during this time due to the increased mitotic activity of Sertoli cells characteristic of this developmental phase. The pubertal period begins at around 30 days of age and continues until the boar has reached sexual maturity. During this final stage of maturation, endocrine and cellular aspects characteristic of adult spermatogenesis develop. Mechanisms involved in the development of male reproductive anatomy and function involve complex interactions among the endocrine, neural, and paracrine systems (Colenbrander et al. 1982b). A chronological outline of several key developmental events is presented in Table 6.3.


6.13. *Interrelationship between the different factors affecting wean to estrus interval.*

Table 6.3. Summary of key developmental events during sexual maturation of boars.

Period	Time[1]	Event
Early Fetal	21 DPC	Indifferent gonad is present
	26 DPC	Testicular differentiation; primordial germ cell in cords
	27 DPC	Germ cells surrounded by Sertoli cells
	26–35 DPC	Testosterone production begins
	26–50 DPC	Wolffian duct and anlage differentiation; development of secondary sex glands and external genitalia
	30–38 DPC	Leydig cell differentiation andproliferation
	42 DPC	Mitotic activity of Sertoli cells increases
	60–85 DPC	Descent of testes into inguinal canal begins
Perinatal	90 DPC	Sertoli cell tubular length increases
	90 DPC to birth	LH, FSH, and prolactin concentrations increase
	95 DPC to 21 d	Germ cell numbers increase; gonocyte morphology characterized by regular, round shape with centrally located nucleus
	Birth	Testicles completely descended into scrotum
	Birth to 14 d	Testosterone production increases
	Birth to 21 d	Leydig cell differentiation; Leydig cells compose 65% of testicle volume at 3 weeks of age
Pubertal	30 d	Sertoli cell proliferation decreases
	42 d	Sertoli cell junctions appear
	70 d	Germ cell differentiation begins
	91 d	Spermatogonia and pachytene spermatocytes are present and sometimes round spermatids can be seen
	100–120 d	Blood-testis barrier is present
	120 d	Leydig cell development is maximal
	160–180 d	Puberty in most breeds

[1]DPC = days postcoitum; d = days after birth.

Adult Reproductive Function

Hypothalamus and Pituitary Gland. The brain is the component of the male reproductive system that gathers internal signals from within the body and external cues from the environment, integrates them, and regulates physiological and behavioral functions associated with reproduction. The hypothalamus secretes GnRH, which controls the production and secretion of LH and FSH from the pituitary gland. These two hormones are responsible for regulating testicular function (Hafs and McCarthy 1978).

Testes. The primary functions of the testes are to produce spermatozoa and hormones. The majority of the testicular mass is composed of seminiferous tubules, the convoluted network of ducts in which spermatozoa are produced. Sertoli cells, specialized cells involved in the maturation of spermatozoa and hormone production, line the lumen of the seminiferous tubules (Ashdown and Hafez 1993). Leydig cells, blood and lymph vessels, and nerves are located in interstitial spaces between the seminiferous tubules. Important interactions between the Sertoli and Leydig cells regulate virtually every aspect of male reproductive function.

The rete testis comprises a series of tubules that leave the seminiferous tubules and connect to form collecting ducts located in the center of each testis. During spermatogenesis, spermatozoa leave the seminiferous tubules and enter the rete testis during their passage into the epididymis. The rete testis is lined with a nonsecretory epithelium (Hargrove et al. 1977).

Because the testes are located externally, special anatomical systems are needed for effective thermoregulation. The most important component for thermoregulation is the pampiniform plexus, a complex vascular arrangement of testicular arteries and veins in the spermatic cord. The testicular artery forms a convoluted structure in the shape of a cone in which arterial coils are enmeshed with testicular veins. From a functional perspective, this countercurrent heat-exchange mechanism enables arterial blood entering the testis to be cooled by venous blood exiting the testis. In most species, the temperature of arterial blood drops between 2°C and 4°C prior to its entry into the testes (Ashdown and Hafez 1993).

Two groups of muscles, the tunica dartos and cremaster, play an important role in thermoregulation. The tunica dartos lines the inside of the scrotum and controls its proximity to the testis. It contracts during cold weather, pulling the scrotal sac closer to the testis for added insulation, and relaxes during warm weather, allowing the scrotum to recoil into a distal position. The cremaster muscle is located in the spermatic cord and is attached to the thick membranous sac surrounding the testis. It contracts during cold weather, pulling the scrotal sac and testis closer to the body core, and relaxes during warm conditions, allowing the testis to return to its normal position (Robertshaw and Vercoe 1980). Both muscles have an abundant supply of adrenergic neural fibers that respond to temperature sensors located in the central nervous system. In the boar, due to the anatomical relationship between the testis and the body core,

the tunica dartos is more important than the cremaster muscle in the regulation of testicular temperature.

Endocrine Activity within the Testes. Leydig cells located in the testicular interstitium and Sertoli cells within the seminiferous tubules are the two primary endocrine-producing cells in the testes. LH released from the anterior pituitary gland stimulates production of androgens from the Leydig cells. The primary androgen produced is testosterone. Testosterone has a variety of important functions in spermatogenesis and male sexual behavior. FSH stimulates the Sertoli cells to produce androgen-binding proteins, convert testosterone to dihydrotestosterone and estrogen, and secrete inhibin (Bartke et al. 1978). Androgen-binding protein forms a complex with androgen and is carried along with the spermatozoa to the epididymis. High local levels of androgen are necessary for the normal function of the epididymal epithelium (Hansson et al. 1976). Inhibin diffuses out of the seminiferous tubules, enters the vascular system, and is transported to the brain, where it has a negative effect on the secretion of FSH. Inhibin production by the testes is an important component of gonadotropin regulation in the male.

In the boar, high quantities of estrogen are found in semen. The source of these estrogens is the Sertoli cells, which convert testosterone to estrogen via the aromatase enzyme. It appears that the primary role of seminal estrogens is to stimulate important reproductive events in the female reproductive tract during breeding (Claus 1990).

Recent investigations have demonstrated that both Sertoli and Leydig cells have receptors for a variety of growth factors, including insulin-like growth factor I (IGF-I), epidermal growth factor (EGF), and transforming growth factor(s) (TGF) (Sharpe 1994). It has been proposed that growth factors may be produced in response to gonadotropin or growth hormone action on testicular tissue and mediate many of the actions of these hormones. In addition, growth factors are believed to be the primary mode in which Sertoli cells and developing spermatozoa regulate each other's secretion of proteins along the length of the seminiferous tubule.

Epididymis. The rete testis enters the efferent ducts, which eventually form a single coiled duct called the epididymis. The epididymis is similar to the seminiferous tubules in that it coils back upon itself many times and forms three distinct sections: the caput (head), corpus (body), and cauda (tail). The convoluted duct of the epididymis is surrounded by a prominent layer of circular muscle fibers and contains pseudostratified columnar, stereociliated epithelium. Masses of spermatozoa are commonly found along the entire lumen of the epididymis (Hemeida et al. 1978).

The primary function of the epididymis is sperm maturation, transport, and storage. Spermatozoa entering the epididymis are neither motile nor fertile. It takes

spermatozoa between 9 and 14 days to migrate from the caput to the cauda epididymis, the primary storage site. It has been estimated that the cauda epididymis contains about 75% of the total epididymal spermatozoa (Swierstra 1968). Spermatozoa become motile and acquire fertilizational competence in the corpus epididymis due to the secretion of factors by the cells located in this region. Movement of spermatozoa through the epididymis is thought to be due to the flow of rete fluid, the action of the stereociliated epithelium, and contractions of the circular muscle layer.

Unejaculated spermatozoa are gradually eliminated by excretion into the urine. Spermatozoa that are not excreted in the urine undergo a gradual aging process. Fertilizational competence is lost first and is followed shortly by a decline in motility. The culmination of dying spermatozoa is disintegration (Garner and Hafez 1993). This is the primary reason that ejaculates collected after prolonged sexual rest usually contain a large number of degenerative spermatozoa.

Vas Deferens, Accessory Sex Glands, and Penile Urethra. The remainder of the boar's reproductive tract is relatively nonfunctional until ejaculation is initiated. The vas deferens is a thick, heavily muscled tube through which sperm are transported from the cauda epididymis to the pelvic urethra, at which point the paired genital systems of the boar meet and converge with the urinary tract just anterior to the bladder. Adjacent to the pelvic urethra are three secondary sex glands: the vesicular glands, or seminal vesicles; the prostate gland; and the bulbourethral glands.

The vesicular glands lie lateral to the terminal portion of each vas deferens. In the boar, they are large, lobulated, and relatively diffuse. They often appear to have an orange color. They are responsible for the majority of the fluid volume of boar semen. In addition, they secrete high levels of fructose and citric acid as well as inositol, ergothioneine, several amino acids, and glycerylphosphorylcholine. Most of these compounds are used as energy substrates by ejaculated spermatozoa.

The prostate gland is located cranial to the vesicular glands, with the majority of its body being embedded in the muscle layer surrounding the pelvic urethra. Secretions from the prostate gland during ejaculation are primarily alkaline and contain calcium, acid phosphatase, and fibrinolysin. The primary function of the fluid from the prostate gland is to neutralize the acidic vaginal secretions. Secretions from the prostate gland also are believed to give semen its characteristic odor.

The bulbourethral glands are long, cylindrical glands in the boar located on either side of the pelvic urethra near the ischial arch of the pelvis. The bulbourethral glands secrete the gel fraction of the semen characteristic of porcine ejaculates. Many functions for the gel component of semen have been postulated, but few have been proven.

The terminal portion of the boar's urogenital system is the penile urethra, which is the central tube within the penis. The penile urethra opens into the glans penis. In the boar, the glans penis has a counterclockwise spiral. The glans penis is highly innervated and must be stimulated properly for normal ejaculation to occur. The porcine penis also contains three cavernous bodies, or sinuses, that surround the penile urethra (Ashdown et al. 1981). During erection, blood is pumped into and retained in these areas. In the resting state, the porcine penis is retracted and forms a characteristic "S" fold called the sigmoid flexure.

The free end of the penis in the retracted state resides in the prepuce or sheath. In young prepubertal boars, the glans penis cannot be extended fully because it is fused with the lining of the prepuce. As a boar matures, androgens produced by the testis initiate keratinization of the inner preputial lining, and the penis is eventually freed from its connection with the prepuce. Persistent frenulum is a condition in which strands of tissue do not keratinize fully and are still attached to the penis. When this occurs, the end of the penis curves back toward the prepuce during erection and ejaculation. Removal of these strands of tissue with a pair of sterile scissors corrects this situation.

Near the end of the prepuce is a diverticulum called the preputial sac. Urine, semen, and secreted fluid collect in this sac and are broken down via bacterial action. The contents of the preputial sac are often expelled during detection of estrus or natural matings and are often believed to be the source of the odor associated with mature boars (Ashdown and Hafez 1993).

Erection and Ejaculation

Sexual stimulation results in dilation of the arteries supplying the cavernous penile areas. It has been postulated that parasympathetic fibers originating from the pelvic nerve are responsible for providing the neural signal for dilation and thus the initiation of erection. At the same time vasodilation begins, the ischiocavernosus muscle begins to contract repeatedly, which causes blood to be pumped into the cavernous spaces in the body of the penis. In the boar, no veins drain the distal portion of these spaces, which facilitates the increase in pressure within the penile body and erection. As pressure increases from blood trapped in the cavernous tissue, the retractor penis muscle relaxes, allowing the sigmoid flexure to straighten and the penis to protrude from the sheath (Benson 1994). Several detailed studies demonstrate that erection failures in boars are caused primarily by structural defects rather than psychological problems (Glossop and Ashdown 1986).

Ejaculation is primarily under neural control and involves contractions of smooth muscles. The process is initiated by rhythmic contractions of smooth muscles lining the cauda epididymis and ductus deferens. These contractions are controlled by sympathetic nerves that arise from the pelvic plexis, which is derived from the hypogastric nerve. During ejaculation, the bulbospongiosus muscle compresses the penile bulb and forces blood into the remainder of the cavernous tissue, resulting in a slight enlargement of the glans penis in boars (Setchell et al. 1993).

Spermatogenesis

Spermatogenesis is divided into two basic processes: spermatocytogenesis and spermiogenesis. In a general sense, spermatocytogenesis is the process involved with the mitotic and meiotic divisions of sperm cells, while spermiogenesis refers to the maturational phase of development. Although both hormones are important, it is believed that LH plays a more active role than FSH in spermatocytogenesis, while FSH is the main gonadotropic hormone involved with spermiogenesis (Garner and Hafez 1993).

Spermatocytogenesis. Just prior to puberty in boars, undifferentiated germ cells called gonocytes differentiate to form type A0 spermatogonia. These are the precursor sperm cells from which all other sperm cells originate. There is some evidence that the number of A0 spermatogonia is directly related to the sperm production capacity of males. In adult boars, A0 spermatogonia differentiate into A1 spermatogonia, which divide progressively to form various types of immature sperm cells. The final mitotic division during spermatocytogenesis occurs in primary spermatocytes. Although the average number of mitotic divisions cells undergo between the A1 and primary spermatocyte stages is a subject of some controversy, a figure of 6–8 is commonly used. After the formation of primary spermatocytes, no new DNA synthesis occurs, and the resulting secondary spermatocytes divide to form haploid cells known as spermatids. The entire divisional process of spermatocytogenesis occurs in the testis. It is interesting to note that many of the divisions are actually incomplete in that small cytoplasmic bridges are retained between most cells originating from a common type A1 spermatogonium. Some researchers speculate that these bridges are important in coordinating development of sperm cells as a group (Swierstra 1968).

Spermiogenesis and Spermiation. The round spermatids are transformed into spermatozoa by a series of morphological changes referred to as spermiogenesis. Maturational changes that spermatozoa undergo during spermiogenesis include condensation of nuclear material, formation of the sperm tail, and development of the acrosomal cap and its contents. During most of spermiogenesis, the sperm cells appear to have their heads embedded in Sertoli cells. In reality, the membrane of the Sertoli cell actually is wrapped around the sperm head. Communication and exchange of materials between the Sertoli and developing sperm cells occur via intercellular bridges.

The actual release of spermatozoa into the lumen of the seminiferous tubule is called spermiation. The elongated spermatids are gradually extruded or pushed out of the Sertoli cells into the lumen of the seminiferous tubule until only a small cytoplasmic stalk connects the head of the sperm to the residual body in the Sertoli cell. Breakage of the stalk results in the formation of a cytoplasmic droplet in the neck region of the sperm. These commonly are referred to as proximal cytoplasmic droplets (Garner and Hafez 1993).

Epididymal Maturation. Spermatozoa enter the caput epididymis incapable of fertilization; however, fertility is acquired at some point during transit to the cauda epididymis. It is believed that epididymal secretions contain maturation factors that stimulate biochemical changes within the sperm cells necessary for fertilization. These changes include development of the potential for progressive forward motility; alteration of metabolic mechanisms; loss of the cytoplasmic droplet; and changes in the plasma membrane, acrosomal cap, and nuclear material. It is interesting to note that during storage in the caudal portion of the epididymis, the metabolic activity of mature sperm is actually suppressed by secretion of a "quiescence factor." The entire process of spermatogenesis requires 45–55 days in the boar (Swierstra 1968). The majority of this time is spent in the testicle and involves changes associated with both spermatocytogenesis and spermiogenesis. Maturation in the epididymis is thought to require only 10–14 days.

SEMEN COLLECTION, EVALUATION, AND PROCESSING

Semen Collection
Boar Training. Two things must be accomplished early in the training period if boars are to be taught to mount successfully and be collected from a dummy sow: boars must be forced to focus their attention on the dummy sow upon entry into the collection pen, and boars must associate the collection area and process with a pleasurable experience.

The primary stimulus for initiation of the mounting reflex in boars is an immobile object that resembles another pig (Chenoweth 1981). Therefore, a collection pen that is clean and free of extraneous items forces boars to focus their attention on the dummy sow and supplies the visual stimulus necessary for a successful mount. Similarly, a collection dummy with a strong swine odor supplies the necessary olfactory cues.

A young boar's attention span is limited. Mounting activity usually occurs within the first 5–7 minutes of a training session. Consequently, if mounting or an interest in the collection dummy has not occurred by this time, the probability that such behavior will occur during the current training session is low.

Boars that associate pain or fear with the collection area or collection process are difficult to train. Unpleasant experiences during collection can reduce the sexual activity of trained AI boars. Avoidance of rough handling and loud noises during the training process is critical.

Young, sexually aggressive boars that have not been used in natural mating are the easiest to train. This does not mean that older, sexually experienced boars cannot be taught to mount and be collected from a dummy sow, but the training interval is usually longer and the success rate lower compared to their younger, more inexperienced counterparts. An inverse relationship exists between the age of the boar at the initiation of the training period and the success rate (Reed 1982). When training was initiated at less than 10 months of age, a success rate of 90% resulted. In contrast, only 70% of the boars that were 10 and 18 months old at the beginning of the training period were successfully trained.

Semen Collection. The most common method of semen collection is the gloved hand technique (Almond et al. 1994). Pressure on the glans penis is the primary physiological stimulus for erection and ejaculation. It is often stated that more pressure is required to stimulate an erection than is required for ejaculation. Consequently, it is common for pressure on the end of the penis to be relaxed slightly after an erection has occurred in order to facilitate ejaculation. Routine management practices such as removal of preputial fluid prior to collection and clipping sheath hairs reduce the risk of contamination of semen during collection. Because of anatomical or behavioral abnormalities, some boars release preputial fluid concomitantly with semen during ejaculation, thus contaminating the semen. The preputial sac can be removed surgically to prevent this form of contamination.

Semen Evaluation
Total Number of Spermatozoa. A complete semen evaluation includes determination of total number of spermatozoa and estimations of sperm cell viability and fertility. The two most common pieces of equipment for determination of total numbers of spermatozoa in a sample of the ejaculate are the hemocytometer and the spectrophotometer. The hemocytometer is a special microscope slide. Multiplication of the number of sperm counted by a correction factor and the volume of semen collected yields the total number of spermatozoa. Determination of the total number of spermatozoa with a spectrophotometer is based on the transmittance (or absorbance) of light by a sample of the collected semen. Sperm and other cells block the movement of light through a solution. Samples with high concentrations of spermatozoa will have low transmittances, while the opposite is true for ejaculates with low concentrations. It is important to note that all spectrophotometers must

be calibrated before they can be used to determine spermatozoa concentrations; otherwise, the sperm counts can be overestimated (Flowers 1994). The most common way to do this is to use a hemocytometer. Consequently, the hemocytometer is the standard by which concentrations of spermatozoa are determined. Details concerning the use of hemocytometers and calibration of spectrophotometers are described elsewhere (Almond et al. 1994).

Motility and Morphology of Spermatozoa. The percentage of sperm cells exhibiting progressive forward motility is the most common measurement recorded during semen evaluations. In general, motility is a better estimator of sperm cell viability than of fertility. When motility scores are 60% or greater, there is no clear relationship between in vitro and in vivo estimates of fertility. In contrast, ejaculates with less than 60% motility fertilize fewer eggs in vitro and yield lower farrowing rates in vivo than those above 60%. Consequently, use of ejaculates exhibiting motilities of 60% or higher in AI programs should not compromise reproductive performance (Flowers 1997).

Morphological evaluations are conducted less frequently than motility estimates, yet such evaluations can provide important information about sperm viability and fertility. Abnormalities of the tail and head, the location of the cytoplasmic droplet on the midpiece, and the integrity of the acrosomal membranes can be observed with a light microscope and the proper histological stain (Woelders 1991). Current industry standards for the maximum acceptable levels of primary and secondary abnormalities for porcine spermatozoa used in AI programs are 10% and 20%, respectively (Flowers 1996a, b).

Other Fertility Tests. In addition to the mechanical requirements associated with egg penetration, spermatozoa must also undergo biochemical, metabolic, and molecular changes to acquire fertilizational competence. Table 6.4 summarizes a variety of tests based on one or more of these events. The most promising of these tests attempt to quantify specific aspects of sperm binding to egg membranes or structural changes within sperm membranes. At the present time, many of these tests are still being developed, and their subsequent use within the swine industry remains to be determined.

Semen Processing

Semen Extenders. Semen extenders provide nutritional and metabolic support for stored semen. Generic ingredients used in semen extenders include glucose, electrolytes, buffers, and antibiotics. Glucose is the predominant energy source; electrolytes assist in the regulation of osmotic pressure; buffers are involved in neutralization of metabolic wastes and maintenance of pH; and antibiotics inhibit bacterial growth. An inverse relationship exists between fertility and length of storage for all semen extenders; as the length of storage increases, fertility decreases. The rate at which fertility decreases during storage is primarily a function of the buffering system of the semen extender.

Interactions among several different factors determine the longevity of stored semen. These include individual boar characteristics, semen extender, sperm concentration, and storage temperature. In general, there is an inverse relationship between sperm concentration and length of storage. In other words, an insemination dose of 2 billion sperm cells in a total volume of 80 mL would be expected to have a longer shelf life than one containing 4 billion spermatozoa in the same volume.

Table 6.4. Summary of various measurements used to estimate the fertilizing ability of boar spermatozoa.

Measurement	Rationale	References
Percoll gradients	Velocity of spermatozoa is positively correlated to fertility. Sperm with increased velocities can be separated via Percoll gradients.	Grant et al. 1994
Fluorescent stains	Some fluorescent stains (Hoechst 33258) enter sperm cell if membrane is damaged and stain only dead cells. Others (SYBR-14) enter sperm with a membrane potential and stain only live cells.	Johnson et al. 1996
Sperm chromatic structure	When subjected to acidic conditions and stained with the metachromatic dye acridine orange, double-stranded DNA gives a green fluorescence, while single-stranded DNA (damaged) gives a red fluorescence. Ratio of green to red sperm is related to fertility.	Evenson et al. 1994
Sperm plasma membrane protein profile	Plasma membrane proteins were separated and quantified. Three proteins were positively correlated with sperm binding to egg membranes ($r = 0.38–0.53$). Two proteins were negatively correlated with sperm binding ($r = -0.42$ and -0.37).	Ash et al. 1994
Oocyte membrane-binding assay	Fertile spermatozoa bind to egg membranes. Correlation between egg binding and in vivo fertility from heterospermic inseminations was high ($r = 0.80$).	Berger et al. 1996
Hemizona-binding assay	Oocytes are bisected and the numbers of sperm from different boars binding to each half of the zona pellucida are counted. Within a hemizona pair, increased binding equates to increase fertility.	Fazeli et al. 1995

6.14. *Changes in viability of spermatozoa over time for two littermate boars. Spermatozoa from both boars were stored in three different semen extenders. Top panel: Data from boar A. Bottom panel: Data from boar B. Pooled standard errors for A and B were 7.3% and 8.2%, respectively.*

An example of the interaction between individual boar characteristics and semen extender type on sperm cell longevity is illustrated in Figure 6.14. In this example, the viability of semen in storage was optimized by use of one semen extender for one boar and a different extender for a second boar. These data indicate that problems with maintenance of semen viability in vitro may be related to an incompatibility between components of the semen extender and seminal fluids of an individual boar. If such incompatibilities exist, then using different semen extenders may solve the problem.

Semen Extension Procedures. Minimization of any potential differences in temperature, osmolarity, and pH between the extender and semen is necessary to maintain high sperm viability during the dilution process. Temperature differences are minimized by monitoring the temperature of both the extender and the semen and adjusting the temperature of the extender to within 1°C of the semen. Previous studies have demonstrated that a reduction in viability of semen is likely to occur when temperature differences between

the two liquids exceed 2°C. Measurement of osmolarity and pH prior to extension probably is not feasible practically or economically in most situations. However, procedural precautions can be taken to minimize the effects of any differences that may exist. First, it is important to allow sufficient time for the stabilization of the pH and osmolarity of freshly prepared extender before it is mixed with semen. The pH of most semen extenders equillibrate 45–60 minutes after preparation. Second, a two-stage dilution process helps minimize any detrimental effects due to mixing by allowing the semen to equilibrate slowly to any differences in pH or osmolarity that may exist between it and the extender. In a two-stage dilution process, an equal amount of extender is added slowly to semen over a 2- to 5-minute period. The resulting mixture is allowed to equilibrate for at least 5–10 minutes before the remaining volume of extender is added.

REPRODUCTIVE DISEASES OF THE BOAR

Breeding Soundness Examination

Breeding soundness examinations (BSE) are not typically conducted on boars that are used for natural service. Producers and veterinarians often rely on conception or farrowing rates as an indicator of boar fertility; however, the use of heterospermic matings interferes with attempts to identify infertile boars by examining farrowing records. Also, several other factors influence farrowing rates and litter size, and thus, it is difficult to identify problem boars solely by record analysis.

Natural-service boars are selected for BSE when infertility is suspected and following disease or injury, especially if the testes or penis are affected. The clinical history should include the boar's previous libido and mating ability, previous injuries, illnesses, and treatments and information regarding litter size and farrowing rates in females inseminated by the boar.

Abnormal sperm cells may not appear in the ejaculate for several weeks after heat stress or illness because it takes about 7 weeks to complete the entire sperm production process. This makes it difficult to identify causes of infertility in boars without the clinical history.

The body condition and general health of the animal should be assessed, with attention given to the soundness of feet and legs. Physical examination of the external genitalia includes palpation of the testes, epididymis, and prepuce. The testis should be 10–15 cm in length and 6–7 cm in width. Abnormalities, such as abscesses, bites, or scars on the scrotum, should be recorded and the preputial fluid examined for purulent material or blood.

The gloved-hand technique is the most practical method to collect semen from natural-service boars. Instead of using a dummy sow, the boar is exposed to a sow in standing estrus and allowed to mount. The penis is grasped before vulva penetration. At this point, the

procedures for semen collection are similar to those used for routine collection from AI boars.

Semen Assessment During the BSE

A complete semen evaluation includes determining the total number of sperm cells and estimating the viability and fertility of sperm cells. There are few differences between semen assessment as part of the BSE and as part of AI programs. However, some components of the evaluation should be emphasized for boars used for natural service:

1. A clean ejaculate has little odor. In contrast, an ejaculate that has been contaminated with preputial fluid or with purulent material has a very distinctive odor.
2. Usually a boar will ejaculate 150–250 mL of semen, but the volume can range from 50 to 500 mL. One must consider the fact that boars without previous experience with gloved-hand collection may not complete ejaculation.
3. Photometers are useful for sperm counts in AI laboratories. However, a hemocytometer and portable microscope should be sufficient for on-farm semen counts.
4. Assessing sperm morphology is time-consuming and requires an above-average microscope with an oil immersion objective. It may be beneficial to stain a sample of sperm cells with eosin-nigrosin and examine the slides at the clinic rather than on the farm. Consider semen with over 30% abnormalities as suspect and reject samples if the percentage of abnormalities exceeds 50%.
5. Assessment of motility is subjective, and motility of sperm cells is highest when temperatures are between 32°C and 38°C. Microscope slides must be within 1–2°C of the semen sample temperature to avoid shocking the sperm cells and reducing motility. The microscope slides can be stored in a portable incubator, or they can be placed on a warming device before dropping the semen onto them. If motility is poor, prepare a second slide, making sure that the slide, the pipette, and the coverslip are at 35°C.

Systemic Infections that Cause Fever

Common causes of poor semen quality include stress and overuse, but overheating of boars is considered the most common cause of abnormal semen. Infectious diseases, wounds, bruising, and cuts on the testes or scrotum can raise the boar's body temperature or the temperature of the injured organ. Because the scrotum plays a role in regulating the temperature of the testes, any defect or abnormal condition of the scrotal area may also have an adverse effect on the production of sperm cells. In general, changes in semen quality after infection are similar to those that occur after boars are exposed to high ambient temperatures.

Abnormal sperm cells may be observed for several weeks after a boar recovers from a disease. The percentage of abnormal sperm cells in an ejaculate depends upon the severity and duration of the illness and the pathogen. Other noninfectious factors affecting semen quality have been reviewed in detail (Almond et al. 1994).

Localized Infections

If the epididymis is infected, there is often swelling of the testes and scrotum. An epididymal infection lowers fertility and should receive immediate attention. Fever, infection, orchitis, or inflammation of the scrotum can cause testicular degeneration of boars with previously demonstrated normal fertility. This condition involves degeneration of the germinal epithelium of the seminiferous tubules and must be diagnosed with a biopsy. Eventually, the testicular tissue will atrophy, resulting in flabby testicles, which may become firm if fibrous growths or calcium deposits accumulate in the testes. Although the boar's libido is unaffected, the ejaculate will have few sperm, sperm motility will be poor, and a high percentage of sperm will be abnormal. If an 8-week rest does not improve the condition, these boars should be culled.

Bacteria that appear to act directly on the function of the testes include *Brucella suis*, *Erysipelothrix rhusiopathiae*, *Mycoplasma hyosynoviae*, *Streptococcus suis*, *Staphylococcus aureus*, and *Escherichia coli*. *Brucella suis* can become localized in the testes and cause inflammation that will impair the boar's ability to manufacture sperm. Brucellosis can also cause testicular degeneration. Erysipelas can cause inflammation and degeneration of the testes. Ubiquitous bacteria, such as *Streptococcus suis*, *Staphylococcus aureus*, and *Escherichia coli*, can localize in the testes. It is not known whether the resulting fertility problems are due to a direct effect on sperm manufacture or to infection of the sow's reproductive tract.

Many viruses, including African swine fever, PPV, and PRRSV, have been shown to infect sows inseminated with contaminated semen. PRRSV can have a marked effect on spermatogenesis, resulting in fewer sperm, impaired motility, and higher percentages of abnormalities for up to 13 weeks after infection (Christopher-Hennings et al. 1995; Preito et al. 1995). Not all affected boars will show clinical signs of PRRS. Under certain circumstances, boars may be included in vaccination protocols intended to control PRRSV. The influence of vaccination, natural infection, or vaccination followed by natural infection on semen quality requires clarification. This confusion is due, at least in part, to apparent differences among the various PRRSV strains in causing disease.

7 Diseases of the Respiratory System

Vibeke Sørensen, Sven Erik Jorsal, and Jan Mousing

The structure of swine production has changed substantially in most swine-producing areas over several years; large groups of animals are housed under intensive conditions, often in regions with an extremely dense pig population. High stocking density in a closed environment facilitates transmission of airborne pathogens within the herd (Donham 1991; Buddle et al. 1997) and between herds as well (Jorsal and Thomsen 1988; Stark et al. 1992; Christensen et al. 1993). Consequently, respiratory disorders and systemic airborne diseases are today regarded as the most serious disease problems in modern swine production.

STRUCTURE OF THE NORMAL RESPIRATORY SYSTEM

The respiratory tract develops from the anterior part of the embryonic gut as a tree-structured tubular organ. The mature respiratory apparatus comprises the nasal cavity, pharynx, larynx, trachea, and lungs with bronchi, bronchioli, and alveoli. The lungs are embedded in the pleural sac.

There are two separate blood-conducting systems in the lungs. The arteria pulmonalis system vascularizes the capillary plexus surrounding the alveoli with venous blood from the right ventricle. The close structural and functional parallelism between this blood stream and the tubular airway system is important to realize when possible infection routes in the lungs have to be interpreted. The supporting structures around the trachea, bronchi, and bronchioli and even the wall of the arteria pulmonalis are vascularized with blood from the arteria bronchialis tree.

Tubular Tract System

The nasal cavity is divided longitudinally by a wall (septum nasi). Two turbinate bones divide each of the two halves of the cavity into three meatuses: dorsal, middle, and ventral (Figure 7.1). The length of the nasal cavity varies between different breeds. The trachea is relatively short and divides posteriorly into two principal bronchi, one for the left and one for the right lung (Figure 7.2). A special stembronchus branches from the trachea leading to the apical lobe of the right lung. The right principal bronchus sends a stembronchus to the right cardiac lobe and another to the intermediate lobe and then continues until it ramifies into the diaphragmatic lobe. The left principal bronchus gives off a stembronchus that divides into one branch for the apical lobe and one for the cardiac lobe. The principal bronchus then continues posteriorly in the diaphragmatic lobe. The finest branches of the tubular system are the bronchioli, each dividing into alveolar ducts and alveoli.

The vestibular region of the nasal cavity is lined with stratified squamous epithelium. Posteriorly, the epithelium changes from stratified columnar to ciliated pseudostratified epithelium with goblet cells (respiratory epithelium). The respiratory epithelium is covered by mucus produced by the goblet cells and this type of epithelium continues through the respiratory section of the pharynx, larynx, trachea, and bronchi. As the bronchioli approach the alveoli, the epithelium is reduced in height, becoming squamous. Sections of the bronchioli (called *respiratory bronchioli*) and the walls of the alveoli are covered by very flat, single-layered epithelial cells (type I alveolar cells) and by a small percentage of cuboidal epithelial cells (type II alveolar cells). Type II alveolar cells produce pulmonary surfactant and serve as progenitor cells for replacement and turnover of type I alveolar cells. The alveolic wall is very intimately attached to the capillary plexus of the pulmonary blood circulaton.
Gross Appearance of the Lung

In the pig the lungs are divided by deep fissures into seven lobes: the right lung comprises the apical, cardiac, diaphragmatic, and intermediate lobes; the left lung comprises the apical, cardiac, and diaphragmatic lobes (refer to Figure 7.2). The left apical and cardiac lobes are not separated by a fissure but only by the cardiac notch.

7.1. Transverse section of nasal structures.

7.2. Schematic outline of lung lobulation and branching of the bronchus tree. LA, RA: left and right apical lobes; LC, RC: left and right cardiac lobes; LD, RD: left and right diaphragmatic lobes; I: intermediate lobe. Numbers = relative lobe weights as percentage of total lung weight based on a study by G. Christensen (unpublished data).

The lobes are subdivided by solid interlobular septa into lobuli. Pathological processes, therefore, often will be retained within lobular structures, typically seen in catarrhal bronchopneumonia as sharp demarcated limits between normal and affected tissue.

When assessing the extent of lung lesions it is necessary to know the relative size or weight of each lobe. Table 7.1 shows the relative weights of the lung lobes as percentages of the total lung weight, as determined in three different studies. The right lung contributes more than half of the total lung weight, with small differences between the investigations. The variations might be caused partly by different average live weights of the animals examined. The animals in study C had a lower average live weight (90 kg) than those in study A (100 kg)

and study B. The difference between the weight of the two lung halves tended to be greater in animals of lower slaughter weight.

FUNCTION OF THE NORMAL RESPIRATORY SYSTEM

The vital gaseous exchange between inhaled air and venous blood from the pulmonary artery takes place at the alveolar level. Each breath renews only a minor part of the total alveolar air volume. In the resting pig, 10–15% of the alveolar air is exchanged per inspiration. The nor-

Table 7.1. Relative weights of lung lobes as percentages of total lung weight.

Study	N	Left Lung Lobes			Right Lung Lobes			Interm.
		Apical	Cardiac	Diaphr.	Apical	Cardiac	Diaphr.	
A	11	7	7	32	12	8	30	5
B	20	5	7	32	6	9	36	5
C	13	5	6	29	11	10	34	5

Note: A = Morrison et al. (1985) (rounding of numbers caused a total percentage of 101 %); B = Heilmann et al. (1988); C = G. Christensen, unpublished data. N = number of pigs examined in each study.

mal respiratory rate (breaths/minute) varies according to age of the animal (piglets and growing pigs, 25–40; finishing pigs, 25–35; sows in gestation, 15–20).

Defense Mechanisms of the Respiratory System

The mucosal surface of the respiratory tract provides a critical interface between the pig and its environment. While the skin is well adapted to prevent invasion of potentially harmful agents and has a limited surface area (about 1.8 m^2 in humans), the epithelial surface of the respiratory tract primarily serves as a diffusion membrane. The gaseous exchange requires a very large surface (in humans more than 100 m^2). Thus, it is understandable that the respiratory tract must be equipped with a potent and specialized defense apparatus. The most important components of the respiratory defense are listed in Table 7.2.

The nasal cavity is designed to remove large particles trapped by hairs in the nostrils and deposited by gravity in the mucus by the eddy currents around the conchal structures. Another function of the nasal cavity with its immense venous sinusoids and wet surfaces is humidification and warming of the air before it reaches the lower airways.

Most inspired particles are trapped in the epithelial mucus of the nasal, pharyngeal, laryngeal, and tracheal cavities. From many experiments it is known that only particles below an aerodynamic diameter of 5 μm (the respirable fraction) are able to reach and settle at the alveolar level. Particles of an aerodynamic diameter greater than 10 μm almost entirely settle before reaching the branches of the bronchial tree (Baskerville 1981).

Mucociliary Defense. Particles trapped in the epithelial mucus are handled by the mucociliary clearance mechanism. The ciliary carpet in the bronchi and bronchioli gives rise to a continuous flow of mucus toward the pharynx. The rhythmic beating of cilia results in a mucus flow of about 4–15 mm/minute (Done 1988). Like the mucus from the nasal cavity, it is delivered to the pharyngeal cavity and subsequently swallowed.

Phagocytes. Alveolar macrophages neutralize foreign material that escapes the mucociliary defense mechanism. Nonpathogenic particles and microbes are handled by simple phagocytic activity and are removed in the mucus flow or by the lymphatic system. Pathogenic microorganisms are neutralized with aid of secretions such as lysozyme, interferons, opsonins, lactoferrins, complement factors, and specific immunoglobulins in the mucus. If the invading agents are not neutralized by the alveolar macrophages, inflammation will occur. Neutrophils from the blood will then invade the alveolus and assist the macrophages in the phagocytic activity. In healthy pigs the normal ratio between the cellular elements in the bronchoalveolar mucus is 70–80%

Table 7.2.   Respiratory system defense components.

Physical/Chemical
  Hairs in nostrils
  Structure of the nasal cavity
  Structure of mucosa
  Properties of mucus (physical and chemical—e.g., adhesiveness, nonspecific lysozymes, interferons, opsonins, lactoferrins, complement factors, specific immunoglobulins)
  Humoral components (mucus contents and multiple types of immune modulators—e.g., lymphokines)
Cellular
  Phagocytes (alveolar macrophages, vascular macrophages, histiocytes, monocytes, neutrophils, eosinophils)
  Bone marrow-derived B lymphocytes (plasma cells)
  Thymus-derived T lymphocytes (helper lymphocytes, suppressor lymphocytes, cytotoxic lymphocytes [natural killer cells])

alveolar macrophages, 11–18% lymphocytes, 8–12% neutrophils, and up to 5% eosinophilic granulocytes (Neumann et al. 1985). The phagocytic cell system also comprises intravascular macrophages, which in the pig are particularly numerous (Bertram 1985; Ohgami et al. 1989) in the lung, and histiocytes with phagocytic properties in the connective tissue.

The activity of the phagocytes is highly accelerated if introduced pathogens are not quickly eliminated or if pathogens are recognized from previous infections. A complex immune response is activated by stimulation of the cell-mediated immune system, followed by local and systemic production of specific antibodies (immunoglobulins—Ig).

Immunoglobulins. The production of specific antibodies is of crucial importance in the respiratory immune defense. Their biological function is neutralization of pathogens by generating antigen-antibody complexes.

The predominant antibodies in mucus are of the IgA type and a secretory component takes part in the secretion. IgM antibodies are potent proteins released in the early immune response, particularly in the newborn pig. IgG originating from blood serum form the greater part of the immunoglobulins in mucus of the lower respiratory tract near the alveoli. Immunoglobulins in the mucus carpet act primarily to prevent the initial establishment and penetration of pathogens. IgE are generated in the immune response against parasites, for example, lungworm (*Metastrongylus* sp.) and migrating ascarid larvae.

Cell-Mediated Immune Response. Traditionally, immunity is divided into a humoral immune response, in which the immunoglobulins play an essential role, and a cell-mediated immune response based on antibody-independent components. Today it is realized that immunity cannot be distinctly separated into these two parts, because many mechanisms and elements are closely linked.

Generally, cell-mediated immunity is identified with: cytotoxic T cells, natural killer cells, activated macrophages, and cells mediating antibody-dependent cytotoxicity. The cell-mediated immune response is assumed to be of special importance in viral infections such as influenza, PRRS, PCV2 and Aujeszky's disease, but is also assumed to play an important role in *Mycoplasma hyopneumoiae* infection.

Surface proteins belonging to the swine leukocyte antigen (SLA) gene complex (major histocompatibility gene complex [MHC]) play a significant role in the cellular, as well as the humoral, immune response. Rothschild et al. (1984) demonstrated that the SLA complex was associated with immune response following vaccination with *Bordetella bronchiseptica,* and Mallard et al. (1989) showed differences in serum IgG concentrations in different SLA haplotypes, indicating that selection for increased serum IgG would be possible. Genetic variability of the SLA complex has been demonstrated in different breeds of pigs (Vaiman et al. 1979).

Since placenta of pregnant sows are impermeable to immunoglobulin passage, the neonates are born without antibodies. Although immunocompetent, the piglets are unable to rapidly develop an active immune response to protect them against respiratory diseases. Thus, their survival depends upon the passive acquisition of maternal immunity including at least three components:

- A systemic humoral immunity, transmitted through colostrum
- A local humoral immunity transmitted through milk
- A cellular immunity transmitted via maternal immunocompetent cells present in mammary secretions (Salmon 2000)

Like lambs, piglets are capable of intestinal absorption of intact immunocompetent maternal lymphocytes from colostrum, but only from their own mother (Tuboly et al. 1988; Tuboly and Bernath 2002). Williams (1993) showed the distribution of such cells to liver, lung, lymph nodes, spleen, and gastrointestinal tissue of the piglets by 24 hours postfeeding. Blecha et al. (1983) found that the capability of lymphocytes to undergo blastogenesis was decreased in pigs weaned at 2 and 3 weeks of age and suppressed in pigs weaned at 4 weeks of age. Their data suggested that weaning pigs younger than 5 weeks old causes physiological changes detrimental to cellular immune reactivity, which could alter disease susceptibility in piglets. This information may be useful when managing the farrowing units, where random distribution of piglets between sows and early weaning may contribute to decreased resistance against respiratory infections before as well as after weaning.

Transepithelial passage from the lumen of the respiratory tract into the blood of antigenically intact macromolecules can take place during the first days of life and also to a considerable degree in older pigs (Folkesson et al. 1990). This indicates future possibilities for aerosol-based vaccines against respiratory diseases. Vaccination experiments with Aujeszky's disease in young piglets with passively acquired antibodies indicate that the systemic immune mechanism can be bypassed and a local immune response obtained by application of antigen on the respiratory epithelium (Schlesinger et al. 1990). Nielsen et al. (1990) obtained good immunological protection against *Actinobacillus pleuropneumoniae* with local application of antigens in the respiratory tract.

RESPIRATORY DISORDERS

Under commercial conditions few pigs can be expected to reach slaughter weight without contracting some sort of respiratory lesion. Pathologic alterations can be categorized into three main disease entities: rhinitis, pneumonia, and pleuritis. Detailed characterizations of microscopic and gross pathologies of the individual diseases will be given in other chapters. However, some general features of pathology will be presented here.

Rhinitis
Catarrhal inflammation of the nasal mucosa is common in young animals. The cause is often infectious (Aujeszky's disease virus, cytomegalovirus, *B. bronchiseptica*, *Mycoplasma hyorhinis*), but ammonia and dust in the air as well as foreign bodies can also provoke mild mucosal inflammation of short duration. However, if toxigenic strains of *Pasteurella multocida* are present, even a slightly damaged mucosa might promote adherence and proliferation of the bacteria and subsequently provoke progressive atrophic rhinitis with permanent alteration of the nasal structure and function. The structural changes in atrophic rhinitis are fundamentally induced by an altered bone metabolic process without inflammation of tissue (Foged et al. 1987).

Pneumonia
Bronchopneumonia. Catarrhal bronchopneumonia, located cranioventrally, is a frequent lesion of the lung in growing pigs. Since *M. hyopneumoniae* generally is involved, such lesions are often given the term mycoplasmal or mycoplasma-like pneumonia. Noncomplicated mycoplasmal pneumonia typically appears as confluent, purple consolidation, more collapsed than normal lung tissue. Early lesions may be somewhat indistinct, but after 2–3 weeks the lesions are clearly demarcated from adjacent normal tissue by a sharp line following the interlobular septa. When incised, the consistency is "meaty" but not excessively firm. Catarrhal exudate may be expressed from the airway openings of affected tissue. Fissures regularly appear in lobes previously affected with catarrhal bronchopneumonia (Bertschinger et al. 1972).

Lesions with secondary bacterial infections may

change to a more grayish color, and the consistency will be firmer due to formation of fibrous tissue. Further, complicated bronchopneumonia due to secondary bacterial infection usually results in purulent bronchitis or abscess formation. Severe cases may also present pleuritis with adhesion to the thoracic wall.

Fibrinous/Necrotizing Pneumonia. Another common pathological entity of the lung is fibrinous/necrotizing pneumonia, which affects the dorsocaudal portions of the organ in contrast to the cranioventrally located catarrhal or mucopurulent bronchopneumonia. Affected tissue is frequently raised above the adjacent area and crosses interlobular septae, unlike catarrhal bronchopneumonia. Fibrinous/necrotizing pneumonia is often called pleuropneumonia since the pleural surface of affected lung tissue is involved in nearly all cases. In the acute state the inflamed pleural surface is covered with fibrinous exudate. In subacute/chronic cases the associated pleural lesion consists of fibrous tissue, often resulting in firm adherence of the lung to the chest wall.

Interstitial Pneumonia. Interstitial pneumonia is a condition where the inflammatory processes primarily involve the alveolar walls and interstitial tissue, in contrast to bronchopneumonia, where inflammation principally affects the finest branches of bronchioles (the bronchioloalveolar junctions). Also, in contrast to bronchopneumonia, interstitial pneumonia is widely distributed throughout the lung. Interstitial pneumonia is most often caused by viral infections.

Embolic Pneumonia. Embolic pneumonia is caused by hematogenically disseminated agents, mostly pyogenic bacteria from lesions somewhere else in the body. Typically this type of pneumonia starts as minute necrotic foci surrounded by a hemorrhagic zone. Usually suppuration of the centers follows and circumscribed abscesses are formed. A secondary bronchopneumonia or a pleuropneumonia-like inflammation may develop around the primary process. Verminous migration through lung tissue induces small hemorrhagic foci, small abscesses, or firm granulomas. The verminous processes are mainly located dorsocaudally in the lung.

Lesion Distribution Patterns. Cranioventral distribution of mycoplasmal and most other bronchopneumonias might be due to less effective defense mechanisms in this region. This assumption is supported by the fact that *Pasteurella hemolytica* causes pneumonia in this region even if the bacteria reach the lung via the blood (Dungworth 1993). Gravitational influence impeding clearance, leading to pooling or reflux of secretions, is probably a contributing factor.

Experimentally, inhaled aerosolized suspensions of *Bacillus subtilis*, *A. pleuropneumoniae* (Sebunya et al. 1983), and *Staphylococcus aureus* (Kastner and Mehlhorn 1989) are deposited primarily in the caudal lobes. This accords with the fact that *A. pleuropneumoniae*–induced pleuropneumonia is predominantly localized dorsocaudally. In another investigation, inhalation of an aerosolized suspension of radioactively labeled *P. multocida* resulted in a relatively uniform deposition in the lung lobes (Heilmann et al. 1988).

Usually, pneumonic lesions due to hematogenically introduced pyogenic bacteria have a random distribution pattern, which makes them easily distinguishable from lesions due to bronchogenically disseminated bacteria (Buttenschøn 1989). Verminous lung lesions have a caudodorsal location in spite of the assumption that the larvae are introduced via the bloodstream. However, some extravascular migration through the diaphragm might take place (Buttenschøn 1990).

Since chronic pleuritis almost always is associated with a present or, more often, a previous inflammation of lung tissue, the localization of pleuritic lesions is of diagnostic value in determining the type of pneumonia involved.

Healing of Pneumonia. The healing of catarrhal bronchopneumonia is a rather slow process requiring several weeks or months. However, the healing period depends greatly on the agents involved. In specific pathogen free (SPF) pigs inoculated with *M. hyopneumoniae*, induced pneumonic lesions were healed after 2 months, whereas fissuring of the lung persisted for more than 3 months (Bertschinger et al. 1972; Kobisch et al. 1993; Sørensen et al. 1997). By comparing the time of seroconversion with lung lesions at slaughter, Wallgren et al. (1994) estimated the duration of active mycoplasmal lesions to be approximately 12 weeks, and Pattison (1956) still found pneumonic lesions 25 weeks after inoculation with *M. hyopneumoniae*, presumably due to secondary bacterial infection. Unlike catarrhal bronchopneumonia, the interval between appearance and disappearance of *A. pleuropneumoniae*-induced fibrinous/necrotizing pneumonia may be surprisingly short (about 3 weeks) if not complicated with secondary pyogenic infections. This is in accordance with Andreasen et al. (2001) and Wallgren et al. (1994) who found no correlation between seroconversion to *A. pleuropneumonia* and lesions at slaughter. Seroconversion to *M. hyopneumoiae* close to slaughter revealed the largest extent of mycoplasma-like bronchopneumonia and early seroconversion was related to ventrocranial pleuritic lesions. However, infections gained during the early fattening period will generally escape detection at slaughter.

Pleuritis

Fibrotic adherence between the visceral and pleural membranes of the pleural sac (chronic pleuritis, pleural scar) is one of the most frequent pathologic alterations seen in slaughter swine. Fibrous pleuritis affecting larger areas is often associated with similar lesions in the peri-

cardial sac (chronic pericarditis). The repairing of such lesions is a long process, with a duration of at least 1 month, more often 2–3 months (Christensen 1984). The resolving of chronic pleuritis in growing pigs may cause younger fatteners to have a higher frequency of this lesion than older pigs (Mousing 1988). In an investigation of infectious and herd-related factors by logistic regression Enoe et al. (2002) found that seropositivity for *A. pleuropneumoniae* serotype 2 and *M. hyopneumoniae* in conventional herds were associated with 51% and 29% of the occurrence of chronic pleuritis at slaughter, respectively. In SPF herds reinfected with *M. hyopneumoniae*, seropositivity for *M. hyopneumoniae* was associated with 33% of the occurrence of chronic pleuritis detected at slaughter.

CAUSAL FACTORS IN RESPIRATORY DISEASE

General Epidemiologic Considerations

Respiratory disease must be seen as the result of a complexity of events, including infectious, environmental, managemental, and genetic factors. Because the etiology of respiratory disease is multifactorial, one should consider not just specific infectious agent, but other relevant factors as well.

A given pathogen or environmental risk factor will tend to increase the incidence of disease. In quantifying this increase, the ratio between the incidence (or prevalence) among pigs exposed to the factor and the incidence (or prevalence) among pigs that are not exposed can be calculated. This ratio is most often referred to as the relative risk. The higher the relative risk, the stronger the association between the risk factor and disease. When two or more risk factors act simultaneously, the total relative risk will often be greater than the relative risk of the individual factors (Mousing et al. 1990).

Relative risks have to be evaluated with caution, for such associations may be confounded by other factors. Several epidemiologic studies have indicated a positive correlation between herd prevalence of pigs with pneumonia and atrophic rhinitis. This association obviously relies on the fact that the two disease entities are provoked by the same external factors, and not that one disease predisposes to the other. In fact, there was no evidence that animals suffering from one of the diseases were more susceptible to the other when correlation studies included individuals in the same herd (Madec and Kobisch 1984; Straw 1986).

Infection

Respiratory infections occur with a high prevalence in all swine-producing areas (Table 7.3). The spread of respiratory diseases from herd to herd involves two distinct mechanisms. First, like other infections, disease may be disseminated through infectious contacts (purchase of pigs, incoming and outgoing vehicles, birds, rodents,

persons, etc.). Second and very important, several respiratory diseases also propagate from herd to herd by means of airborne transmission. The virus causing PRRS can be introduced into a herd with semen (Swenson et al. 1994; Gradil et al. 1996).

Airborne Transmission of Respiratory Diseases Between Herds. Respiratory infections in swine with the capability of airborne transmission over distances up to several kilometers include *M. hyopneumoniae* (Goodwin 1985; Jorsal and Thomsen 1988; Stark et al. 1992;) and porcine respiratory coronavirus (PRCV) (Henningsen et al. 1988). Systemic viral infections such as foot-and-mouth disease (Gloster et al 2003), PRRS (Mortensen et al. 2002) and Aujeszky's disease (Mortensen et al. 1990) follow this pattern. Airborne transmission between small pig units at close range has been induced experimentally with PRRSV, *A. pleuropneumoniae* and *B. bronchiseptica* (Torremorell et al. 1997; Brockmeier and Lager 2002; Kristensen et al. 2004a, b). However, airborne transmission of bacterial infections between herds has still to be documented. The typical pattern of simultaneous influenza outbreaks in many herds is highly suggestive of the airborne transmission of this infection. In Danish epidemics, even though special precautions are taken against introduction of infectious diseases, SPF herds are attacked by influenza just as frequently as conventional neighboring herds. Epidemics in Brittany also seem to follow an airborne transmission (Madec et al. 1982). Table 7.4 lists factors affecting the risk of a herd receiving an airborne infection.

Airborne spread of disease between herds is facilitated by several meteorological factors—most significantly, the direction and velocity of the prevailing winds. Factors such as cloud cover, turbulence, and topography are also important. Overcast skies, night (when the turbulence is often low), and relative humidity of more than 90% (Gloster et al. 1981) facilitate airborne transmission.

Respiratory Infection in Individuals and in Herds. The upper respiratory tract is the natural habitat for myriads of commensal microorganisms, including viruses, mycoplasmas, chlamydias, and other bacteria. The commensal flora may have a favorable competitive effect for their host in outnumbering pathogenic agents. There is no distinct division between commensals and potentially pathogenic microorganisms. Different studies categorize the same microorganism as either commensal or potentially pathogenic. For example, *Mycoplasma flocculare*, *M. hyorhinis*, and *Haemophilus parasuis* belong to a group of microorganisms that can regularly be isolated in the upper respiratory tract and in the bronchial tree of healthy pigs.

Ganter et al. (1990) examined the bacterial flora in live, healthy, 20–30 kg SPF pigs. The bacteria normally found by alveolar lavage belonged to two or three

species, most often streptococci (nonhemolytic, alpha-hemolytic), staphylococci, *Escherichia coli*, *Klebsiella,* and *Arcanobacterium pyogenes*. *Haemophilus parasuis* and *B. bronchiseptica* were rarely isolated, and *P. multocida* was never isolated in the bronchial tree of healthy pigs. *Haemophilus parasuis* and *M. hyorhinis* were detected in bronchial lavage from about 40% of conventionally reared healthy pigs (Castryck et al. 1990). Møller and Kilian (1990) found that the porcine upper respiratory tract harbors a much wider spectrum of V factor–dependent *pasteurellaceae* species than hitherto recognized, probably with no or low pathogenicity.

   Haemophilus parasuis and *M. hyorhinis* behave as commensals only as long as their pathogenicity is neutralized by the respiratory defense. In nonimmune individuals *H. parasuis* (Nielsen and Danielsen 1975) and to some extent *M. hyorhinis* may become pathogenic, resulting in severe systemic disease (polyserositis, polysynovitis, meningitis). Maintenance of the fine balance between animal population and pathogens evidently re-

Table 7.4. Important herd-related factors that increase the risk of airborne disease transmission between herds.

Factor	Disease
Increasing herd size	Porcine respiratory corona virus (PRCV)[1]; Aujeszky's disease[2,3]
Short distance between herds	*Mycoplasma hyopneumoniae*[4,5]; PRCV[1]
Large size of neighboring herd	*Mycoplasma hyopneumoniae*[4,5]; PRCV[1]
High regional pig density	*Mycoplasma hyopneumoniae*[5]
Herd infected with *Actinobacillus pleuropneumoniae*	Aujeszky's disease[3]

quires that all the pigs are exposed to the pathogens in question in early life. Outbreaks appear under circumstances where the normal infection mechanism does not work properly because of restricted contact between individuals—for example, in small herds, in herds with very early weaning or strict separation between animals of different ages, and in SPF herds established originally from cesarean-derived piglets (Nielsen and Danielsen 1975; Smart et al. 1989).

Actinobacillus pleuropneumoniae and *M. hyopneumoniae* can be regarded as representatives of a different type of respiratory microorganisms: they may be common at herd level but are relatively seldom isolated from healthy individuals (Friis 1974; Castryck et al. 1990). Their presence is usually associated with disease, subclinical more often than clinical.

These two groups of microorganisms behave differently, especially in the immunologically weak state between passive and active immunity, for several reasons. First, *A. pleuropneumoniae* and *M. hyopneumoniae* have a higher pathogenicity than *H. parasuis* and *M. hyorhinis.*

Second and very important, it is known that *H. parasuis* and *M. hyorhinis* invade the nasal and tracheobronchial epithelium very early in the piglet's life (Ross 1984). This might facilitate a gradual development of active immunity under the cover of humoral colostral antibodies, a situation beneficial to host as well as to pathogen. A third reason is that the sites (pleural, pericardial, peritoneal, meningeal, articular serotic cavities) where the real pathogenic properties of *H. parasuis* and *M. hyorhinis* predominate are outside the respiratory tract. Here a clear physical barrier exists between the effector site and the residential site of the microorganism. In contrast, *A. pleuropneumoniae* and *M. hyopneumoniae* are easily brought to their point of attack with the inhaled air, directly from the environment or from the nasal and tonsillar epithelium.

Finally, the ability of strains with low pathogenicity to generate protective antibodies against closely related but more pathogenic strains, as demonstrated for *A. pleuropneumoniae* (Nielsen 1988), must be considered.

In conclusion, the constant presence of pathogens that cannot permanently be excluded from the herd

and that behave like *H. parasuis* and *M. hyorhinis* is acceptable for the herd. However, the presence of pathogens that behave like *A. pleuropneumoniae* and *M. hyopneumoniae* cause potential risk of recurrent disease.

The group of acceptable respiratory microorganisms includes species such as *Haemophilus* "minor group," *B. bronchiseptica*, staphylococci, streptococci, most strains of nontoxigenic *P. multocida*, and some strains of *A. pleuropneumoniae*. In contrast, the most pathogenic strains of *A. pleuropneumoniae* and *P. multocida* are highly disadvantageous because herd infections may give rise to episodes of respiratory problems.

Pasteurella multocida probably is the most frequent and damaging invader of the lung. However, this bacterium is a typical secondary invader (Amass et al. 1994). Even the most pathogenic strains are apparently not capable of infecting a healthy lung, unlike *A. pleuropneumoniae Bordetella bronchiseptica* induces only a discrete pneumonia in conventionally reared 7-day-old piglets (Lambotte et al. 1990), but in gnotobiotic piglets the infection causes severe and long-lasting pneumonia (Underdahl et al. 1982). *Bordetella bronchiseptica* is categorized as an acceptable microorganism, because like *P. multocida*, it is not easily kept out of herds due to the fact that several other animal species, including cats and dogs, are reservoirs.

Interaction Between Infectious Agents. Clinically significant disease seldom is the result of an infection with only one pathogen. Several pathogens are very often involved in respiratory disease. One pathogen acts as the key agent, the "door opener," for secondary invaders by lowering the local and sometimes also the systemic defense mechanisms of the host.

Generally, key agents are viruses or mycoplasmas, but secondary invaders are bacteria. For example, susceptibility in swine to *A. pleuropneumoniae* is increased following an influenza infection (Scatozza and Sidoli 1986), PRRS infection (Pol et al. 1997), or Aujeszky's disease (Lai et al. 1986). A similar effect was observed in experiments in mice infected first with influenza virus and subsequently with *A. pleuropneumoniae* (Bröring et al. 1989). Pigs infected with *M. hyopneumoniae* had a de-

creased resistance against *A. pleuropneumoniae* (Yagihashi et al. 1984), and in another study (Kubo et al. 1995) *M. hyorhinis* increased the severity of pulmonary lesions in piglets infected with PRRS virus. Van Reeth et al. (1994) found higher pathogenicity of a dual infection with influenza virus and PRRS virus than with infection with one of the viruses. Thacker et al. (1999) found that *M. hyopneumoniae* severely potentiated both clinical and pathological manifestations of disease induced by PRRS virus. When disease was induced by swine influenza virus, *M. hyopneumoniae* also potentiated the clinical manifestations, but to a lesser degree the pathological manifestations (Thacker et al. 2001). These findings demonstrate that the relationship between mycoplasmas and viruses varies with the individual agent. In the nasal cavity *B. bronchiseptica* frequently acts as a predisposing key agent facilitating the invasion and replication of toxigenic strains of *P. multocida* (Pedersen and Barfod 1981).

Lesions caused by key agents themselves are often faint and without clinical significance. It is well known from field experiences that influenza and Aujeszky's disease seldom are followed by severe pneumonic complications in herds where *A. pleuropneumoniae* and *M. hyopneumoniae* are absent (e.g., SPF herds), whereas serious respiratory complications regularly follow these viruses in other herds.

As a rule one pathogen intensifies the proliferation of another, but the reverse effect also can be demonstrated. In a cross-sectional seroepidemiological study, Mousing (1991) examined 4800 slaughter pigs for serological evidence of *A. pleuropneumoniae* serotype 2 and serotype 6, *H. parasuis* and swine influenza virus (type H1N1 with American and European variants). The interrelationship between these five respiratory infections is illustrated in Table 7.5, demonstrating the relative risk of confirming a specific infection when a pig also possesses antibodies against another agent.

Most infections appeared to be positively associated with *A. pleuropneumoniae* serotype 2, except for *A. pleuropneumoniae* serotype 6. The probable explanation is that *A. pleuropneumoniae* serotypes share antigens that provoke generation of cross-protecting antibodies (Nielsen 1988). The reverse effect was demonstrated for the two influenza variants.

The effect of an increasing number of infections on prevalence of chronic pleuritis is graphed in Figure 7.3. The prevalence of chronic pleuritis increases from 12.5% in pigs free from all of the five infections to more than 60% in pigs infected with four or all five of them.

Transmission of Infection Between Age Groups. Although the structure of modern pig production is rap-

idly changing, preferably toward all-in/all-out and multi-site systems, farrow-to-finish operations still exist. With continuous flow of animals through the system a steady transmission of respiratory pathogens occurs from sows to piglets and, maybe more important, from older to younger pigs. Replication of respiratory pathogens may concentrate in the facilities for growing pigs, which act as "pathogen generators" in the herd. From here the breeding animals are periodically infected. This mechanism explains why it is simpler by far to control respiratory disease in breeding herds marketing all growers and feeders than in herds that also finish the pigs.

Origin of Pigs

The origin of introduced animals significantly influences the risk of the herd contracting respiratory diseases. It is evident that respiratory problems can be expected if pigs with low health status are introduced into a herd. However, there also is a risk when introducing animals with a high health status into herds with a lower health status without taking any precautions to protect the healthy animals against infection. Such animals, insufficiently protected by specific immunity, easily develop clinical disease. Consequently, a sudden rise in infection pressure occurs, and an established herd balance between infection and immunity is jeopardized.

In Danish SPF herds it is clearly illustrated that the risk of a herd contracting respiratory problems increases with the number of animal groups introduced and the number of different sources (Jorsal and Thomsen 1988). Castryck et al. (1990) made the same observation in Belgian conventional pig production systems. Awareness of the herd's status regarding respiratory pathogens and solely buying in breeding animals from a single herd with similar status can contribute to prevent outbreaks of respiratory disease. Establishment of quarantine facilities for introducing breeding animals can often be beneficial for maintaining the herd health status. Furthermore, it is important to keep a good biosecurity in order to prevent unwanted respiratory pathogens to enter the facilities by other routes.

Number of Individuals in Herd or Room

Most empirical epidemiologic studies have revealed that the risk of contracting respiratory disease increases significantly with increasing herd size, and also with the pig density in the vicinity of the herd (Aalund et al. 1976; Bäckström and Bremer 1976; Flesja and Solberg 1981; Mehlhorn and Hoy 1985; Jorsal and Thomsen 1988; Cubero et al. 1992; Stark et al. 1992; Christensen 1995; Goldberg et al. 2000; Maes et al. 2000; Enoe et al. 2002). The theoretical background of the herd size effect has been explained by Willeberg et al. (1994, 1995). Hartley et al. (1988a) and Tielen (1989) found no relationship between respiratory disease at slaughter and herd size, and Martinsson and Lundeheim (1988) found only weak relations. A very large herd might have a somewhat lower level of respiratory disease than one not quite so large (Willeberg et al. 1984/85; Martinsson and Lundeheim 1988). The probable explanation is that very large herd facilities must be subdivided and pigs moved into groups to control infectious diseases.

The number of animals placed in the same airspace significantly affects the incidence of disease. Experience from several investigations (Lindqvist 1974; Tielen et al. 1978; Pointon et al. 1985) indicates that respiratory problems are difficult to control if more than 200–300 animals are housed in the same barn; in the Netherlands housing only 80 fatteners together is advised (Tielen 1989).

Theoretically, for pigs sharing airspace, the risk of exchanging suspended particles increases substantially with increasing number of pigs ($n^2 - n$, where n = number of individuals). The same effect is seen when floor space per pig is decreased (Lindqvist 1974; Bäckström 1978; Mehlhorn and Hoy 1985; Pointon et al. 1985).

Climate

Goodall et al. (1993) combined data from abattoirs with meteorological data from Northern Ireland in 1969–1989 and found significant trends in the occurrence of condemnations due to pleurisy and pneumonia and also significant correlations between the percentage of condemnations and air temperature. In Belgium, Maes et al. (2001) found an increased prevalence of pleuritis at slaughter in January and more severe lesions when pigs were slaughtered in March to April. In Denmark, Bille et al. (1975) found a significantly higher incidence of pneumonia in piglets during the winter season than during the summer months. This indicates that climatic factors are included in the etiology of pneumonia.

A high exchange rate of air often causes local drafts and chilling of animals. As with humans, a sudden chilling by drafts predisposes pigs to respiratory infections. In weaned pigs subjected periodically to drafts, Scheepens (1996) reported a higher frequency of sneezing and coughing than in controls. Subjecting controls and pigs with atrophic rhinitis to similar climatic stress caused an 8-day difference in days to slaughter, compared to a 3-day difference in the two groups of pigs when not exposed to adverse climatic conditions. Flesja et al. (1982) found that solid-sided pens were associated with a reduction in incidence of pneumonia, presumably by preventing drafts and Maes et al. 2001 found that pigs raised in pens with slatted floors were at higher risk of contracting severe pneumonic lesions. According to Kelley (1980) cold drafts and wide temperature differentials stress the immune mechanisms, thus increasing susceptibility to disease. This is confirmed in weaner pigs, where exposure to cold drafts significantly reduced immune response (Scheepens et al. 1988). Prolonged cold stress in suckling piglets experimentally infected with *P. multocida* resulted in lowered levels of serum IgG, lowered phagocytic activity of the polymorphonuclear

granulocytes, and delayed local cellular reaction in the lungs of some of the piglets compared with controls. However, the course of infection, the clinical response, and postmortem findings were not influenced by cold stress (Rafai et al. 1987).

Air Pollution

High concentrations of ammonia in the air may be detrimental to respiratory health. Ammonia in concentrations of 50–100 ppm particularly interferes with normal mucociliary function (Curtis et al. 1975a; Johannsen et al. 1987; Neumann et al. 1987). Under normal conditions the ammonia concentration in pig pens does not exceed 20 ppm. Clark et al. (1993) did not find that ammonia concentrations of 18 ppm influenced development of mycoplasmal pneumonia. Nevertheless, epidemiologic studies have revealed the highest incidence of respiratory disease in herds with the highest ammonia concentrations in the air (Pointon et al. 1985). Also, when pigs were given the choice of moving between fresh air and ammoniated air (100 ppm ammonia) they preferred the fresh air (Smith et al. 1996). Donham (1991) found several air contaminants—such as dust, ammonia, and microbes—to be correlated with pneumonia and pleuritis in swine and has proposed maximal safe concentrations on the basis of dose-response correlation to swine health and human health problems: dust 2.4 mg/m^3, ammonia 7 ppm, endotoxin 0.08 mg/m^3, total microbes 10^5 cfu/m^3, and carbon dioxide 1,540 ppm.

However, many investigations have failed to demonstrate significant relation between dust and respiratory disease (Martin and Willoughby 1972; Curtis et al. 1975b; Gilmour 1989; Jansen and Feddes 1995).

Enteritis

A high prevalence of respiratory lesions at slaughter was found in pigs previously experiencing enteritis (Aalund et al. 1976). A highly significant correlation was found between pigs that needed treatment for enteritis and pigs that were treated for pneumonia (Jørgensen 1988). Litters that shed rotavirus during the preweaning period had higher incidence rates of respiratory diseases than virus-free litters (Svensmark et al. 1989). Marois et al. (1989) demonstrated aggravation of experimentally induced mycoplasmal pneumonia in piglets also infected with transmissible gastroenteritis (TGE) virus. Digestive disorders seem to reduce resistance to pneumonia, and also some swine diseases, like postweaning multisystemic wasting syndrome (PMWS) (Allan and Ellis 2000), include both dyspnea and diarrhea in the symptoms.

Gender

From surveillance of slaughter swine at Danish abattoirs it has continuously been revealed that the prevalence of pneumonia and pleuritis in castrated males is 10% higher than in females. Furthermore, Andreasen et al. (2001) found that castrated males have larger pleuritic lesions than females at the time of slaughter. In the Netherlands lesions in lungs, pleura, and pericardium were also more prevalent in castrated males than in females (Kruijf and Welling 1988). Castration may have been responsible for the differences through stress and hormonal changes. Another explanation could be that male pigs grow faster and reach slaughter weight at a younger age than females, which may prevent lung lesions to be healed in males at the time of slaughter.

Heredity

Several investigations indicate that respiratory disorders are to some extent influenced by heredity. In genetically selected obese swine, the phagocytic functions of pulmonary alveolar macrophages were found significantly more effective than those from genetically selected lean swine. The difference was most pronounced during winter and spring months (Caruso and Jeska 1990). Clinical observations in a herd having purebred Hampshires and Yorkshires revealed a much lower level of respiratory diseases in Hampshire than Yorkshire pigs (Lundeheim and Tafvelin 1986). The same investigators examined 45,000 slaughter pigs consisting of Hampshire, Landrace, and Yorkshire crosses. The Hampshire crosses had a significantly lower incidence of pneumonia and pleuritis than the other crosses. The susceptibility to atrophic rhinitis is greater in Yorkshire pigs than in Landrace pigs (Lundeheim 1979; Smith 1983; Straw et al. 1983). Ruiz et al. (2002) provided evidence of different patterns of colonization of *Mycoplasma hyopneumoniae* between pigs sired by three different boars, suggesting a possible genetic effect.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF RESPIRATORY DISEASE

Definitive diagnoses of respiratory diseases are based upon a combination of history, clinical observations, laboratory tests, and necropsies, including slaughter checks. A clinical diagnosis can only be tentative, since visible signs from the respiratory system may be the result of dysfunction of other organs. Also, pathological disorders of the respiratory system such as acute/subacute pleuropneumonia, chronic pneumonia, and pleuritis will often be without clinical signs or signs typical for respiratory disorders. Acute pleuropneumonia may be widespread in a herd before the disease is revealed at slaughter. Therefore, depression and decreased appetite in fatteners, often misinterpreted and attributed to bad feed, should remind the observer of the possibility of an outbreak of acute pleuropneumonia. Table 7.6 summarizes some principal respiratory disorders. The basic elements in the table are typical pathological-anatomical disease entities. Useful differential diagnostic facts concerning gross pathology, clinical signs, and agents involved are given for each disease entity leading

Table 7.6. Principal respiratory disorders, clinical signs, causative agents, and diagnosis.

Disease Based on Pathology	Important Clinical Signs	Causative Agents	Diagnosis
01 Rhinitis: possibly slight but reversible turbinate atrophy	Sneeze; nasal discharge; conjunctivitis	*Bordetella bronchiseptica*	Nasal swabs; cultivation
02 Progressive atrophic rhinitis: varying turbinate atrophy and nasal wall alteration	Sneeze; nasal discharge; tear tracks below eyes; occasional nasal bleeding; no or varying degree of brachygnathia and snout deviation	Toxigenic *Pasteurella multocida*; predisposing: *Bordetella bronchiseptica*, aerial ammonia, dry air	Necropsy; slaughter checks; nasal swabs; cultivation; ELISA; PCR
03 Catarrhal pneumonia (mycoplasma-like pneumonia): cranioventrally located; lobular; meaty structure	Hard nonproductive cough, particularly when pigs are forced to move; slight fever; slightly decreased appetite	*Mycoplasma hyopneumoniae*; *Mycoplasma hyorhinis;* streptococci, and other bacteria in piglets	Necropsy; slaughter checks; cultivation; immunohistochemistry (IHC); serology
04 Complicated bronchopneumonia (enzootic pneumonia): located as 03; mostly lobular; purulent exudate; eventual formation of abcesses; red to gray; firm fibrous structure; often associated with pleuritis	Productive cough particularly when pigs are forced to move; abdominal "thumping" respiration; periodically high fever; decreased appetite	As 03 + *Pasteurella multocida*, *Bordetella bronchiseptica*, streptococci, staphylococci, *Arcanobacterium pyogenes*, and others; *Salmonella choleraesuis* and viral infections may act as primary agents	As 03; virus detection
05 Disseminated/lobular catarrhal pneumonia: mainly cardiac and apical lobes; red to gray; firm, fibrous structure	Coughing, dyspnea	*Bordetella bronchiseptica*	Cultivation; history: usually in piglets younger than 3 weeks
06 Peracute fibrinous/necrotizing pneumonia (pleuropneumonia): extensive dissemination; associated with blood-tinged fluid in the pleural cavity; extensive fibrinous pleuritis	Depression; prostration; high fever; severe dyspnea, open mouth breathing; occasional blood-tinged foam from nose and mouth; dogsitting or sternal recumbency	*Actinobacillus pleuropneumoniae*	Necropsy; cultivation; serotyping; PCR
07 Acute/subacute fibrinous/necrotizing pneumonia (pleuropneumonia): predominantly caudodorsal; fibrinous pleuritis	Varying depression; respiration normal to superficial; depressed coughing or no cough; normal to high temperature; decreased appetite	*Actinobacillus pleuropneumoniae*	Necropsy; cultivation; serotyping; PCR
08 Chronic necrotizing pneumonia (pleuropneumonia): located as 07; firm capsulated processes with necrosis and abscesses; local fibrous pleuritis	Slight depression; cough and decreased appetite if secondary infection occurs	*Actinobacillus pleuropneumoniae;* eventually secondary infection with pyogenic bacteria	Necropsy; slaughter checks; cultivation; serotyping; PCR; serology
09 Embolic pneumonia: randomly distributed usually minute abscesses in the lung	Usually no clinical signs from the respiratory system	Pyogenic bacteria; streptococci, staphylococci, *Arcanobacterium pyogenes* and others	Necropsy; slaughter checks; primary conditions causing septicemia
10 Acute disseminated lobular pneumonia: dark purple; bleeding from cuts; lobular emphysema and edema	Varying degree of depression; from no to hard cough; rapid, superficial respiration; fever; prostration; complete anorexia	Swine influenza virus	Virus isolation; PCR; IHC from nasal swabs or affected lung tissue; serology
11 Interstitial pneumonia: variable amount of tan and red mottling; increased amount of clear fluid in thoracic cavity	Varying degree of symptoms from subclinical to inappetence; fever and dyspnea; reproductive failure; suboptimal herd performance	Porcine reproductive and respiratory syndrome virus (PRRS virus); often complicated by other infections	Virus isolation from lung, lymph nodes or serum; PCR; IHC on lung tissue; serology
12 Interstitial pneumonia: often accompanied by other types of pneumonia; lymphadenopathy; enteritis; hepatitis; nephritis	Postweaning multisystemic wasting syndrome (PMWS): wasting; enlarged lymph nodes; dyspnea; diarrhea; pallor; jaundice	Porcine circovirus type 2 (PCV2); often complicated by other infections	Histopathology; detection of PCV2 and characteristic microscopic lesions in lymphatic and other tissues

Table 7.6. (*continued*)

Disease Based on Pathology	Important Clinical Signs	Causative Agents	Diagnosis
13 Verminous pneumonia: small focal areas with hemorrhage, later granulomas or capsulated abscesses	Cough with minimal other signs	*Ascaris suum* and other ascarids	Necropsy; slaughter checks; white spots in the liver
14 Verminous bronchitis: bronchitis, bronchiolitis in caudoventral margins of diaphragmatic lobes; atelectatic areas	Cough with minimal other signs	*Metastrongylus* sp.	Necropsy; history: access to dirt
15 Hemorrhagic pleuritis: associated with 06	As 06; no or depressed cough	As 06	Necropsy
16 Fibrinous pleuritis: associated with 07 or 04, occasionally with 09 and 10; also associated with Glasser's disease	As 07; if associated with Glasser's disease: lameness, central nervous signs	As 07, occasionally other bacteria	Necropsy; cultivation
17 Fibrous pleuritis	None	As 16	Necropsy; slaughter checks

to the diagnosis. Additionally, in Tables 7.7 and 7.8 differential diagnostic information can be found concerning disease entities usually associated with important respiratory signs such as sneezing and coughing.

Monitoring Respiratory Disease

The purpose of monitoring respiratory diseases is to transform observed phenomena in a swine population into numeric values suitable for analysis. Assessment of the level of disease and the effect of therapeutic or preventive measures can be obtained by monitoring disease levels at a point in time (prevalence) or during periods (incidence). Respiratory tract disease data include information collected in the herd, laboratory tests, and slaughter examinations. Large-scale data collection and evaluation on the respiratory health of slaughter swine are routinely carried out in some countries—for example, Finland (Rautiainen et al. 2001), Denmark (Willeberg et al. 1984/85; Mousing 1986), the Netherlands (Van der Valk et al. 1984), and Sweden (Bäckström and Bremer 1976).

Registrations in the Herd. Clinical observations, results of routine slaughter checks, and postmortem ex-

aminations of dead or euthanized animals are traditionally the basis for diagnosing and estimating the severity of respiratory disease. The clinical examination is of greatest value in acute outbreaks when fever and specific signs from the respiratory tract are observed. Conditions such as pleuropneumonia, chronic enzootic pneumonia, and pleuritis will often be without clinical signs; thus, a diagnosis based upon clinical observations always will be tentative.

The value of in-herd disease surveillance naturally increases with the quality and amount of objective information. In many situations valuable data can be

Table 7.7. Respiratory disease entities and agents associated with sneezing.

Disease	Agent
Rhinitis (only piglets)	*Bordetella bronchiseptica;* cytomegalovirus; hemagglutinating encephalomyelitis virus
Rhinitis	Dust; ammonia
Atrophic rhinitis	*Bordetella bronchiseptica* and toxigenic *Pasteurella multocida*
Aujeszky's disease	Aujeszky's disease virus

Table 7.8. Respiratory disease entities and agents associated with coughing.

Type of Coughing	Disease	Agent
Hard, nonproductive	Mycoplasmal-like pneumonia	*Mycoplasma hyopneumoniae*
	Acute disseminated lobular pneumonia	Influenza virus
Nonproductive	Disseminated pneumonia (only in piglets)	*Bordetella bronchiseptica*
	Glässer's disease	*Haemophilus parasuisaemophilus parasuis*
	Aujeszky's disease	Aujeszky's disease virus
Productive	Enzootic pneumonia	*Mycoplasma hyopneumoniae* and *Pasteurella multocida* and other species
	Chronic pleuropneumonia	*Actinobacillus pleuropneumoniae* with other infections
Depressed, productive	Cardiac insufficiency	
	Acute pleuropneumonia	*Actinobacillus pleuropneumoniae*

readily obtained by staff recordings, either continuously or during a defined period. Relevant data are number of deaths and treatments associated with respiratory problems, age or weight of affected animals, and performance records—for example, days to market (Pijoan and Leman 1986), daily weight gain or feed efficiency.

Clinical signs are difficult parameters to handle in quantifying a disease problem (Baadsgaard and Jorgensen 2003). Assessment of pneumonia levels through measurement of the amount of coughing has been proposed (Straw et al. 1986). However, in the field such procedures may be too laborious and time consuming.

Laboratory Tests. In recent years tremendous progress in biotechnology has accelerated the development of new, highly specific, and sensitive laboratory tests for respiratory diseases. Useful diagnostic data may be obtained from laboratory examinations made on blood samples, meat juice samples, colostrum or milk samples, nasal swabs, tonsil scrapings, and tissue. It is particularly advantageous to combine data from clinical and pathological examinations with laboratory test results in monitoring the health status of swine herds. For health surveillance, serological analyses are often performed on samples taken from the herds monthly or quarterly, but also samples taken at the abattoirs when the pigs are slaughtered may be used for the analyses. Blood samples are preferable, but often not convenient at the slaughterline, and meat juice samples taken when the carcasses are registered may be a good alternative (Wallgren and Persson 2000). For final verification in the herds, methods like cultivation, PCR, immunohistochemistry or antigen-ELISA, which detect the pathogen directly, may be applied. Here, special attention will be given to diagnostic methods suitable for large-scale monitoring purposes.

When laboratory assays are used for monitoring herd health status or to elucidate the infection dynamic, the sensitivity and specificity of the assays need to be known to interpret the results. These test characteristics are defined and listed for a number of diseases in Chapter 2.

Polymerase chain reaction (PCR) is a relatively new technique for detecting *M. hyopneumoniae* DNA in lungs, tracheobronchiolar washings, nasal swabs, and air (Mattsson et al. 1995; Blanchard et al. 1996; Sørensen et al. 1997; Stark et al. 1998; Verdin et al. 2000). This technique is not as time-consuming as traditional cultivation and can be applied for large-scale use and thereby for surveillance in health programs. Problems with the sensitivity of the PCR technique when using nasal swabs seem to be solved with the nested PCR (Calsamiglia et al. 1999; Kurth et al. 2002; Sibilia et al. 2004). Toxin-producing *P. multocida* can likewise be diagnosed by PCR on nasal and tonsillar swabs (Kamp et al. 1994). Furthermore, an ELISA based on monoclonal antibodies directed against the toxin of *P. multocida* is used on nasal

swabs for health surveillance of progressive atrophic rhinitis in swine herds (Foged et al. 1990).

Much effort has been put into developing PCR tests for direct identification of *A. pleuropneumoniae* in lungs and tonsils (Sirois et al. 1991; Hennessy et al. 1993; Gram et al. 1994, 1996), and in the last years such tests have been implemented for routine identification and serotyping (Fittipaldi et al. 2003; Jessing et al. 2003; Hussy et al. 2004). Three RTX-toxins have been shown to constitute important virulence factors for *A. pleuropneumoniae* infection (Frey 1995). Thus, these toxins might be interesting targets in the development of future diagnostic assays. Already, the hemolytic and cytolytic effects of these toxins form the basis of laboratory assays, and Nielsen et al. (2000) developed ELISAs detecting antibodies against them. However, these assays cannot be expected to be totally specific for *A. pleuropneumoniae* infections, because other bacteria like *Actinobacillus suis* produce similar, but not identical, toxins (Kamp et al. 1994). Schaller et al. (1999) found a fourth toxin, ApxIVA, which is excreted in vivo by all known serotypes of *A. pleuropneumoniae* and this toxin seems to be more species-specific.

A nested PCR for diagnosing PRRS virus in boar semen has proved to have a higher sensitivity than the traditionally used cultivation and is able to distinguish between U.S. and European viruses (Christopher-Hennings et al. 1995).

In the development of new serological assays, biotechnology is introduced in the form of monoclonal antibodies (MABs) against specific epitopes of the agents. MABs are used in blocking ELISAs to detect antibodies against *M. hyopneumoniae* (Feld et al. 1992; Le Potier et al. 1993), toxin-producing *P. multocida* (Foged et al. 1990), and *A. pleuropneumoniae* serotype 2 (Stenbaek and Schirmer 1994) and serotype 5 (Klausen et al. 1996). The *M. hyopneumoniae* ELISA (Feld et al. 1992) has high sensitivity and specificity and can be used on both serum and colostrum (Sørensen et al. 1992, 1993).

The serological *P. multocida* ELISA can also be used on both serum and colostrum. However, serological monitoring of progressive atrophic rhinitis in growing pigs is difficult because only a few of infected pigs seroconvert, and then only in a late stage of infection (Nielsen et al. 1991a). MABs used in serological assays for diagnosing *A. pleuropneumoniae* infections have not been successful so far, probably due to variations in the *A. pleuropneumoniae* strains, giving variable serological response in herds. Serotype-specific blocking ELISAs based on polyclonal antibodies directed against capsular polysaccharides seem more appropriate for *A. pleuropneumoniae* serodiagnosis (Nielsen et al. 1991, 1993; Klausen et al. 1996, 2001; Andresen et al. 2002) Also, serotype specific indirect ELISAs for *A. pleuropneumoniae* based on purified antigen have been used (Gottschalk et al. 1994, 1997; Klausen et al. 2002). For serological herd surveillance it often will be neccesary to analyze the samples

for more than one serotype, and ELISAs with mixed antigens (Bosse et al. 1993; Grondahl-Hansen et al. 2003) can facilitate such measurements. Dreyfuss et al. (2004) developed an ELISA based upon recombinant ApxIV toxin for serological screening of all serotypes at one time. Furthermore, this ELISA is expected to give positive results only if the pigs are infected with *A. pleuropneumoniae,* because they do not respond to ApxIV after vaccination with the vaccines available for the time being.

Indirect ELISA (Albina et al. 1992), blocking ELISA (Houben et al. 1995), and immunoperoxidase monolayer assay (Wensvoort et al. 1991) are used for serological monitoring of PRRS infection at the herd level. Combinations of these methods are used in serological profiling of herds to distinguish between chronically and acutely PRRS-infected herds (Bøtner 1997).

For laboratory diagnosis of swine influenza, isolation of the virus in cell culture or embryonated chicken eggs and immunofluorescence on lung tissue are used. Hemagglutination-inhibition tests, which mainly measure antibodies against H-antigens (e.g., H1 and H3), are used for the serological analysis (Palmer et al. 1975).

In countries, where Aujeszky's disease has been eradicated and vaccination is not allowed, serological surveillance of the disease can be carried out using a polyclonal blocking ELISA (Sørensen and Lei 1986) that detects antibodies from both infected and vaccinated pigs. In countries where Aujeszky's disease is common, vaccination programs with vaccines lacking the geneencoding glycoprotein E (formerly glycoprotein I) can be established, and serological differentiation between infected and vaccinated pigs is possible with an ELISA described by Van Oirschot et al. (1988).

Diagnosis of PMWS is based on a combination of clinical and pathological findings together with evidence of PCV 2 infection. As the etiology of this disease is not yet clearly understood there is no large scale laboratory assays available for the time being.

Examinations on Slaughter Swine. National herd health monitoring programs by means of slaughter inspection are designed for long-term surveillance of herd health. Concurrent and specific examinations on selected groups of swine can be obtained by slaughter checks. Slaughter checks can be a profitable supplementary tool in handling respiratory problems (Pijoan and Leman 1986; Schulz 1986) and are used routinely in the surveillance of the health state of SPF herds (Keller 1988).

Examining the Snout for Atrophic Rhinitis. Slaughter checks for atrophic rhinitis are usually performed by examining a transverse section of the snout. Optimal results are obtained if the cut is placed between premolar 1 and 2 (Martineau-Doizé et al. 1990). Several methods of scoring atrophic rhinitis have been used (Bendixen

1971; Straw et al. 1983; Bäckström et al. 1985). These methods are based on subjective and visual assessment of structures. Results from different slaughter checks should be compared with caution, as demonstrated by D'Allaire et al. (1988). Comparisons should be performed by the same experienced observer using the same scoring system.

A morphometric technique described by Collins et al. (1989) and modified by Gatlin et al. (1996) yielded highly reproducible results. The method is rather time-consuming and therefore of particular interest in experimental work. A rapid method using inspection of longitudinal snout sections may be performed at slaughter (Visser et al. 1988). However, mild cases of atrophic rhinitis can hardly be differentiated from normal cases by this method.

Examining Thoracic Organs (Plucks). Retrospective evaluations of respiratory health by means of slaughter checks are based on the presence of chronic lesions. As demonstrated by Noyes et al. (1988), the progression and regression of pneumonia in growing pigs are highly dependent on the type of pneumonia involved. Generally, infections with *M. hyopneumoniae* gained during the early fattening period cannot be detected macroscopically at slaughter (Wallgren et al. 1994).

Several investigators have described methods of recording enzootic pneumonia in slaughter checks (Morrison et al. 1985), whereas little interest has been given to recording other types of lesions. However, all significant pathological conditions, including cranioventral fissures, pleuritis, and pericarditis should be recorded and categorized according to type and extent.

A reasonable history of respiratory health can be revealed by means of slaughter check, but only if all significant pathologic conditions are included. Also, in estimating the effect of respiratory disease on weight gain, a detailed recording of lesions is important. In a study based on 1700 swine from five herds (Christensen and Mousing 1994) only a weak association was found between uncomplicated catarrhal bronchopneumonia and daily weight gain from weaning to slaughter. However, a significant association was established between daily weight gain and complicated bronchopneumonia, cranioventral fissures, chronic pleuritis, and pericarditis.

Careful slaughter checks of thoracic organs cannot normally be performed at the slaughter line. The material has to be transferred to an appropriate place for a thorough examination. Christensen (unpublished data) devised a method by which 50–100 plucks per hour can be examined per investigator. The extents of all lesions detected are sketched on a special form containing two schematic drawings of the lung (Figure 7.4, left). Lesions affecting lung tissue are marked on the upper drawing, and pleuritis on the lower drawing. The type of lesion is marked by a character indicating lesion category, other than mycoplasmal pneumonia or chronic pleuritis, one

of which occurs in almost 90% of all cases. Following macroscopic examination and sketching, the extent of the lesions is quantified and recorded using the marked lobe measures as guidelines. The recording form illustrated in Figure 7.4, right, is used when experimental studies require detailed data collection.

The result of a slaughter check is presented in Figure 7.5. Specially programmed personal computer software automatically executes the calculations and printing.

The localization of pleuritis is categorized as dorsocaudal or ventrocranial. The border is drawn through the dorsal endpoints of the interlobular fissures. The dorsal areas of the apical and cardiac lobes are regarded as belonging to the dorsocaudal lung surface area. Based on experience with Danish herds we consider dorsocaudally localized pleuritis as nearly pathognomonic for a previous pleuropneumonic lesion.

In most situations slaughter checks should be performed on at least 30 pigs (with similar or known age if possible) to get a sufficient sample and thus a reliable picture of the herd problem (Morrison et al. 1985; Straw et al. 1989).

The use of a simplified slaughter check procedure based on right-lung examination has been reported by Mousing and Christensen (1993). The procedure interferes much less with normal slaughterhouse routines than a traditional slaughter check and demands fewer people.

CONTROL OF RESPIRATORY DISEASE

Pathogenic microorganisms are involved in all important respiratory disorders, and in practice it can be very difficult to protect pig herds from pathogenic microorganisms. Therefore, the in-herd incidence and prevalence of respiratory disease fundamentally depends on the balance between infection pressure and the pigs' ability to resist this pressure. This balance is fragile and highly affected by numerous factors.

Control of respiratory diseases at the herd level may be based on one of two principles: either to eliminate

pathogens from the herd or to diminish the infection pressure in the herd and simultaneously sustain the animal's defense mechanisms (nonspecific, immunological, and inherited). Elimination of pathogens is by far the most effective remedy in controlling many respiratory disorders. However, understanding of the etiology of respiratory diseases and the transmission route of the pathogens involved is of crucial importance for implementation of succesful reduction/eradication programs. Enzootic pneumonia is a good example of a respiratory disease where intensive research on *M. hyopneumoniae* has made eradication possible (Zimmermann et al. 1989), not only in single herds, but also in geographical areas (Rautiainen et al. 2001). However, in the recent years, the pig industry has struggled with new emerging diseases like PRRS and PMWS, which have increased the significance of respiratory diseases in many pig herds.

Much research has been performed worldwide on PRRS and effective eradication programs have been installed (Dee et al. 1997, 2001). The etiology of PMWS is still not clarified although porcine circovirus type 2 (PCV2) is part of the syndrome, and therefore eradication of this disease is not possible for the time being.

Elimination of Pathogens from the Herd
The United States, Denmark, and Switzerland have implemented specific pathogen free (SPF) pig production many years ago and thereby succesfully controlled respiratory diseases like enzootic pneumonia, pleuropneumonia, and progressive atrophic rhinitis. SPF pig production is principally based on a cesarean-derived and isolator-raised first generation of rather vulnerable breeding animals, which are gradually adapted to a very clean environment. The next generations of SPF pigs are

born naturally, but kept and transported with strict biosecurity measures (Barfod 2004). Implementation of such a production system is therefore technically advanced, logistically laborious, and costly, but once established, economical and welfare related benefits from raising healthier pigs may be obtained.

Other methods for eliminating respiratory pathogens from herds include early weaning, strict separation of age groups of pigs, preferably on different geographical sites (multisite systems), removal of certain age groups of pigs, removal of infected individuals, and intensive herd medication. Such elements can be used together in different combinations.

Weaning at 1–3 weeks of age is recommended in segregated early weaning to minimize the risk of infection of piglets from the sow with pathogens like toxigenic *P. multocida*, *M. hyopneumoniae*, and *A. pleuropneumoniae*. Transmission of *M. hyopneumoniae* from sow to offspring was prevented without use of medication by weaning piglets at 7–10 days of age and segregating them off-site (Dritz et al. 1996). However, weaning at such young ages will not be accepted in several countries (Von Borell 1996). *Mycoplasma hyopneumoniae* was successfully eradicated from herds by removing pigs younger than 10 months from the herd and simultaneously stopping farrowings for 2 weeks (Zimmermann et al. 1989). *Actinobacillus pleuropneumoniae* was eliminated from piglets by medicated early weaning (Larsen et al. 1990a) and sometimes from infected herds by means of heavy medication and culling of seropositive animals (Larivière et al. 1990). However, in many countries heavy medication of animals is not accepted anymore in order to prevent problems with antimicrobial resistance. Atrophic rhinitis seems to be impossible to eliminate by medication programs alone (Larsen et al. 1990b), but intensive research and development of effective vaccines within the last decades have minimized the welfare—and economical problems caused by this disease.

PRRS can succesfully be controlled in well-immunized sow herds by nursery depopulation for 14 days (Dee et al. 1996), and Batista et al. (2002) found results indicating that persistence and shedding of PRRS virus are of short duration in breeding-age gilts, which may facilitate maintenance of immunity against PRRS in the sow units. Eradication programs for Aujeszky's disease in geographical areas can be carried out by test and slaughter (Andersen 1991) or by intensive vaccination (Stegeman et al. 1994a, b; Van Oirschot et al. 1996) or by combining the two methods (Leontides 1994).

To prevent reinfection of high-health herds with respiratory pathogens, strict control of brought-in pigs, vehicles, persons, etc., must be maintained. Nielsen and Frederiksen (1990) have demonstrated that human isolates of toxigenic *P. multocida* can induce progressive atrophic rhinitis in pigs, indicating that humans may act as carriers of swine pathogenic *Pasteurella* strains between herds.

Infection Pressure and Sustaining Herd Defense Mechanisms

The influence of several herd factors is decisive in sustaining herd resistance against respiratory pathogens and in reducing the level of such pathogens in the herd. Herd factors influencing the host/pathogen balance are numerous. In Table 7.9, examples of such factors are listed and arbitrarily weighted according to their importance. Short-term control measures against respiratory disease predominantly include correcting managerial factors such as vaccination and antibiotic treatment of sick animals, isolation arrangements, etc. Permanent improvement of respiratory health often requires more radical and expensive changes in production systems and housing. Important long-acting herd factors to take into consideration are stocking rate, flow of animals to

Table 7.9. Herd factors with detrimental effects on respiratory system.

Factors	Degree of Effect
Production system	
Large herd size	+++
High stocking density	+++
Conventional health system (not SPF or minimal disease production system)	+++
Introduction of animals from herds with unknown or low health status	+++
Continuous flow of animals through facilities (no movement of pigs in batches)	+++
Use of genetically disposed breeds	+
Use of purebreds instead of crosses	+
Housing	
Badly insulated and ventilated facilities (causing improper temperature regulation and air exchange, drafts)	+++
Insufficiently divided facilities combined with housing of differently aged animals in same airspace	+++
Pens divided without solid separations	+++
Large grower or finishing rooms (containing more than 200–300 pigs)	++
Slatted floors	+
Nutrition	
Insufficient caloric intake	+
Improper content of macro- and microelements in feed	+
Feed not supplemented with fat (dust from feed)	+
Presence of nonrespiratory pathogens	
Colibacillosis	++
Dysentery	++
Mange	+
Ascarids	+
Management deficiencies	
Insufficient control of climate	+++
Poor monitoring of signs of disease	++
Lack of or incorrect preventive measures	++
Poor caretaking of sick animals (isolation, treatment)	++
Random distribution of piglets between sows	++
Multiple moving and mingling of pigs during growth period	++
Poor hygiene	++
Poor biosecurity	++

and from the herd and internal flow of animals through the facilities, insulation and ventilation of buildings, separation of large barns, and separation of different age groups in multisite production systems. Also, avoidance of mixing the piglets between sows in the suckling period and weaning the pigs a little older may improve the immunological capacity against respiratory diseases.

Management.   Management remains the central factor in controlling respiratory problems. A constant and competent supervising of installations and animal behavior allows immediate and appropriate intervention when problems arise. In this context it has to be recognized that respiratory diseases are not always associated with obvious clinical signs. In fact, most cases of respiratory disease occur subclinically or with only vague symptoms. Even outbreaks of acute pleuropneumonia may occur without clear respiratory symptoms.

Introduction of Genetic Material.   The risk of introducing disease through purchase of traditionally reared breeding animals can be avoided if a necessary supply of genetic material is ensured by means of artificial insemination, embryonated eggs, or cesarean-derived piglets. However, under commercial conditions a more practicable alternative will be to introduce breeding animals in batches from a breeding herd with the same health status as the buyer's. Prior to introduction into the herd, the animals could be quarantined for 6 to 12 weeks, blood-tested, and vaccinated if neccesary.

Stocking Density.   In spite of the fact that crowding greatly increases the incidence of respiratory diseases, it may be difficult to motivate managers to decrease stocking rate, since calculations do not always reveal a profit by this remedy. In the case of only moderate respiratory problems, the profit due to better health often will be counterbalanced by the loss due to decreased utilization of herd facilities. Nevertheless, lowering stock density remains one of the most effective remedies against serious respiratory problems.

Barriers Between Differently Aged Animals.   In herds with an inadequate separation between pigs of different ages microbes are continuously transmitted from older to younger animals, with a subsequently continuous replication of pathogens. Dissimilar climatic needs of different age groups in the same room may be a contributing adverse factor. To limit the multiplication of pathogens, it is of crucial importance in larger herds to build barriers between groups of differently aged animals and to move pigs in batches. The facilities should be adapted to all-in/all-out production, with rooms containing not more than 200–300 individuals. Ideally, the age difference in weaner batches should not exceed 2 weeks.

The potential of age group separation for preventing transmission of infection increases with the distance between groups. Maximal effect is achieved in multisite production systems with segregated herds for the breeding, nursery, and growing pigs.

Air Pollutants.   To prevent massive air pollution and to maintain an acceptable relative humidity, forced ventilation is necessary in confined facilities. The lower the airspace per pig, the higher the air exchange is necessary. However, it is difficult to compensate completely for overcrowding. For example, if the stocking rate is doubled, the ventilation rate should be increased tenfold to maintain the same clearance of air contaminants (Wathes 1983). If a significant effect on the dust concentration is to be achieved, large air-cleaning equipment is necessary (Gustafsson 1989).

Ventilation systems often recirculate room air with fresh air. This mixing of air contributes to the spread of respiratory pathogens. Accordingly, the level of respirable dust is increased in high-speed recirculation systems (Meyer and Manbeck 1986). Hunneman et al. (1986) indicate that respiratory diseases can be controlled better in buildings with negative pressure ventilation, where the polluted air is removed and exchanged for totally fresh air. Nicks et al. (1989) found that the aerial ammonia concentration was 21 ppm and 12 ppm in two compartments of a farrowing house. In the former compartment a larger proportion of the extracted air was recirculated.

Climate.   Respiratory problems often arise in cold and humid barns with no artificial heating. Frequently, the choice is between reducing humidity by means of a high air exchange rate, resulting in lower room temperature, or warming up the room by means of a lower air exchange rate. The first alternative is advisable according to experience. Cold, clean, dry air is by far superior to warm, polluted, humid air. Besides, the microclimate in a cold barn can be improved and protected against draft by providing straw bedding or/and some sort of covering for resting places (Feenstra 1985) and by establishing solid separations between pens; pen separations should be solid to a height of 60 cm.

Nutrition.   In practice, malnutrition is rarely of importance in creating respiratory problems. Nevertheless, the relevance of vitamin E and selenium for immunity (Hayek et al. 1989) has to be considered. A major part of the dust particles in the air in swine barns arises from the feed. The addition of fat or wet feeding systems significantly reduces the dust problem.

Nonrespiratory Pathogens.   There is a well-documented association between enteric disorders and respiratory problems. Therefore, solving respiratory problems is not possible if concurrent enteric problems are neglected. Mange and ascarids also have to be considered. Severe at-

tacks of mange weaken the general resistance, and migrating ascarids cause lung lesions, increasing the susceptibility to respiratory pathogens.

Medication. Due to development of antimicrobial resistance in many bacterial species, restrictions have been put on prophylactic use of antibiotics in livestock production in many countries. However, the ability to quickly combat outbreaks of respiratory disease depends on immediate medication of diseased individuals. Pigs with signs of pneumonia should be treated parenterally with the appropiate antibiotics because their consumption of water and feed might be significantly decreased (Goovaerts et al. 1986; Pijpers et al. 1990). Medication for 2–3 days will be sufficient in most cases. Jørgensen (1988) found that pigs receiving immediate and intensive parenteral treatment against clinical pneumonia had a better weight gain than pigs receiving a less intensive treatment. In outbreaks of pneumonia, it can be necessary that pigs in contact with clinically diseased individuals receive medication in feed or water for 4–7 days.

Vaccination. Vaccines have been developed against progressive atrophic rhinitis, *A. pleuropneumoniae*, *M. hyopneumoniae*, PRRS, and Aujeszky's disease. Vaccines against atrophic rhinitis can be based on a recombinant derivative of the *P. multocida* toxin (Nielsen et al. 1991a) and can be used for vaccination of both sows and pigs. However, some vaccines are still based on *P. multocida* and *B. bronchiseptica* bacterins. *Actinobacillus pleuropneumoniae* vaccines comprise subunit vaccines based on Apx toxins and an outer membrane protein (Bosch 1994), which can be used to vaccinate pigs against all serotypes, and bacterin-based vaccines where it is important to use the homologues serotypes in order to get proper protection (Nielsen, 1982). *Mycoplasma hyopneumoniae* vaccines are based on bacterins and are used for very young pigs (Dayalu et al. 1992; Weiss and Petersen 1992). However, a study by Opriessnig et al. (2003) showed that vaccination with *A. pleuropneumoniae* and *M. hyopneumoniae* bacterins using the approved protocol in the U.S. significantly increased the length of viremia with PCV2. Also, they found a higher copy number of the PCV2 genome in serum, a wider range of tissue distribution of PCV2 antigen, and an increased severity of lymphoid depletion. Thus, veterinarians may need to consider changes in vaccination protocols in herds with recurrent PCV2-associated PMWS. Vaccines against PRRS can be based on live attenuated U.S. or E.U. virus strains or they can be inactivated. The marker vaccines against Aujeszky's disease are gene-deleted (Mettenleiter et al. 1985; Quint et al. 1987; Moormann et al. 1990), which makes it possible to distinguish serologically between vaccinated and naturally infected pigs (Van Oirschot et al. 1986). Vaccines against swine influenza is based on an inactivated whole influenza virus or split-products vaccines prepared from detergent-treated virus. The virus strains used are of human origin and include H1N1 and H3N2, which are the most common types, both in humans and in pigs.

Hygiene. To prevent transmission of respiratory pathogens between herds, particularly in production systems where certain respiratory pathogens are totally prohibited (SPF), it is important to clean, wash, and disinfect possible outside transmitters such as vehicles, delivery rooms, entrance rooms, tools, etc. In all-in/all-out production systems it is also of crucial importance to clean and disinfect the facilities between the batches of animals. However, too much washing in rooms which still are housing pigs can even aggravate a respiratory disease problem by cooling and humidifying the rooms.

ECONOMIC IMPORTANCE OF RESPIRATORY DISEASES

Respiratory disorders cause substantial losses to the swine industry. In a survey of swine health expenditures in Missouri, pneumonia and rhinitis were the two disease categories with the greatest impact on total disease expenses (14% and 10%, respectively) (Kliebenstein et al. 1982/83). Data from the National Animal Health Monitoring System in Ohio, 1986–1987, revealed that pneumonia was by far the most costly disease in swine, accounting for $5.42 U.S. per pig per year out of total costs of $21.34 per pig due to diseases (Miller and Dorn 1987). Respiratory disease expenditures for swine production in the former German Democratic Republic were estimated at DME 700 million per year. This reduction in returns was allocated among damaged lungs, 3%; destroyed and disposed diseased animals, 37%; and reduced growth rate, 60% (Hoy et al. 1987).

Losses associated with respiratory disease vary considerably between herds (Lindqvist 1974; Wilson et al. 1986) but also between seasons. Boessen et al. (1988) reported a seasonal variation of more than 30% in the losses due to pneumonia (from $1.31 per hog in the winter of 1986, to $0.89 in the following summer, and back up to $1.26 in the winter of 1987). Similarly, the variation in losses due to rhinitis was more than 60% (from $0.54 per hog in the winter of 1986, to $1.37 in the following summer, to $0.50 in the winter of 1987). At herd level the total cost of respiratory disease is the sum of output losses—namely, increased mortality, decreased weight gain, increased feed consumption, and decreased meat quality or payment—and of control expenditures—for example, treatments, vaccination programs, hygiene procedures, and extra labor (Schepers 1990). On a national scale, this method of calculation of the costs has been used by Mousing et al. (1996) for PRRS and by Bækbo et al. (1996) for *M. hyopneumoniae*.

In practical situations, the estimated economic impact of respiratory disorders in a herd must be based on slaughterhouse information and data on productivity

and disease recordings in the herd: current weight gain or days to slaughter, feed efficiency, incidence of clinical respiratory disease and other diseases, mortality rate, results of necropsies, severity of lesions observed at slaughter, and finally the costs of current treatment and prophylaxis strategy.

The economic effect of each single respiratory disease is difficult to clarify, as reflected in inconsistent results from different studies. It is understandable that disease effects vary between studies: respiratory diseases are always the result of numerous interacting microbial and physical insults, different in type and grade as well. For example, clinical studies on the effect of *M. hyopneumoniae* will show significantly greater losses in areas with a high burden of different pathogens than in areas with few pathogens in the swine population. Thacker et al. (1999) found for example that *M. hyopneumoniae* potentiates the severity and duration of PRRS virus–induced pneumonia. Each disease situation is unique; and data from an investigation can be assessed only by an observer with a detailed knowledge of the situation in question.

Output Losses due to Enzootic Pneumonia

Most investigations on the economic effect of enzootic pneumonia are based on the prevalence of pneumonia at slaughter and the association with daily weight gain. However, in herds where pneumonia predominantly occurs in young pigs, the lesions may be resolved by the time of slaughter (Wallgren et al. 1990). In studies that compare daily weight gain between pigs with pneumonia and control pigs without pneumonia, this could contribute to underestimation of the effect. This may be the main reason for the great variability in reported effects on daily weight gain, varying from positive effect to about 20% decrease (Bäckström et al. 1975; Christensen 1984; Hoy et al. 1985; Love et al. 1985; Wilson et al. 1986; Le Foll et al. 1988; Cowart et al. 1990; Clark et al. 1993). Based on a review and analysis of 27 studies, Straw et al. (1989) concluded that, on the average, mycoplasmal pneumonia caused a 17% decrease in daily weight gain and a 14% decrease in feed efficiency. From different studies on the association between the severity of pneumonia and the decrease in weight gain, Straw et al. (1989) deduced that, on the average, for every 10% of the lung with pneumonic lesions, the mean daily gain is reduced by 37 g.

Lundeheim (1979), Wallgren et al. (1990), and Clark et al. (1993) suggested that pneumonia possesses its greatest influence on total weight gain when it occurs in young pigs. Contrary to this, Dijk et al. (1984), Hartley et al. (1988b), and Jørgensen (1988) proposed that pneumonia in older pigs is more damaging to the average weight gain. The importance of differentiating between uncomplicated and complicated bronchopneumonia in slaughter checks was documented in a study by Christensen and Mousing (1994). The decrease in daily weight gain was 6 g in pigs with uncomplicated bronchopneumonia and 38 g in pigs with complicated bronchopneumonia. Maes et al. (1999) made cost benefit analyses on *M. hyopneumoniae* vaccination in multisite herds and found that vaccination significantly improved daily weight gain, feed conversion ratio, medication costs, prevalence of pneumonia, and severity of pneumonic lesions. Vaccination was found economically attractive because it resulted in an increase of the net return to labor with 1.3 ECU per finishing pig sold.

Output Losses due to Pleuropneumonia

As with enzootic pneumonia, results from examinations of the effect of pleuropneumonia on daily weight gain vary over a wide range. Decreases in daily weight gain from none to 20% are reported (Saunders et al. 1981; Christensen 1982; Hunneman 1983; Rosendal and Mitchell 1983; Weibel et al. 1983; Desrosiers 1986; Wilson et al. 1986; Rohrbach et al. 1993). In an *A. pleuropneumoniae*–infected herd, pigs with pleuropneumonic lesions at slaughter had significantly better daily weight gain than pigs without this lesion (Christensen and Mousing 1994). This astonishing observation may indicate that many pigs that did not have lesions at slaughter had nevertheless suffered from pleuropneumonia earlier in the growing period, with high detrimental effect on weight gain. Also, this observation clearly demonstrates the risk of miscalculating the effect of disease from slaughter data for lesions of relatively short duration. Straw et al. (1989) concluded from their review that, on average, pleuropneumonia caused a 34% decrease in daily weight gain and a 26% decrease in feed efficiency.

Occasionally, 10–20% or more of individuals in batches of slaughter swine from newly infected herds are totally condemned at slaughter due to acute pleuropneumonia. The risk of condemnation highly increases if pigs are stored alive at the slaughterhouse for more than 24 hours (Christensen 1986). Slaughter pigs from nonimmune herds, in particular pigs from SPF herds, also are at risk of contracting acute pleuropneumonia if housed for more than 24 hours with infected pigs. The mortality may be as high as 10–20% in acute outbreaks but is usually below 1% in chronically infected herds. Total losses due to pleuropneumonia, including mortality, were assessed at 2% of the value of produced slaughter swine, estimated in three pleuropneumonia-infected herds with high prevalences of pleuritis at slaughter (Christensen 1981).

Output Losses due to Chronic Pleuritis

In Danish pig herds a high frequency of chronic pleuritis at slaughter is closely associated with *A. pleuropneumoniae* infection (Christensen 1981; Mousing et al. 1989). Several studies have been conducted describing the economic implications of pleuritis; in many herds, chronic pleuritis resulted in 7–12 extra days to attain slaughter weight (Christensen 1982, 1984). Following a

clinical outbreak of respiratory disease in a large integrated herd, pigs with chronic pleuritis grew slower than pigs without this lesion (requiring 8 extra days to attain market weight), but prior to the outbreak there was no apparent association between chronic pleuritis and days to market (Hartley et al. 1988b). Results from several other studies indicate that pigs with chronic pleuritis have a reduced rate of weight gain (Bäckström et al. 1975; Rasmussen 1984; Hoy et al. 1985; Love et al. 1985). On the other hand, Le Foll et al. (1988) reported no effect of chronic pleuritis on growth rate.

Output Losses due to Atrophic Rhinitis

In experimental studies considerable decrease in daily weight gain has been reported (Nielsen et al. 1991a), but as for pneumonia, the output losses reported for atrophic rhinitis vary from one study to another (Pedersen and Barfod 1977; Love et al. 1985; Straw and Ralston 1986; Le Foll et al. 1988; Lieschke et al. 1989; Cowart et al. 1990; Dumas et al. 1990; Riising et al. 2002). The effect on daily weight gain in these studies varied from no effect to a 13% decrease. Not only have results differed between surveys, but researchers often have found a varying effect between herds in a given survey. In a study of two herds, a decreased rate of weight gain could be attributed to atrophic rhinitis in only one of them (Wilson et al. 1986), and Scheit et al. (1990) could demonstrate a negative effect of atrophic rhinitis in only one out of three herds.

Output Losses due to PRRS

Acute outbreaks of PRRS can give substantial economical losses due to dramatic increase in the mortality rate. In a large breeding farm, Pejsak et al. (1997) observed a mortality rate of nearly 76% during the 5th week of the outbreak when 1,562 out of 2,067 piglets were either born dead or died prior to weaning. Preweaning mortality rates gradually returned to normal values within 16 weeks. However, the incidence of respiratory disease in the weaned and fattening pigs increased during this time. Although prophylactic treatment against respiratory diseases were administered, the mortality rate doubled for the weaned and fattening pigs. Dee et al. (1997) showed that controlling the disease by nursery depopulation reduced the margin over variable costs in 32 out of 34 pig herds. Test and removal of infected animals have also shown to be a way of eliminating PRRS in 5 chronically infected breeding herds (Dee et al. 2001). Garner et al. (2001) estimated that if the disease became established in Australia opportunity losses in gross national income of 5–11% per year would occur.

8 Diseases of the Skin

Ranald Cameron

STRUCTURE AND FUNCTION

The skin acts as both a barrier and a communication between the external environment and the internal organs. Its functions include maintenance of body fluids, electrolytes, and macromolecules; protection against chemical, physical, and microbiological damage or invasion; and sensory perception of touch, pressure, pain, itch, and temperature change. Skin also regulates body temperature through support of hair coat, regulation of cutaneous blood supply, and sweat gland function (Scott 1988). Skin has an important function of immunoregulation.

The skin of swine is basically similar in histologic structure to that of other domestic animals and, compared with other species, has many more similarities to human skin (Meyer et al. 1978).

The skin is the largest body organ and can in some animals constitute 12–24% of body weight according to age. In the pig the skin represents between 10% and 12% of body weight at birth and around 7% in adult animals, although in some breeds, such as the Meishan, skin can be 10–12% of adult body weight.

The skin of the pig is divided into two layers, the epidermis and dermis. In most areas the epidermis consists of four layers, since the stratum lucidium is absent except in the snout. The epidermis is relatively thick, the major cells being the keratinocytes in the stratum basale, the polyhedral cells in the stratum spinosum, flattened cells in the stratum granulosum, and cornified cells in the stratum corneum. The thickness of the epidermis varies considerably in different areas of the body (Meyer et al. 1978). Generally the skin of the dorsum is thicker and hairier than the skin of the ventrum. Maximum thickness is between the toes and on the lips, the snout, and the shield, which is unique to the scapular and costal region in older boars. The thinnest layers are found in the axilla, eyelids, and ventral areas of the thorax and abdomen (Marcarian and Calhoun 1966).

The dermis consists of two ill-defined layers beneath which is a prominent layer of adipose tissue (hypodermis). The two layers of the dermis, the stratum papillaris and stratum reticularis, are composed of connective tissue in which are situated blood vessels, nerves, lymphatics, and associated epidermal appendages. Cells found in the dermis include fibroblasts, melanocytes, and mast cells. Origins of hair follicles and sweat glands are found in the hypodermis.

The holocrine sebaceous glands of the pig are branched alveolar and open into the neck of the main hair follicle. The sweat glands are coiled, tubular, and apocrine, and are found in all areas, although there are relatively few (about $25/cm^2$) compared with other species, except on the snout.

In swine the short, stout hair follicles possess arrectores pilorum muscles attached to the outer root sheath; the bristles occur either singly or in groups of two or three. The hair coat consists of 60–70% bristles and 30–40% fine downy hair. Specialized forms of hair are also found—in particular, tactile hairs in the region of the snout (Marcarian and Calhoun 1966; Mowafy and Cassens 1975). Specialized seromucoid glands are found in the carpal glands, located behind the carpus, and in the mental (mandibular) organ, located in the intermandibular space.

CLINICAL EXAMINATION AND DIAGNOSIS

Skin diseases may involve the skin only or be cutaneous manifestations of internal disease (Tables 8.1 and 8.2). Diseases restricted to the skin are, for example, ear necrosis, pityriasis rosea, and swine pox. Examples of skin lesions symptomatic of a more general pathophysiological condition are erysipelas, classical swine fever, and dermatitis/nephropathy syndrome. It is essential therefore that an accurate history be taken, followed by a thorough clinical examination, involving the entire animal first and then the skin itself. Examination of the skin should aim to define the nature of lesions (primary or secondary) or abnormality (vesicles or pustules,

Table 8.1.   Causes of diseases of the skin in swine.

A. Infectious			
Bacterial	Viral	Fungal	Parasitic
Exudative epidermitis	Swine pox	Microsporosis	Sarcoptic mange
Streptococcosis	Swine vesicular disease	Trichophytosis	Demodectic mange
Ear necrosis	Vesicular stomatitis	Cutaneous candidiasis	Lice
Spirochetosis	Vesicular exanthema		Fleas
Facial necrosis	Porcine parvovirus		Mosquitoes
Abscesses	Idiopathic vesicular		Flies
Erysipelas	disease		
Salmonellosis	Classical swine fever		
Pasteurellosis	African swine fever		
Mastitis			
Edema disease			
Anthrax			
Malignant edema			

B. Noninfectious				
Environmental	Nutritional	Hereditary	Neoplastic	Miscellaneous
Sunburn	Parakeratosis	Pityriasis rosea	Melanoma	Porcine dermatitis/
Photosensitization	Fatty acid deficiency	Dermatosis vegetans	Rhabdomyoma	nephropathy syndrome
Skin necrosis	Iodine deficiency	Epitheliogenesis imperfecta	Lymphangioma	
Bursitis	Riboflavin deficiency		Papilloma	
Callosities	Pantothenic acid deficiency		Fibroma	
Limb and foot lesions	Biotin deficiency		Hemangioma	
	Vitamin A, C, and E		Sweat gland adenoma	
	deficiencies		Polyp	

Table 8.2.   Differential diagnosis of skin diseases.

Location	Lesions and Signs	Diseases
Head and neck	Macules, vesicles, pustules, greasy exudate (seborrhea), crusts in suckling piglets and weaners especially around the eyes	Exudative epidermitis
	Pustules, erosions, crusts, and abscesses	Streptococcosis
	Plaques, pustules, crusts, alopecia with pruritus	Sarcoptic mange
	Pustules, erosions, necrosis, crusts below the eye, cheek, and lips in suckling piglets	Facial necrosis
	Edema around eyes, conjunctiva, and frontal area mainly in weaners and young growers	Edema disease (*E. coli*)
	Edema of head and throat	Malignant edema (*Clostridium* sp.)
	Red to purple discoloration of snout, face, and neck (jowls)	Septicemia
	Discrete ulcer and crust over mandible in sows	Pressure necrosis
	Vesicles, pustules, erosions on snout, lips, mouth, and tongue	Foot-and-mouth disease
		Swine vesicular disease
		Vesicular exanthema
		Vesicular stomatitis
		Porcine parvovirus
		Idiopathic vesicular disease
	Vesicles, erosions, black crusts	Swine pox
Ears	Black necrosis, ulcers on the tips and posterior edge of the pinna in piglets	Ear necrosis
		Salmonellosis
		Erysipelas
	Deep ulcers at the base of the pinna in growers, often bilateral	Ulcerative spirochetosis
	Erythema, red to purple blotchy discoloration	Septicemia
		Classical swine fever
		African swine fever
		Sunburn
	Plaques, brown or gray crusts on the inner ear, ear shaking, pruritus, gray thick crusts on adult animals	Sarcoptic mange
	Macules, pustules, black crusts	Exudative epidermitis
		Streptococcosis
	Circular macules, patches, small scales, pink to red discoloration behind ears and neck	Ringworm (Microsporosis)

Table 8.2. (*continued*)

Location	Lesions and Signs	Diseases
Dorsum	Hyperkeratosis, dry scales along spine, some alopecia	Essential fatty acid; vitamin A, C, or E; or zinc deficiency
		Sarcoptic mange
	Complete absence of epithelium (large red shiny areas) in newborn piglets	Epitheliogenesis imperfecta
	Abscesses and pressure necrosis over spine between last ribs and lumbar area in sows	Pressure sores, due to confinement in farrowing crates, pressure from crate bars or prongs
Shoulder	Large deep discrete ulcer, necrosis and crust over spine of scapula in sows often in poor body condition	Pressure sore due to confinement on solid or mesh floors, low energy intake
Ventral abdomen	Erythema, pustules, dark brown crusts, exudate	Exudative epidermitis
		Streptococcosis
		Sarcoptic mange
		Candidiasis
		Biotin deficiency
	Erythema, round to diamond-shaped red plaques, often with necrotic centers, fever, anorexia, arthritis	Erysipelas
	Papules seen as ringlike lesions, collarettes, flakes and scales (3- to 14-week-old pigs)	Pityriasis rosea
	Circular pink to red macules, scales, or crusts around periphery	Ringworm (Microsporosis, Trichophytosis)
	Papules, thick crusts, fissures, exudate	Zinc deficiency (Parakeratosis)
		Dermatosis vegetans
		Exudative epidermitis
	Vesicles, pustules, black scabs, round raised areas with depressed centers	Swine pox
	Erythema, red to purple or black discoloration, skin necrosis in lactating sows	Acute mastitis
	Necrosis of teats, especially pectoral teats in piglets, end of teat appears as red or black (scab) spots	Trauma and infection due to rough floors and poor hygiene in farrowing crates
Lateral abdomen and flank	Erythema, round to diamond-shaped red plaques, often with necrotic centers, fever, anorexia, arthritis	Erysipelas
	Papules, vesicles, pustules, scales, crusts, greasy exudate	Exudative epidermitis
		Streptococcosis
	Pustules, scales, thick wrinkled skin, alopecia, crusts, with hyperkeratosis	Sarcoptic mange
		Niacin, pantothenic acid, riboflavin, or vitamin A deficiency
	Erythema, erosion or ulcer on flank	Flank biting
	Papules, plaques seen as ringlike lesions, collarettes, scales (3- to 14-week-old pigs)	Pityriasis rosea
	Circular pink to red macules varying in size, scales or crusts around periphery	Ringworm (Microsporosis, Trichophytosis)
Hindquarters	Erythema of the scrotum, vulva, and perineum	Septicemia
		Sunburn
	Tail necrosis, ulceration, abscesses (growers)	Tail biting
	Large discrete ulcer, necrosis, scab over hip bone (adult)	Pressure sore
	Erythema, black necrosis, especially scrotum or vulva	Porcine dermatitis/nephropathy syndrome
	Small round raised wheals, urticarial reaction	Insect bites: flies, mosquitoes, fleas
Legs (limbs)	Erythema, red to purple discoloration especially around hocks	Septicemia
	Papules, plaques seen as ringlike lesions, collarettes, scales on medial thighs and legs (3- to 14-week-old pigs)	Pityriasis rosea
	Papules, thick crusts, fissures, papillomas	Parakeratosis (zinc deficiency)
		Exudative epidermitis
	Complete absence of epithelium (red shiny area) in newborn piglets	Epitheliogenesis imperfecta
	Thick fibrotic areas over joints (hocks, elbows, fetlocks, tuber ischii) often ulcerated	Callosities
		Bursitis
	Necrosis of carpus, hocks especially, in suckling piglets	Trauma due to rough farrowing-crate floors
Distal limb, coronary band, feet	Thick, dry crusts, deep fissures	Parakeratosis
		Dermatosis vegetans
		Exudative epidermitis
		Sarcoptic mange
	Vesicles, pustules, erosions around coronary band and accessory digits, with lameness	Foot-and-mouth disease
		Swine vesicular disease
		Vesicular stomatitis
		Vesicular exanthema
		Porcine parvovirus
		Idiopathic vesicular disease
	Abscesses, discharges, swelling of the coronary band	Bush foot, ascending infections of hoof
	Thickening, ridges and furrows parallel to coronary band	Dermatosis vegetans

edema or erythema). This should be followed by formulation of a differential diagnosis. Tests should then be carried out to confirm a diagnosis (skin scraping, culture, or biopsy) in order to determine the approach to treatment and subsequent prevention.

History
Information obtained should include the following:

Type of Husbandry and Housing System. Extensive or free-range systems may predispose to sunburn or photosensitization. Intensive indoor housing often leads to conditions such as pressure sores in sows or teat necrosis in piglets. Infectious conditions such as exudative epidermitis are more frequently seen in continuous flow through systems than in all-in/all-out systems.

Specific Environmental Conditions. Poor hygiene and high ambient temperatures, relative humidity, and stocking density may predispose to outbreaks of staphylococcal and streptococcal pyoderma. Pityriasis rosea is also more frequently seen with high stocking densities and high humidity. A seasonal pattern may be evident for some skin diseases.

Recent Movement. The mixing of pigs—for example, at weaning—may result in fighting and biting and increase the incidence of exudative epidermitis in the nursery.

Signs of Trauma. Self-inflicted trauma may be due to pruritus associated with sarcoptic mange or lice infestation.

Nutrition. Deficiencies of the B group vitamins, zinc, or essential fatty acids can result in dry, scaly, dandrufflike dermatitis or parakeratosis.

Breed. Breed may indicate a congenital or hereditary condition. Pityriasis rosea has been commonly seen in Landrace pigs and in the progeny of pigs that have had pityriasis rosea as weaners. Other inherited conditions include dermatosis vegetans and epitheliogenesis imperfecta.

Age. A number of diseases are more frequently seen in certain age groups. Exudative epidermitis rarely affects pigs older than 6 weeks of age, and pityriasis rosea is seen only in pigs between 2 and 6 weeks of age. Teat necrosis usually occurs within 24 hours after birth. Nutritional deficiencies are unlikely to occur before weaning.

Chronology of Lesions. Information relating to initial lesions observed and their location may indicate a typical clinical evolution. In swine pox, for example, macules are observed initially, and then vesicles and pustules that rupture to form a dark circumscribed crust before healing. Exudative epidermitis often commences as macules and pustules around the eyes before spreading over the entire body of piglets.

Other Clinical Signs. A history of other signs such as anorexia, depression, loss of body condition, reluctance to move, or diarrhea may indicate the skin lesions are the result of an internal disease.

Incidence. The number of animals affected, the contagious nature, and the history of mortalities may suggest an infectious disease such as exudative epidermitis or erysipelas, which tends to spread rapidly, whereas congenital and hereditary conditions such as pityriasis rosea are seen at a constant rate within a herd.

Response to Therapy. Variation in response to therapy may help to differentiate between viral, bacterial, and fungal infections—for example, swine pox, streptococcal dermatitis, and ringworm. Pityriasis rosea does not respond to any treatment, whereas parakeratosis responds dramatically to the addition of zinc and essential fatty acids to the diet.

Clinical Examination
Before carrying out a detailed examination of the skin a general clinical examination is necessary to determine whether the skin disease is symptomatic of an internal disease.

Internal diseases causing skin lesions or skin abnormalities such as abnormal color changes include erysipelas, salmonellosis, pasteurellosis, mastitis, classical swine and African swine fever, and dermatitis/nephropathy syndrome. Almost any septicemia or toxemia can cause erythema or cyanosis characterized by red to purple discoloration, especially on the extremities and easily seen in the white breeds. Urticaria, seen as multiple pink to purple raised areas of skin, commonly occurs in cases of erysipelas, beta-hemolytic streptococcal infections, food allergy, or insect bites. Blue to black skin discoloration with necrosis can indicate gangrene. Necrosis of the ears and tail of piglets is also black. Pallor is often an indication of blood loss due to conditions such as proliferative enteropathy or gastric ulcerations.

Pruritus causes scratching and should be looked for as a possible sign of sarcoptic mange or lice infestation. Scratching is frequently accompanied by shaking of the head due to the presence of mites in the ears and can result in aural hematomas. Alopecia and excoriation may also be an indicator of intense scratching seen in chronic sarcoptic mange.

Edema of the skin can indicate a systemic disease, for example, hypoproteinemia, vasculitis, increased vascular permeability such as in malignant edema caused by *Clostridium septicum* and in edema disease associated with *Escherichia coli*, the last two conditions producing edema around the head.

Skin lesions are classified as primary, the direct result of the insult or disease, or as secondary, a result of evolutionary changes to the skin dictated by factors such as the cause of the disease, secondary infection, self-trauma, etc.

It is essential for the clinician to differentiate between primary lesions and secondary lesions; however, when the animal is presented, only secondary lesions may be seen. Examination of the entire body of several animals may be necessary to locate primary lesions on recently affected cases.

Primary Lesions. Macules, defined as circumscribed flat discolorations less than 1 cm in diameter, and papules, more solid, raised areas of skin of varying color, are seen in the early stages of exudative epidermitis, erysipelas, and swine pox.

Plaques, elevated superficial lesions more than 0.5 cm in diameter, scattered over the whole body surface of young growing pigs have been associated with erysipelas, pityriasis rosea, and Aujeszky's disease.

Vesicles are well-demarcated, dome-shaped lesions (<1 cm) usually containing serum or inflammatory exudate. They are pale or translucent and are characteristic of a number of the viral skin diseases in swine, such as swine pox, foot-and-mouth disease, swine vesicular disease, and vesicular stomatitis. Similar lesions have been reported in swine with porcine parvovirus infection (Kresse et al. 1985).

Pustules are elevated lesions filled with inflammatory cells (leukocytes) and can be follicular or epidermal. They are white, yellow, or red (hemorrhagic) and, in some cases, are surrounded by erythema. Pustules in swine are commonly associated with streptococcal infections, exudative epidermitis, and swine pox.

Wheals are circumscribed, raised, round or oval areas of skin due to edema. They may be blanched or slightly erythematous. The edema is usually associated with the dermis. Fly and mosquito bites frequently cause wheals.

Secondary Lesions. Scales or flakes can indicate abnormal keratinization and shedding caused by ectoparasites, such as *Sarcoptes scabiei*, or by bacterial skin diseases. Scales are seen on the thinner skin of piglets with exudative epidermitis, on the inner side of the margin of the ringlike lesions of pityriasis rosea, and on the outer periphery of ringworm lesions. Scales may be mixed with sebum and sweat, giving a greasy or oily appearance—seborrhea.

Crusts are a very common secondary skin lesion of swine and are due to a combination of serum, sebum, blood, and cutaneous debris adhering above the normal skin surface. Crusts are seen following bacterial infections and viral vesicular diseases, especially swine pox, and as a result of pruritus associated with sarcoptic mange or lice infestation.

Hyperkeratosis, an increased thickening of the stratum corneum, develops with nutritionally related metabolic disorders such as vitamin A, zinc, and fatty-acid deficiencies or with local callus formation due to trauma associated with pressure and friction. Erythema and intense pruritus with hyperkeratosis and acanthosis have been associated with in-feed tiamulin therapy (Laperle et al. 1988).

Erosions involving the epidermis only and ulcers involving also the dermis are caused by deep bacterial infections (*Staphylococcus* spp., *Streptococcus* spp., *Fusobacterium necrophorum*, and a spirochete referred to as "*Borrelia suis*") or may be due to trauma or pressure.

Severe scratching will result in alopecia, commonly seen over the shoulders and hindquarters in pigs with sarcoptic mange or lice and in pigs irritated by insects such as flies and mosquitoes. The characteristic lesions of pityriasis rosea are typical epidermal collarettes, described as ruptured pustules spreading peripherally with a ring of scales on the inner margins of the ring.

Diagnostic Tests

Diagnosis of skin diseases can be confirmed by a number of relatively simple tests. In swine the most frequently used tests include skin biopsy for histopathological examination, direct smears for identification of bacteria and fungi, and culture for isolation and identification of bacteria and viruses.

Skin Biopsy. Skin biopsy should be used on

- All neoplastic lesions
- Any persistent ulceration
- Skin lesions not responding to treatment

Fully developed primary lesions or early vesicles and pustules are best for biopsy, whereas secondary lesions may be of little value. The technique described by Scott (1988) involves removal of 6–9 mm of skin using a biopsy punch or surgical excision with a scalpel, which may be more suitable for larger lesions, vesicles, and pustules and where the skin is very thick. The skin surface should be cleaned with soap and water but not scrubbed or prepared with antiseptics. Local anesthetic may be indicated. The biopsy should be gently blotted to remove blood and surface material, placed subcutaneous side down on a wooden spatula or cardboard, and gently flattened for 30–60 seconds. The tissue and spatula or cardboard support are immersed within 1–2 minutes in a fixative such as 10% neutral phosphate buffered formalin for at least 24 hours. The volume of fixative should be 10–20 times that of the specimen. Skin biopsies are usually stained with hematoxylin and eosin (H & E).

Skin biopsy, unfixed, can also be used for isolation of bacteria and viruses. For virus isolation, the skin should be cleaned with water or saline only and not with alcohol. Samples should be stored and transported at 4°C in a virus transport medium.

Direct Smear. Direct smear is commonly used for identification of bacteria or fungi. For bacteria, samples of pus or exudate from pustules, macules, or ulcers can be smeared on glass slides, air-dried, and stained with methylene blue, Gram stain, or Diff-Quik for light microscope examination to identify the type of bacteria (cocci or rods, gram-positive or gram-negative) (Scott 1988). Skin scrapings or direct touch impression can be used for suspected fungal diseases. Skin scrapings should be made after defatting the skin with alcohol. Scrapings are warmed in a 20% solution of sodium hydroxide, and spores appear as round highly refractile bodies in chains or mosaics in hair follicles, in epithelial scales, and on the surface of hair fibers.

Culture. Best results are obtained by aspirating samples from intact pustules, vesicles, or abscesses with a needle and syringe. Cultures of open sores (erosions, ulcers, and sinuses) generate confusion (Scott 1988). Bacterial culture is usually done on blood agar or in thioglycolate broth. Virus identification can be done from tissue culture or by electron microscopy. Hair and skin scrapings (surface keratin) can be inoculated onto Sabouraud's dextrose agar or Dermatophyte Test Medium (DTM) for fungal culture (Scott 1988).

BACTERIAL DISEASES

Exudative Epidermitis (Greasy Pig Disease, Impetigo Contagiosa, Seborrhea Contagiosa)

Exudative epidermitis is a generalized dermatitis involving the entire body surface. In the acute form, it usually affects suckling piglets, whereas the chronic form is more commonly seen in older, weaned pigs (Chapter 39).

The disease is caused by *Staphylococcus hyicus*, certain strains of which produce a heat-labile exfoliative toxin (Andresen et al. 1993). Other bacteria frequently isolated from the skin lesions in field cases include *Streptococcus* spp. and *Arcanobacterium pyogenes* (L'Ecuyer and Jericho 1966). Additional factors that may affect the severity and progress of the disease include nutrition, hygiene, immunity, abrasions of the skin, and infection with *Sarcoptes scabiei* var. *suis*. Recent reports have suggested that porcine circovirus type 2 (PCV2) and porcine parvovirus (PPV) could also play an important role in outbreaks of exudative epidermitis (Wattrang et al. 2002; Kim and Chae 2004).

Although pigs develop resistance with age, *S. hyicus* can be recovered from the skin of older pigs, the vagina of sows, and the preputial diverticulum of boars. Piglets can become infected during birth and develop dry scales or flakes over the entire body within 12 hours. These animals are often devoid of hair. Infection usually occurs during the suckling period from sows or in a contaminated farrowing environment. Weaners can be infected after mixing with carrier animals in the nursery.

Suckling piglets, 1–4 weeks old, are the most commonly and often severely affected animals. The morbidity can range from 10% to 90% and mortality from 5% to 90% (average 20%) in suckling piglets. In weaned piglets 3–6 weeks of age, the morbidity can be up to 80% in some groups; however, mortality is usually low. In my experience, lesions may be seen on older animals, especially in immunologically naive gilt herds.

The disease may be acute, subacute, or chronic. In the acute form, the skin lesions are first seen around the eyes, nose, lips, and gums and behind the ears as red-brown spots (macules) that increase in size and develop a vesicular or pustular appearance. The skin soon appears damp and oily as a result of the greasy exudate of sebum, sweat, and serum. Erythema is marked, often over the entire body, and the exudate becomes thick and crusts develop on the skin surface, giving a drier appearance. During this period an obnoxious, rancid odor may be present. When the crusts lift, a raw, highly inflamed skin is left underneath. The feet are frequently affected with erosions on the coronary band and heel. Lesions may develop around the conjunctiva, causing the eyelids to become swollen and matted together. Constipation or, less frequently, diarrhea accompanied by emaciation, dehydration, and often death may be seen 3–5 days after the first signs. The disease has also been associated with lesions of the kidney involving the renal pelvis and tubules (Blood and Jubb 1957). Ulcerative glossitis and stomatitis have been reported by Andrews (1979). Nervous signs were recorded in one outbreak of exudative epidermitis by Blood and Jubb (1957).

The more chronic form (Figure 8.1A) is seen in older pigs 6–10 weeks of age (L'Ecuyer 1966) and up to 5 months of age (Piercy 1966). Occasionally in weaners the disease is seen as only discrete, round, raised lesions (papules), dark red-brown in color, especially on the face and head, with fewer over the body.

The differential diagnosis includes sarcoptic mange, parakeratosis associated with zinc and other nutritional deficiencies, swine pox, pityriasis rosea, and ringworm. Confirmation can be made by biopsy and culture of *S. hyicus*. The biopsy should sample the early typical macules, vesicles, or pustules, before lesions become chronic.

In the early stages of the disease, parenteral antibiotics will greatly reduce the severity and duration as well as mortalities. Antibiotic-resistant *S. hyicus* has frequently been reported but may represent regional differences. The antibiotics of choice include penicillin, ampicillin, amoxicillin, cloxacillin, tetracycline, tylosin, trimethoprim-potentiated sulfonamides, and gentamycin. Resistance to lincomycin, erythromycin, and streptomycin has been reported. Local treatment of the affected areas or the entire body using antibacterial shampoos or skin antiseptics is of value. Preparations used include chlorhexidine, iodophores (providone-iodine), and chloramine. Success when treating large
8.1. *(A) Exudative epidermitis (chronic); (B) ear necrosis (spirochetosis); (C) erysipelas; (D) swine pox; (E) ringworm* (Microsporum nanum)*; (F) sarcoptic mange. (Color printing courtesy of Pfizer Animal Health Group, New York, N.Y., and MERIAL.)*
8.2. *(A) Skin necrosis; (B) parakeratosis; (C) pityriasis rosea; (D) epitheliogenesis imperfecta; (E) porcine dermatitis/nephropathy syndrome; (F) porcine dermatitis/nephropathy syndrome. (Color printing courtesy of Pfizer Animal Health Group, New York, N.Y., and MERIAL.)*

numbers of affected animals with in-feed or in-water medication using amoxicillin, oxytetracyclines, or trimethoprim-potentiated sulfonamides has been observed.

During an outbreak, attention should be paid to hygiene, especially in the farrowing and weaner accommodation. Increasing the level of zinc and B group vitamins (especially biotin) in the diet may help in treatment and control. Removal of factors predisposing to skin injury, together with strict hygiene, is important in prevention. Spraying weaner pigs with a skin disinfectant such as chloroxylenol daily for 3 days at the time of weaning and mixing can eliminate outbreaks associated with postweaning fighting. Prevention of sarcoptic mange is also indicated.

Herds derived by hysterectomy or medicated early weaning commonly experience outbreaks of exudative epidermitis soon after being established. Amtsberg (1978) found vaccination to be effective in the prevention of experimentally induced exudative epidermitis. An autogenous vaccine used in commercial herds given to sows twice at 3-week intervals and then every 6 months has also been reported to give good results in eliminating clinical exudative epidermitis (Sieverding 1993).

Pustular Dermatitis (Streptococcosis, Contagious Pyoderma)

Streptococcal infections (Chapter 47) can cause skin necrosis and pustular dermatitis. These conditions are usually caused by the beta-hemolytic streptococci of the Lancefield groups C and L. *Streptococcus zooepidemicus* and *S. equisimilis* have been isolated from abscesses (Miller and Olson 1978, 1980) and porcine ear necrosis (Maddox et al. 1973). Secondary or concurrent infections of the skin frequently involve *S. hyicus*, *Arcanobacterium pyogenes*, and *Borrelia suis* (Penny et al. 1971).

Transmission can be directly from sows to newborn piglets and through skin abrasions and tissue damage associated with tail docking, ear notching, needle teeth clipping, and bite wounds. Abrasions of feet caused by new concrete floors may be associated with streptococcal infections. Outbreaks are usually associated with poor hygiene.

Wounds on any region of the body can become infected, resulting in cellulitis, necrosis, abscess formation, and ulceration. Hare et al. (1942) described the lesions of pustular dermatitis first seen as erythema, occasionally with petechiae over the ventral surface of the abdomen and around the eyes. This is followed by flattened pustules in the inguinal region, on the inner surfaces of the thighs, along the dorsum and tail, and around the eyes, lips, and edge of the ears. On rupture, the pustules heal, forming circular scabs composed of several concentric layers, darker at the center, and resembling large fish scales when peeled. This stage is associated with pruritus. Pustules may form abscesses or

ulcers on the snout, cheeks, tail, legs, and feet. Similar lesions are seen on the udder and teats of sows. The early stages of pustular dermatitis resemble exudative epidermitis and may involve initial infection with *S. hyicus*.

Differential diagnosis includes ulcerative dermatitis, exudative epidermitis, sarcoptic mange, swine pox, and erysipelas. Isolation and identification of streptococci from biopsy material or swabs will confirm a diagnosis.

Treatment with ampicillin, amoxicillin, tetracyclines, or erythromycin can be effective. Local treatment of lesions with disinfectants such as tincture of iodine or iodophores (providone-iodine) is useful. Strict hygiene is essential, especially when carrying out procedures such as clipping needle teeth, ear notching, and tail docking, as well as prevention of injuries by removal of rough, corroded, or splintered surfaces. Regular disinfection in conjunction with all-in/all-out management, especially in the farrowing and nursery accommodation, will help to reduce the buildup of streptococci.

Vaccination with autogenous bacterins has been used as a control measure in herds with contagious pustular dermatitis (Scott 1988).

Ear Necrosis (Necrotic Ear Syndrome, Ulcerative Spirochetosis of the Ear)

Ear necrosis is a syndrome seen in pigs aged from 1 to 10 weeks. It is characterized by bilateral or unilateral necrosis of any part of the ear, but especially in young pigs on the tip and around the posterior edge of the pinna. In growers, necrosis at the base of the ear can occur, with many pigs being affected at any one time. Outbreaks often occur in one pen of pigs, with up to 80% affected.

It is likely that the lesions are the result of a mixed infection following damage to the skin. It has been suggested that infection with *S. hyicus* may take place first, followed by the more invasive streptococci and spirochetes, resulting in necrosis and ulceration (Fraser et al. 1991). Biting following mixing of pigs is a common predisposing factor. In older pigs ear biting can be a vice similar to flank and tail biting, and lead to infection. Self-inflicted trauma resulting from the irritation of *Sarcoptes scabiei* infection in the ears can initiate the early lesions.

The lesions can range from mild, superficial dermatitis (plaques) of the tip, edges, and base of the pinna to more severe inflammation with exudation, ulceration (Figure 8.1B), and necrosis (Harcourt 1973). The areas of necrosis may become dry, crusty, and curled over, with eventual loss of some of the ear or the entire ear. Some pigs may show signs of inappetence, unthriftiness, and fever; death may occur in a few cases.

Bacterial culture and histopathological examination will help to confirm a diagnosis. Injections of penicillin, ampicillin, amoxicillin, or tetracyclines for at least 4–5 days will be of value, especially if combined with local application of a suitable skin disinfectant such as tincture of iodine, iodophore, or chlorhexidine. General hygiene of the environment and elimination of predispos-

ing factors such as ear biting and fighting are essential for control.

Ulcerative Dermatitis (Granulomatous Dermatitis)

Ulcerative dermatitis can occur as ulcerative, necrotic, or tumorlike lesions found on most areas of the body surface and around the buccal cavity of pigs. More specific syndromes such as ear necrosis, facial necrosis, infected bursae, and calluses over joints and bony prominences can be forms of spirochetosis.

The etiology involves initial trauma of the skin, followed by infection, often involving several organisms. Although the typical lesions appear to be caused by a spirochete, which was reported as *Borrelia suis*, early infection with *S. hyicus* and beta-hemolytic *Streptococcus* spp. is most likely. *Arcanobacterium pyogenes* is a common secondary invader (Cameron 1984).

Skin trauma or damage that results in infections can be associated with bite wounds, especially around the face and head and on the flank and tail. Infection following castration, pressure sores, and ulceration of swollen bursae and calluses often leads to spirochetosis. Gum damage following teeth clipping can result in lesions in the buccal cavity.

Lesions are most commonly seen in young pigs or, in the case of pressure sores and bursitis, in older growers and adults. The initial lesions are characterized by erythema and edema followed by necrosis, ulceration, or tumefaction, with fistulae discharging a grayish brown glutinous pus. Lesions may continue to enlarge for several months and involve deeper structures of the body. The central area will often slough.

A differential diagnosis would include foreign-body abscesses, neoplasms, other infectious granulomas, and pressure necrosis. A diagnosis can be made by identification of spirochetes from direct smears, dark-field illumination of wet preparations, or biopsy examination. Culture of secondary invaders will also be of value.

Procaine or benzathine penicillin, ampicillin, or amoxicillin are the drugs of choice. Treatment should continue for at least 5 days. Surgical removal of large granulomas may be indicated. Local treatment may be of value using aerosol preparations of tetracycline or skin disinfectants. Fly repellents are indicated to prevent myiasis. Control of ulcerative dermatitis is by the elimination of factors that result in skin damage and trauma. Improved hygiene at teeth clipping and castration and attention to wounds due to fighting, flank biting, and pressure sores are essential to avoid infection.

Facial Necrosis (Facial Pyemia)

Facial necrosis is a common condition in suckling pigs less than 1 week of age and is characterized by bilateral necrotic ulcers that are often covered by hard brown crusts and that extend from the side of the face to the lower jaw area.

The condition is the result of infection of wounds inflicted by piglets on each other during feeding, often because inexperienced stockpersons have failed to carry out teeth clipping correctly. Lacerations to the side of the face become infected with organisms such as *Fusobacterium necrophorum*, *Streptococcus* spp., and *Borrelia suis*.

Facial necrosis is commonly seen in large litters and especially in the disadvantaged weaker piglets and when milk letdown is slow, that is, when sows suffer from agalactia or hypogalactia.

Facial necrosis occurs during the first few days of life and any number of piglets in a litter can be affected. Initially lesions can be seen as striated lacerations caused by bites from other piglets. The lesions become infected, resulting in shallow ulcerations covered with hard brown crusts. The encrustation may extend over a large area involving the lips and eyelids, making it difficult for the piglet to open its mouth or eyes. These animals have difficulty in feeding and may starve. Facial necrosis can predispose to outbreaks of exudative epidermitis.

The condition is easily diagnosed by the nature and distribution of the lesions on the face of young piglets. Bacteriological examination of the lesions will help identify the organisms involved.

Careful removal of the crusts and application of a mild disinfectant solution of chlorhexidine or iodophores or of an antibiotic cream will help remove the infection as well as soften the lesions. Prevention is by clipping the canine and lateral incisor teeth just above the level of the gum surface during the first 24 hours of life in all piglets in the litter. Instruments used should be thoroughly disinfected. Fostering piglets to eliminate large litters will help reduce competition for teats at feeding. Hygiene in the farrowing accommodation and prevention of milk letdown problems are also important.

Abscesses

Subcutaneous abscesses are common in pigs, usually as a result of fighting, bite wounds, and lacerations from rough floors and housing. Abscesses may also result from injections when using contaminated needles or through dirty skin following castration or tail biting. Tail abscesses can result in infection spreading by lymphatic drainage to the pelvic inlet, sacral region, and vertebral column.

The organisms commonly present in abscesses of the skin in swine include *Arcanobacterium pyogenes*, *Streptococcus* spp., *Bacteroides* spp., and anaerobic gram-positive cocci. *Actinobacillus equuli* and *A. suis* have also been reported as causing subcutaneous abscesses in the neck, withers, and flanks in swine (Mullowney 1984).

The treatment of choice is surgical drainage followed by flushing the open wound with a suitable antiseptic and treatment with antibiotics such as ampicillin, tetracycline, or trimethoprim/sulfonamide.

Erysipelas

Erysipelas is an infectious disease of pigs that manifests in several forms, including septicemia, nonsuppurative arthritis, vegetative endocarditis, and skin lesions (Chapter 37). The disease is seen mainly in pigs between 3 months and 3 years of age. Younger pigs are protected by passive immunity acquired from suckling immune sows. The disease is caused by *Erysipelothrix rhusiopathiae*.

In acute erysipelas, the skin of the extremities—including the snout, ears, lower limbs, tail, and scrotal area, as well as the jowls and ventral surface of the abdomen—is erythematous. The color varies from pink to purple, typical of many systemic infections and not necessarily diagnostic of erysipelas.

The more specific skin lesions associated with erysipelas first appear as small pink or red raised areas (papules) or larger plaques ranging from 3 to 6 cm in diameter. Many of these lesions will develop the characteristic diamond or rhomboidal shape and are raised, firm, and easily palpated (Figure 8.1C). The outer area is pink in color and the center becomes blue to purple (necrosis) as the disease progresses. These discrete lesions are associated with arteritis; the small arterioles show acute cellular infiltration and cellular thrombi with the presence of mainly neutrophils (Jubb et al. 1985). In the chronic stage, skin lesions become more necrotic; appear dark, dry, and firm; and easily peel away from the underlying tissues. Occasionally, sloughing of the ears, tail, or a foot can occur (Scott 1988). Alopecia may be seen in more long-standing cases.

The systemic signs generally associated with the disease, together with the typical skin lesions, usually make the diagnosis of erysipelas on clinical grounds relatively easy. Acute septicemia and erythema have to be differentiated from classical swine fever (hog cholera), African swine fever, salmonellosis, and pasteurellosis. The early, smaller plaques can be confused with insect bites, sarcoptic mange, or exudative epidermitis. Culture of the organism (from the live animal) may be possible in the early stages of the disease from blood and skin biopsy of typical lesions. Several animals should be sampled. Culture is usually more successful at necropsy from a variety of organs: heart, lung, liver, spleen, kidneys, and joints (Wood 1992). A number of serological tests have been used for detecting infection; however, they have limited practical value for clinical diagnosis.

Penicillin is the drug of choice and should be given daily for 3–5 days. In the case of very sick pigs, the first two injections may be given 12 hours apart. At-risk, in-contact animals should also be treated with penicillin. Long-acting preparations can be used.

Prevention is by regular vaccination of sows and boars. Sows should be vaccinated twice at selection and 4 weeks before farrowing, and boars twice yearly. If outbreaks occur in grower stock, a weaner vaccination program may be of value. Reducing contact with effluent and maintaining a good standard of hygiene will help prevent outbreaks.

Salmonellosis

Salmonellosis (Chapter 45) in pigs can cause septicemia and thus skin lesions and changes in skin color. This form of the disease is generally caused by *Salmonella choleraesuis*. All age groups of pigs can be affected, although pigs from weaning to 4 months of age are most frequently affected.

In the acute form associated with septicemia, mortalities can be high, and other pigs may be weak and moribund. Cyanosis of the extremities and abdomen may be seen. The discoloration of the skin is due to intense capillary dilation and congestion in the dermal papillae, followed by thrombosis in the capillaries and venules and, to a lesser extent, arterioles, leading to necrosis and sloughing of the skin. Skin necrosis commonly involves the ears, tail, and feet in young pigs.

Discoloration of the skin is similar to that in other septicemic diseases—that is, swine fever, erysipelas, and pasteurellosis—which therefore have to be considered in a differential diagnosis. Ear necrosis also has to be differentiated from necrosis associated with other infectious agents.

Diagnosis will be made on the basis of clinical signs and isolation and serotyping of the organism—in particular, at necropsy from spleen, liver, lungs, mesenteric lymph nodes, and small intestines.

Acute Mastitis

Some of the acute forms of infectious mastitis in sows immediately following farrowing are accompanied by extensive discoloration of the skin. The affected mammary glands are pink to red and later may become dark purple or black (gangrene).

VIRAL DISEASES

Swine Pox (Contagious Impetigo, Louse-Borne Dermatitis)

Swine pox is a typical poxvirus infection mainly affecting young pigs. There is little or no systemic illness, and lesions are usually confined to the ventrolateral abdomen and thorax (see Chapter 29).

The virus is abundant in the lesions and transmission is by direct contact. Injury to the skin will aid in the infection becoming established. Lice and possibly other blood-sucking insects are an important means of disease transmission in swine herds. Congenital swine pox has been reported (Borst et al. 1990; Thibault et al. 1998a).

The lesions follow the typical pox evolution of erythematous macules becoming papules, and then vesicles progressing to pustules, which rupture and form crusts (Figure 8.1D). Lesions are seen mainly on the side of the body, ventral abdominal wall, and inner thighs. Occasionally lesions are seen on the back, face, and

udder. Skin lesions develop within 5 days after experimental intradermal inoculation (Kasza and Griesemer 1962). After first appearance of the lesions, the papules enlarge to 6 mm in diameter. The lesions of the pustular stage become umbilicated, ischemic, and yellow in color. The center of the lesions decreases in height and the peripheral tissue hypertrophies. Within 10 days dark crusts appear, and within 20 days the crusts desquamate, leaving small white discolored spots. The nature and distribution of the lesions may be influenced by secondary bacterial infections. The site of the lesions affects the various stages in the progress of the disease. Vesicles do not form on the thick skin of the back, but proliferative changes with necrosis of the epithelium take place, producing crusts.

Swine pox has to be differentiated from the other vesicular diseases, early cases of sarcoptic mange, and erysipelas. Vesicular diseases such as foot-and-mouth disease and swine vesicular disease are more severe, and lesions are mainly confined to the snout, lips, tongue, palate, coronary band, and feet. Swine pox is relatively mild, and eruptions on mucosal surfaces are rare. Diagnosis can be confirmed by host range studies, serological tests, histological examination, and virus isolation or detection of viral antigens.

Treatment is directed at control of secondary bacterial infections using antibiotics and improving the general health of the animals. No vaccines are available, and prevention of outbreaks is by avoiding the introduction of carrier animals, good sanitation, and control of the pig louse.

Vesicular Diseases

Foot-and-mouth disease, swine vesicular disease, vesicular stomatitis, and vesicular exanthema can all cause vesicular skin lesions in swine. The diseases all produce very similar lesions with similar distribution.

The characteristic lesions of foot-and-mouth disease are vesicles filled with straw-colored fluid that form in the mucosa of the mouth, including the tongue, lips, gums, pharynx, and palate, and in the coronary band. Lesions are also seen between and above the claws and on the snout. Sows may develop lesions on the udder and teats (Mann and Sellers 1989).

Vesicles rupture rapidly, leaving a raw hemorrhagic eroded area with ragged fragments of necrotic epithelium. The lesions heal quickly, beginning with a serofibrinous exudate and a gradual replacement that may or may not be pigmented depending on the cells involved (Callis et al. 1975). With swine vesicular disease, lameness may be severe, as lesions most commonly involve the coronary band, hoof, heel, and supernumerary digits. Separation of the horn of the hoof often occurs, commencing from the coronary band.

The clinician should collect samples for virus isolation and serology, fixed tissue for histopathology, and epithelial and vesicular fluid for complement-fixation and ELISA testing for viral antigens. Animal inoculation studies may also be used.

Porcine Parvovirus

Kresse et al. (1985) reported erosions and vesicles on the snout, mouth, coronet, and interdigital space of swine in the midwestern United States in several herds. The virus was isolated from the skin as well as from serum and other organs.

Idiopathic Vesicular Disease

Several cases of vesicles of unknown or doubtful etiology have been reported in swine. Gibbs et al. (1983) reported vesicles and erosions on only the feet in swine in Florida. Munday and Ryan (1982) and Montgomery et al. (1987) reported vesicles on the snout and feet of swine fed marine products, parsnips, or celery.

Classical Swine Fever (Hog Cholera)

Classical swine fever is caused by a pestivirus of the family Togaviridae. Diffuse erythema followed by purplish discoloration of the skin over the abdomen, snout, ears, and thighs is common in acute cases. Necrosis of the edges of the ears, tail, and vulva may develop. Purple blotching of the ears is characteristic, with generalized hypotrichosis in the chronic form of the disease. Congenital alopecia has been reported in piglets infected in utero (Carbrey et al. 1966).

African Swine Fever

African swine fever is caused by a DNA virus at present unclassified. Besides general signs of fever, depression, anorexia, and incoordination similar to hog cholera, skin changes include cyanotic blotching and purple discoloration of the limbs, snout, abdomen, and ears. Hemorrhages may also occur on the skin of the ears and flanks.

Porcine Reproductive and Respiratory Syndrome (PRRS)

An unusual case of severe cutaneous hemorrhages with dermal and subcutaneous capillary angioplasia has been reported in aborted, stillborn, and live-born weak piglets during an outbreak of PRRS virus abortions (Scruggs and Sorden 2001). The affected full-term stillborn piglets and live-born weak piglets had single or multiple coalescent dark reddish-blue cutaneous hemorrhages on the pinnae, cranium and lateral cervical and shoulder areas. Less severely affected piglets had small (2–10 mm) hemorrhages on the skin of the lateral neck and hind limbs. Because the lesions were seen only during the outbreak of PRRS and disappeared after the abortion storm and localization of PRRS virus antigen within macrophages adjacent to proliferating capillaries was demonstrated, it was suggested the PRRS virus played a role in the development of the lesions.

FUNGAL DISEASES (RINGWORM)

Fungal diseases of swine tend to be superficial mycoses involving the keratinized epithelial cells and hair only. Fungi reported in swine include *Microsporum nanum, M. canis, M. gypseum, Trichophyton mentagrophytes, T. rubrum, T. tonsurans, T. verrucosum,* and *Candida albicans.*

Ringworm is found in both extensively and intensively reared swine. All age groups can be affected and the incidence appears to be higher where sanitation is poor and stocking densities are high with moderate temperatures and high humidity. Bedding may be an important source of infection. Fungal spores can remain viable for many years in a dry and cool environment. Mycelial growth is promoted when the environmental conditions are warm and humid with a slightly alkaline skin pH. Ringworm fungi are strictly aerobic.

Microsporosis

Microsporum nanum is the most common fungal infection in swine; however, *M. canis* produces ringworm in piglets and *M. gypseum* is also found on pigs. Ringworm lesions can be found on almost any part of the body.

Ginther (1965) described the typical lesions as beginning as circumscribed spots, which tend to enlarge in a circle, some to enormous size covering the complete side of the pig (Figure 8.1E). The skin is reddish to light brown in color, roughened but not raised. Dry crusts form around the periphery, the hair is usually not lost, and no pruritus develops. Dirt and dust may obscure the lesions, which often are not noticed until the pigs are washed.

Experimental infection with *M. nanum* (Connole and Baynes 1966) produced lesions that first appeared as pustules or moist brown areas of desquamated tissue 2 cm in diameter. As the lesions extended, fresh pustules were often seen near the periphery. Scales, crusts, and deposits of black material similar to the natural infection appeared. Lesions developed in 2–3 weeks and resolved by 9 weeks. Chronic infections are often seen behind the ears of adult swine and appear as thick, brown crusts that spread over the ear and neck.

Trichophytosis

Trichophyton mentagrophytes is the most common cause of trichophytosis in swine, but *T. rubrum, T. tonsurans,* and *T. verrucosum* can also cause ringworm in swine. Lesions are found on the thorax, flank, and neck, behind the ears, and on the legs. The size and shape of lesions vary; some measure up to 12.5 cm across and are roughly circular. Typical lesions are red or covered by a thin brownish dry crust. The disease tends to be self-limiting and lasts about 10 weeks (McPherson 1956). Similar lesions have been described by Pepin and Austwick (1968) in a herd of Wessex pigs. The same authors reported an outbreak of ringworm in a litter of Large White piglets caused by *T. verrucosum.* Arora et al. (1979) described lesions caused by *T. rubrum* as rough

and reddish and appearing on several sites; 10% of piglets and 4% of sows in a herd were affected.

Cutaneous Candidiasis

Candidiasis in swine is caused by the yeast *Candida albicans* and appears to cause disease when the host's resistance is lowered. The disease has been reported in grower pigs fed garbage and kept in unsanitary conditions. The morbidity was 40%. The lesions on the most severely affected animals consisted of circular areas approximately 2 cm in diameter coated with moist gray exudate. Lesions were found on all limbs and the lateral and ventral surfaces of the abdomen. The skin was thickened, wrinkled, devoid of hair, and hung loose in folds (Reynolds et al. 1968).

Treatment and Control

Treatment, if indicated, consists of removal of the crusts and local application of products such as a weak solution of iodine, Whitfield's ointment, copper sulfate or copper naphthenate, or thibendazole ointment (2–4%) as a suspension in glycerine. Agriculture Bordeaux mixture (an aqueous solution of copper sulfate and unslaked lime) has been used with good results (Blood and Radostits 1989). Systemic treatment employs oral administration of griseofulvin at a dose rate of 1 g/100 kg body weight daily for up to 40 days.

Control is by maintaining good sanitation. Housing can be disinfected with phenolic disinfectant (2.5–5%), sodium hypochlorite (0.25% solution), or a 2.0% formaldehyde and 1.0% caustic soda solution used as a spray.

PARASITIC DISEASES

Sarcoptic Mange (Scabies)

Sarcoptic mange is the most commonly encountered parasitic skin disease of swine. It is one of the most important skin diseases and of major economic importance (Chapter 53). The disease is caused by the mange mite *Sarcoptes scabiei* var. *suis.*

The disease is more likely to be seen where nutrition, management, and hygiene are of a low standard. The disease affects weight gain (McPherson 1960) and efficiency of feed conversion by as much as 10% in pigs between 18 and 68 kg (Cargill and Dobson 1979b).

The first skin lesions appear about 3 weeks after contact with mites as small encrustations around the ears, eyes, and snout that develop into plaques about 5 mm in diameter. The lesions in the ear may regress and disappear in 12–18 weeks (Cargill and Dobson 1979a). Early pruritus is due to the local irritation from the mites establishing themselves in the skin. As the ear lesions regress, focal erythematous papules associated with hypersensitivity occur on the rump, flank, and abdomen (Cargill and Dobson 1979a). Mites are not usually found in these lesions. The hypersensitivity causes further pru-

ritus, which results in excessive rubbing and the liberation of tissue fluids, giving the animal a greasy or shiny appearance. This is followed by coagulation and drying of the serum, sebum, and sweat to form crusts. In more chronic cases (Figure 8.1F) excessive keratinization and proliferation of the connective tissue occur, with the result that the skin becomes thickened and wrinkled (Dobson and Davies 1992). A common sign seen in grower pigs is shaking of the ears and, in some, the development of large hematomas on the inner surface of the ear.

Chronic cases, usually in adults, develop thick gray-colored, loosely attached scales lining the inner surface of the ears, around the neck, and down the lower limbs, especially over the hock joints. Considerable loss of hair is associated with chronic mange.

Sarcoptic mange needs to be differentiated from exudative epidermitis, parakeratosis associated with zinc and fatty-acid deficiency, B group vitamin deficiency, sunburn, pityriasis rosea, and ringworm. Mange may be present with and predispose to exudative epidermitis. Pruritus may be caused by other parasites such as lice, fleas, and mosquitoes. The clinical signs, together with a range of lesions, will be suggestive of mange. When investigating a herd for evidence of the disease, the ears of adult stock should be examined for chronic lesions.

Demonstration of the mites is best done by examination of the crusts inside the ears. The material can be placed on black paper for a few minutes and then gently tipped or blown off leaving the mites, which will have adhered to the paper. They can be easily examined with a magnifying glass (Brackenridge 1958).

Another method is to place the scales or material from skin scrapings in a 10% solution of sodium or potassium hydroxide for 24 hours, and then concentrate the sediment by centrifugation and examine it for the mites on a glass slide under low power of a microscope. Skin scrapings obtained with a scalpel blade placed on a glass slide and mixed with mineral oil can also be examined in the same way. The movement of live mites allows easy detection.

Sarcoptic mange has been treated with varying success by many remedies and acaricides used in the form of sprays, dusting powders, and pour-ons, in feed medication, and by injection. Insecticides used as sprays or washes (dips) include amitraz, coumaphos, diazinon, lindane, malathion, toxaphene, and trichlorfon. Products that have a systemic action have proved to be more effective, such as the pour-on phosmet and oral or injectable administration of avomectins, such as doramectin, a long-acting endoectocide for use in swine (Cargill et al. 1996). These products are more likely to be successful in eradication of sarcoptic mange, although results have been variable.

For control, monthly treatment of all pigs is effective (Cargill 1981); however, programs are best aimed at sow treatment just before farrowing, followed by weaning

into mite-free accommodations (Cargill and Dobson 1979b). Complete elimination of sarcoptic mange in pig populations can be achieved by the use of hysterectomy-derived piglets and maintained by strict biosecurity. Herds have been kept free of sarcoptic mange for over 20 years in my experience.

Demodectic Mange (Follicular Mange)

Demodectic mange is relatively uncommon and of little economic importance in swine. Clinical signs are seen when pigs are in a poor or debilitated condition. The disease is caused by *Demodex phylloides*, which lives in the hair follicles or sebaceous glands of the skin.

The mites usually invade the soft skin of the snout and around the eyes but can spread over the entire body. Infection is not uncommon on the abdomen between the legs. Lesions start as small red spots which become scaly with a nodular appearance. The nodules contain white caseous material and many mites. Mites can be found on skin scrapings from around the eyes in pigs showing no clinical signs. Treatment is usually not successful and severely affected animals should be culled.

Lice

The pig louse, *Haematopinus suis*, which affects pigs only, causes severe irritation resulting in continual scratching and rubbing against objects.

Lice are easily found around the neck, base of the ears, inner ears, and inside the legs and flank, and the white eggs can also be seen on the bristles, especially in colored pigs. The blood feeding causes considerable irritation; the resultant scratching and rubbing against objects damages the skin, which becomes lacerated and bleeds. Lice tend to congregate around the areas where skin damage has taken place. The continual irritation results in loss of body weight and reduces weight gains. Lice may spread the swine pox virus and erysipelas.

Lice can be controlled by spraying with products such as coumaphos, diazinon, malathion, lindane, or ronnel. Ivermectin in feed or injected also controls lice.

Fleas, Mosquitoes, and Flies

Swine may be affected by fleas (*Ctenocephalides canis*, *C. felis*, *Pulex irritans*, and *Echinophaga gallinaceae*), mosquitoes (*Aedes* spp.), flies (*Musca domestica*, *Stomoxys calcitrans*), and screwworm flies (*Callitroga* spp.).

Clinical signs can include varying degrees of rubbing, scratching resulting in alopecia, excoriations, and bleeding from the skin and circumscribed, raised, rounded (wheal) lesions or edema associated with urticarial reactions.

ENVIRONMENTAL DISEASES

Sunburn

Sunburn is frequently seen in white pigs managed under open-range conditions without adequate protection

from sunlight. It is caused by the direct effect of ultraviolet rays upon the skin.

Young pigs and pigs not previously exposed to sunlight are often seriously affected. Erythema occurs within a few hours of exposure and develops most commonly on the back and behind the ears. Edema can develop and affected areas become warm and painful to the touch. Severely affected pigs walk very carefully and are occasionally seen to experience a sudden bout of muscular twitching and jump into the air. The skin becomes dry, scales develop, and the skin peels. In young pigs the tail and ears become necrotic and slough.

A simple and effective treatment is to cover the skin with a bland oil, for example, vegetable oil or light mineral oil. Animals should be removed from direct sunlight and adequate shade provided for prevention.

Photosensitization

Photosensitization is a condition seen in extensive, free-range-managed swine exposed to photodynamic agents and sunlight. Photosensitivity (hypersensitivity to light) results from the ingestion of photodynamic agents such as hypericin found in Saint-John's-wort (*Hypericum perforatum*) and fagopyrin found in buckwheat (*Fagopyrium esculentum* and *Polygonum fagopyrum*). Other plants, including rape (*Brassica* sp.), lucerne (*Medicago sativa*), and *Trifolium* sp., cause photosensitization of unknown etiology. Other substances causing photosensitization in swine are phenothiazine, tetracyclines, sulfonamides (Amstutz 1975), and possibly aphids (McClymont and Wynne 1955).

Lesions are seen in white-skinned breeds and on areas most directly exposed to the sunlight. The severity of the condition depends on the concentration of the photodynamic agent and the length of exposure to light (Jubb and Kennedy 1970).

Erythema and edema develop and serum may exude from the skin and become dry and matted in the hair. Pain causes swine to walk carefully, and severely affected animals may suddenly drop into sternal recumbency and immediately rise again or stagger sideways (Hungerford 1990). The ears become thickened; congestion of the conjunctiva may occur with matting together of the eyelids (Amstutz 1975). Skin becomes dry, hard, and fissured and extremely pruritic. Areas of skin may become necrotic and peel off in strips. Ears and tail may slough.

Sunburn, erysipelas, and sarcoptic mange have to be included in a differential diagnosis. The typical lesions confined to unpigmented or white areas of skin exposed to sunlight and a history of ingestion of a photodynamic agent or plants known to cause photosensitization will suggest a diagnosis.

Affected animals should be placed in darkened housing. Parenteral use of corticosteroids or antihistamines may be of value. Local application of antibiotic creams may also be useful. Control is by preventing access to photodynamic agents, grazing only at night, or keeping pigs indoors.

Skin Necrosis

In piglets, skin necrosis most frequently affects the knees, fetlocks, hocks, elbows, teats, coronets, and soles of the feet. Necrosis of the hocks, vulva, and tail is common in piglets with splayleg. In sows, skin necrosis is common on the shoulder, over the hip region, and on the side of the jaw.

In piglets, necrosis starts as small abraded areas often developing 12–24 hours after birth and reaching maximum severity in 7 days (Penny et al. 1971). Lesions are due to trauma from hard abrasive floors, especially rough concrete in farrowing crates. The alkaline pH of new concrete floors and slats may also affect older pigs. Necrosis of the soles of the feet can be caused by the abrasive surface of rusting wire mesh or metal floors (Figure 8.2A).

Teat necrosis is best looked for at 3 days of age (Stevens 1984). The lesions develop as blackish brown scales or crusts that easily peel off, leaving a new, fresh wound. Teat necrosis usually affects the pectoral (first four) teats, resulting in blind, nonfunctional teats. The highest incidence was found in pigs on heated concrete floors, with decreasing incidence on expanded-metal floors, rubber mats, and plastic-coated wire mesh. A genetic basis for teat necrosis associated with sire lines was demonstrated, but nongenetic causes were more common than genetic causes (Stevens 1984). Females are most commonly affected.

Necrosis of the knees (carpus) is very common in the weaker smaller piglets in large litters and where sows have problems of milk letdown or mastitis. Necrosis of the tail starts at the base, usually encircling the whole tail, which becomes black and may slough. Ear necrosis may be due to fighting or infections.

Skin necrosis in sows is due to a combination of pressure from lying for long periods on hard floors (both concrete and mesh) and poor body condition associated with rapid weight loss during lactation or old age. The condition can occur in young sows after their first litter.

Local application of antibiotic or antiseptic ointments may be of value. Aerosol sprays for wound treatment give good results. Open wounds may require parenteral antibiotic therapy. Control should be aimed at avoiding rough, wet concrete floors and rusting mesh floors and providing bedding or rubber mats in the creep area of farrowing crates. Spreading mash feed over the floors of new pens will help prevent necrosis in young grower pigs. Reducing the incidence of splayleg by selection should be considered.

Stevens (1984) stated that 80% of teat necrosis can be eliminated by replacing concrete floors with raised plastic-coated decks. Resin-reinforced plastic skin has been used to protect teats immediately after birth

(Muirhead 1978). Skin necrosis of sows is best prevented by maintaining good body condition through appropriate feeding before and during lactation, using plastic-coated floors in farrowing crates, and encouraging sows to stand and exercise frequently.

Callosities

Hypertrophy with fibrosis of the skin over joints and bony prominences results in callus formation. Calluses are seen mainly over the fetlocks, elbows, hocks, and tuber ischii. They become very large and hard and contain fluid, which may become infected and result in subcutaneous abscesses. Pigs with leg weakness, foot lesions, or muscular weakness or that spend a lot of time lying down due to illness frequently develop callosities or bursitis.

NUTRITIONAL DISEASES

Swine Parakeratosis

Scott (1988) describes parakeratosis as a nutrition-related metabolic disorder of growing pigs characterized by a generalized nonpruritic, crusting dermatosis. The cause of this condition is now considered to be complex, involving deficiencies of zinc and essential fatty acids or high levels of calcium, phytates, and other chelating agents that affect zinc absorption. Gastrointestinal diseases may also predispose to a more severe zinc deficiency and parakeratosis.

Early lesions (macules and papules) develop on the ventral surface of the abdomen, medial thighs, and distal parts of the legs. The lesions rapidly become covered with scales and then hard dry crusts (Figure 8.2B). The typical keratinous lesions are characterized by crusts and deep fissures. The surface of the skin may be dry and rough, but moist brownish sebum, dirt, and debris accumulate in the fissures. In severe cases animals will have reduced growth rates and reduced appetite, diarrhea, and in some cases vomiting. Testicular development may be affected. Mortalities are rare.

The condition has to be differentiated from chronic sarcoptic mange, exudative epidermitis, and deficiencies of the B group vitamins and iodine.

A history of feeding a diet likely to be deficient in zinc or essential fatty acids or including factors that may interfere with zinc absorption, together with the characteristic lesions and their distribution, will suggest parakeratosis.

Skin biopsy for histopathology will be of value. Serum alkaline phosphatase and zinc levels may be decreased. Response to supplementary zinc and essential fatty acids will support a diagnosis.

Treatment and prevention involve feeding a diet that provides zinc in the form of a zinc salt (zinc sulfate or carbonate) at the rate of 0.02%, or 2 kg per tonne of feed. Fats should provide 1% of the total ration. The calcium levels should not exceed 1% of the ration.

Other Nutritional Deficiencies

Skin changes can result from a number of nutritional deficiencies and excesses. Typical changes are poor hair coat, alopecia, parakeratosis, and eczematous dermatitis.

Essential fatty-acid deficiencies produce a dull, dry hair coat and scaly, dandrufflike dermatitis. Brownish exudate appears on the ears and axillary spaces and under the flanks. This can be followed by necrotic lesions and skin eruptions with loss of hair.

Iodine deficiency is seen as a congenital defect in piglets born to sows fed iodine-deficient diets. Piglets are born full-term but hairless. They have thickened edematous skin over the head, neck, and shoulders.

Riboflavin (vitamin B_2) deficiency in swine produces a dermatitis seen as scales and ulcers with some loss of hair and heavy sebaceous exudate. Conjunctivitis, swollen eyelids, and cataracts may occur. Infertility, weak pigs, and lactation failure are seen in sows.

Pantothenic acid deficiency results in signs of poor growth rate, coughing, diarrhea, and loss of hair. Dermatitis develops as dark brown exudate around the eyes. Incoordination, seen as "goose-stepping," is also characteristic.

Biotin deficiency produces skin changes characterized by dermatitis; dry rough skin with scales, crusts, and brown exudate; generalized alopecia; and ulcerations (Cunha 1977). Lesions of the feet include bruising, erosions, and ulceration of the soles and cracking of the outer wall of the claw (Brooks et al. 1977; Penny et al. 1980).

Vitamin A, C, and E deficiencies have been associated with scurfy (scales) skin lesions. Vitamin E and selenium deficiencies have also been associated with ear necrosis.

CONGENITAL AND HEREDITARY DISEASES

Pityriasis Rosea (Pustular Psoriaform Dermatitis)

Pityriasis rosea in swine is the name used to describe a pustular dermatitis that takes on the appearance of epidermal collarettes, or rings, seen only in young swine, mainly on the ventral abdomen and inner thighs. The disease is self-limiting. The condition, however, does not resemble pityriasis rosea in humans clinically or pathologically; therefore, *pustular psoriaform dermatitis* may be a more suitable name (Scott 1988).

Although the actual cause is unknown, the condition appears to be inherited. Swine that have had the condition are more likely to produce affected progeny. The incidence may be higher in Landrace swine. Attempts to transmit the disease or demonstrate an infectious agent have failed. The condition is seen in piglets derived by hysterectomy and reared in isolation.

The disease is seen in young pigs 3–14 weeks of age. Entire litters or only a few piglets in a litter may be affected. The disease begins as small erythematous

papules on the skin of the abdomen and inner thighs. The papules are raised with a central crater and rapidly expand to produce a ring, or collarette, with a raised bright red periphery behind which are scales (Figure 8.2C). As the ring expands, the central area returns to normal. The rings coalesce as they expand to produce mosaic patterns. The hair is usually not lost and little pruritus is seen. The condition usually lasts about 4 weeks, regressing slowly and leaving normal skin as lesions heal.

The extent and severity of the lesions appear to increase when pigs are reared in weaner cages where stocking densities are high with high temperatures and high humidity. Lesions may become infected with bacteria—for example, *S. hyicus*—and resemble an exudative dermatitis.

The condition has to be differentiated from ringworm, dermatosis vegetans, and swine pox. Failure to isolate fungi or microorganisms will help confirm a diagnosis.

Skin biopsy will show psoriaform epidermal hyperplasia and superficial perivascular dermatitis. There is mild to moderate mucinous degeneration of the superficial dermis, and the predominant inflammatory cells are eosinophils and neutrophils. Parakeratotic hyperkeratosis is usually prominent (Scott 1988).

Treatment does not appear to affect the course of the disease. Good hygiene will reduce the chance of secondary infections, whereas overstocking with high humidity and high temperatures appears to increase the incidence. It may be best to cull breeding stock known to produce progeny that develop the condition from the breeding herd.

Dermatosis Vegetans

Dermatosis vegetans is a hereditary and often congenital disease of swine due to a semilethal autosomal recessive factor believed to have originated in the Danish Landrace breed (Done et al. 1967). The condition is seen as an erythematous maculopapular dermatitis with lesions on the coronary band and hoof together with pneumonia.

The main features of the condition are skin lesions, abnormalities of the feet, poor growth, and respiratory dysfunction. The skin lesions may be present at birth or, more commonly, develop within 2–3 weeks of birth. They first develop on the abdomen and inside the thighs as small (0.5–2.0 cm in diameter) raised pink swellings that enlarge rapidly. The lesions spread over the flanks and back of the pigs and become covered with yellowish brown, brittle, papillomatous crusts that are easily removed, leaving a pink granular surface. The lesions become very thick with a hard, horny surface that develops cracks and fissures, giving a characteristic papillomatous appearance. Swine may die after 5–8 weeks, but some will survive and the skin lesions regress.

Lesions of the hoof are usually present at birth and consist of marked swelling and erythema over the coronary band of both the main and the accessory digits and are covered with a yellowish brown greasy exudate. The walls of the hooves are thickened with ridges and furrows parallel to the coronary band. The horn becomes discolored and blackened.

Respiratory dysfunction is due to giant-cell pneumonitis. Respiratory signs of interstitial pneumonia or bronchopneumonia precede death, usually following a course of 4–6 weeks. However, some pigs may survive for 2–3 months but become weak and emaciated. On rare occasions affected pigs have reached maturity and bred.

The condition has to be differentiated from pityriasis rosea, chronic exudative epidermitis, and vitamin deficiencies. The clinical appearance of the skin and hoof lesions seen in young pigs 2–3 weeks of age is, however, characteristic. The very thick papillomatous crusts of the skin lesions are also typical and together with respiratory distress will suggest a diagnosis of dermatosis vegetans.

Skin biopsy reveals intraepidermal pustular dermatitis and microabscesses containing eosinophils and neutrophils, with parakeratotic hyperkeratosis. Older lesions show hyperplastic superficial perivascular dermatitis with multinucleated giant cells in the dermis (Percy and Hulland 1967, 1968). Histopathology of the lungs will help a diagnosis. Done et al. (1967) recommend that lungs should be fixed by filling with, as well as immersing in, 10% neutral formalin, and several samples from each lung should be examined.

There is no treatment for the condition, and prevention is aimed at detection and removal of breeding stock known to have produced affected progeny.

Epitheliogenesis Imperfecta (Aplasia Cutis)

Epitheliogenesis imperfecta is an inherited congenital condition of both white and colored swine and is caused by a simple autosomal recessive trait thought to result in a primary failure of embryonic ectodermal differentiation.

The lesions appear as clearly demarcated discontinuities of the squamous epithelium of varying sizes and shapes but usually on the back, loins, or limbs (Figure 8.2D). The condition may be seen in individual piglets or with a familial incidence in litters. The defect may also affect the dorsal and anterior ventral surface of the tongue with concurrent hydroureter and hydronephrosis (Jubb and Kennedy 1970). Lesions develop as large ulcers and frequently become infected; they may fail to heal or cause septicemia, which may lead to death.

Congenital Swine Pox

Borst et al. (1990) and Thibault et al. (1998a) reported the birth of pigs with pox lesions over the entire body to unrelated sows on different farms. Only one or two pigs in each litter were affected. At the time of the births, no other pigs on the farms had pox lesions, and histological and electron microscopic examination confirmed

swine pox in the newborn pigs with lesions. The infections were generally fatal.

NEOPLASTIC DISEASES

Tumors are reported relatively rarely in swine, probably because the majority are slaughtered at 6–8 months of age or around 4–5 years of age for breeding stock. However, a variety of neoplastic conditions have been reported, including lymphangioma, rhabdomyoma, papilloma, sweat gland adenoma, fibroma, and hemangioma.

Melanomas, the result of proliferation of melanoblasts, have been reported most commonly in the Duroc breed and are often found at birth. The tumors are frequently seen on the flank region and have been described as being 1–4 cm in diameter, raised with an irregular black shiny surface. Metastases have been seen in lymph nodes, kidney, liver, lung, heart, brain, and skeletal muscle.

Rhabdomyosarcomas have been reported as solitary or multiple tumors on piglets less than 1 week old in at least 25 piglets in a short period of time in one herd in the Netherlands, indicating a common, possibly genetic cause (Voss et al. 1993).

Small fibrous polyps or wartlike lesions have been seen on sows, especially around the neck, along the back, and on the ears. These lesions frequently bleed and can easily be removed under local anesthetic.

MISCELLANEOUS

Porcine Dermatitis and Nephropathy Syndrome (PDNS)

Porcine Dermatitis and Nephropathy Syndrome (PDNS) has relatively recently been reported in pigs (Smith et al. 1993; White and Higgins 1993; Cameron 1995; Hélie et al. 1995) and is characterized by multifocal skin lesions, weight loss, edema of the limbs, vasculitis, and glomerulonephritis.

The cause is unknown, but histopathological and immunological findings suggest the pathogenesis involves an immune-complex disorder (antibody-antigen complex deposition) possibly due to an infectious agent. Thibault et al. (1998b) suggested that porcine reproductive and respiratory syndrome virus (PRRSV) infection may play a role in the pathogenesis of the disease, because PRRSV antigens were detected by immunochemistry in macrophages located around vessels of skin and kidney tissue examined in acute and chronic cases. Wellenberg et al. (2004) considered that porcine circovirus type 2 (PCV2) was likely to be the primary agent in the development of PDNS. They reported excessively high PCV2 antibody levels in a case-control field study of PDNS and hypothesized that PCV2 plays an important clinical and immuno-pathological role in the development of PDNS. They suggested that the excessive high levels of PCV2 antibodies trigger the development of fibrinous deposits (immune complexes) in, for example, kidneys that can initiate an inflammatory process when deposited within the vascular or glomerular capillary wall. They also found an epidemiological association in herds that had experienced postweaning multisystemic wasting syndrome (PMWS) also caused by PCV2. However, their study did not indicate that PRRSV infection was a primary cause of PDNS, nor did they consider *Pasteurella multocida* a primary agent as has previously been suggested (Sierra et al. 1997; Thompson et al. 2001).

Seen mainly in growing swine, 20–65 kg liveweight, the most obvious clinical signs are skin lesions and a rapid loss in body weight with concurrent depression. The skin lesions range from large areas of erythema, macules, and hemorrhagic papules to dark brown to black thick crusts of necrosis on the ears, face, lower limbs, hindquarters, scrotum in boars, and vulva of sows (Figures 8.2E, 8.2F).

Other clinical signs include subcutaneous edema along the ventral abdominal wall and limbs. The lower parts of the legs are obviously swollen, and swelling of the joints is not uncommon. An outbreak in a large specific pathogen free (SPF) herd soon after it had been established by medicated early weaning was investigated. Typical cases were seen in at least 20 growing pigs over a 3-month period. Most pigs had to be destroyed or died within a few weeks (Cameron, unpublished data).

The condition could be confused with erysipelas, with skin necrosis, or, in its early stages, with sarcoptic mange. Of serious concern is that the clinical signs and lesions closely resemble those of classical swine fever and African swine fever. The autopsy findings will reveal enlarged, pale, spotted (petechiation) kidneys, fluid in the body cavities, subcutaneous fluid, and excessive synovial fluid in the joints. Gastric ulceration and hemorrhage are commonly seen. The histopathology of the kidney lesions is consistent with a diffuse necrotizing and proliferating glomerulonephritis. Glomerular spaces contain precipitated protein, necrotic cells (particularly polymorphs), and red blood cells. Secondary renal changes include formation of hyalin/granular casts and distended tubules. Necrotizing vasculitis of arterioles in the dermis and subcutis is associated with skin lesions. Small-vessel vasculitis can be detected in other organs, including lymph nodes, spleen, stomach, liver, bladder, brain, and joints (Higgins 1993). A significant increase in plasma urea and creatinine with a decrease in sodium and chloride and very high levels of protein and red and white blood cells in urine are characteristic. Because the actual causative agent is unknown, control is difficult.

9 Diseases of the Urinary System

Richard Drolet and Scott A. Dee

ANATOMY

The kidneys of swine are bean-shaped, generally smooth on the surface, and brown. They are elongated, flattened dorsoventrally, and at least twice as long as wide (Figure 9.1). At the middle of the medial border of each of them is an indentation, the hilus of the kidney, where the vessels, nerves, and ureter communicate with the organ. The kidneys are located ventrally to the psoas muscles at the level of the first four lumbar vertebrae. Their relative location is slightly asymmetrical, but contrary to what is observed in many other species, the left kidney of most individuals is often situated cranially to the right one; the extremity of the cranial pole of the former may reach the last intercostal space. In the adult, the ratio of the combined weight of the kidneys to that of the body is about 0.50–0.66% (Sisson 1975).

The kidneys are enveloped by a rather thin fibrous capsule that can be easily peeled off. In a kidney section, the relative surface occupied by the cortex and the medulla is readily apparent (Figure 9.2). Pigs have multipyramidal or multilobar kidneys but without the external lobation typically found in the bovine species. The medullary portion of each lobe is called a pyramid; some are simple, whereas others are compound, that is, formed by the fusion of two or more primitively separate pyramids. The pale apical portion of a pyramid, called the papilla, projects into the renal pelvis or its ramifications; these latter are referred to as calyces (refer to Figure 9.2). Papillae of simple pyramids are generally narrow and conical, whereas those of compound pyramids, often located in the area of the renal poles, are broad and flattened. There are 8–12 papillae per kidney. Collecting ducts of the kidneys have their openings at the tips of the papillae.

The ureters, which are continuous with the renal pelvis, leave the kidneys in a sharp caudal curve. They ultimately reach the dorsolateral sides of the bladder neck area, penetrating its muscular coat at almost right angles, and pass obliquely through the submucosa, raising the mucosa slightly before ending at the ureteric orifices. In newborn piglets, the length of the portion of the ureter running beneath the bladder mucosa is about 5 mm, whereas it reaches a mean length of about 35 mm in the adult (Carr et al. 1990). The intravesical portion of the ureters acts as a valve that prevents vesico-ureteral reflux of urine.

The urinary bladder of the pig is large and has a long neck. When full, it lies well down into the abdominal cavity. The bladder is supported by one median (ventrally located) and two lateral ligaments. The urethra of the adult female is about 7–8 cm long and its external ostium is located ventrally, at the junction of the vagina and vestibule; beneath it is a small depression, the suburethral diverticulum. In the male, the urethra opens into a slitlike structure at the tip of the penis.

PHYSIOLOGY

Histophysiology

The kidney is involved in many vital functions: the elimination of waste products from the body, the conservation of water, and the regulation of the acid-base balance and electrolyte composition. In addition, it has an endocrine function: it produces a variety of hormones, including erythropoietin, renin, prostaglandins, and vitamin D_3.

Most of these functions are achieved by a multitude of microscopic anatomical structures called nephrons, which, all together, form the bulk of the renal parenchyma. The kidney of a pig contains well over one million nephrons. Newborn piglets have immature kidneys, and nephrogenesis continues during the first 3 months of life (Friis 1980). The nephron, the functional unit of the kidney, consists of a renal corpuscle, proximal tubule, loop of Henle, and distal tubule. The renal corpuscle comprises the glomerulus, a tuft of arterial capillaries, and Bowman's capsule. The first mechanism used to accomplish renal function is glomerular filtra-
9.1. *Kidneys of pig in situ, ventral view. 1, left kidney; 2, vena cava; 3, aorta; 4, renal vein; 5, renal artery; 6, ureter; 7, adrenal gland; 8, renal lymph node; 9, psoas major; 10, urinary bladder.*

tion. The volume of plasma filtered depends essentially on the renal perfusion, blood pressure, and integrity of the glomerulus itself. The glomerular filtrate is an ultra-filtrate of blood plasma that contains water, glucose, salts, ions, amino acids, and small amounts of protein of low molecular weight. The glomerular filtrate entering the tubular components of the nephron is profoundly modified by various processes of absorption and secre-

tion that are, at least in part, governed by the needs of the animal. A significant part of these changes takes place in the proximal tubule, a segment of the nephron lined by well-developed and metabolically very active epithelial cells. At that site, for example, 100% of the filtered glucose (in a normoglycemic animal) is reabsorbed by an active transport mechanism, and many other substances, such as water, sodium, amino acids, albumin,

and bicarbonate, are also reabsorbed in significant amounts (Banks 1986). Pigs are distinctive in that they reabsorb very few urates from glomerular filtrate compared to most other species. Tubular secretion of various endogenous and exogenous compounds complements the clearance of substances that are filtered at the glomerulus. The filtrate finally enters the collecting ducts, where it may be further concentrated. Under normal conditions, urine expelled into the pelvis is not further modified as it travels through the rest of the lower urinary tract, the mucosa of which is lined with a transitional epithelium often referred to as *urothelium*.

Urine

The volume of urine produced daily depends on several variables, including diet, fluid intake, ambient temperature and humidity, and the size and weight of the animal. Accurate data on the normal ranges of the amount of urine excreted per day in pigs are limited. Salmon-Legagneur et al. (1973) reported a mean urinary output of 9 L and 5.3 L/day in gestating and lactating sows, respectively. Other factors, such as the water distribution system used, may also affect the production of urine if they influence drinking behavior.

The mean specific gravity of urine in adult swine is about 1.020 (plasma >1.010), one of the lowest found in domestic animals (Ruckebusch et al. 1991). Young animals have even lower values. Specific gravity of urine is usually inversely related to urine volume. Urinary pH is usually between 5.5 and 7.5. It is influenced by the metabolism and the composition of the feed; starvation or a high protein intake lowers urinary pH. Urinary infection with urea-splitting bacteria (e.g., *Actinobaculum suis*, formerly *Actinomyces suis*) may result in a significant alkalinization of urine.

As mentioned (see previous section), the small amount of protein that passes through the glomeruli is, for the most part, reabsorbed by the proximal tubules, so normally no protein is detected in urine by usual methods. The presence of proteinuria may be of diagnostic significance and must be interpreted in conjunction with the specific gravity. Significant proteinuria is associated with various renal diseases such as glomerulonephritis (increased permeability to protein), tubular necrosis (decreased reabsorption of protein), and pyelonephritis (inflammation), and with lower urinary tract inflammation. The presence of protein in the urine is, however, not always pathologic, because transient physiological or functional proteinuria also occurs in some instances. Proteinuria is observed in baby pigs in their first few days of life, their glomeruli being permeable to colostral protein found in high levels in the blood. Transient proteinuria may also occur following excessive physical activity (e.g., transport) or intense stress or when excessive amounts of protein are ingested.

The color of urine is usually yellow to amber depending on the concentration of urochromes. Abnormal col-oration of urine is observed with some underlying urinary tract diseases. Urine sediment examination is very informative because it may reveal findings of diagnostic significance (e.g., in the case of cystitis-pyelonephritis).

Impaired Renal Function

In some pathological situations, renal function is impaired so much that renal failure ensues. Renal failure may have a prerenal (e.g., any condition that reduces renal blood flow), postrenal (e.g., obstructive uropathy), or primary renal origin (e.g., extensive renal parenchymal disease). Renal failure can cause metabolic acidosis, electrolytic imbalances, and intravascular accumulations of various metabolic waste products, including blood urea nitrogen (BUN) and creatinine. Determination of both BUN and serum creatinine concentration may be used to assess the renal function. The serum creatinine concentration is a more accurate index of the glomerular filtration rate than is the BUN because it is less dependent on nonrenal factors. Concentrations of BUN may rise in animals with high dietary protein intake or in any conditions resulting in increased protein catabolism. Friendship et al. (1984) reported normal-range values for BUN and serum creatinine in weaned and feeder pigs, gilts, and sows. In sows, for example, the mean BUN concentration has been reported as 5.3 mmol/L (n = 102) (Friendship et al. 1984) and 5.0 mmol/L (n = 120) (McLaughlin and McLaughlin 1987), whereas the mean serum creatinine concentrations reported in the same two studies are 160 µmol/L and 186 µmol/L, respectively.

DEVELOPMENTAL ANOMALIES

Anomalies of development occur in all body systems, and the urinary tract is no exception. These anomalies may involve the kidneys as well as the lower urinary tract. Many of these conditions in swine are relatively rare and of little economic significance. Few of these malformations in pigs are common, and only rarely are they associated with clinical signs. In some instances, developmental anomalies have been shown to be inherited.

Malformations of the Kidneys

Most of the well-characterized renal anomalies of development occurring in domestic animals have also been documented in pigs. Depressions of the external surface and partial persistence of fetal lobation of the kidneys have been reported to be relatively common in Norwegian slaughtered pigs (Jansen and Nordstoga 1992). Unilateral renal agenesis (aplasia) occurs sporadically in pigs and is relatively common compared to other domestic animals (Höfliger 1971). Bilateral renal agenesis is obviously incompatible with life and would be encountered in the fetus or stillborn piglet. Cases of bilateral renal agenesis and renal hypoplasia have been described in pigs and linked to a genetic cause (Cordes and Dodd

1965; Mason and Cooper 1985). Malposition of the kidneys (renal ectopia) is not rare and is often characterized by caudal displacement of one kidney, often the left, to the pelvic area (Sisson 1975). Duplication of one kidney has been observed on a number of occasions in pigs (Nieberle and Cohrs 1967). Horseshoe kidney, rarely observed in swine, is a condition in which the kidneys have fused at either the cranial or the caudal poles, resulting in a horseshoe-shaped organ (Nieberle and Cohrs 1967). Renal dysplasia, a disorganized development of renal parenchyma due to anomalous differentiation, also is relatively rare (Maxie 1993).

Congenital renal cysts are not infrequently seen in the kidneys of various species but are more common in swine. The presence of one or a few cysts in the kidney, often referred to as simple renal cysts, is a common incidental finding at abattoirs, and the affected organs are generally condemned. These cystic cavities, filled with serous fluid, vary from a few millimeters in diameter to larger than the organ itself. They are commonly found in the cortex and often protrude from the surface of the organ, where they may appear translucent or opaque depending on the amount of fibrous connective tissue present in their wall (Figure 9.3). Histologically, these cysts are lined with a layer of tubular epithelial cells surrounded by a fibrous capsule.

Polycystic kidney disease represents another form of congenital cysts, occurring far less frequently. This form is characterized by the presence of numerous and generally smaller cysts that occupy a significant proportion of the renal parenchyma. Cystic structures may be found in the liver (cystic bile ducts) as well. Affected piglets usually die from renal failure during the neonatal period (Webster and Summers 1978).

The distinction between simple renal cysts and polycystic kidney disease is not always well demarcated. Wells et al. (1980) reported a prevalence of renal cysts of nearly 50% from a single herd that experienced an abnormally high rate of kidney condemnations at the abattoir. Affected kidneys had variable numbers and

sizes of cysts, ranging from one extreme to the other. Further investigation showed that affected animals were the progeny of a Landrace boar. The disease was found to be inherited as an autosomal dominant trait, the number of cysts being determined by polygenic inheritance (Wijeratne and Wells 1980).

Malformations of the Lower Urinary Tract

Developmental anomalies of the lower urinary tract appear to be rare in swine, and like those found in the kidneys, their true prevalence is unknown. Cases of duplication of the ureter (Benko 1969), persistent urachus (Weaver 1966), and congenital ureteral occlusion (Nieberle and Cohrs 1967) have been reported in pigs.

CIRCULATORY DISTURBANCES

Circulatory disturbances may occur in the urinary tract as well as in any other tissues of the body. Some of these disturbances of the circulation produce lesions that may be of diagnostic significance on postmortem inspection.

Hemorrhage

Hemorrhages, in the form of widespread petechiae or less commonly ecchymoses, may be found in any part of the kidney or lower urinary tract in various septicemic illnesses (Figure 9.4). Bacterial infections commonly associated with these lesions include septicemia due to salmonellae, streptococci, *Erysipelothrix rhusiopathiae*, and *Actinobacillus* spp. These lesions are often seen in acute cases of hog cholera and African swine fever and in other viremic diseases such as cytomegalovirus infection (Orr et al. 1988). Petechiation of the renal cortex is also observed occasionally in acute glomerulonephritis, in some acute intoxications, and in electrocuted animals.

Larger intrarenal or subcapsular hemorrhages are usually caused by trauma, necrosis, or clotting defect, including poisoning by anticoagulant rodenticides. They may also occur in some cases of disseminated intravascular coagulation. Widespread hemorrhages in al-

9.3. *Congenital renal cysts in slaughtered sows.*

most all body systems, including the urinary tract, are a striking pathologic feature in suckling piglets with isoimmune thrombocytopenic purpura due to passively transferred antiplatelet antibody from the dam's colostrum (Andersen and Nielsen 1973; Dimmock et al. 1982). In this relatively common disease, affected piglets appear normal at birth but eventually die between 1 and 3 weeks of age from hemorrhagic diathesis.

Infarction

Renal infarcts, infrequently found in the kidneys of swine, are localized areas of ischemic coagulative necrosis produced by the occlusion of the renal artery or one of its tributaries. The localization and size of the infarct reflect the area vascularized normally by the involved blood vessel. The occlusion is usually due to thrombosis or to aseptic emboli (the consequences of septic emboli are discussed under embolic nephritis). In some instances infarction of the renal parenchyma is primarily associated with renal vasculitis (Jansen and Nordstoga 1992), including polyarteritis nodosa (Nieberle and Cohrs 1967).

Bilateral renal cortical necrosis is seen on rare occasions in pigs and is considered to be the result of an infarct of a major part of the cortex of both kidneys (Häni and Indermühle 1980). The reaction is characterized by disseminated intravascular coagulation with a marked tropism for the small arterial blood vessels of the renal cortex. The etiopathogenesis of these lesions remains unclear but the condition has been associated with septicemia, endotoxemia, and hemorrhagic shock due to bleeding gastric ulcers.

GLOMERULAR DISEASES

Renal diseases that involve primarily the glomeruli include amyloidosis and glomerulonephritis. Renal amyloidosis has been rarely reported in pigs (Jakob 1971; Maxie 1993). Glomerulonephritis represents an important category of renal diseases in animals and in recent years this condition has been recognized with increasing frequency in swine.

Glomerulonephritis

Inflammatory changes in renal glomeruli may take place via a number of mechanisms, including immunologic, thrombotic, toxic, and as yet uncharacterized mechanisms. Most cases of glomerulonephritis (GN) in humans and animals are thought to be immune-mediated.

The main types of glomerular immunologic injury recognized are trapping of circulating immune complexes (antigen-antibody complexes), in situ immune complex formation, activation of the alternate pathway of complement, and cell-mediated processes (Spargo and Taylor 1988). Because immunoglobulins and complement components are frequently found in inflamed glomeruli, antibody-mediated injury has received the most attention. In veterinary medicine, the commonly used classification for the various morphologic types of immune-mediated GN are membranous, proliferative, and membranoproliferative.

Although the pathogenesis of GN is now reasonably well understood, knowledge of the etiology or triggering event is still unknown in most cases (idiopathic immune-mediated GN). Theoretically GN may be triggered by a variety of factors including drugs, chemicals, food allergens, endogenous antigens, and infectious agents (Drolet et al. 1999).

GN is not often diagnosed in swine but does occur occasionally as a sporadic event (Nieberle and Cohrs 1967; Slauson and Lewis 1979; Maxie 1993; Bourgault and Drolet 1995). It has also been reported as a sequel to chronic infectious diseases such as hog cholera, African swine fever (Maurer et al. 1958; Cheville et al. 1970; Martin-Fernandez et al. 1991; Hervas et al. 1996; Choi and Chae 2003), systemic cytomegalovirus infection (Yoshikawa et al. 1988), and group A streptococcal abscesses (Morales and Guzman 1976). In these cases, the resulting GN appears to be caused by the presence of glomerular immune complexes in which the antigen is related to the agent responsible for the underlying disease (Slauson and Lewis 1979). Nutritionally induced GN has also been reported on a few occasions in pigs. Ingestion of a protein-rich by-product (Elling 1979) and ingestion of "smut fungus" contained in the feedstuff (Müller 1977) have been incriminated.

An inherited renal disease, classified morphologically as membranoproliferative GN type II, has been described in Yorkshire piglets from Norway (Jansen 1993). This familial disease is not associated with the presence of intraglomerular immune complexes but rather is caused by an autosomal recessive deficiency of the complement inhibitory protein "factor H" (Hogasen et al. 1995; Jansen et al. 1995). Deficiency of factor H ultimately provokes activation of the alternate pathway of complement, with subsequent massive deposits of complement in renal glomeruli. This disease in Norwegian Yorkshire pigs represents a promising animal model for the study of membranoproliferative GN type II in humans (Jansen et al. 1998).

In many species, generalized or focal GN is also observed in some cases of systemic vasculitis (mainly immune-mediated vasculitis). In pigs, the best example of this certainly is porcine dermatitis and nephropathy syndrome (PDNS). The condition, first described in the United Kingdom in 1993 (Smith et al. 1993; White and Higgins 1993), was subsequently observed in other parts of Europe, North and South America, Oceania, and Africa, suggesting a worldwide distribution (Segalés et al. 2003). The disease affects nursery and growing pigs and, less commonly, breeding animals (Drolet et al. 1999). Although notable exceptions have been observed, the prevalence of the syndrome in affected herds is usually less than 1%. Affected animals present a sys-

9.5. *Sow affected with PDNS. Note multifocal to coalescent erythematous macules and patches of typical distribution.*

temic necrotizing vasculitis with marked tropism for the skin and kidneys (Smith et al. 1993; Hélie et al. 1995; Thibault et al. 1998). Vascular lesions in the skin provoke a conspicuous dermatopathy (Figure 9.5) (see Chapter 8). Kidney lesions in acute cases may include exudative and occasionally necrotizing GN and vasculitis. Vascular lesions in other tissues vary considerably in frequency and distribution in individual pigs (Thomson et al. 2002). In some atypical cases there may be cutaneous lesions without renal lesions and vice versa. An animal with GN without any other vascular lesions elsewhere should probably not be diagnosed as PDNS since other glomerular diseases not related to this syndrome are known to occur in pigs.

In PDNS, the glomerular and systemic vascular damages are thought to be immune-mediated, possibly through a type III hypersensitivity reaction (Smith et al. 1993; Helie et al. 1995; Sierra et al. 1997; Thibault et al. 1998; Thomson et al. 2002; Wellenberg et al. 2004). The precise etiology of the condition remains unknown at this time. Porcine reproductive and respiratory syndrome (PRRS) virus and porcine circovirus type 2 (PCV2) have been so far the two infectious agents most suspected of being responsible for the development of the disease, either as primary causal agents or as important cofactors (Segalés et al. 1998, 2003; Thibault et al. 1998; Drolet et al. 1999; Rosell et al. 2000; Thomson et al. 2002; Wellenberg et al. 2004). In both of these infections, viremia may coexist with the presence of antibodies, a situation that may facilitate the formation of immune complexes. Also of interest is the fact that these two viruses infect cells of the monocytes/macrophages lineage and may theoretically act indirectly by affecting the efficiency of the mononuclear phagocytic system in removing immune complexes from the circulation (Thomson et al. 2001). Recently it has been shown that animals with PDNS often have relatively low PCV2 loads (Olvera et al. 2004) but very high PCV2 antibody titers (Wellenberg et al. 2004).

Renal fibrosis combined with proliferative glomerular lesions was rather common in Norwegian slaughter pigs (Jansen and Nordstoga 1992, 1994). Further studies are needed to confirm the relationship between this interstitial fibrosis and the mesangioproliferative glomerulopathy observed. Other examples of glomerular disease in swine have been reported in the literature in recent years (Shirota et al. 1984, 1995; Tamura et al. 1986; Yoshie 1991; Pace et al. 1998; Carrasco et al. 2003).

Although several of the previously described glomerulonephropathy types are associated with an underlying disease process (chronic infections, genetic defect, systemic vasculitis, etc.) that gives insight into the likely etiology of the condition, many spontaneous cases of GN, however, remain idiopathic (primary idiopathic GN) (Slauson and Lewis 1979; Shirota et al. 1986; Bourgault and Drolet 1995).

The clinical significance of GN is highly variable, with a spectrum ranging from a subclinical condition to a fulminating and rapidly fatal disease. Shirota and coworkers (1986) found deposition of immune complexes containing IgG and third-complement component (C3) in the glomerular mesangium of most of the 100 normal slaughtered swine they examined. The mesangioproliferative GN, disclosed only upon microscopic examination of the kidneys, was seemingly not associated with clinical disease. On the other end of the spectrum, the proliferative and exudative GN observed in most of the cases of spontaneous GN reported by Bourgault and Drolet (1995) was found to be responsible for the death of at least one-third of the pigs affected. The hereditary GN of Norwegian Yorkshire pigs appears to be invariably fatal; affected piglets die of renal failure within 11 weeks of birth (Jansen et al. 1995). Mortalities are also commonly recorded in pigs affected with PDNS (Smith et al. 1993; White and Higgins 1993; Kavanagh 1994; Hélie et al. 1995; Segalés et al. 1998; Thomson et al. 2002). In this latter condition, the survival of the affected pigs depends on the extent and severity of the vascular lesions in the internal organs, particularly within the kidneys.

Unlike most other domestic animals affected with GN (with the exception of the familial glomerulopathies), pigs appear to be affected at a relatively young age. The condition has been described most commonly in weaned and feeder pigs (1.5–6 months old), occasionally in breeding animals, and rarely in nursing piglets. Clinical signs, when present, may include anorexia, lethargy, unwillingness to move, subcutaneous edema, rapid loss of condition, and death. GN is rarely recognized clinically because most of the signs are nonspecific, and analysis of urine and blood from an individual is rarely considered of practical value in the herd medicine approach applied in our large units of production. Pigs affected with PDNS are often more easy to detect clinically because of the presence of hemorrhagic and necrotizing skin lesions, mainly located on the hind-

limbs and perineal area (Segalés et al. 2003). Pigs with GN may show concomitant hypoproteinemia, hypoalbuminemia, and persistent proteinuria which are highly suggestive of a protein-losing glomerulopathy. The urine protein/creatinine ratio may also be increased (Hélie et al. 1995). Proteinuria, hematuria, and pyuria, which are usually compatible with lower urinary tract lesions, may also occur in severe types of GN—namely, in acute proliferative and exudative GN. Blood of affected animals may also reveal elevated urea and creatinine levels suggestive of renal failure (White and Higgins 1993; Hélie et al. 1995; Jansen et al. 1995; Drolet et al. 1999; Thomson et al. 2002).

Gross lesions of GN may be absent, subtle, or very conspicuous. The appearance of the kidneys will depend largely on the severity of the glomerular lesions and the stage (acute vs. chronic) of the disease process. In acute GN, the kidneys may be slightly to markedly enlarged, pale, edematous, often with cortical petechiation (Figure 9.6). The most important differential diagnoses to consider for such acutely affected kidneys are various bacterial septicemia (*Erysipelothrix rhusiopathiae, Actinobacillus suis, Salmonella choleraesuis*), acute viremia (classical swine fever, African swine fever, cytomegalovirus) and intoxications. With time, the surface of the kidneys may become finely granular, and in the chronic phase of the disease, the organs may appear shrunken and contracted due to progressive cortical fibrosis. At this stage, the gross lesions are indistinguishable from chronic interstitial nephritis. They may, however, be differentiated from chronic pyelonephritis, which tends to produce a more irregular pattern of fibrosis, often with intervening areas of normal parenchyma and evidence of lesions upon careful examination of renal calyxes and papillae. Perirenal and subcutaneous edema and serous effusions in body cavities may be observed in some cases of GN. On several occasions a high prevalence of gastric ulcers has been associated with GN (Jansen 1993; White and Higgins 1993; Kavanagh 1994; Bourgault and Drolet 1995).
Treatment of GN, which is usually symptomatic, has received little attention in swine since the disease is not often diagnosed in live animals under normal farm-raising conditions. Pigs affected with PDNS have been tentatively treated with various antimicrobial agents, anti-inflammatory drugs and multivitamin supplements without significantly conclusive results (Segalés et al. 2003).

TUBULAR DISEASES

Renal diseases characterized primarily by degenerative changes affecting the tubular epithelial cells of the nephrons may occur under certain circumstances. In these cases, the epithelial lining cells of the tubules may undergo degeneration, followed by necrosis and sloughing of the cells.

Acute tubular necrosis, often called nephrosis, represents an important cause of acute renal failure in animals. The epithelial cells of the proximal tubules, because of their high metabolic activity, are especially susceptible to damage caused by prolonged ischemia or nephrotoxins, the two main causes of this type of nephropathy.

Ischemic Tubular Necrosis

Ischemic tubular necrosis is generally the result of a severe and prolonged period of hypotension associated with shock of endotoxic, hypovolemic, cardiogenic, or neurogenic origin (Maxie 1993). These renal lesions are potentially life-threatening, and the clinical signs of the resulting renal failure are often hidden by the marked systemic effects of the primary disease responsible for the state of shock.

Nephrotoxic Tubular Necrosis

Nephrotoxic tubular necrosis has been documented in domestic animals in association with a wide variety of exogenous natural and synthetic compounds. These toxic substances may affect tubular function and ultimately cause cellular damage by several mechanisms, including metabolic alterations affecting cellular respiration, interference with the tubular transport system, and damage to specific organelles (Brown and Engelhardt 1987).

Plants, mycotoxins, antimicrobial drugs, heavy metals, ethylene glycol, and some other industrial compounds are potential nephrotoxins in swine. Some of these toxic products are covered in Chapters 56 and 60.

Many plants are nephrotoxic to animals, especially ruminants. Several species of pigweed, particularly redroot pigweed (*Amaranthus retroflexus*) (Figure 9.7), may cause acute renal failure in pigs when ingested. The disease occurs in summer and early fall, corresponding to the months in which animals may have access to the

plants. The onset of clinical signs usually occurs about a week after the ingestion. Characteristic signs include weakness, trembling, and incoordination, rapidly progressing to posterior paralysis and sternal recumbency, and finally to death (Osweiler et al. 1969).

Fungi of some species of *Aspergillus* and *Penicillium* produce nephrotoxins that can contaminate grains used as feedstuff. Ochratoxin A and citrinin are the most common nephrotoxic mycotoxins. Monogastric animals, particularly pigs, may develop significant disease when moldy feed containing ochratoxin A is ingested. Acute clinical signs are relatively rare; a subacute to chronic wasting disease is more commonly associated with this poisoning (Osweiler 1996).

Antibiotic-associated nephropathies are well documented in domestic animals. Classes of antibiotics considered potentially nephrotoxic include the aminoglycosides, tetracyclines (or their degradation products), and sulfonamides. Predisposing factors associated with the toxicity of these agents include the dosage and the route of administration, the duration of the treatment, the solubility of the products, and the general health status (dehydration, shock, preexisting renal disease) of the animal.

Ethylene glycol is another potential cause of poisoning in pigs. This product, found in high concentration in many antifreeze solutions, is not toxic per se, but once it is ingested and absorbed from the gastrointestinal tract, a proportion is enzymatically oxidized in the liver and successively transformed into several nephrotoxic compounds and finally to oxalate. Poisoning occurs in swine with the ingestion of 4–5 ml of ethylene glycol/kg of body weight (Carson 1999). Pigs may be poisoned when they have accidental access to antifreeze solution expelled during engine maintenance or from the plumbing systems in which these products are used to prevent freezing.

Many metallic compounds are nephrotoxic, including inorganic mercury, arsenic, cadmium, lead, thallium, and bismuth. Cases of poisoning with these products are relatively rare in pigs.

Gross renal lesions observed in acute cases of nephrotoxic tubular necrosis are not always conspicuous, but the kidneys may appear slightly swollen, pale, and moist (Figure 9.8). In pigweed (*Amaranthus retroflexus*) poisoning these renal lesions are often accompanied by a marked perirenal edema that may contain blood and possibly by serous effusions elsewhere in the body (Osweiler et al. 1969). In severe acute tubular necrosis, death from acute renal failure may ensue. Animals that survive the acute phase of the disease either recover or develop progressive fibrosis of the kidneys that may or may not lead to chronic renal failure. This chronic evolution appears relatively common in pigs with ochratoxin A toxicosis (Krogh 1977; Rutqvist et al. 1978; Cook et al. 1986).

Histologically, acute tubular necrosis is generally characterized by swelling and necrosis of the lining epithelial cells of the proximal and distal tubules, the presence of granular casts in the tubular lumen, dilated tubules, and mild interstitial edema. The presence of large numbers of calcium oxalate crystals within tubules is a characteristic finding in ethylene glycol poisoning. Kidneys of animals surviving the acute toxic insult show evidence of epithelial regeneration and eventually, at least in some cases, interstitial fibrosis accompanied by focal loss of nephrons and a mild interstitial inflammatory infiltrate.

Since specific therapies for most of these toxicoses is virtually lacking, treatment of affected animals is essentially supportive and symptomatic. When a specific nephrotoxin is suspected, action should be taken to ensure that the offending toxin is rapidly withdrawn or that the pigs are immediately removed from the source of the intoxication. Practical measures can be taken to

prevent intoxication by some of these nephrotoxins. Proper drying and storage of grain, for example, is one of the best methods of preventing mycotoxicosis, such as from ochratoxin A.

TUBULOINTERSTITIAL DISEASES

Tubulointerstitial diseases include a relatively large group of conditions characterized primarily by interstitial inflammation and tubular damage: namely, interstitial nephritis (such as that occurring from leptospirosis), embolic nephritis, and pyelonephritis (one of the most significant urinary tract diseases in swine). Immunologically mediated tubulointerstitial disease as occurs in humans has only rarely been documented in domestic animals.

Interstitial Nephritis

Leptospirosis is probably one of the best known causes of interstitial nephritis in pigs. Many serovars of *Leptospira* spp.—those of the serogroups Pomona, Tarassovi, and Australis, for which pigs act as maintenance hosts—cause significant disease in swine, most notably linked with reproductive problems, including infertility, abortion, and birth of weak or dead piglets. The pathogenesis of the disease involves the penetration by the leptospires of mucosal surfaces or skin, a bacteremia of a few days that lasts until the beginning of the humoral immune response, and the preferential localization and persistence of the organisms at sites physically protected from antibodies, such as in the ocular vitreous humor, the cerebrospinal fluid, the genital tract, and the lumen of the renal proximal tubules (Prescott 1993). The passage of the leptospires from the bloodstream to the interstitial tissue of the renal parenchyma and finally to the tubular lumen elicits multifocal lesions of interstitial nephritis (Cheville et al. 1980).

The severity of the interstitial nephritis varies and ranges from grossly undetectable to extensive lesions, particularly when serovars of the Pomona serogroup are involved. The lesions are randomly distributed and appear as poorly circumscribed whitish foci of various shapes and sizes, becoming confluent in severe cases (Figure 9.9). Histologically these foci correspond to the infiltration of lymphocytes, plasma cells, and macrophages in the interstitial tissue, along with some degenerative changes of the surrounding nephrons. In chronic cases, interstitial fibrosis occurs.

In most cases these lesions are not extensive enough to cause renal failure, so the generally asymptomatic animal may shed the leptospires in urine for a relatively long period of time and become an important source of contamination of the premises. With time, the leptospiruria becomes less intense and intermittent, but it has been reported to occur for up to 2 years in some cases (Mitchell et al. 1966).

The association between lesions of interstitial

9.9. *Severe interstitial nephritis associated with leptospirosis. (Courtesy of Dr. J.-B. Phaneuf.)*

nephritis in pigs and the detection of leptospires within these kidneys is highly variable among studies (McErlean 1973; Hunter et al. 1987; Jones et al. 1987; Baker et al. 1989; Boqvist et al. 2003). Factors that may influence these results include the serovar of *Leptospira* spp. involved, the methods of leptospiral detection used, the phase of the infection and also the prevalence of leptospirosis and of other infectious causes of interstitial nephritis in swine in a given geographical area. For instance, the prevalence of leptospirosis in fattening pigs and sows in southern Vietnam was found to be high (Boqvist et al. 2002, 2003), whereas similar studies conducted in slaughtered pigs in southwestern Quebec have shown a very low prevalence of this infection (Ribotta et al. 1999; Drolet et al. 2002).

Postweaning multisystemic wasting syndrome (PMWS), a condition affecting nursery and growing pigs, was first described in Canada in 1996 (Clark 1996; Harding 1996). The disease has been linked to PCV2 and is now occurring in many parts of the world. It is characterized by progressive weight loss, respiratory signs, hypertrophic lymphadenopathy, and, in some cases, diarrhea, pallor, or icterus (Allan and Ellis 2000; Segalés and Domingo 2002). Lesions involve several organs and include lymphohistiocytic to granulomatous interstitial pneumonia, nephritis, and hepatitis. The interstitial nephritis is in some cases grossly detectable as whitish foci within renal parenchyma (Figure 9.10). In lymphoid tissues there is lymphocyte depletion and infiltration of histiocytes and multinucleated giant cells that may contain grapelike clusters of basophilic cytoplasmic viral inclusion bodies.

Multifocal lesions of interstitial nephritis also occur in swine with other bacterial (see the section on embolic nephritis) and viral hematogenous infections. Although in most of these cases the lesions do not impair renal function, they are of diagnostic significance because they are suggestive of a systemic disease. Lesions of interstitial nephritis caused by systemic viral infections are often disclosed only upon microscopic examination and are characterized by the presence of foci of nonsup-

9.10. *Interstitial nephritis in a pig naturally infected with porcine circovirus type 2.*

purative inflammation. Viral infections that may produce these lesions include cytomegalovirus (Kelly 1967), adenovirus (Shadduck et al. 1967; Nietfeld and Leslie-Steen 1993), PRRS virus, and possibly others. Multifocal lesions of nonsuppurative interstitial nephritis have been reproduced experimentally in PRRS virus–infected piglets examined 2–3 weeks postinoculation (Rossow et al. 1995; Cooper et al. 1997). These lesions are found in the renal cortex as well as in the medulla. Similar renal lesions are also frequently found in naturally infected pigs.

Gross lesions of multifocal interstitial nephritis, often called white-spotted or white-dotted kidneys, represent a common cause of kidney condemnation at the slaughterhouse in some areas (Drolet et al. 2002). Lesions generally appear either as few randomly distributed or numerous widely disseminated whitish foci, 1–3 mm in diameter (Figure 9.11). Histologically these foci are composed of mononuclear inflammatory cells that often take up a distinct lymphofollicular pattern (follicular nephritis) (refer to Figure 9.11). This type of interstitial reaction probably represent a nonspecific immunological response to prolonged local antigenic stimulation. In one study it was shown that, although the precise cause of these lesions was uncertain, there was a statistically significant association between the le-

sions and the presence of porcine parvovirus and PCV2 with a stronger association when both viruses were identified in the same kidney (Drolet et al. 2002).

Embolic Nephritis

Embolic nephritis may occur with bacteremia or septic thromboembolism when any of various species of bacteria is seeded within the vasculature of the kidneys. In bacteremia, small aggregates of microorganisms localizing in the renal microcirculation (in particular, in the interstitial and glomerular capillaries) cause the formation of small suppurative foci. Early lesions appear grossly as small hemorrhagic foci bilaterally scattered throughout the renal cortex. They gradually form small (1–3 mm) whitish to yellowish abscesses that may be surrounded by a hyperemic rim (Figure 9.12). These lesions, although more numerous in the cortex, may also be found in the medulla. The finding of such renal lesions, when performing a necropsy, strongly suggests the possibility of a septicemia. In swine, infections with *Streptococcus* spp., *Erysipelothrix rhusiopathiae*, *Actinobacillus suis*, *Escherichia coli*, *Staphylococcus* spp., *Arcanobacterium pyogenes*, and others have to be considered.

Septic thromboembolism occurs when fragments of a septic thrombus enter the bloodstream and occlude the arterial vasculature of the kidneys, resulting in necrosuppurative foci of variable size (Figure 9.13). Such renal lesions, if disclosed during a postmortem examination, should prompt a careful examination of the left cardiac valves (mitral and aortic) for the presence of vegetative endocarditis. In these cases, bacteria most often involved include *Streptococcus* spp., *Erysipelothrix rhusiopathiae*, and *Escherichia coli*.

Cystitis-Pyelonephritis Complex

Urine is formed by the kidneys and stored in the bladder by way of the ureters. The ureteric valves prevent retrograde flow of urine from the bladder to the kidneys. Urine is removed from the bladder via the urethra, which, in females, communicates with the vagina. The distal portion of the urethra and the vaginal tract are not sterile; the composition of the microflora is primarily
9.11. *(A) Kidney from a slaughter pig with multifocal interstitial nephritis. Note the relatively well-demarcated white dots randomly distributed throughout the cortex. (B) Well-demarcated focal area of interstitial nephritis showing a distinct lymphofollicular pattern (follicular nephritis).*

bacterial. Ascending infection of the sterile portions of the urinary tract may lead to cystitis and pyelonephritis.

The cystitis-pyelonephritis complex has been documented as a leading cause of mortality in sows (D'Allaire and Drolet 1999). Porcine cystitis-pyelonephritis has been reported throughout the world, and the increased incidence appears to be correlated with changes in management, particularly the adoption of confinement housing for gestating sows.

Etiology. A wide variety of bacteria have been isolated from cases of porcine cystitis and pyelonephritis, including *E. coli*, *Arcanobacterium pyogenes*, *Streptococcus* spp., and *Staphylococcus* spp. (Carr and Walton 1993). These endogenous and opportunistic organisms typically inhabit the lower urinary tract and are often referred to as being responsible for "nonspecific" urinary tract infections, which are reviewed in detail in Chapter 38. *Actinobaculum suis*, a specific urinary pathogen, is an important cause of ascending infection in swine. Infection with *A. suis* frequently results in elevated sow mortality, and *A. suis* has been isolated, either alone or

in combination with other bacteria, from nearly half of the reported cases of cystitis and pyelonephritis reviewed by Carr and Walton (1993). Due to the importance of *A. suis* in the pathogenesis of urinary tract infection in swine, the remainder of this section will focus on its role in the disease process.

Formerly classified in the genera *Eubacterium* and *Actinomyces*, *Actinobaculum suis* is a gram-positive rod-shaped bacterium that grows well under anaerobic conditions. *Actinobaculum suis* is urease positive and catalase negative, ferments maltose and xylose, and hydrolyzes starch. Methyl red, Voges-Proskauer, indole, and nitrate reduction tests are negative. A slight alkalinity is produced in litmus milk, but liquification of egg or serum media does not occur. It is nonhemolytic on blood agar, producing pinpoint colonies 2–3 mm in diameter after 2–3 days of incubation under anaerobic conditions at 37°C. During days 4 to 5 postinoculation, colonies flatten and develop a dry, opaque appearance, reaching a diameter of 4–5 mm (Taylor 1999).

Epidemiology. *Actinobaculum suis* is a commensal organism of the porcine urogenital tract. It has been isolated from the preputial cavity of boars at slaughter (Pijoan et al. 1983; Pleschakowa et al. 2004), the vaginal tract of neonatal piglets sampled immediately following parturition, and the vaginal tract of females sampled throughout all stages of production (Dee et al. 1993). *Actinobaculum suis* has been isolated from voided urine, contaminated parturition sleeves of farrowing attendants, pen floors of the farrowing and nursery rooms, and the boots of stockpersons working in the breeding area (Carr and Walton 1990; Dee et al. 1993). The sole route of transmission was believed to be copulation, but it is now understood that the organism is ubiquitous, and colonization of the vaginal tract can take place anytime in the life of the pig.

As the popularity of confinement gestation housing has risen, so has the incidence of *A. suis*–related urinary tract disease. Problems frequently encountered in confinement facilities are the reduced availability of water, increased fecal contamination of the perineal area, excessive weight gain, and leg injuries, all of which result in a reduction in the frequency of urination and enhanced bacterial survival in the urogenital tract. Distinguishing features of endemic cystitis and pyelonephritis within a herd include lack of a temporal relationship between the vulvar discharge and the estrous cycle, minimal effect on herd fertility, low morbidity, high mortality, and an increased frequency in advanced-parity (6+) sows (Pointon et al. 1990).

Pathogenesis. *Actinobaculum suis* is fimbriated, and the short, wide urethra of the sow enhances accessibility to the bladder (Larsen et al. 1986). Once within the bladder lumen, the alkalinity of the environment increases due to the cleavage of urea into ammonia through the

use of the urease enzyme. The elevated pH enhances bacterial proliferation and causes an inflammatory reaction of the mucosal surface. The alkaline environment also inhibits the growth of competitive microflora and promotes the precipitation of urinary salts and crystals, particularly struvite. Such precipitates not only further increase inflammatory changes in the bladder mucosa but provide a nidus for bacterial growth and protection from antibiotics and host defense mechanisms. Although the primary means for accessibility to the kidneys is not yet completely understood, it is hypothesized that damage to the ureteric valves secondary to bacterial products (possibly originating from *E. coli*) may predispose the affected animal to pyelonephritis (Carr et al. 1990).

Clinical Signs and Lesions. Clinical signs associated with infections of the urinary tract caused by *A. suis* vary according to the severity and the phase of the disease. In acute and severe cases, affected animals may be found dead, probably from acute renal failure. Symptomatic animals are usually afebrile and may show anorexia, hematuria, and pyuria. The urine is typically reddish brown in color with a strong odor of ammonia. Urinary pH may increase from normal values of 5.5–7.5 up to 8–9. Animals that survive the initial infection frequently experience weight loss and reduced productivity secondary to end-stage renal disease, resulting in premature removal from the breeding herd.

Inflammatory reaction on the mucosal surface of the bladder may be catarrhal, hemorrhagic, purulent, or necrotic, and the bladder wall may be thickened. Struvites can also be found in the lumen. The ureters, often filled with exudate, may increase to as much as 2.5 cm in diameter. Unilateral or bilateral pyelonephritis or pyelitis is the primary lesion detected in the kidneys. The pelvic region, frequently distended with blood, pus, and foul-smelling urine, often shows irregular ulceration and necrosis of the papillae. These suppurative lesions may eventually extend irregularly through the renal medulla and even into the cortex, causing exophytic and discolored deformations of the renal surface (Figure 9.14). These foci of cortical inflammation, when present, seem to occur more frequently at the renal poles. Compound papillae that are mainly located in these latter areas are considered more susceptible to intrarenal reflux of septic urine because of the inability of their papillary ducts to close under intrapelvic pressure (Ransley and Risdon 1974; Carr et al. 1991). In long-standing cases of pyelonephritis, fibrosis ultimately replaces inflammation (Figure 9.15).

Microscopically, necrotizing ureteritis and pyelitis with accumulation of bacterial colonies can be seen, along with epithelial hyperplasia, desquamation of superficial epithelial cells, and goblet cell metaplasia with intraepithelial cyst formation (Woldemeskel et al. 2002). Renal tubules may contain protein casts, bacte-

9.15. *Chronic pyelonephritis in a sow.*

ria, and purulent exudate. The interstitium contains mononuclear inflammatory cells, neutrophils, and possibly some fibrosis. Examination of the ureteric valves may reveal inflammation, necrosis, and fibrosis.

Diagnosis. Presumptive diagnosis of cystitis and pyelonephritis in live animals is best achieved when frequent micturition of bloodstained and cloudy urine can be observed. Examination of the urine sediments may also be very informative, because it may reveal the presence of inflammatory cells, erythrocytes, granular renal casts, bacteria, and crystals (Carr and Walton 1992). Due to the striking gross lesions, confirmatory diagnosis of the condition is usually not difficult. In some cases, determination of urea concentration in ocular fluids is a useful aid to postmortem diagnosis of pyelonephritis, especially if it is difficult to ascertain that the lesions found in the urinary tract are responsible for the death of the animal (Drolet et al. 1990; Chagnon et al. 1991). In order to isolate the causative organism properly, care must be taken during sample collection to minimize exposure to oxygen (Dee 1991). In the field, the bladder should remain unopened, and the neck of the bladder should be sealed with umbilical tape. Similar care

should be taken with renal tissue. Demonstration of lesions of pyelonephritis can be carried out through the examination of one kidney; however, the other should remain unopened with the ureter sealed as previously described. Upon arrival at the laboratory, a small incision should be made over a portion of the serosal surface of the bladder and kidney, previously seared with a hot iron to reduce surface contamination. A cotton swab should be inserted into the bladder lumen and streaked for isolation on colistin nalidixic acid (CNA) agar and then incubated at 37°C under anaerobic conditions for 5–7 days. If the culture process is to take place at a distant location, swabs can be placed into Kary Blair anaerobic transport media for shipment. Colonial morphology and biochemical characteristics of *A. suis* have been described earlier in the section.

Finally, an indirect fluorescent antibody test for the detection of serum antibodies against *A. suis* has been described (Wendt and Amtsberg 1994). The test appears to be highly specific (100%) but of low sensitivity (79%).

Treatment and Prevention. Treatment of urinary tract infections may be successful if the correct antibiotic is administered early in the course of the disease. Studies have demonstrated consistent susceptibility of *A. suis* to penicillin, cephalosporins, chloramphenicol, tetracyclines, and macrolides, with variable susceptibility to fluoroquinolones, and resistance to aminoglycosides (Biksi et al. 2003). Penicillin and ampicillin are frequently the products of choice, due to their ability to function under alkaline conditions and their propensity for excretion through the urinary tract. Dosages of 2.2 mg/kg are typically administered intramuscularly for 3 consecutive days. Oral administration of penicillin and ampicillin is also possible; however, feed-grade products are of little value, due to the high degree of anorexia in acutely infected sows and a reduced bioavailability, secondary to destruction by gastric enzymes, low pH, and colonic bacteria. Water-soluble ampicillin can be administered at 2.3 mg/kg for 5 consecutive days; however, bioavailability is questionable and cost may become an issue.

Acidification of the urine through oral administration of feed-grade citric acid has been described in the literature (Dee et al. 1994). Results from this study showed a reduction in the incidence of clinical urinary tract disease, as well as highly significant (p <0.0001) differences in urinary pH and bacterial concentration/ml of urine in medicated versus nonmedicated groups. A level of 70 mg of citric acid was administered daily for 14 consecutive days in this study, and palatability problems were not detected in treated animals.

Prevention of urinary tract disease is similar to the steps required to control other diseases of the urogenital system (Dee 1992). The maintenance of a high degree of hygiene during breeding and parturition, as well as throughout the gestation period, is critical. Facilities

9.16. *Improper facility design enhances the incidence of cystitis-pyelonephritis in gestating sows.*

need to be properly designed to reduce the spread of pathogens within the breeding herd and allow efficient removal of feces from the environment (Figure 9.16).

Restricting water availability through the use of intermittent delivery systems or poor husbandry results in an increase in abnormal urine parameters in gestating sows (Almond et al. 1996). Abnormalities included reduced urine output, elevated specific gravity (≥1.026), and increased creatinine concentration. Therefore, it is recommended that free-choice water be available at all times. Finally, because a higher degree of urinary tract disease can be seen in older sows, proper culling procedures are important to ensure that an optimal parity distribution is maintained within the breeding herd.

NEOPLASIA

Neoplasms are infrequent in pigs because of the low average age of the population. However, those most often recorded have been from young animals (Nielsen and Moulton 1990). Tumors of the urinary tract in swine involve mainly the kidneys. Neoplasms of the lower urinary tract, although they have been reported (Nieberle and Cohrs 1967), are generally considered exceedingly rare.

Embryonal nephroma, also named *nephroblastoma,* is one of the most common neoplasms of swine and is certainly the most common primary renal tumor observed in this species, although its relative prevalence varies from one region to another. As its name implies, this neoplasm appears to originate from the embryonic renal blastema. The tumor arises from the kidney or, rarely, from the perirenal tissues (probably from remnants of embryonic renal tissues). Affected animals are typically young, and most of them reach market age without significant clinical signs, the tumor being discovered at postmortem inspection. Embryonal nephroma is most commonly found as a single mass involving one kidney but it may be multiple or bilateral (Nielsen and Moulton 1990). The tumor, which can

9.19. *Leukemic lymphoma in a gilt showing multiple renal hemorrhagic foci. Histologically these focal interstitial hemorrhages also contain neoplastic lymphoid cells.*

reach impressive size, often appears firm, pale, and nodular (Figure 9.17). Metastasis infrequently occurs in swine compared to other mammals affected with embryonal nephroma. Histologically, this tumor is very peculiar and resembles disorganized embryonic renal tissue. The primitive tissue from which it arises is pluripotent and accounts for the presence of neoplastic epithelial and mesenchymal elements simultaneously observed within the tumor. Hayashi et al. (1986) classified porcine nephroblastomas into four types according to their contents: nephroblastic, epithelial, mesenchymal, and miscellaneous. Only a few of the nephroblastic tumors described in their case series had metastasized.

Other primary renal tumors are believed to be uncommon in swine. Renal carcinomas have been occasionally reported (Sandison and Anderson 1968; Anderson et al. 1969). Neoplasms originating from the renal pelvis are very rare (Vitovec 1977).

Secondary renal involvement may occur with some multisystemic or generalized cancers such as the malignant lymphoma (lymphosarcoma). In pigs, this relatively common neoplasm occurs predominantly as multicentric and thymic forms. In advanced cases of multicentric and thymic lymphomas, which involve primarily the lymph nodes and the thymus, respectively, infiltration of liver, spleen, kidneys, and other organs may occur. Renal involvement is diffuse or more often nodular so that the organs appear either enlarged and pale or dotted with pale nodules often protruding from the cortical surface (Figure 9.18). In the course of the disease some animals may develop a leukemic phase. Renal lesions in some of these cases appear rather hemorrhagic (Stevenson and DeWitt 1973; Marcato 1987) and may be confused with some systemic infectious diseases (Figure 9.19). The precise pathogenesis of these latter lesions is uncertain but may involve either a coagulation defect or a phenomenon of acute infarction caused by the presence of intravascular neoplastic cells.

MISCELLANEOUS CONDITIONS

Urolithiasis

Urolithiasis is the presence of calculi, or uroliths, in the urinary passages. Uroliths are macroscopic mineral (polycrystalline) concretions that may contain small quantities of organic material; the term *crystalluria* is used for abnormal microscopic crystalloid precipitates in urine. The mineral composition of calculi found in pigs and their relative importance have not been extensively studied. Nevertheless, various types of calculi can be found, including calcium carbonate, calcium apatite (calcium phosphate), struvite (magnesium ammonium phosphate hexahydrate), and uric acid and urate. Factors known to predispose to the formation of uroliths include the diet, urinary pH, reduced water intake, urinary stasis, and preexisting urinary tract diseases.

Swine are rarely afflicted with urolithiasis in comparison to other domestic animals. The condition is sporadically found in pigs of all ages and is also occasionally
observed as incidental findings in slaughtered pigs. Outbreaks of obstructive urolithiasis have been reported on several occasions (Inoue et al. 1977; Sim 1978; Smyth et al. 1986). In these outbreaks, which involved weaned and feeder pigs as well as breeding animals, the predisposing cause for the condition was not elucidated. Animals affected with obstructive urolithiasis may demonstrate decreased appetite, oliguria or anuria, abdominal distension and pain, and death from postrenal uremia. Ruptured bladder may also occur in some cases. Treatment of pigs with obstructive urolithiasis is theoretically feasible but is generally not considered cost-effective.

The bladder of sows sometimes contains yellowish sediments that do not seem to be of clinical significance. On postmortem examination, such sediments, admixed with desquamated epithelial cells, may give the false impression of a cystitis because of the turbidity of the urine. Infection-induced calculi are also observed occasionally in sows with cystitis and pyelonephritis (Figure 9.20).

Uric acid and urate uroliths are frequently found in the kidneys of newborn piglets. These often appear as fine orange precipitates in the medulla and pelvis (Figure 9.21). This peculiar form of urolithiasis is observed mainly in piglets that have no access to the sow's milk (which contains both fluids and nutrients) or are afflicted by a debilitating disease associated with anorexia and diarrhea (e.g., transmissible gastroenteritis), thus contributing to dehydration. Accelerated catabolism of tissue proteins and purines to supply energy needs and decreased kidney function related to dehydration are responsible for the high levels of blood urea and uric acid found in these piglets. The excess solute, poorly reabsorbed from the glomerular filtrate, is ultimately deposited in the inner medulla and pelvis (Maxie 1993).

9.21. *Urate calculi in medulla (arrows) of a dehydrated suckling piglet.*

Hydronephrosis

Distension of the renal pelvis and calyces with urine, associated with progressive atrophy of the kidney parenchyma, is the hallmark of hydronephrosis, which is uncommon and sporadic in swine. The pathogenesis of this condition always involves some form of obstructive impediment to the normal passage of urine within the lower urinary tract, anywhere from the pelvis to the distal urethra. The causes of the obstruction include urinary calculi, exudate within urinary passages, ureteral kinking, focal external compression (abcesses, tumors), and posttraumatic or postinflammatory strictures.

Severe unilateral hydronephrosis may develop unnoticed since the remaining kidney, if normal, may compensate adequately. In these cases, the affected kidney shows extensive dilatation of the pelvis and calyces at the expense of the renal parenchyma, which may appear as a thin layer of cortical tissue (Figure 9.22). Depending on the location of the obstruction, hydroureter may also develop. In long-standing cases, the kidney may be virtually transformed into a large fluid-filled sac delimited by a severely distended renal capsule. These extreme lesions may take months to de-

9.20. *Infection-induced calculi in the bladder of a sow with a chronic suppurative cystitis.*
9.22. *Chronic unilateral hydronephrosis.*

velop. Since stagnation of urine predisposes to infection, the urine may be transformed into a purulent exudate in some instances. In cases of bilateral hydronephrosis, affected animals usually die from uremia before renal lesions get fully developed.

Parasitic Infections

The pig is the final or intermediate host of a number of parasitic helminths (see Chapter 55). Compared to some other body systems, the urinary tract is the niche of very few of these parasites. Renal infections with *Dioctophyma renale*, the giant kidney worm, and with larval stages of certain tapeworms may occur on rare occasions. The most significant helminth with tropism for the urinary system of swine is the nematode *Stephanurus dentatus*, the so-called kidney worm of swine.

Stephanurus dentatus is a widely distributed strongyloid worm and is most prevalent in warm climates, including the southern United States. In enzootic areas, this parasitic infection may have significant economical impact since it is associated with deaths, retarded growth, decreased feed efficiency, and condemnations at the abattoir (Batte et al. 1960). Larvae of this nematode need moisture and shade for optimal survival, so pigs raised on soil in this type of environment are the most prone to the disease. Infective larvae penetrate the skin or are ingested by the pigs. Transplacental fetal infection is also possible (Batte et al. 1966).

After being introduced into the host, the larvae molt and migrate to the liver, where they remain for several months, causing severe hepatic damage and inflammation. The presence of the parasite within the hepatic parenchyma is often responsible for extensive liver condemnation in some herds (Hale and Marti 1983). Eventually some larvae escape from the liver and migrate to the abdominal cavity and potentially to various ectopic sites, eliciting a severe inflammatory reaction. To complete the cycle, some adults establish themselves in the perirenal tissues or, more rarely, within the kidney. At that site, the worms, measuring about 3 cm in length, are found in cystic inflammatory nodules that communicate with either the pelvis or the ureter in order to shed their eggs successfully into urine. The prepatent period in most cases is at least 9 months, and adults may shed ova in urine for over 2 years (Batte et al. 1960, 1966). Preventive and curative measures for the control of parasites are addressed in detail in Chapter 55.

Others

Mineralization of the kidneys occurs in swine with acute vitamin D toxicosis. This poisoning is usually observed when excessive amounts of vitamin D_3 are inadvertently added to their feed (Kurtz and Stowe 1979; Long 1984). Affected pigs show lethargy, vomiting, diarrhea, respiratory distress, and death. Salient gross necropsy findings include hemorrhagic gastritis or gastroenteritis, myocardial necrosis, and pulmonary edema and congestion. Histologically, besides the gross lesions described above, there is widespread mineralization accompanied by degenerative changes of varying severity in the kidneys, myocardium, lungs, gastrointestinal tract, and blood vessels.

Mucinous metaplasia of the epithelial cells lining the renal pelvis, ureter, and urinary bladder is occasionally observed in pigs. This rather nonspecific lesion, of uncertain pathogenesis, has been reported in pigs with various conditions, including exudative epidermitis, *E. coli* enteritis, hog cholera, and suppurative arthritis (Brobst et al. 1971), as well as in urinary tract infections.

Ossification of the renal pelvis of unknown etiology has been reported in slaughtered pigs (Bundza 1990).

10 Interpretation of Laboratory Results

Ian A. Gardner and Patricia C. Blanchard

Veterinarians use diagnostic tests to assess the health, productivity, and reproductive status of individual pigs and herds. Although tests can take many forms, including history taking, physical examination, and pregnancy testing, the most frequently used tests are those that involve the submission of samples to a laboratory. Laboratory tests are used to

- Detect pathogens or toxins that are responsible for disease outbreaks or suboptimal production.
- Evaluate the infection/exposure status of individual pigs.
- Determine whether a herd was infected with or exposed to a pathogen and, if so, which age or production groups (subpopulations) were affected.
- Estimate the percentage of herds or pigs with antibodies to an infectious agent.
- Monitor a herd's serologic response to vaccination.
- Monitor the progress and success of disease control and eradication programs.

The optimal approach for each of these objectives may differ; a different test, number of samples, and diagnostic strategy may be indicated depending on the information needed. Choice of tests to answer specified objectives is in part determined by the quality and types of sample that are submitted and in part by the availability of tests at the receiving laboratory or at other collaborating laboratories. Additional factors, such as cost, rapidity, ease of performance of the test, and its accuracy (sometimes termed validity) are important considerations. For many tests that are used for swine diseases, estimates of accuracy (commonly measured as sensitivity and specificity) are not published, although it is common for developers to claim that their tests are both highly sensitive and specific. Also, data on the reproducibility (repeatability) of different tests among and within laboratories often are not available.

Although technical modifications to tests (e.g., antigen purification, use of monoclonal vs. polyclonal antibodies, and use of selective culture media) often improve the ability of the test to discriminate infected from noninfected pigs, it is clear that all tests are imperfect.

In this chapter, we describe the principles that are necessary for rational use of tests and interpretation of their results and provide examples of testing strategies and sample sizes that might be appropriate. The increasing availability of rapid serologic, microbiologic, and parasitologic test kits, polymerase chain reaction (PCR)-nucleic acid probes, immunohistochemistry and in situ hybridization, and the continuing expansion of tests offered by laboratories necessitate an understanding of the diagnostic principles of each test and a careful evaluation of its strengths and weaknesses. Most of our examples involve serologic tests for infectious diseases because these tests are commonly used in swine practice. Issues relevant to test interpretation in both a general (Tyler and Cullor 1989) and a food animal setting (Martin 1988) are described elsewhere, but there are few papers that focus specifically on swine disease. Interpretation of surveillance data for swine diseases is described in Chapter 69.

VARIATION IN TEST RESULTS

Some tests yield only a positive or a negative result (e.g., bacterial and viral isolation), and others (including many hematologic, clinical chemistry, and serologic tests) yield a quantitative result that varies among pigs. Results from quantitative serologic tests are of two types:

- Those, such as serum neutralization (SN), for which results are typically reported as a finite number of doubling dilutions or titers
- Those, such as enzyme-linked immunosorbent assays (ELISAs), in which an infinite number of optical density (absorbance) values or sample-to-positive (S/P) ratios theoretically can occur

Variability in results of a quantitative serologic test arises from two sources:

- Biologic variation in the response of infected and noninfected pigs
- Variation inherent in the test system or assay

Animal Sources of Variation

For infected pigs, the serologic response depends on the duration of infection, challenge dose of organisms, whether the infection is subclinical or clinical, whether disease is systemic or mild and localized, other concurrent infections, and host factors including age. For acute infectious diseases where the agent is removed by the immune system, pigs that were previously infected might no longer be infected when tested, and therefore, it is often more appropriate to describe infected pigs as "exposed." For noninfected pigs, exposure to cross-reacting organisms, vaccination against the agent, or vaccination against other agents through nonspecific immune stimulation might cause elevated responses in some pigs and lead to false-positive serologic results.

Laboratory Sources of Variation

Sources of variation attributable to the test include variation in the way that different laboratories or technicians perform (e.g., use reagents) or interpret the test (interlaboratory or interobserver variability) and variation in interpretation by the same person at different times (intraobserver variability). As evidenced by a comparison of test variables for the immunoperoxidase monolayer assay (IPMA) for porcine reproductive and respiratory syndrome (PRRS) virus among eight European laboratories, test conditions often are not standardized from laboratory to laboratory (Drew 1995). In addition, laboratory errors (e.g., sample mix-up, error in entry of results, and cross-contamination of samples) might also result in false-positive or false-negative results. Most specialized laboratories, however, have internal and external quality assurance programs that ensure that the internal laboratory sources of test variation are small compared with animal sources. In the following examples, variation attributable to sample quality and handling by the veterinarian and the laboratory is ignored. We describe the effects of these factors later in the chapter.

SENSITIVITY AND SPECIFICITY

Gold Standard Test

We assume that the infection or disease status of each pig can be correctly defined by a so-called gold standard (also known as the diagnostic standard, definitive test, or reference test). A gold standard is a method or combination of methods which determine absolutely and without error whether a pig is infected or diseased. For many diseases the true status might be determined only at necropsy, and for some diseases, there is no gold standard. In other cases, this perfect diagnostic method is not practical to use in the field due to cost, labor, or invasiveness, so other, less expensive and more practical methods are often used as a compromise. For some diseases such as postweaning multisystemic wasting syndrome (PMWS), definition of a gold standard is difficult, and a working standard such as "compatible histopathology" is used for laboratory diagnosis. For international trade purposes, tests prescribed in the Office International des Epizooties (OIE) *Manual of Standards for Diagnostic Tests and Vaccines* (www.oie.int/eng/normes/mmanual/A_summry.htm) are considered gold standards even though most tests are not perfectly sensitive and specific.

Sometimes, the gold standard is a combined standard where a positive result from one or more perfectly specific tests is considered positive. Bager and Petersen (1991) compared three selective media for isolation of *Salmonella* spp. from pig feces. Because each culture medium detected some *Salmonella* spp. isolates not detected by the other two media, the gold standard for infection was a positive culture by at least one of the methods. The number of positive cultures by each method was expressed as a percentage of the number of samples that tested positive by one or more methods. One hundred and fifteen isolates were detected. Incubation in Rappaport-Vassiliadis broth for 24 hours in combination with plating on brilliant green agar detected 88% (101/115) of the isolates, compared with 51% (59/115) for the selenite broth.

When culture or antigen detection is used as the gold standard for evaluation of a new test, a negative culture result might be viewed with some suspicion depending on the methods used and whether there is other evidence of absence of infection. Confidence in the use of a negative culture result as a standard can usually be increased by inclusion of larger amounts of tissue or material and by culture of more sites from within the same pig. Sometimes, however, the improvements can be negligible. White et al. (1996) compared the sensitivity of serologic tests for detecting latent pseudorabies virus (PRV) infection 2–27 months after experimental infection. Fifty-one pigs were documented as being infected based on a positive PCR assay result of trigeminal nerve and tonsil. Of the 51 positive pigs, 46 were PCR positive on trigeminal nerve and tonsil, 4 were positive on trigeminal nerve and not tonsil, and 1 pig was positive on tonsil and not trigeminal nerve. Therefore, in field investigations where confirmation of PRV infection is necessary, inclusion of tonsillar samples in addition to trigeminal nerve would offer little practical advantage. Confidence in a negative culture result as a standard also might substantially increase if other criteria are incorporated in the definition of negativity. For definition of absence of *Mycoplasma hyopneumoniae* infection, a negative culture result on a pig from a herd without clinical

or pathologic evidence of infection would be a more appropriate standard than a negative culture result from a pig from an infected herd or from a herd of unknown status.

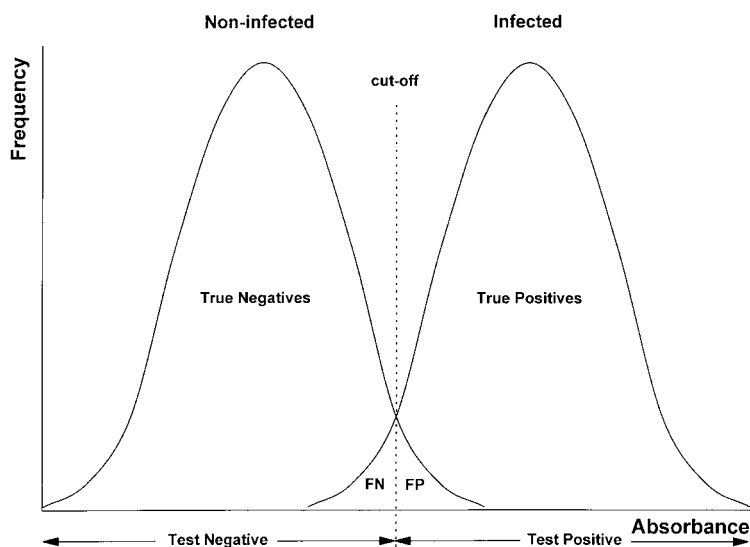
For some viral diseases, SN or other serologic tests are used as the standard against which new serological tests are compared. For example, Weigel et al. (1992) compared the performance of two ELISAs with SN for the detection of antibodies to PRV glycoprotein X, and Lanza et al. (1993) compared a monoclonal antibody-capture ELISA with SN for the serodiagnosis of transmissible gastroenteritis (TGE). The problem with use of a serologic test as the standard against which the sensitivity and specificity of a new serologic test are estimated is that if the original serologic test is of poor accuracy and results of the two tests disagree, it may be difficult to determine whether the new test is more accurate. Many authors, including Martin (1988), recommend only measuring the extent of agreement beyond chance between test results using a kappa statistic. If the results of the new test show a sufficiently high level of agreement beyond chance with the standard test, a decision might be made to substitute the new test based on cost and rapidity and ease of use. Questions about the sensitivity and specificity of the new test, however, would remain unanswered.

Statistical approaches that don't require a gold standard (Hui and Walter 1980; Enøe et al. 2000) offer a promising alternative for obtaining sensitivity and specificity estimates for chronic diseases. These methods have been applied to evaluation of serologic tests for *Actinobacillus pleuropneumoniae* serotype 2 (Enøe et al. 2001), evaluation of the accuracy of detection of slaughter lesions in Danish pigs (Enøe et al. 2003), and the detection of classical swine fever virus in tonsillar tissue (Bouma et al. 2001).

Definition of Terms

Results of a quantitative serologic test such as an ELISA used on samples from known infected and noninfected pigs can be displayed graphically as two overlapping frequency distributions (Figure 10.1). Typically, pigs with test results exceeding a predetermined threshold or cutoff value are classed as positive and pigs with values less than the cutoff are considered negative. In contrast, for some tests, such as particle concentration fluorescence immunoassay (PCFIA) and blocking ELISA, a low test value is more indicative of infection.

Because the distributions of test results of infected and noninfected pigs overlap, the designation of a cutoff value results in misclassification of the infection status of some pigs. Four mutually exclusive categories of results are possible: true positives (test-positive and infected), false negatives (test-negative but infected), false positives (test-positive but noninfected), and true negatives (test-negative and noninfected).

Sensitivity, when used with its diagnostic or epidemiologic meaning, is the probability that the test correctly identifies infected pigs: true positives / (true positives + false negatives). For example, a test with 80% sensitivity would correctly identify an average of 80% of infected pigs as test-positive and would incorrectly identify 20% as noninfected because they tested negative (false negatives). The diagnostic definition of sensitivity differs from the use of the term in an analytic context (Saah and Hoover 1997). In the latter context, the term *sensitivity* is often used interchangeably with the minimal or lower detection limit of the test: the smallest number of bacteria or amount of DNA, toxin, antibody, or residue that can be detected. An immunologically more sensitive test (ELISA compared with SN) would be expected to detect antibodies earlier in the course of infection in an individual pig, but for herd diagnosis where prevalence is mod-


10.1. *Frequency distributions of ELISA results for noninfected (left curve) and infected pigs (right curve). A positive result is an absorbance (optical density) exceeding the cutoff value. (FN = false negatives; FP = false positives.) Although frequencies are depicted as following a normal (Gaussian) distribution, often the distributions are skewed (non-normal).*

erate to high and pigs are at different stages of infection, the need for high sensitivity might not be as great. The contrast in use of the term *sensitivity* is shown in the following example. The PCR for *Mycoplasma hyopneumoniae* is reported by Blanchard et al. (1996) to have a sensitivity (lower detection limit) of between 400 and 5000 organisms per assay. When used on tracheobronchiolar washings, the PCR correctly detected 101/116 experimentally infected pigs (diagnostic sensitivity = 87.1%).

Specificity is the probability that the test correctly identifies noninfected pigs: true negatives / (false positives + true negatives). A test with 90% specificity would correctly classify 90% of noninfected pigs on average as negative and would falsely classify 10% of pigs as infected (false positives). The analogous term in an analytic context is the cross-reaction profile (Saah and Hoover 1997), which indicates the likelihood of cross-reactivity with related pathogens or diseases that present with similar signs. The cross-reaction profile relies substantially on laboratory and clinical experience of the test developers or researchers. For example, a validation study of 8 PCR tests for detection of *Actinobacillus pleuropneumoniae* in tonsillar tissue of chronically infected pigs considered cross-reactions with *A.suis*, *A. minor*, *A.equuli*, *A.lignieresi*, "*A.porcitonsillarum*," and 2 other pathogens often isolated from tonsils, *Streptococcus suis* and *Haemophilus parasuis* (Fittipaldi et al. 2003).

In most field situations, high diagnostic sensitivity and specificity are both desirable although it might be difficult to have both attributes with a single test. Lowering the minimal detection limit of the test will often improve diagnostic sensitivity, depending on the numbers of bacteria, concentration of antibody, etc., typically found in infected pigs, but such a change might lower the specificity of the test. Buyers of pigs and regulatory officials in importing states and countries usually want tests of almost 100% sensitivity to minimize the risk of introducing new pathogens. A similar line of reasoning can also be applied to tests for agents of public health concern—for example, *Salmonella* spp., *Trichinella* spp., and antibiotic residues. Typically, owners of breeding herds want tests of high specificity to maximize their chance of selling replacement boars and gilts. High specificity is also desirable for commercial producers participating in eradication programs based on test and slaughter, where economic losses from false-positive results can be substantial.

One consequence of using multiple imperfectly specific tests is an increased chance of abnormal results in otherwise healthy and nonexposed pigs. The probability of at least one abnormal test result increases as the number of independent tests is increased. For example, suppose that a sow was screened for 10 unrelated bacterial and viral infections. If the sow was never really exposed to any of the agents (unknown to the veterinarian) and each test had a specificity of 95%, the probability that all 10 tests are negative would be 0.95^{10},

or 60%. Hence, the probability that at least one test would yield a positive result is 40%.

Estimation of Sensitivity and Specificity

Diagnostic sensitivity and specificity are determined from experimental and field studies, although it is quite common that an experimental study for an infectious disease will overestimate the sensitivity and specificity of the test when used in the field. One advantage of an experimental study is that it is easier to establish unequivocally a pig's infection status, and the associated serologic response can be followed temporally. From these data, the time to a specified titer value (or time to seroconversion) and duration of titer above the positive cutoff value can be determined. Sørensen et al. (1997) used aerosol challenge of 200 SPF pigs with *Mycoplasma hyopneumoniae* to monitor clinical, serologic, and pathologic responses to the organism and to compare the sensitivity and specificity of culture, immunofluorescence, antigen ELISA, and PCR for detection of the organism in lungs. Because of cost limitations, experimental studies are restricted primarily to infections with short incubation periods but can be very useful for obtaining preliminary data on the sensitivity and specificity of tests and the optimal sampling site. The major limitation of an experimental study is that it may bear little or no resemblance to field situations because the selected experimental conditions are necessarily subjective. In experimental studies, challenge doses are often selected that will ensure clinical disease in most, if not all, pigs, and yet many tests are used in the field to detect subclinical disease in pigs whose immune systems might respond differently because of suboptimal environments and concurrent infections. The control group of noninfected pigs in an experimental study is often comprised of healthy SPF pigs; yet when a test is used for clinical diagnosis, the relevant comparison group of pigs is those with clinical signs caused by pathogens other than the one that the test detects. For example, evaluation of the specificity of an immunochromatographic test for detection of group A rotavirus included samples from pigs with neonatal diarrheas caused by other pathogens (e.g., *Escherichia coli*) as well as samples from healthy rotavirus-free pigs (Klingenberg and Esfandiari 1996).

Even when an experimental infection is used to evaluate a test initially, samples from representative infected and noninfected pigs (age, clinical status, stages of infection, etc.) from commercial herds should be assessed to ensure that test performance is adequate for naturally acquired infections. Test results should be compared with the gold standard (reference test) in a blinded fashion to avoid introducing bias. Sensitivity and specificity and their respective confidence intervals are calculated. As sample sizes to derive these values increase, sensitivity and specificity estimates become more precise, as reflected by narrower confidence intervals. Epidemiologic
10.2. *Frequency distributions of modified agglutination test titers for* Toxoplasma gondii *for infected and noninfected pigs based on the data from Table 10.1 (Dubey et al. 1995).*

Table 10.1. Modified agglutination test titers for *Toxoplasma gondii* for 170 infected and 830 noninfected sows.

Titer	Infected (n = 170)	Noninfected (n = 830)
<20	29	749
20/40	25	31
80	25	25
200	20	12
320/400	21	10
800	21	3
1280/4000	23	0
≥8000	6	0

Source: Adapted from Dubey et al. (1995).

Table 10.2. 2 × 2 table for hypothetical frequency distributions for modified agglutination test (MAT) results.

		Infection Status	
		+	−
MAT Result	+	141	81
	−	29	749
		170	830

sensitivity = 141/170 = 0.829 (95% confidence interval, 0.764–0.883)
specificity = 749/830 = 0.902 (95% confidence interval, 0.880–0.902)

considerations for test evaluation studies are described in detail elsewhere (Greiner and Gardner 2000a).

Example. Dubey et al. (1995) evaluated the sensitivity and specificity of five diagnostic tests for toxoplasmosis in pigs. The gold standard was isolation of viable *Toxoplasma gondii* by cat or mouse bioassay using heart muscle collected from sows at slaughter. Sows whose samples yielded a positive bioassay result on either bioassay (n = 170) were considered infected, and sows whose samples yielded a negative bioassay result (n = 830) were considered noninfected. Although frequencies of titer values for infected and noninfected sows were not reported in the paper, we generated two hypothetical frequency distributions for modified agglutination test (MAT) results consistent with the published data. Table 10.1 and Figure 10.2 show that results for noninfected and infected pigs overlap over an extensive range of titers (<1:20 to 1:800).

In the study, MAT results were considered positive if titers were ≥1:20, and negative if otherwise. Categor-

ized results were cross-tabulated in a 2 × 2 table, and sensitivity, specificity, and exact binomial confidence intervals were calculated; see Table 10.2.

If a cutoff with 100% specificity is preferred for serologic diagnosis, the cutoff for the MAT would need to be increased to 1:1280. At the cutoff of 1280, however, only 29/170 infected sows (sensitivity = 17.1%) would be correctly identified. These changes in estimates demonstrate the compromise between sensitivity and specificity that is inherent in changing the cutoff value of a quantitative test. Shifting the cutoff point to a lower value will usually increase sensitivity at the expense of specificity and vice versa. In this example, a perfectly sensitive cutoff could not be defined because both infected and noninfected pigs gave negative results at the lowest screening dilution for the test (1:20). The authors discussed the limitations of their gold standard and indicated that false-negative bioassays may have occurred because *T. gondii* were located in tissues other than cardiac muscle or because *T. gondii* were not isolated from inoculated animals even though they

were present. Accordingly, if some test-positive pigs that were classed as noninfected by the bioassay were truly infected, the specificity of the MAT might have been underestimated.

Evaluation of a Test at Various Cutoff Values

Sensitivity and specificity values are useful for determining a test's diagnostic limitations and comparing the accuracy of two or more tests. Because many cutoff points are possible for a quantitative test, comparison of tests over a range of cutoff values is often more appropriate than comparison at a single value. The trade-off between sensitivity and specificity as the cutoff value is changed may be represented graphically as a receiver-operating characteristic (ROC) curve (Zweig and Campbell 1993; Greiner et al. 2000). ROC curves, which are graphs of sensitivity (y-axis) versus specificity or 1-specificity (x-axis) for all possible cutoff values of a test, are well accepted in human medicine as a method to quantify test performance. Their acceptance in veterinary medicine and use for swine diseases has been limited. Nodelijk et al. (1996) used an ROC curve to represent the accuracy of a commercial ELISA for PRRS virus, and Elbers et al. (2002; 2003) used ROC analysis to evaluate the use of clinical signs and gross lesions at postmortem to detect outbreaks of classical swine fever in the 1997–1998 epidemic in The Netherlands.

Using the data in Table 10.1 for the *T. gondii* MAT, all sensitivity and specificity pairs at cutoff points from 1:20 to ≥1:8000 were calculated and graphed as an ROC curve (Figure 10.3). The area under the curve (AUC), below and to the right, can be interpreted as the probability that a randomly selected infected pig will have a MAT result greater than a randomly selected noninfected pig. For these data, the AUC was estimated to be 0.88. The cutoff value closest to the upper-left corner of the figure (≥1:20) is the point that minimizes the number of misclassifications (false positives and false negatives), but as indicated in the following section, other factors are important in selection of a cutoff value.

Selection of Test Cutoff Values

Several factors are considered in selection of test cutoff values, including the purpose of the testing (e.g., screening vs. confirmation), the relative costs (economic, social, or political) of false-positive and false-negative diagnoses, the availability of confirmatory tests of high specificity, and the prevalence of disease (Greiner et al. 2000). Indeed, various cutoffs might be appropriate given different circumstances for testing and consequences of misclassification (costs of a false-positive result compared with costs of a false-negative result). For simplicity, many diagnostic laboratories report results of ELISAs and other tests as positive or negative at a single cutoff. There are two drawbacks to this approach. First, when the cutoff is chosen by the laboratory or test kit manufacturer, and the result is reported only as positive or negative, information is lost to the practitioner. When an S/P ratio for an ELISA or a titer value is well beyond the cutoff value used for test interpretation, a practitioner usually has a stronger belief that a pig is truly infected than if the test result is close to the cutoff value. In the *T. gondii* example, a MAT titer of 1:800 is more likely to come from an infected sow than a titer value of 1:20 (refer to Table 10.1). Likelihood ratios, which range from 0 to infinity, quan-
10.3. *Receiver-operating characteristic curve for the modified agglutination test for* Toxoplasma gondii *based on the data from Table 10.1 (Dubey et al. 1995).*

tify how many times more frequently a specific titer value is obtained from infected compared with noninfected pigs. Second, the cutoff chosen by the laboratory may be the one that minimizes the total number of errors, both false positives and false negatives, but it may not take into account the different costs of the two types of misdiagnosis. Depending on the situation, a false-positive diagnosis may be much more damaging than a false negative and vice versa. For example, a veterinarian relying on the results of a test to make a decision about culling a sow probably wants to minimize the chance of a false-positive diagnosis by using a highly specific test, particularly if the sow is asymptomatic and pregnant and there are no other reasons for culling. On the other hand, when screening breeding pigs for purchase into a herd, a false-positive result would be much less harmful to a client than a false-negative, which might allow infected pigs to enter a noninfected herd. Ideally, practitioners need the information to choose the cutoff that best meets their decision requirements at a particular time.

One possible solution to the dilemma of where to set the cutoff value for individual-pig diagnosis is to specify two cutoffs—one value that is 100% sensitive (no false negatives) and another that is 100% specific (no false positives). These cutoffs define an intermediate range of values where false-positive and false-negative results occur. Using this approach, results are reported as negative if they are less than the cutoff value that is 100% sensitive, as positive if they are greater than the cutoff value that is 100% specific, and as suspicious or indeterminate if they are between these values. Suspicious or indeterminate values might be clarified by additional tests, if warranted.

Evaluating Published Sensitivity and Specificity Values

Although sensitivity and specificity estimates might be available on test kit inserts or in industry publications or might be obtained from laboratory diagnosticians, the veterinary medical literature should be consulted, wherever possible, as the most reliable source. Regardless of the source of estimates, practitioners should ask appropriate questions about how the test was validated and how the test will be used:

1. Was the test evaluated under field conditions similar to those in which it will be used?
2. Were test results evaluated with respect to the gold standard in a blinded fashion?
3. Were the positive and negative gold standards appropriate choices given existing technology?
4. Were adequate numbers of representative infected and noninfected pigs included in the study so that sensitivity and specificity estimates are precise? At least 100 infected and 100 noninfected pigs should be used in validation studies, wherever possible.

5. Why was the chosen cutoff value selected, and are estimates of sensitivity and specificity reported at other cutoff values?
6. Will the test be used for individual or herd diagnosis? A test that has low to moderate sensitivity at an individual level might be perfectly appropriate for herd diagnosis if adequate numbers of tests are done and the test has high specificity.
7. Will the test be used by itself or in combination with other tests? If the test is used in combination with other tests, how will multiple test results be interpreted?

If claims are made in publications that one test is more sensitive or more specific than another test, these claims should be based on tests of duplicate samples and appropriate statistical analyses. Often a closer evaluation of the claims shows that the numeric difference in sensitivity or specificity is small and not statistically significant or practically important. If true, other criteria such as cost, ease of use, and rapidity of use become more important in test selection.

PREDICTIVE VALUES

The major advantage of sensitivity and specificity as measures of test accuracy is that they are independent of prevalence and therefore are particularly useful for reporting test performance in the veterinary medical literature. However, these measures have shortcomings in the field, where the diagnostic value of a test varies with the test's inherent accuracy and also with the situation in which the test is used. Because absolute determination of a pig's infection status often is not feasible or economically justified, a veterinarian must estimate the likelihood of infection or absence of infection given test results. These likelihoods are the predictive values of positive and negative test results. Positive predictive value (PPV) is the proportion of the test-positive pigs that are truly infected, and negative predictive value (NPV) is the proportion of test-negative pigs that are truly noninfected.

The distinction between predictive values and sensitivity/specificity might at first seem unclear. Sensitivity and specificity provide estimates of test accuracy given that the disease status is known, whereas predictive values estimate test accuracy given that the test results are known.

Predictive values (also known as posttest or posterior probabilities) are dependent on sensitivity, specificity, and prevalence and can be calculated using Bayes' theorem formulas:

$$PPV = (\text{sensitivity} \times \text{prevalence})/[\text{sensitivity} \times \text{prevalence} + (1 - \text{specificity}) \times (1 - \text{prevalence})]$$

$$NPV = [\text{specificity} \times (1 - \text{prevalence})]/[\text{specificity} \times (1 - \text{prevalence}) + (1 - \text{sensitivity}) \times \text{prevalence}]$$

Effects of Prevalence on Predictive Values

Clinically, the term *prevalence* means the best estimate of the probability of disease before performing the test. Prevalence is used synonymously with the term *pretest* or *prior probability*. Wherever possible, estimates of prevalence should be based on prior data: for example, frequency of the condition among all cases with similar presenting signs, prior test results for the herd, or test results from herds of similar size in the same geographic area. In the absence of prior data, the following values of prevalence might be reasonable starting values for calculations of predictive values:

1%   Pigs with risk factors for a common disease but without clinical signs, or a herd with no previous history of infection

10%   If a disease is unlikely but possible clinically and a veterinarian wishes to rule it out

50%   If there is substantial uncertainty but the clinical presentation is compatible with the disease

90%   When a disease is very likely clinically or if the herd has a prior history of infection but a practitioner wishes to rule it in using a diagnostic test

To "rule out" disease, a negative result on a highly sensitive test is necessary. This might be done in the initial stage of a diagnostic workup to reduce the number of possibilities on the differential list. To "rule in" or confirm a diagnosis, a positive result is necessary with a nearly perfectly specific test. In general, when a veterinarian does not believe that a disease is present (prevalence $\leq$10%) or strongly believes that it is (prevalence $\geq$90%), the test result often does not substantially influence the diagnosis (Martin 1988). Laboratory tests tend to be of greatest value in establishing a diagnosis when a practitioner is most uncertain about infection status (i.e., when presence and absence of infection are equally likely, which is equivalent to a prevalence of 50%).

The effect of prevalence on predictive value can be demonstrated by considering the performance of the MAT test for *T. gondii* (sensitivity = 82.9% and specificity = 90.2%) in two populations, one with a 20% prevalence of infection, which is similar to the prevalence in Dubey et al. (1995), and one where control of *T. gondii* infection is effective and the overall prevalence is 1% (Table 10.3). At 20% prevalence, the positive predictive value of 67.9% indicates that about two in every three pigs with test-positive results is truly infected. At the same prevalence, the negative predictive value is approximately 95%. Hence, the probability that a test-negative pig is truly infected (1 − negative predictive value) is 5%. For the same test at 1% prevalence, the positive predictive value decreases to less than 15% and the negative predictive value becomes almost 100%.

Predictive Value Curves

Prevalence is often not known exactly and a range of values is possible. Predictive value curves can be gener-

Table 10.3.   Performance of the MAT test for *T. gondii* (sensitivity = 82.9% and specificity = 90.2%).

prevalence = 20% (assuming a population size of 10,000)

		Infection Status		
		+	−	
MAT Result	+	1658	784	2442
	−	342	7216	7558
		2000	8000	10,000

prevalence = 2000/10,000 = 0.2
positive predictive value = 1658/2442 = 0.679
negative predictive value = 7216/7558 = 0.955

prevalence = 1% (assuming a population size of 10,000)

		Infection Status		
		+	−	
MAT Result	+	97	554	651
	−	3	9346	9349
		100	9900	10,000

prevalence = 100/10,000 = 0.01
positive predictive value = 97/651 = 0.149
negative predictive value = 9346/9349 = 0.999

ated to show how well the test performs in different circumstances. At moderate prevalences (30–70%), most tests, including the MAT (Figure 10.4), perform well regardless of whether results are positive or negative. As prevalence increases above 70%, positive predictive value increases toward 100% with an associated decrease in negative predictive value. As prevalence decreases toward 0%, positive predictive value decreases while negative predictive value increases.

When testing for rare conditions, test specificity is the most important determinant of positive predictive value. As specificity increases at a fixed prevalence value, positive predictive value increases. Only if the test is close to 100% specific will the problem of low positive predictive value be avoided when infection is rare (Figure 10.5).

Practical Implications

The implications of these relationships can be summarized as follows. Given a certain test sensitivity and specificity, a positive finding in a herd without clinical signs or previous history of infection should be interpreted differently from a positive test result in a herd where the infection is endemic and clinical disease is common. However, it is important to note that the clinical usefulness and value of a positive test result are not measured by the positive predictive value (posttest probability) but by the change in probability or diagnostic certainty brought about by use of the test. For example, if a herd had a clinical disease event consistent with either swine influenza or PRRS and the herd had no prior history of either infection but both infections were being commonly diagnosed in other herds at the time of
10.4. *Predictive value curves for the modified agglutination test for* Toxoplasma gondii *with sensitivity equal to 82.9% and specificity equal to 90.2%.*
10.5. *Effect of specificity of a laboratory test with a sensitivity equal to 100% on a predictive value of a positive test for prevalence between 0% and 10%.*

the investigation, a practitioner might believe that the pretest probability of each infection was 50%. Isolation of PRRS virus through laboratory testing, assuming perfect specificity, would result in a posttest probability of 100% for PRRS (a 50% gain in probability). If, however, the herd had the same clinical episode and a recent history of PRRS infection, the pretest probability would be higher, perhaps 80%, and even though the posttest probability of PRRS was still 100%, the gain in certainty (20%) would be much smaller. Therefore, the value of

the laboratory test in the second situation would be less than the first, which has more diagnostic uncertainty. Similar reasoning can be used to assess the gain in certainty from negative test results.

USE AND INTERPRETATION OF MULTIPLE TESTS

To improve diagnostic accuracy, tests might be repeated or additional tests might be included in the diagnostic

workup. Indeed, most diagnoses are based on the use of multiple tests (e.g., history, physical examination, laboratory tests, etc.). Multiple tests can be used either simultaneously or sequentially and results interpreted in series or parallel. The sensitivity and specificity of a combination of tests differ from the individual sensitivity and specificity values. Interpreting combinations of tests in parallel results in higher sensitivity than any of the individual tests, and interpretation in series results in higher specificity than any of the individual tests. Sometimes, the change in sensitivity and specificity of the combination of tests is less than theoretically predicted because the test results are correlated (also termed *dependent*) for infected or noninfected pigs (Gardner et al. 2000). Correlated results would be expected for serologic tests that measure the same class of antibody but would be far less likely with two tests that measure different biologic responses (e.g., histopathology and serologic testing).

Parallel and Series Interpretation

When two tests are used, one of four results is possible: both tests positive, test 1 positive and test 2 negative, test 1 negative and test 2 positive, and both tests negative. In parallel interpretation, a pig is considered positive if it reacts positively to either test—this increases sensitivity but tends to decrease the specificity of the combined tests. This parallel testing strategy works well when neither test has a particularly high sensitivity but each detects a different type of disease (e.g., early vs. late, rapidly progressing vs. slowly progressing). Culture for a pathogen might be more sensitive than serologic testing early in the course of an infection, but the latter might be more sensitive later in the infection as the pathogen load decreases. Parallel testing with culture and serology should therefore lead to higher sensitivity, although specificity of the combination would be lower than if culture was used alone.

In series interpretation, a pig must be positive on both tests to be considered positive; this increases specificity at the expense of sensitivity. The use of two tests in series might lead to a diagnosis in the following way. The first test might be very sensitive and inexpensive and pigs that test positive are retested with a second test of high specificity to identify false positives. As a cost-saving measure, pigs testing negative on the first test are considered negative and are not tested with the second test. This testing strategy allows veterinarians to rule out disease using fewer tests, although serial testing often takes more time. The probability of disease after both tests are positive is calculated by regarding the predictive value of a positive after the first test as the same as the prevalence of disease before performing the second test. In the example of the MAT for *T. gondii*, the positive predictive value was 67.9% when the test was used in a population with 20% prevalence. If pigs with a positive MAT result were tested with an additional test—for ex-

ample, a latex agglutination test (LAT) with sensitivity of 45.9% and specificity of 96.9% (Dubey et al. 1995)—the value of 67.9% would become the new prevalence before running the LAT test. Substitution of these values in the Bayes' theorem formula would yield a positive predictive value of 96.9% after the second test, assuming that MAT and LAT results were uncorrelated. If the assumption of no correlation was correct, positive results on both the MAT and the LAT would be more indicative of infection than a positive result on the MAT alone.

Choosing Among Testing Strategies

To establish a diagnosis when two tests are available, a veterinarian might decide to use a single test or use both tests. The latter choice incurs additional costs, which need to be passed on to the client. If both tests are used, parallel or series interpretation can be selected depending on the need to emphasize sensitivity or specificity, respectively. As demonstrated in the brucellosis example that follows, the benefits of multiple serologic tests to detect the same pathogen are often less than expected because of correlation between test results. Factors that need to be considered in the final selection of a testing strategy include the sensitivities and specificities of the individual tests, the sensitivities and specificities of the combination of tests when interpreted in series or parallel, costs of false-positive and false-negative diagnoses, prevalence of infection, and the additional costs incurred by adding more tests.

Example. Ferris et al. (1995) estimated the sensitivity and specificity of six serologic tests for brucellosis in 231 swine using bacteriologic culture results from multiple lymph nodes as the gold standard. Sensitivities ranged from 57% (automated complement fixation test) to 85% (particle concentration fluorescence immunoassay [PCFIA] with a cutoff value of 0.81), and specificities ranged from 62% (standard tube test [STT]) to 95% (rivanol test). Sensitivities of the PCFIA and STT were estimated as 85% and 83%, respectively, and specificities were 74% and 62%, respectively. When results of the PCFIA and STT were interpreted in parallel (a positive on any test being considered positive), the sensitivity of the combined tests was 87% and the specificity was 54%. The use of both tests interpreted in parallel yielded a 2% improvement in sensitivity over the higher of the two tests and an 8% loss in specificity compared with the less specific test. Assuming that the two test results were uncorrelated, the sensitivity of the combined tests theoretically should have been 98% and the specificity should have been 46%. The most likely explanation for the difference between the observed and expected values is that the test results were correlated. In this case, use of PCFIA and STT together would increase diagnostic cost for little gain in information. Indeed, even when results of the four additional tests were considered and

interpreted in parallel, the sensitivity of the combination did not further increase (40/46 were positive on one or more tests).

Herd-Level Interpretation of Test Results

Assessment of the health status of a population unit (herd, barn, litter, or other grouping of pigs) often is more important than that of an individual pig in the group. A key point that is not widely understood is that herd-level tests must be interpreted differently from individual tests. Interpretation of herd test results often is more complicated, especially when tests are imperfectly specific.

Herd Infection Status

Correct classification of herd status, with respect to one or more pathogens, is important in specific pathogen free (SPF) and other health certification schemes, in assessments of disease introduction risk associated with purchase of pigs, and in studies of risk factors for disease. Similar to the situation for test interpretation for individuals, data are needed on the herd-level sensitivity and specificity of the test being used to determine herd status. The likely performance of a herd test is usually extrapolated from published individual sensitivity and specificity values as described in Martin et al. (1992). With the exception of *Mycoplasma hyopneumoniae* in the Danish SPF scheme (Sørensen et al. 1992; Sørensen et al. 1993), there are few published field studies that have estimated the performance of herd tests used for swine diseases.

Herd Sensitivity and Specificity. Herd-level sensitivity is the probability that an infected herd yields a positive herd-test result, and herd-level specificity is the probability that a noninfected herd yields a negative herd-test result. The respective false-negative and false-positive herd rates can be calculated by subtracting herd sensitivity and herd specificity values from 1. Herd-level sensitivity and specificity depend not only on the respective individual-level sensitivity and specificity values but also on other factors: the number tested, the prevalence of infection within infected herds, and the number of positives (1, 2, 3, etc.) used to classify the herd as positive (Martin et al. 1992; Christensen and Gardner 2000). Usually the individual and herd-level estimates differ. Based on findings from an experimental infection study of 200 SPF pigs (Sørensen et al. 1997), the blocking ELISA for *M. hyopneumoniae* has an individual sensitivity and specificity of 100% and 100%, respectively, at the cutoff of 50% blocking. When samples from 20 pigs are used for herd diagnosis of *M. hyopneumoniae* infection in the SPF scheme, the herd-level sensitivity and specificity were 93% and 96%, respectively, when at least one ELISA positive pig designated a positive herd test (Sørensen et al. 1992). The estimates of herd sensitivity were imprecise because only 15 new infections were

detected during the study period. A follow-up study yielded similar estimates (Sørensen et al. 1993).

Some important relationships among factors affecting herd-level sensitivity and specificity warrant comment. First, as the number tested increases, herd-level sensitivity increases. Consequently, the probability of a false-negative herd diagnosis decreases with increasing sample numbers at all values of within-herd prevalence. An increase in sample numbers from 10 to 20 for a perfectly specific test with sensitivity of 50% produces a greater reduction in the probability of a false-negative herd diagnosis if the underlying prevalence is moderate rather than low (30% vs. 1% in Figure 10.6). Second, as the number of pigs used to classify the herd as positive is increased, there is a corresponding increase in herd-level specificity with a decrease in herd-level sensitivity. A change in the number of test-positive pigs in a sample of 20 from at least 1 to at least 2 decreased herd sensitivity for *M. hyopneumoniae* in the Danish SPF system from 100% to 69% but increased herd specificity from 85% to 98% (Sørensen et al. 1993). Third, when testing a fixed number of samples, it is easier to discriminate infected from noninfected herds as within-herd prevalence increases (refer to Figure 10.6). Fourth, as the number of pigs tested with an imperfectly specific test increases, the probability of detecting at least one false-positive pig increases, leading to a lower herd-level specificity (Figure 10.7). This is the same effect that was noted when multiple tests of imperfect specificity were used to evaluate the infection or pathogen exposure status of an individual pig. Testing of pooled rather than individual samples can be used for herd diagnosis (e.g., culture of fecal pools for *Salmonella* spp.; Christensen et al. 2002). Factors affecting the herd sensitivity and specificity of pooled tests are described elsewhere (Christensen and Gardner 2000).

Issues to be considered in the trade-off between herd sensitivity and herd specificity are as described for individual test interpretation. For SPF schemes, herd-level sensitivity is considered more important than herd-level specificity because the costs of failing to detect infection usually outweigh the costs of a false-positive diagnosis in some herds.

Herd-Level Predictive Values. Herd-level predictive values, which are analogous to individual test predictive values, are dependent on herd sensitivity and specificity and the prevalence of infected herds. In this context, prevalence of infected herds means the best guess of the probability that a herd is infected before doing the herd test. Although such estimates might be obtained from state or national surveys, local data based on knowledge of the infection status of herds visited by a veterinarian would be more appropriate. In Denmark, it has been estimated that about 10–15% of SPF herds become reinfected with *M. hyopneumoniae* each year. If 1% is used as the likely prevalence of infected herds as detected by a
10.6. *Effect of sample size and within-herd prevalence on the probability of a false-negative herd diagnosis (1—herd sensitivity) for a test with an individual-level sensitivity of 50% and individual-level specificity of 100%.*
10.7. *Effect of sample size and specificity of a laboratory test on the probability of a false-positive herd diagnosis (1—herd specificity).*

single monthly sampling of 20 pigs, and then using Bayes' theorem and the herd-level sensitivity and specificity estimates of 93% and 96% reported by Sørensen et al. (1992), the positive and negative herd-level predictive values are 19% and 99.9%, respectively. These calculations indicate that only about 1 in 5 test-positive herds is confirmed as infected when followed up by gold standard methods, yet a negative herd test provides strong evidence of freedom from *M. hyopneumoniae* infection.

Because of the lack of sensitivity and specificity data for many individual tests, herd-level sensitivity and specificity and predictive values usually are unknown. Frequently, veterinarians are required to interpret herd results with incomplete knowledge of individual test performance. The number of positive pigs and the apparent prevalence of infection (0–100% test-positive pigs) are both considered in determining the status of the herd. If the seroprevalence is high, the answer to the question about the exposure status of the herd is clear. But what if a low seroprevalence (e.g., <20%) is detected when the herd is tested? In these situations, knowledge of specificity alone would facilitate judgments about the herd's infection status. This question has important practical implications because it is more difficult to use laboratory tests to discriminate herds with a low, rather than a high, prevalence of infection from noninfected herds.

Example. If all sows in a 100-sow nonvaccinated breeding herd were tested by complement fixation test (CFT) for *Actinobacillus pleuropneumoniae* serotype 2 (AP2) and 5 test-positive sows were detected (i.e., seroprevalence is 5%), what can we conclude about the AP2 status of the breeding herd? Without knowing test characteristics, one approach in the absence of a detailed herd history might be to slaughter test-positive sows and culture the upper respiratory tract, including tonsils and nasal cavities, to determine whether AP2 was present. A positive culture would confirm infection, but a negative culture would not rule out infection since culture is imperfectly sensitive. Recently, various PCR assays have been shown to be more sensitive than standard isolation methods on tonsillar tissue (biopsies and whole tonsil collected at slaughter) and would offer an alternative diagnostic strategy for evaluation of the microbiologic status of seropositive sows (Fittipaldi et al. 2003).

If a published estimate of CFT specificity were available, however, a more rational judgment could be made that might avoid unnecessary slaughter and culture of test-positive sows. First, if the CFT had specificity of 95%, the expected number of positives in a noninfected herd of 100 sows would be 5; exactly what was found on the test. Second, if specificity was <95%, the belief that these were false positives would increase since the expected number of false positives even in a noninfected herd would be >5. Third, if the specificity of the test was approximately 99% (as estimated in Enoe et al. 2001),

detection of 5 test-positive pigs would be highly suggestive of infection in the herd.

The conclusions that were made in the example would be less well met in the situation where interpretation was based on a small sample of the herd rather than the whole herd. Even when 30 samples are randomly collected in a large herd, the proportion of positive samples may not always reflect the underlying proportion of positive pigs in the herd (Carpenter and Gardner 1996). Guidelines for selection of an appropriate sample size for evaluation of herd status are described in a following section.

Prevalence Estimation

An estimate of the proportion of infected pigs often is necessary as part of national and regional health-monitoring schemes and for making decisions about vaccination and other disease control and eradication programs. If a random sample of pigs is tested for exposure to an infectious agent, the proportion of positive test results (number positive/number tested) is an estimate of the apparent (test-based) prevalence of infection. If the test is serologic, the term *seroprevalence* is used interchangeably with *apparent prevalence*. The apparent prevalence may over- or underestimate the true prevalence, depending on the sensitivity and specificity of the test that is used. True prevalence can be estimated from apparent prevalence by correcting for the imperfect sensitivity and specificity of the test (Rogan and Gladen 1978):

> true prevalence = (apparent prevalence + specificity −1) / (sensitivity + specificity-1)

Confidence intervals for the estimate of true prevalence should be calculated, and for this the reader is referred elsewhere (Greiner and Gardner 2000b). The precision of the estimate or a practitioner's confidence in the accuracy of the estimate is primarily dependent on sample size, with larger samples yielding more precise estimates. Occasionally the calculation yields a negative or zero estimate for true prevalence: such a finding might suggest that the herd is not infected. If sensitivity and specificity are unknown, however, this formula cannot be applied and the true prevalence of infection in the population cannot be calculated directly.

Examples. Assume that a seroprevalence estimate of 15% was obtained when sows in a herd were screened for *T. gondii* using the MAT of sensitivity = 82.9% and specificity = 90.2%. What is the true prevalence of infection in the herd? By substitution of the values in the equation, true prevalence = (0.15 + 0.902 − 1)/(0.829 + 0.902 − 1) = 0.071 (7.1%). This estimated true prevalence is only about one-half of what the test suggests is present, indicating that about 50% of the positive tests are false positives.

Baggesen et al. (1996) found an apparent prevalence of *Salmonella* spp. infection of 6.2% in Danish slaughter pigs based on culture of 5 g of cecal contents. Although the sensitivity of culture can depend on the volume of contents examined and choice of selective medium, the procedure was estimated to be 50% sensitive and 100% specific. Because only 50% of the infected pigs would have been detected by culture, prevalence would have been underestimated twofold. Hence, true prevalence would be 6.2% × 2 = 12.4%.

SAMPLE QUALITY AND OPTIMAL LABORATORY INTERPRETATION

For optimal interpretation of results of animal and tissue submissions to a diagnostic laboratory, a thorough herd history—which includes morbidity and mortality, age of onset, sequence of clinical signs, time from onset to recovery, response to therapy, and recent management and environmental changes—should be obtained. Evidence of differences in incidence or prevalence among different age groups of pigs or those housed under different management conditions could yield important information about the disease agent(s). Valuable insight into a diagnostic investigation often is gained by asking the producers what they suspect is the cause and why they suspect the health or production problem recently occurred. The response to this inquiry also might yield useful information on other issues, which need to be addressed during the farm visit and help focus the laboratory testing.

Goals of Submission and Sample Collection

After completely assessing the problem, the veterinarian and producer should jointly agree on the goals of performing laboratory testing, because this will be critical in selecting appropriate types and numbers of samples from the correct pig groups. The goal of laboratory testing should likewise be communicated to the laboratory performing the testing; laboratory consultation before submission often is valuable to ensure samples are collected, processed, and shipped in a manner which will allow optimal results (i.e., freezing may decrease the recovery of certain bacteria and viruses or may be essential to maintain viability of other agents). Sample collection for detection of toxins may require freezing for labile toxins (i.e., cyanide) or special and individual packaging for toxins which are diffusible or can be contaminated by contact with plastic (i.e., polychlorinated biphenyls) or rubber (i.e., zinc). During consultation with a laboratory diagnostician, the veterinarian should be sure to request information on the various testing methods available and their strengths and weaknesses in detecting the agent(s) of interest, which may vary with the syndrome under investigation and the stage of infection (for PRRS, see Benson et al. 2002, Rossow 1998). The laboratory's ability to detect the agent in the syndrome suspected, quality control procedures used to ensure the test method is working, and, most importantly, whether the laboratory has ever detected this agent before are important issues to be addressed prior to submission.

Selection of Pigs

After the goal is decided and the specimen type and shipping requirements have been determined, it is critical to select pigs for sampling or submission that will provide the information necessary to meet the predetermined goals. For example, if the goal is to determine the initiating cause of a herd outbreak of respiratory disease with high morbidity but low mortality, several agents will be of particular interest to the veterinarian. Diagnosis might require sampling of pigs during the acute phase of illness if the isolation of the agent is desired, whereas sera from acute and convalescent pigs or sera from three groups—nonexposed, acutely infected, and recovered pigs—are more appropriate to confirm the presence of the agent through an immunologic response in infected animals. If, however, the goal is to determine what complicating factors might be leading to the low mortality because most affected pigs recover, pigs late in the disease process will be more appropriate, recognizing that the initiating agent(s) may no longer be present or may be masked by the presence of secondary invaders.

Although gross pathology and histopathology are the diagnostic disciplines that have been the least evaluated in a quantitative manner, this testing is commonly used to diagnose disease problems. Ideally, the veterinarian should be involved in selecting pigs for necropsy to ensure they meet the criteria decided upon. If the veterinarian is unavailable to select the animals, clear communication with the producer on the type of pig required and reasons for the choice will assist the laboratory in providing optimal return for the investment of time and money to perform diagnostic testing. Evaluation of gross lesions and/or histopathology for the early detection of several swine diseases such as classical swine fever and *Lawsonia intracellularis* has shown these methods to be both insensitive and nonspecific (Elbers et al. 2003; Huerta et al. 2003). Therefore, the veterinarian should be cautious when relying on field necropsies alone to either diagnose or exclude various diseases particularly in their early stages.

Additional Considerations

For optimal serologic testing, the quality of serum samples is important. SN tests, for example, are especially susceptible to sample hemolysis and bacterial and chemical contamination of samples. Accordingly, to decrease the risk of samples being toxic to cells in the assay, blood should be collected using sterile equipment, and serum should be separated from the clot and chilled during submission. Toxic samples should not lead to false-positive or false-negative results, but practitioners

and owners might be inconvenienced or incur additional costs if pigs need to be resampled (Hill 1988).

Laboratories commonly use PCR-nucleic acid probe assays on fresh tissues or body fluids and immunohistochemistry (IHC) on formalin preserved samples for the detection of infectious agents. Both procedures offer the advantage of not requiring the presence of viable organisms. Both methods have also provided critical information on determination of optimal sampling sites, frequency of repeat sampling, and numbers of samples from one organ to attain a high sensitivity (for PRRS, Benson et al. 2002, Rossow 1998, Yaeger 2002). For example, Yaeger (2002) determined that the likelihood of detecting PRRSV infection in the lung by IHC increased from 48% to >90% when the number of lung sites tested was increased from one to five. PCR has the added advantage of detecting much lower levels of the agent; thus it has a higher sensitivity, but this does not always correlate with a better positive predictive value for the syndrome under investigation as was found with PMWS (Pogranichniy et al. 2002). In fact, increased use of PCR has provided valuable information on the frequency of asymptomatic, subclinical, and carrier states for a number of agents. PCR, because of its much lower detection limit, is more susceptible to problems arising from cross-contamination between sites within the same animal, such as normal nasal flora contaminating lung sites or between animals when using common instruments or gloves during sample collection and processing or when samples are collected in an environment that contains the agent in the air, such as *M. hyopneumoniae* (Kurth et al. 2002). Poorly validated PCR tests may also result in false-positive results through detection of near-neighbor agents, such as bovine viral diarrhea virus with a classical swine fever PCR.

After laboratory testing of samples is completed, interpretation of the results on a herd basis should include evaluation of the agreement of the herd history with the laboratory's gross findings and the individual histories of the pigs submitted. For example, if pigs of appropriate age are submitted to determine the cause of postweaning diarrhea but the gross findings indicate normal feces and significant pneumonia, or if fecal samples are submitted from 10-week-old emaciated pigs, the findings in both cases will be of little or no value in determining the cause of postweaning diarrhea. However, the results in the former case disclose a previously unrecognized respiratory disease. In the latter example, the age and nutritional status indicate pigs are growing poorly, and some agents that initiate postweaning diarrhea (i.e., hemolytic *E. coli*, TGE, or rotavirus) will no longer be present. Another key element in the necropsy report, which complicates interpretation of the results, is the presence of injection sites or medication in the gastrointestinal tract. The use of parasiticides or antibiotics can suppress or kill potential agents under investigation, resulting in false-negative results.

In order to correlate test results with the presence of pathologic lesions or clinical disease, it is important that the samples are labeled with unique animal identifications. The submission paperwork should also indicate the number of pigs sampled. In the absence of identifying information, tissue, swabs, feces, or serum samples from multiple pigs might be assumed to be from the same animal and pooled or only a portion of the samples might be tested.

CAUSE AND EFFECT

Almost all infectious diseases in swine production are multicausal, with environmental and management factors playing a central role in the clinical expression of overt disease and in the determination of a disease's effect on productivity. PMWS is an excellent example of the influence of multiple factors on the expression of clinical disease (Pogranichniy et al. 2002). Although a diagnostic laboratory can help identify agents potentially involved in a disease outbreak or poor-production problem, the importance of infectious agents relative to other host, management, and environmental factors must be determined by the submitting veterinarian.

Considerations if an Agent Is Isolated

Even when an agent is isolated with a 100% specific test and hence there is direct evidence of its presence, questions may arise as to the role of the agent in the disease process. In most investigations that are not done prospectively or that do not include similar testing of healthy cohorts, it is difficult to establish unequivocally that the suspected cause (e.g., agent) preceded the outcome (e.g., morbidity or mortality) or prove that the agent caused disease. Factors that impact a causal interpretation of the agent's role in the disease process need to be considered. Because a certain number of subclinical or normal carriers of an organism occur, it is important to determine whether the goal is to ascertain the presence or absence of a potential disease-causing agent or to determine the role of the agent in causing clinical disease (Huerta et al. 2003, Pogranichniy et al. 2002). The site from which the organism is identified (e.g., nasal vs. lung), the purity of the culture or types of organisms found in mixed cultures, and the quantity of agent present can be important factors in determining the causal relationship of a potential agent to the disease process.

Site of Isolation. The site is important because a number of organisms found in pathologic lesions have also been found in healthy pigs as part of the flora of the skin, respiratory, gastrointestinal, or reproductive tracts (Amass et al. 1996; Dritz et al. 1996; Straw et al. 1996). Therefore, events at the time of death may lead to contamination of deeper organs. For example, the lung may become contaminated with aspirated nasopharyngeal

flora, leading to isolation of potential pathogens such as *Haemophilus parasuis* or *Streptococcus suis*, which are reported in the nasal cavities and tonsils of healthy pigs (Amass et al. 1996; Dritz et al. 1996). Most respiratory pathogens are reported more commonly in pneumonic lungs, but they have also been found in a low percentage (2–16%) of normal lungs (Straw et al. 1996). Postmortem contamination can also occur during the organ removal process, such as when nasal flora are found in mixed cultures from a brain that was removed by sawing through the nasal cavity and calvarium.

Pure or Mixed Culture Result.   Though uncommon in pigs, finding a single potential pathogen lends greater support to a causal relationship between an agent and a lesion. Co-infections are more common, however; Choi et al. (2003) demonstrated in their findings that 88% of 2872 cases of pneumonia in pigs had two or more pathogens present.

Interpretation of mixed culture results requires knowledge of the flora at the site cultured, as well as the type and relative number of organisms identified. In the absence of inflammation or when potential pathogens are found in mixed culture, determining a causal relationship of any single agent to disease is difficult. Often pigs submitted for evaluation may have been sick and treated with antibiotics for several days, so determining which agents are the primary or secondary pathogens is tricky. The finding of the same pathogens at multiple sites within an affected organ lends support to a causal relationship compared with finding only environmental bacteria, such as coliforms, streptococci and staphylococci. These mixed cultures of environmental bacteria in a parenchymal organ or mixed with rare pathogens suggest aspiration in the lung, postmortem contamination of organs, or poor technique in obtaining cultures. This interpretation is supported by reports that these environmental organisms are found with similar frequency in normal and pneumonic lung cultures (Straw et al. 1996).

Molecular Characterization.   In some situations, establishing causality when an agent is identified might require further characterization of the strain found if it is generally of low pathogenicity or if live vaccines, that are detectable by the assay (e.g., PCR), have recently been used. Molecular epidemiologic methods might be required in some instances to determine whether an outbreak is attributable to the introduction of a new, more virulent strain of bacteria or virus or to the reemergence of an endemic strain (e.g., PRRS; Larochelle et al. 2003). Sometimes there is a need to differentiate pathogenic field virus from closely related cross-reacting viruses (e.g., porcine respiratory coronavirus from TGE) or vaccine strains (e.g., PRRS; Wesley et al. 1998), because the first may produce clinical disease whereas cross-reacting viruses and vaccine isolates do not (Mengeling et al. 1996).

Quantity of the Agent.   The quantity of an agent present has significance in interpretation of toxicologic and nutritional results. A low level of a toxin might simply reflect a residue rather than clinical toxicosis. However, since toxins are absorbed and metabolized at various rates, a very low level might be significant if clinical signs exist for toxins that are highly volatile (e.g., zinc phosphide) or rapidly broken down (e.g., anticoagulants, ionophores). Some toxins can also result in changes in tissues with a slow turnover, such as hooves, so that lesions persist after the tissue levels have returned to normal (e.g., selenium). The amount of decline below normal levels for minerals in pig sera and tissues is important in determination of clinical or subclinical nutritional deficiencies. In general, antigen and nucleic acid detection assays—such as PCR, IHC, fluorescent antibody (FA), and virus isolation—provide positive or negative results and are not quantitative. Even semi-quantitative testing—such as real-time PCR, bacterial cultures, and fecal parasite counts—will be strongly influenced by the presubmission use of therapeutics, sample handling, nonuniform distribution of the agent in the sample and the stage of infection (e.g., pre-patent). Therefore, quantity of a pathogenic microorganism, though a consideration, should not be a major factor in determining the significance of the agent.

Considerations if No Agent Is Isolated

As described in a previous section, a negative result on laboratory samples should not necessarily rule out an agent as a cause of disease, especially if the negative predictive value of a test is only moderate. False-negative results—such as failure to isolate a viral or bacterial agent or identify a specific pathogen by electron microscopy, FA, histopathology, and other antigen detection or PCR technique—can occur for a variety of reasons. The laboratory performing the test might have little or no experience with isolating some of the fastidious swine pathogens and are not using alternative more sensitive detection methods. For example, a laboratory report stating "*Mycoplasma* cultures were negative" would not exclude the presence of *M. hyopneumoniae*, since most laboratories use a culture technique that is incapable of growing this agent. Nonuniform distribution of the pathogen may be a problem for viral and bacterial respiratory and enteric pathogens when limited sections are taken for laboratory testing (e.g., FA for TGE, IHC for PRRS; see Yaeger 2002) A prolonged time interval since initial onset of disease may lead to a decline in the quantity of the agent to below the detection limit of the assay and would necessitate an alternative assay such as serology or a more sensitive detection method like PCR. The test may detect only specific strains of the pathogen (e.g., commercial ELISA assays detect only group A rotavirus). The combination of transport media, time delay, and shipping and storage temperature may not be

conducive to the survival of some pathogens for agent isolation methods, but PCR or antigen detection may still be effective due to greater leeway in their time and temperature requirements. For example, tissue samples maintained at room temperature for 24 hours had less than 50% recovery of PRRS virus by isolation compared with 100% recovery from sequential samples maintained at 4°C (VanAlstine et al. 1993). However, PCR was able to detect PRRSV in 94% of positive samples maintained at room temperature for up to 4 days (Benson et al. 2002). False-negative results on fecal sample PCR for various enteric pathogens may occur within a shorter time frame postcollection and more readily at room temperature or higher temperatures due to the impact of normal flora. In addition, inhibitory substances in feces can result in false-negative PCR results, but new internal control methods have improved the laboratories' ability to detect these substances, thereby rendering the negative results invalid (Jacobson et al. 2003). The incorrect sample (e.g., feces) might be submitted for conditions that many laboratories diagnose on histopathology or IHC (e.g., *Lawsonia intracellularis*, attaching and effacing *E. coli*). For some agents like PRRS, prolonged formalin-fixation can also result in false-negative results by IHC (VanAlstine et al. 2002). In general, problems arising from the inability of the laboratory to identify specific pathogens, nonuniform distribution of lesions, shipping and storage conditions, insensitive assays for the stage of disease, and incorrect samples can be prevented if the laboratory is consulted prior to collection and submission of the samples.

Even when sample selection and shipping conditions are optimal and the laboratory is capable of testing for the agent(s) of interest, a negative result will not rule out the presence of fastidious agents or organisms found in very low numbers. However, in pigs undergoing a thorough pathologic evaluation, the absence of lesions or clinical signs considered specific to that agent is usually adequate evidence to rule out the agent as a cause of disease, although the agent may still be present without causing clinical disease (e.g., *Lawsonia intracellularis,* see Huerta et al. 2003). False-negative results will also occur when pigs are treated prior to sampling. Gram-positive organisms are easily suppressed or killed by the use of penicillin and other antibiotics, substantially reducing the likelihood of isolation of *Erysipelothrix* or beta-hemolytic *Streptococcus* spp. from treated pigs.

Additional Considerations for Serologic Results

Because serologic results often are quantitative and values can vary between laboratories performing the same assay, the relationship of a serologic response to disease can be best interpreted by knowledge of the laboratories' experience with the assay in their submission area. Laboratories should be able to provide information on the common response detected in pigs in their area and

in pigs that have been vaccinated. However, for many diseases titers induced by natural infection may not be readily distinguished from vaccinal titers (Hill 1988). An exception is PRV infection for which tests are available for differentiation of field infection from vaccinal responses in pigs vaccinated with gene-deleted PRV vaccines (Weigel et al. 1992). Also of importance is how soon after infection titers become detectable with the assay being used, the time period to reach peak titers, and the duration of detectable antibody after infection or vaccination (Yoon et al. 1995). Lack of a titer on an assay with high sensitivity can be valuable information to rule out the agent in question if the animals sampled have been sick or recovered from the disease within 2–4 weeks prior to sampling.

In young pigs, repeated sampling might help differentiate maternally acquired antibodies from those induced by natural infection. If a veterinarian is interested in using serology to identify TGE as a cause of postweaning diarrhea in a chronically infected herd, a single serum sample taken at weaning might be inadequate because such antibodies could have been passively or actively acquired (Hill 1988). Repeated sampling at 2- to 4-week intervals with evidence of increasing or decreasing titers would provide evidence of active infection or passively acquired antibodies, respectively. However, when interpreting the results of such a sampling strategy, the potential role of porcine respiratory coronavirus maternal antibody or infection, which induces cross-reacting antibody to TGE, would also have to be considered (Sestak et al. 1996; Wesley and Woods 1996).

Although unequivocally establishing a cause-and-effect relationship is difficult, consideration of the above-mentioned factors and testing the diagnosis with an intervention (especially if there is an untreated control group) should provide increased confidence in a causal interpretation of the laboratory findings.

SELECTING APPROPRIATE SAMPLE SIZES

As part of disease investigations and health monitoring of herds, several sample size questions need to be addressed before sample collection. Although collection of too few samples is the most common mistake, the additional cost of submission of more samples must be weighed against the economic cost of the disease and the importance of establishing a correct diagnosis.

Detection of Infection if Present in the Herd

Veterinarians often need to determine whether an infection is or has ever been present in the herd or a subpopulation of the herd. For tests of 100% specificity, a single positive is usually considered sufficient to class the herd as positive, although for serologic tests of imperfect specificity more than one positive might be necessary. To estimate required numbers to detect infection, two values are necessary: the required level of confi-

dence, usually 95%, and the likely prevalence of infection in the herd or in the specific group of pigs being evaluated. The selected prevalence value should be realistic, but if there is doubt, erring toward a lower prevalence is preferable to ensure that adequate numbers of pigs are sampled. If the calculated sample size is large relative to the total population size, these numbers can be adjusted downward.

If a veterinarian's only goal is to detect infection, sampling does not need to be random but can be directed to higher-prevalence groups—for example, different age groups when there is an age-related risk of infection or clinically affected versus otherwise healthy pigs. If there is an age-related risk of exposure—e.g., *Salmonella* spp. in pigs in Denmark (Christensen and Gardner 2000)—this information can be used to target risk-groups for sampling. To detect *T. gondii* in a herd, sows are a better population to sample because prevalence is likely to be higher than in grower-finisher pigs. To detect PRRS virus, samples from older nursery pigs (6–8 weeks old) would be better than samples from sows or finisher pigs. To detect enteric pathogens by fecal culture or antigen detection methods, preference should be given to sampling pigs with diarrhea rather than pigs with normal feces.

A benefit of nonrandom, or targeted, sampling is that a diagnosis can often be established with fewer samples. In an outbreak investigation when samples are selected for culture from typical lesions identified at necropsy (prevalence close to 100%), few samples will be necessary. In other situations, where infection is subclinical and prevalence is lower, more samples should be submitted. For example, a sample size of 30 will give 95% confidence of detecting at least 1 positive in the sample if the prevalence of infection is at least 10% and the test is perfectly sensitive. When sensitivity is less than 100%, numbers should be increased. For example, if culture of feces for *Salmonella* spp. was only 50% sensitive, a sample size of about 60 (double the number needed for a 100% sensitive test) would be needed to satisfy the specified criterion.

Despite adequate planning of sample sizes, laboratory results are sometimes negative. If zero positive test results occur for a sample of pigs from the herd, this should be interpreted differently from negative results based on testing the entire herd. Appropriate interpretation is shown in the example on prevalence estimation that follows.

Prevalence Estimation
Detection of infection and estimation of prevalence can often be done with the same sample of pigs, providing that the sampling is truly random. Usually the random sample for prevalence estimation is collected at a single point in time (cross-sectional sample). Required sample sizes to estimate prevalence with desired accuracy or error limits (usually from 5% to 20%) are presented in

Tables 10.2 and 10.3, including corrections for finite population sizes. When prevalence is unknown and a study is planned, we recommend calculating a sample size at 50% prevalence, which represents the maximum number that could be needed. Selection of error limits will be more subjective, although ±10% and ±20% are used more frequently than ±5% because of the substantially increased cost when a more precise estimate is needed.

We emphasize two points with respect to prevalence estimation. First, at moderate prevalences (30–70%), much larger sample sizes are necessary to estimate prevalence accurately than at either low or high prevalences. For a fixed sample size, the precision of the estimate is greater the more the prevalence differs from 50%. Second, small sample sizes can result in sample test results that are very different from the true population values. For example, Gardner et al. (1996) compared samples of 5 and 30 pigs to estimate the prevalence of porcine parvovirus in a large herd and found that sample sizes of 5 frequently failed to reflect herd prevalence, and even a sample size of 30 yielded poor estimates of herd prevalence on some occasions.

Sometimes, even though the sample size is calculated a priori, no positives are found on a random sample of pigs when tested with a perfect test. What conclusions, if any, can be drawn? If there are no positives, the upper 95% confidence limit for prevalence is approximately 3/n where n = number sampled (DiGiacomo and Koepsell 1986). Therefore, if 30 pigs were tested and all were negative, the upper 95% confidence limit would be 3/30, or 10%. Although a veterinarian initially might conclude that a herd was not infected (prevalence = 0%), a more appropriate interpretation would be that the herd has a prevalence of ≤10% with 95% confidence.

This issue of how to interpret negative results correctly extends to health certification schemes. Only if all pigs are tested in a herd with a test of 100% sensitivity and negative results are obtained is there sufficient evidence, based on the test results alone, to certify freedom from a pathogen. In practice, certifications are usually based on a combination of herd history and repeated testing of samples from the herd and are made in the context of knowledge that many herds become infected over time by the spread of pathogens from neighboring herds. Experience from the Danish SPF scheme indicates that the annual reinfection rate of herds with *M. hyopneumoniae* is about 10–15% (Sørensen et al. 1992; Sørensen et al. 1993).

Detection of a Difference in Prevalence or Incidence Between Two Groups
For some investigations a veterinarian might want to determine whether one group of pigs has a higher prevalence or incidence of infection than another group. The grouping factor could be age, reproductive status (preg-

Table 10.4.   Sample sizes necessary to detect a significant difference in prevalence or incidence of infection or disease between two groups (one with and one without the risk factor) with 95% confidence and 80% power.

Prevalence in Risk-Factor Positive Group (%)	Prevalence in Risk-Factor Negative Group (%)									
	0	10	20	30	40	50	60	70	80	90
10	93									
20	44	219								
30	27	71	313							
40	19	38	91	376						
50	14	24	45	103	407					
60	11	17	27	48	107	407				
70	9	12	18	28	48	103	376			
80	7	9	13	18	27	45	91	313		
90	5	7	9	12	17	24	38	71	219	
100	4	5	7	9	11	14	19	27	44	93

Note: By convention, the risk-factor positive group is assumed to have a higher prevalence than the risk-factor negative group. Sample sizes assume independence of groups and random sampling. Tabulated numbers are those required in each of the two groups.

nant vs. nonpregnant or aborting vs. nonaborting), production system or husbandry type, or any other comparison factor. If this diagnostic approach was used and a significant association was detected between an infectious agent and an outcome such as clinical disease, reproductive failure, or the prevalence of emaciated pigs, this would provide additional evidence for a causal role of the agent in the syndrome. This comparative approach is often used in serum-profiling schemes where different age groups in the herd are evaluated for exposure to one or more infectious agents.

If a comparison of prevalences is the primary goal of the submission, the required sample size is determined by the level of confidence and the best a priori estimates of prevalence in the groups. As the percentage point difference between the groups decreases, much larger sample sizes become necessary (Table 10.4). For example, to detect a significant difference at the 5% level between 40% and 10% prevalence with 80% power would require 38/group, whereas 91/group would be needed to detect a difference between 40% and 20% prevalence. These calculations indicate that the small sample sizes (5–10 per age group) that are often recommended for serum profiling of herds are typically too small for unequivocal comparisons. Sample sizes necessary to compare prevalences are listed in book tables (Fleiss 1981) or can be calculated with public domain computer software such as Epi Info (available at www.cdc.gov/epiinfo/).

CONCLUSIONS

Laboratories can assist in establishing a diagnosis, but ultimately, practitioners need to assess the laboratory results in the context of other herd information and existing knowledge about the relative importance of infectious agents and other factors in disease occurrence. To maximize the benefits of laboratory testing, veterinarians should do the following:

1. Clearly define the goal of the submission—e.g., confirm a diagnosis, screen for a pathogen, estimate prevalence of a pathogen.
2. Select a laboratory with good internal and external quality control procedures and with experience working with the agent or test of interest.
3. Give the laboratory the maximum chance to achieve the goals desired by
   A. Selecting appropriate sample types—e.g., tissue versus serum;
   B. Using the correct method of submission—e.g., chilled versus frozen versus room temperature;
   C. Ensuring samples are from pigs that are truly representative of the problem under investigation and are collected from pigs at the appropriate stage of disease;
   D. Submitting adequate numbers of samples to meet the specified submission goal, balancing the additional cost of more samples versus the need to establish a diagnosis correctly;
   E. Considering inclusion of a comparison group of samples (controls) if interpretation without them might be equivocal or previous attempts to establish diagnosis have been unproductive.
4. Be knowledgeable about the strengths and limitations of available tests.
5. Interpret results taking into account the predictive values of positive and negative test results, and for quantitative tests, the magnitude of the test result in relationship to the cutoff value.

11 Differential Diagnosis of Disease

Barbara E. Straw, Catherine E. Dewey, and M. R. Wilson

This chapter contains a collection of tables designed to provide assistance in the field diagnosis of swine diseases. These aids do not comprehensively cover all the diseases that could possibly occur in pigs. Diseases that affect only one animal or arise due to unusual circumstances have not been included, since this would greatly lengthen the tables without substantial addition of information useful for diagnosing herd problems that are of real economic importance. In general, diseases have been included that cause herd problems or at least involve a group of animals.

This chapter has been divided into major categories according to the body system affected and subdivided into sections by specific clinical signs. Sometimes pigs will show signs referable to two or more systems. Then the clinician will need to exercise judgment in determining which is the principal one affected or may pursue all signs and look for diseases in common.

Each section begins with a definition of the signs included there and some general remarks about approach to diagnosis. Also included is information about patterns of disease and certain characteristics or signs that are typically associated with specific classes of etiologic agents. When applicable, a table indicates the different ages at which the various diseases are more prominent. Although diseases may be shown to affect pigs in a certain age category, age must not be interpreted to have discrete boundaries. Age categories should be used as a guide to the most common age at which the diseases are seen and should not necessarily be a cause of rejecting a disease as a differential just because the affected pigs are not within the specified category.

The tables list the various possible causes of clinical signs and their differentiating features. Whenever possible, these tables have been designed in a format that leads from clinical signs to the etiologic agents since this most closely parallels the procedure of clinical diagnosis in the field. However, with problems like abortion, there are just not enough differentiating clinical features to proceed from signs to diagnosis and so some charts are in the traditional disease-first format.

GASTROINTESTINAL SYSTEM

Diarrhea

The consistency of feces may vary according to the diet fed, but diarrhea may be considered to occur when there is a change to a more fluid consistency than normal, especially when associated with signs of either large- or small-intestine disease. Signs frequently associated with disease of the small intestine include vomiting, melena, poorly digested feces, bulky voluminous feces, and borborygmus. Vomiting seldom occurs in cases of disease of the large intestine; however, there may be bloody stools, gross mucus on the feces, small frequent defecations, and tenesmus.

Unweaned Pigs (Tables 11.1, 11.3). Many times, a presumptive diagnosis of the cause of baby pig diarrhea can be made on the basis of history, clinical signs, and necropsy findings. Often, however, the clinical picture does not point to a likely etiology because of the variation in clinical signs that can be produced by one disease agent and because of concurrent problems with more than one disease. Therefore, as much information as possible should be collected rather than trying to base a diagnosis on one or two signs.

The most common causes of diarrhea in baby pigs are colibacillosis, hypoglycemia, transmissible gastroenteritis (TGE), clostridial enteritis (CE), coccidiosis, and rotaviral enteritis (RE). These six entities account for the major portion of all preweaning diarrhea. Diseases that occur less frequently or rarely in baby pigs but have diarrhea as their principal sign include *Strongyloides* infestation, swine dysentery (SD), erysipelas, and salmonellosis. Pseudorabies (PR) and toxoplasmosis may cause diarrhea in baby pigs, but generally diarrhea is not their main clinical manifestation.

Table 11.1. Ages at which certain diseases causing diarrhea in pigs are more likely to occur

Age of Pig							
24 hours	5 days	3 weeks	5 weeks	10 weeks	20 weeks	30 weeks	Adult
Strongyloides		Soybean meal hypersensitivity					
Colibacillosis							
Severe signs		Transmissible gastroenteritis				Mild signs	
Severe signs		Porcine epidemic diarrhea				Mild signs	
Hog cholera, African swine fever							
Clostridial enteritis							
Rotaviral enteritis							
	Coccidiosis						
		Salmonella enterocolitis					
				Trichuris suis			
				Swine dysentery			
				Necrotic enteritis, proliferative ileitis			
					Proliferative hemorrhagic enteritis		
						Gastric ulceration	

Table 11.2. Change in effective environmental temperature due to various conditions

Condition		Change in Effective Environmental Temperature	
		°C	°F
Airspeed:			
0.2 m/sec	(0.7 ft/sec)	−4	−7
0.5 m/sec	(1.6 ft/sec)	−7	−13
1.5 m/sec	(4.9 ft/sec)	−10	−18
Floor type:			
Straw		+4	+7
Concrete slats		−5	−9
Wet concrete slats		−5 – −10	−9 – −18
Air-to-wall temperature gradient:			
13°C (23°F)		−7	−13
3°C (5°F)		−1.5	−3
1°C (2°F)		−0.5	−1

An explosive onset of diarrhea and rapid spread are usually associated with a viral etiology. An insidious onset, slow spread, and gradual increase in severity over time tend to be seen with bacterial or parasitic disease.

Knowledge of the vaccination status of the herd and previous exposure to infectious disease assists in diagnosis. Diseases such as enzootic TGE, coccidiosis, RE, colibacillosis, and CE are difficult to eliminate once they have become a problem in the herd; and they may still contribute to diarrhea even when control measures are being used. In a herd chronically infected with one of the above diseases, the means of implementing control measures should be reviewed to determine if failure to adequately carry out preventive programs (vaccination or medication) has allowed disease to reoccur.

The age at which pigs are first affected with diarrhea is an indication of the cause (Table 11.1). Diarrhea that occurs on the first or second day after birth is likely to be caused by colibacillosis, hypoglycemia, or CE. Coccidial scours first occur at 5–7 days of age. Diarrhea caused by enzootic TGE, RE, SD, salmonellosis, and erysipelas usually occurs after the first week of life. In addition to appearing during the first few days of life, diarrhea from *Escherichia coli* and agalactia is commonly seen at 3 weeks of age. Sometimes rather than diarrhea that starts at a certain age, there will be a wide range of ages affected simultaneously. An acute onset of severe diarrhea that affects all ages of piglets over 24 hours of age is typical of epizootic TGE and PR. Less severe diarrhea that has no clear time of onset and affects piglets of all ages can be produced by colibacillosis and RE.

Usually when diarrhea occurs in baby pigs, the entire

litter is affected. This occurs because for most infectious diseases either the sow is immune and able to supply sufficient antibodies to the piglets through the milk or the sow is not immune and lacks lactogenic antibodies. CE is an exception since it may affect only a few pigs in the litter and these are usually the biggest and healthiest. Hypoglycemia can also produce disease in only a few pigs in the litter, usually the smallest.

Fecal pH has been used to help differentiate between causes of diarrhea. Fecal materials to be tested should be obtained from several affected piglets by applying pressure to their abdomens, not by collecting fecal material from the floor. Diseases that cause moderate to severe villous atrophy (TGE and RE) produce diarrhea with an acid pH. Other enteric diseases cause diarrhea in which feces are alkaline.

Often, the first sign of diarrhea noticed is dehydration in which the bony prominences are clearly seen and the skin is dry, bluish in color, said to resemble parchment, and remains tented after being pinched between thumb and finger.

Sows tend not to be affected by most disease agents that cause enteritis in their piglets. This general rule is not applicable in cases of piglet hypoglycemia caused by agalactia in the sow and in epizootic TGE and PR, in which sows become sick and may vomit or have diarrhea.

Rare causes of diarrhea in baby pigs include infection with Bacteroides fragilis, Enterococcus durans, and Chlamydia sp.

Noninfectious Contributing Factors (Table 11.2). Two major contributors to baby pig diarrhea are effective environmental temperature (EET) and availability of milk.

The baby pigs' lower critical temperature (LCT)—the temperature below which they must utilize extra energy to maintain their body temperature—is 90°F (33°C). The LCT for recently weaned pigs is about 75°F (28°C). The EET experienced by a pig is a combination of the heat transfer that occurs by radiation through the air, conduction through the floor, evaporation due to wet surfaces and humidity, and convection to walls and windows. The EET may be estimated by measuring the air temperature and adding or subtracting according to the conditions listed in Table 11.2.

Adequate amounts of milk are necessary to provide piglets with lactogenic antibodies and with energy to maintain body temperature. Any factor that limits availability of milk to piglets such as agalactia or impedances of physical access to mammary glands (bars on the farrowing crate that hinder nursing, slippery floors) contributes to the severity of clinical disease.

Baby pig diarrhea is more likely to develop in some environments than in others. Continuous farrowing operations are predisposed to colibacillosis and enzootic TGE. Colibacillosis is found most often where management and sanitation are poor. Within herds affected by colibacillosis, litters of gilts are more often affected than those of sows. In addition to a continuous farrowing schedule, frequent additions of pigs from outside sources is a common practice on farms with enzootic TGE.

Necropsy (Table 11.4). Three areas deserve close attention in the necropsy of pigs with diarrhea. First, examine the lacteals in the mesentery; the presence or absence of fat there reflects the ability of the disease to cause villous atrophy and diminish absorptive capacity of the small intestine. The absence of fat in the lacteals is a prominent finding with TGE and is a variable finding in RE. Colibacillosis does not interfere with the ability of the intestine to absorb fat. Absence of fat in the lacteals also occurs when the pig is not nursing. Milk or a milk curd in the stomach provides evidence that the pig was nursing and makes hypoglycemia unlikely. The second area to examine is the serosal surface of the intestine for reddening (clostridial infection) or transparency (TGE). The mucosal surface is the third area that should be closely examined for signs of petechial or frank hemorrhage (CE, salmonellosis) and a fibrinonecrotic membrane that may be diphtheritic (coccidiosis, chronic CE) or hemorrhagic (acute CE, SD).

Weaned Pigs to Adults (Tables 11.1, 11.5, 11.6). Diarrhea in older pigs may be the only sign of disease or part of a disease syndrome with other signs. The clinician should determine what signs exist, if disease is systemic or confined to the gastrointestinal system, and whether it is likely to involve the large or small intestine or both. Necropsy is similar to that for small pigs.

Loose stools are sometimes seen in pigs a few days to a week after weaning, when pigs have a hypersensitivity to the soybean meal in the diet. *Cryptosporidia* rarely produces diarrhea in weaned pigs.

Vomiting

Vomiting is the ejection of stomach contents through the mouth and should be differentiated from regurgitation, in which food is swallowed, does not reach the stomach, and is ejected through the mouth. If there is any question of whether vomiting or regurgitation is occurring, it may be settled by measuring the pH of the ejected material. Vomitus has an acid pH and regurgitated material is alkaline. In pigs, the act of vomiting may have been observed or the vomitus seen on the floor of the pen.

Unweaned Pigs (Table 11.7). Vomiting is a prominent clinical sign of hemagglutinating encephalomyelitis, porcine epidemic diarrhea, and TGE. Vomiting can also be seen with RE, PR, hog cholera (HC), African swine fever (ASF), and rarely in enteric colibacillosis. Diseases that feature vomiting in baby pigs usually have a viral etiology. Determination of the cause of vomiting in baby pigs is best accomplished by identifying the major system involved and then differentiating between diseases that affect that system.

Table 11.3. Diseases that cause diarrhea in unweaned pigs

Disease	Age When Signs Occur	Morbidity	Mortality	Season	Other Signs in Piglets	Appearance of Diarrhea	Signs in Other Pigs	Onset and Course	Associated Factors
Colibacillosis	Anytime, but see a peak of infection at 1–4 days and 3 weeks of age.	Variable, usually moderate. Typically all of one litter is affected, but nearby litters can be normal.	Variable, moderate.	Any but winter if chilled piglets, summer if agalactia.	Dehydration. Pasty peritoneum. Tail may necrose.	Yellowish white, watery with gas, fetid odor, pH 7.0–8.0.	Sows not affected. Litters often of gilts worse than litters of sows.	Gradual onset and slow spread through the room. Severity worsens toward the end of the farrowing group.	Often associated with poor management, dirty environment, and suboptimal environmental temperatures.
Epizootic transmissible gastroenteritis	Any age over 1 day and all ages at once.	Near 100%.	Near 100% in pigs under 1 week old. Near 0% in pigs over 4 weeks old.	Cold months, November to April.	Vomiting, dehydration.	Yellow-white (possibly greenish), watery, characteristic odor, pH 6.0–7.0	Sows anorexic, may vomit, loose feces, agalactia, rapid spread to other swine.	Explosive, all litters affected at once.	
Enzootic transmissible gastroenteritis	6 days and older.	Moderate, 10–50%.	Low, 0–20%	None.	Vomiting, dehydration.	Yellow-white (possibly greenish), watery, characteristic odor, pH 6.0–7.0	Sows usually not sick. Nursery pigs may have diarrhea.	Litters affected sporadically. Chronic low level.	Frequent additions of pigs and continuous farrowing. Very large farms.
Coccidiosis	Not in pigs under 5 days old. Usually 6–15 (especially at 7) days of age.	Variable, up to 75%.	Usually low.	Peaks in August and September.	Gaunt, rough hair coat. Lower weight at weaning.	Pasty to profuse, watery, yellow-gray, fetid, pH 7.0–8.0. Some pigs with diarrhea, others may have "sheep pellet" feces.	Sows normal.	Slow spread and gradual buildup.	Solid floors.
Rotaviral enteritis	1–5 weeks old.	Variable, up to 75%.	Low, 5–20%.		Occasionally will vomit, gaunt, rough hair coat.	Watery, pasty with yellow curdlike material, pH 6.0–7.0.	Sows rarely sick.	Epizootic: abrupt onset and rapid spread. Enzootic: like TGE.	

(continued)

Table 11.3. Diseases that cause diarrhea in unweaned pigs (*continued*)

Disease	Age When Signs Occur	Morbidity	Mortality	Season	Other Signs in Piglets	Appearance of Diarrhea	Signs in Other Pigs	Onset and Course	Associated Factors
Clostridium perfringens type C or A: PA: Peracute A: Acute SA: Subacute C: Chronic	Typically 1–7 days old. PA: 1 day A: 3 days SA: 5–7 days C:10–14 days	1–4 pigs per litter showing signs. Often the biggest, healthiest piglets are affected.	Nearly 100% of acutely affected pigs. Higher survival if chronic.		PA: Paddling, prostration, occasional vomiting. SA, C: emaciation, rough hair coat.	PA: watery, yellow to bloody; A:reddish brown liquid feces; SA: nonhemorrhagic, watery, yellow-gray; C: yellow-gray, mucoid.	Sows normal.	Slow spread throughout the farrowing room. All four forms may be seen at same time in different litters.	First outbreak often seen after addition of new pigs.
Clostridium difficile	Typically 1–7 days old	10–90%. Often 2/3 of litters and 1/3 of pigs.	Up to 50%. Typically 20%.	None.	Sudden death, with no clinical signs, sometimes dyspnea, mild abdominal distension and scrotal edema.	Pasty yellow to watery.	Sows normal		Treatment at birth with antibiotics
Strongyloides	4–10 days old.		Up to 50%.		Dyspnea, CNS signs.		Sows normal.		Southern states.
Swine dysentery	7 days and older. Especially at 2 weeks of age.	Sporadic by litters.	Low.	Late summer and fall.	No dehydration.	Watery with blood and mucus, yellow-gray.	Sows normal. Older pigs may have diarrhea.		First outbreak often seen after addition of new pigs.
Salmonellosis	3 weeks of age.				Septicemia.	Mucohemorrhagic.			
Erysipelas	Usually over 1 week of age.	Entire litter. Sporadic.	Moderate to High.			Watery.			Sows not vaccinated.
Epizootic pseudorabies	Any age. More severe in younger piglets.	High, up to 100%.	High, 50–100%.	Winter.	Dull, salivate, vomit, dyspnea. ataxia, CNS signs.		CNS signs, abortion.	Explosive outbreak in previously uninfected herd.	
Hypoglycemia (agalactia)	Postpartum agalactia, 1–3 days; inadequate underline, 2–3 weeks.	Variable, 5–15% of litters.	High in affected litters.		Weak, inactive, hypothermia, CNS signs.	Watery.	Sow agalactia, anorexia, mastitis, inverted nipples.		Slick floor, improper crate design or adjustment, failure to remove eyeteeth.
Toxoplasmosis	Any age.	Variable.	Variable.		Dyspnea, CNS signs.	Watery.	Sows normal.		
Porcine epidemic diarrhea	Any age.	Variable, but often high.	Moderate to high.		Vomiting, dehydration.	Watery.	Older pigs may have more severe signs.	Explosive onset and rapid course.	

Table 11.4. Necropsy findings in unweaned pigs with diarrhea

Disease	Gross Necropsy Findings	Microscopic	Diagnosis
Colibacillosis	Stomach is often full, lacteals contain fat, congestion in intestine present or absent, slight edema of intestinal wall, intestine distended with fluid, mucus, and gas.	No lesions.	Demonstration of *E. coli* adhering to the intestinal wall. Culture of 10^4 colonies/mL from the small intestine. Demonstration of the toxin.
Transmissible gastroenteritis	No fat in lacteals, yellow fluid and gas in intestine, congested intestinal vessels, thin-walled small intestine, hemorrhage in stomach wall, stomach contents: first 2–3 days, milk; next 4–5 days, green mucin.	Severe villous atrophy in jejunum and ileum. Possible nephrosis.	Fluorescent antibody test on small intestine. Direct electron microscopic examination of intestinal contents. Isolation of virus.
Coccidiosis	Fibrinonecrotic, diphtheritic membrane, especially in jejunum and ileum. No lesions in large intestine.	Mild to severe villous atrophy, fibrinonecrotic membrane.	Mucosal smear of jejunum or ileum stained with Wright's, Giemsa, or New Methylene Blue for merozoites.
Rotaviral enteritis	Milk or curd in stomach, thin-walled intestines filled with fluid, colon and cecum distended, variable fat in the lacteals.	Moderate villous atrophy in jejunum and ileum.	Fluorescent antibody test on small intestine. Direct electron microscopic examination of gut contents. Virus isolation.
Clostridium perfringens type C or A	Lesions found in the jejunum and ileum. Peracute: hemorrhage in intestinal wall, bloody fluid in lumen, serosanguinous peritoneal fluid, hemorrhagic peritoneal lymph nodes. Acute: jejunal wall, thickening and necrosis of emphysema of mucosa, necrotic membrane. Subacute and chronic: less hemorrhage and thicker membrane.	Hemorrhage throughout wall of gut, mucosal necrosis, presence of gram-positive rods.	Stained mucosal smear and observation of gram-positive rods. Histopathology. Culture of organism and identification of toxin.
Clostridium difficile	Mesocolonic edema	Colon lesions: supporative foci In lamina propria, segmental mecosal erosion, presense of large gram-positive rods.	Isolation of organism. Presence of toxins A and B.
Strongyloides	Petechial hemorrhage in intestinal mucosa. Occasionally hemorrhage in the lungs.		Eggs in feces.
Swine dysentery	Lesions limited to large-intestinal wall are hyperemic and edematous, mild ascites, mucofibrinous, hemorrhagic mucosa, often with pseudomembrane.	Superficial necrosis and hemorrhage.	Culture. Histopathology.
Salmonellosis	Catarrhal to hemorrhagic to necrotic enteritis throughout gastrointestinal tract. Hemorrhage and necrosis in parenchymal organs and lymph nodes. Focal necrotic areas in liver. Diffuse or focal ulcers of gastrointestinal tract.	Intestinal mucosal ulceration. Necrotic foci in liver and spleen.	Culture. Histopathology.
Hypoglycemia	Empty stomach, no fat in lacteals.	No lesions.	Typical signs, absence of disease agents.
Pseudorabies	Necrotic tonsillitis, pharyngitis. Necrotic foci in the liver and spleen. Pulmonary congestion.	Nonsuppurative meningoencephalitis, perivascular cuffing.	Virus isolation from frozen tonsil and brain. Fluorescent antibody of chilled tonsils and brain. Serum antibodies.
Toxoplasmosis	Intestinal ulceration. Necrotic foci in any organ. Lymphadenitis.	Focal necrotic areas.	Histology and demonstration of organism. Serology.

Table 11.5. Diseases of recently weaned and older pigs with diarrhea as the main clinical sign

Blood	Site of Lesions	Possible Causes	Further Differentiation
Diarrhea not bloody	Small intestine.	Transmissible gastroenteritis. Rotaviral diarrhea. Lawsonia-related enteropathies (porcine intestinal adenomatosis [PIA]). Porcine epidemic diarrhea.	Fluorescent antibody test. Direct electron microscopy. Histopathology. Paired serology.
	Large intestine.	*Salmonella enterocolitis. Oesophagostomum* spp.	Bacterial culture. Fecal analysis.
	Both large and small intestine.	Tricothecene toxin.	Feed assay.
	No gross lesions.	Colibacillosis. Lincomycin or tylosin. Soybean meal hypersensitivity. Early sign of edema disease prior to neurologic signs. Acute leptospirosis.	Bacterial culture. History.
Bloody diarrhea, melena	Stomach.	Gastric ulceration.	Blood in feces is black and tarry. Necropsy.
	Large intestine, colon.	Swine dysentery. *Trichuris suis. Salmonella enterocolitis.*	Blood in feces is fresh and red. Histopathology. Fecal assay. Bacterial culture.
	Both large and small intestine.	Proliferative hemorrhagic enteropathy. Tricothecene toxin. Intestinal anthrax.	Histopathology. Feed assay.

Note: Minimal other signs of gastrointestinal tract disease such as vomiting, anorexia, or colic may be present. No signs referable to other systems.

Table 11.6. Diseases of recently weaned and older pigs with diarrhea as part of a clinical syndrome that primarily involves signs referable to systems other than the gastrointestinal tract

Blood	Clinical Signs	Possible Causes	Further Differentiation
Diarrhea not bloody	Reluctance to rise, fever, anorexia, depression, skin discoloration.	Septicemic salmonellosis. Hog cholera. African swine fever.	Bacterial culture. Fluorescent antibody test. Serology.
	Respiratory signs, coughing.	*Ascaris suum.* Just prior to the onset of acute *A. pleuropneumoniae.*	Milk spot liver. Culture of lung.
	Polyuria, polydipsia, dehydration.	Ochratoxin.	Feed assay.
	Increased respiratory rate, dyspnea, ataxia, tremors to convulsions.	Overdose of levamisole, dimetridazole, piperazine. Acute toxoplasmosis.	History of treatment. Histopathology. Mouse inoculation. Serology.
	Wasting, ill-thrift.	Porcine intestinal adenomatosis.	Histopathology.
Bloody diarrhea, melena	Lameness, reluctance to move, anemia.	Warfarin toxicity.	History of access. Stomach contents analysis.
	Wasting, ill-thrift.	Gastric ulceration. Proliferative hemorrhagic enteropathy.	Necropsy. Histopathology.
	Depression, prostrate, fever, anorexia, dyspnea, hyperemia.	Terminal stage of African swine fever.	Fluorescent antibody test. Serology

Table 11.7. Diseases that cause vomiting in unweaned pigs

Disease	Ages Affected	Prominence of Vomition	Primary System Affected[a]	Other Signs	Signs in Sow
Hemagglutinating encephalomyelitis (HEV): encephalitic form	4–14 days old.	Prominent.	Nervous.	Lethargy, huddling, constipation, cyanosis, cough, grinding of teeth, stilted gait, squeal and paddle when handled, posterior paresis, convulsions.	None.
HEV: vomiting and wasting disease	4–14 days old.	Prominent.	Systemic disease.	Thirsty but unable to drink, unthrifty, may have diarrhea, then constipation.	None.
Transmissible gastroenteritis	All ages, younger pigs more severe.	Prominent.	Gastrointestinal.	Profuse, watery diarrhea.	Normal or anorexia, vomit, diarrhea.
Porcine epidemic diarrhea	All ages, younger pigs more severe.	Prominent.	Gastrointestinal.	Profuse, watery diarrhea.	Normal or anorexia, vomit, diarrhea.
Pseudorabies	All ages, younger pigs more severe.	Seen with moderate frequency.	Nervous.	Dyspnea, hypersalivation, diarrhea, trembling, CNS signs, seizures.	Normal or cough, anorexia, constipated, neurologic signs.
Rotaviral enteritis	Uncommon in nursing pigs.	Occasional.	Gastrointestinal.	Watery diarrhea.	None.
Hog cholera	All ages.	Seen with moderate frequency.	Systemic disease.	Lethargy, cyanosis, fever, diarrhea, hemorrhages.	Similar to signs in piglets.
African swine fever	All ages.	Seen with moderate frequency.	Systemic disease.	Lethargy, cyanosis, fever, diarrhea, hemorrhages.	Similar to signs in piglets.

[a]For further differentiation, consult the sections dealing with neurologic, systemic, and gastrointestinal disease.

Weaned Pigs and Adults (Tables 11.8–11.9). Vomiting in older pigs is also frequently associated with viral infection. It also may result from toxins or agents that produce local irritation to the gastrointestinal tract. Usually it is accompanied by other signs that are helpful in making a diagnosis.

Rectal Prolapse
See Table 11.10.

RESPIRATORY SYSTEM

Dyspnea and Cough
Unweaned Pigs (Table 11.11). Labored respiration in baby pigs is generally due to anemia or pneumonia, especially associated with porcine reproductive and respiratory syndrome (PRRS). PR and toxoplasmosis infection can also produce signs of respiratory distress.

In newborns and nursing piglets, PRRS infection produces respiratory distress, thumping, mouth breathing, listlessness, and fading piglet syndrome. Respiratory signs in piglets are more common when the herd is initially infected with PRRS but may also be seen in chronically infected herds experiencing a recurrence of disease.

Anemia causes labored respiration in unweaned pigs. Iron deficiency anemia develops gradually, with signs beginning to be noticeable at about 1.5–2 weeks of age and becoming more severe in older pigs.

Bacterial pneumonias are more rarely seen in baby pigs but when present may cause signs as early as 3 days of age. Coughing is a prominent sign of pneumonia, but it is absent with anemia. Anemic pigs are noticeably pale compared to pneumonic pigs. On necropsy, anemic pigs have an enlarged heart with excess pericardial fluid, an enlarged spleen, and edema in the lung, but no other pulmonary lesions. Bacterial pneumonia in baby pigs may be due to *Actinobacillus, Pasteurella, Bordetella,* or *Streptococci* organisms and these agents should be differentiated in the same way as for older pigs (see Table 11.12). *Bordetella bronchiseptica* can cause a bronchopneumonia in young pigs that has a patchy distribution predominant in the apical and cardiac lobes but also in the dorsal aspects of the lungs.

The respiratory signs caused by PR, toxoplasmosis, HC, and ASF are usually secondary to other signs of systemic or neurologic disease.

Weaned Pigs and Adults (Table 11.12). Most respiratory problems in weaned and growing pigs are due to parasitic, bacterial, or viral invasion of the lungs. In sows, respiratory problems are more commonly caused by anemia or conditions that result in a great increase in

Table 11.8. Diseases that cause vomiting in weaned pigs and adults

Disease	Ages Affected	Prominence of Vomition	Primary System Affected[a]	Nursery Pigs	Other Signs Growing Pigs	Adults
Transmissible gastroenteritis	All ages. More severe in younger pigs.	Moderate in younger pigs and occasional in older pigs.	Gastrointestinal.	Watery diarrhea, dehydration, anorexia lasting up to 1 week.	Inappetence and diarrhea for 1 or a few days.	Brief anorexia, mild diarrhea. Lactating sows may have agalactia, diarrhea.
Porcine epidemic diarrhea	All ages. More severe in younger pigs.	Moderate in younger pigs and occasional in older pigs.	Gastrointestinal.	Watery diarrhea for 4–6 days, dehydration.	Depression and anorexia, watery diarrhea.	Anorexia.
Pseudorabies	All ages. More severe in younger pigs.	Occasionally seen.	Nervous.	CNS signs.	Sneezing, coughing, anorexia, constipation, occasional neurologic signs, pregnant sows may abort.	
Rotaviral enteritis	Nursery pigs, especially after weaning.	Occasionally seen.	Gastrointestinal.	Diarrhea, dehydration.	Not usually a clinical problem at this age.	
Vomitoxin, T-2, diacetoxyscirpenol	All ages.	Moderately frequent.	Gastrointestinal.	Anemia, diarrhea (possibly bloody), ill-thrift, slowed growth rate, occasional feed refusal.		
Hog cholera	All ages.	Moderately frequent.	Systemic disease.	Lethargy, anorexia, ocular discharge, constipation, then diarrhea, weaving, staggering, huddling, posterior paresis, cyanosis, abortion.		
African swine fever	All ages.	Occasionally seen.	Systemic disease.	Lethargy, hyperemia, dyspnea, mucoid to bloody diarrhea, abortion.		
Peracute *Actinobacillus pleuropneumoniae*	All ages, but outbreaks usually in finishing pigs.	Occasionally seen.	Respiratory.	Dyspnea, cough, blood-tinged fluid from the nose and mouth, cyanosis.		
Anthrax:						
Pharyngeal	All ages.	Moderately frequent.	Systemic disease.	Cervical edema, dyspnea, depression.		
Intestinal	All ages.	Moderately frequent.	Systemic disease.	Anorexia, bloody diarrhea.		
Strongyloides	Weaned to finishing pigs.	Occasionally seen.	Gastrointestinal.	Diarrhea, rapid emaciation, anorexia, anemia.		
Gastric ulcers	Finishing pigs and adults.	Occasionally seen.	Gastrointestinal.	Uncommon.	Anemia, tarry feces, grinding of teeth, weight loss.	
Hairballs, foreign bodies	Finishing pigs and adults.	Occasionally seen.	Gastrointestinal.	Uncommon.	Drop feeding systems that place feed on pigs' backs.	
Thiamin deficiency	Usually only experimental.	Moderately frequent.	Systemic disease.	Anorexia, slow growth, diarrhea, cyanosis.		
Riboflavin deficiency	Usually only experimental.	Moderately frequent.	Systemic disease.	Slow growth; cataracts; stiff gait; scaling, eruption, ulceration, and alopecia of skin.		
Other toxicities (See Table 11.9.)						

[a]For further differentiation, consult the sections dealing with neurologic, systemic, and gastrointestinal disease.

249

Table 11.9. Toxicities associated with vomiting

Toxin	System Affected	Seen in Pigs with Access to:
Inorganic arsenicals	Gastrointestinal and central nervous.	Ant bait, herbicides, insecticides.
Antimony	Gastrointestinal.	Alloys, paint, tartar emetic.
Cadmium	Gastrointestinal.	Paint, solder, batteries, fungicides.
Fluorine	Gastrointestinal and locomotor.	Water or forage contaminated with industrial waste.
Levamisole	Gastrointestinal and central nervous.	Anthelmintic.
Piperazine	Gastrointestinal.	Anthelmintic.
Organophosphates, carbamates	Neurologic.	Insecticides.
Carbadox	Gastrointestinal.	Swine dysentery treatment.
Ethylene glycol	Neurologic.	Antifreeze.
Solanum nigrum	Gastrointestinal and central nervous.	Nightshade in woods or permanent pastures.

Table 11.10. Causes of rectal prolapse

Cause	Comments
Diarrhea	Abnormally acid stool in the rectum causes irritation, tenesmus, and prolapse. Refer to the section on diarrhea for differentiation between causes of diarrhea.
Cough	Increased abdominal pressure generated during coughing (especially chronic prolonged bouts) causes displacement of the rectum. Refer to the section on cough for differentiation between causes of cough.
Piling	Environmental temperatures too low. Abdominal pressure on the pig at the bottom of the pile produces prolapse.
Zearalenone	Estrogens cause swelling of perineal area, tenesmus, and prolapse.
Floor design	Excessively sloped floors for crated sows causes increased pressure on pelvic structures as pregnancy progresses.
Antibiotics	Rectal prolapse has been reported in pigs in the first few weeks after lincomycin or tylosin has been added to the feed. Prolapses cease later as pigs apparently become accustomed to the antibiotic.
Inherited predisposition	Sporadic reports in the literature of herd outbreaks that occurred in the offspring of certain boars.
Postpartum	Complex etiology surrounding farrowing.
Prepartum	Constipation and pressure of heavily gravid uterus.
Any condition that is associated with tenesmus	Urethritis, vaginitis, rectal or urethral injury postbreeding, urethral calculi. Excess salt in the diet.

Table 11.11. Diseases that cause respiratory distress and cough in unweaned pigs

Disease	Ages Affected	Signs	Necropsy Findings
Iron deficiency anemia	1.5–2 weeks and older.	Pale pigs with normal temperature. Easily exhausted by exertion. Rapid respiratory rate, rough hair coat.	Dilated heart with excess pericardial fluid, lung edema, enlarged spleen.
Porcine reproductive and respiratory syndrome	Any age.	Respiratory distress, open-mouth breathing, fever, palpebral edema. Fading-piglet syndrome.	Mottled-tan, multifocal-to-diffuse pneumonia, enlarged edematous thoracic lymph nodes.
Bordetella bronchiseptica pneumonia	3 days and older.	Coughing, debilitation, rapid respiration, high mortality in affected pigs.	Patchy distribution of pneumonic lesions throughout the lung.
Bacterial pneumonia: *H. parasuis, P. multocida, A. pleuropneumoniae,* or *M. hyopneumoniae, A. suis*	1 week and older.	Dyspnea, cough.	Varies with organism. Often hemorrhage and fibrin.
Pseudorabies	Any age.	Respiratory distress, fever, salivation, vomiting, diarrhea, neurologic signs, high mortality.	Pneumonia, intestinal ulceration, hepatomegaly, white necrotic foci in any organ.
Toxoplasmosis	Any age.	Respiratory distress, fever, diarrhea, neurologic signs.	Pneumonia, intestinal ulceration, hepatomegaly, white necrotic foci in any organ.
Barking-piglet syndrome	Apparent at birth.	Immature domed heads; sparse, erect hair coat; grunting noise produced during attempts to breathe.	Small thyroid, inadequate lung expansion.
Streptococcus spp.	1 week and older.	Dyspnea, cough.	Fibrinous pneumonia.

body temperature. If infectious agents are involved, they tend to be viruses, except in cases where new adult animals have been introduced onto a farm that is infected with a bacteria (especially *A. pleuropneumoniae*) to which they lack previous exposure.

Sneezing

Unweaned Pigs (Table 11.13). Sneezing in piglets can be caused by atrophic rhinitis (AR), porcine cytomegalovirus (PCMV) infection, PRRS, hemagglutinating encephalomyelitis virus infection (encephalitic form), PR infection, or environmental contaminants such as dust, ammonia, or other noxious gases.

AR caused by *Pasteurella multocida, B. bronchiseptica,* and possibly other organisms is by far the most common cause of sneezing in unweaned pigs. AR seldom causes sneezing in pigs that are less than a week old but produces increasing frequencies as pigs approach weaning. Except for nasal discharge and tear staining, AR produces few clinical signs. Piglets are generally in good health otherwise and do not experience higher mortality. On necropsy, lesions are confined to the nose and may include a serous to purulent or blood-tinged exudate, along with turbinate atrophy and nasal septum deviation.

PCMV infection is most severe in newborn pigs. Infection in pigs older than 3 weeks is usually without clinical signs. In addition to sneezing, affected piglets may show edema around the jaw or tarsal joints, shivering, anemia, and respiratory distress. Mortality may reach 25%. In sows, there may be an increase in the numbers of stillbirths and mummies. A mild rhinitis is seen at necropsy. More prominent lesions include subcutaneous edema, generalized petechiation, pericardial and pleural effusion, and enlargement of lymph nodes.

Environmental dust and concentration of ammonia greater than 25 ppm irritate the respiratory mucosa and produce excessive lacrimation, serous nasal discharge, and shallow respiration. Ammonia-induced lesions are differentiated from infectious causes by their complete remission when the pig is removed from the contaminated environment.

PRRS causes a mild rhinitis and associated sneezing which is usually most frequently seen in nursery pigs but can also occur in unweaned pigs or in growing pigs.

Sneezing can be an early sign of PR or part of the clinical picture of hemagglutinating encephalomyelitis. However, in unweaned pigs these infections progress so rapidly to central nervous system involvement that by the time the veterinarian is called, the diagnosis is made from differentials of neurologic disease.

Weaned Pigs to Adults (Table 11.14). Sneezing in older animals is primarily due to AR, PR, or environmental contaminants. Concurrent infections are not uncommon. Rarely, cytomegalovirus affects nursery or growing pigs, in which it produces an acute, severe rhinitis with stenotic breathing that rapidly resolves without treatment in a few days.

EXTERNAL BODY SURFACE

Skin (Tables 11.15–11.18)
If the practitioner is not certain of the appearance of normal pig skin, the neonatal pig should be used as a reference. Mange is so widespread in the swine population that even people who have a long history of association with swine may not recognize how smooth, flat, and unblemished the normal skin is. Changes that are within the skin proper rather than within any of the structures beneath it are covered in Tables 11.16 and 11.17. Lumps or swellings that remain stationary when the skin is moved are covered in Table 11.18. Skin lesions should be examined for color changes, proliferation, distribution, and relation of lesions to normal skin. Pigs should be observed for pruritus. Color changes in the skin without associated lesions are covered in Table 11.17.

NEUROLOGIC SYSTEM

General Signs
Neurologic disorders include diseases that cause behavioral abnormalities, ataxia, abnormal gait, incoordination, paresis, paralysis, muscular tremors, trembling, paddling, dog-sitting, opisthotonos, convulsions, deafness, blindness, nystagmus, coma, or death.

Unweaned Pigs (Table 11.19). One of the major aids in diagnosis of neurologic disease in baby pigs is the distribution of affected piglets. By observing whether disease is occurring sporadically in single pigs, only in certain litters, or across all litters, the range of diagnostic possibilities can be greatly narrowed.

Diseases that occur sporadically and at a low level include middle-ear infection, tetanus, rabies, hypoglycemia, and streptococcal infections. Generally these can be differentiated by clinical signs and necropsy, although streptococcal infections require bacterial culture for confirmation of diagnosis.

Hypoglycemia and streptococcal infections, as well as PR, congenital tremors, vitamin A deficiency, blue eye disease, and iron or organophosphate toxicity may occur in a large number of litters within the farrowing group. History and the presence of signs in the sow are primary aids to differentiating between causes.

HC and ASF cause neurologic signs in baby pigs along with other signs of systemic disease. Inherited or congenital abnormalities that produce neurologic disorders include congenital motor defect in Large White and British Saddleback pigs, Landrace trembles, and Pietrain creeper syndrome. Occasionally Japanese encephalitis causes mild neurologic disease in baby pigs.

Table 11.12. Diseases that cause dyspnea and coughing in weaned and older pigs

		Clinical Signs	Associated Agents
Weaned to growing-finishing pigs		Signs primarily referable to respiratory tract. Dyspnea, cough, anorexia, fever, abdominal respiration, varying severities of clinical signs in an affected group of pigs.	*Mycoplasma hyopneumoniae, Actinobacillus pleuropneumoniae, Salmonella choleraesuis,Bordetella bronchiseptica, pseudorabies,* blue eye disease, *Mycoplasma hyorhinis, Pasteurella multocida, Haemophilus parasuis, Streptococcus suis, Streptococcus* spp., *Staphylococcus* spp., *Klebsiella* spp., *Moraxella* spp., *Corynebacterium* spp., *Fusiformis* spp.
			Porcine reproductive and respiratory syndrome virus. Swine Influenza virus.
		Rapid clinical course, fever, anorexia, depression, severe dyspnea, open-mouth breathing, cyanosis, foamy blood-tinged discharge from nose and mouth.	*Actinobacillus pleuropneumoniae.*
		Coughing with minimal other signs.	*Ascaris suum.*
			Metastrongylus spp.
		No coughing, but dyspnea and cyanosis, depression, fever, anorexia, and reluctance to move, lameness, stiff gait, swollen joints, ataxia, convulsions.	*Haemophilus parasuis, Mycoplasma hyorhinis, Streptococcus suis.*
	Adults	Very acute onset, near 100% morbidity, extreme prostration, complete anorexia, labored jerky respiration, hard paroxysmal cough, fever.	Swine influenza.
		Signs of systemic disease, sneezing, coughing, dyspnea, fever, anorexia, vomiting, constipation initially, then diarrhea, possibly tremors, ataxia, and convulsions.	Hog cholera, African swine fever.
			Pseudorabies.
		Rapid or abdominal respiration, moist nonproductive cough if present, pale.	See Table 11.29 on causes of anemia.
		Rapid, panting respiration, no cough, open-mouth breathing, gasping, extremely high temperature.	Porcine stress syndrome, heat prostration, puffer sow syndrome.
		Rapid or abdominal respiration, moist nonproductive cough, subcutaneous edema, enlarged abdomen.	Cardiac insufficiency.
		Dyspnea, abdominal breathing.	Diaphragmatic hernia caused by selenium deficiency, trauma, or genetics.
		Dyspnea.	Fumonisin.

Necropsy	Diagnosis
Usually anterioventral distribution of lesions. Firm areas of tissue with variable intralobular edema. Fibrinous pleuritis suggests involvement with *A. pleuropneumoniae, H. parasuis, P. multocida, M. hyorhinis,* or *S. choleraesuis.*	Culture of organism. Fluorescent antibody test for *M. hyopneumoniae.* Serology for pseudorabies.
Tan to mottled interstitial pneumonia. Enlarged, edematous tan-colored lymph nodes.	Virus isolation. Serology. Immunoperoxidase, polymerase chain reaction.
Acute hemorrhagic necrosis distributed throughout the lungs, especially dorsally in the diaphragmatic lobes. Fibrinous pleurisy, some blood-tinged fluid in the pleural cavity. Bloody foam in the trachea.	Isolation of organism. Serology. Pathology.
Areas of atelectasis, hemorrhage, edema, and emphysema in lungs. Septal and periseptal hemorrhage and necrosis in the liver.	Fecal examination for eggs (may be negative early). Necropsy findings. History of access to soil(absolute requirement for *Metastrongylus*).
Bronchitis, bronchiolitis in posterioventral margins of the diaphragmatic lobes. Areas of atelectasis.	
Fibrinous to serofibrinous pleuritis, pericarditis, arthritis, and meningitis.	Isolation of organism.
Often there is no opportunity to do a necropsy since death due to uncomplicated swine influenza is rare. Tenacious mucus in pharynx, larynx, trachea, and bronchi. Depressed deep purple areas in lung.	Physical examination. Serology. Virus isolation from pharyngeal swab.
Edematous tissue, swollen edematous lymph nodes with mottled hemorrhage, petechial or ecchymotic hemorrhage in bladder and kidneys, enlarged liver and spleen, splenic infarcts.	Hog cholera: fluorescent antibody test. African swine fever: fluorescent antibody test.
Few gross lesions, necrotic tonsillitis and pharyngitis, small white necrotic foci in liver.	Virus isolation or fluorescent antibody test on tonsil. Serology.
Pale musculature, lung edema, dilated heart, excess pericardial fluid, contracted spleen.	Packed-cell volume: 15–20%. Hemoglobin concentration: 6–7 g/dL.
Areas of pale, soft, or exudative muscle. Edema and congestion of lungs. Rapid autolysis.	Creatine kinase. Physical examination.
Enlarged, dilated heart, valvular endocarditis, pulmonary edema, enlarged liver.	Necropsy.
Viscera in thoracic cavity.	Necropsy. Selenium level in liver.
Marked pulmonary edema and serous pleural effusions.	Necropsy. Feed analysis.

Table 11.13. Diseases that cause sneezing in unweaned pigs

Disease	Ages Affected	Associated Signs	Signs in Other Pigs	Necropsy Findings	Diagnosis
Atrophic rhinitis	Signs not usually seen in pigs less than 1 week old. Sneezing occurs more often as pigs near weaning.	Tear stains below the eyes, nasal discharge.	Older pigs may sneeze or have tear-stained eyes and distortion of snout.	Turbinate atrophy, nasal septum deviation, serous to purulent nasal exudate.	Typical necropsy findings. Nasal culture and isolation of toxigenic Pasteurella multocida.
Porcine cytomegalovirus infection	Most severe signs in pigs less than 1 week old. Infection seldom apparent in pigs older than 3 weeks. Occasional outbreak in nursery.	Edema around the jaw and tarsal joints, petechiae, respiratory distress, mortality up to 25%.	Sows: mummification and stillbirths	Mild rhinitis, no turbinate atrophy, petechiae, subcutaneous edema, pericardial and pleural effusion, pulmonary edema, enlarged lymph nodes.	Virus isolation from the nose, lung, or kidney. Indirect fluorescent antibody test on sera of finishing pigs. Histology: inclusion bodies and cytomegaly.
Porcine reproductive and respiratory syndrome	Seen most often in nursery pigs but also in piglets and growers.	Respiratory distress, eyelid edema, poor growth.	Varies.	Mild rhinitis, no turbinate atrophy, interstitial atrophy, enlarged tan lymph nodes.	Virus isolation. Serology. Immunoperoxidase, polymerase reaction chain.
Environmental contaminants: ammonia, dust	Any age.	Excessive tearing, shallow respiration, serous nasal discharge.	Sow may also have mild signs.	Mild inflammation of respiratory epithelium.	Measurement of dust and ammonia levels in the environment.
Pseudorabies, hemagglutinating encephalomyelitis	Sneezing is a minor sign. In young pigs, neurologic signs predominate and the section on neurologic disease should be consulted to eliminate a diagnosis of pseudorabies or hemagglutinating encephalomyelitis.				

Table 11.14. Diseases that cause sneezing in weaned and older pigs

Disease	Course and Animals Affected	Other Signs	Diagnosis
Atrophic rhinitis	Chronic. Usually see signs in nursery through finishing pigs.	Conjunctivitis, tear-stained areas below eyes, distortion of the snout, occasional epistaxis.	Necropsy: turbinate atrophy, nasal septum deviation. Nasal culture and isolation of toxigenic *Pasteurella multocida*.
Environmental contaminants: ammonia, dust	Chronic. Signs in any age pig but more frequent in younger pigs, especially if on a slatted floor with a pit or a solid floor with urine accumulation.	Excessive tearing, tear-stained areas below eyes, serous nasal discharge, shallow respiration.	Measurement of concentrations of ammonia in the environment greater than 25 ppm. Dust in the environment, especially around feeding time.
Porcine reproductive and respiratory syndrome	Chronic. Other signs of respiratory disease usually more prominent than sneezing.	Coughing, dyspnea, poor growth, mild rhinitis, no turbinate atrophy.	Virus isolation. Serology. Immunoperoxidase, polymerase chain reaction.
Enzootic pseudorabies	Chronic. May see signs to some extent in all age groups but usually worst in one age group.	Cough.	Positive serology from live animals. Necropsy: rhinitis but no turbinate atrophy.
Epizootic pseudorabies	Fairly acute onset of signs. May start in one group of pigs and then spread to others. Signs more severe in younger pigs.	Cough, anorexia, constipation, depression, CNS signs and salivation, vomiting, convulsions.	Necropsy: especially in older pigs may not see any lesions, or may see necrotic tonsillitis, rhinitis, 1–2 mm necrotic foci in liver.
Blue eye paramyxovirus	Transient sneezing and coughing.	Ataxia, swaying, and circling.	Virus isolation.

Table 11.15. Ages at which certain skin diseases are more frequently seen

	Flat	Nonproliferative	Discrete	Immune complex disorder possibly associated with circovirus

[a]Foot-and-mouth disease, vesicular exanthema, vesicular stomatitis, swine vesicular disease, San Miguel sea lion virus, porcine parvovirus, drug eruption.

[b]Salmonellosis, *H. parasuis, A. pleuropneumoniae,* porcine reproductive and respiratory syndrome, colibacillosis, organophosphate toxicity, hemagglutinating encephalomyelitis.

Weaned Pigs to Adults (Tables 11.20–11.22). As with diagnosis of neurologic disease in baby pigs, a major aid is the distribution of affected animals. Disease occurrence should be identified as to whether it is sporadic or of low, medium, or high prevalence. Since toxicities are seen more frequently in older pigs, recent treatments, changes in the diet, and access to pasture or to chemicals in the pen should be investigated.

EYE AND ADNEXA

Serous Lacrimation

Ammonia in concentrations higher than 25 ppm is the most common cause of lacrimation in swine. Humans can detect ammonia at 10 ppm, so diagnosis can be made by sniffing the environment at pig level and, if ammonia is suspected, removing the pig to an area with clean air, where signs will gradually disappear. Excess tearing is also caused by organophosphate, carbamate, or iodine toxicity. Sources of organophosphates and carbamates include miscalculation of dosage used to treat animals or accidental incorporation of agricultural insecticides into animal feeds. Ethylenediamine dihydroiodide is an expectorant that may cause coughing and increased lacrimation when used in high doses for a prolonged period of time.

Mucopurulent Lacrimation and Conjunctivitis

Conjunctivitis and lacrimation are associated with AR, swine influenza (SI), HC, PR, exudative epidermitis, blue eye disease, and chlamydial and streptococcal infection. The conjunctivitis seen with AR, SI, and PR tends to be

Table 11.17. Cyanosis/hyperemia: discoloration of the skin in the absence of gross skin lesions

	Cause	Pigs Affected and Time of Occurrence	Appearance of Discolored Skin	Associated Conditions
Primary lesion is in the skin	Dermatosis erythematosus	White pigs	Red discoloration over the ears, sides, and abdomen	Possible association with clover pasture but also seen in confinement
	Benign peripartal cyanosis	Sows around the time of farrowing	Generalized cyanosis, especially on the udder and hindquarters	Seen in sows bedded on urine-soaked sawdust
	Sunburn	White pigs	Red discoloration of the dorsum and sides	Recent exposure to the sun
	Transit erythema	Warm months, white pigs	Erythema, especially of ventral areas	Contact with urine, feces, phenolic disinfectants, or lime
	Carbon monoxide toxicity	Perinatal pigs, winter	Uniform, bright red color	Incomplete combustion of fuel in the heater
	Porcine dermatitis and nephropathy syndrome	Weaned and older pigs. Usually finishers.	Multiple flat circular coalescing dark red to purplish, especially over the ham and thighs.	Possible association with circovirus
Primary lesion is in a system other than the skin	Porcine stress syndrome	Heavily muscled pigs, especially Pietrain and Landrace	Blotchy cyanosis becoming coalesced on the dependent side	Triggered by physical exercise, excitement, heat, or halothane anesthesia
	Systemic salmonellosis	Pigs 2–4 months old	Cyanotic ears, tails, ventrum, and extremities	Continuous flow operation, especially after addition of new pigs
	Mastitis	Sows postpartum	Red to purplish udder	
	Haemophilus parasuis	Nursery and grower pigs	Cyanosis of ears, tail, and extremities	Associated with systemic disease
	A. pleuropneumoniae	Growing and finishing pigs	Cyanosis of the nose, ears, and legs progressing to whole body	Associated with peracute respiratory disease
	Organophosphate or carbamate toxicity	Any age pig	Cyanosis of the extremities	Hypoxia develops secondary to increased respiratory tract secretion, bronchoconstriction, erratic slow heart beat and CNS signs
	Porcine reproductive and respiratory syndrome	Sows	Cyanosis of the extremities, blotchy dark red to purple areas over the body	Anorexia, abortion, respiratory signs in younger pigs
	Transitory change prior to onset of typical signs	Has been seen in hog cholera, African swine fever, and *Strep. suis* infections. Transitory hyperemia, especially over the snout, ears, belly, and hindquarters.		
	Terminal sign in disease	Cyanosis of extremities is seen in terminal stages of *E. coli* enteritis and hemagglutinating encephalomyelitis in baby pigs.		
	Porcine dermatitis nephropathy	Nursery to finish	Multiple flat circular coalescing dark red or purplish, especially over the ham and thighs	Possible association with circovirus

Table 11.18.   Diseases that cause lumps or swellings under the skin of pigs

Location of Lumps or Swellings	Possible Causes	Aspirate Appearance
Submandibular region	Jowl abscess (*Streptococcus* group E)	Pus with organisms
	Pharyngeal anthrax	Edema
	Tuberculosis	"Sulfur granules"
Variable distribution	Neoplasia:	Solid tissue, neoplastic cells
	lymphosarcoma	
	malignant melanomatoma	
	cavernous hemangioma	
	others	
	Arcanobacterium pyogenes	Pus with organisms
	Fusiformis necrophorus	Pus with organisms
Over the back, shoulders, thighs	Lumpy skin disease	Solid, dermal cells
Neck caudal to the ear or in the ham	Injection reaction	Pus with or without organisms
Epididymis or testicles	Brucellosis	Pus with organisms
Shoulder, flank, vulva, ear, or over the hindquarters	Hematoma	Blood or serum
Posterior aspect of the hocks, usually bilateral	Adventitious bursitis of the hocks	Synovial fluid (procedure not recommended)
Base of tail, hindquarters	Infection secondary to tail biting	Pus with organisms

fairly mild and to produce a serous to mucopurulent discharge. A more severe conjunctivitis is seen with HC, exudative epidermitis, blue eye disease, and streptococcal and chlamydial infections. In these diseases the discharge is frequently so tenacious as to cause the eyelids to adhere and blind the pig.

Palpebral Edema

Palpebral edema is frequently seen in edema disease and is not uncommon in PRRS, *Haemophilus parasuis,* and blue eye paramyxovirus infection.

Cataracts

Cataract formation has been associated with riboflavin or niacin deficiency and hygromycin toxicity.

Blindness (Table 11.23)

Blindness in pigs is seldom seen in the absence of other signs. The associated signs are usually indicative of the etiology. Two diseases that may cause blindness in the absence of other signs are PR, when blindness occurs in a pig that has recovered from the acute stage of the infection, and arsenilic acid toxicity occurring over a prolonged period of time.

SIGNS NOT REFERABLE TO ANY ONE SYSTEM

Systemic Disease (Tables 11.24, 11.25)

Occasionally pigs become ill or poor-doing without a specific predominant clinical sign. These pigs may be lethargic, depressed, anorexic, febrile, dehydrated, or prostrate with a varying amount of morbidity and mortality. Infectious disease, especially in a subclinical or chronic form, is frequently the cause.

Sudden Death (Table 11.26)

While it might be argued that death is always sudden (i.e., that the transition from living to not living always occurs in a fraction of a second), the term "sudden death" as commonly used in the field refers to the death of an otherwise normal appearing animal.

Wasting and Ill-Thrift (Table 11.27)

Wasting and ill-thrift are signs of chronic disease. Frequently the cause of ill-thrift in one pig cannot be determined even with the aid of a necropsy. This is often the case with diseases that may damage the brain, such as colibacillosis and PR. Because the lesions are microscopic, they are frequently overlooked. When there is a high percentage of poor-doers in a herd, diagnosis should include necropsies of the affected pigs, and in addition the types and levels of acute diseases in the herd should be determined. The combined findings from pigs acutely and chronically affected are most likely to provide a diagnosis.

Anemia

Anemia is the condition of having a blood hemoglobin level that is lower than normal. Minimum normal hemoglobin levels (g/100 mL) for pigs of different ages are as follows: birth, 11; 1 week, 10; 3 weeks, 10; 4 months and older, 12.

Unweaned Pigs (Table 11.28). Anemia in baby pigs is primarily due to iron deficiency. Occasionally eperythrozoonosis, and rarely umbilical hemorrhage, will produce anemic pigs. The primary features that distinguish iron deficiency, eperythrozoonosis, and umbilical hemorrhage are the ages of the affected piglets and the presence of icterus. Icterus is often prominent with eperythrozoonosis and is not seen with iron deficiency or umbilical hemorrhage. Umbilical hemorrhage occurs during the perinatal period, eperythrozoonosis tends to be seen in pigs less than 5 days of age, and iron deficiency is seen in pigs 10 days of age or older. Generally in iron deficiency anemia there is a history of failure to administer an adequate iron preparation. Umbilical hem-

orrhage is sometimes associated with the use of sawdust for bedding.

Porcine cytomegalovirus infection in utero may cause pigs to be born stunted, anemic, and with edema around the jaw and tarsal joints.

Anemia in baby pigs has also been reported following infestation with *Strongyloides ransomi* and *Balantidium coli*. The primary clinical signs in these pigs are anorexia, diarrhea, and reduced growth rate. Diagnosis is best made at necropsy.

Weaned Pigs to Adults (Table 11.29). Gastric ulceration and parasitism are the most common causes of anemia in weaned to adult pigs. Toxicities that cause anemia other than mycotoxins are rarely encountered clinically. However, anemia has been shown to occur after intoxication with cadmium, cobalt, coal tar, iodine, phenothiazine derivatives, and vitamin D. Nutritional deficiencies are rarely encountered in modern feeding systems, but anemia will result from deficiency of copper, folacin, protein, riboflavin, vitamin B_6, or vitamin K.

MUSCULOSKELETAL SYSTEM

Lameness is the inability to use one or more limbs in a normal fashion while generally displaying a normal degree of alertness and coordination in the other unaffected limbs. Lameness may present as reduced ability or inability to bear weight, alteration or shortening of stride, or recumbency.

Unweaned Pigs (Table 11.30). The major causes of lameness prior to weaning are trauma and infectious polyarthritis. Trauma is more common in pigs that are less than 1 week of age, and infectious polyarthritis is more frequently seen in 1- to 3-week-old pigs. Joint swelling and fever are frequent findings in polyarthritis but are only occasionally seen with trauma.

Splayleg occurs with moderate frequency and is easily recognized by its clinical signs.

Occasionally injections made into the hindleg will produce lameness due to either muscle irritation or nerve damage. In the first case the leg will be swollen and possibly hot, and the pig will tend to carry it. Damage to the sciatic nerve will produce muscle atrophy and the leg will be extended. Injection of iron creates a microenvironment in tissue that favors the growth of *Clostridium perfringens* carried in by a contaminated needle. Diagnosis of improper injection technique is aided by changing the site of the injection to the neck and observing whether lameness continues in the herd.

Arthrogryposis, syndactyly, polydactyly, and thick legs occur rarely and are easily diagnosed by their physical appearance.

Weaned Pigs to Adults (Tables 11.31, 11.32). A major portion of the lameness experienced by young pigs in the age range of 2–4 months is due to infectious polyarthritis. In pigs this age, the clinician should look for multiple sites of infection. Lameness in one leg is easily overlooked because of more severe signs in another leg. Older growing pigs and adults mainly experience lameness that results from injury, especially to the foot. The damage may be limited to the foot or may ascend into one or more joints. Floors that have abrasive, slippery, wet, dirty, or uneven surfaces, protruding sharp edges, exposed aggregate, and uneven or inappropriately sized slats for the size of the pigs predispose to lameness. The amount of competition between pigs should be evaluated when investigating lameness in older pigs. Lameness that occurs in gilts and less so in sows is likely to be due to trauma and secondary infection. Lameness in sows just after weaning may be caused by calcium or phosphorus imbalance in the ration. Osteochondrosis is another common cause of lameness in pigs in the finishing stage or in young adults.

UROGENITAL SYSTEM

Abortion, Stillbirth, and Mummies (Tables 11.33, 11.34)

Diagnosis of the cause of abortion in swine is seldom straightforward and is frequently unsuccessful. Often, the agent that produced death in the fetuses or abortion is no longer present when the problem is recognized clinically. However, there are some characteristic features that are helpful in at least determining the general class of agents likely to be involved. Two major classes exist. First are the agents that cause primary infection of the reproductive tract and that are probably responsible for 30–40% of abortions, mummies, and stillbirths. The second class (including toxins, environmental and nutritional stresses, and systemic disease in the sow) is responsible for the other 60–70%.

A primary aim in diagnosis of abortion is to differentiate between these two major classes by measuring levels of immunoglobulins in aborted fetuses. At 70 days of gestation (17 cm crown-to-rump length) swine fetuses are immunocompetent and will produce antibodies in response to contact with an infectious agent. In the normal pregnancy, the uterine environment is sterile and pigs are born without immunoglobulins. Therefore, the finding of immunoglobulins in fetuses indicates the presence of an infectious agent in the uterus. In abortions that occur in the last third of gestation, fetal serum or thoracic fluid should be collected and submitted for total immunoglobulin determination. If antibodies are present, specific serologic testing against common agents may be done (see Table 11.41).

The age of the fetuses should be determined by crown-to-rump length measurements (Table 11.33) and compared to the stage of gestation. When maternal fail-

Table 11.19. Diseases that cause neurologic signs in unweaned pigs

Disease	Proportion of Litters	Proportion of Affected Piglets within a Litter	Mortality	Age at Onset	Signs in Sow	Signs	Necropsy Findings	Diagnosis
Hypoglycemia	Sporadic.	May be 1 or 2 in a litter if more pigs than teats, or whole litter if sow agalactic.	High, 90–100% of affected pigs.	Usually 2–3 days but can be any age.	May be off feed, not milking, in sternal recumbency.	Ataxia, sternal or lateral recumbency, convulsions, paddling of the forelegs, gasping and chomping of the jaws, bradycardia, subnormal temperature.	No food in the stomach. Absence of body fat, mahogany brown muscles.	Blood glucose less than 50 mg/100 mL, necropsy findings, evidence of lack of milk.
Pseudorabies	High, up to 100%.	High, up to 100% in pigs from nonimmune sows, 20–40% in pigs from immune sows.	High, up to 100%.	Initial outbreak affects all ages of unweaned pigs.	Abortion, vomiting, sneezing, coughing, constipation, CNS signs.	Dyspnea, fever, hypersalivation, vomiting, diarrhea, ataxia, nystagmus, convulsions, coma. Younger pigs are more severely affected.	Few visible gross lesions. Congestion of nasal mucosa and pharynx, edema in lung, necrotic tonsillitis, 1–2 mm white foci in liver and spleen.	Virus isolation and fluorescent antibody on tonsils and brain. Serum antibodies.
Congenital tremors	High.	80% or more.	Low, 0–25%.	Birth.	None.	Severe tremors at birth that gradually diminish within 3 weeks. Tremors disappear when pigs are asleep. Tremors most severe in pigs infected at the beginning of the outbreak.	No gross lesions.	Histological evidence of myelin deficiency.
Streptococcal meningitis	Low to 50%.	Up to 70% of the litter.	High in affected pigs.	A few days up until weaning.	None.	Elevated temperature, hindquarter weakness, stiff gait, stretching movements, tremors, incoordination, paddling, paralysis, opisthotonos, convulsions, blindness, deafness, lameness, sudden death.	Congestion of brain and meninges, suppurative meningitis and polyarthritis, excess turbid cerebrospinal fluid, valvular endocarditis.	Isolation of alpha- and beta-hemolytic streptococci in Lancefield group D, I, and II from lesion of suppurative meningitis.
Teschen	High, up to 100%.	High, up to 100%.	High in affected pigs.	Any.	Similar to piglets.	Fever, anorexia, ataxia, progressing to convulsions, paralysis, opisthotonos, and coma.	No gross lesion. Histological lesions in CNS.	Virus isolation. Fluorescent antibody. Serology.
Talfan	Sporadic.	Low.	Low.	First few weeks.	None.	Fever, anorexia, ataxia, seldom convulsions or paralysis.		
Iron toxicity	As many as were given iron injection.	Usually the entire litter.	High.	Shortly after administration of iron.	None.	Apathy, drowsiness, dyspnea, and coma.	Edema around injection site, pallor of muscles, swollen kidneys, epicardial hemorrhage, hydrothorax, and liver necrosis.	History of iron injection. Necropsy findings.

(continued)

Table 11.19. Diseases that cause neurologic signs in unweaned pigs (*continued*)

Disease	Proportion of Litters	Proportion of Affected Piglets within a Litter	Mortality	Age at Onset	Signs in Sow	Signs	Necropsy Findings	Diagnosis
Organophosphate toxicity	Can be high, depending on how many treated.	High, up to 100%.	High.	Seen at birth.	Usually none.	Salivation, vomiting, stiffness, sawhorse stance, diarrhea, colic, lacrimation, sweating, dyspnea, muscle tremors.	Pulmonary edema.	History of sow being treated prior to farrowing.
Vitamin A deficiency of the sow	High.	High.	High.	At birth.	None.	Incoordination, head tilt, hindleg paralysis, paddling, eye lesions.	Yellow-gray liver, kidney lesions, fluid in body cavities.	Liver biopsy for vitamin A analysis.
Congenital malformation	Sporadic.	Low.	High.	At birth.	None.	Variable: hydrocephalus, cyclops, brain hernia, eyeless, catlin mark, hindleg paralysis, string halt. Cerebellar hypoplasia.	Anomaly of nervous (and other) systems.	Physical exam and necropsy findings. Except for cerebellar hypoplasia, the familial relationships of affected pigs indicate that the trait is heritable.
Blue eye paramyxovirus	High, 20–65%.	High, 20–50%.	High, 80–100%.	Any, especially 2–15 days old.	Mild anorexia, few with corneal opacity.	Depression, ataxia, dilated pupils, nystagmus, ocular discharge, palpebral edema, corneal opacity.		Virus isolation.
Hemagglutinating encephalomyelitis virus	Low to 50%.	Up to 100%.	High.	Usually about 4 days.	None.	Lethargy, vomiting, paddling, squealing.	No gross abnormalities.	Histopathology. Serum antibodies.

Table 11.20. Differential diagnosis of neurologic disease in weaned and older pigs

Condition	Ages Affected	Distribution of Affected Pigs	Clinical Signs	Mortality	Necropsy	Diagnosis
Pseudorabies	All ages. In younger pigs, signs more apt to affect central nervous system and be more severe.	Entire herd affected.	Young to mature swine: sneezing, coughing, constipation, salivation, vomiting, muscle spasms, ataxia, convulsions, paddling, coma. Pregnant swine: resorption, mummification, stillborn piglets.	High, especially in younger pigs.	Few visible gross lesions. Congestion of nasal mucosa and pharynx, pulmonary edema, necrotic tonsillitis, 1–2 mm white necrotic foci in liver and spleen.	Virus isolation from tonsils and brain. Fluorescent antibody test on chilled tonsils and brain. Serum antibodies.
Edema disease	1–2 weeks after weaning.	Up to 15% of pigs in the nursery.	Sudden death in some pigs. Incoordination and staggering gait, ataxia, tremors, paddling, palpebral edema.	High, 50–90%.	Ventral reddening of skin. Edema in subcutaneous tissue, stomach wall, and mesocolon.	Signs, epidemiology. Pure culture of *E. coli* from intestine and colon. Isolation of toxin.
Salt poisoning (water deprivation)	Any age but more commonly seen in nursery to finishing pigs.	Affected by pens.	Blindness, muscle weakness and fasciculations, dullness, anorexia, vomiting, diarrhea, seizures, head tremor, opisthotonos, backing up, falling over, paddling and chomping. Hemoconcentration, eosinopenia (Na >160 mEq/L).	High.	Gastritis, gastric ulcers, enteritis, constipation.	Histopathology: pathognomonic eosinophilic cuffing of blood vessels in cerebrum.
Brain stem malacia	Nursery pig or occasionally finishing pig.	Sporadic.	Dullness, mild incoordination, unthriftiness, disproportionately large head, failure to grow.	Low.	None.	Histologic evidence of brain stem malacia.
Meningitis due to *Streptococcus suis* (or *Salmonella*)	Usually in nursery pigs. Occasionally in finishing pigs.	A few pigs affected over a few weeks. Occasionally outbreaks.	Elevated temperature, hindquarter weakness, stiff gait, stretching movements, tremors, incoordination, paddling, paralysis, opisthotonos, convulsions, blindness, deafness, lameness.	High.	Congestion of brain and meninges, suppurative meningitis, excess turbid cerebrospinal fluid, suppurative polyarthritis.	Isolation of alpha- and beta-hemolytic streptococci in Lancefield group D, I, and II from lesions or suppurative meningitis (isolation of *Salmonella choleraesuis*).
Middle-ear infection	Any age.	Sporadic.	Abnormal head carriage, tendency to circle.	Low.	Inflammation and/or suppuration in middle ear.	Clinical signs and necropsy findings.

(*continued*)

Table 11.20. Differential diagnosis of neurologic disease in weaned and older pigs (*continued*)

Condition	Ages Affected	Distribution of Affected Pigs	Clinical Signs	Mortality	Necropsy	Diagnosis
Haemophilus parasuis meningoencephalitis	Usually nursery pigs 5–8 weeks old.	10–50%, especially if recently commingled.	Fever, muscle tremors, incoordination of hindlegs, recumbency, paddling.	Moderate, 20–50%.	Fibrinous meningitis with pleuritis, pericarditis, peritonitis, and arthritis.	Isolation of *Haemophilus parasuis*.
Teschen disease	Any age.	Entire herd may be affected.	Fever, anorexia, ataxia, progressing to convulsions, paralysis, opisthotonos, and coma.	High.	No gross lesions. Histologic lesions in CNS.	Virus isolation. Fluorescent antibody test. Serology.
Organic arsenical toxicity	Any age, but especially in pigs treated for swine dysentery or eperythrozoonosis.	Several to many pigs affected.	Ataxia, posterior paresis, goose-stepping, blindness, paralysis.	Low.	None.	Sciatic nerve demyelination. Kidney and liver arsenic levels >2 ppm.
Brain or spinal cord injury	Any age.	Sporadic.	Tend to show local neurologic deficit.	Low.	Localized damage to brain or spinal cord.	Necropsy reveals trauma, skull or vertebrae fracture, abscesses, parasite migration; *S. dentatus*, fibrocartilaginous emboli.
Tetanus	Any, but most common in recently castrated pigs.	Sporadic.	Stiff gait, erect ears and tail, protrusion of the nictating membrane, progresses to lateral recumbency, opisthotonos, rigid muscles, stiff-legged gait, spasms.	High.	No gross lesions.	Gram-positive bacilli with terminal spores seen at site of injection if found.
Rabies	Usually older than 2 mos.	Sporadic.	Preoccupation with and twitching of nose, prostration, chewing, salivation, generalized clonic muscle spasms.	High, 100%.	No gross lesions.	Fresh brain for animal inoculation. Histopathology. Negri bodies. Fluorescent antibody test.
Listeriosis	Any. Signs more severe in younger pigs.	Sporadic.	Fever, trembling, incoordination, dragging hindlegs while showing stiff gait with forelegs, hyperexcitability.	High in young pigs.	Meningitis, focal hepatic necrosis.	Isolation of *Listeria monocytogenes* from brain, spinal cord, or liver.

Toxicities (See Table 11.21.)
Nutritional deficiencies (See Table 11.22.)

Table 11.21. Toxicities resulting in neurologic disease

Major Signs	Toxic Agent	Other Signs	Neurologic Signs	Source
Clinical signs largely gastrointestinal	Inorganic arsenic	Vomiting, diarrhea	Convulsions	Herbicides, cotton defoliants, insecticides
	Lead (rare)	Vomiting, diarrhea, salivation, anorexia	Muscle tremors, ataxia, clonic seizures, blindness	Motor oil, paint, grease, batteries
Frequently characterized by violent activity	Chlorinated hydrocarbons		Hyperexcitability, hyperesthesia, muscle tremors, tonoclonic seizures	Insecticides
	Strychnine		Tetanic seizures	Rodenticide
	Sodium fluoroacetate		Convulsions, running fits	Rodenticide
	Water intoxication	Anorexia, diarrhea	Depression, blindness, muscle tremors, hyperesthesia, ataxia, convulsions, coma	Unrestricted access to water after deprivation
Signs of cholinesterase inhibition	Dichlorvos	Lacrimation, miosis, cyanosis, reddening of skin, salivation, diarrhea, vomiting	Muscle rigidity, tremors, paralysis, depression	Anthelmintic
	Organophosphates	Lacrimation, miosis, cyanosis, reddening of skin, salivation, diarrhea, vomiting	Muscle rigidity, tremors, paralysis, depression	Insecticides
	Carbamate	Lacrimation, miosis, cyanosis, reddening of skin, salivation, diarrhea, vomiting	Muscle rigidity, tremors, paralysis, depression	Insecticides
Generalized central nervous system signs	Nitrofurans		Hyperirritability, tremors, weakness, convulsions	Antibacterial used to treat swine enteric diseases
	Ammonia salts		Depression, tonoclonic seizures	Cattle feed
	Mercury	Vomiting, diarrhea	Ataxia, blindness, paralysis, coma	Grain treated with mercury as a fungicide, paint, batteries
	Pentachlorophenol	Vomiting	Depression, muscle weakness, posterior paralysis	Wood preservative
	Phenoxy herbicides	Anorexia	Depression, muscle weakness, ataxia	Herbicides
Seen in pigs with access to pasture or fencerows	Pigweed		Weakness, tremors, ataxia, posterior paralysis, coma	Pasture
	Cocklebur	Vomiting	Depression, ataxia, muscle weakness, muscle tremors	Pasture
	Nightshade	Anorexia, vomiting, constipation	Depression, ataxia, muscle tremors, convulsions, coma	Pasture
	Nitrate, nitrite	Salivation, polyuria, miosis	Muscle weakness, ataxia, convulsions	Lamb's-quarter, Canada thistle, simonweed, sweet clover
Deafness	Hygromycin		Deafness, blindness due to cataracts	Anthelmintic
	Streptomycin		Deafness	Antibiotic

Table 11.22. Nutritional imbalances resulting in neurologic disease

Nutrient Imbalance	Signs
Calcium and phosphorus deficiency	Stiff gait, hyperesthesia, posterior paralysis
Magnesium excess	Generalized anesthesia, complete muscular relaxation
Magnesium deficiency	Lameness, bowed legs, hyperirritability, tetany
Sodium chloride deficiency	Ataxia, decreased feed intake and weight gain
Iron toxicity	See Table 11.19
Copper deficiency	May result in demyelinization of nerves, but anemia, cardiac hypertrophy, and crooked hindlegs are more prominent signs
Vitamin A deficiency	Growing pigs: head tilt, incoordination, stiff gait, lordosis, hyperexcitability, muscle spasms, night blindness, paralysis. Pregnant sows: see Table 11.19
Niacin or riboflavin deficiency	May result in demyelinization of nerves, but lameness, skin lesions, cataracts, and poor growth are more prominent signs
Pantothenic acid deficiency	Goose-stepping, incoordination, diarrhea, coughing, hair loss, and poor growth
Vitamin B_6 deficiency	Poor growth, diarrhea, anemia, hyperexcitability, ataxia, epileptiform convulsions

Table 11.23. Diseases that cause blindness in pigs

Cause	Pigs Affected	Other Signs	Associated Factors
Arsenilic acid toxicity	Pigs fed arsenilic acid for swine dysentery or eperythrozoonosis.	Acute: posterior paresis or paralysis. Chronic: blindness, quadriplegia.	History of arsenicals added to the feed in improper dosage.
Salt poisoning (water deprivation)	Usually nursery or finishing pigs but can occur in adults.	CNS signs, ataxia, muscle weakness and fasciculations, convulsions.	Usually a high percentage of affected pigs in one or more pens, associated with disruption in water supply or whey feeding.
Pseudorabies	Usually in 2- to 4- month-old pigs.	Ill-thrift, failure to grow.	Sequelae to pseudorabies infection in an apparently recovered pig.
Lead or mercury toxicity	Nursery to adult.	CNS and gastrointestinal signs.	Access to paint, batteries, motor oil, or seeds treated with organic mercurial fungicides.
Botulism	Grower to adults.	Flaccid paralysis.	Access to a decomposing carcass.
Blue eye disease	Nursery to finishing pigs.	CNS signs. Corneal opacity.	Acute onset of disease in herd with high piglet mortality.
Vitamin A deficiency	Nursery to finishing pigs.	Stiff gait, restlessness, paralysis of rear legs.	Rare. Possible after feeding improperly stored grain.
Hygromycin toxicity	Usually sows.	Cataracts.	Longer feeding period than recommended.
Hemagglutinating encephalitis or *Strep. suis*	Unweaned pigs.	CNS signs, convulsions.	Blindness not apparent until neurologic signs are well advanced.

Table 11.24. Systemic disease in unweaned pigs

Disease	Signs in Sow	Piglet Necropsy	Diagnosis
Streptococci (*S. equisimilis, S. suis*)	None.	Congestion of parenchymatous organs, strands of fibrin, meningitis, polyarthritis, enlarged lymph nodes.	Culture of organisms.
Hypoglycemia	Mastitis or nonfunctional mammary glands.	No gross lesions, absence of body fat or food in the stomach.	Necropsy findings.
Iron toxicity	None.	Muscle edema and necrosis around the injection site.	History of recent iron injection and necropsy findings.
Escherichia coli septicemia	None.	Possibly congested organs, enlarged lymph nodes, edema, fibrin tags in abdomen, or minimal changes.	Isolation of *Escherichia coli*.
Porcine reproductive and respiratory syndrome	None or anorexia, agalactia.	Interstitial pneumonia, enlarged tan lymph nodes.	Virus isolation, fluorescent antibody.
Haemophilus parasuis	None.	Fibrinous meningitis, pericarditis, peritonitis, and arthritis.	Isolation of *Haemophilus parasuis*.
Pseudorabies (chronic)	Usually none, may be salivation, constipation, vomiting, abortion.	Usually no gross lesions. Congestion of nasal mucosa, necrotic tonsillitis, focal necrosis in liver and spleen.	Tonsils for fluorescent antibody or virus isolation. Serology.
Erysipelas	Usually none but may show lameness, fever, skin lesions.	Diffuse cutaneous hemostasis, petechial hemorrhage in kidneys.	Isolation of *Erysipelothrix rhusiopathiae*.
Leptospirosis	Possibly abortion, fever, jaundice, or agalactia.	Grayish-white foci in kidneys.	Culture of organism or presence on dark field exam of kidneys.

ure is the cause of pregnancy termination, the fetuses will all be the same age and this age will match the day of gestation. Often when fetal death occurs, fetuses within the litter will have different ages, with the youngest ones having died at some time earlier than the abortion occurred. Viral infection is the major cause of mummified fetuses, but mummies are also seen with a number of other etiologic agents. When there is only one or a few stillborn pigs in an otherwise normal litter, these tend to be caused by events at farrowing such as large litter size, later birth order, prolonged farrowing, or anoxia. When stillbirths are part of a litter that also contains mummies, then an infectious agent is more likely to be involved.

Antibody titers of blood samples taken from the sow must be interpreted carefully. A positive titer only confirms the presence of the organism on the farm; it does not indicate whether that organism was the cause of the reproductive failure. Paired sera and demonstration of a rising titer are more reliable evidence of a recent infection. Positive titers on sera from aborted fetuses are diagnostic for the disease; since there is no transfer of antibodies across the placenta, antibody in the fetus is evidence of infection.

Positive fluorescent antibody tests done on fetal tissue may be diagnostic; however, negative tests in fetuses over 70 days of gestational age do not rule out a diagnosis, since immunocompetent pigs may have produced enough antibody to complex with the infecting agent and interfere with the test.

Polyuria/Polydipsia
Polyuria is not easily recognized in pigs on slatted floors; however, astute stockpersons occasionally observe sows drinking and urinating excessively. In sows, cystitis and nephritis are the most common causes of polyuria. Intoxication with citrinin or ochratoxin may also produce polyuria. Especially during the winter, underfeeding sows causes protein catabolism with increased blood urea nitrogen and subsequent increase in urine volume.

Hematuria
The most common cause of hematuria is cystitis, sometimes associated with pyelonephritis due to organisms such as *Actinobaculum suis, Streptococcus spp., Klebsiella spp., and E. coli*. Leptospirosis and *Stephanurus dentatus* infections also may produce hematuria.

Vaginal Prolapse
There is probably a hereditary predisposition to vaginal and uterine prolapse. Sows housed on a floor with an excessive slope, especially if they are kept in a dirty or wet environment, are more prone to developing prolapse. Other causes include zearalenone toxicity, injury from service, and causes of undetermined etiology that occur around the time of farrowing and in gilts following their first estrus.

Vulvar Discharge (Table 11.35)
A purulent or blood-tinged discharge may be due to cystitis, pyelonephritis, vaginitis, or metritis. The first two diseases occur in sows at any stage but are especially noted during gestation, whereas metritis and vaginitis usually occur after farrowing or breeding.

Vulval Enlargement
Unilateral enlargement of one lip of the vulva can be caused by traumatic injury at any time or by hematoma

Table 11.25. Systemic disease in weaned pigs to adults

Disease	Pigs Affected and Clinical Signs	Necropsy Findings	Diagnosis
Generally Seen in Nursery to Finishing Pigs			
Septicemic salmonellosis	Weaning to 4 months of age. Fever, a few pigs found dead, huddling, low morbidity (10%), high mortality, possibly diarrhea after 3–4 days, depression, anorexia.	Diffuse cutaneous hemostasis, infarcts in gastric mucosa, enlarged liver and spleen, moist swollen lymph nodes, miliary white necrotic foci in liver, serous to necrotic colitis after 3 days.	Isolation of *Salmonella choleraesuis* from liver or spleen.
Haemophilus parasuis	Pigs 1–4 months old. Anorexia, fever, depression, cyanosis, stiff gait, reluctance to move, dog-sitting, eyelid edema, and dyspnea.	Fibrinous or serofibrinous meningitis, pericarditis, pleuritis, peritonitis, and arthritis.	Isolation of *Haemophilus parasuis*.
Mycoplasma hyorhinis infection	Pigs 3–10 weeks old. Moderate fever, depression, reluctance to move, anorexia, possible dyspnea.	Serofibrinous to fibrinopurulent pericarditis, peritonitis, pericarditis, and arthritis.	Isolation of *Mycoplasma hyorhinis*.
Edema disease	Pigs 4–12 weeks old. Usually 1–2 weeks after weaning. Morbidity <15%, mortality 50–90%, often a few pigs found dead. Ataxia, tremors, staggering, eyelid edema, temperature usually normal.	Edema in subcutaneous tissues, submucosa of the stomach, and mesocolon, full stomach, empty small intestine, possibly serous fluid with a few strands of fibrin in the pleural, pericardial, and peritoneal cavities.	Isolation of edema-associated *E. coli* serotypes.
Erysipelas	Pigs 3 months to 3 years old, but also adults. Fever (40–42°C), recumbency, reluctance to rise, anorexia, depression, urticarial skin lesions, cyanosis, often a few pigs found dead.	Diffuse cutaneous hemostasis, congested or edematous lungs, petechial or ecchymotic hemorrhage on epicardium, gastritis, enlarged liver and spleen, excess fluid in joints, and proliferation of synovia.	Isolation of *E. rhusiopathiae* from heart, lungs, spleen, liver, joints, or kidneys.
Postweaning multisytemic wasting syndrome	Usually nursery.	Interstitial pneumonia, enlarged lymph nodes and spleen.	Histopathology.
Any Age from Weaned Pigs to Adults			
Porcine reproductive and respiratory syndrome	Usually nursery to grower pigs. Dyspnea, slow growth, rough hair coat.	Interstitial pneumonia, enlarged tan lymph nodes.	Virus isolation. Fluorescent antibody. Serology.
Porcine dermatitis nephropathy syndrome	Nursery to (especially) finisher pigs.	Reddened and enlarged abdominal lymph nodes, ascites, swollen mottled kidneys.	Histopathology kidneys and skin.
Hog cholera	Any age pigs. Anorexia, fever, depression, conjunctivitis, constipation early, severe watery diarrhea later, huddling, staggering, weaving, cyanosis, possibly convulsions, a few pigs found dead, abortion in pregnant sows.	Edematous tissues, swollen edematous lymph nodes with mottled hemorrhage, petechial to ecchymotic hemorrhage in kidneys, bladder, larynx, and heart, splenic infarcts, button ulcers in the large intestine, bronchopneumonia or lung congestion.	Fluorescent antibody virus determination on tonsil, pharyngeal lymph nodes, or spleen.
African swine fever	Any age pigs. Depression, reluctance to rise, fever, anorexia, hyperemia of skin, dyspnea, possibly diarrhea and vomiting, abortion of pregnant sows.	Edema, ascites, hydrothorax, petechial ecchymotic hemorrhage of epicardium and lungs, swollen edematous lymph nodes, especially gastrohepatic, enlarged spleen with infarcts, edematous noncollapsing lungs, enlarged liver, hemorrhage in kidneys, variable enteritis, ulcers in colon.	Fluorescent antibody test or inoculation of susceptible swine.
Aflatoxin	Any age pigs. Depression, anorexia, anemia, icterus, temperature normal.	Ascites, enlarged fatty liver to liver necrosis or cirrhosis.	Find 200 ppb aflatoxin in the feed.
Citrinin or ochratoxin	Any age pigs. Diarrhea, normal temperature, polyuria, polydipsia, dehydration.	Possibly fibrotic kidney, possibly fatty change and necrosis of liver.	Find 200 ppb mycotoxin in the feed.

Table 11.26. Causes of death without prior clinical signs in weaned pigs to adults

Cause	Pigs Most Commonly Affected and Time
Edema disease	Nursery pigs 1–2 weeks after weaning, especially in the most rapidly growing animals.
Salt poisoning(water deprivation)	Usually nursery or growing and finishing pigs but can be any age.
Vitamin E/selenium deficiency (Mulberry heart disease)	Usually nursery or growing and finishing pigs.
Acute pneumonias due to *A. pleuropneumoniae, Actinobacillus sp., Pasteurella multocida*	Growing and finishing pigs, rarely in adults.
Haemophilus parasuis infection or *Actinobacillus suis* infection	Nursery and growing pigs.
Porcine stress syndrome	Finishing to adult pigs. Heavily muscled animals, especially Pietrain and Landrace breeds.
Gastric ulceration	Finishing pigs to adults.
Hemorrhagic bowel syndrome associated with *Lawsonia intracellularis*	Usually older finishing pigs or young adults.
Hemorrhagic bowel syndrome associated with whey feeding	Usually older finishing pigs or young adults.
Gastric volvulus	Adults, especially sows.
Mesenteric volvulus	Growing and finishing pigs to adults.
Exhaustion	Finishing pigs and adults, especially adults.
Systemic salmonellosis	Growing and finishing pigs and adults.
Electrocution	Any age.
Encephalomyocarditis virus	1–20 weeks of age.
Coal tar toxicity	Usually growing and finishing pigs but also adults.
Clostridium novyi infection	Any age.
Cardiac insufficiency	Any age but more common in heavy finishers or sows.
Asphyxiation from H_2S, CO, CO_2	Any age but more common in finishing pigs.

Necropsy Findings	Associated Factors
Edema in subcutaneous tissue, eyelids, gastric mucosa, and mesocolon, full stomach, empty intestine.	May be associated with ad libitum feeding of highly nutritious and palatable feed.
Usually no gross lesions, may see gastritis or enteritis.	History of recent interruption of the water supply, feeding of whey.
Acute hemorrhagic hepatic necrosis, hemorrhage in the cardiac muscle, excessive pericardial fluid. White, edematous skeletal and cardiac muscle.	Most common in selenium-deficient areas east of the Mississippi River.
Cyanosis, acute necrotizing hemorrhagic pneumonia with fibrin in the pleural cavity, trachea and bronchi filled with foamy blood-tinged mucus.	
Cyanosis, fibrinous peritonitis, pericarditis, pleuritis, arthritis, and meningitis, especially in recently purchased high-health pigs.	
Blotchy cyanosis coalescing on the ventral abdomen, rapid onset of postmortem rigor, areas of pale muscle.	Occurs in pigs that have been moved or were fighting, mating, or farrowing.
Erosion of the pars oesophagea, large amount of blood in the stomach, marked pallor.	Feeding of finely ground feed or whey; interruption of feed availability.
Marked pallor, terminal small intestine and upper spiral colon filled with blood.	Associated with *Lawsonia intracellularis* infections.
Small intestine filled with blood-stained fluid. Bloody fluid in abdomen. Possible volvulus. Gas-distended colon.	Associated with feeding whey, especially acid whey.
Enlarged, gas-filled stomach, splenic engorgement.	Improper crate size that allows the sow to turn around.
Hyperemic segment of the intestine with distinct demarcation between normal and affected areas.	Excessive competition for feed, feeding whey or other large-volume feeds.
Skin abrasions and bruising, pulmonary edema, and froth in the trachea and bronchi.	Fighting, especially in hot, humid environment or after mixing or moving.
Cyanotic extremities, enlarged spleen and liver, enlarged mesenteric lymph nodes, small white, necrotic foci in liver.	Finishing facilities that practice continuous addition of new stock.
Usually no gross lesions, may be petechial hemorrhage in the lungs, singed hair above the coronary band, red streaks on the medial surface of the legs.	Electrical short in the building, lightning during a recent rainstorm.
Cyanotic ventrum, dilated right heart, with areas of pale muscle, fibrin in peritoneal, pericardial, and pleural cavities.	May be more common in rodent-infested buildings, since disease is carried by rodents.
Greatly enlarged and friable liver.	Access to a source such as tar paper, shingles, or clay pigeons.
Rapid postmortem tympany, bloody fluid in pleural, pericardial, and peritoneal cavities, splenomegaly, hepatic necrosis and emphysema, neck swelling.	
Vegetative valvular endocarditis.	*Erysipelas rhusiopathiae, Strep. suis, Actinobacillus pleuropneumoniae.*
	Agitation and pumping of pit, fan failure.

Table 11.27. Ages at which wasting and ill-thrift are seen in baby pigs to adults

Baby Pigs	Nursery Pigs	Growing-Finishing Pigs	Adult Pigs
Nutritional deficiency, water deprivation			
Stray voltage			
Vomiting and wasting disease			
Subclinical swine influenza in pigs whose dams were infected during pregnancy			
	Internal parasites		
Anemia			
	Mange		
	Postweaning multisystemic wasting syndrome		
	Malabsorption secondary to scours, transmissible gastroenteritis, rotavirus		
	Brain stem malacia secondary to prior colibacillosis		
	Pigs recovered from acute pseudorabies infection		
	Pneumonia, severe atrophic rhinitis		
	Proliferative enteritis		
	Salmonellosis		
		Gastric ulceration	
			Cystitis/ pyelonephritis

Table 11.28. Diseases that cause anemia in unweaned pigs

Disease	Pigs Affected	Signs	Hematologic Findings	Diagnosis
Iron deficiency anemia	Normal at birth; anemia becomes more severe as age increases.	Rough hair coat, pale, rapid respiration, uneven growth.	Microcytic, hypochromic red blood cells.	History that pigs did not receive an appropriate iron injection. Heart dilated, pericardial fluid, pulmonary edema, splenomegaly.
Eperythrozoonosis	Especially pigs under 5 days old but any time from birth to weaning.	Icterus, rough hair coat, uneven growth, listless, swollen yellow-brown liver, splenomegaly.	Organisms seen in red blood cells.	Wright-Giemsa stain of blood from a febrile pig or positive serology from the sow.
Umbilical hemorrhage	Die within a few hours of birth. May be associated with use of wood shavings or vitamin C or zinc deficiency.	Cord remains large and fleshy, fails to shrivel, blood-stained skin.	Normal.	Clinical signs.

Table 11.29. Diseases that cause anemia in weaned pigs to adults

Disease	Ages Affected	Other Signs	Associated Factors	Diagnosis
Gastric ulcer	Older growing pigs and adults.	Inappetence, weight loss, occasional grinding of teeth. Normal feces or firm, dark, and tarry.	Finely ground feed, vitamin E deficiency.	Ulcer observed in the pars oesophagea at necropsy.
Iron deficiency	Nursery pigs.	Reduced growth rate, rough hair coat.	Failure to give sufficient iron before weaning.	Hematology, history, and absence of other lesions.
Sarcoptes scabeii	Nursery pigs to adults. Anemia is more severe in younger pigs.	Scratching and rubbing against walls, rough hair coat, keratinization of skin.	Poor mange control program.	Deep skin scraping from the ear canal to demonstrate mites.
Trichuris suis	Usually in 2- to 6-month-old pigs.	Anorexia, diarrhea with mucus, weight loss. Dark feces, diarrhea with mucus, melena.	Lack of good parasite control program.	Lesions in the large intestine, favorable response to treatment.
Hemorrhagic ileitis	Usually young breeding-age gilts.	Bleeding from the anus, usually with normal body condition.	Seen more often in herds with other *Lawsonia*-associated enteropathies.	Clinical signs and lack of lesions on gross necropsy.
Proliferative enteritis	Nursery to adult pigs, especially 2–5 months old.	Various degrees of weight loss, anorexia. Black, tarry feces to frank blood.	Seen more often in herds with other *Lawsonia*-associated enteropathies.	Necropsy lesions primarily in small intestine. Histopathology: mucosal hyperplasia.
Eperythrozoonosis	Nursery pigs to adults.	Lethargy, reduced growth, occasional icterus, acute episode in sows: mammary and vulvar edema.	Poor mange and lice control program.	Stained blood smear to demonstrate organisms. Indirect hemagglutination titer of 1:80 or higher.
Aflatoxin	All ages. Signs more severe in younger pigs.	Depression, anorexia, ascites, elevated liver enzymes, occasional icterus.	Moldy feed; grains raised, harvested, or stored during wet weather; especially damaged kernels.	Liver lesions of fatty change to necrosis and cirrhosis. Feed analysis for toxin.
Tricothecenes	All ages. Signs more severe in younger pigs.	Gastroenteritis.	Moldy feed; grains raised, harvested, or stored during wet weather; especially damaged kernels.	Feed analysis for toxin.
Zearalenone	All ages. Signs more severe in younger pigs.	Swollen vulvas and mammary glands in prepubertal gilts.	Moldy feed; grains raised, harvested, or stored during wet weather; especially damaged kernels.	Feed analysis for toxin.
Warfarin toxicity	Any age.	Lameness, stiff gait, lethargy. Dark, tarry feces.	Access to rodenticides.	Prolonged clotting time. Demonstrate toxin in blood and liver.

Table 11.30. Diseases that cause lameness in unweaned pigs

Condition	Ages Affected	Clinical Signs	Associated Factors	Diagnosis
Infectious polyarthritis: *Streptococcus, Staphylococcus, E. coli*	1–3 weeks old.	Lassitude, rough hair coat, joint swelling, fever.	More frequent in low-parity sows, unsanitary tooth clipping and tail docking.	Necropsy: culture and Gram or Giemsa stain of bacteria in joint fluid.
Trauma	Any, but especially in the first 36–40 hours after birth.	Variable.	Poor crate design, no heat source to draw pigs away from the sow, sows with agalactia.	Presumptive based on lack of heat and poor farrowing crate design.
Splayleg	Birth or within a few hours. 1–4 pigs/litter, occasionally whole litter.	Hindlegs (sometimes forelegs) abducted to the side, pig unable to stand or moves with difficulty.	Birth weight of affected pigs is below average, slippery floors.	Clinical signs. Histology: myofibrillar hypoplasia in semitendinosus or triceps.
Injections	Any time after injection.	Tendency to carry or drag one hindleg.		History of injection.
Arthrogryposis	At birth. 40–50% of a litter affected.	Fixation of the joints in the limbs or vertebral column in various degrees of extension or flexion.	Maternal toxicity (wild black cherry, tobacco stalks, jimsonweed, poison hemlock), deficiency of vitamin A or manganese, or heredity.	Clinical signs in piglets, history of sow access to pasture. Feed analysis.
Syndactyly, polydactyly, thick legs	At birth.	Abnormal number of toes, front legs more likely to be affected.	Genetic.	Clinical signs.
Clostridium perfringens	1–5 days old.	Marked swelling of hindleg, dark reddish-brown discoloration of skin over swelling.	Iron injected within the last 24 hours with contaminated needle.	Necropsy and isolation of the organism.

Table 11.31. Ages at which diseases causing lameness in weaned pigs to adults are more common

Age in Months										
1	1.5	2	3	4	5	6	18	30	42	54
Trauma: muscle bruising, sprains, strains, dislocations, fractures										
Clostridium tetani or septicum infection										
Vesicular diseases: foot-and-mouth, vesicular exanthema, swine vesicular disease, vesicular stomatitis, San Miguel sea lion virus										
Streptococcus suis infection / *S. equisimilis* infection			Chronic suppurative arthritis due to *S.suis, S. equisimilis, M. hyorhinis, M. hyosynoviae, H. parasuis, Corynebacterium, Staphylococcus*								
	Acute *Mycoplasma hyorhinis* infection									
		Haemophilus parasuis infection								
			Bursitis							
			Rickets							
				Acute erysipelas			Chronic erysipelas			
				Asymmetrical hindquarter syndrome						
				Foot rot						
				Back-muscle necrosis						
					Osteochondrosis					
						Osteoarthrosis, degenerative joint disease				
						Epiphysiolysis				
							Brucellosis			
							Laminitis			
							Apophysiolysis			
								Osteomalacia		
								Tarsitis		
								Arthrosis deformans		
								Leg weakness syndrome		

at farrowing or mating. Bilateral enlargement is seen with zearalenone toxicity and edema secondary to eperythrozoonosis.

Agalactia (Table 11.36)

Agalactia, the failure to produce milk, becomes apparent because of the behavior of the suckling pigs. They are often noisy and restless and make frequent nursing attempts. With time they become gaunt and emaciated. Agalactic sows should be examined if they show clinical signs, such as pyrexia, depression, or anorexia, which tend to be associated with infectious causes of agalactia; normally bright, alert sows tend to be agalactic due to hormonal or nutritional causes.

POOR REPRODUCTIVE PERFORMANCE
(Tables 11.37–11.41)

Although diseases that deform fetuses or cause abortion attract a great deal of attention when they occur, greater concern should be directed to the "normal" level of reproductive performance, since when it is suboptimal, a much greater loss of potential profit occurs. Currently, with the advent of computerized record-keeping systems and the use of consultants, requests for assistance in improving poor reproductive performance are common.

Efficiency of reproductive performance is measured by the number of pigs weaned/sow/year (PW/S/Y). Typical North American farms only produce about 14–16 PW/S/Y, although the best farms have demonstrated that 25 PW/S/Y is possible. Three components directly influence PW/S/Y: litters/sow/year (L/S/Y), average live-born litter size, and preweaning mortality. Each of these three major components is in turn influenced by a number of environmental, managemental, genetic, and nutritional factors.

The first step is to determine L/S/Y, average number of live-born per litter, and preweaning mortality. Performance may be suboptimal in one or more areas.

Table 11.32. Diseases that cause lameness in weaned pigs to adults

Clinical Signs	Causes	Diagnosis
Gross swelling of muscles or soft tissue	Trauma.	Physical examination.
	Clostridium septicum infection.	Necropsy, identification of organisms.
	Back-muscle necrosis.	Necropsy, creatine kinase.
	Asymmetric hindquarter syndrome.	Necropsy.
Generalized stiffness, reluctance to move, altered gait, fever, usually also other signs of septicemia	Acute *Mycoplasma hyorhinis infection,* acute *Haemophilus parasuis infection,* acute erysipelas, *Streptococcus suis* infection.	Culture of organisms from heart, liver, spleen, or lesion.
	Tetanus.	Identification of organisms.
Swollen joints	Chronic *Mycoplasma hyorhinis, Haemophilus parasuis,* or erysipelas infection. Infection with *Strep. equisimilis* or *Mycoplasma hyosynoviae.* Suppurative arthritis due to *Staphylococcus, Arcanobacterium pyogenes,* or *Streptococcus*.	Isolation of organisms from the joints.
	Rickets.	Necropsy, bone ash determination, ration analysis.
Posterior paresis or paralysis	Brucellosis.	Necropsy, serology.
	Rickets, osteomalacia.	Necropsy, bone ash determination, ration analysis.
	Apophysiolysis of ischiatic tuberosity; proximal femoral epiphysiolysis; trauma; vertebral, lumbosacral, or pelvic fracture; spondylosis.	Necropsy.
Tail bitten	Abscess in vertebral column.	Necropsy culture.
No external abnormalities	*M. hyosynoviae* infection.	Culture.
	Osteochondrosis, proximal femoral epiphysiolysis, degenerative joint disease, osteoarthrosis, trauma, apophysiolysis of ischiatic tuberosity.	Necropsy.
	Leg weakness syndrome.	Physical examination.
	Fibrocartilaginous embolism. Osteomalacia and fracture.	Necropsy, bone ash determination, ration analysis.
	Selenium toxicity.	Necropsy, selenium levels.
Quarter crack in the hoof wall, pain, heat, swelling	Foot rot (*Arcanobacterium pyogenes* and other opportunist invaders).	Physical examination, culture.
No external deformity, pain, heat, and swelling	Laminitis.	Physical examination, history of postparturient fever.
Hoof abnormalities	Overgrown hooves, bush foot, sand crack, heel separation, trauma.	Physical examination.
Cracks in hoof wall, erosion and bruising of the heel	Rough hooves, wet environment, biotin deficiency.	Physical examination. Ration analysis.
Vesicles and/or hoof separation at coronary band. Shifting lameness.	Foot-and-mouth disease, vesicular stomatitis, vesicular exanthema, swine vesicular disease.	Vesicular fluid for virus isolation.
	Selenium toxicity.	Feed analysis.

Table 11.33. Crown-to-rump length and fetal age

Crown-to-Rump Length (mm)	Approximate Fetal Age (days)
20	25
27	30
46	40
89	50
135	60
170	70
207	85
270	110

Table 11.34. Diseases causing abortion, stillbirth, and mummification in swine

Disease	Signs in Sow	Age of Fetuses	Signs in Fetus and Placenta	Diagnosis
		Nutritional Causes		
Overfeeding	None.	Embryonic loss.	None.	Suggestive from history, feed levels after mating.
Underfeeding	Extremely thin sow, possible polyuria, polydipsia.	All the same age, any age.	None.	History, sow condition, competition for feed.
Zinc deficiency	Delayed or prolonged parturition.	At birth.	Low viability, umbilical hemorrhage.	Feed analysis.
		Viruses		
Porcine parvovirus	None.	Often fetuses are dead at different stages of development.	Resorption (small litter size), mummies frequent, stillborn or weak pigs, decomposed placenta tightly wrapped around fetus.	Virus isolation.
Japanese B encephalitis	None.	Often fetuses are dead at different stages of development.	Similar to parvovirus with hydrocephalus, subcutaneous edema, hydrothorax, petechial hemorrhage, ascites, necrotic foci in liver and spleen.	Fluorescent antibody test on fetus.
Pseudorabies	Can be mild to severe, sneezing, cough, anorexia, constipation, salivation, vomiting, neurologic signs.	Often fetuses are dead at different stages of development.	Focal necrotic areas in liver, mummies, stillborn pigs, resorption (small litter size). Necrotizing placentitis.	Paired serology from sow.
Swine influenza	Extreme prostration, lethargy, labored respiration, cough.	Often fetuses are dead at different stages of development.	Resorption (small litter size), mummies, stillborn pigs, or pigs born weak.	Paired serology from sow. Virus isolation.
Enterovirus, adenovirus, reovirus, cytomegalovirus	Usually none.	Often fetuses are dead at different stages of development.	Resorption (small litter size), mummies, stillborn pigs, or pigs born weak.	Paired serology from sow.
Hog cholera	Lethargy, anorexia, fever, conjunctivitis, vomiting, dyspnea, erythema, cyanosis, diarrhea, ataxia, convulsions.	Often fetuses are dead at different stages of development.	Mummies, stillbirths, edema, ascites, deformities of head and limbs, petechial hemorrhages, hypoplasia of lungs and cerebellum, liver necrosis.	Fluorescent antibody test on fetal tissue, especially tonsil.
Bovine viral diarrhea virus	None, but sows may be kept in contact with cattle.	Often fetuses are dead at different stages of development.	No lesions.	Virus isolation, serology.
Encephalomyocarditis	None.	Any age, but usually all the same age.	Edema.	Virus isolation.
African swine fever	Lethargy, anorexia, fever, hyperemia, dyspnea, vomiting, diarrhea.	Any age, but usually all the same age.	Petechial and ecchymotic hemorrhages.	Fluorescent antibody test on fetal tissues.
Swine vesicular diseases[a]	Vesicles on snout, mouth, and coronary band.	Any age, but usually all the same age.	No gross lesions.	Vesicular fluid fluorescent antibody or serum neutralization test.
Porcine reproductive and respiratory syndrome	Fever, anorexia, lethargy, blotchy reddening of skin and cyanosis.	Any age, but usually all the same age.	Necrotizing arteritis in the umbilical cord. Edema.	Virus isolation.
Blue eye disease	May be anorexia, fever, depression, rare corneal opacity.	Any age, but usually all the same age.	Stillbirths, mummies, abortions, resorbtion.	Virus isolation.
		Bacteria		
Leptospirosis	Few animals showing signs, mild anorexia, fever, diarrhea, abortion.	Usually all near the same age, often mid- to late-term.	Stillbirths or weak neonatal pigs, occasional abortions, diffuse placentitis.	Demonstration of organisms by dark-field examination. Culture or laboratory animal inoculation. Paired sera from sow or single titer >1:800. (*continued*)

275

Table 11.34. Diseases causing abortion, stillbirth, and mummification in swine (*continued*)

Disease	Signs in Sow	Age of Fetuses	Signs in Fetus and Placenta	Diagnosis
Uterine infection with *E. coli, A. pyogenes, S. aureus, Pasteurella, E. rhusiopathiae, Pseudomonas, Listeria monocytogenes, Strep. equisimilis, Bacillus, Salmonella,* etc.	Generally no clinical signs.	May be any age but usually all are the same age.	May be almost normal or somewhat autolytic with edema, suppurative placentitis.	Culture of organism from fetus.
Brucellosis	Signs seldom recognized, abortion at any time during gestation.	May be any age but usually all are the same age.	May have undergone autolysis or subcutaneous edema. Peritoneal fluid or hemorrhage may be present. Suppurative placentitis.	Culture of organisms from fetus. Positive serology from the herd, paired sera from the sow.
Pyrexia				
Any systemic infection: erysipelas, transmissible gastroenteritis, eperythrozoonosis, *A. pleuropneumoniae,* etc.	Fever. Other signs of disease will vary with the specific agent.	All the same age, any age.	Usually none.	History and clinical signs.
Hostile Environment				
Carbon monoxide	No signs in sows but tends to occur during the coldest weather.	Usually at term, stillborn pigs.	Bright red tissues large amount of serosanguinous pleural effusion.	Suggestive from clinical signs and history. Improvement when fossil fuel replaced.
Carbon dioxide	No signs in sows but tends to occur during the coldest weather.	Usually at term, stillborn pigs.	Muconium on skin and in respiratory tract.	Suggestive from clinical signs and history. Improvement when fossil fuel replaced.
High environmental temperature	High temperature at time of breeding.	Abortion or resorption.	None.	Clinical signs and history.
	High temperature at time of farrowing, sows panting and hyperemia.	Stillborn pigs at term.	None.	Clinical signs and history.
Physical trauma	Sows of different body size and condition penned together, skin abrasions.	All the same age, any age.	None.	Clinical signs and history.
Low environmental temperature	Thin sows and possibly polyuria and polydipsia.	All the same age, any age.	None.	Clinical signs and history.
Seasonal abortion	None.	All the same age, any age.	None.	September–November.
Mold				
Claviceps purpura	Possibly dry gangrene of extremities and tail.	All the same age.	Abortion, stillbirth, weak neonates. No gross lesions.	Feed analysis.
T_2 toxin	Rare but may cause anorexia or lethargy.	Late term.	Abortion, stillbirth, weak neonates. No gross lesions.	Feed analysis.
Zearalenone	Tumescence, edema of the vulva, occasional mammary development in gilts.	Failure of embyro to implant.	Abortion, stillbirth, weak neonates. No gross lesions.	Feed analysis.
Parasite				
Toxoplasma gondii	None.	Any age.	Abortion, stillbirths, weak pigs. Rarely mummies.	Histopathology, serology.
Toxicities				
Organophosphate toxicity	Salivation, defecation, emesis, muscle tremors, paralysis.	All the same age, any age.	None.	Signs, history, whole-blood cholinesterase activity.

Table 11.34.   Diseases causing abortion, stillbirth, and mummification in swine (*continued*)

Disease	Signs in Sow	Age of Fetuses	Signs in Fetus and Placenta	Diagnosis
Chlorinated hydro-carbon (CH) toxicity	Hyperexcitability, muscle spasms, seizures.	All the same age, any age.	None.	Signs, history, CH level in liver, kidney, brain.
Pentachlorophenol toxicity	Depression, emesis, muscle weakness, posterior paralysis.	Usually stillborn pigs at term.	None.	Access to pentachlorophenol-treated wood, pentachlorophenol in the blood.
Teratogens				
Vitamin A deficiency	None.	May vary in age or be all the same age.	Stillborn or weak, anophthalmia, cleft palate, microphthalmia, blind, general edema.	History, eye abnormalities.
Methallibure, metrifone, tri chlorfon, iodine deficiency, tobacco stalks	None.	May vary in age or be all the same age.	Mummies, stillbirths, low birth weight, deformed pigs.	History and signs.
Farrowing Complications				
Fatigue: old or fat sow, disturbed or prolonged birth	Prolonged labor, more than 5 hours, especially with large litters or hot weather.	Stillbirths at term.	None.	History, physical exam of sow.
Low maternal hemoglobin level	Pallor, rapid respiration.	Stillbirths at term.	None.	Packed-cell volume or blood hemoglobin too low.

[a]Foot-and-mouth disease, vesicular stomatitis, vesicular exanthema.

Then a systematic investigation can be carried out using the flowchart in Table 11.37.

Maximization of L/S/Y occurs when the proportion of nonpregnant females in the herd is minimized. Unproductive days in the breeding herd are caused by sows that were not bred after weaning, sows that abort or resorb litters, and gilts that remain too long in the gilt pool. About 10% of weaned sows are culled because they fail to show estrus. On the average, unbred weaned sows stay in the herd for 75 days prior to culling, which adds greatly to the number of unproductive herd days. Gilts may spend from 2–20 weeks in the gilt pool and up to one-third of them may never join the breeding herd, again making a major contribution to the total unproductive herd days. When L/S/Y is low (less than 2) then the problem should be characterized as to whether females are anestrus or whether females are returning to heat after breeding. Returns to heat can be further characterized by whether they occur at intervals of 18–21 days postbreeding (failure of conception) or at other intervals (early embryonic loss). Additional observation of management, environment, genetics, and nutrition is used to identify specific contributing factors (Tables 11.39–11.40).

Problems of small litter size are generally due to noninfectious, rather than infectious, causes. Investigation of the cause(s) can be a major undertaking since numerous factors influence litter size, and although each factor may cause only a small reduction by itself, litter size may be considerably reduced when all factors are considered. To investigate small litter size it is necessary to examine information on all farrowings that occur over a 6-month period. Each litter farrowed should be characterized by parity of the sow, number of live-born, number of stillborn, and number of mummies. Data should be recorded and summarized and then analyzed for mean values and trends. When small litter size is due to large numbers of stillborns or mummies, the information in Table 11.34 should be used to assist diagnosis. Other causes of small litter size are given in Table 11.40.

Factors influencing preweaning survival are covered in Chapter 62.

Table 11.35. Causes of vulvar discharges in gilts and sows

Characteristics of Discharge Signs and Animals Affected

Site of Infection	Amount	Appearance	Frequency and time of occurrence	Parity and stage of reproduction affected	Other clinical manifestations
Vagina	10–50 mL	Purulent, occasionally bloody.	Sporadic with multiple discharges per day. Not related to estrus cycle. Persists days to weeks.	More common in gilts. May be occasional female 10–20% of or herd. Pregnant and open females affected but especially shortly after mating.	Usually no other clinical signs.
Cervix	Less than 20 mL	Purulent.	Not related to estrus. Sporadic over days to weeks.	Usually in cycling females of all parities. Results in delayed return to heat. Also rarely in pregnant females.	Usually no other clinical signs.
Uterus	10–50 mL	Whitish, chalky, odorless.	Normal postpartum discharge.	Any parity after farrowing.	Normal.
	50–100 mL or more	Purulent, occasionally bloody.	Proestrus/estrus: discharge sporadic for 1–2 days near estrus.	Usually in sows after weaning or sows with cystic ovaries. Rarely in pregnant females. More common in higher-parity sows.	Mild fever and inappetence.
	50–100 mL or more	Purulent, occasionally bloody, fetid odor. Decomposing fetal remnants.	Postparturition: somewhat constant discharge for days after farrowing.	More common in older sows after prolonged or assisted farrowing and especially if retained fetuses.	Depression , fever, anorexia, sternal or lateral recumbency.
Urinary bladder	Less than 20 mL	Purulent, mucoid, mucopurulent or mucohemorrhagic.	Seen at urination, especially at end of stream.	Frequent urination of small quantities. Dysuria and straining.	Chronic weight loss and if infection ascends to kidneys may cause uremia and death.

Table 11.36. Causes of agalactia in sows

Condition of Sow	Clinical Findings	Causes	Further Differentiation
Sick sow, elevated temperature, depressed, anorexic	Sternal recumbency. Red, swollen, hot, painful mammary gland(s).	Mastitis due to *E. coli, Klebsiella, Streptococcus, A suis.*	Culture of milk. California mastitis test.
	Hyperemia, cyanosis, anorexia, panting, dyspnea.	Porcine stress syndrome. Heat prostration.	Physical exam. Environmental temperature. DNA test.
	Swollen, edematous, painful mammary glands visible 1–2 weeks prior to farrowing.	Vitamin E/selenium deficiency often with mastitis due to secondary bacterial infection.	Ration analysis. Response to injection of selenium 4–6 weeks prefarrowing.
	Foul-smelling purulent or bloody vaginal discharge, anorexia.	*Metritis due to E. coli, Streptococcus, Klebsiella.*	Uterine culture.
	Anorexia, anemia, possible edema of udder and vulva.	Acute eperythrozoonosis.	Demonstration of organism in blood. Serology.
	Vesicles on snout, mouth, and feet.	Vesicular stomatitis or other vesicular diseases.	Complement fixation or virus neutralization tests.
Normal sow, bright and alert, normal temperature	Abnormal mammary gland conformation.	Blind teats, inverted or damaged nipples.	Physical examination.
	Normal mammary gland conformation with lack of development of underlying glandular tissue.	Undeveloped gilt, asynchrony of hormones (excess 17 beta-estradiol). Feed related: ergot, zearalenone, or deficiency of energy, water, vitamin E, selenium, pantothenic acid, riboflavin.	Ration analysis and observation of feeding practices. Mycotoxin assay.
	Normal mammary gland conformation with excessive firmness of underlying glandular tissue (hard udders).	Excess salt in diet, overfeeding prior to and in first days after farrowing, anything limiting piglets' ability to nurse (splayleg, failure to remove needle teeth, small weak pigs), stray voltage in farrowing pen.	Ration analysis. Observation of feeding. Physical examination. Voltage readings between metal of pens and ground.

Table 11.37. Flowchart for investigation of low numbers of pigs weaned/sow/year (PW/S/Y)

PW/S/Y is less than desired

- Determine L/S/Y
  - If ≥2.2 → Stop
  - If <2.2
    - Determine proportion of anestrous females
      - If high proportion of females are anestrous, use Table 11.38
    - Determine percentage of returns to heat after breeding
      - If high proportion return to heat after breeding, use Table 11.39
- Determine preweaning mortality
  - If greater than 10%, see Chapter 62
- Determine litter size (live-born, stillborn, mummies)
  - If stillbirth rate ≥38%, refer to Table 11.34
  - If live-born/litter <10
    - Record litter characteristics of live-born, stillborn, and mummies for each parity
      - Use parity distribution and aids in Table 11.40
  - If live-born/litter ≥10 → Stop

Table 11.38. Causes of anestrus

Factor Contributing to Anestrus	Comments	
	Gilt	Sow Postweaning
Age	The first estrus usually occurs in gilts between 5 and 8 months of age. Gilts raised in outside pens reach puberty earlier than gilts raised in enclosed buildings.	
Breed	There is a large breed variation in age at puberty. Crossbreds reach puberty earlier than purebreds. The percentage of gilts that show estrus by 8.5 months of age in common breeds is Large White, 86%; Landrace, 78%; Duroc, 71%; Hampshire, 71%; and Yorkshire, 56%.	Early weaning (i.e., 10 days). There is a large variation between breeds and lines of sows in percentage of sows returning to heat after weaning at 10 days or less.
Anatomical anomaly	Hermaphrodites, pseudohermaphrodites, intersexuality.	
Exposure to a boar	Gilts raised in contact with a boar reach puberty 20–40 days earlier than gilts raised in isolation.	Sows weaned into an area where they have contact with boars will show earlier and stronger signs of estrus.
Light	Gilts exposed to at least 14 hours of light per day reach puberty earlier than gilts in darker environments.	At least 14 hours of light per day in the farrowing area is associated with a greater percentage of weaned sows returning to estrus within 5 days of weaning.
Season	More fall-born gilts will reach puberty by 8 months of age than spring-born gilts.	Between July and September (in the Northern Hemisphere) a decrease occurs in the number of sows returning to estrus within 7 days after weaning. Primiparous sows are particularly affected.
Length of lactation		Sows weaned earlier than 18 days of lactation show a lower percentage of animals coming into estrus within 7 days.
Nutrition	Undernourished animals are less likely to show estrus.	Animals that were thin prior to entering the farrowing area or lost more than 20 kg because of heavy milk production during lactation are less likely to show estrus within 7 days postweaning.
Management	Many complaints of anestrus or "silent heats" are due to inadequate heat checking by breeding-herd personnel. The boar and sow should be put together in a pen for heat detection. Although the presence of a boar assists the herdsperson to identify females in estrus, the boar should not be relied on to locate estrous sows. Heat checking should be done when there are no distracting influences such as feeding.	
Pregnancy	Usually associated with poor record-keeping and inability to identify animals.	
Pseudopregnancy	May be associated with early pregnancy loss. Corpus luteum maintains pregnant state, even in the absence of fetuses in the uterus. Zearalenone may cause pseudopregnancy.	
Cystic ovaries	Both follicular and luteal cysts develop in swine. Cystic ovarian structures are more common in sows than in gilts.	

Table 11.39. Causes of return to estrus in sows after breeding

	Possible Causes	Diagnosis
		Failures of Ovulation
Regular intervals (18–24 days after breeding)	Zearalenone	Examine prepuberal gilts for vulval redness and enlargement. Test feed samples for presence of zearalenone.
	Seasonal infertility	Between July and September (in the Northern Hemisphere). Problem is more pronounced in gilts and primiparous sows.
	Cystic ovaries	Evaluation of reproductive tracts at slaughter.
		Failures of Conception
	Female anatomical anomaly	Physical examination and evaluation of reproductive tract at slaughter.
	Iatrogenic with artificial insemination	Poor semen handling or insemination technique when using artificial insemination.
		Boar Failure
	Overuse of boar	Examine records of boar usage. Boars should not be used more frequently than four times per week.
	Failure to breed	Physical examination of boar for anatomical defects of reproductive tract and ability to stand and mount. Observation of mating performance for libido and experience. History of recent illness with pyrexia or treatment with corticosteroids.
	Improper timing of mating	Review of mating procedures in the herd. Verification that each female is bred at least twice during estrus. Infections: Early Abortion-Resorption
Irregular intervals (more than 25 days after breeding)	Various diseases: porcine parvovirus, pseudorabies, leptospirosis, brucellosis, eperythrozoonosis, Japanese B encephalitis, cytomegalovirus, and other bacteria, fungi	Serologic demonstration of the presence of the organism in the herd and evidence that there is a susceptible population of animals in the herd.
	Any illness associated with pyrexia	History of illness in the herd. Noninfectious: Early Abortion-Resorption
	High environmental temperatures	History of high environmental temperatures at time sows were mated.
	Trauma	History of excessive fighting among sows. Sows typically kept in large groups of different-sized animals.
	Seasonal	July through September (in the Northern Hemisphere). Most noticeable in gilts and primiparous sows.
	Overfeeding	Consumption of large amounts of feed in the period after mating has been associated with embryonic death.

Table 11.40. Causes of small numbers of pigs per litter at birth

Possible Causes of Small Litters	Diagnosis	Parities Affected
Poor timing and frequency of mating	Observation of estrus detection and mating procedures. Verification that all females are mated twice during estrus.	All
Use of different boars	Double mating with two different boars results in litters 0.4 pigs larger than if the same boar was used twice.	All
Length of previous lactation	Investigation of time of weaning, average, and range. Between 16 and 35 days, for each delay of 5 days, litter size increases by 0.2–0.4 pigs.	2+
Age and weight at first mating (gilts)	History of breeding practices. Waiting to breed a gilt on her second vs. first estrus results in 0.5 more pigs per litter.	1
Split weaning of litters	Split-weaned sows have larger subsequent litters.	2+
Parity	Determination of the parity distribution in the herd. Litter size is smallest in gilts and increases with increasing parities, with the best production in parities 3, 4, 5, and 6.	All
Breed	Analysis of breed composition of herd. White breeds are more prolific than colored breeds.	All
Heterosis	Analysis of breeding program. Determination of heterosis is being appropriately maximized with maternal breeds.	All
Season	Litter size is 0.4 pigs larger in sows bred in January through April than in other months.	All, especially 1
Low lactation feed intake	Examination of sows' condition at the end of gestation and lactation. Evaluation of feeding program for amount and nutrient density. Sows that lose more than 20 kg in weight during a farrowing and lactation have smaller subsequent litters. Too many overweight sows just prior to farrowing.	2+
Low lactation protein	Feed analysis to verify that sows of highly prolific breeds are receiving a ration that contains 1.1% lysine during the lactation period.	2+
Gilt feeding practices	Examine gilt feeding practices. Gilts that are "flushed" (i.e., fed additional amounts 3 weeks prior to mating) produce one more pig per litter.	1
Amount of stress	Examine sow housing for the amount of competition between animals. Large groups of sows, especially when different-sized animals are housed together, or excessive movement or sorting of sows within the first 30 days after mating may result in resorption of embryos.	All
Environmental temperature	History of high environmental temperature just after breeding. Hot environments are associated with resorption.	All
Porcine parvovirus and other viruses	Pattern of titers in breeding herd. Gilts in gilt pool and breeding area negative, bred gilts and older sows positive.	Usually 1

Table 11.41.   Interpretation of serology

Disease	Test	Results and Interpretation		

Brucellosis — Standard tube test

If all of the following apply:
a. No animals on test with titers greater than 1:1000
b. Not a retest of an infected herd
c. Complete herd test or incomplete test of a validated herd.
Then use the following:

1:25	1:50	1:100	
'	–	–	Negative
+	–	–	Negative
+	'	–	Negative
+	+	–	Negative
+	+	'	Negative

If one or more of the following apply:
a. One or more animals on test with titer greater than 1:1000
b. Retest of an infected herd
c. Incomplete test of a herd of unknown status

Then use the following:

1:25	1:50	1:100	
'	–	–	Negative
+	–	–	Reactor
+	'	–	Reactor
+	+	–	Reactor
+	+	'	Reactor
+	+	+	Reactor

Eperythrozoonosis — IHA

Results are useful as a herd test; individual titers have not been correlated with clinical signs of disease or production. In herd studies, no consistent correlation was found between disease problems in the herd and the prevalence and magnitude of the titers.

Less than 1:40	Negative
1:40 to 1:80	Suspect
1:80 and greater	Positive

Circovirus — IFA

Positive at 1:20

Porcine reproductive and respiratory syndrome — IFA

IFA (IgG) is first detected at 9–11 days post infection; the peak titer occurs at 4–5 weeks and gradually declines to undetectable levels at 5–6 months.

IFA (IgM) is first detected at 5 days post infection and declines to undetectable levels at 28 days. IgM-positive pigs are likely to be carrier pigs with recent infection. IFA tests do not detect all strains of the virus.

A titer of 1:16 is considered low, while 1:256 is high.

ELISA

Detects both American and European strains of the virus. Antibody is first detected at 9–13 days postinfection; the peak titer occurs at 4–6 weeks and gradually declines to undetectable levels at 4–5 months. An S/P ratio of 0.4 is considered positive.

		VACCINATED PIGS	NONVACCINATED PIGS	

Leptospirosis — MA

Vaccinated Pigs	Nonvaccinated Pigs	
2–3 weeks after vaccination, titers may be as high as 1:6400, especially in animals previously vaccinated.	1:100	Of doubtful significance; possibly an old residual titer; however, confirmed cases of leptospiral abortion have resulted in titers no greater than 1:100.
2–3 weeks after vaccination, titers may be as high as 1:6400, especially in animals previously vaccinated.	1:200 or 1:400	Interpretation difficult; should be checked against another sample 10–20 days later.
2–3 weeks after vaccination, titers may be as high as 1:6400, especially in animals previously vaccinated.	31:800	Possibly indicates recent infection; sows aborting due to leptospirosis may have titers of 1:12,800.

Actinobacillus pleuropneumoniae — CF

Vaccination may produce titers as high as 1:128, but more typically in the range of 1:8 to1:32. Titers fall to undetectable levels by 2–3 months postvaccination.

Young pigs' (<3 months old) passive immunity: Passively acquired immunity results in titers as high as 1:128. Passive titers usually decline to undetectable levels by 3 months old. Older pigs (34 months): >1:4 = suspect.

ESAP-ELISA

2 weeks after a second vaccination, titers are as high as 6.5 on the ESAP scale (0–13).

Because of cross-reaction with _Actinobacillus suis_ and other organisms, results should be interpreted with caution, and along with clinical and pathological observation. Early field exposure 10–14 days) gives titers ranging from 2 to 10 on the ESAP scale. The highest titers are seen at 3 weeks postexposure. In late-phase exposure (108–120 days), 87% of the pigs are still seropositive with ESAP titers as high as 13.

Table 11.41. Interpretation of serology

Disease	Test	Results and Interpretation	
		VACCINATED PIGS	NONVACCINATED PIGS
Porcine parvovirus	HI	At 2 weeks postvaccination, titers generally range from 1:40 to 1:320. Vaccination titers frequently decay to nondetectable levels within 3–4 months.	Young pigs (<6 months old): Passive titers derived from colostral immunity may be up to 1:5120; these titers decline to subdetectable levels by 3–8 months of age. Breeding animals: Within 1 week after exposure to the virus, titers may be as high as 1:10,000. After 2 weeks, the range of values for previously exposed sows in an endemically infected herd is 1:320 to >1:2560.
Pseudorabies	SN	Vaccination may produce titers of 1:32, but more typically at 1:4 to 1:8. Vaccine titers may persist up to 6 months but generally are not detectable after 3 months.	A titer of 1:2 in only one animal of a group generally indicates the need to retest. A 1:4 or greater titer is positive. By 2 weeks after exposure to the virus, titers may reach 1:512.
	ELISA	Results are usually reported as positive or negative and SN tests are run to determine titer. Differential tests are available to detect titers that result from vaccination with gene-deleted vaccines.	
Swine Influenza	HI	At 2 weeks postvaccination, 55% of pigs have titers >1:20. The highest titers are seen 4 weeks postvaccination. Titers are 31:320. Passive immunity of 1:20 interferes with vaccination.	Titers positive 1 week after infection, may be as high as 1:320 by 2 weeks post infection and will persist for 4 weeks before declining. Passive immunity usually declines by 12 wks of age.
	ELISA	At 2 weeks postvaccination, 50% of pigs are seropositive. At 4 weeks postvaccination, 100% have seroconverted.	Specificity 99.7%. Range of values is 0.0–2.5 with the positive cut-off at 0.4. True negative herds have values of 0.05 to 0.2.
Transmissible gastroenteritis	SN	Vaccine titers may reach levels as high as 1:400 but usually are between 1:40 and 1:200. Titers can rise dramatically at farrowing. Cross-reactions occur with porcine corona respiratory virus.	Any titer is considered positive. Titers may range from 1:40 to 1:800. Paired serum samples are the most diagnostic.
	VN	Usually 1:16.	1:4 is positive although recent infection produces titers of 1:32.
Mycoplasma hyopneumoniae	CF	Vaccination usually produces titers in the range of 1:4 to 1:32.	1:8 = positive 1:4 = suspect Titers usually range from 1:4 to 1:128.
	ELISA	2 weeks after a second vaccination, titers are usually 0.4 to 1.6.	Seroconversion starts around 2–3 weeks post exposure. <0.3 is negative, 0.3–0.4 is suspect, and >0.4 is positive. Test may cross-react with *M. hyorhinis* and *M. flocculare*.

Note: CF = complement fixation; ELISA = enzyme-linked immunosorbent assay; IFA = indirect fluorescent antibody; IHA = indirect hemagglutination; HI = hemagglutination inhibition; MA = microtiter agglutination; VN = virus neutralization; SN = serum neutralization; ′ = suspect/borderline.

II Viral Diseases

12 Porcine Adenovirus

Steven B. Kleiboeker

An adenovirus was first isolated from a rectal swab of a piglet with diarrhea four decades ago (Haig et al. 1964). A second isolation, made from the brain of a pig with encephalitis, was reported a short time later (Kasza 1966). Since then, porcine adenoviruses have been isolated from a wide variety of samples and associated with pneumonia, diarrhea, and kidney lesions, as well as encephalitis. In swine, however, the virus has been isolated from the feces of normal pigs and the majority of porcine adenovirus infections appear to be asymptomatic. In recent years, porcine adenoviruses have been developed for use as expression vectors and vaccine vectors (Reddy et al. 1999), similar to those based on human adenoviruses.

ETIOLOGY

The three species of porcine adenoviruses (A, B, and C) are classified in family *Adenoviridae*, genus *Mastadenovirus*. Up to six serotypes have been identified by virus-neutralization tests (Clarke et al. 1967; Haig et al. 1964; Hirahara et al. 1990a; Kadoi et al. 1995; Kasza 1966). Serotypes 1, 2, and 3 belong in species porcine adenovirus A, serotype 4 in porcine adenovirus B, and serotype 5 in porcine adenovirus C (Büchen-Osmond 2003).

The structural, chemical, and physical characteristics of porcine adenoviruses are indistinguishable from other members of the *Adenoviridae*. Adenovirus virions are nonenveloped with icosahedral capsid symmetry and are 80–90 nm in diameter. Virions are composed of 240 hexon molecules that form 20 equilateral triangular facets of the icosahedron. A total of 12 pentons per virion are located at the vertices. Fiber proteins, 20–50 nm long with a terminal knob, project from each penton. Adenovirus particles have a precise hexagonal outline when viewed by negative stain electron microscopy (Figure 12.1), and the fiber and terminal knob can occasionally be observed.

Characteristic of family *Adenoviridae*, the porcine adenovirus genome is a single, linear molecule of double-stranded DNA. The genome is approximately 32–34 kilobases in length (Kleiboeker et al. 1993; Reddy et al. 1998; Nagy et al. 2001), based on full-length genome sequencing and restriction fragment length mapping of several porcine adenovirus serotypes. Approximately 40 proteins are encoded by the viral genome and transcribed following complex RNA splicing. About one-third of the genes encode structural proteins. The genome organization is typical of other adenoviruses with early and late gene expression profiles. The ends of the genome form inverted terminal repeats.

Porcine adenoviruses can be isolated and grown in vitro in primary porcine kidney cells using standard virological methods. In addition, continuous porcine kidney cell lines, such as PK-15 cells, and primary porcine cells cultures, such as thyroid cells (Dea and Elazhary 1984a) and testicular cells (Hirahara et al. 1990b), will support productive replication of porcine adenovirus isolates. Viral replication in vitro produces a cytopathic effect characterized by enlargement, clumping, and rounding of cells, followed by detachment. Visible cytopathic effect is typically observed 2–4 days postinoculation and progresses to complete destruction of the cell monolayer. Intranuclear inclusion bodies can be observed in stained cell monolayers. When viewed by thin section electron microscopy, it can be seen that inclusion bodies are formed by crystalline arrays of virus aggregates in the nucleus of the cell.

EPIDEMIOLOGY

Serological studies suggest that porcine adenoviruses are distributed worldwide. Strains of porcine adenovirus B appear to be the most widely distributed, both in North America and Europe.

Swine are the only species known to be susceptible to porcine adenoviruses, although extensive studies on the host range of these viruses have not been performed. Swine appear to be susceptible to infection with human adenoviruses, but in general, the host range of adenoviruses is quite narrow and zoonotic transmission of
12.1. *Negative stain electron micrograph of porcine adenovirus. A typical adenoviral particle was identified following ultracentrifugation of cell culture supernatant from PK-15 cells showing cytopathic effect. Bar, 100 nm.*

porcine adenoviruses from swine to humans has not been reported.

Transmission of porcine adenoviruses is primarily through the fecal-oral route, although aerosol transmission by inhalation of infectious particles may be possible. Fecal shedding of virus occurs, most commonly after weaning (Derbyshire et al. 1966). The duration of shedding following infection of swine with porcine adenoviruses is unknown, although pathogenesis studies have shown viral antigen in enterocytes up to 45 days postinfection, suggesting that long-term shedding is possible. Adult swine rarely shed virus and frequently have high serum antibody titers, which may prevent productive viral replication in these animals.

Adenoviruses are relatively resistant to heat and are stable at room temperature for up to 10 days, but are readily inactivated by common disinfectants, such as bleach, formaldehyde, alcohol, and phenolic compounds (Derbyshire and Arkell 1971).

PATHOGENESIS

The initial isolation of porcine adenovirus was from the brain of a pig with neurological disease, but porcine adenoviruses are most commonly associated with gastrointestinal disease in swine, although respiratory disease may also be possible. Infection of swine occurs following inhalation or ingestion and the primary sites of replication include the tonsils and distal small intestine (Ducatelle et al. 1982; Shadduck et al. 1967; Sharpe and Jessett 1967). Infection of pregnant swine can result in abortion, and virus will replicate in a number of internal organs of the fetus (Dee 1995). In some disease processes, porcine adenovirus may play a role as a secondary or co-pathogen. For example, research showed that sero-

type 4 and *Mycoplasma hyopneumoniae* produced a more severe pneumonia when inoculated together (Kasza et al. 1969).

CLINICAL SIGNS

The only consistent clinical sign observed following experimental inoculation of piglets with porcine adenovirus was diarrhea (Coussement et al. 1981; Derbyshire et al. 1969; Derbyshire et al. 1975; Sanford and Hoover 1983). Experimental oronasal inoculation of cesarian-derived, colostrum-deprived piglets resulted in diarrhea after an incubation period of 3–4 days. Thus, clinical signs, if present, most often involve generalized gastroenteric disease with watery to pasty diarrhea. Experimental inoculation of pigs with porcine adenovirus did not result in mortality and is considered unlikely to do so in cases of natural infection. Based on pathogenesis studies and clinical reports, clinical signs compatible with respiratory disease are possible, but less likely than gastoenteric disease. Dea and El Azhary (1984b) reported that 15% of adult swine with respiratory disease were seropositive to serotype 4, but did not establish a causal relationship between the two. Porcine adenoviruses have been isolated from aborted fetuses (Dee 1995), although there is little evidence to support a significant etiologic role in swine reproductive failure.

LESIONS

Gross lesions are not likely to be observed in swine with adenovirus infections. Moderate enlargement of lymph nodes has been noted following experimental inoculation. Histological lesions characterized by the presence of intranuclear, basophilic inclusion bodies are suggestive of porcine adenoviral infection. These inclusions can most readily be observed in enterocytes of the distal jejunum and ileum, which is presumably where primary viral replication occurs (Ducatelle et al. 1982). Experimental inoculation has also demonstrated destruction of epithelial cells and blunting of the intestinal villi in the lower jejunum and ileum (Ducatelle et al. 1982). Other lesions attributed to both natural and experimental infection of swine with porcine adenovirus include meningoencephalitis with perivascular infiltration and microglial nodule formation (Edington et al. 1972; Kasza 1966) and kidney lesions involving dystrophy of tubules and capillary dilatation plus severe peritubular infiltration. Pneumonia associated with porcine adenovirus infection is characterized by interstitial pneumonia with alveolar thickening due to proliferation of septal cells and infiltration of inflammatory cells.

DIAGNOSIS

The differential diagnosis for infection of swine with adenoviruses includes other causes of gastroenteric dis-

ease, and possibility respiratory disease. Techniques used for diagnosis of porcine adenovirus infection include negative stain electron microscopy (EM) and virus isolation. Electron microscopy is commonly used to detect enteric viral pathogens from diarrheic feces. The relatively large size and characteristic morphology make adenovirus particles straightforward to detect, if present in reasonably high concentrations. In cell culture, the cytopathic effect of porcine adenoviruses is somewhat distinctive, characterized by rounding and the formation of grape-like clusters as cells detach. However, a secondary technique such as EM of cell culture supernatant, neutralization with specific antiserum, or fluorescent antibody (FA) staining with specific antiserum is necessary to confirm the isolation of an adenovirus. For FA staining, an anti-porcine adenovirus fluorescent antibody conjugate is available from the National Veterinary Services Laboratory (United States Department of Agriculture, Animal and Plant Health Inspection Service, Ames, Iowa U.S.A.), although the ability of this conjugate to detect all known species of porcine adenovirus has not been demonstrated. Serologic typing of new isolates by virus neutralizing may be attempted, although reference antiserum may be difficult to obtain.

Serological diagnosis of adenoviral infection may also be attempted using virus neutralization, plaque reduction neutralization assays, or indirect immunofluorescence assays using cells infected with viral stocks in vitro. Demonstration of a rising titer in conjunction with compatible clinical disease is suggestive of a role for porcine adenovirus infection. No commercially available serodiagostic tests specifically for the detection of porcine adenoviruses are available, nor have any been reported in the scientific literature for use in research studies.

In postmortem samples, amphophilic to basophilic adenoviral inclusions that fill the entire nucleus are observed in the early stages of infection. In experimental infections, viral antigen may be detected in enterocytes as early as 24 hours postinoculation. In later stages of infection, inclusions become smaller and are surrounded by a halo. The inclusions are mainly located in enterocytes on the tips and sides of the villi, which may be short and blunt. Viral antigen may persist and can be detected by techniques such as immunoperoxidase staining for up to 45 days following infection (Ducatelle et al. 1982). Specific anti-porcine adenovirus antiserum is available from the same source as the FA conjugate. The presence of intranuclear inclusion bodies is suggestive, but not diagnostic, of porcine adenovirus infection, unless confirmed by positive viral antigen staining by immunofluorescence or immunohistochemistry.

To date, only one report has described a polymerase chain reaction (PCR) assay for detection of porcine adenoviruses (Maluquer de Motes et al. 2004). The assay was validated using fecal samples and a single strain of porcine adenovirus serotype 3. The performance of the assay for other serotypes of porcine adenovirus and other sample matrices is not known.

PREVENTION AND CONTROL

No specific antiviral treatment is available for porcine adenovirus infection of swine. Vaccines have proven useful in control of adenoviruses in other species, but the level of disease caused by porcine adenovirus has not justified the development of vaccines or other control and prevention measures.

13 African Swine Fever

José Manuel Sánchez-Vizcaíno

African Swine Fever (ASF) is caused by a DNA virus in family *Asfarviridae,* genus *Asfivirus*. ASF is considered a List A disease by the Office International des Epizooties (OIE) because of its potential for rapid dissemination and significant socioeconomical consequences. ASF is currently endemic in many sub-Saharan countries of Africa and Sardinia (Italy). Under natural conditions, ASF virus (ASFV) infects only porcine species, both wild and domesticated. Inapparent infection with ASFV is common in wart hogs (*Phacochoerus aethiopicus*) and bush pigs (*Potamochoerus porcus*) and both species act as reservoir hosts in Africa (De Tray 1957; Heuschele and Coggins 1965). Soft ticks have been shown to be both reservoirs and vectors of ASFV, especially *Ornithodorus moubata* and *O. erraticus*. ASFV has been introduced into free areas by feeding contaminated pork products collected from international airports and seaports. Once established in domestic herds, infected and carrier pigs become the most important source of virus dissemination. Clinical signs and lesions range from acute to inapparent and can resemble several other hemorrhagic diseases of pigs, especially classical swine fever (hog cholera) and erysipelas. Laboratory tests are required to establish a definitive diagnosis. There is no treatment or effective vaccine available for ASFV. Therefore, control of ASF is based on rapid laboratory diagnosis and the enforcement of strict sanitary measures.

ETIOLOGY

ASFV is the only member of the family *Asfaviridae* genus *Asfivirus* (Murphy et al. 1995). ASFV is a complex, icosahedral, deoxivirus with features common to both the iridovirus and poxvirus families. The virion is composed of several concentric structures and an external hexagonal membrane (Figure 13.1.) acquired by budding through the cell membrane (Carrascosa et al. 1984). By electronic microscopy, the average diameter of ASFV particles is 200 nm (Breese and DeBoer 1966).

ASFV has a double-stranded linear DNA genome 170–190 kilobases in size, depending on the virus strain (Blasco et al. 1989; Tabares et al. 1980), with terminal inverted repeats (Sogo et al. 1984), a conserved central region of about 125 kilobases, and variable ends. The complete DNA sequence of the BA71v strain of ASFV was composed of 170,101 nucleotides, with 151 open reading frames encoding five multigene families (Yañez et al. 1995).

ASFV is a very complex virus. At least 28 structural proteins have been identified in intracellular virus particles (Tabares et al. 1980), and more than 100 virus-induced proteins have been identified in infected porcine macrophages. At least 50 of the latter react with sera from infected or recovered pigs (Alcaraz et al. 1992) and 40 of these polypeptides are incorporated in the viral particle (Carrascosa et al. 1985). Some of these proteins—e.g., p73, p54, p30, and p12—are highly antigenic. Although their role in inducing protective immunity is unresolved (Neilan et al. 2004), they are used in ASF serodiagnosis (Arias and Sánchez-Vizcaíno 1992).

ASFV has been adapted to grow in a large number of stable cell lines, including VERO, MS, and CV, (Hess et al. 1965). In infected pigs, ASFV replicates primarily in monocytes and macrophage cells (Malmquist and Hay 1960; Minguez et al. 1988), but also in endothelial cells (Wilkinson and Wardley 1978), hepatocytes (Sierra et al. 1987), renal tubular epithelial cells (Gomez-Villamandos et al. 1995), and neutrophils (Carrasco et al. 1996). No infection has been observed in T or B lymphocytes (Gomez-Villamandos et al. 1995; Minguez et al. 1988). In nature, ASFV replicates in some soft ticks, principally *Ornithodoros moubata* (Plowright et al. 1970) and *O. erraticus* (Sanchez Botija 1963).

EPIDEMIOLOGY

Montgomery first described ASF in Kenya in 1921. The virus spread from infected warthogs (*Phacochoerus aethiopicus*) to domestic pigs (*Sus scrofa*), causing a disease with a 100% mortality. Since then, ASF has been rec-

13.1. *Electron micrograph of an ASF virus particle.*

ognized as endemic in many African countries: Angola, Mozambique, Republic of South Africa, São Tomé and Príncipe, Senegal, Sudan, Uganda, and Zimbabwe.

In 1957, ASFV was detected for the first time outside the African continent. It appeared in Lisbon (Portugal) in a peracute form with a mortality of almost 100% (Manso Ribeiro et al. 1963). In 1960, it reappeared near Lisbon, apparently as a new outbreak, spread through the rest of Portugal, and reached Spain the same year (Polo Jover and Sanchez Botija 1961). ASF remained endemic in Portugal and Spain until 1995 when, as a result of an intensive eradication program, both countries were declared ASF-free.

In 1978, ASFV again appeared outside of Africa, this time in Malta, Sardinia (Italy), Brazil, and the Dominican Republic. In 1979, it appeared in Haiti and, in 1980, in Cuba. Today, ASF is present only in Africa, mainly in sub-Saharan countries, and in Sardinia. Elsewhere it has been successfully eradicated

Pigs are the only domesticated animals naturally infected by ASFV. European wild boars are also susceptible to ASFV infection, with clinical signs and mortality rates similar to those observed in naturally infected domesticated pigs in Spain, Portugal, and Sardinia (Italy) (Contini et al. 1983; Sanchez Botija 1982). In contrast, ASFV usually induces an inapparent infection in three African wild suid species: warthogs (*Phacochoerus aethiopicus*), giant forest hog (*Hylochoerus meinertzhageni*) and bushpigs (*Potamochoerus porcus*). Several species of soft ticks have been shown to be ASFV reservoirs and biological vectors, including *Ornithodoros moubata* in Africa (Plowright et al. 1969) and *O. erraticus* in the Iberian Peninsula (Sanchez Botija 1963).

ASFV is maintained in Africa by a cycle of infection between African wild suid species and soft ticks. In some of these wild suids infection is characterized by low levels of virus in tissues and low or undetectable levels of viremia (Plowright 1981). These levels of virus are sufficient for transmission to domestic pigs through tick vec-

tors, but usually not by direct contact between animals. This transmission cycle makes it very difficult to eradicate ASF in Africa.

In contrast to African wild suids, European wild boars are susceptible to ASFV infection and show clinical signs and mortality rates similar to those observed in domestic pigs. In Europe, direct transmission by contact between sick and healthy animals is the most common route of transmission. Indirect transmission by biological vectors, like *O. erraticus*, has also been described in the Iberian Peninsula, especially in outdoor pig productions.

An important difference in the epidemiology of ASFV in Africa vs. Europe is related to ASF virus replication in soft ticks. Transovarial and transtadial transmission of ASFV has been described for *O. moubata* (Plowright et al. 1970), but in Europe only transtadial transmission has been observed in *O. erraticus*. *Ornithodoros savignyi*, also present in Africa, can experimentally transmit ASF virus to domestic pigs (Mellor and Wilkinson 1985). A number of other tick species widely distributed in North and South America are considered capable of harboring and transmitting ASFV (Groocock et al. 1980).

Once ASFV is established in domesticated pigs, carrier pigs become an important source of virus, and their role in the epidemiology of the disease is a major consideration in designing a strategy for ASF eradication. The serological recognition of carrier pigs was an importance facet in the successful eradication of ASF in Spain (Arias and Sánchez-Vizcaíno 2002).

The ASFV is very resistant to inactivation in the environment, particularly by temperature and acid pH. ASFV can be isolated from sera or blood stored at room temperature for 18 months. However, it is inactivated by heat treatment at 60°C for 30 minutes (Plowright and Parker 1967) and by many lipid solvents and commercial disinfectants. In meat products, ASFV may persist for weeks or months in frozen or uncooked meat. In cured or processed products, such as Parma ham, infectious virus was not demonstrated after 300 days of processing

and curing (McKercher et al. 1987). Spanish cured pig meat products, such as Serrano hams and Iberian hams and shoulders, were free of viable ASFV by day 140 and Iberian loins by day 112 (Mebus et al. 1993). No infectious ASFV has been found in cooked or canned hams heated to 70°C.

PATHOGENESIS

ASFV is generally spread among domestic pigs via oral or nasal routes of dissemination and exposure (Colgrove et al. 1969; Plowright et al. 1968). Pigs can also be infected by a number of other routes, including tick bite (Plowright et al. 1969), cutaneous scarification, and intramuscular, subcutaneous, intraperitoneal, or intravenous injection (McVicar 1984). The incubation period varies widely (4–19 days), depending on the ASFV isolate and the route of exposure.

The sites of primary replication are the monocytes and macrophages of the lymph nodes nearest to the point of virus entrance. When the exposure is oral, the monocytes and macrophages of the tonsils and mandibular lymph nodes are the first involved. From these sites, the virus spreads through the blood and/or lymphatic system to the main sites of secondary replication—i.e., lymph nodes, bone marrow, spleen, lung, liver, and kidney. Viremia usually begins 4–8 days post infection and, due to the absence of neutralizing antibodies, persists for weeks or months.

ASFV is associated with red blood cell membranes (Quintero et al. 1986) and platelets (Gomez-Villamandos et al. 1996) and causes hemadsorption in affected pigs (Sierra et al. 1991). Recently, the protein involved in hemadsorption was identified (Galindo et al. 2000).

The pathogenesis of the hemorrhage observed in the acute form is believed to be phagocytic activation of endothelial cells aggravated by virus replication in the same cells in the final stages of the disease. In the subacute form, hemorrhages are due mainly to an increase in vascular permeability (Gomez-Villamandos et al. 1995). The pathogenesis of the lymphopenia in the acute form has been related to apoptosis of lymphocytes, mainly on the T area of lymphoid organs (Carrasco et al. 1996). However, there is no evidence of virus replication in T- or B-cells (Gomez-Villamandos et al. 1995; Minguez et al. 1988).

The subacute form is characterized by a transitory thrombocytopenia (Gomez-Villamandos et al. 1996). The alveolar edema observed in the last stages of the acute and subacute form of ASF (and main cause of death) is a consequence of the activation of pulmonary intrasvascular macrophages (Carrasco et al. 1996; Sierra et al. 1990).

CLINICAL SIGNS

Clinically, ASF can resemble several other diseases of pigs, especially classical swine fever (hog cholera) and erysipelas. Therefore, laboratory tests are required to establish a definitive diagnosis (Sánchez-Vizcaíno 1986). Moreover, ASF can present a range of clinical signs, depending primarily on virus virulence, exposure dose, and exposure route. The clinical forms of ASF range from peracute (i.e., sudden death with few, if any, previous clinical signs) to subclinical or inapparent. In Africa, ASF appears mostly as an acute disease characterized by loss of appetite, high temperature (40–41°C), leukopenia, hemorrhages in internal organs, hemorrhages in the skin (especially the skin of the ears and flanks), and high mortality (Mebus et al. 1983; Moulton and Coggins 1968).

Outside of Africa, it is possible to see acute outbreaks of ASF, but subacute or chronic forms are more common. The subacute form is characterized by transitory thrombocytopenia, leukopenia, and numerous hemorrhagic lesions (Gomez-Villamandos et al. 1997). The chronic form is characterized by respiratory alteration, abortion, and low mortality (Arias et al. 1986).

LESIONS

A wide variety of lesions have been observed in ASF, depending on the virulence of the viral strain. The acute and subacute forms are characterized by extensive hemorrhages and lymphoid tissue destruction. Conversely, lesions may be minimal or absent in the subclinical and chronic forms (Gomez-Villamandos et al. 1995; Mebus et al. 1983).

The principal gross lesions are observed in the spleen, lymph nodes, kidneys, and heart (Sanchez Botija 1982). The spleen may be darkened, enlarged, infarcted, and friable (Figure 13.2). Sometimes lesions are large infarcts with subcapsular haemorrhages. Lymph nodes are hemorrhagic, edematous, and friable (Figure 13.3). They often look like dark-red hematomas. Because of congestion and subcapsular haemorrhage, cut sections of affected lymph nodes sometime have a marbled appearance. Kidneys usually have petechial hemorrhages on the cortical (Figure 13.4) and cut surfaces, as well as in the renal pelvis. An intense hydropericardium with serohemorrhagic fluid is present in some cases. Petechial and echymotic haemorrhages can be observed in epicardium and endocardium. Other lesions can also be observed in acute ASF, such as serohemorrhagic fluid in the abdominal cavity, with edema and hemorrhages throughout the alimentary tract. Congestion of the liver and the gall bladder can be observed, as well as petechial hemorrhages in the mucosa of the urinary bladder. Hydrothorax and petechial hemorrhages of the pleura are frequently found in the thoracic cavity, and lungs are usually edematous. Intense congestion is observed in the meninges, chorioid plexus, and encephalon (Arias et al. 1986).

The most predominant form of ASF outside Africa has been the subacute form, which is similar to the

13.2. *Enlarged and darkened spleen from acute ASF.*
13.3. *Lymph nodes from a normal pig (left), a pig with subacute ASF (center), and a pig with acute ASF (right).*
13.4. *Kidney from a pig with acute ASF showing numerous petechiae on the cortical surface.*

294

acute form except for milder lesions. The subacute form is characterized by large hemorrhages in lymph nodes and kidney. The spleen is enlarged and hemorrhagic. Congestion and edema can be observed in lungs and, in some cases, an interstitial pneumonia has been found (Arias et al. 1986).

In the acute form of ASF, histopathological lesions are present in blood vessels and in lymphoid organs. These lesions are characterized by hemorrhages, microthrombosis, and damage of the endothelial cells with accumulations of dead cells in the subendothelium (Gomez-Villamandos et al. 1995). Hemorrhagic splenomegaly, characteristic of the acute and subacute forms, is a consequence of the loss of splenic architecture caused by viral replication and resulting necrosis of the splenic fixed macrophages (Carrasco et al. 1997). The lymphoid tissue destruction in the acute form is mainly observed on the T area of the lymphoid organs, but no evidence of virus replication in lymphocytes has been observed (Carrasco et al. 1996; Minguez et al. 1988).

The chronic form of ASF is characterized by alterations in the respiratory tract, but lesions in the chronic form may be minimal or absent (Gomez-Villamandos et al. 1995; Mebus et al. 1983). Lesions include fibrinous pleuritis, pleural adhesions, caseous pneumonia, and hyperplasia of the lymphoreticular tissues. Fibrinous pericarditis and necrotic skin lesions are also common (Arias et al. 1986; Moulton and Coggins 1968).

IMMUNITY

The immune mechanisms involved in protection against ASF are poorly understood, and all attempts to develop an effective vaccine have been unsuccessful. The difficulty in inducing effective immunity may be related to the great variability observed among ASFV isolates. It may also be related to the fact that ASFV replicates in some cells typically involved in the immune response. Although there is no evidence for replication of ASFV in either T- and B-cells (Gomez-Villamandos et al. 1995; Minguez et al. 1988), it does replicate in monocytes and macrophages. If immune suppression has a role, however, it is not obvious (Sánchez-Vizcaíno et al. 1981).

ASFV is highly antigenic, and high levels of specific antibodies are produced during ASFV infection. IgM can be detected by 4 days post infection and IgG by 6–8 days post infection (Sánchez-Vizcaíno et al. 1979). Antibodies are detectable for a long time after the initial exposure. Antibodies against ASFV have been shown to delay the onset of the ASF clinical signs, to reduce the levels of viremia, and to protect pigs against the potential fatal consequences of infection (Onisk et al. 1994; Schlafer et al. 1984).

Early experiments demonstrated the absence of neutralizing antibodies against ASFV in sera from naturally or experimental infected pigs. However, recovered pigs produced normal levels of neutralizing antibodies in response to foot and mouth virus vaccine, suggesting that humoral responses are not adversely affected by ASFV (De Boer 1967). Other authors (Ruiz Gonzalvo et al. 1986) have demonstrated that different ASFV isolates are largely neutralized by convalescent porcine sera, but a persistent 10% fraction of nonneutralized virus remained. On the other hand, Gomez-Puertas et al. (1996) reported that ASFV-induced antibodies in serum collected from convalescent pigs effectively neutralized ASFV before and after it was bound to susceptible cells. However, ASFV-specific antibodies have never been demonstrated to entirely fulfill the classic definition of virus neutralization. On the other hand, cytotoxic T lymphocytes from recovered pigs can destroy infected macrophages (Martins and Leitao 1994), suggesting that cell-mediated immunity may be an important component of the protective response. Overall, the relative roles of antibodies and cell-mediated immunity in protecting against ASF are still not well understood.

DIAGNOSIS

Laboratory studies are essential to establish a definitive diagnosis of ASF because of the similarity of ASF clinical signs and lesions to other hemorrhagic pig diseases—e.g., classical swine fever (hog cholera), erysipelas, and septicemic salmonellosis. As in other viral diseases, the laboratory diagnosis of ASF is based on the demonstration of infectious virus, viral antigens, viral DNA, or specific antibodies. A wide variety of laboratory tests are available for detecting either ASFV or homologous antibodies (Arias and Sánchez-Vizcaíno 2002; Sánchez-Vizcaíno 1986).

Several techniques have been adapted for the identification of ASFV. However, at present, the most convenient, safe, and frequently used techniques are direct immunofluorescence (DIF) (Bool et al. 1969), the hemadsorption test (HA) (Malmquist and Hay 1960), and polymerase chain reaction (PCR) (Wilkinson 2000; Aguero et al. 2003).

Direct immunofluorescence (DIF) is based on the demonstration of viral antigen in impression smears or frozen tissues sections from spleen, lung, lymph nodes or kidney reacted with a conjugated immunoglobulin against ASFV. It is a fast, economical test with high diagnostic sensitivity for the acute form of ASF. However, for subacute or chronic forms, DIF has a diagnostic sensitivity of only 40%. This decrease in sensitivity seems to be related to the formation of antigen-antibody complexes in the tissues of infected pigs, which block the reaction between the ASFV antigen and ASF conjugate when such tissues are tested in the laboratory (Sánchez-Vizcaíno 1986).

HA, because of its diagnostic sensitivity and specificity, is useful under the widest range of circumstances.
13.5. *Hemadsorption phenomenon: the attachment of erythrocytes to macrophages infected with ASFV.*

It should be performed to confirm any new outbreak, especially when other tests are negative. The HA test is based on the attachment of erythrocytes to the external (cytoplasmic) membrane of ASFV-infected porcine macrophages cultured in vitro. Typically, the erythrocytes form a rosette around the infected macrophages before the appearance of the ASFV-induced cytopathic effects (Figure 13.5) (Malmquist and Hay 1960). However, although HA is the most sensitive test for ASFV detection, it is important to recognize that a few field strains of ASFV have been isolated that induce cytopathic effect in macrophages but do not induce HA (Sanchez Botija 1982). These strains were identified using DIF sediments of these cell cultures.

The detection of a wide range of ASFV isolates by polymerase chain reaction (PCR) was made possible by using primers from a highly conserved region of the viral genome. PCR has been used to identify ASFV isolates from all the known virus genotypes, including both nonhemadsorbing and low virulence viruses (Wilkinson 2000; Aguero et al. 2003). PCR has been particularly useful for identifying viral DNA in tissues unsuitable for other diagnostic tests. It is an excellent and rapid technique that can be used as a routine diagnostic method for ASFV in surveillance, control, and eradication programs (Aguero et al. 2003). A confirmatory method based on restriction endonuclease analysis has been developed recently (Aguero et al. 2003).

The study of antibodies to ASFV is important for two reasons. First, the presence of ASFV antibodies is indicative of infection, since no vaccines are yet available. Second, specific ASFV IgG is detectable in blood from the 6th to 8th day after inoculation and for a long time, even years, thereafter. The early appearance and subsequent persistence of antibodies is the reason they are so useful in studying subacute and chronic forms of the disease. For the same reason, they play an important role in testing strategies implemented as part of eradication programs (Arias and Sánchez-Vizcaíno 2002).

Several techniques have been adapted to ASF antibody detection, but at present indirect immunofluorescense (IIF), indirect enzyme-linked immunosorbent assay (ELISA) (Sánchez-Vizcaíno et al. 1979, 1983) and the immunoblotting assay (IB) (Pastor et al. 1987), are the most frequently used.

The IIF test is a fast technique with high sensitivity and specificity for the detection of ASF antibodies from either sera or tissue exudates (Sanchez Botija et al. 1970). IIF is based on the detection of ASF antibodies that bind to a monolayer of cell lines infected with a cell culture-adapted ASFV. The antibody-antigen reaction is detected by fluorescein-labelled A-protein. Using both tests IIF and DIF, it is possible to detect from 85–95% of ASF cases (acute, subacute, and chronic) in less than 3 hours. (Sánchez-Vizcaíno 1986).

At present, ELISA is the most useful method for large-scale ASF serological studies. It is based on the detection of ASF antibodies bound to the viral proteins by addition of protein A conjugated with an enzyme that produces a visible color reaction when it reacts with the appropriate substrate.

The IB test is a highly specific, sensitive, and easy-to-interpret technique that has been successfully used as an alternative method to IIF for confirmation of questionable ELISA results (Arias and Sánchez-Vizcaíno 1992).

Samples that should be collected for ASF laboratory diagnosis are lymph nodes, kidneys, spleen, lung, blood, and serum. Tissues are used for virus isolation (HA test), viral antigen and DNA detection (DIF, PCR), blood is used for virus isolation (HA, PCR), and tissues exudates and serum for antibodies detection (IIF, ELISA, IB).

PREVENTION AND CONTROL

No treatment or effective vaccine against ASF virus is available. Many attempts have been made to develop a satisfactory vaccine, beginning in 1963, when the first live-attenuated vaccine was used in Portugal (Manso

Ribeiro et al. 1963). Inactivated vaccine does not produce any protection. Live-attenuated vaccine protects some pigs against challenge with the homologous strain of virus, but some of these pigs become carriers and develop chronic lesions, the likelihood of which increases when large numbers of pigs are vaccinated (Manso Ribeiro et al. 1963; Sanchez Botija 1963). Other studies have shown that serum from pigs resistant to homologous and some heterologous strain of ASFV inhibits (in vitro) infection of cells with different, but related, heterologous strains (Ruiz Gonzalvo et al. 1986). However, ASFV-specific antibodies have never been demonstrated to neutralize virus in the classical concept of neutralization. Recently, it has been shown that neutralizing antibodies to ASFV proteins p30, p54, and p72 are not sufficient for antibody-mediated protection (Neilan et al. 2004). The analysis of the complete nucleotide sequence of ASFV (Yañez et al. 1995) has opened new opportunities to explore immune mechanisms of protection and the roles of various ASF virus genes. However, the eradication of ASF from Portugal and Spain, after more than 20 years of endemicity, proved that vaccine is not essential in the eradication of this complex disease.

Because ASF is a costly disease and because there are no effective vaccines for its control, it is especially important that ASF-free areas be maintained free by preventing the introduction of ASFV. Retrospective epidemiological studies have shown that an important source of ASFV has been contaminated garbage from international airports or ports. Therefore, all food leftovers from planes and ships should be incinerated. In infected European areas such as Sardinia, where the disease is endemic and where mild or inapparent clinical signs have been recognized, the most important aspects of prevention are controlling pig movements and implementing extensive serological surveys to detect carriers. In areas of Africa where ASF is endemic, the most important aspects of prevention are controlling natural reservoirs—i.e., soft ticks (*O. moubata*) and warthogs—and preventing their contact with domestic pigs. When ASF is suspected for any reason, pig movement should be restricted and diagnostic evaluations should be performed immediately. Moreover, it is important to remember that low-virulence ASFV strains do not cause signs or lesions that signal their presence.

14 Porcine Circovirus Diseases

Joaquim Segalés, Gordon M. Allan, and Mariano Domingo

In the late 1990s, an apparently novel porcine circovirus (PCV)-like virus was detected worldwide in diseased and nondiseased pigs (Allan and Ellis 2000). This virus was distinct from the known PCV contaminant of PK-15 cell cultures (Tischer et al. 1974, 1982). It was proposed that the original PCV should be designated porcine circovirus type 1 (PCV1), and the new virus associated with clinical disease be designated porcine circovirus type 2 (PCV2) (Allan et al. 1999).

PCV2 infection has been associated with postweaning multisystemic wasting syndrome (PMWS) (Clark 1996; Harding 1996), porcine dermatitis and nephropathy syndrome (PDNS) (Rosell et al. 2000), porcine respiratory disease complex (Allan and Ellis 2000), and reproductive disorders (West et al. 1999). Recently, the terminology "porcine circovirus diseases" (PCVD) has been proposed to group diseases or conditions linked to PCV2 (Allan et al. 2002a). Among PCVD, only PMWS is considered to have a severe impact on swine production, with an estimated cost of approximately 600 million Euros per year to the pig industry in Europe.

ETIOLOGY

PCV2 belongs to the genus *Circovirus* in the family *Circoviridae* (Figure 14.1) (McNulty et al. 2000). The circular, single-stranded DNA genome of PCV2 contains 1767–1768 nucleotides (Hamel et al. 1998; Meehan et al. 1998) and analysis of PCV2 viruses from around the world has shown that they all belong to a phylogenetic cluster with a nucleotide sequence identity greater than 93% (Larochelle et al. 2002).

Little information is available on the biological and physicochemical characteristics of PCV2. However, it is known that PCV1 has a buoyant density of 1.37 g/ml in CsCl, is not able to hemagglutinate erythrocytes from a wide range of species, is resistant to inactivation at pH 3 and by chloroform, and is stable at 70°C for 15 minutes (Allan et al. 1994). It is probable that these properties are also common to PCV2. Exposure of PCV2 for 10 minutes at room temperature to a number of commercial disinfectants based on chlorhexidine, formaldehyde, iodine, and alcohols lead to a reduction in virus titer (Royer et al. 2001).

EPIDEMIOLOGY

PCV2 is considered ubiquitous (Allan and Ellis 2000) and domestic and feral swine appear to be the natural host (Segalés and Domingo 2002; Vicente et al. 2004). Non-suidae species are apparently not susceptible to PCV2 infection (Segalés and Domingo 2002).

Oronasal exposure is considered the most likely and frequent natural route of PCV2 transmission. Attempts to infect fetuses by intranasal inoculation of pregnant sows or artificial insemination have yielded differing, inconclusive results (Cariolet et al. 2001; Nielsen et al. 2004).

PCV2 nucleic acid can be detected by PCR in all excretions and secretions (Bolin et al. 2001; Calsamiglia et al. 2004a; Krakowka et al. 2000; Larochelle et al. 2000) of both PMWS and non-PMWS affected pigs and has also been demonstrated in serum from pigs up to 28 weeks of age under field conditions (Rodríguez-Arrioja et al. 2002).

PMWS is a multifactorial disease of pigs where PCV2 infection is needed for the full expression of the clinical condition. Barrow pigs are considered more prone to develop PMWS than females (Corrégé et al. 2001). Other risk factors for PMWS include litter of origin (Madec et al. 2000), low birth weight, low weaning weight, and low weight at the beginning of the fattening period (Corrégé et al. 2001). PMWS-affected farms commonly have other infections or diseases (Ellis et al. 2004). Field observations from farmers and veterinarians have suggested that certain genetic lines of pigs, specifically in relation to boar lines, are more or less susceptible to PMWS. This observation has been supported by recent experimental studies where Landrace pigs were experimentally shown to be more likely to develop PMWS le-
14.1. *Transmission electron photomicrograph of negatively stained PCV2 particles isolated from an affected pig. Virions are 15–20 nm in diameter.*

sions than Duroc and Large White pigs (Opriessnig et al. 2004a). Studies reported contradictory results with the use of the Pietrain boar line. The use of this genetic line did not have an effect on the offspring in one study (Rose et al. 2003a), but another study showed lower general postweaning and PMWS associated mortalities (López-Soria et al. 2004).

PATHOGENESIS

The cells that support PCV2 replication in vivo have not been identified. The large amount of PCV2 virus antigen found in macrophages and dendritic cells of diseased pigs appears to be the result of the accumulation of viral particles (Gilpin et al. 2003, Vincent et al. 2003) and not the result of virus replication in these cells. PCV2 replicates in fetal myocardiocytes in experimentally infected porcine fetuses (Sánchez et al. 2003). PCV2 is also able to replicate in in vivo produced zona pellucida-free morulae and blastocysts (Mateusen et al. 2004), although the importance of this finding in naturally occurring reproductive disease is unknown. To date, studies on tissue sections from pigs with PDNS have failed to consistently demonstrate PCV2 antigen or nucleic acid associated with PDNS lesions.

The effect of PCV2 on the immune system in PMWS-affected and PCV2-subclinically infected pigs may be important in the pathogenesis of the disease. The most repeatable PMWS disease models have been obtained using PCV2 inoculation in combination with infectious and noninfectious cofactors (Allan et al. 2004a). It has been shown experimentally that stimulation and/or activation of the immune system of PCV2-infected pigs by some viruses or noninfectious factors up-regulates PCV2 replication and increases viral loads in tissues and serum (Allan et al. 1999, 2000; Harms et al. 2002; Krakowka et al. 2000, 2001; Rovira et al. 2002), indicating

that PCV2 infection and immunostimulation can be pivotal events in the development of PMWS (Krakowka et al. 2001). The mechanism by which co-infection or immunostimulation may trigger the development of PMWS in PCV2 infected pigs is still unknown (Darwich et al. 2004). Conversely, typical microscopic lymphoid lesions in tissues from PMWS affected pigs (Clark 1997; Rosell et al. 1999), the association of the disease with opportunistic pathogens (Clark 1997; Carrasco et al. 2000; Nuñez et al. 2003; Segalés et al. 2003), and other changes in immune cell subpopulations of lymphoid tissues and peripheral blood mononuclear cells (Chianini et al. 2003; Darwich et al. 2002, 2003b; Nielsen et al. 2003; Segalés et al. 2001) are regular features of PMWS in severely affected pigs, suggesting an immunosuppressive status in diseased pigs (Segalés et al. 2004a).

Recent studies on field cases of PMWS have shown that pigs with clinical disease have an evident and significant alteration of the cytokine mRNA expression patterns of several proinflammatory and regulatory cytokines in different lymphoid tissues (Darwich et al. 2003b). However, it was not clear from these studies whether the altered profiles were related to the development of PMWS or a consequence of the severely altered cell population dynamics in lymphoid tissues of diseased animals. In these studies, a significant overexpression of IL-10 mRNA in the thymus of PMWS-affected pigs, compared to nonaffected pigs, was reported. This was associated with thymic depletion and atrophy (Darwich et al. 2003b). In contrast, Sipos et al. (2004) reported no significant differences in the expression of cytokines in blood and tissue samples from field cases of PMWS-affected pigs when compared to nonaffected pigs and concluded that their results did not support either a Th1 profile response to viral infection or a profile indicative of T cell immunosupression. However, the same authors suggested that animals under investigation were probably at the remitting stage of the disease, potentially ameliorating differences between both groups (Sipos et al. 2004).

Studies on sequential blood samples from pigs experimentally infected with PCV2 have also indicated an increase in IL-10 production in PMWS-affected inoculates, compared to inoculates that remained subclinically infected. This increase was detected only late in the infection and was interpreted by the authors to reflect the effects of clinical PMWS development, rather than contributing to the initiation of the disease (Stevenson et al. 2004). However, in the same study a consistent down-regulation of interferon was noted early in infected pigs that developed PMWS, when compared to infected pigs that remained subclinically infected. It was concluded that the inability of some PCV2-infected pigs to produce interferon early in the infection process may be a key factor in an inappropriate immune response to PCV2 infection that leads to disease (Stevenson et al., 2004). Reduction in interferon production and increase

of IL-10 production in PCV2 experimentally infected pigs that develop PMWS have now been confirmed by other workers using a different experimental model (Hasslung et al. 2004). Additionally, it has recently been shown in in vitro studies that PCV2 interaction with porcine natural interferon producing cells (NIPC) results in a down-regulation in the ability of these cells to produce interferon (Vincent et al. 2004).

In vitro studies on peripheral blood mononuclear cells (PBMC) from healthy and PMWS-diseased pigs have revealed substantial and specific effects on functional capabilities of PBMC of PMWS pigs in terms of cytokine release (Darwich et al. 2003a). On the other hand, no specific differences were seen in expression of cell surface markers of PBMC or alveolar macrophages exposed in vitro to PCV2 when compared to mock-infected controls (Gilpin et al. 2001, Vincent et al. 2003)

To date, the results on the interactions of PCV2 with the porcine immune system are controversial and further studies are required. These studies should focus on the interactions following infection and prior to the development of clinical disease in an attempt to elucidate the pathways that determine clinical and/or subclinical infections.

In regard to PDNS, it has been postulated that excessive PCV2 antibody titers may trigger the disease (Wellenberg et al. 2004), but this hypothesis awaits experimental confirmation.

CLINICAL SIGNS AND LESIONS

Postweaning Multisystemic Wasting Syndrome (PMWS)

PMWS most commonly affects pigs at 2–4 months of age. Morbidity in affected farms is commonly 4–30% (occasionally 50–60%), and mortality ranges from 4–20% (Segalés and Domingo 2002). PMWS is characterized clinically by wasting, pallor of the skin, respiratory distress, and occasionally, diarrhea and icterus (Figure 14.2) (Harding and Clark 1997). Enlarged subcutaneous lymph nodes are a common finding in the early clinical phases of PMWS.

PMWS lesions are primarily found in lymphoid tissues and enlargement of lymph nodes is the most prominent feature of the early clinical phases of PMWS (Clark 1997; Rosell et al. 1999). Normal sized, or even atrophied, lymph nodes are usually seen in more advanced phases of PMWS (Segalés et al. 2004b) and the thymus is frequently atrophied in diseased pigs (Darwich et al. 2003b).

The histopathological lymphoid lesions observed in PMWS-affected pigs are characterized by lymphocyte depletion together with infiltration by large histiocytic cells and giant multinucleate cells (Figure 14.3) (Clark 1997; Rosell et al. 1999). In thymus, cortical atrophy is a prominent finding (Darwich et al. 2003b). Cytoplasmic

Note the lack of follicles in the affected pig together with a marked loss of lymphoid cells and the presence of macrophages and multinucleate giant cells. (Hematoxylin and eosin stain. Original magnification: ×100.)*

viral inclusions may be found in histiocytes or dendritic cells (Figure 14.4).

Lungs may be enlarged, noncollapsed, and rubbery in consistency, in a diffuse or patchy distribution. These findings correspond microscopically to interstitial pneumonia. Peribronchial fibrosis and fibrous bronchiolitis occurs in advanced cases (Clark 1997; Segalés et al. 2004b).

In a few cases of PMWS, the liver is enlarged or atrophied, pale, and firm, with a fine granular surface that corresponds microscopically to widespread cytopathic changes and inflammation (Clark 1997; Segalés et al. 2004b). Pigs may show generalized icterus at this latter stage.

Some pigs show white spots in the kidney cortex

(nonpurulent interstitial nephritis). Foci of lymphohistiocytic inflammatory infiltrates may be seen in many tissues of pigs affected by PMWS (Segalés et al. 2004b).

Porcine Dermatitis and Nephropathy Syndrome

PDNS affects nursery, growing, and adult pigs (Drolet et al. 1999). The prevalence of the syndrome is usually below 1% (Segalés et al. 1998), although higher frequency has been described (Gresham et al. 2000). Mortality approaches 100% in pigs older than 3 months of age versus approximately 50% of affected younger pigs. Severe, acutely affected pigs die within a few days after the onset of clinical signs. Surviving pigs tend to recover and gain weight 7–10 days after the beginning of the syndrome (Segalés et al. 1998).

PDNS-affected pigs are anorexic and depressed, with little or no pyrexia (Drolet et al. 1999). They may be prostrate, reluctant to move, and/or stiff-gaited. The most obvious sign of PDNS is the presence of irregular, red-to-purple macules and papules in the skin, primarily on the hind limbs and perineal area (Figure 14.5), but sometimes more generally distributed. With time, the lesions become covered by dark crusts. The lesions gradually fade, sometimes leaving scars (Drolet et al. 1999). Macules and papules are seen microscopically as necrotic and hemorrhagic tissue associated with necrotizing vasculitis (Segalés et al. 2004b). Necrotizing vasculitis is a systemic feature.

Pigs that die acutely with PDNS have bilaterally enlarged kidneys with fine granular cortical surface, small reddish pinpoint cortical lesions, and edema of the renal pelvis (Segalés et al., 2004b). These lesions correspond to a fibrino-necrotizing glomerulitis with nonpurulent interstitial nephritis. Pigs with prolonged disease may show chronic glomerulonephritis (Segalés et al.

1998). Normally, both skin and renal lesions are present in PDNS, but in few occasions, skin or renal lesions may occur alone.

Lymph nodes may be enlarged and red in color. Splenic infarcts may be also present (Segalés et al. 1998). Microscopically, lymphoid lesions similar to PMWS are frequently observed in PDNS affected pigs (Rosell et al. 2000).

Reproductive Disease

PCV2 has been linked to late term abortions and still-births (West et al. 1999). However, PCV2-associated reproductive disease under field conditions is rare (Pensaert et al. 2004). This is probably due to the fact that the seroprevalence of PCV2 in adult pigs is high and, therefore, most breeding herds are not susceptible to the clinical disease. In PCV2-associated reproductive disease, stillborn and nonviable neonatal piglets show chronic, passive, hepatic congestion and cardiac hypertrophy with multifocal areas of myocardial discoloration (West et al. 1999). The main microscopic lesion corresponds to a fibrotic and/or necrotic myocarditis (West et al. 1999).

IMMUNITY

In experimentally infected pigs, seroconversion to PCV2 has been demonstrated to occur between 14 and 28 days post infection (PI) (Allan et al. 1999; Balasch et al. 1999; Krakowka et al. 2001; Pogranichniy et al. 2000). Seroconversion has been demonstrated in experimentally infected pigs with and without clinical disease, but some studies have shown that clinically diseased pigs seroconvert at a later stage post infection with PCV2 (Bolin et al. 2001).

Under field conditions, colostral antibodies typically

decline during the lactating and nursery periods, followed by an active seroconversion (Blanchard et al. 2003; Larochelle et al. 2003; Rodríguez-Arrioja et al. 2002; Rose et al. 2002). Seroconversion usually occurs around 7–12 weeks of age, and antibodies may last at least until 28 weeks of age (Rodríguez-Arrioja et al. 2002). PMWS is not usually observed in pigs younger than 4 weeks of age (Segalés and Domingo 2002), which may be associated with maternal immunity against the development of PMWS (Allan et al 2002b; Calsamiglia et al. 2004b). However, other studies have shown no significant protective effect in relation to high levels of colostral-derived serum antibodies to PCV2 in piglets and development of PMWS (Allan et al. 2004b; Hassing et al. 2004). Although a humoral immune response to PCV2 in the field takes place at 2–3 months of age, a variable percentage of growing or finishing pigs may be viremic, suggesting that PCV2 antibodies are not fully protective against the infection (Larochelle et al. 2003; Rodríguez-Arrioja et al. 2002; Sibila et al. 2004). This situation also seems to occur in adult pigs under field conditions, since they can be infected but do not show apparent or detectable clinical signs (Calsamiglia et al. 2002). Whether this is due to humoral immunity to PCV2 or natural age resistance is not known at present.

Only one report has dealt with neutralizing antibodies to PCV2 (Pogranichniy et al. 2000). Virus-neutralizing antibodies were not detected until day 28 post infection. As neutralizing antibodies developed, cross-reactivity with PCV1 also developed using this serological test.

DIAGNOSIS

The respiratory form of porcine reproductive and respiratory syndrome (PRRS) and all diseases and conditions that cause wasting must be differentiated from PMWS (Harding and Clark 1997). For PDNS, differential diagnoses include any condition that causes red to dark discoloration of the skin, as well as conditions that cause petechial hemorrhages in the kidneys (Segalés 2002). Special note should be made of the similarity of gross lesions between PDNS, classical swine fever, and African swine fever. The reproductive form of PCV2 is clinically indistinguishable from other swine diseases that cause late-term abortions and stillbirths.

Postweaning Multisystemic Wasting Syndrome

A pig or group of pigs suffer from PMWS if they fulfill the following criteria (Sorden 2000):

1. Growth retardation and wasting, frequently with dyspnea and enlargement of inguinal lymph nodes and occasionally with jaundice
2. Moderate-to-severe characteristic histopathological lesions in lymphoid tissues

3. Moderate-to-high amounts of PCV2 within the lesions in lymphoid and other tissues of affected pigs

This case definition does not exclude the concomitant presence of other diseases together with PMWS. Neither clinical signs nor gross lesions observed in suspected PMWS affected pigs are sufficient to diagnose the disease.

A herd diagnosis of PMWS is based on the occurrence of a clinical process characterized mainly by wasting and mortality in excess of the expected and/or historical level for the farm and the individual diagnosis of PMWS, as described above, in a number of pigs (Segalés et al. 2003).

Porcine Dermatitis and Nephropathy Syndrome

The diagnosis of PDNS is based on two main criteria (Segalés 2002):

1. The presence of hemorrhagic and necrotizing skin lesions, primarily located on the hind limbs and perineal area, and/or swollen and pale kidneys with generalized cortical petechia
2. Presence of systemic necrotizing vasculitis, and necrotizing and fibrinous glomerulonephritis

Reproductive Disease

The diagnosis of PCV2-associated reproductive disease should include three criteria:

1. Late-term abortions and stillbirths, sometimes with evident hypertrophy of the fetal heart
2. The presence of heart lesions characterized by extensive fibrosing and/or necrotizing myocarditis
3. The presence of high amounts of PCV2 in myocardial lesions and other fetal tissues

Laboratory Confirmation

Several methods have been developed to detect PCV2 in tissues. In situ hybridization (ISH) and immunohistochemistry (IHC) are the most widely used tests (McNeilly et al. 1999; Rosell et al. 1999) for the diagnosis of PCVD. PCV2 nucleic acid or antigen in PMWS and PDNS affected pigs is usually found in the cytoplasm of histiocytes, multinucleate giant cells and other monocyte/macrophage lineage cells (Allan and Ellis 2000), as well as in other cell types (Segalés et al. 2004b). In aborted fetuses, PCV2 is found in the myocardiocyte (Sánchez et al. 2001).

A strong correlation has been observed between the quantity of PCV2 seen in tissues and the severity of microscopic lymphoid lesions in PMWS (Figure 14.6) (Rosell et al. 1999). Since the amount of PCV2 in damaged tissues is the major difference between PMWS affected pigs and PCV2 subclinically infected pigs, techniques that allow PCV2 quantification in tissues and/or
14.6. *Mesenteric lymph node. Marked presence of PCV2 nucleic acid in the cytoplasm of multinucleate giant cells and macrophages (dark-stained cells) in a PMWS-affected pig. (In situ hybridization to detect PCV2; fast green counterstain. Original magnification: ×100.)*

serum could potentially be used to diagnose PMWS (McNeilly et al. 2002, Olvera et al. 2004). Nonquantitative polymerase chain reaction (PCR) techniques should not be used to diagnose PCVD because the virus is ubiquitous and positive results in the absence of clinical disease are common.

Several serological techniques to detect antibodies to PCV2 have been developed (Segalés and Domingo 2002). However, diagnosis of PCVD using serological techniques is problematic because PCV2 is ubiquitous and seroconversion patterns are relatively similar in PMWS affected and nonaffected farms.

PREVENTION AND CONTROL

PMWS is considered a multifactorial disease. In addition to PCV2 infection, environmental conditions are postulated to cause the expression of disease (Madec et al. 2000). Viral and bacterial coinfections with PCV2 are also conjectured to serve as triggers for PMWS (Rose et al. 2003b, Ellis et al. 2004). Consequently, control measures have focused on the control or elimination of postulated cofactors and triggers. The implementation of "Madec's 20-point plan," a list of management practices intended to lower the impact of the disease, significantly decreased the mortality in severely affected farms (Guilmoto and Wessel-Robert 2000). Likewise, the control of concurrent viral and bacterial infections in the postweaning area may decrease the incidence of PMWS.

Some experimental and field studies suggest that immune activation may be an important triggering factor of PMWS in some farms. From a practical point of view, to exclude the use of vaccines from sanitary programs may be inappropriate, since the risk of eliminating effective vaccines may be greater than the risk of inducing

PMWS in a low percentage of pigs in a given pig population. Therefore, producers with PMWS affected herds should consider determining the approximate timing of PCV2 infection, with the final objective of rescheduling the timing of vaccination as a potential plan to minimize the disease (Opriessnig et al. 2004b).

It has been reported that PCV2 infection or low serological titers to PCV2 in sows at farrowing increased the overall mortality of their offspring to PMWS (Allan et al. 2002b, Calsamiglia et al. 2004b). Although these observations were not corroborated in later studies (Hassing et al. 2004, Allan et al. 2004b), measures that increase maternal immunity and decrease sow viremia at farrowing may diminish piglet PMWS mortality in problem herds.

Changes in the diet of affected pigs reportedly led to partial control of PMWS on some farms (Donadeu et al. 2003). Although these results have not been confirmed by other workers, a recent study found that conjugated linoleic acid (CLA) ameliorated PCV2 experimental infection (Bassaganya-Riera et al. 2003). It has been suggested that the addition of vitamin E and/or selenium in the feed may be of benefit in those farms with PMWS (Baebko et al. 2004).

An inactivated, adjuvanted PCV2 vaccine for use in sows and gilts is now commercially available and in use under special license in some countries. In previous studies this vaccine reduced the incidence of PMWS on affected farms (Reynaud et al. 2004). Its efficacy under a wide range of farm conditions still has to be evaluated. Experimental PCV2 vaccines, including inactivated, recombinant, and DNA vaccines, as well as chimeric infectious DNA clones, have shown significant protection when evaluated on the basis of growth rate and rectal temperatures after PCV2 challenge (Blanchard et al. 2003; Fenaux et al. 2004; Pogranichniy et al. 2004).

Subcutaneous injection of suckling or nursery pigs with serum collected from commercial market age pigs (serum therapy) was reportedly successful in reducing mortality in several PMWS affected farms (Ferreira et al. 2001). However, the results of this procedure have been variable and even deleterious in some cases. It is important to note that the use of "serum therapy" presents significant health and biosecurity risks.

15 Classical Swine Fever and Other Pestiviruses

Marie-Frédérique Le Potier, Alain Mesplède, Philippe Vannier

Classical swine fever (CSF), formerly known as "hog cholera," is a highly contagious viral disease of worldwide importance and one of the Office International des Epizooties (OIE) List A diseases. Wild and domestic pigs are the only natural reservoirs of classical swine fever virus (CSFV). Clinical outbreaks suggestive of CSF were reported in the early 19th century (Fuchs 1968; Kernkamp 1961; USDA 1889), and CSF was recognized as viral in nature by 1903 (Wise 1981). Historically, peracute, acute, chronic, or prenatal forms of CSF were attributed to distinct levels of virus virulence. However, characterization of strain virulence is difficult since the same isolate can induce different signs depending on pig age, breeding, health status, and immune status.

Pigs are also susceptible to other pestiviruses, including bovine viral diarrhea virus (BVDV) and border disease virus (BDV) (Carbrey et al. 1976; Terpstra and Wensvoort 1988). Bovine viral diarrhea was first described in 1946 as an infectious and contagious disease of cattle; mucosal disease was reported in 1953. Border disease in sheep, characterized by congenital disorders in lambs, was first described in 1959 along the border between England and Wales, but the immunological relationship of BDV with BVDV was only recognized later (Hamilton and Timoney 1973). Cross-species transmission among artiodactyls has been reported for both BVDV and BDV and the terms "bovine viral diarrhea virus" and "border disease virus" are used to indicate that the virus was isolated from either cattle or sheep. In fact, these two viruses cannot be differentiated morphologically or structurally (Laude 1979).

Natural infection of swine with BVDV was first reported in Australia in 1964, but BVDV was not isolated from a naturally infected pig until 1973 (Fernelius et al. 1973). The teratogenic properties of pestiviruses are well established (Terpstra and Wensvoort 1988; Vannier et al. 1988; Wensvoort and Terpstra 1988), and infection of pregnant sows with BVDV or BDV may induce a pathology resembling congenital CSF. Pestivirus isolates from pigs are usually CSFV, but cross-neutralization tests and

tests using monoclonal antibodies (Leforban et al. 1990a; Wensvoort 1989) suggest that BVDV may have been isolated from pigs in the past and misidentified as CSFV by tests based on polyclonal antibodies. Likewise, serum antibodies against BVDV or BDV have the potential to cross-react in assays for the detection of CSFV antibodies. Because of cross-reactions among pestiviruses, it is essential to identify the specific etiologic agent when pestivirus antibodies are detected in CSF eradication programs.

CSFV is endemic in parts of Eastern Europe, Southeast Asia, Central America, and South America. Although eradicated from domestic pigs in Western Europe, CSFV remains endemic in some populations of wild boar, and farms in these areas are at risk of reinfection. At present, the risk of reintroducing CSFV into free areas is high. Producers and veterinarians are in the best position to detect CSF outbreaks in free areas, but early detection will require both vigilance and training in the recognition of clinical signs. A "no vaccination" policy is logical in CSFV-free areas, but emergency vaccination must be included in contingency plans in order to avoid destroying millions of pigs. For this reason, research on efficacious marker vaccines and reliable differential tests should continue. Likewise, the development of simulation models should be encouraged in order to be able to respond to changing epidemiological situations with the most effective control measures.

ETIOLOGY

CSFV, BVDV, and BDV are small, enveloped, positive, single-strand RNA viruses in the genus *Pestivirus* of the family *Flaviviridae* (Becher et al. 1999). Currently the genus *Pestivirus* includes four approved species: CSFV, BVDV-1, BVDV-2, and BDV. A single strain (H138) isolated from a giraffe in Kenya more than 30 years ago represents a tentative fifth species (Becher et al. 1999). Recent phylogenetic and antigenic analysis have led the same authors to propose splitting the BDV group into 3

309

subgroups: BDV-1 for classical sheep isolates; BDV-2 for isolates, primarily from sheep, related to the previous strain V60 isolated from reindeer; and BDV-3 for the ovine Gifhorn isolate that differs significantly from all previously described pestiviruses, including BDV (Becher et al. 2003).

The majority of pestiviruses are noncytopathogenic in cell culture, but some BVDV isolates from cases of mucosal disease and some CSFV strains are cytopathogenic in vitro. Cytopathogenicity of BVDV is correlated with the expression of the nonstructural protein NS3, which is generated by processing a fusion protein termed NS2-3 (Kummerer and Meyers 2000; Zhang et al. 2003).

The pestivirus genome is 12.5–16.5 kilobases in size and encodes for a single polyprotein (Meyers et al. 1989):

$$NH_2\text{-}(N^{pro}\text{-}C\text{-}E^{rns}\text{-}E1\text{-}E2\text{-}p7\text{-}NS2.3\text{-}NS4A\text{-}NS4B\text{-}NS5A\text{-}NS5B)\text{-}COOH$$
The single polyprotein is co- and posttranslationally converted to mature proteins by a combination of virus and host cell proteases (Rumenapf et al. 1993). The structure and function of some envelope proteins has been studied in some detail, but the nonstructural proteins are not well characterized. Little is known about mechanisms of viral RNA replication, packaging, or how viral particles are assembled. Virions are released from the host cell by exocytosis, usually without morphological cell damage.

CSFV is relatively stable for an RNA virus (Vanderhallen et al. 1999), but is antigenically and genetically diverse, nonetheless. Antigenic variability among CSFV isolates can be characterized using monoclonal antibodies (Edwards et al. 1991) and genetic variability evaluated using genomic sequencing. For example, two panels of monoclonal antibodies, directed against E2 and Erns glycoproteins defined 21 antigenic virus types (Kosmidou et al. 1995). Genetic characterization of new CSFV isolates has become standardized in terms of the genomic fragment sequenced, the algorithms used in constructing phylogenetic trees, and the classification of the genetic groups. Three regions of the viral genome are usually evaluated: the 3' end of the polymerase gene (NS5B), 150 nucleotides of the 5'NTR, and 190 nucleotides of the gene encoding E2. The E2 glycoprotein is most commonly used for genetic typing because abundant sequence data are available.

CSFV is divided into three major genetic groups (Lowings et al. 1996), each with three or four subgroups: 1.1, 1.2, 1.3; 2.1, 2.2, 2.3; 3.1, 3.2, 3.3, 3.4. (Paton et al. 2000c). The phylogenetic analyses of the last decade have demonstrated a link between genotype and geographic origin (Bartak and Greiser-Wilke 2000; Stadejek et al. 1997; Vilcek 1997; Vilcek et al. 1996). Most viruses isolated from outbreaks in Western Europe in the 1990s belonged to Group 2. The situation is more complex in Central and Eastern Europe where isolates usually belong to groups 2.2 or 2.3. Group 1 isolates are present in South America (Frias-Lepoureau and Greiser-Wilke 2002) and Russia (Vlasova et al. 2003); and Group 3 viruses are apparently confined to Asia (Parchariyanon et al. 2000). The Community Reference Laboratory for CSF in Hanover Germany has developed a web-accessible database of sequences from isolates throughout the world (Greiser-Wilke et al. 2000b). This database is a useful tool for identifying possible viral sources for outbreaks occurring in previously uninfected areas (Greiser-Wilke et al. 2000a; Sandvik et al. 2000).

EPIDEMIOLOGY

Classical Swine Fever

Domestic pig populations in Australia, New Zealand, North America, and Western Europe are free of CSF (Paton and Greiser-Wilke 2003). In South America, Chile and Uruguay have been declared CSF-free. Argentina, free of outbreaks since 1999, stopped vaccination in April 2004. CSF remains endemic in Asia (Paton et al. 2000c) and, although the situation in Africa is not well characterized, the disease has been identified in Madagascar. Extensive areas of Central and South America continue using vaccination to control the disease (Morilla and Carvajal 2002; Morilla and Rosales 2002).

The reemergence of CSF is always a risk and several areas previously free of CSF have had incursions in recent years. For example, CSF reemerged in Cuba in 1993 after an absence of more than 20 years. The outbreaks in western Cuba were apparently caused by strain Margarita (group 1.2) used in vaccine potency trials, but outbreaks in eastern Cuba were of uncertain origin, with no demonstrated relationship to Caribbean strains. The outbreaks were exacerbated by the presence of a highly susceptible (unvaccinated) swine population; the result of worsening economics on the island (Frias-Lepoureau 2002). In spite of a campaign of total depopulation carried out in the Caribbean, new infections have occurred, leading the authorities to turn to vaccination as the method of control.

Under natural circumstances, the primary routes of transmission are oronasal by direct or indirect contact with infected wild or domestic pigs, or oral by ingestion of contaminated foodstuffs (Edwards et al. 2000; Fritzemeier et al. 2000; Horst et al. 1997). People should be regarded as the single most important factor in transmission of the virus between herds. In finishing units and in areas with small pig farms, transport and introduction of infected pigs accounts for the majority of outbreaks and for the spread of the disease (Terpstra 1987).

Airborne spread of CSFV has been demonstrated under experimental conditions (Dewulf et al. 2000), although its importance under field conditions is uncertain. However, in a fully susceptible population and in a

densely populated region, even a minor route of transmission can have major consequences. A matched case-control study of 135 infected and 99 uninfected pig herds in the 1997 to 1998 CSF epidemic in the Netherlands suggested that airborne transmission did not occur over long distances, but did occur within a holding pen or within a radius of less than 500 meters. In one case, transmission occurred when an aerosol was produced during high-pressure cleaning of the electrocution equipment used to depopulate herds (Elbers et al. 2001).

The possibility of CSFV transmission by semen was raised during the epidemic in the Netherlands. Following infection of two artificial insemination centers, 1680 pig herds were declared CSF-suspect (Elbers et al. 1999; Hennecken et al. 2000). Experimental studies have shown that infected boars could shed CSFV in semen, and it is assumed that the disease might be transmitted by artificial insemination (de Smit et al. 1999; Floegel et al. 2000).

Rodents and pets have been postulated to act as mechanical vectors, but recent work proved that transmission of CSFV by rats, dogs, and cats is unlikely (Dewulf et al. 2001a). Thus, euthanasia of pets during an outbreak cannot be justified, as long as they do not leave the infected farm.

Indirect transmission via people can occur when biosecurity is deficient and, for example, visitors enter the premises without changing into clothing and boots supplied by the farm (Elbers et al. 2001). Vehicles (trucks, trailers, cars) can carry virus-contaminated feces and urine over long distances, but an experiment mimicking the conditions of transport showed that transmission via excretions without direct contact between pigs was unlikely (Dewulf et al. 2002).

A quantitative approach to understanding CSFV spread among animals and herds is an area of active interest, but relatively few studies have been conducted to date. One objective of this approach is to identify the biological and population factors that affect the rate of transmission (Klinkenberg et al. 2002; Laevens et al. 1998). Another objective is to construct mathematical models that predict the course of an epidemic. Ideally, such models could provide insight into the decisions to make to control an outbreak. Such models have been created and tested with data from the epidemic in the Netherlands (Horst et al. 1997; Horst et al. 1999) and in Belgium (Mintiens et al. 2001; Mintiens et al. 2003).

Typical of enveloped viruses, CSFV is inactivated by organic solvents (ether or chloroform) and by detergents. Sodium hydroxide (2%) is still considered the most suitable for disinfection of contaminated premises.

Despite being an enveloped virus, CSFV survives for prolonged periods in favorable environments—i.e., cool, moist, protein-rich conditions, such as those found in meat, but in liquid manure CSFV can survive for 2 weeks at 20°C and more than 6 weeks at 4°C (Haas et al. 1995). CSFV is relatively stable in a range of pH 5–10. The rate of inactivation under pH 5 is dependent on the temperature (Depner et al. 1992).

Thermal and pH stability may vary by strain, but inactivation of the virus is primarily dependent on the medium. For example, CSFV in cell culture loses its infectivity after 10 minutes at 60°C, but survives for up to 30 minutes at 68°C in defibrinated blood. For these reasons, it is difficult to give guidelines for the survival of CSFV in the environment. The survival and inactivation of CSFV was recently reviewed (Edwards 2000).

Bovine Viral Diarrhea Virus and Border Disease Virus

The prevalence of BVDV antibodies in the pig populations of CSFV-free countries (Australia, Ireland, Great Britain, Denmark) have been estimated at 1.6–43.5%, depending on the age of the animals and possibly on the degree of contact with cattle (Jensen 1985). In countries where CSFV is present, the situation with regard to BVDV antibodies seems to be about the same.

Cattle are the most common source of BVDV infection in pigs. In units with dairy farming, one potential source of infection is BVDV-contaminated whey or milk fed to sows (Terpstra and Wensvoort 1988). In some cases, pigs have had contact with cattle recently vaccinated with BVDV 2 (Stewart et al. 1971). In other reports, pigs and cattle were kept in separate lots and buildings, but personnel and equipment moved freely between the different farm units (Carbrey et al. 1976).

The prolonged presence of a persistently infected litter of pigs is the most likely source of BVDV or BDV to susceptible, pregnant sows (Terpstra and Wensvoort 1988; Vannier et al. 1988). Persistent BDV infection of piglets occurs when sows are infected during early pregnancy—i.e., fetuses are transplacentally infected and piglets become immunotolerant and persistently infected (Vannier et al. 1988). The course of the infection is quite similar to that described for BVD infection in pregnant cows (Baker 1987). When a pregnant sow is infected under experimental conditions, the litter may consist of a mixture of virus-positive and antibody-positive piglets. This suggests variability in the time at which individual fetuses became infected (Edwards et al. 1995). Congenitally BDV-infected piglets appear to excrete large amounts of virus, since susceptible young animals kept in contact rapidly seroconvert and produce high antibody titers. Conversely, when piglets are infected after birth, spread of infection to in-contact animals does not occur; suggesting low or perhaps no excretion of virus (Vannier et al. 1988).

Pigs may also become infected through the use of modified live virus vaccines (CSF or Aujeszky's disease) or other biologicals contaminated with virus (Vannier et al. 1988; Wensvoort and Terpstra 1988). In such cases, either ovine or bovine contaminants may be involved.

CLINICAL SIGNS

Classical Swine Fever

In the acute form of the CSF, the initial clinical signs include anorexia, lethargy, conjunctivitis, respiratory signs, and constipation followed by diarrhea. In the chronic form, the same clinical signs are observed, but the pigs survive for a time (2–3 months) before dying. Nonspecific signs—e.g., intermittent hyperthermia, chronic enteritis, and wasting—may also be seen.

Historically, peracute, acute, chronic, or prenatal forms of CSF have been attributed to distinct levels of virus virulence. However, virus strain virulence is difficult to define because clinical signs also depend on pig age, breed, health status, and immune status (Depner et al. 1997; Floegel-Niesmann et al. 2003; Moennig et al. 2003).

Since the early 1980s, the diagnosis of CSF on the basis of clinical signs has been problematic and resulted in the belated recognition of CSF outbreaks, thereby giving time for the virus to spread. CSF is one of several diseases characterized by cutaneous hyperemia or cyanosis and nonspecific clinical signs. Particularly when CSFV strains of low virulence are involved, it may be difficult to differentiate CSF from African swine fever (ASF), porcine reproductive and respiratory syndrome (PRRS), postweaning dermatitis and nephropathy syndrome (PDNS), salmonella, or cumarin poisoning. The one constant sign in CSF is hyperthermia (Davila et al. 2003; Floegel-Niesmann et al. 2003), usually greater than 40°C, and piglets are often seen piled in a corner. Clinical signs are more marked in piglets than adults and hyperthermia may be lower (39.5°C) in adults.

CSFV is able to cross the placenta of pregnant sows and infect fetuses at any stage of pregnancy. Depending on the strain and the time of gestation, infection can cause abortion and stillbirths. However, infection at 50–70 days of gestation can lead to the birth of persistently viremic piglets. Such piglets initially appear clinically normal, but subsequently begin to waste or develop congenital tremors (Vannier et al. 1981). This course of infection has been described as "late onset CSF" (van Oirschot and Terpstra 1977). Similar to BVDV in ruminants, these animals shed high levels of virus for several months and are important reservoirs of CSFV.

Bovine Viral Diarrhea Virus and Border Disease Virus

In the field, infection of pigs with BVDV usually occurs without clinical signs. In some cases, however, natural infection of pig herds with pestiviruses other than CSF has been associated with breeding problems—e.g., poor conception rates, small litters, and a few abortions. Hyperthermia and colic spasms have also been described (Carbrey et al. 1976). In the Netherlands and France, signs compatible with congenital CSF infection were described in piglets born to sows vaccinated 4

months earlier with CSF or Aujeszky's disease vaccines contaminated with a ruminant pestivirus (Vannier et al. 1988; Wensvoort and Terpstra 1988). Clinical signs in piglets included anemia, rough hair coats, growth retardation, wasting, congenital tremors, conjunctivitis, diarrhea, polyarthritis, petechiae in the skin, and blue ear tips (Terpstra and Wensvoort 1988).

Natural infection of sows with BDV has been reported to result in reproductive signs—e.g., repeat breeding, and mummified and stillborn pigs at farrowing (Vannier et al. 1988). A high proportion of piglets from infected sows showed eyelid edema, locomotor disorders, and occasionally, diarrhea and arthritis. The mortality rate in affected litters at 2 days of age ranged from 30–70%.

There are a number of reports of experimental inoculation of pigs, primarily pregnant sows, with BVDV and BDV via oral, intranasal, intramuscular, or intrauterine routes (Leforban et al. 1990b; Stewart et al. 1980; Wrathall et al. 1978). The results are inconsistent, but depend primarily on the strain used and the stage of pregnancy.

Inoculation of pregnant sows with the NADL strain of BVDV between 28 and 54 days of gestation did not produce transplacental infection of the fetuses (Stewart et al. 1980), but eyelid edema was seen in a few piglets (Leforban et al. 1990b). Inoculation of 9–18 kg piglets with the Singer strain of BVDV (Coria and McClurkin 1978) did not produce clinical disease, but the virus could be recovered from blood and tissues of inoculated pigs, and antibodies were detected in their sera after 3 weeks. When later challenged with a virulent CSFV strain, these piglets developed severe disease, but 6 of 7 survived (Stewart et al. 1971). The same strain of BVDV, when administered to fetuses at 41–65 days of gestation by transuterine injection caused death or small-sized fetuses (Mengeling 1988). Dahle et al. (1993) intranasally inoculated weaned pigs with BVDV strain OSLOSS ÷ 2482, and then challenged with decreasing doses of CSFV 4 weeks later. After CSFV challenge, the only clinical sign observed was fever in one animal, although most animals became viremic.

Experimental inoculation of pregnant sows with BDV field strains at 30–32 days of gestation produced transplacental infection of fetuses and newborn piglets with low body weights and short body lengths (Wrathall et al. 1978). Leforban et al. (1990b) reported an increase in perinatal mortality and eyelid edema, hyperthermia, and anemia in survivors during the second week of life. Slow growth rates, respiratory signs, and diarrhea developed in pigs, some of which died by 2 months of age. Pigs without respiratory and enteritic signs survived and had normal growth despite marked snout deformations, including prognathism in one individual. BDV was isolated from blood and organs of all dead piglets, but not from survivors. When 40-day-old specific pathogen free (SPF) pigs were placed in contact

with BDV transplacentally infected piglets, they did not show clinical signs, but they developed high levels of antibody to BDV, which was able to protect them completely against challenge with a virulent strain of CSFV.

PATHOGENESIS

Classical Swine Fever

Transmission of CSFV is most commonly oronasal, with primary virus replication in the tonsils. From the tonsils, it spreads to the regional lymph nodes, then via the peripheral blood to bone marrow, visceral lymph nodes, and lymphoid structures associated with the small intestine and spleen. The spread of the virus within the pig is usually complete in less than 6 days.

Within the pig, CSFV replicates in monocyte–macrophage cells and vascular endothelial cells. CSFV is immunosuppressive, and neutralizing antibodies may not appear until 2–3 weeks after infection. Leukopenia, in particular lymphopenia, is a classic early event (Susa et al. 1992). CSF leukopenia impacts leukocyte subpopulations unequally, with B lymphocytes, helper T cells, and cytotoxic T cells the most affected. Depletion of lymphocyte subpopulations occurs 1–4 days before virus can be detected in serum by reverse transcription-polymerase chain reaction (RT-PCR).

The severity of the changes in bone marrow and circulating leukocytes suggest that cytopathic effects in uninfected cells are induced indirectly—e.g., by a soluble factor or by cell-to-cell contact, and are not a direct effect of the virus or viral protein(s). Research has shown that, at high concentration, the glycoprotein Erns induces apoptosis in lymphocytes *in vitro* (Bruschke et al. 1997). However, exposure to supernatant from infected cells did not induce apoptosis in target cells. Although still undescribed, such a mechanism could also account for the delay in cellular and humoral immune responses (Summerfield et al. 2001).

In cell culture, most CSFV strains grow without producing cytopathic effect and without inducing interferon alpha secretion by infected cells. Indeed, CSFV infection causes cells to acquire a greater capacity to resist apoptosis (Ruggli et al. 2003). These observations provide evidence that CSFV interferes with cellular antiviral activity and suggest the possibility that the lesions seen in pigs have an immunopathological basis.

Interactions between CSFV and the monocyte-macrophage system result in the release of mediator molecules that promote the progression of the disease. Changes in hemostatic balance are thought to be caused by proinflammatory and antiviral factors that mediate the thrombocytopenia and hemorrhage characteristic of CSFV infection (Knoetig et al. 1999). The production of inflammatory cytokines by infected endothelial cells could play a role in immunosuppression and facilitate virus dissemination by attracting monocytic cells (Bensaude et al. 2004). It has recently been recognized that

CSFV can replicate in dendritic cells. It is possible that these highly mobile cells disseminate CSFV to various sites in the body, especially lymphoid tissues. Of themselves, interactions between CSFV-infected dendritic cells and lymphocytes are not sufficient to induce lymphocyte depletion without other interactions within the environment of the lymphoid follicles (Carrasco et al. 2004).

Understanding the CSFV–host interactions that lead to the evasion of the host's innate immune responses, delay the onset of acquired immunity, and produce the resultant pathogenic effects is currently an active focus of research.

Bovine Viral Diarrhea Virus and Border Disease Virus

BVDV and BDV are pathogenic for fetal pigs, but relatively apathogenic for pigs after birth. The ability of BVDV and BDV to establish intrauterine infections in swine is well established (Stewart et al. 1980; Vannier et al. 1988; Wrathall et al. 1978). The degree of clinical disease depends on the stage of gestation at which the infection occurred. Clinical signs are more serious if sows are infected during the first trimester of pregnancy. The most severe clinical signs and lesions in fetuses or piglets are observed when sows are infected 25–41 days postbreeding (Leforban et al. 1990b; Mengeling 1988). Under experimental conditions, piglets infected in utero with BVDV or BDV became persistently infected and immunotolerant (Leforban et al. 1990b; Vannier et al. 1988). After the disappearance of maternal antibodies, no active humoral response was detected in the majority of piglets. Furthermore, the virus was isolated from piglets and was shed by some, as evidenced by infection in young animals placed in contact.

In some experimental infections of pregnant sows with BDV, the onset of the clinical signs in the piglets was delayed until 13–14 days after birth. The reason for the delayed response is unknown, but colostral antibodies ingested by piglets would presumably block the replication of the virus and/or delay disease in transplacentally infected piglets (Leforban et al. 1990b; Mengeling 1988; Vannier et al. 1988).

The pathogenicity of BVDV or BDV seems to depend on the strain used in the experiment. BDV seems to be more consistently pathogenic for fetuses, whereas variable results are obtained with BVDV viral strains. The Singer strain, adapted to replicate in porcine cells, and BVDV strain 87/6 can infect and cause mortality in porcine fetuses, whereas the NADL strain does not induce clinical disease in piglets (Edwards et al. 1995; Leforban et al. 1990b; Mengeling 1988).

LESIONS

Classical Swine Fever

CSF lesions vary in severity and distribution, depending on the course of the disease. In acute forms, the patho-

logical picture is often hemorrhagic. Leukopenia, thrombocytopenia, petechiae and ecchymoses in the skin, lymph nodes, larynx, bladder, kidney (Figure 15.1), and ileocecal junction are often described. Multifocal infarction of the margin of the spleen is characteristic, but not always present (Figure 15.2). Swollen or hemorrhagic lymph nodes or tonsils are common (Figure 15.3). In chronic forms, button ulcers in the cecum or large intestine may be present (Figure 15.4), as well as a generalized depletion of lymphoid tissues. Hemorrhagic and inflammatory lesions are less common, or even absent, despite the degeneration of endothelial cells. Congenital CSF can result in abortion, fetal mummification, stillbirths, and congenital malformations, such as central dysmyelinogenesis, cerebellar hypoplasia, microen-

cephaly, pulmonary hypoplasia (van der Molen and van Oirschot 1981).

Floegel-Niesmann et al. (2003) compared the clinical signs and lesions produced by four field strains isolated during the 1990s from domestic pigs or wild boars in Europe with the reference Alfort 187 strain. Comparing lesions in skin, subcutis and serosae, tonsil, spleen, kidney, lymph nodes, ileum and rectum, brain, and respiratory system, they found that lymph nodes were the tissues most severely affected by all isolates, followed by necrotic lesions in the ileum and hyperemia of the brain blood vessels (Table 15.1). Thus, these tissues were the most reliable for pathological diagnosis of CSF. Infarction of the spleen and necrotic lesions of the tonsil, although commonly described in the earlier

literature, were infrequent. Likewise, respiratory signs were absent or mild.

Bovine Viral Diarrhea Virus and Border Disease Virus

When infected postnatally with BVDV or BDV, no or very mild lesions are observed in pigs.

Hyperemia of the small intestine was seen in one pig 11 days after being placed in contact with calves infected with NADL strain BVDV (Stewart et al. 1971). A transient leukopenia was detected during the first week following

experimental infection of pigs with a pig isolate of BVDV (Carbrey et al. 1976). In utero infection of fetuses by transplacental transmission is followed by consistent pathological disorders in fetuses or piglets. In 13 naturally occurring BVDV outbreaks in Holland, chronic gastroenteritis and septicemia with hemorrhages in lymph nodes, epicardium, and kidneys were the most consistent lesions reported. Inflammation of the digestive tract was frequently characterized by catarrh, hypertrophy, or ulceration of the mucosa. Necrotic tonsillitis, icterus, polyserositis, polyarthritis, and atrophy of the

thymus were also noted (Terpstra and Wensvoort 1988). A porcine BVDV isolate administered to gilts at 42–46 days of gestation produced significant microscopic lesions in the leptomeninges and the choroid plexus of the fetus, characterized by collections of lymphocytes, histiocytes, and cellular accumulation in the vascular adventitia and perivascular spaces (Stewart et al. 1980).

In the case of BDV, experimental inoculation of sows on day 34 of gestation produced cerebellar hypoplasia in 9 of 19 liveborn piglets, with a small meningocele in one of the nine (Wrathall et al. 1978). The French BDV isolate Aveyron (Chappuis et al. 1984) inoculated into sows at day 30 of gestation produced lesions in lymphoid tissues in some piglets. Marked hemorrhages in lymph nodes and other lymphoid tissues were found in stillborn fetuses or in piglets that died shortly after birth. Histological examination of lymph nodes, spleen, and tonsil revealed marked subacute inflammatory lesions, characterized by accumulations of lymphocytes, plasmocytes, and eosinophilic polymorphonuclear leukocytes, numerous secondary follicles, increased populations of reticulocytes, and lymphoid hypoplasia with pyknosis and karyorrhexis. Thymus, liver and nervous tissues were normal (Leforban 1990).

DIAGNOSIS
Classical Swine Fever
Recent CSF epidemics in Europe have shown that early recognition of CSF and prompt elimination of CSFV-infected animals is the key to control. The longer CSF remains undetected, the greater the opportunity for the virus to spread (Elbers et al. 1999).

It should be recognized that farmers and veterinarians detected 75% of the recent CSFV epidemics on the basis of clinical observations. The need to establish a standardized protocol for evaluating herds for CSF has been recognized (Davila et al. 2003; Elbers et al. 2002; Mittelholzer et al. 2000). However, the list of clinical criteria cannot be overly complex if it is to be used in the field. Average daily gain and feed consumption are two quantifiable measures that may be of use. Body temperature may also be useful, since hyperthermia is consistently associated with CSF and appears before, or concurrently, with the first clinical signs.

Because there are no pathognomonic clinical signs in CSF, laboratory diagnosis is always required for confirmation. Although it is not a specific diagnostic, leukopenia is an indicator of CSFV infection and a leukocyte count can be used as a screening assay (Dewulf et al. 2004). A variety of specific methods are available for diagnosis of CSFV infection. Since CSFV, BVDV, and BDV share common antigens, it is of the utmost importance to discriminate between these. Clearly, the consequence of a diagnosis of CSF is very distinct from the diagnosis of another pestivirus. Monoclonal antibodies are used in a variety of techniques to specifically identify the virus —e.g., virus isolation (VI), fluorescent antibody test (FAT), or ELISA tests.

Detection of CSFV. Virus isolation (VI) is still the most sensitive and specific method of virus detection. Virus may be isolated from tissue homogenates, serum, plasma, buffy coat, and whole blood collected in heparin or EDTA (Terpstra 2000). The tissues most likely to contain virus are tonsils, spleen, kidney, ileocecal lymph node, and retropharyngeal lymph node (Narita et al. 2000). CSFV can be isolated on porcine kidney cell lines (PK-15 or SK6). It is critical that all cells, media, and reagents have been previously determined to be free of pestiviruses or antibodies against pestiviruses. Although virus isolation is the reference method in most CSFV eradication programs, it is labor intensive, time consuming, and incompatible with the rapid response required to prevent further spread of virus.

The direct fluorescent antibody test (FAT) on frozen sections was the method of choice for detecting viral antigen during the last epidemic in the Netherlands (de Smit et al. 2000). It is rapid and reliable, but requires well-trained technicians. To discriminate between CSFV and other pestiviruses, it is necessary to use monoclonal antibodies. Tonsil tissue, the first site of virus replica-

Table 15.1. Pathological parameters to be evaluated for the diagnosis of CSF during postmortem examination. Scale from 0 points for no alteration up to 3 points for severe alterations, from (Floegel-Niesmann et al., 2003)

Points

Parameter	1—Slight Alteration	2—Distinct Lesion	3—Severe CSF Lesion
Skin	Nonspecific erythema	Single CSF-specific hemorrhage	Multiple CSF-specific hemorrhages
Subcutis and serosac	Individual petechiae	Petechiae in several places	Generalized petechiae
Tonsil	Swelling	Erythema	Necrosis
Spleen	Tiny infarction	Obvious infarction	<50% infarction
Kidney	Individual petechiae	Petechiae on surface and interstitium	Multiple petechiae
Lymph nodes	Swelling	Swelling and irregular hemorrhages	Swelling and generalized hemorrhages
Ileum and restum	Erythema	Erythema and small necrosis	Multiple necrosis or "button ulcer"
Brain	Slight hyperemia	Hyperemia	Hyperemia, vessels swollen
Respiratory system	Bronchitis	Bronchopneumonia or pleuritis	Bronchopneumonia and pleuritis

tion, is the most suitable sample. In chronic and subacute cases, ileum is often the only tissue to display fluorescence. FAT is not as sensitive as virus isolation and a negative FAT result is not sufficient to rule out a CSF suspect case.

Antigen-capture enzyme-linked immunosorbent assays (ELISAs) may be used for early diagnosis of CSFV in live pigs. Double-antibody sandwich ELISAs are based on monoclonal and/or polyclonal antibodies directed against a variety of viral proteins. Serum, buffy coat fraction, whole blood in heparin or EDTA, or tissue homogenates can be tested in these assays. The technique is relatively simple to perform, does not require tissue culture facilities, is suitable for automation, and provides results within 36 hours.

It is important to recognize the diagnostic limitations of antigen-capture ELISAs. All currently available commercial ELISAs are less sensitive than virus isolation on cell culture (Dewulf et al. 2004). In addition, their diagnostic sensitivity is significantly better on blood samples from piglets as compared to samples from adult pigs or samples from mild/subclinical cases (Anonymous 2002). To compensate for lack of diagnostic sensitivity, all pigs showing pyrexia in suspect herds should be tested. These tests also have lower diagnostic specificity (Anonymous 2002), and false-positive reactions may occur. For these reasons, the use of antigen-capture ELISAs is recommended only on samples from animals with clinical signs or pathological lesions compatible with CSF and for screening herds suspected to have been recently infected.

A variety of polymerase chain reaction (PCR)–based assays have been described for the detection of CSFV (Hofmann et al. 1994; McGoldrick et al. 1998, 1999; Vilcek et al. 1994), usually targeting the 5' noncoding region. Viral RNA can be detected in blood samples collected from live animals, as well as in tissue samples. Although PCR-based methods have been evaluated in two European ring-tests (Paton et al. 2000a, 2000b), no official PCR protocol has been established. Additional improvement in test performance is required to obtain a rapid, reliable, and automated test for use in routine diagnostics. Theoretically, the use of pooled samples could reduce costs, but the sensitivity of the technique must be validated before implementation on a routine basis.

Detection of Antibodies Against CSFV. ELISAs for the detection of anti-CSFV antibodies are useful for conducting epidemiological surveys and for monitoring CSFV-free areas. Competitive ELISAs are based on competition between anti-CSFV serum antibodies and a CSFV-specific monoclonal antibody directed against the viral glycoprotein gp 55 (E2). Cross-reactions with antibodies against other pestiviruses are reduced in the competitive ELISA format. A baculovirus recombinant E2 protein is often used as the antigen in the system. ELISA-detectable antibodies appear 10–15 days post infection,

similar to the time frame described for the appearance of neutralizing antibodies.

CSFV neutralizing antibody levels are determined by end-point titration of the serum. Briefly, the assay is performed as follows. Serial twofold dilutions of serum are mixed with an equal volume of CSFV (Alfort 187 is usually used as reference strain) prepared to contain around 100 $TCID_{50}$ per ml. After incubation for 1 hour, this is added to plates containing PK-15 cell monolayers. Two to four days later, the cells are stained with CSFV-specific antibodies. The titer of neutralizing antibody is expressed as the reciprocal of the highest serum dilution that prevented virus growth in 50% of two replicate wells.

Because of antibody cross-reactions among pestiviruses, the serum-virus neutralization assay is performed as a double neutralization test. That is, CSFV neutralizing antibody levels are compared to neutralizing antibody titers against BVDV or BDV reference strains. A difference of fourfold or more between the end points of the two titrations is considered conclusive for infection by the virus species yielding the highest neutralizing antibody titer (Terpstra 2000). This method is frequently used to screen neighboring herds around an outbreak prior to lifting control measures.

It is not feasible to perform all available diagnostic assays during an outbreak. Therefore, it is of the utmost importance to perform the assay(s) most appropriate to the situation and intended purpose. Since the key to controlling an outbreak is prevention of virus spread among farms, the assay of choice in terms of diagnostic sensitivity, diagnostic specificity, and speed is reverse transcription-polymerase chain reaction (RT-PCR). However, since the period of viremia is short, antibody detection assays are also useful, especially in herds where clinical signs have been present for more than 2 weeks (Dewulf et al. 2004).

Bovine Viral Diarrhea Virus and Border Disease Virus

BVDV or BDV may be isolated using the same methods previously described for CFSV and from the same tissues submitted for CSFV diagnosis—i.e., tonsils, spleen, kidney, and whole blood collected in heparin or EDTA. In CSF-free countries, BVDV and BDV must be considered in the differential diagnosis of CSFV and all suspect cases of CSF should be tested for BVDV and BDV. If BVDV or BDV is isolated from pigs, it is reported to grow better and to a higher titer in cells of ruminant origin, rather than in porcine cells (Wensvoort et al. 1989).

Pestiviruses share common antigenic structures (or patterns) and serological tests for the detection of antibodies against CSFV may cross-react with antibodies to ruminant pestiviruses. The practical importance of this is that the presence of ruminant pestivirus antibodies in pig sera often cause false positive reactions in serological surveys for CSFV. This presents problems in CSFV eradi-

cation campaigns and in epidemiological surveys for CSFV (Jensen 1985).

PREVENTION AND CONTROL

Classical Swine Fever in Domestic Pigs

Classical swine fever remains endemic in many parts of the world and continues to be a disease of worldwide importance. Although some regions are free of the disease, CSFV is still present at the borders between free and endemic areas and in some wild boar populations (Laddomada 2000).

For purposes of international trade, free areas maintain a "no vaccination" policy against CSF, although safe and efficacious live vaccines are available. Thus, control is based on stamping out infected or suspected herds, with the implementation of concomitant quarantine measures. In the last decade, however, the eradication of CSF outbreaks in Europe has raised concerns regarding the "no vaccine" policy. This is especially true in areas of high pig density, where a variety of factors increase the risk of disease spread (Elbers et al. 1999; Koenen et al. 1996; Mintiens et al. 2003). For instance, during the 1997 epidemic in the Netherlands, 9 million pigs were euthanized for reasons linked to movement restriction measures. However, even if emergency vaccination were not prohibited (EU council directive 80/217/EEC), the use of vaccine would have imposed severe economic consequences because vaccinated areas are banned from international trade for at least 1 year. Nevertheless, a more recent council directive (2001/89/EC) (Anonymous 2001) takes recent experiences into account and authorizes emergency vaccination around an outbreak.

Various CSFV vaccines are available, including the well-known live "Chinese" C strain, the Thiverval strain, and the newer marker vaccines that allow differentiation of field virus-infected versus vaccinated animals (for an in-depth review, see van Oirschot 2003). The traditional live vaccines induce a high level of protection against clinical disease, and neutralizing antibodies are detectable at 2 weeks post-challenge (Dahle and Liess 1995; Vandeputte et al. 2001). Duration of immunity is 6–10 months, regardless of the route of administration (intramuscular or oronasal) (Kaden and Lange 2001; Terpstra et al. 1990).

The primary drawback of live vaccines is that it is impossible to differentiate vaccine antibodies from field-virus induced antibodies. Researchers have evaluated a variety of marker vaccines to solve this problem, including nonreplicative Aujeszky's disease (pseudorabies) virus expressing the E2 of CSFV (Peeters et al. 1997), a porcine adenovirus-vectored vaccine (Hammond et al. 1999), and a chimeric pestivirus (Reimann et al. 2004; van Gennip 2001). DNA vaccines have also been developed, but need a prime-boost strategy (DNA-adenovirus) to induce real protection (Hammond et al. 2001).

At present, two differentiable, baculovirus-expressed E2 recombinant protein subunit vaccines are commercially available. The efficacy of the two E2 marker vaccines has been extensively evaluated in vaccination-challenge and transmission trials, but with variable results. A single dose of 32 µg E2 in a water-oil-water adjuvant prevented clinical signs and mortality due to a CSFV challenge 3 weeks after vaccination (Bouma et al. 1999). At least 14 days were needed to obtain clinical protection in growing pigs vaccinated with a single dose (Bouma et al. 2000; Uttenthal et al. 2001). If challenged earlier, no protection against clinical disease and no reduction of virus shedding were observed (Uttenthal et al. 2001).

The ability of the two marker vaccines to prevent transplacental transmission of CSFV has also been evaluated. However, transplacental transmission occurred even when two doses of vaccine (days 25 and 46 of pregnancy) were administered and challenge occurred 14 days after the second dose (Depner et al. 2001). Thus, transplacental infection could not be prevented in most vaccinated animals under the conditions of emergency vaccination. Vaccination could not prevent the "carrier sow syndrome" and, subsequently, the late onset form of CSF (Depner et al. 2001). It was concluded that the two-dose vaccination protocol protected pregnant gilts from clinical disease, but did not prevent horizontal or vertical spread of the CSFV (Dewulf et al. 2001b). Although these results indicated that the efficacy of these vaccines was not ideal, the possible use of these vaccines in an emergency has not been disallowed by the EC.

Differential ELISAs for the E2 marker vaccines are based on the detection of antibodies to the Erns protein (Floegel-Niesmann 2001). Improvement and assessment of these assays has been ongoing. In 2003, the EC conducted a large-scale inter-laboratory assessment of the diagnostic performance of a new version of a companion Erns ELISA test. Although the diagnostic specificity and the sensitivity of the test was improved relative to the kits tested in 1999 (Floegel-Niesmann 2001), it was concluded the need remained for a test that could determine with greater reliability whether a vaccinated pig had been infected and become a CSFV carrier.

Classical Swine Fever in Wild Boars

In Western Europe, vaccination in domestic pigs has been prohibited in EU member states since 1990, but the virus has been periodically reintroduced into domestic pigs via contact with wild boars. In some areas of Germany, an increase in the number of wild boars has promoted the persistence of virus within these populations and created an endemic situation (Fritzemeier et al. 2000; Moennig 2000). CSFV infection is seemingly harmless for wild boars as little mortality has been reported in recent outbreaks. In the presence of natural or manmade barriers, CSFV can be confined to a defined

area until it is eliminated (Schnyder et al. 2002), as was done in Moselle (France) (Le Potier et al. 2003) or in Tessin (Switzerland). Classic measures for CSF control in wild boars involve reducing hunting activities to allow the virus to spread within the susceptible population and induce mortality or immunity, followed by targeted hunting of the most susceptible animals—i.e., juveniles and the young sows.

In some areas where it has been difficult to eradicate CSFV using standard methods, oral vaccination using live C strain distributed in bait has been attempted (Kaden et al. 2000). The safety of this vaccine has been demonstrated for other wild animal species (Chenut et al. 1999). In pigs, this oral vaccine can induce strong protective immunity in 10 days (Kaden and Lange 2001). However, recent analysis of the data from oral vaccination field campaigns has shown that three doses were required to induce immunity in the field. Due to poor access to baits, young boars did not acquire sufficient protective immunity in most field studies (Kaden et al. 2002). When vaccine is used, monitoring of the disease becomes very difficult as the only tool to differentiate between infected and vaccinated boars is the detection of the virus. Therefore, there is a real need for the development of an effective marker vaccine delivered by the oral route that would allow for serological monitoring of the spread of the virus among a vaccinated population.

Prevention of BVDV or BDV Infections

To prevent BVDV or BDV infection in pigs, it is necessary to avoid direct or indirect contact with cattle or sheep. Natural infection with BVDV often occurs when pigs are fed with cow's milk or bovine offal and this practice should be avoided.

Inadvertant transmission of these viruses is a risk when live-virus vaccines are used because of contamination of media and/or cells used in production of the vaccine. Cells used for multiplication of master seed virus used to prepare vaccine can be contaminated by BVDV or BDV. Indeed, some batches of CSF and Aujeszky's disease (pseudorabies) vaccines were contaminated by a pestivirus (probably BDV) because secondary lamb kidney cells were used to propagate the vaccine strain virus (Vannier et al. 1988; Wensvoort and Terpstra 1988). Both bovine and non-bovine cell lines can be contaminated with pestiviruses, and all cell cultures need to be monitored carefully for their presence (Potts et al. 1989). The primary source of contamination of cells is bovine serum added to the nutrient medium. BVDV is extremely common and collection from BVDV-infected calves or fetuses results in contaminated bovine serum. Rossi et al. (1980) reported that up to 62% of the lots of nonirradiated bovine fetal sera examined were found positive for BVDV. Therefore, the systematic testing and treatment of bovine serum and of biological products used for the preparation of vaccines is strongly recommended (Makoschey et al. 2003).

16 Porcine Cytomegalovirus

Kyoung-Jin Yoon and Neil Edington

Porcine cytomegalovirus (PCMV) infection was originally termed "inclusion body rhinitis" because basophilic intranuclear inclusions were seen in cytomegalic cells in the turbinate mucosa of pigs with rhinitis (Done 1955). Electron microscopy demonstrated herpes virions in turbinate mucous glands, lachrymal glands, salivary glands, and renal tubular epithelium (Duncan et al. 1964). The virus grew slowly in cell culture and produced cytomegaly with intranuclear inclusions (Booth et al. 1967; L'Ecuyer and Corner 1966), placing it in the cytomegalovirus group (Plummer 1973).

PCMV infection is usually subclinical in adults, but often produces a fatal, generalized infection in young swine, particularly piglets infected congenitally or perinatally (Edington et al. 1976a). In susceptible herds, the virus causes fetal and piglet deaths, runting, rhinitis, and pneumonia (Cameron-Stephen 1961; Corner et al. 1964; Duncan et al. 1964; Edington et al. 1977; L'Ecuyer et al. 1972; Orr et al. 1988; Rac 1961; Smith 1997; Yoon et al. 1996). The virus may also cause neurologic disease (Stephano-Hornedo and Edington 1987).

The potential for using live porcine cells, tissues, and organs in humans (xenotransplantation) has heightened interest in PCMV. PCMV is ubiquitous in swine, induces latent infections, and is similar to human and primate CMVs (Garkavenko et al. 2004; Tucker et al. 1999). Cross-species transmission of PCMV was reported in pig-to-primate xenotransplantation (Mueller et al. 2002), but the actual risk of PCMV infection in a human recipient remains unknown.

ETIOLOGY

PCMV (suid herpesvirus 2) is classified in the genus *Cytomegalovirus* in the subfamily *Betaherpesvirinae* of family *Herpesviridae* (Roizman 1982). The PCMV genome is linear, double-stranded, DNA of $130-150 \times 10^6$ kilodaltons. Full-length sequences and details of the organization of the viral genome are still lacking. Recent molecular studies of the polymerase, putative glycoprotein B (gB), and major nucleocapsid protein genes indicate that PCMV is genetically closer to human herpesvirus type 6 and 7 (genus *Roseolovirus*) than cytomegaloviruses (Rupasinghe et al. 1999, 2001; Widen et al. 1999, 2001).

The morphology of PCMV is typical of a herpes virion (Duncan et al. 1965; Shirai et al. 1985; Valiček and Smid 1979). The virion is approximately 150–200 nm across. It contains an electron-dense core (30–70 nm) of variable shape surrounded by capsid proteins forming the icosahedral nucleocapsid (80–120 nm). Viral nucleocapsids are present in the nucleus of host cells and acquire an electron-dense coat separated by a translucent halo from the envelope. The envelope is obtained by budding through the membrane of the host cell nucleus or Golgi apparatus. The envelope of extracellular and cytoplasmic virions has 10 nm external projections. The density of the PCMV virion is 1.275 g/ml by CsCl equilibrium-density centrifugation (Shirai et al. 1985).

No distinct PCMV serotypes or genotypes have been identified, although some degree of genetic variation was noted in polymerase and gB genes among PCMV isolates of different geographic origins (Goltz et al. 2000; Widen et al. 2001). Possible antigenic variability has also been reported (Tajima and Kawamura 1998).

The virus is sensitive to chloroform and ether (Booth et al. 1967). Virus infectivity is preserved at subzero temperatures (Booth et al. 1967).

L'Ecuyer and Corner (1966) propagated PCMV in primary pig lung (PL) cells for several passages, and Watt et al. (1973) found that only pig lung macrophages (PLM) were highly sensitive for primary isolation and/or serial propagation. Other culture systems used include primary swine testicle (ST) (Shirai et al. 1985; Kanitz and Woodruff 1976), a porcine fallopian tube (PFT) cell line (Bouillant et al. 1975; Kawamura et al. 1992), PK-15 cell line (Kanitz and Thacker 1974), and porcine turbinate (PT) (Yoon et al. 1996).

Cytomegaly and basophilic intranuclear and, occasionally, small acidophilic intracytoplasmic inclusions

16.2. *Lung macrophage cultures showing fluorescence after IIF, using specific PCMV antiserum. The nuclear staining (N) is most intense at the membrane. Cytoplasmic and discrete paranuclear fluorescence P) can also be seen (×480).*

(Figure 16.1) are generally seen in infected cells at 3–14 days postinoculation (Watt et al. 1973). Infected cells are about six times larger than normal cells, with swelling of the mitochondria, endoplasmic reticulum, and Golgi apparatus (Duncan et al. 1965).

Progeny virus reaches a maximum titer of up to 10^{5-6} $TICD_{50}$ per ml at 10–14 days. Progeny virus yield in cell lines is lower than in primary systems. The absence of lytic cytopathic effect in cell culture requires immuno- or histochemical staining for confirmation of virus growth (Figure 16.2).

EPIDEMIOLOGY

PCMV is found throughout the world (Corner et al. 1964) and infection is ubiquitous, with herd prevalence greater than 90% in Europe, North America, and Japan. Within infected herds, more than 98% of pigs may be seropositive (Goltz et al. 2000; Hamel et al. 1999; Kanitz and Woodruff 1976; Rondhuis et al. 1980; Tajima et al. 1993).

PCMV is transmitted horizontally via the oronasal route, but congenital transmission is well documented (Edington et al. 1977, 1988b; L'Ecuyer et al. 1972). Infection most commonly occurs perinatally or early postnatally in commercial farms (Plowright et al. 1976; Watt 1978).

PCMV can be recovered from nasal and ocular discharge, urine, and cervical fluid (Booth et al. 1967; Edington et al. 1976a–c, 1977). Nasal excretion was demonstrated in gnotobiotic pigs for up to 1 month when exposed at 1 day of age, but for shorter periods (up to 9 days) in older pigs under the same conditions. In the field, the majority of pigs shed PCMV in nasally secretion between 3 and 8 weeks of age (Plowright et al. 1976).

Boars can be infected without apparent clinical signs and Shirai et al. (1985) were able to isolate PCMV from the testis and epididymis. Semen shedding of virus has not been determined.

Typical of herpesviruses, PCMV is able to establish latent infections that can be reactivated and result in

virus shedding (Edington et al. 1976c; Narita et al. 1985).

Non-porcine reservoirs and arthropod vectors have not been reported and PCMV infection is considered limited to pigs. The virus does not replicate in mice, rabbits, dogs, cattle, and chicken embryos. However, Mueller et al. (2002) detected virus replication in tissues of baboons that received xenografts of pig origin.

The stability and persistence of PCMV in the environment is unknown. The efficacy of specific disinfectants against PCMV has not been described.

PATHOGENESIS

The primary replication site of PCMV is the nasal mucosa and/or the lachrymal or harderian glands. Cell-associated viremia follows primary replication 14–21 days post infection in animals greater than 3 weeks of age and 5–19 days post infection in neonatal gnotobiotic pigs (Edington et al. 1976c; Edington et al. 1977). Following viremia, virus is shed in nasal, pharyngeal and/or conjunctival secretions, and urine (Booth et al. 1967; Edington et al. 1976c, 1977). Nasal excretion of virus lasts from 10 to over 30 days. Congenitally infected pigs excrete virus until death (Edington et al. 1977).

In sows experimentally infected with PCMV at mid- to late-gestation, the virus was also isolated from cervical fluids, but later than nasal excretion (30–35 days post infection). Neither virus nor inclusions were detected in the cervix or endometrium at this stage, which suggested that cervical shedding was of fetal origin. Excretion in cervical fluids coincided with fetal deaths, implying that the virus required an additional 14–20 days to replicate in the fetus.

The site of secondary viral replication varies with age. In nursery or growing pigs (Edington et al. 1976a, 1977; Kelly 1967; Plowright et al. 1976; Shirai et al. 1985), the virus disseminates predominantly to epithelial sites, particularly the nasal mucosal glands, harderian and lachrymal glands, kidney tubules, and more rarely, the epididymis and mucous glands of the esophagus. Hepatocytes and duodenal epithelium are even more rarely infected.

In the fetus or neonate, there is a predilection for infection of reticuloendothelial cells, particularly capillary endothelium and the sinusoids of lymphoid tissues, thus resulting in generalized lesions (Edington et al. 1977, 1988a). When fetuses were exposed at early gestation, PCMV preferentially replicated in the meninges, Küpffer cells, peritoneal macrophages, and periosteal cells (Edington et al. 1988b). Embryos can be infected shortly after implantation, resulting in embryonic deaths.

Infectious virus persists in lung macrophages, blood monocytes, and CD8+ T cells (Edington et al. 1977; Guedes et al. 2004). Latent infection can be reactivated in vivo by administration of corticosteroids (Edington et al. 1976c; Narita et al. 1985) or in vitro by allogeneic co-cultivation (Guedes et al. 2004).

CLINICAL SIGNS

Uncomplicated infection is usually subclinical in pigs older than 3 weeks, but can be fatal for the fetus or newborn pig. Affected pigs show respiratory signs, e.g., sneezing, nasal discharge, and coughing, and develop rhinitis or neurological disease (Cameron-Stephen 1961; Corner et al. 1964; Done 1955; Duncan et al. 1964; Orr et al. 1988; Rac 1961). PCMV infection does not induce atrophic rhinitis (Rondhuis et al. 1980).

Reproductive problems are another feature of PCMV infection in susceptible herds (Edington et al. 1977, 1988b; L'Ecuyer et al. 1972; Smith 1997; Yoon et al. 1996).

The incubation period of the infection may be 10–20 days (Edington et al. 1977; Goodwin and Whittlestone 1967). During the short viremic phase, animals become lethargic and anorexic, but not febrile. Some congenitally or neonatally infected piglets die without any overt clinical signs. Others often exhibit shivering, sneezing, and respiratory distress, poor weight gain, and rhinitis. The disease is generally self-limiting if uncomplicated. Morbidity is 100%; the average mortality in a naive herd is about 10%, but can rise to 50%.

At farrowing, increased numbers of mummified fetuses and stillbirths are observed, although infected sows may not show any clinical abnormality throughout gestation except lethargy and anorexia. Preweaning mortality also increases. Up to 25% of the litter may be lost and the remainder may show runting. Piglets may be grossly pale and show a variable edema, often around the jaw and tarsal joints.

Although early field observations suggested that the concurrent infection of PCMV and *Bordetella bronchiseptica* might exacerbate the severity of atrophic rhinitis (Cameron-Stephen 1961; Corner et al. 1964), a synergistic effect was not reproducible under experimental conditions (Edington et al. 1976b). Concurrent infection and possible synergism with other agents has not been investigated. However, a field-based, case-control study suggested that PCMV-infected pigs were at a higher risk for respiratory disease than PCMV-uninfected pigs (Yoon et al. 1998).

LESIONS

It is useful to distinguish between disseminated infection of epithelial tissues in the older pigs and generalized infection of reticuloendothelial tissues in the fetus or neonate (Edington et al 1976a).

Epithelial Lesions

No macroscopic changes are seen in epithelial tissues. Microscopically, basophilic intranuclear inclusion bodies and cytomegaly are seen in the nasal mucous glands (Figure 16.3), acinar and duct epithelium of harderian and lachrymal glands, and renal tubular epithelium. In these tissues, the proportion of affected cells may be
16.3. *The basophilic intranuclear inclusion, translucent halo, and defined nuclear membrane are prominent in the enlarged superficial mucous gland epithelium of an animal 18 days after experimental intranasal inoculation (H&E; ×480).*
16.4. *The lamina propria is heavily infiltrated with lymphocytes and plasma cell 24 days after inoculation of PCMV. Many of the acini of the mucous glands still show cytomegaly and prominent inclusion bodies (H&E; ×120).*

high. Isolated inclusions are occasionally seen in the mucous glands of the esophagus, the epithelial lining of the ductus epididymis and the seminiferous epithelium, as well as the epithelial lining of the duodenum and jejunum. The major sites of replication develop focal lymphoid hyperplasia (Figure 16.4). The reparative lesions in the kidney are those of an interstitial nephritis (Kelly 1967). Sparsely distributed focal gliosis is seen in the central nervous system, with inclusions occasionally seen in the glial cells.

Generalized Lesions

In young pigs, petechiae and edema are widespread. Subcutaneous edema is most marked around the throat and tarsal joints. Edema most commonly involves the thoracic cavity and subcutaneous tissues. In the thorax, pericardial and pleural effusions are present. Lungs are edematous, with the interlobular septa becoming distended and the ventral tips of the lobes appearing purple and consolidated (Figure 16.5). The lymph nodes are all enlarged and edematous, and petechial hemorrhages are observed. Petechiae are most extensive in the kidneys, particularly subcapsular, the appearance varying from speckling to completely purple or black coloration.

In some fetal infections, only reproductive failure, i.e., stillbirths, mummified fetuses, embryonic death, and infertility, is seen. The mummified fetuses are randomly distributed and sometimes of variable age. In the acute fatal syndrome, most inclusions are seen in the capillary endothelial and sinusoidal cells, and thus occur in all lymphoid and parenchymatous tissues. The damaged endothelium is associated with local edema and/or hemorrhage and with macrophages and erythrocytes in the distended extracellular space. Mononuclear cells with inclusions are found in blood vessels and also in the spleen. Infected macrophages are prevalent in alveolar tissues. Replication in hepatocytes results in focal necrosis. In the kidney, inclusions are most common in areas of differentiating renal tissue and in glomerular capillary endothelium (Figure 16.6). Hemor-
16.5. *This pig was inoculated with PCMV when 1 day old. It died at 16 days of age with widespread petechiae and subcutaneous edema. The interlobular septae of the lungs are distended with transudate, and the tips of the apical, cardiac, and diaphragmatic lobes are also consolidated.*

rhage and gliosis occur throughout the central nervous system, with a predilection for the choroid plexus, cerebellum, and olfactory lobes (Stephano-Horendo and Edington 1987).

IMMUNITY

Experimentally, antibody is detected by the indirect immunofluorescent antibody (IFA) test 2–3 weeks after in-

oculation, peaks at around 6 weeks postinoculation, and remains at high levels for at least 10–11 weeks postinoculation (Edington et al. 1976c, 1977). Development of serum antibody levels detectable by IFA coincides with the disappearance of viremia, but nasal excretion of virus continues for another 2–3 weeks. Longer periods of excretion have been associated with lower levels of antibody (Edington et al. 1988b). A similar pattern of antibody response was seen in commercial farms (Plowright et al. 1976), with antibody persisting until animals were marketed at 23 weeks of age. Neutralizing antibody develops, but very slowly and to very low levels.

Edington et al. (1988a) demonstrated that transplacental infection could be established by superinfection of sows only with low levels of IFA antibody, which suggests that high levels of IFA antibody are indicative of protective immunity.

Piglets with congenital and neonatal infection do not seroconvert, but excrete virus and develop fatal, systemic infections (Edington et al. 1977). Piglets acquire maternal antibodies and these provide some protection, but virus is shed even in the presence of circulating maternal antibody in PCMV-endemic farms (Plowright et al. 1976). Maternal antibody lasts approximately 2 months after birth (Tajima et al. 1994).

No information is available on important aspects of immunity, e.g., cross-protection among isolates or cell-mediated immune responses.

DIAGNOSIS

PCMV-associated respiratory or reproductive diseases must be differentiated from infection with classical swine fever virus, enterovirus, parvovirus, porcine re-
16.6. *Section of kidney from a piglet with viral inclusions (arrows) in capillary endothelium in both the glomerulus and interstitial tissue. Infected cells show enlargement but only reach the size of normal tubular epithelium (H&E; ×240).*

productive and respiratory syndrome (PRRS) virus, and Aujeszky's disease (pseudorabies) virus. Inclusion body rhinitis (IBR) is typically limited to piglets. The initial signs of IBR are sneezing, with nasal discharge in a small number of pigs, which progresses to infrequent coughing. Sometimes a ring of black discoloration can be observed around the eyes due to excessive conjunctival discharge. Clinically affected sows produce smaller litters that may include mummified fetuses and stillborns. Congenitally or perinatally infected piglets present macroscopic lesions of widespread petechiae and edema. No macroscopic changes are seen in older pigs.

Virus isolation or detection must be done to include PCMV as a component of rhinitis. Qualitative or quantitative PCR-based assays for detection of viral DNA can be substituted for virus isolation in clinical cases (Fryer et al. 2001; Hamel et al. 1999; Widen et al. 1999). Antemortem samples of choice are nasal secretion or scrapings and whole blood (Edington et al. 1976a; Watt et al. 1973). Preferred postmortem samples are turbinate mucosa, lung, lung lavage, and kidney (Edington et al. 1976c; Watt 1978). In cases of early reproductive failure, PCMV can occasionally be demonstrated in the brain, liver, and bone marrow of fetuses (Edington et al. 1977, 1988a, 1988b).

Virus isolation can be done on primary or line cells, as previously described. The isolation rate can be increased by incorporating a centrifugal technique into the sample inoculation procedure (Yoon et al. 1998). Kawamura and Matsuzaki (1996) reported that 12-O-tetradecanoylophobol 12-acetate accelerated viral replication in a porcine fallopian tube cell line.

If the carcass is kept chilled, viral antigen can be detected by immunostaining on frozen tissue sections at least 24 hours after virus infectivity has disappeared. Alternatively, pathognomonic inclusions and cytomegaly may be detected in histologic sections.

The presence of PCMV in a herd is most easily confirmed by serology using serum samples from randomly selected grower-finishers. An IFA test on infected PLM, ST, PK-15, or PT cells fixed in acetone has been described (Plowright et al. 1976; Kanitz and Thacker 1974; Kanitz and Woodruff 1976). IFA titers of 1:64 to 1:128 are frequently observed in commercial pigs and occasionally reach titers of 1:1024. Enzyme-linked immunosorbent assays (ELISA) have been described (Assaf et al. 1982; Tajima et al. 1993) and adapted to distinguish IgG and IgM responses (Tajima et al. 1994). It should be noted that no PCMV antibodies are induced by in utero infection. Therefore, antibody is not expected in colostrum-deprived neonatal sera.

PREVENTION AND CONTROL

No PCMV vaccine or specific treatment for PCMV is available. Some antiviral nucleoside analogues, such as ganciclovir, have been shown to inhibit PCMV replica-

tion in vitro in a dose-dependent fashion (Fryer et al 2004; Mueller et al. 2003), but the therapeutic efficacy of these drugs remains to be assessed. No therapeutic efficacy for PCMV was achieved using 6-azauridine and 5-iododeoxyuridine (Steffenhagen et al. 1976). Medication to minimize secondary problems due to concurrent or secondary bacterial infections may be beneficial (Cameron-Stephen 1961; Corner et al. 1964).

Introduction of new stock into herds is a risk since it may stimulate latent infection or give rise to the problems of primary infection in susceptible herds.

A virus-free herd may be established by hysterotomy (Clark et al. 2003). The potential for PCVM transplacental infection should be taken into consideration and monitored.

17 Encephalomyocarditis Virus

Frank Koenen

EMCV is noteworthy for its widespread geographic distribution and the large number of species susceptible to EMCV infection. Encephalomyocarditis virus (EMCV) was first isolated from rodents in 1940 (Jungeblut and Sanders 1940). EMCV was later isolated from a chimpanzee in Florida with myocarditis (Helwig and Schmidt 1945). Thereafter, antibodies or virus were detected in a variety of animal species (Tesh and Wallace 1977).

Murnane et al. (1960) isolated EMCV from the lung and spleen of a pig that had abruptly collapsed and died during an outbreak of acute disease in Panama in 1958. This was the first recognition of EMCV as a swine pathogen. In pigs, disease due to the EMCV may take one of two main forms: acute myocarditis, usually causing sudden death in young pigs, and/or reproductive failure in sows.

Even without surveillance mechanisms to track EMCV infections actively, outbreaks in pigs have been reported throughout the world. Several major outbreaks with high mortality have been reported in Australia since 1970 (Acland and Littlejohns 1975; Seaman et al. 1986). Outbreaks have also been reported in South Africa (Williams 1981), New Zealand (Sutherland et al. 1977), Cuba (Ramos et al. 1983), and Canada (Dea et al. 1991). In Europe, clinical disease caused by EMCV was first observed in domestic pigs in 1986 and with greater frequency thereafter. Outbreaks of acute myocarditis have been reported in Italy (Sidoli et al. 1988), Greece (Paschaleri-Papadopoulou et al. 1990), Switzerland (Hani et al. 1992), Belgium (Koenen et al. 1999), and Cyprus (Loukaidis et al. 1996). In Belgium, EMCV has also been frequently isolated from cases of reproductive failure (Koenen et al. 1999).

Infection with EMCV is not uncommon, but clinical disease is infrequent. EMCV outbreaks are often clustered in so-called "endemic areas" (Maurice et al. 2004a). In Italy, 50% of farms without clinical signs in an endemic area had seroprevalence levels similar to farms with clinical EMCV, providing evidence of considerable subclinical infections (Maurice et al. 2004a).

Likewise, in the United Kingdom, antibodies against EMCV were detected, but without isolation of virus (Sangar et al. 1977).

ETIOLOGY

EMCV is an RNA virus in the genus *Cardiovirus* of the family *Picornaviridae*. Several antigenically similar viruses, including Columbia-SK and Mengo viruses, were isolated during the 1940s and are considered to be in the same group as EMCV. Tinsley et al. (1984) reported EMCV to be antigenically related to the cricket paralysis virus.

EMCV virions contain single-stranded RNA of 2.6×10^6 daltons. The viral genome encodes a leader protein that lacks proteolytic activity. The leader protein is cleaved from P1 by the virus- encoded protease 3Cpro. The 1D/2A junction is also cleaved by 3Cpro rather than by 2A. The 2A protein causes cleavage, or polypeptide chain interruption, between P1-2A and downstream sequences at an essential sequence, -NPGP-. EMCV has a poly (C) tract of variable length (usually 80–250 nucleotides) (van Regenmortel et al. 2000).

Although antigenically stabile (Meroni et al. 2000), the D region of EMCV (coding for the capsid protein VP1) displays considerable genetic variability. A single nucleotide mutation can be involved in attenuation or conferring diabetogenicity to a particular EMCV strain (Nelsen-Salz et al. 1996). In particular, isolates from Greece differed from other isolates (Knowles et al. 2000). Limited variability between pig- and rodent-derived EMCV isolates was observed.

EMCV shares many properties with other picornaviruses. It is ether-resistant and stable over a wide pH range. It is inactivated after 30 minutes at 60°C, but some strains have shown a marked thermal stability (Joo 1999).

EMCV replicates well in cell cultures originating from several animal species, including rodents, swine, and primates. Baby hamster kidney (BHK-21) and Vero

cells are most commonly used for virus propagation. The virus also replicates in mice and chicken embryos and is pathogenic to many laboratory animals.

The virus hemagglutinates guinea pig, rat, horse, and sheep erythrocytes. Most EMCV strains require KCl-borate (0.12M KCl; 0.05 H_3BO_3) buffered solution for optimal hemagglutination. Some differences in hemagglutinating activity between EMCV strains have been reported (Kim et al. 1991). Serial passage of EMCV in cell culture can alter in vitro growth characteristics, reduce virulence, and affect hemagglutinating activity (Zimmerman 1994).

EPIDEMIOLOGY

EMCV is generally regarded as a virus of rodents, although EMCV has been isolated from over 30 species, including mammals, birds, and insects. In mammals, the host range includes rodents, monkeys (even chimpanzees), elephants, lions, squirrels, mongooses, raccoons, and swine. In some species, EMCV infection may have serious consequences, e.g., lion deaths at a zoo resulted from their feeding on the carcasses of African elephants that had died of EMCV infection (Simpson et al. 1977).

Transmission of EMCV in swine has been poorly described, but rodents are generally believed to serve as a reservoir and as the means of introduction and subsequent spread of the EMCV in pig facilities. The virus usually persists in rodents without causing disease (Acland 1989; Zimmerman 1994) and infected rodents have high levels of EMCV in their tissues and excrete virus in feces and urine. Thus, exposure of swine to EMCV-contaminated feed or water or infected rodent carcasses is considered important in transmission (Acland 1989; Seaman et al. 1986; Spyrou et al. 2004; Tesh and Wallace 1977).

These assumptions were supported by the results of a matched case-control study of an area of Belgium where clinical EMCV outbreaks were regularly reported (Maurice et al. 2005b). At the univariate level, the analyses indicated that rodents, the general farm setup, and general level of hygiene were associated with clinical EMCV. Multivariate relationships between clinical EMCV and potential risk factors were analyzed using conditional logistic regression, and the presence of mice was the most significant risk factor for clinical EMCV infections.

Infected pigs can excrete the virus, at least for a short period of time, and pig-to-pig contacts or contact with infected dead pigs are potential mechanisms of virus spread (Billinis et al. 1999; Foni et al. 1993; Maurice et al. 2002). Transplacental infection has also been described as a potential route of virus spread (Christianson et al. 1992; Koenen and Vanderhallen 1997; Links et al. 1986). Other factors, such as infectious dose, route of infection, and age of the pigs, have been found to be important in the spread of the virus under experimental conditions (Billinis et al. 2004; Littlejohns and Acland 1975). In certain countries, a seasonal pattern in the outbreaks has been observed, with peaks during the autumn (Maurice et al. 2005a).

CLINICAL SIGNS

Pig age at the time of infection is an important determinate of clinical disease, with particularly severe disease if infected in the first weeks of life. Extremely high mortality, approaching 100%, is limited to pigs of preweaning age (Joo 1999). Infections in pigs from postweaning age to adulthood are usually subclinical, although some mortality may be observed even in adult pigs. Under experimental conditions, Billinis et al. (2004) found no difference in mortality between 20- and 40-day-old pigs, but none of the 105-day-old pigs died.

In young pigs, EMCV infection is most commonly characterized by acute disease with sudden death due to myocardial failure. Other clinical signs may be observed, including anorexia, listlessness, trembling, staggering, paralysis, or dyspnea. Experimentally infected swine (Craighead et al. 1963; Littlejohns and Acland 1975) had body temperatures of up to 41°C and died 2–11 days postinoculation (DPI) (usually 3–5 days) or, occasionally, recovered with chronic myocarditis.

In breeding females, clinical signs may vary from no obvious illness to various forms of reproductive failure, including abortion and increased numbers of mummified and stillborn fetuses (Dea et al. 1991; Koenen and Vanderhallen 1997).

Non-Porcine Species

Among laboratory animals, clinical manifestations and pathogenesis of EMCV are variable. Acute fatal disease is most often produced in mice and hamsters after inoculation by various routes. Neurologic disease due to encephalitis has been reported, but myocarditis is more frequently seen at necropsy. In mice, certain virus strains cause predominantly fatal encephalitis, or widespread myocardial damage, or specific destruction of pancreatic beta cells (Cerutis et al. 1989).

The course of the infection varies in rats, guinea pigs, rabbits, and monkeys, depending on the age of the animals and the virus strain used. In rats experimentally infected with a myocardial EMCV strain, no clinical signs or gross lesions were observed. Regardless, virus was isolated from several tissues from 3 DPI until the end of the observation at 62 DPI. EMCV was most frequently isolated from Peyer's patches and thymus, even in rats killed 60 DPI. The results suggested that these tissues represented a site of persistence after oral infection (Spyrou et al. 2004). Owls, monkeys, and marmosets were reportedly highly susceptible to infection. The virus has seldom been pathogenic for rabbits and rhesus monkeys, causing no apparent infections despite high levels of viremia.

PATHOGENESIS

Divergent reports regarding the clinical picture, in combination with evidence of subclinical infection, suggest that EMCV strains vary in pathogenicity. It is now recognized that some strains cause only reproductive failure or myocarditis, and others can cause both (Koenen and Vanderhallen 1997). Australian strains were shown to be more virulent than New Zealand strains (Littlejohns and Acland 1975; Horner and Hunter 1979), and certain isolates in Florida were found to cause only myocarditis without death (Gainer 1967; Gainer et al. 1968). Thus, the course of EMCV infection in pigs may be influenced by virus strain, virus dose, passage history, level of virus passage, and individual animal factors, e.g., age and pregnancy status.

Natural infection of swine is most likely to occur by the oral route. Following experimental oral inoculation of young pigs, virus was detected as early as 6 hours postinoculation in the intestinal tract. In heart and tonsils, focal positive reactions were found in the cytoplasm of single macrophages and myocardial cells during the first 30 hours postinoculation (acute phase). Thereafter, some animals died with typical postmortem lesions, and clear immunohistochemistry-positive reactions were observed in the tonsils and in the heart. Three days postinoculation, virus was isolated from liver, kidneys, spleen, and lungs. The persistence of virus beyond the viremic period suggests viral replication in the intestine. The highest virus titers were in heart muscle, both in experimental and natural infections. Myocardial lesions were predominant at necropsy. Animals that survived the infection produced EMCV antibodies. Virus detection decreased with the appearance of antibodies (Gelmetti et al. 2006).

The pathogenesis of transplacental EMCV infection in pregnant sows is not well understood. Following intramuscular exposure of pregnant sows with EMCV, transplacental infection and fetal death was observed as early as 2 weeks postinoculation. Early farrowing, abortion, and fetal mummification were observed in sows infected in mid- or late-gestation, and fetal infection in sows during early pregnancy was not conclusive (Koenen and Vanderhallen 1997; Love and Grewal 1986). Antibodies and virus were recovered from the fetuses, but the lesions varied from none to large diffuse patches, depending on the experiment (Kim et al. 1989b; Koenen and Vanderhallen 1997). Little pathogenicity was observed following infection of swine fetuses in utero with laboratory-passaged strains.

LESIONS

Pigs dying during the acute phase of cardiac failure may show only epicardial hemorrhage and no gross lesions. Hydropericardium, hydrothorax, and pulmonary edema are frequently observed at necropsy. The heart is usually enlarged, soft, and pale. The most striking lesions are found in the myocardium (Figures 17.1, 17.2). Multiple foci of various sizes are found, especially in the right ventricle, which may extend to varying depths within the myocardium. These foci are often ill-defined, circular or linear, and an uneven grayish-white in color. These lesions are observed more frequently in fattening pigs than in suckling piglets (Castryck et al. 1996; Littlejohns and Acland 1975).

Infected fetuses are most often apparently normal, but may be hemorrhagic and edematous. With some strains, fetuses may become mummified at various states of development, depending on the stage of infection. Visible myocardial lesions are exceptional.

Histopathologically, the most significant findings in young pigs are seen in the heart. Immunohistochem-

17.1. *Sagittal section of the heart of a pig with EMCV infection showing multiple foci of various sizes (especially in the right ventricle) extending to varying depths (Regional Animal Health Centre Flanders, Torhout, Belgium).*

17.2. *Interstitial myocarditis and calcification in heart muscle fibers (Prof. Dr. R. Ducatelle, Faculty of Veterinary Medicine, University of Ghent, Belgium).*

17.3. *Heart of a pig with EMCV infection showing typical white foci in myocardium (Regional Animal Health Centre Flanders, Torhout, Belgium).*

istry (IHC)-positive myocardial cells are seen, with the reaction primarily localized to the cytoplasm of myocardial cells as a fine and granular signal. The intensity and distribution of the reaction correlates with the severity of the lesions. Sometimes, IHC-positive reactions are detected in the Purkinje fibers and in the adjacent endothelial cells. Mineralization of necrotic heart muscle is common, but is not always present (Figure 17.3). In the tonsils, positive reactions are located in the necrotic debris filling the crypts and in the cytoplasm of monocyte-macrophage lineage cells. This last finding has also been reported in lymph nodes (Craighead et al. 1963; Gelmetti et al. 2006; Papaioannou et al. 2003; Psychas et al. 2001). Congestion with meningitis, perivascular infiltration with mononuclear cells, and some neural degeneration may be observed in the brain (Acland and Littlejohns 1975). Nonsuppurative encephalitis and myocarditis have also been described in swine fetuses with natural EMCV infection (Kim et al. 1989a).

DIAGNOSIS

In newborn and suckling piglets, the disease is often characterized by sudden death between 3 days to 5 weeks of age. In most cases, piglets are found dead without any prior clinical signs. In other cases, vomiting and dyspnea, i.e., rapid abdominal breathing due to heart failure, may be observed. Frequently, an entire litter dies in 1 to a few hours, with mortality confined to single, affected litters. Spread of the disease by cross-fostering of piglets has been reported. The most striking lesions, white necrotic areas, are found in the myocardium.

In finishers, sudden death is also the most characteristic sign. All age categories may be affected, but mostly pigs weighing 60–70 kg are involved. The disease is often limited to a single building, and deaths often occur in the late afternoon, when the pigs are most active. In some pigs, squealing can be heard just prior to death. In others, dyspnea can be observed.

A clinical history of reproductive failure and pre-

weaning mortality is suggestive of EMCV infection (Joo 1999). EMCV-induced reproductive problems should be differentiated from other pathogens causing reproductive problems in sows. EMCV causes reproductive failure in sows of all parities, whereas porcine parvovirus infection is manifested as an increase in mummification, primarily in gilt litters, without neonatal mortality. Other infections such as porcine reproductive and respiratory syndrome (PRRS), Aujeszky's disease (pseudorabies), and leptospirosis, should also be considered.

Histopathology may be important in achieving a diagnosis. As described previously, a variable degree of nonsuppurative interstitial myocarditis or encephalitis (infiltration of lymphocytes, histiocytes, and plasma cells) is indicative of EMCV infection. A conclusive diagnosis of EMCV should be demonstrated by virus isolation in mice or cell culture. BHK-21 cell culture is the most sensitive, but HeLa or Vero cell lines are also commonly used. Infected cell monolayers show a rapid and complete cytopathic effect. Identification of the virus can be achieved by cross virus neutralization (VN) using a reference antiserum or by staining with EMCV fluorescent antibody conjugate. Nucleic acid probes and reverse transcription-polymerase chain reaction (RT-PCR) for the detection of EMCV have been reported (Bakkali et al. 2002; Meng et al. 1993; Vanderhallen and Koenen 1997). If available, molecular biotechnological methods may provide sensitive and specific methods of diagnosis, especially when followed by sequencing.

Serologic tests for the detection of serum antibodies against EMCV include the hemagglutination-inhibition (HI) test, ELISA (Brocchi et al. 2000), latex agglutination, immunofluorescent antibody assay (IFA), agar gel immunodiffusion (AGID), and virus neutralization (VN). The VN and ELISA are the most commonly used methods and are considered specific for EMCV. No cross-neutralization was found between EMCV and 62 human enterovirus serotypes or 11 porcine enterovirus serotypes (Zimmerman 1994). For VN, antibody titers of ≥1:16 appear to be significant (Joo 1999). VN antibody reaction starts as soon as 7 DPI and may persist for an extended period (6 months to 1 year).

PREVENTION AND CONTROL

There is no treatment for EMCV infection, but during the acute phase, mortality may be minimized by avoiding situations that stress or excite the pigs at risk.

Rodents are thought to play a role in the introduction and subsequent spread of the EMC virus within pig facilities. Therefore, to prevent clinical outbreaks of EMCV, producers are advised to maintain good hygiene and keep facilities and feed sources as rodent-free as possible, especially in EMCV-endemic areas. The virus can be inactivated by water containing 0.5 ppm residual chlorine. For disinfectants, iodine based preparations or mercuric chloride can also be used.

The direct exposure of pigs to manure has been found to be significantly protective (Maurice et al. 2004b). In pig houses with slatted floors or where manure was moved between "open" manure pits, animals acquired immunity without displaying clinical signs, probably due to infection by exposure to low titers of virus.

An inactivated EMCV-vaccine is commercially available in the United States. The vaccine appears to be effective, since high humoral immunity is detected in vaccinated pigs and vaccinates were protected from clinical disease when challenged with virulent EMCV that killed 60% of unvaccinated controls. Likewise, protection against transplacental infection was demonstrated under experimental conditions.

Public Health

At present, the impact of EMCV on public health is believed to be minimal. Despite the frequency of infection in swine, no association between infection and disease in humans has been recorded (Zimmerman 1994), even in persons at the greatest risk of acquiring the infection (veterinarians, animal caretakers, laboratory staff). In light of the ubiquitous presence of EMCV around the world, secondary EMCV infection in immunocompromised persons can be expected to occur. The outcome of EMCV coinfection under such conditions is not known and there have been no reports of such cases to date. The likelihood of this event is heightened by the current interest in using porcine cells, tissues, and organs in humans (xenotransplantation). Experimental infection of a mouse through the transplantation of pig organs infected with EMCV (Brewer et al. 2003) confirmed this concern.

18 Porcine Enteric Picornaviruses

Nick J. Knowles

In previous editions of *Diseases of Swine* this chapter was entitled "Enterovirus." However, complete genome sequences of representatives of all the porcine enterovirus (PEV) serotypes have resulted in the reclassification of the group I serotypes into a new genus, *Teschovirus*, within the family *Picornaviridae* (King et al. 2000). Thus, this chapter will cover the true porcine enteroviruses and the porcine teschoviruses (PTV). Other picornaviruses infecting swine (foot-and-mouth disease virus, swine vesicular disease virus, and encephalomyocarditis virus) are covered in separate chapters.

The first report of porcine teschovirus infection was the occurrence of Teschen disease, a polioencephalomyelitis with high mortality, in Czechoslovakia over 75 years ago. This severe disease has continued to occur sporadically, mainly in Central Europe, but also in Africa. Milder forms of polioencephalomyelitis (Talfan disease, benign enzootic paresis), caused by serologically related but less virulent strains of PTV, have been reported in the last 50 years in Western Europe, North America, and Australia. In France, the encephalomyelitis is intermediate in severity between Teschen and Talfan diseases (Métianu 1986). Porcine enteroviruses and teschoviruses are ubiquitous and no conventional herd of pigs has been shown to be free of infection. Although the majority of infections are asymptomatic, porcine enteroviruses and teschoviruses have been associated with a variety of clinical conditions, including polioencephalomyelitis, female reproductive disorders, enteric disease, and pneumonia. Strains that have not been shown to be pathogenic have been referred to as enteric cytopathogenic swine orphan (ECSO) or enteric cytopathogenic porcine orphan (ECPO) viruses; however, these terms are no longer in general use.

There are no known public health problems associated with any of these viruses.

ETIOLOGY

Taxonomy and Classification

The serotypic classification of porcine enteroviruses and teschoviruses is based upon the virus neutralization (VN) test (Dunne et al. 1971; Knowles et al. 1979). In the 1960s and 1970s there were numerous attempts to achieve a uniform classification. These studies culminated in a classification of eight serotypes proposed by Dunne et al. (1971). This was later extended to 13 serotypes (Auerbach et al. 1994; Knowles et al. 1979) (Table 18.1). A complement-fixation test, suitable for the rapid screening and typing of porcine enteroviruses, has also been described (Knowles and Buckley 1980). Subsequent findings (Knowles 1983) suggested that additional serotypes may exist. Honda et al. (1990a) compared the prototype strains found in Japan with 11 internationally recognized PTV and PEV serotypes by virus neutralization and suggested a further four candidate serotypes. Some limited cross-reactivity among the existing serotypes is evident, and Hazlett and Derbyshire (1978) showed that gastrointestinal antibodies were more broadly specific than serum antibodies.

More recently, the genome sequences of the prototype strains of all the PEV serotypes have been determined, as well as partial genomic data on a number of additional isolates (Doherty et al. 1999; Kaku et al. 1999, 2001; Krumbholz et al. 2002; Peng, Lin, Kitching and Knowles 1998, GenBank accession no. AJ001391; Peng, McCauley, Kitching and Knowles 1997, GenBank accession no. Y14459; Zell et al. 2001). Comparative analyses of these data indicated that PEV types 1 to 7 and 11 to 13 formed a genetic cluster distinct from PEV-8 to 10 and human and bovine enteroviruses. They also possessed a leader polypeptide and a 2A/2B cleavage mechanism similar to the aphthoviruses, cardioviruses, and erboviruses. Thus, these 10 serotypes were renamed porcine teschovirus 1 to 10 and reclassified as a single species, *Porcine teschovirus*, in a new genus, *Teschovirus*. An additional serotype, PTV-11, was also designated, based on

Table 18.1. Classification of porcine enteric picornaviruses

serological and molecular sequence data (Zell et al. 2001).

The remaining porcine enterovirus serotypes are currently classified in two species, *Porcine enterovirus A* (PEV-8) and *Porcine enterovirus B* (PEV-9 and PEV-10), in the genus *Enterovirus*. PEV-9 and PEV-10 are typical enteroviruses most closely related to bovine enteroviruses. However, the taxonomic position of PEV-8 is presently under discussion. Although it clusters genetically with the enteroviruses and rhinoviruses (two genera which may, in the future, be combined), PEV-8 has some distinct genome features that may be the basis for reclassification in a new genus (Krumbholz et al. 2002):

1. The 5' untranslated region (UTR) has an internal ribosome entry site (IRES) that more closely resembles that of hepatitis C virus (a flavivirus) (Kaku et al. 2002; Pisarev et al. 2004).
2. It has a leader polypeptide, absent in all other entero/rhinoviruses.
3. The sequences of the 2A, 2B, and 3A polypeptides are unlike those of the entero/rhinoviruses.

Genetically PEV-8 is most closely related to some simian picornaviruses (Krumbholz et al. 2002; Oberste et al. 2003) and a duck picornavirus (Tseng and Tsai 2004, GenBank accession no. AY563023) that are also in taxonomic limbo (Figure 18-1).

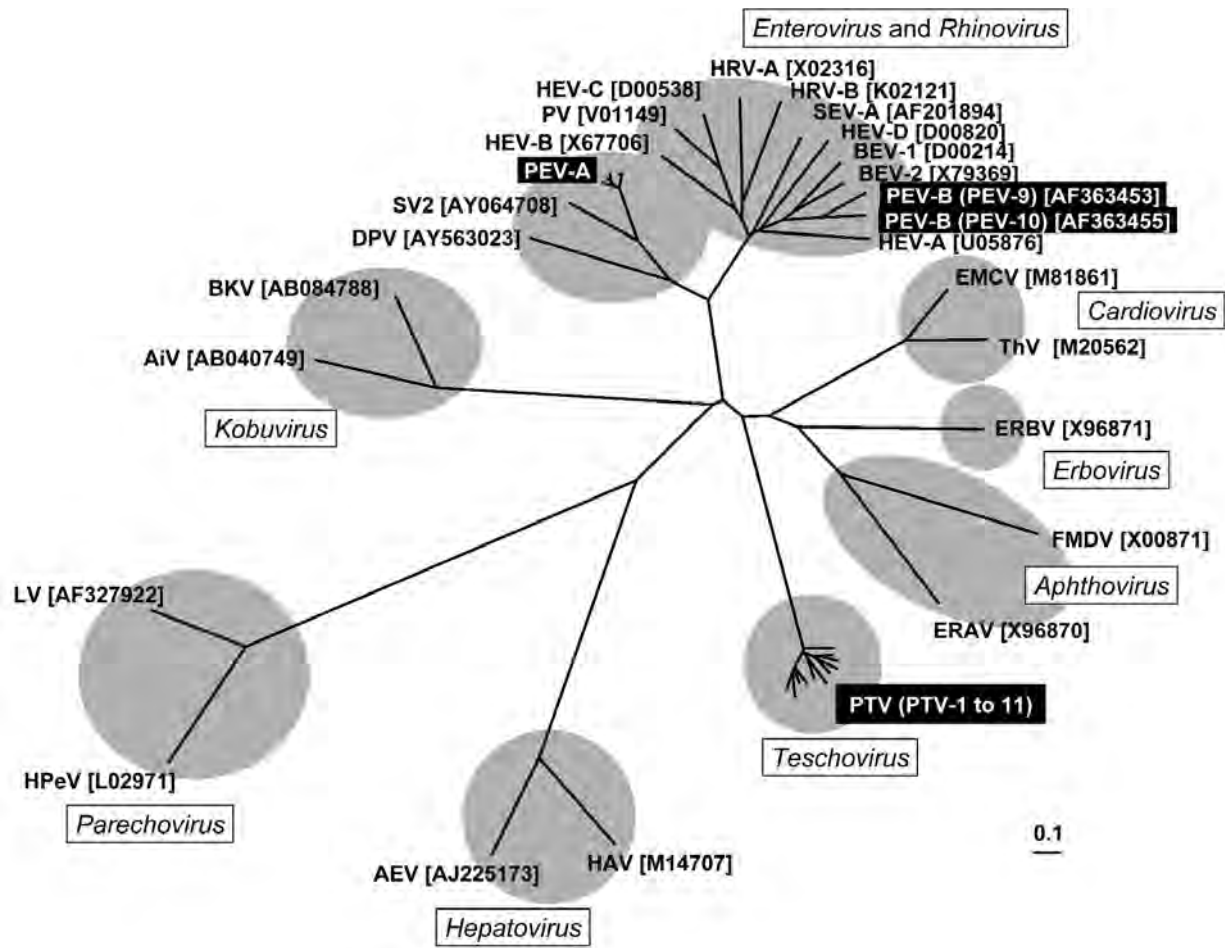
Morphology (Size and Structure)

As with all picornaviruses, the virions of PTVs and PEVs are spherical and nonenveloped with a diameter of 25–30 nm. A single-stranded ribonucleic acid (RNA) genome is surrounded by an icosahedral capsid consisting of 60 copies of four polypeptides. A small basic virus-encoded protein (VPg) is linked to the 5' end of the genome. No three-dimensional structure data is yet available.

Genomic Organization and Gene Expression

The polyproteins of all the porcine enteroviruses and teschoviruses conform to the general picornavirus L-4-3-4 layout (Rueckert and Wimmer 1984) and all processed polypeptides occur in equimolar amounts. A leader polypeptide (absent in PEV-9 and PEV-10) is followed by four structural polypeptides (VP4, VP2, VP3 and VP1, also known as 1A to 1D, respectively) and seven nonstructural polypeptides (2A, 2B, 2C, 3A, $3B^{VPg}$, $3C^{pro}$ and $3D^{pol}$). The latter three are a small genome-linked protein, a cysteine proteinase, and an RNA-dependent RNA polymerase, respectively. In the true enteroviruses and rhinoviruses, 2A is also a cysteine proteinase. In the PEVs, primary polyprotein cleavages occur between the precursor polypeptides P1, P2, and P3. However, in the PTVs a self-cleaving mechanism operates between the P1-2A and 2BC polypeptides. Most subsequent processing of PEV and PTV polypeptide precursors is carried out by the 3C protease.

Physicochemical and Biological Properties

The complete PTV virions have a buoyant density of 1.34 g/ml in cesium chloride, which is similar to that of enteroviruses; the PEVs have not been characterized. Lipoprotein is lacking and the viruses are stable when treated with lipid solvents. Porcine teschoviruses are relatively stable to heat, whereas the enteroviruses are more heat labile, unless treated with 1M $MgCl_2$. Heating porcine teschoviruses in the presence of halide ions tends to destabilize the virus. All these viruses are stable at pH values between 2 and 9. Hemagglutination has not been demonstrated for porcine enteroviruses or teschoviruses. Prior to reclassification porcine enteroviruses were divided into three subgroups based on physicochemical properties, type of cytopathic effect (CPE) produced in pig kidney cells, and different cell culture host ranges (Knowles et al. 1979; Zoletto 1965; Zoletto et al. 1974).


18.1. *Phylogenetic tree showing the relationships between the P1 capsid polypeptides of porcine enteroviruses, porcine teschoviruses, and other members of the Picornaviridae.*

Amino acid sequences were aligned and a neighbor-joining tree constructed using Clustal X. Sequences of the 11 prototype porcine teschoviruses (see Table 18.1) and the following five PEV-A (PEV-8) sequences were included in the tree: V13 [AF406813], 16-S-X [AY392543], 26-T-XII [AY392544], Sek 1562/98 [AY392556], Po 5116 [AY392538].

The following abbreviations are used for the picornavirus species: PV, Poliovirus; HEV-A, Human enterovirus A; HEV-B, Human enterovirus B; HEV-C, Human enterovirus C; HEV-D, Human enterovirus D; SEV-A, Simian enterovirus A; BEV, Bovine enterovirus; PEV-A, Porcine enterovirus A; PEV-B, Porcine enterovirus B; HRV-A, Human rhinovirus A; HRV-B, Human rhinovirus B; EMCV, Encephalomyocarditis virus; ThV, Theilovirus; FMDV, Foot-and-mouth disease virus; ERAV, Equine rhinitis A virus; ERBV, Equine rhinitis B virus; HAV, Hepatitis A virus; AEV, Avian encephalo-myelitis-like viruses; HPeV, Human parechovirus; LV, Ljungan virus; AiV, Aichi virus; BKV, Bovine kobuvirus. The following are unclassified entero-like viruses: SV2, Siman virus 2; DPV, Duck picornavirus TW90A. Genus names are enclosed in boxes.

Laboratory Cultivation

Porcine teschoviruses and enteroviruses are readily cultivated in the laboratory in cell cultures of porcine origin. They are normally grown in primary or secondary pig kidney (PK) cell cultures or in established cell lines, such as IB-RS-2. They may also be cultivated in other cells of porcine origin such as the SST cell line or in primary swine testes cells. PEV-8 may additionally be cultivated in monkey kidney (e.g., Vero) and BHK-21 cells (Knowles et al. 1979). Isolates of PEV-9 and PEV-10 are also able to grow in a wide range of established cell lines, including BHK-21, Vero, and HeLa (Knowles et al. 1979).

EPIDEMIOLOGY

The virulent PTV-1 strains associated with classical Teschen disease appear to be restricted to those areas in which the disease occurs and they have not been isolated in North America. Less virulent PTV-1 strains and representatives of the other PTV serotypes appear to be ubiquitous, as is PEV-8 (Odend'hal 1983). However, PEV-9 and PEV-10 have only been identified in Italy, the United Kingdom, and Japan (Caracappa et al. 1985; Honda et al. 1990a; Knowles et al. 1979; Zoletto 1965).

The only known natural host for porcine enteroviruses and teschoviruses is the pig. Experimentally,

pregnant guinea pigs infected with PEV-8 developed placental lesions (Lieu 1976).

Transmission of PEV and PTV infection is most frequently by the fecal-oral route. Indirect transmission by fomites is extremely likely to occur since the viruses are relatively resistant.

Endemic infection with several PTV serotypes and PEV-8 can usually be demonstrated in conventional herds and is probably maintained in groups of weaned piglets. Singh and Bohl (1972) demonstrated waves of infection with six different serotypes over a period of 26 months in a long-term study of infection in a single herd. Infection is normally acquired by piglets shortly after weaning, when maternally derived antibodies are withdrawn and pigs from several litters are mixed together, and it persists for at least several weeks. Adults rarely excrete virus, but have high antibody levels. Pigs of any age are, however, fully susceptible to infection with a virus belonging to a serotype to which they have not previously been exposed.

Porcine enteroviruses and teschoviruses are highly resistant to the environment, with Teschen disease virus surviving for more than 168 days at 15°C (Ottis 1976). These viruses survive for long periods in liquid manure, but they are inactivated more rapidly if the manure is aerated (Lund and Nissen 1983). Likewise, they are inactivated in liquid manure by ionizing radiation (Simon et al. 1983) and by anaerobic digestion (Derbyshire et al. 1986).

Porcine enteroviruses and teschoviruses are relatively resistant to many disinfectants. Of 10 commonly used disinfectants tested by Derbyshire and Arkell (1971) against Talfan virus, only sodium hypochlorite or 70% ethanol completely inactivated it.

PATHOGENESIS

Natural infection occurs by ingestion of the virus. It is well established (Long 1985) that initial replication occurs in the tonsil and intestinal tract. The large intestine and ileum are infected more frequently than the upper small intestine, and the former tissues contain higher titers of virus. It has not been clearly established which cells in the intestine support viral replication, but by analogy with experiments on poliovirus (Kanamitsu et al. 1967) it is probable that the reticuloendothelial tissue

of the lamina propria is involved. Epithelial cell destruction is not a feature of these infections. Viremia follows regularly in infections with the virulent PTV-1 strains, but occurs less regularly with the less virulent strains, leading to infection of the central nervous system (CNS) (Holman et al. 1966). It may be assumed that the pregnant uterus is also infected by viremic spread of the virus, since embryonic or fetal infections were demonstrated in gilts following nasal or oral inoculation of PEV-8 or PTV (Huang et al. 1980).

Intranasal inoculation of the virus may lead experimentally to lung infection (Meyer et al. 1966), but the significance of the natural inhalation of viral aerosols is not known. It has also been clearly demonstrated that when piglets are inoculated parenterally with porcine teschoviruses, the virus rapidly infects the intestine. Extraintestinal infections are relatively transient, whereas the virus persists in the large intestine for several weeks.

CLINICAL SIGNS

Although porcine teschovirus and enterovirus infections are most frequently subclinical, various clinical syndromes have been associated with certain serotypes, as indicated in Table 18.2 and outlined below.

Polioencephalomyelitis

The most severe form of polioencephalomyelitis is that produced by the highly virulent PTV-1 strains that cause Teschen disease. This is a disease of high morbidity and high mortality, affecting all ages of swine and associated with major economic losses. The early signs of Teschen disease include fever, anorexia, and listlessness, rapidly followed by locomotor ataxia. In severe cases there may be nystagmus, convulsions, opisthotonus, and coma. Paralysis ensues, and the animal may assume a dog-sitting posture or remain in lateral recumbency. Stimulation by sound or touch may elicit uncoordinated limb movements or opisthotonus. Death is common within 3 or 4 days of the onset of clinical signs. Since the appetite returns after the acute phase, some animals may be kept alive by careful nursing, but these cases show muscle wasting and residual paralysis.

The less virulent PTV-1 strains (Talfan disease, benign enzootic paresis) and strains belonging to other serotypes associated with polioencephalomyelitis pro-

Table 18.2. Natural or experimental clinical syndromes associated with porcine enteric picornavirus infection

Syndrome	PTV Serotypes	PEV Serotypes
Polioencephalomyelitis	PTV-1, PTV-2, PTV-3, PTV-5	—
Reproductive disorders	PTV-1, PTV-3, PTV-6	PEV-8
Diarrhea	PTV-1, PTV-2, PTV-3, PTV-5	PEV-8
Pneumonia	PTV-1, PTV-2, PTV-3	PEV-8
Pericarditis and myocarditis	PTV-2, PTV-3	—
Cutaneous lesions	—	PEV-9, PEV-10

duce a milder disease with relatively low morbidity and mortality. Mainly young pigs are affected, and the disease rarely progresses to complete paralysis.

Recently, encephalomyelitis due to teschovirus infection has been reported in pigs in both the U.S. (Pogranichniy et al. 2003) and Japan (Yamada et al. 2004). No neurological disease has been observed during infection with porcine enteroviruses.

Reproductive Disease

The term SMEDI was initially introduced (Dunne et al. 1965) to designate a group of viruses, subsequently shown to be porcine enteroviruses or teschoviruses, that had been isolated in association with stillbirth (S), mummified fetuses (M), embryonic death (ED), and infertility (I). Subsequent studies by the same group of workers and by others (De Meurichy et al. 1976) indicated that the syndrome could be reproduced experimentally.

However, parvovirus infection may also lead to embryonic death and fetal mummification and this virus may be more frequently associated with these disorders of early and midgestation. Other findings (Cropper et al. 1976) substantiated a role for teschoviruses, as well as parvoviruses, in these disorders, and experimental (Bielanski and Raeside 1977) and field data (Kirkbride and McAdaragh 1978) confirmed an association between teschovirus infection and abortion in swine. These reproductive disorders are not usually accompanied by clinical signs in the sow or gilt. Infection with encephalomyocarditis virus (family *Picornaviridae*, genus *Cardiovirus*) may also result in female reproductive failure.

Porcine teschoviruses have also been isolated from the male genital tract (Philips et al. 1972), although the insemination of gilts with contaminated semen did not influence their fertility (De Meurichy and Pensaert 1977).

Diarrhea

The role of porcine enteroviruses and teschoviruses as enteric pathogens is uncertain. They have frequently been isolated from the feces of piglets with diarrhea, but since they can be readily isolated from normal piglets, particularly postweaning, and since diarrhea can be caused by a variety of other viral and bacterial agents, their presence may be coincidental. However, diarrhea has been produced experimentally by porcine teschoviruses in piglets believed to be free of other pathogens. The diarrhea is mild and relatively transient, and it seems clear that porcine teschoviruses are considerably less important enteric pathogens than rotaviruses or coronaviruses. When piglets were infected with porcine teschoviruses together with rotaviruses, the disease was less severe than in piglets infected only with the rotavirus (Janke et al. 1988). An association between PEV-8 and diarrhea has been suggested based on the relative frequency of isolation of this virus from pigs showing symptoms (Honda et al. 1990b). Conversely, the relative infrequency of isolation of PEV-9/PEV-10 from pig feces would argue against any involvement of these viruses in gastrointestinal disease (Knowles 1988).

Pneumonia, Pericarditis, and Myocarditis

The role of enteroviruses and teschoviruses as respiratory pathogens is also uncertain. It is probable that alone they rarely cause clinical signs of respiratory disease, although Pospisil et al. (1971) noted increased respiration, coughing, snorting, reduced appetite, and depression in piglets exposed to an aerosol of porcine teschovirus. Although pathogenic studies indicate some degree of tropism of these viruses for the lung, the pneumonia produced is usually subclinical. Two serotypes of porcine teschovirus have been shown experimentally to be capable of producing pericarditis, and in one experiment, myocardial involvement occurred (Long et al. 1969). These findings might lead to a suspicion of teschovirus infection in the case of sudden death in piglets, although encephalomyocarditis virus might be more likely candidate.

Possible Association with Cutaneous Lesions

During the course of investigations of swine vesicular disease outbreaks in the United Kingdom, many adventitious agents were isolated from samples of epithelium and feces. Most of these isolates were identified as teschoviruses or enteroviruses (Knowles 1983). Porcine teschoviruses and PEV-8 were evenly distributed in fecal samples (41% and 44%, respectively) and in epithelial samples (21% in each case). However, PEV-9/PEV-10 were rarely found in feces (15%), but were more commonly found in epithelial samples (58%) (Knowles 1988). Examination of another virus collection again revealed an approximately even distribution of PTV and PEV-8 (57% and 43%, respectively), but PEV-9 and PEV-10 were not identified (Knowles 1988). It was assumed that most of the PTV and PEV-8 isolates identified in epithelial samples were incidental contaminants; however, the low level incidence of PEV-9 and PEV-10 in feces could not explain the much higher isolation rate from epithelial tissue collected from atypical skin lesions. This association has yet to be explained.

LESIONS

No specific changes have been associated with intestinal enterovirus or teschovirus infections. They do not appear to cause villous atrophy, which is characteristic of primary intestinal pathogens such as coronaviruses and rotaviruses. Other than muscle atrophy in chronic cases, no gross lesions are found in polioencephalomyelitis. The histological lesions associated with the latter are widely distributed in the CNS but are especially numerous in the ventral columns of the spinal cord, the cerebellar cortex, and the brain stem. The changes are more marked and extensive in Teschen disease than in milder encephalomyelitides, such as Talfan disease. The

neurons show progressive diffuse chromatolysis (Koestner et al. 1966) and focal areas of gliosis and perivascular lymphocytes, particularly over the cerebellum, may also occur.

The SMEDI syndrome is remarkable for the lack of specific lesions in stillborn or neonatal piglets, although mild focal gliosis and perivascular cuffing in the brain stem have been found occasionally. Placental changes are restricted to nonspecific degeneration.

Pneumonic lesions have been produced by several investigators. Smith et al. (1973) describes areas of grayish-red consolidation in the ventral anterior lobes of lungs infected with a PTV-2 strain. There were exudates in the alveoli and bronchi, slight perivascular and peribronchiolar cuffing, and some hyperplasia of the bronchiolar epithelium.

A PTV-3 strain consistently produced serofibrinous pericarditis experimentally, and the more severely affected piglets showed focal myocardial necrosis (Long et al. 1969).

IMMUNITY

Infected pigs mount a classical humoral protective immune response (IgM and IgG). Mucosal immunity (IgA) may be produced and have a protective effect in the gastrointestinal tract. In an experimental study of porcine teschovirus infection in piglets, it was shown that cell-mediated responses were weak and localized and not associated with significant antiviral activity (Brundage et al. 1980).

Humoral antibody is thought to be important for protection. In one experiment, immunosuppression (using cyclophosphamide) of pigs infected with a porcine teschovirus led to the lack of a serological response and a persistent infection of the intestinal tract (Derbyshire 1983). This resulted in severe diarrhea and, in one case, signs of encephalomyelitis. Presence of high levels of virus neutralizing IgA antibody in the gastrointestinal tract may protect against oral challenge (Hazlett and Derbyshire 1977).

Since humoral antibody is probably the most important factor in protection, at least in teschoviruses, the relatively large number of serotypes would suggest that cross-protection may not be effective.

It has been reported for both PTV-1 and PEV-8 that maternal antibody has no effect on embryonic or fetal infections after the virus has reached the uterus (Huang et al. 1980). However, possession of preinfection antibody in sows would probably limit infection and prevent the virus from reaching the uterus. Colostral antibody would be expected to protect piglets from infection.

DIAGNOSIS

Teschen disease (Enterovirus Encephalomyelitis) is designated as a List A disease by the World Organisation for Animal Health (OIE) and details of internationally accepted methods for its diagnosis can be found on the World Wide Web as an on-line document (Office International des Epizooties 2004).

The occurrence of clinical signs associated with polioencephalomyelitis is suggestive of viral infection, but the differentiation of teschoviral infection from other neurotropic viruses requires isolation of the virus from the CNS, the demonstration of viral antigen by specific immunofluorescence or presence of viral RNA by RT-PCR. Similarly, with reproductive disorders, diarrhea, pneumonia, pericarditis, and myocarditis, there are no diagnostic clinical signs that would suggest enterovirus or teschovirus involvement and laboratory diagnosis is required.

Virus isolation from the CNS requires the collection of tissues from a piglet showing early nervous signs since animals that have been paralyzed for several days may no longer contain infectious virus in the CNS (Lynch et al. 1984). The virus may be isolated in PK cell cultures from suspensions of the spinal cord, brain stem, or cerebellum. It may subsequently be identified on the basis of its physicochemical characteristics, by immunofluorescence (Watanabe 1971) or immunoperoxidase staining (Sulochana and Derbyshire 1978). Serologic identification of the isolate is desirable. The isolation of a teschovirus or enterovirus from the gastrointestinal tract of a piglet with nervous signs does not establish the etiology of the disease, since the enteric infection may be coincidental. In the SMEDI syndrome, mummified fetuses carried to term rarely contain live virus but may contain viral antigen detectable by immunofluorescence.

Virus isolation in PK cell culture may be attempted from tissues of aborted or stillborn fetuses. Lung tissue appears to be the most reliable source for the isolation of porcine enteroviruses and teschoviruses from fetuses (Huang et al. 1980). VN tests on the body fluids of such fetuses can be carried out against the SMEDI-associated PTV and PEV serotypes. In the investigation of pneumonia or diarrhea, virus isolation from the respiratory or intestinal tract may be attempted, but the virological findings should be interpreted cautiously, especially in relation to diarrhea, since enteric infections with teschoviruses and enteroviruses are common in healthy piglets. In one study porcine enteroviruses and teschoviruses were isolated from 57% of porcine fecal samples submitted for swine vesicular disease diagnosis over a 7-year period (Knowles 1983).

Isolated viruses may be identified by virus neutralization (Knowles et al. 1979), complement fixation (Knowles and Buckley 1980), or immunofluorescence (Auerbach et al. 1994; Dauber 1999) if suitable reference reagents are available. Monoclonal antibodies that are capable of detecting porcine teschoviruses have been described (Dauber 1999).

Now that genomic sequence data is available for all the porcine enteroviruses and teschoviruses, it is possi-

ble to use RT-PCR to detect viral RNA in clinical samples or to identify viruses isolated in cell culture. Palmquist et al. (2002) described an RT-PCR using a single set of primers for the simultaneous detection and differentiation (based on amplicon size) of PTVs and PEV-8. Nested RT-PCR assays to specifically detect PTV-1 and to differentiate the PTVs, PEV-8, and PEV-9/10 from each other using virus-specific primer sets have also been described (Zell et al. 2000). More recently, improvements to these assays resulted in the development of a one-step, real-time PCR (Krumbholz et al. 2003).

Serology is of little value for diagnosis, unless paired sera are available and the serotype known. In this case the virus neutralization test would be suitable. An enzyme-linked immunosorbent assay, suitable for mass screening, has been described for the detection of antibodies against Teschen disease virus (Hubschle et al. 1983). However, because these viruses are ubiquitous, serological surveys may not be very helpful.

PREVENTION AND CONTROL

As in most viral infections, control measures for porcine enteroviruses depend on prevention rather than treatment. Potential antiviral chemotherapeutics for porcine enteric picornaviruses have received little attention. Piglets with mild polioencephalomyelitis may recover if nursing care is provided during the period of transient paresis.

Vaccination has been practiced in the field only for the control of Teschen disease. The earlier Teschen disease vaccines, containing inactive virus of pig tissue origin, have been superseded by attenuated or inactivated cell culture vaccines. Mayr and Correns (1959) attenuated Teschen disease virus by cell culture passage and showed that live or formalin-inactivated vaccines prepared from this virus induced similar levels of protection in piglets. Success has been claimed for a Teschen disease eradication program involving ring vaccination and slaughter (Schaupp 1968). Restrictions on the import of swine and pork products from areas in which Teschen disease is endemic seem to be effective in limiting the spread of virulent PTV-1 strains. If such strains were introduced into North America, they would be controlled by a policy of quarantine and slaughter.

Vaccination has not been practiced against the milder forms of polioencephalomyelitis or against the other clinical manifestations of PTV or PEV infection in swine. Only the SMEDI syndrome is of sufficient economic importance to justify specific control measures in the field, but the multiplicity of serotypes that may be involved complicates the development of an effective vaccine.

The best current approach to the prevention of reproductive disorders associated with porcine enteroviruses and teschoviruses would appear to be the application of management practices that ensure that gilts are exposed to the infection with endemic viruses at least 1 month before breeding. This can be achieved naturally if the animals remain in a single building from birth to breeding, with thorough mixing of piglets from different litters at weaning. If breeding stock is segregated at an early age, they should be contaminated with fecal material from recently weaned piglets. This can be readily accomplished by adding fresh feces to the feed of gilts or by dosing gilts with capsules of feces, which should be a pooled sample collected from weaned piglets in several pens to ensure exposure to as wide a range as possible of the virus present in the herd.

The operation of a closed-herd system reduces the risk of introducing extraneous viruses, but it is not possible to eliminate this risk, since the relatively resistant enteric picornaviruses can be transmitted by a variety of fomites. If the introduction of fresh stock is essential for breeding purposes, before the gilts or sows are bred they should be exposed (by fecal contamination as described above) to any virus that may be present or introduced.

Exclusion of porcine enteroviruses or teschoviruses by repopulation of herds with specific pathogen free (SPF) stock seems to be difficult or impossible to achieve over a prolonged period. These viruses have been isolated from commercial SPF herds (Derbyshire et al. 1966) and the accidental introduction of Talfan virus into SPF gilts maintained under strict isolation has been described (Parker et al. 1981). Since transplacental infection of fetuses may occur, even gnotobiotic pigs may be infected.

19 Porcine Enteric Caliciviruses and Astroviruses

Janice C. Bridger and Nick J. Knowles

Porcine enteric caliciviruses were first recognized when diarrheic feces from postweaning and nursing pigs in the United Kingdom and the United States were examined by electron microscopy (Bridger 1980; Saif et al. 1980). Porcine enteric caliciviruses have not been widely studied and much is unknown concerning their role in naturally occurring swine disease. This is in contrast to the recognized role of caliciviruses in human gastroenteritis (Green et al. 2001). Likewise, research is establishing a role for caliciviruses of the *Norovirus* genus in enteric disease of cattle (Deng et al. 2003; Oliver et al. 2003; Smiley et al. 2003; Wise et al. 2004). Thus, based on their role as disease agents in other species, it may be postulated that caliciviruses play a significant role in porcine enteric disease. Based on the limited data available, there is no evidence that porcine enteric caliciviruses pose a threat to human health.

ETIOLOGY

Human enteric caliciviruses belong to two genera, *Norovirus* (formerly Norwalk-like) and *Sapovirus* (formerly Sapporo-like), in the family *Caliciviridae* (Mayo 2002). Both are common causes of human gastroenteritis. Caliciviruses belonging to both the *Norovirus* and *Sapovirus* genera have also been identified in pigs.

Porcine sapoviruses have been studied the most, but only one isolate (PEC/Cowden) has been studied in any detail (Flynn and Saif 1988; Flynn et al. 1988; Guo et al. 1999; Guo et al. 2001a; Parwani et al. 1990; Saif et al. 1980). PEC/Cowden shows typical calicivirus morphology with clear cup-shaped depressions (Figure 19.1). The virus is approximately 35 nm in diameter and has an RNA genome of 7,320 base pairs organized into two open reading frames, similar to the human sapoviruses and lagoviruses. The highest amino acid identities were with the sapoviruses, with which it grouped phylogenetically, but PEC/Cowden was assigned to genogroup III, a new genogroup distinct from the human sapoviruses (Schuffenecker et al. 2001; Figure 19.2).

Consistent with all other caliciviruses, PEC/Cowden has one major structural capsid protein with a molecular weight of 58 kilodaltons. Antigenic relationships to nonenteric caliciviruses have not been well studied, but PEC/Cowden and a likely porcine sapovirus identified in the United Kingdom were antigenically unrelated to vesicular exanthema of swine virus and feline caliciviruses (Bridger 1980; Saif et al. 1980). Nothing is known about genetic or antigenic variation among porcine sapoviruses because only one isolate has been studied in detail.

The PEC/Cowden sapovirus may be cultured on primary porcine kidney cells and a continuous porcine kidney cell line (LLC-PK), but only by inclusion of intestinal contents in the culture medium (Flynn and Saif 1988; Parwani et al. 1991). It is the only enteric calicivirus to be cultured to date. Bile acids were identified as the active factor that allowed cultivation by affecting the protein kinase A cell signaling pathway (Chang et al. 2002; Chang et al. 2004).

Less is known about porcine noroviruses. A virus with an indistinct morphology was reported in the United Kingdom (Bridger 1980), and six partial gene sequences with close similarity to each other and to human noroviruses have been demonstrated in pigs in the Netherlands and Japan (Sugieda et al. 1998; Sugieda and Nakajima 2002; van Der Poel et al. 2000; Figure 19.2). Phylogenetic analysis grouped the porcine sequences with the genogroup II human noroviruses, but they formed a separate genetic cluster distinct from human noroviruses. Additional data will be required to determine whether human and porcine noroviruses are genetically distinct and whether humans and pigs might share noroviruses. Porcine noroviruses have not been cultured and nothing is known about their physicochemical and other biological properties.

EPIDEMIOLOGY

Porcine enteric caliciviruses have been identified in the United States (Guo et al. 1999; Saif et al. 1980), United

347
19.1. *Negative stain electron microscopy. Panels A and B: the sapovirus virion has a typical calicivirus morphology with clear cup-shaped depressions and measures approximately 35 nm in diameter. Panel C: the 30 nm diameter, non-enveloped astrovirus particles are distinctive in appearance with some particles showing a 5- or 6-pointed star pattern on their surface. Kingdom (Bridger 1980), the Netherlands (van Der Poel et al. 2000), Hungary (Nagy et al. 1996), and Japan (Shirai et al. 1985; Sugieda et al. 1998; Sugieda and Nakajima 2002). The virus identified in the United States was typed as a sapovirus; in the Netherlands and Japan as a norovirus; and in the United Kingdom and Hungary, it was not genetically typed.

The one prevalence study conducted to examine porcine sapoviruses related to PEC/Cowden showed that at least 83% of 30 sow serum samples from Ohio pig herds with PEC-associated postweaning diarrhea had antibodies reactive to PEC/Cowden (Guo et al. 2001b).

Two porcine norovirus prevalence studies have been reported. In Japan, 4 samples were reverse transcription-polymerase chain reaction (RT-PCR) positive among 1,117 cecal content samples collected from healthy pigs on 26 farms in 1997 (Sugieda and Nakajima 2002). In the Netherlands (1998–1999), 2 samples were RT-PCR positive among 100 pooled fecal samples collected from 3–9-month-old pigs on 100 farms (van Der Poel et al. 2000). These studies are likely to have underestimated the prevalence of porcine norovirus infections because PCR primers designed for human noroviruses were used and because investigators did not select for pre- and postweaning diarrheic piglets.

Little is known regarding porcine enteric caliciviruses and natural disease. A study in Hungary found no association with diarrhea when diarrheic and nondi-

arrheic weaned and unweaned pigs were examined for evidence of porcine calicivirus infection by electron microscopy (Nagy et al. 1996).

It is assumed that natural enteric calicivirus transmission is fecal-oral. Whether porcine enteric caliciviruses are species-specific has not been established. It has been postulated that the close genetic similarity of porcine noroviruses and human noroviruses indicates zoonotic potential (Sugieda and Nakajima 2002; van Der Poel et al. 2000).

PATHOGENESIS

Experimental infections with the porcine sapovirus PEC/Cowden produced enteric lesions and disease (Flynn et al. 1988; Guo et al. 2001a). Unusual for a viral enteric pathogen, disease and small intestinal lesions in the duodenum and jejunum resulted from intravenous inoculation of PEC/Cowden, as well as by oral exposure. Viral replication in enterocytes was demonstrated by immunofluorescence with anti-PEC/Cowden antiserum. Calicivirus particles were demonstrated in intestinal contents and in the blood stream, the first time viremia has been associated with an enteric calicivirus. The mechanism by which the virus reached the small intestine and villous enterocytes from the blood stream was not determined. When infected by the oral route, fecal shedding of the sapovirus PEC/Cowden occurred for up to 9 days. When infected by the intravenous route, fecal shedding was observed for at least 8 days.

Experimental infections with porcine noroviruses have not been reported.

CLINICAL SIGNS

With PEC/Cowden, the one strain of porcine sapovirus that has been studied, the incubation period ranged from 2–4 days after oral infection and clinical signs of diarrhea persisted for 3–7 days (Flynn et al. 1988; Guo et al. 2001a). All inoculated pigs became infected and developed clinical signs ranging from mild to severe diarrhea. Control pigs and pigs infected with tissue culture-adapted PEC failed to develop clinical signs, although intestinal lesions were observed in the exposed pigs.

There are no reports of experimental studies with porcine noroviruses.

LESIONS

Infection with PEC/Cowden produced lesions indistinguishable from those produced by other enteric viral pathogens, such as rotaviruses (Flynn et al. 1988; Guo et al. 2001a). Lesions included shortening, blunting, fusion or absence of duodenal and jejunal villi and, by scanning electron microscopy, an irregular microvillous coat on enterocytes. Crypt cell hyperplasia and a reduc-

tion of villus/crypt ratios occurred with cytoplasmic vacuolation and infiltration of polymorphonuclear and mononuclear cells into the lamina propria.

IMMUNITY

Immune responses against porcine sapoviruses and noroviruses, protective immunity, and/or the role of maternal antibodies have not been assessed. It may be assumed that protective immune mechanisms are similar to those for other enteric virus pathogens, although the recognition of an extraintestinal phase to the pathogenesis of a porcine sapovirus suggests that other immune strategies might be used in their control. Porcine sapovirus and norovirus infections in pigs may potentially provide useful insights into protective immunity of the equivalent viruses of humans.

DIAGNOSIS

No diagnostic tests for porcine sapoviruses or noroviruses have been developed for use outside the research

laboratory. An antigen and antibody ELISA was developed and used to study PEC/Cowden (Guo et al. 2001b). Porcine noroviruses have been detected using RT-PCR (Sugieda et al. 1998; Sugieda and Nakajima 2002; van Der Poel et al. 2000).

PREVENTION AND CONTROL

Assuming that porcine sapovirus and norovirus epidemiology and immunology are similar to porcine rotaviruses, it is likely that these viruses persist in the environment and that sows pass maternal antibodies in colostrum and milk that limit enteric infection and disease in neonates. Likewise, if these viruses are similar to porcine rotaviruses, it is probably impossible to eliminate infection from pig herds and/or prevent natural infection of piglets. In the case of severely affected pigs, oral rehydration with fluids is likely to be successful.

Porcine Astroviruses

INTRODUCTION

Porcine astroviruses were first recognized when diarrheic feces were examined by electron microscopy (Bridger 1980; Geyer et al. 1994; Shimizu et al. 1990). Their causal role in porcine enteric disease remains undetermined. In some species—for example, humans and sheep—astroviruses have been linked to enteric disease (Matsui and Greenberg 2001), but bovine astroviruses failed to cause clinical disease when inoculated into calves (Woode and Bridger 1978; Woode et al. 1984).

ETIOLOGY

Porcine astroviruses are members of the family *Astroviridae* which is divided into two genera, *Mamastrovirus* (astroviruses of mammals) and *Avastrovirus* (astroviruses of birds). Approximately 30 nm diameter and nonenveloped, astrovirus particles are distinctive in appearance, with some particles showing a 5- or 6-pointed star surface pattern when viewed by negative stain electron microscopy (Figure 19.1; Bridger 1980; Shimizu et al. 1990). Not all particles show this distinctive appearance, and care is needed so as not to confuse them with the indistinct appearance of noroviruses, particularly in the presence of antibody.

The genome is composed of positive sense, single-stranded RNA 6.8 to 7.9 kilobases in length composed of three open reading frames (Matsui and Greenberg 2001). Two porcine astroviruses from Japan have been partially sequenced (Jonassen et al. 2001; Lukashov and Goudsmit 2002; Wang et al. 2001). Phylogenetic analyses grouped human and porcine astroviruses closely together, whereas astroviruses from sheep and avian species were less related to human astroviruses (Figure 19.3). There is evidence that astroviruses from different animal species are antigenically distinct (Matsui and Greenberg 2001). For example, antibodies against porcine astroviruses do not react with bovine astroviruses.

Porcine astroviruses have not been widely studied. In Japan, a cytopathic astrovirus from diarrheic pigs was successfully isolated on a porcine kidney cell line by incorporating trypsin into the medium (Shimizu et al. 1990). Immunofluorescent cells and astrovirus particles were detected. A virus with a buoyant density of 1.35 g/ml was cloned and a serum-virus neutralization test developed. The isolate was stable to treatment with lipid solvents and resisted heating at 56°C for 30 minutes, but showed some lability to acid treatment at pH 3.0. Five structural proteins with molecular masses 13–39 kilodaltons were identified. At present, the number of astrovirus structural proteins is uncertain and has varied in

studies with astroviruses from different animal species (Matsui and Greenberg 2001).

EPIDEMIOLOGY

Porcine astroviruses have been identified in feces of pigs in the United Kingdom (Bridger 1980), Japan (Shimizu et al. 1990), and South Africa (Geyer et al. 1994). In a serological survey in Japan, 39% of 128 pigs in 8 herds had serum neutralizing antibodies to porcine astroviruses (Shimizu et al. 1990). All but one herd had antibody and the in-herd prevalence ranged from 7–83%. Transmission is presumed to be fecal-oral.

A study of evolutionary genomic relationships showed that human and animal astroviruses belonged to distinct genomic clusters (Jonassen et al. 2001; Lukashov and Goudsmit 2002; Figure 19.3). However, the genetic data supported the hypothesis that two cross-species transmission events involving pigs, cats, and humans, possibly through intermediate hosts, may have occurred in the past.

Cross-species infectivity of porcine astroviruses has not been demonstrated, and astroviruses are believed to be species-specific.

PATHOGENESIS, CLINICAL SIGNS, LESIONS, IMMUNITY

Porcine astroviruses have been associated with severe diarrhea in natural infections, but only in the presence of other known enteric pathogens (Bridger 1980; Shimizu et al. 1990). Mild diarrhea developed in 4-day-old pigs after oral inoculation with porcine astroviruses grown in cell culture (Shimizu et al. 1990). Diarrhea commenced 1 day after inoculation and continued for 5–6 days. Cytopathic astrovirus was recovered from feces and pigs seroconverted. Intestinal pathology was not studied, but it is reasonable to hypothesize that astroviruses might contribute to the intestinal pathology and clinical signs commonly observed in pre- and postweaning diarrhea. Nothing is known about antigenic differences between porcine astroviruses or the immunity induced by infection with astrovirus.

DIAGNOSIS

Diagnostic assays have not been developed for routine diagnosis, but methods such as isolation on cell culture and identification with immunofluorescence and RT-PCR can be used to diagnose natural porcine astrovirus infection. The serum-virus neutralization and immunofluorescent antibody assays can be used to demonstrate seroconversion (Shimizu et al. 1990).

PREVENTION AND CONTROL

Porcine astroviruses may be just one of several viruses that contribute to pre- and postweaning diarrhea. Elimination of astroviruses from infected farms would be difficult to achieve because of their resistance in the environment. In addition, such an effort would be difficult to justify on the basis of their clinical effects. Assuming that astrovirus pathology is confined to the intestinal tract, oral rehydration would be expected to be effective in affected pigs. There are no commercially available vaccines.

20 Hemagglutinating Encephalomyelitis Virus

Maurice B. Pensaert

In 1962, a previously unrecognized viral pathogen was isolated in Canada from the brains of suckling pigs with encephalomyelitis (Greig et al. 1962). The virus responsible for this disease was named hemagglutinating encephalomyelitis virus (HEV) and was later classified as a coronavirus (Greig et al. 1971). In 1969, an antigenically identical virus was isolated in England from suckling pigs showing anorexia, depression, and vomiting, but without clear signs of encephalomyelitis (Cartwright et al. 1969). Animals that did not die remained stunted in growth; the condition was therefore called "vomiting and wasting disease" (VWD). Mengeling and Cutlip (1976) were later able to experimentally reproduce both forms of the disease using the same field isolates. Although epidemiologic studies have revealed that infection of swine with HEV is prevalent, naturally occurring disease is uncommon. Neonatal pigs are usually protected by passively acquired colostral antibody, and they subsequently develop an age-related resistance to the potential clinical effects of the virus. Therefore, studies on virus-animal interactions have been scarce in recent years.

ETIOLOGY

HEV belongs to group 2 of the family *Coronaviridae*, a group characterized by the presence of a gene encoding for the hemagglutinin-esterase (HE) protein (Gonzalez et al. 2003). Other members of group 2 include bovine coronavirus (BCV), human respiratory coronavirus OC43 (HCV-OC43), and mouse hepatitis virus (MHV).

Nucleotide sequence analysis of the region covering the S2 probe revealed 92.6% nucleotide sequence homology to BCV and 91.9% to HCV-OC43 (Vieler et al. 1995). An antigenic relationship between HEV and BCV was shown by virus neutralization (VN), hemagglutination-inhibition (HI), immunofluorescence, and immuno-electron microscopy. Moderate cross-reactivity was observed between HEV and turkey enteric coronavirus (Dea and Tijssen 1989). Although HEV is known to be the cause of two distinct clinical syndromes in pigs, only one serotype of the virus is known to exist.

Under electron microscopy, HEV's appearance is similar to other coronaviruses. Negatively stained particles are spherical in shape, with an overall diameter of 120 nm (Greig et al. 1971). Club-shaped surface projections arranged as a solar "corona" protrude from the envelope. Lamontagne et al. (1981) showed that the viral particle contains two concentric membranes—an external envelope and an inner membranous bag—encircling a central core. Virus particles can be seen by electron microscopy in cytoplasmic vesicles of infected cells. Assembly occurs by budding through membranes of the endoplasmic reticulum (Ducatelle et al. 1981).

Studies on the chemical composition of HEV revealed that the virus contains RNA and five polypeptides, four of which are glycosylated, with molecular weights from 31,000–180,000 daltons (Callebaut and Pensaert 1980; Greig and Girard 1969; Pocock and Garwes 1977). The buoyant density was 1.21 g/ml in cesium chloride (Mengeling and Coria 1972) and 1.18 g/ml in potassium tartrate (Greig and Bouillant 1972).

HEV is stable between pH 4 and 10. All viral infectivity is lost after 30 minutes at 56°C, but the titer of infectious virus is reduced by only 0.8 $\log_{10}$ after 7 days at 4°C. HEV was shown by Greig and Girard (1969) to be sensitive to lipid solvents, including sodium desoxycholate.

HEV was first isolated in primary cultures of pig kidney (PK) cells by Greig et al. (1962), who described a cytopathic effect (CPE) characterized by the appearance of syncytia. An immunofluorescence test showed that HEV was also able to propagate in several other porcine cell cultures, including adult thyroid gland, embryonic lung, testicle cell line, PK-15 cell line (Pirtle 1974), IBRS$_2$ cell line (Chappuis et al. 1975), SK cell line (Lucas and Napthine 1971), SK-K cell line (Hirano et al. 1990), and swine embryo kidney cell line KSEK6 (Kadoi et al. 1994). Non-porcine cell cultures have little susceptibility for growth of HEV.

HEV possesses two virion-associated hemagglutinins: the hemagglutinin-esterase (HE) and the S protein (Sasseville et al. 2002; Schultze and Herrler 1993). The virus spontaneously agglutinates erythrocytes of mice, rats, chickens, and several other species of animals (Girard et al. 1964). Elution of HEV from red blood cells has not been observed. These erythrocytes can be used in a hemadsorption test to demonstrate viral growth in inoculated cell cultures.

The natural host of HEV is the pig, but the virus has been adapted experimentally to replicate in mice (Kaye et al. 1977; Yagami et al. 1986) and Wistar rats (Hirano et al. 1993). The virus is neurotropic in mice, but susceptibility was found to be influenced by age and route of inoculation (Yagami et al. 1993). In contrast, 4-week-old Wistar rats died of encephalitis after inoculation of HEV via different routes (Hirano et al. 1993).

EPIDEMIOLOGY

Pigs are the only species known to be naturally susceptible to HEV infection. Most of the infections in this species are subclinical and the economic impact of the disease is low.

The distribution of HEV in the pig population has been studied in several countries. The HI and VN tests proved to be almost equally sensitive for detection of HEV antibodies in swine sera (Mengeling 1975), but the VN test is more specific (Sasaki et al. 2003). Serologic surveys revealed that infection of swine with HEV is very common and probably worldwide. In fattening pigs, 31% of the sera were positive in Canada (Girard et al. 1964), 46% in Northern Ireland (McFerran et al. 1971), 49% in England (Cartwright and Lucas 1970), 52–82% in Japan (Hirai et al. 1974; Hirano and Ono 1998), 75% in Germany (Hess and Bachmann 1978), and 0–89% in the United States, depending on the region surveyed (Mengeling 1975). The percentage of sows with antibodies at slaughter varied from 43% in Northern Ireland to 98% in the United States. A high number of seropositive animals were also found in Denmark (Sorensen 1975), France (Vannier et al. 1981), Australia (Forman et al. 1979), Belgium (Pensaert et al. 1980), and Austria (Mostl 1990). Conversely, Neuvonen et al. (1982) found that 40 Finnish elite breeding pig herds were free of seropositive animals.

HEV was isolated from the respiratory tract of pigs with respiratory illness in Japan in 1984 (Hirahara et al. 1987). The first isolation of HEV in Taiwan was from 30–50-day-old pigs with signs of central nervous disease (Chang et al. 1993).

Under experimental conditions, disease has been reproduced in most instances in which nonimmune pigs were exposed oronasally to HEV during the first few weeks of life (Alexander 1962; Appel et al. 1965). Clinical signs may vary, however. In a study in which the virulence of several HEV field isolates was compared, the severity of signs was related to a difference in host susceptibility (even among littermates), as well as to the apparent virulence of each isolate (Mengeling and Cutlip 1976). In contrast, older pigs and neonatal pigs that had received antibody in colostrum were usually clinically unaffected when exposed to HEV under otherwise similar conditions (Appel et al. 1965).

These observations are believed to explain why naturally occurring disease is relatively uncommon, even though HEV is ubiquitous among swine. That is, in herds where HEV infection is endemic, most pigs receive protective antibody in colostrum, and circulating maternal antibodies persist for 4–18 (mean 10.5) weeks (Paul and Mengeling 1984). By the time maternal antibody wanes, the pigs have already developed an age-related resistance to the disease. Additional support for this concept is provided by a serologic study on two Belgian breeding farms, which showed that passively acquired colostral immunity was replaced by active immunity as a consequence of subclinical infection of pigs between 8 and 16 weeks of age (Pensaert et al. 1980).

Outbreaks of HEV-associated disease are now rarely described in the literature. In a relatively recent outbreak, HEV was isolated from newborn and early-weaned pigs with vomiting and posterior paralysis on a Canadian farm (Sasseville et al. 2001). Remarkably, this recent isolate showed a high degree of genetic and antigenic homology with the 1962 reference strain HEV-67N (Sasseville et al. 2002).

CLINICAL SIGNS

Infection with HEV can produce two clinical syndromes: an acute, clinically apparent encephalomyelitis and vomiting and wasting disease (VWD). Both syndromes are primarily confined to pigs less than 3 weeks of age, although older swine may occasionally vomit and exhibit a brief period of inappetence, listlessness, and nervous signs. Encephalomyelitis caused by HEV was diagnosed in 30–50-day-old pigs in Taiwan (Chang et al. 1993). Prior to the Taiwanese report, the typical encephalomyelitic form had only been described in Canada (Alexander et al. 1959) and the United States (Werdin et al. 1976). Both the nervous and VWD syndromes have many clinical signs in common and varying degrees of severity may be seen, from acute encephalomyelitis to chronic VWD.

Sneezing or coughing may occur at the start of a VWD outbreak. After an incubation period of 4–7 days, the primary sign is repeated retching and vomiting. Pigs under 4 weeks of age start suckling, but soon stop, withdraw from the sow, and vomit the milk they have taken in. Pigs huddle together, appear pale and listless, and often have an arched back. Body temperature may be elevated at the beginning of the outbreak, but returns to

normal in 1–2 days. Affected pigs often grind their teeth. They dip their mouths into water bowls, but drink little or nothing, indicating a possible pharyngeal paralysis. Persistent vomiting and decreased food intake result in constipation and a rapid decline in condition.

The youngest pigs become severely dehydrated after a few days, become dyspneic and cyanotic, fall into a coma, and die. Older pigs lose their appetite and rapidly become emaciated. They continue to vomit, although less frequently than in the early stage of the disease. Some animals develop a large distension of the cranial abdomen. This "wasting" state may persist for several weeks until the pigs die of starvation. Mortality approaches 100% within litters and survivors remain permanently stunted.

An outbreak of the encephalomyelitic form may start as a VWD outbreak. Some pigs begin to vomit 4–7 days after birth. The vomiting continues intermittently for 1–2 days, but is rarely severe and does not result in dehydration. In other outbreaks, the first sign is acute depression and a tendency to huddle. Pigs may become sick as soon as 2 days after birth. Occasionally, sneezing, coughing, or upper respiratory compromise is observed. The pigs lose weight rapidly and their hair loses its luster and becomes rough. After 1–3 days, signs of severe encephalomyelitis arise. Younger pigs are most severely affected and exhibit various combinations of nervous signs. Generalized muscle tremors and hyperesthesia are common findings. Pigs that are able to stand usually have a jerky gait and tend to walk backwards, often ending in a dog-sitting position. They soon become very weak, are unable to rise, and paddle their limbs. Their noses and feet become cyanotic. Blindness, opisthotonus, and nystagmus can also occur. Finally, affected animals become prostrate, dyspneic, and lay on their sides. In most cases, coma precedes death.

Mortality in younger pigs is usually 100%. Older pigs usually suffer a mild transient illness in which posterior paralysis may be the most common sign. The paresis in a few cases is accompanied by blindness. The outbreak described in Taiwan (Chang et al. 1993) in 30–to 50-day-old pigs was characterized by fever, constipation, hyperesthesia, muscular tremor, progressive anterior paresis causing pigs to assume a "rabbit-like" posture, posterior paresis, prostration, recumbency, and paddling movements. Morbidity was 4%, but mortality was 100%, with pigs dying 4–5 days after the onset of clinical signs.

The time interval from onset of the disease in the first litter to cessation of the disease or its failure to appear in new litters is usually 2–3 weeks (Werdin et al. 1976). The disappearance of clinical signs coincides with the time it takes sows to develop immunity and to pass this protection on to their offspring. It has been shown that pigs exposed to HEV develop neutralizing and hemagglutination-inhibiting serum antibodies (Pensaert and Callebaut 1974).

PATHOGENESIS

HEV is able to replicate in the upper respiratory tract with or without producing clinical signs. HEV can be isolated from the nasal cavity, trachea, and lungs of diseased or healthy pigs (Hirahara et al. 1989; Mengeling et al. 1972; Pensaert et al. 1980). The virus is excreted for 8–10 days in oronasal secretions (Hirahara et al. 1989; Pensaert and Callebaut 1974), with transmission occurring through exposure to nasal secretions.

Most infections under field circumstances have a subclinical course, but the typical clinical disease can be reproduced by oronasal inoculation of colostrum-deprived piglets. In a series of studies on the pathogenesis of the disease, Andries and Pensaert (1980c) inoculated newborn colostrum-deprived pigs oronasally with an HEV strain from pigs showing the VWD syndrome. Anorexia and vomiting were seen after an incubation period of 4 days. Earlier studies had shown that viremia was probably of little or no importance in the pathogenesis (Andries and Pensaert 1980b). Immunofluorescence studies at different times after inoculation revealed that the epithelial cells of nasal mucosa, tonsils, lungs, and small intestine served as sites of primary viral replication.

After local replication near the sites of entry, the virus spread via the peripheral nervous system to the central nervous system (CNS). At least three pathways appeared to be involved. One pathway led from the nasal mucosa and tonsils to the trigeminal ganglion and the trigeminal sensory nucleus in the brainstem. A second pathway followed along the vagal nerves via the vagal sensory ganglion to the vagal sensory nucleus in the brainstem. A third pathway led from the intestinal plexuses to the spinal cord, also after replication in local sensory ganglia.

In the CNS, the infection started in well-defined nuclei of the medulla oblongata, but later progressed into the entire brainstem, the spinal cord, and sometimes also the cerebrum and cerebellum. Fluorescence in the brain was always restricted to the perikaryon and processes of neurons (Figure 20.1). Vomiting was induced by viral replication in the vagal sensory ganglion (ganglion distale vagi) or by impulses to the vomiting center produced by infected neurons at different sites (Andries 1982).

Experimental inoculation of rats and mice also leads to infection of the central nervous system. In these animals, HEV spreads transsynaptically along the neuronal pathways from the peripheral nerves to the central nervous system (Hirano et al. 2004).

To elucidate the pathogenesis of the wasting in pigs, radiological studies were performed on chronically infected animals, vagotomized animals, and controls (Andries 1982). The stomach of control pigs was always empty within 10 hours, whereas barium was retained in
20.1. *Viral multiplication in the brain stem of a pig inoculated with HEV. Fluorescence is seen in the axon and the perikaryon of a neuron (×500).*

the stomachs of pigs with HEV for 2–7 days. In pigs with a bilateral abdominal vagotomy, the stomach emptying was less disturbed. This indicated that the delayed gastric emptying in pigs with HEV was not solely due to earlier viral replication in the vagal ganglion and vagal nuclei in the brain. The virus-induced lesions in the intramural plexi of the stomach were probably also responsible for gastric stasis. The disturbance in normal gastric emptying was considered to play an important role in the pathogenesis of wasting.

LESIONS

The only significant gross lesions reported in natural HEV infections are cachexia and a distension of the abdomen that develops in some chronically affected pigs (Hoorens et al. 1977; Schlenstedt et al. 1969). In these pigs, the stomach is dilated and filled with gas.

Microscopic lesions are found in the tonsils, the nervous system, respiratory system, and stomach of acutely diseased pigs. The lesions tend to disappear in animals surviving acute stages of the disease.

A nonsuppurative encephalomyelitis was reported in 70–100% of pigs with nervous signs and in 20–60% of pigs with the VWD syndrome. The lesions are characterized by perivascular cuffing, gliosis, and neuronal degeneration (Alexander 1962; Chang et al. 1993; Hoorens et al. 1977; Narita et al. 1989b; Richards and Savan 1960). Lesions are most pronounced in the gray matter of the pons Varoli, the medulla oblongata, and the dorsal horns of the upper spinal cord. It has been hypothesized that encephalitic lesions are a specific immune response to HEV following its replication in the CNS (Narita et al. 1989b). Neuritis of peripheral sensory ganglia, particularly the trigeminal ganglia, also occurs.

Changes in the tonsil are characterized by epithelial degeneration and lymphatic cell infiltration into the crypts (Narita et al. 1989a). Degeneration of the epithelial cells of the turbinates, bronchi, and alveoli, as well as interstitial peribronchiolar pneumonia with infiltration of neutrophils and macrophages, were observed in 20% of naturally infected animals (Hoorens et al. 1977) and a much higher proportion of experimentally infected pigs (Cutlip and Mengeling 1972; Hirahara et al. 1989).

Microscopic changes in the stomach wall and the lungs were found only in pigs showing the VWD syndrome. Degeneration of the ganglia of the stomach wall and perivascular cuffing were present in 15–85% of diseased animals. The lesions were most pronounced in the pyloric gland area (Hoorens et al. 1977; Schlenstedt et al. 1969; Steinicke and Nielsen 1959).

DIAGNOSIS

To isolate HEV, the tonsils, brain, and lungs are collected aseptically from young, diseased piglets euthanized shortly after the first signs of infection. It is very difficult to isolate the virus from pigs that have been sick for more than 2 days. Tissue homogenates are inoculated onto primary PK cells, secondary pig thyroid cells, or permissive porcine cell lines. The presence of HEV is shown by the development of syncytia, hemadsorption, and hemagglutination (Andries and Pensaert 1980a). A single blind passage with cells and culture fluid is recommended because clinical specimens from pigs infected with HEV often contain very small amounts of infectious virus.

Antibodies to the virus can be detected by the VN, plaque reduction, or HI tests (Mengeling 1975; Sato et al. 1983). However, since subclinical HEV infections are common, serum antibody titers must be evaluated very carefully. Interpretation of paired serum samples may be difficult. A significant rise in antibody titer will only be observed if acute sera are taken very soon after the appearance of clinical signs. Pigs with clinical signs after an incubation period of 6–7 days may already have produced high serum antibody titers.

The differential diagnoses for HEV include Teschen-Talfan disease and Aujeszky's disease (pseudorabies). In the latter two, clinical signs of encephalomyelitis, including locomotor disorders, are more severe than those associated with HEV infection and may appear in older pigs, as well as in piglets. Aujeszky's disease in unvaccinated animals may also induce respiratory signs in older pigs and abortions in sows. These viruses can be grown in PK and pig thyroid cells; in PK cells they are distinguishable on the basis of cytopathic effect. They can be further differentiated using specific virus identification tests and the production of hemagglutinin by HEV.

PREVENTION AND CONTROL

In most breeding herds, HEV infection is maintained in an endemic cycle through subclinical infection of the respiratory tract. Sows usually come into contact with the virus before their first farrowing and, therefore, provide protective colostral antibodies to their offspring. Infection in such pigs is subclinical. However, if sows are not immune at the time of farrowing, as may occur in newly populated farms or on farms too small to maintain an endemic cycle, infection of pigs within the first weeks after birth will result in clinical signs. Thus, maintaining the virus on farms to obtain immune sows at the time of their first farrowing creates a situation favorable to avoiding disease in piglets.

Once clinical signs are evident, the disease will run its course; spontaneous recoveries are rare. Litters born 2–3 weeks after the onset of disease are usually protected by maternal immunity. Before that time, piglets born to nonimmune sows can be protected by specific hyperimmune serum injected at birth. However, the lapse of time between diagnosis and cessation of the disease is usually too short to gain much benefit from this procedure.

21 Japanese Encephalitis and West Nile Viruses

K. B. Platt and Han Soo Joo

Japanese encephalitis virus (JEV) and West Nile virus (WNV) are significant mosquito-borne human and animal pathogens. JEV is considered to be the most important vector-borne virus that causes encephalitis in humans. The rate of apparent to inapparent JEV infection in humans ranges from 1 in 200–300 and the case fatality rate of humans infected with JEV can exceed 40% (Burke and Monath 2001). The virus is also an economically important reproductive pathogen of swine and will cause encephalitis and death in horses. It is widely distributed in Asia, from Southeastern Russia through Japan, Eastern China, Southeastern Asia, to Northern Australia in the south and India in the West.

JEV was first isolated from humans by Fujita (1933) and later by Taniguchi et al. (1936) who concluded that it was the cause of "summer encephalitis" in Japan. A temporal relationship was also recognized between "summer encephalitis" of humans and cases of encephalitis in horses, and abortion and stillbirths in swine (Hosoya et al. 1950). Subsequently Shimizu et al. (1954) demonstrated that JEV was responsible for reproductive failure in swine.

West Nile virus was first isolated in 1937 from a febrile woman in Uganda (Murgue 2002). Prior to 1999 the virus was distributed throughout Africa, the Middle East, and parts of Europe and Asia. WNV first emerged in the U.S. during an outbreak in New York City in 1999. The mechanism of its introduction has not been established. The virus subsequently spread rapidly throughout North America and south through Mexico to Central America and the Caribbean (Gould and Fikrig 2004; Roehrig et al. 2002). The case fatality rate of WNV in humans increases with age and can vary from 2–15% (O'Leary et al. 2004; Tsai et al. 1998). West Nile virus, like JEV, causes fatal disease in horses. Unlike JEV, its role as a swine pathogen has not been thoroughly explored and there are no reports of death or reproductive failure in swine.

ETIOLOGY

JEV and WNV are members of the *Flavivirus* genus of the family *Flaviviridae*. The family contains two other genera, the genus *Pestivirus* represented by viruses causing classical swine fever (hog cholera), bovine viral diarrhea virus, and border disease virus, and genus *Hepacivirus* represented by hepatitis C virus of humans (Lindenbach and Rice 2001). Genus *Flavivirus* is organized into 8 separate antigenic complexes based on serum cross-neutralization assays: Japanese encephalitis (JE), Ntaya, Dengue (DEN), tick-borne encephalitis (TBE), Uganda, Tyuleniy, Rio Bravo, and Modoc serocomplexes. Yellow fever virus, the prototype virus for genus *Flavivirus,* does not fall into any specific serocomplex (Burke and Monath 2001). Notable members of the JE serocomplex include JEV, the prototype of the group, St. Louis encephalitis virus, Murray Valley encephalitis virus, WNV, and Kunjin virus. The latter, which is found in Australia, is currently considered to be a subtype of WNV (Lanciotti et al. 2002).

JEV is classified into 4, and possibly 5, distinct genotypes based on the nucleotide sequences encoding the capsid, prM, and E proteins. Genotype I is the most broadly distributed genotype throughout Asia. Genotypes I and III are most commonly associated with epidemic disease. Genotypes II and IV are found in Southeast Asia and are commonly associated with endemic disease (Solomon et al. 2003). Two major immunotypes of JEV are currently recognized by kinetic neutralization, monoclonal antibody reactivity, and other serological methods. These immunotypes are represented by the Nakayama strain that was isolated from a human brain in 1935 and the JaGAr 01 strain that was isolated from a mosquito in 1959. Antigenic and genetic variation exists among isolates of the same genotype (Burke and Monath 2001). Variations between strains within genotypes and immunotypes can be demonstrated by nucleotide analysis (Holbrook and Barrett 2002).

WNV is represented by 2 genetic lineages based on genomic differences. Lineage 1 viruses are further subdivided into 3 clades: 1a, 1b, and 1c. Lineage 1 viruses are found in Africa, the Middle East, Asia, Europe, and North America. Lineage 2 viruses are found primarily in Africa (Lanciotti et al. 2002). In general, lineage 1 viruses are more virulent than lineage 2 viruses. Serological and molecular techniques can be used to differentiate WNV strains.

Morphology

The JEV and WNV are enveloped, single-stranded, positive polarity RNA viruses approximately 50 nm in diameter. Their genomes are approximately 11 kb in length and surrounded by a polyhedral capsid consisting of a single protein (C) of about 11 kd. The envelope consists of two proteins, E and M, of approximately 50 and 8 kDa, respectively. The E and M protein together form small spikes of approximately 6 nm on the surface of the envelope. The M protein exists as the prM protein before the release of mature virions from infected cells. Nonstructural proteins include NS1, 2A, 2B, 3, 4A, 4B and 5. The E and NS1 proteins are associated with the induction of immunity (Kurane 2002). It is of interest to note that the prM protein of another flavivirus, Dengue, has been reported to induce immunity (Lindenbach and Rice 2001). Neuro-virulence of JEV and WNV strains is associated with common determinants on the E protein (Ni and Barrett 1998; Lee et al. 2004).

The structural proteins of flaviviruses are encoded at the 5' end of the genome and nonstructural proteins are encoded at the 3' end. The flavivirus genome is expressed as a single polyprotein that is cleaved during and after the translation process by both cellular and virus encoded proteases.

Biophysical and Biochemical Properties

Flaviviruses have a buoyant density of 1.22–1.24 g/cm^3 in CsCl. Their sedimentation rates range from 140–200 S20w. In general, flaviviruses are inactivated in whole blood after 30 minutes exposure to 56°C and by low pH, bile, and proteolytic enzymes (Burke and Monath 2001). A study by Remington et al. (2004) demonstrated a loss of WNV infectivity of over 6 orders of magnitude in 5% and 25% albumin solutions after 30 minutes exposure to 60°C. Mayo and Beckwith (2002) demonstrated that WNV maintained in cell culture medium with 10% fetal bovine serum at 28°C lost infectivity at the rate of 1 order of magnitude per 24 hours. In contrast, no infectivity was lost when virus was maintained at 4° over a 4-day period. This point should be considered when submitting clinical specimens for diagnostic evaluation. No information is available on the stability of JEV under dry conditions. However, Johansen et al. (2002) reported that virus activity was lost within 24 hrs when dead JEV-infected mosquitoes were held at 28–32°C in a humidified atmosphere. This suggests that both WNV and JEV virus rapidly lose infectivity outside of their living host.

EPIDEMIOLOGY

A wide range of domestic and wild avian and mammalian species including humans, horses, and swine are susceptible to JEV and WNV infection. These viruses are transmitted almost exclusively by the bite of infected mosquitoes, although experimental tick transmission of WNV has been reported (Lawrie et al. 2004). Rosen (1986) cited two studies, one in which JEV was isolated from midges (*Lasiohelea taiwana*) feeding on humans and the other from the tick *Haemmaphysalis japonica*. There are no reports of contact transmission of either virus between swine. However, contact transmission of WNV between avian species, from which virus can be isolated from throat and cloacal swabs, has been reported (Komar et al. 2003). Contact transmission of WNV between alligators has also been described (Klenk et al. 2004), as has oral infection of cats (Austgen et al. 2004).

Both JEV and WNV are naturally maintained in a mosquito-bird-mosquito cycle. JEV epidemics in human populations typically occur in late summer and early fall in northern temperate climates after JEV amplifies in the fledgling and young bird populations during the nesting season, and subsequently in susceptible pigs and other mammalian species. In endemic tropical areas, JEV infection can occur in swine populations almost immediately after the mosquito season begins. Pigs serve as a significant JEV reservoir for both opportunistic and zoophilic mosquito species that spread the virus to humans which are dead end hosts.

The primary mosquito species involved in transmission of JEV in Asia is *Culex tritaeniorhynchus,* and its role in this capacity has been well documented in reviews by Rosen (1986) and Endy and Nisalak (2002). *Culex tritaeniorhynchus* is opportunistic and feeds on both avian and mammalian species. The titers of blood meals capable of infecting 50% of feeding *Cx. tritaeniorhynchus* vary from $10^{2.9}$–$10^{4.8}$ mouse lethal dose$_{50}$ (LD$_{50}$) per ml of serum depending on the strains of mosquitoes and viruses (Takahashi 1976). These levels of viremia are exceeded in young avian species (Boyle et al. 1983; Buescher et al. 1959) and in young pigs. Maximum serum titers exceeding $10^{6.0}$ LD$_{50}$ per ml were reported by Kodama et al. (1968) in 2-day-old pigs challenged with 10^1 or 10^2 LD$_{50}$. Gresser et al. (1958) observed maximum virus titers in serum of $10^{4.7}$ and $10^{3.9}$ LD$_{50}$ per ml in a 3- and a 5-month-old pig challenged with $10^{5.3}$ LD$_{50}$ and Konishi et al. (1992) reported virus titers in serum that exceeded 10^3 PFU ml in six of ten 25 kg pigs that were challenged with $10^{5.2}$ PFU of JEV. Virus titers exceeded 10^4 PFU per ml of serum in 2 of these pigs. The virus challenge used in these studies was within or near the amounts of JEV that can be delivered

by *Cx. tritaeniorhynchus* to a host during feeding (Takahashi 1976).

Several other mosquito species are competent JEV vectors. Examples include; *Cx. pipiens quinquefasciatus*, *Cx. tarsalis* (Endy and Nisalak 2002), *Aedes albopictus* (Weng et al. 1997), and *Ochlerotatus japonicus* (Takashima and Rosen 1989). Each of these species is present in the Western hemisphere. Consequently, if JEV is introduced into this region it will most likely become established.

The mechanisms of interepidemic survival of JEV and WNV have not been fully elucidated. In temperate regions of Asia, outbreaks of JEV are seasonal and occur in late summer after virus has been amplified in fledging bird populations (Buescher and Scherer 1959). Ardeids, such as herons and egrets, are frequently cited as playing a principle role in the epidemiology of JEV. Whether ardeids play a more important role in the epidemiology of JEV than other avian species remains to be determined. Rosen (1986) commented that ardeids have received more attention than other avian species because they are large enough to be bled repeatedly and are found in environments in which the principle *Culex* vectors are present. Virus could be reintroduced into the same general regions by infected mosquitoes that are carried on the wind from warmer endemic regions. However, Takashima et al. (1988) presented a compelling argument that supports the contention that JEV is maintained endemically. Possible mechanisms for interepidemic maintenance include persistence of virus in diapausing adult *Culex* spp., (Nasci et al. 2001), vertical transmission in *Aedes* and *Ochlerotatus* spp., (Rosen et al. 1978; Rosen et al. 1989) and persistent infection in hibernating bats and cold blooded animals (Rosen 1986).

The epidemiology of WNV is similar to that of JEV. In the US, 60 species of mosquitoes from 11 genera are susceptible to WNV (CDC 2005), but the ability to transmit WNV by all of these species has not been established. *Culex* species that feed primarily on birds, such as *Cx. pipiens*, and *Cx. tarsalis,* are considered to be the primary mosquito vectors of WNV. Several other mosquito species that feed primarily on mammals, including humans, can serve as bridge vectors between birds and mammals such as pigs. These species include *Culex quinquefasciatus*, *Aedes albopictus* (a.k.a. Asian tiger mosquito), *Aedes vexans*, *Ochlerotatus trivittatus*, *Ochlerotatus triseriatus*, and others (Turell et al. 2005; Tiawsirisup et al. 2004). The general consensus is that the primary reservoir of WNV are birds, especially crows, jays, house sparrows, and grackles (Komar et al. 2003). The role of mammals, including swine, in the epidemiology of WNV has not been fully evaluated.

CLINICAL SIGNS

The primary disease manifestation of JEV infection in sows and gilts is reproductive failure manifested by abortion and abnormal farrowings (Figure 21.1). Litters contain stillborn and mummified fetuses, and weak neonates that may present with hydrocephalus and subcutaneous edema. Live normal piglets can also be present in these litters (Burns 1950). Sexually mature swine do not show any significant clinical signs of infection, but transient anorexia and a mild febrile response have been observed. Reproductive failure occurs in nonimmune sows that become infected before 60–70 days of gestation. Infection after this time does not appear to affect piglets significantly (Sugimori et al. 1974). There have not been any reports of reproductive failure in sows due to WNV infection.

Japanese encephalitis virus has also been associated with infertility in boars. Hashimura et al. (1976) isolated JEV from the testicles of a boar with orchitis. Ogasa et al. (1977) showed that infection of susceptible

21.1. *Mummified and stillborn fetuses from a gilt following a natural infection with JEV.*

boars resulted in edematous, congested testicles that produced semen with numerous abnormal spermatozoa and significantly depressed total and motile sperm counts. Virus was also excreted in the semen. These changes were usually temporary and most boars recovered completely.

Natural infection of young piglets with JEV resulting in clinical disease has not been recognized as a common occurrence, possibly due to the prevalence of JEV-specific maternal antibody in endemic areas. However, Yamada et al. (2004) reported that JEV was isolated from tonsils of 2 of 4 40-day-old pigs that presented with a wasting syndrome. These pigs did not exhibit neurological signs, but histological examination revealed a nonsuppurative meningoencephalitis. These investigators were able to reproduce nonsuppurative meningoencephalitis in 3-week-old piglets with the isolated viruses. The affected pigs also showed varying degrees of depression and hind limb tremors. Whether or not an association with a wasting syndrome exists was not established, but it is noteworthy that JEV infection in humans can present with wasting of limbs as a result of flaccid paralysis (Solomon and Vaugh 2002). Kodama et al. (1968) also reported that experimental infection of 2-day-old piglets produced tremors and paralysis of the hindlimbs. However, other researchers who infected pigs ranging in age from 10 days to 2–3 months with JEV did not note any significant clinical signs (Gresser et al. 1958; Hale et al. 1957; Ilkal et al. 1994). These differences could have been due to differences in virus strain, virus dose, and the genetic background and age of the piglets.

No clinical signs of infection have been observed in pigs infected with WNV. Ilkal et al. (1994) reported that 4 pigs injected with an Asian isolate of WNV developed viremias that persisted for 1–4 days and reached a maximum titer of $10^{2.2}$ LD$_{50}$ per ml. No mention of adverse clinical effects in the piglets was made. A more recent study by Platt (2004) described experimental infection, by needle and by mosquito bite, of 26 weanling pigs with a New York 1999 WNV isolate. The mean duration of viremia was 4.2 days. The mean daily WNV titer of all pigs was $10^{3.3} \pm 0.5$ TCID$_{50}$ per ml. Some individual pigs had titers in excess of $10^{5.0}$ TCID$_{50}$ per ml. No marked clinical signs of infection were observed. Platt (2004) also reported that nonsuppurative encephalitis and spinal cord lesions were observed in some of these pigs, suggesting that clinical signs, e.g., incoordination, tremors, and paralysis, could occur. A similar study with a NY 1999 WNV strain was reported by Bowen (2003) in which 3 of 6 infected weanling pigs developed maximum WNV titers ranging from $10^{1.9}$–$10^{3.1}$ PFU per ml of serum during an average viremic period of 2.5 days. Only 1 of 6 infected young adult pigs developed a detectable titer that reached 10^1 PFU per ml and persisted for less than a day. None of the pigs developed clinical signs of infection.

PATHOGENESIS

There are no complete studies on the pathogenesis of flaviviruses in swine. However, several studies have been done using the mouse and baby hamster as models (see Burke and Monath 2001). From these studies it can be deduced that virus initially replicates in the skin and regional lymph nodes following injection of virus by mosquito bite. A primary viremia ensues, which is the source of infection for several cell types, including connective tissue, skeletal, cardiac and smooth muscle cells, lymphoreticular cells, and cells of the endocrine and exocrine system. Virus from these tissues constitutes a secondary viremia, which generally occurs within 1–2 days after infection. It is during this period that transplacental infection can occur in pregnant gilts and sows, and virus can reach the fetus by 7 days after infection. The variable mixture of normal piglets, weak neonates, stillborns, and mummified fetuses of different sizes in affected litters indicates that sequential infection of fetuses occurs in utero. These observations suggest that the pathogenesis of JEV in swine is similar to that of porcine parvovirus (Joo et al. 1976).

Whether a causal relationship exists between the level of viremia and transplacental infection remains to be determined. A study by Shimizu et al. (1954) did not find any such relationship among 9 sows that were inoculated with $10^{6.0}$–$10^{9.5}$ LD$_{50}$ with the Fuji or Kanagawa strains of JEV. Viremia persisted for 1–4 days and maximum titers in individual sows ranged from $10^{1.5}$–$10^{5.7}$ LD$_{50}$ per ml of serum. Fetal infection occurred in 4 of the 9 pregnant sows that were infected between 40 and 97 days (mean = 62 days) of gestation. The maximum virus titers in these sows ranged from $10^{1.7}$ to greater than $10^{5.7}$ LD$_{50}$ per ml of serum. Sows in which fetuses were not infected were inoculated with virus between 36 and 92 days (mean = 85 days) of gestation and had maximum virus titers that ranged from $10^{2.1}$ to >$10^{5.7}$ LD$_{50}$ per ml. Fujisaki et al. (1982) concluded from a study using the mouse model that transplacental infection was dependent on the degree of development between placenta and fetal tissue and not on the level of viremia, since the highest rate of transplacental infection by JEV in mice occurred between days 7 and 10 of gestation.

Japanese encephalitis virus can reach the central nervous system as early as 3 days after infection by crossing the blood-brain barrier (Yamada et al. 2004), an event that is more common in neonates and the very young than in older animals. The precise mechanism by which JEV breaches the blood brain barrier has not been definitively established. Liou and Hsu (1998) demonstrated by electron microscopy that JEV could be translocated across endothelial cells in endocytotic vesicles in infected mice. Penetration of the blood brain barrier appears to be enhanced by a JEV-induced cytokine (Mathur et al. 1992).

LESIONS

Significant gross or microscopic lesions caused by JEV in sows have not been reported. The testes of naturally infected boars frequently have a large amount of mucous fluid in the cavity tunica vaginalis. Fibrous thickening along the edge of the epididymis and the visceral layer of the tunica vaginalis is also observed. Microscopically, there are edema and inflammatory changes in the interstitial tissue of the epididymis, tunica vaginalis, and testes. Degenerative changes are often seen in the seminiferous epithelium (Hashimura et al. 1976; Ogasa et al. 1977).

Gross lesions may or may not be seen in stillborn and weak neonatal pigs. When present, they may include hydrocephalus, subcutaneous edema, hydrothorax, ascites, petechial hemorrhages on serosal surfaces, congestion of lymph nodes, necrotic foci in liver and spleen, and congested meninges or spinal cord (Burns 1950). Cerebellar hypoplasia and spinal hypomyelinogenesis have also been described (Morimoto 1969). Microscopic lesions appear to be restricted to the brain and spinal cord. Diffuse nonsuppurative encephalitis and spondylitis may be observed. Yamada et al. (2004) described similar lesions in 3-week-old pigs that were experimentally infected with JEV. These lesions were distributed throughout the cerebrum, midbrain, and cerebellum. Perivascular cuffing, neuronal necrosis, neurophagia, and glial nodules were present. No other macroscopic or microscopic lesions were noted in other organ systems. Similar lesions of the central nervous system were observed in weanling pigs experimentally infected with a New York strain of WNV (Platt 2004).

DIAGNOSIS

Definitive diagnosis of reproductive disease in swine caused by JEV is based on isolating and identifying virus from fetuses, stillborns, neonates, and young piglets. Differential diagnosis must consider porcine parvovirus, porcine reproductive and respiratory syndrome virus, pseudorabies virus, classical swine fever virus, cytomegalovirus, enterovirus, Getah virus (Shibata et al. 1991), toxoplasmosis, and leptospirosis. Seasonal incidence and lack of clinical signs in infected sows and piglets are useful criteria in excluding many diseases.

Tissues from which JEV has been isolated from fetuses and neonates include brain, liver, spleen, lung, and placenta (Shimizu et al. 1954). However, it appears that successful isolation of JEV from pigs of abnormal litters is dependent on the time that pigs were exposed to the virus in utero. Shimizu et al. (1954) isolated JEV from fetuses of 3 litters that were collected 7–22 days after experimental infection of sows with the Kanagawa strain, but not from affected pigs of 2 litters that were collected 62 and 84 days after infection of sows. Susceptible cells for virus isolation include Vero cells, baby hamster kidney cells, pig kidney cells, and the C6/36 cell line derived from *Aedes albopictus*. Virus can also be isolated from infected tissue, such as brain and placenta, by intracerebral inoculation of suckling mice. Neurological signs and death usually occur in mice between 4 and 14 days after inoculation. Final confirmation of the identity of isolated virus can be made serologically using flavivirus-specific monoclonal antibodies (Broom et al. 1998) and/or by the reverse transcription-polymerase chain reaction (RT-PCR) (Huang et al. 2004).

Infection by JEV can also be confirmed by detecting viral antigen in fetal tissue and the placenta by immunohistochemistry (Iwasaki et al. 1986; Kurata et al. 1983; Yamada et al. 2004). The use of flavivirus-specific monoclonal antibodies in these procedures enhances the specificity of the test. Detection of JEV-specific antibody in body fluids of aborted fetuses, weak neonates, and piglets by hemagglutination inhibition, serum virus neutralization, and ELISA is also of diagnostic importance. In older pigs, interpretation of serological results must take vaccination history and maternal antibody into account. Maternal antibody specific for JEV can be detected in some pigs until 8 months of age (Hale et al. 1957). The use of paired serums and tests to detect JEV reactive IgM can facilitate interpretation of serological tests. Burke et al. (1985) demonstrated that porcine IgM antibodies to JEV could be detected within 2–3 days after infection and persist for 2 weeks. Interpretation of serological tests must also take into account whether affected swine could have been exposed to other flaviviruses such as WNV, because there is a high degree of serological cross reactivity between members of the Japanese encephalitis serocomplex (Williams et al. 2001). RT-PCR has also been developed to detect and differentiate JEV and WNV genomic material in clinical specimens (Kleiboeker et al. 2004; Shirato et al. 2003; Yang et al. 2004).

PREVENTION

Japanese encephalitis virus can be controlled by preventing exposure of swine to JEV-infected mosquitoes. However, this method of control is not practical unless pigs are maintained in appropriate confinement facilities. Consequently, vaccination is the method of choice. Monath (2002) reviewed the history of JE vaccine development. The first effective vaccines were formalin inactivated JEV-infected mouse brains. These vaccines were initially developed in Japan during the 1930s. Highly purified inactivated mouse brain vaccines are currently in use throughout the world in humans. Inactivated vaccines derived from infected cell cultures are in various stages of development. A live JE attenuated vaccine based on strain SA-14-2 was licensed in 1988 for human use in the Peoples Republic of China. Live vectored vaccines based on the attenuated vaccinia and canarypox viruses containing the JEV genes for prM, E, and NS1 induce both neutralizing antibodies and cytotoxic T cells.

An effective canarypox recombinant vaccine for WNV has been developed for horses (Siger et al. 2004) and is currently being marketed. A chimeric yellow fever–Japanese encephalitis vaccine virus containing the prM and E genes from the attenuated SA-14-2 strain of JEV induces protective immunity in monkeys and mice (Lai and Monath 2003). Experimental DNA vaccines containing prM and E genes of JEV and WNV have also been developed and induce protective immunity to JEV in swine (Konishi et al. 2000) and to WNV in horses (Davis et al. 2001). Live attenuated and inactivated JEV vaccines are commercially available for swine in Asia. The vaccines are available with porcine parvovirus and Getah virus. It is recommended that boars, gilts, and sows at risk be vaccinated for JEV before the mosquito season.

22 Porcine Epidemic Diarrhea

Maurice B. Pensaert and Sang-Geon Yeo

In 1971, previously unrecognized acute outbreaks of diarrhea were observed in feeder pigs and fattening swine in England (Oldham 1972). The clinical appearance was similar to transmissible gastroenteritis virus (TGEV) infection, except for the important difference that suckling pigs did not become sick. TGEV and other known enteropathogenic infectious agents were ruled out. The disease spread to other European countries and the name "epidemic viral diarrhea" (EVD) was adopted.

In 1976, TGE-like outbreaks of acute diarrhea were observed in swine of all ages, including suckling pigs (Wood 1977), but again TGEV and other known enteropathogenic agents were ruled out as the cause. The name "EVD type 2" was used to differentiate these outbreaks from the "type 1" outbreaks observed in 1971, the difference being that baby piglets were involved in type 2 outbreaks.

In 1978, a coronavirus-like agent was associated with the type 2 outbreaks (Chasey and Cartwright 1978; Pensaert and DeBouck 1978). Experimental inoculations with an isolate designated CV777 revealed its enteropathogenic character both for piglets and fattening swine (DeBouck and Pensaert 1980). It appeared that this coronavirus was involved in outbreaks of type 1 as well as of type 2, and the name "porcine epidemic diarrhea" (PED) was proposed (Pensaert et al. 1982) and is still used. The basis for the clinical difference between type 1 and type 2 outbreaks is unknown.

ETIOLOGY

On the basis of genetic and antigenic criteria, PED virus (PEDV) has been categorized in group 1 of the genus *Coronavirus* of the family *Coronaviridae*, together with TGEV, feline coronavirus, canine coronavirus, and human coronavirus 229E (Gónzales et al. 2003; Utiger et al. 1995a). Immunoblotting and immunoprecipitation assays showed that PEDV shares common antigenic determinants with feline coronavirus and that these are located in the N protein (Yaling et al. 1988). The entire genome of CV777 has been sequenced and determined to contain 28,033 nucleotides. Based on the amino acid sequence of the replicase gene, PEDV is considered most closely related to human coronavirus 229E and TGEV (Kocherhans et al. 2001). Sequence determination of the N protein gene confirmed that PEDV holds an intermediate position between 229E and TGEV (Bridgen et al. 1993).

The pattern of the structural proteins of PEDV is similar to that of other coronaviruses. The virus possesses a glycosylated peplomer (spike, S) protein with a molecular weight of 180,000–200,000 daltons, a glycosylated membrane (M) protein of 27,000–32,000 daltons, and an unglycosylated RNA-binding nucleocapsid (N) protein of 57,000 to 58,000 daltons (Duarte and Laude 1994; Egberink et al. 1988; Knuchel et al. 1992; Utiger et al. 1995a, 1995b).

PEDV particles show characteristics of the family *Coronaviridae* (Chasey and Cartwright 1978; Pensaert and DeBouck 1978). The morphogenesis of PEDV in intestinal epithelial cells is identical to that of other coronaviruses. Assembly of the virus occurs by budding through intracytoplasmic membranes (Ducatelle et al. 1981b; Sueyoshi et al. 1995). The particles detected in fecal material are pleomorphic, with a tendency to a spherical shape. Their mean diameter, projections included, is 130 nm, with a range of 95–190 nm. Many particles have an electron-opaque central area. The club-shaped projections measure 18–23 nm and are radially spaced from the core.

Physicochemical characterization has shown that the virus is ether- and chloroform-sensitive. Its density in sucrose is 1.18 g/ml. Cell culture-adapted PEDV loses its infectivity when heated to ≥60°C for 30 minutes, but it is moderately stable at 50°C. The virus is stable between pH 4.0 and 9.0 at 4°C and between pH 6.5 and 7.5 at 37°C (Callebaut and DeBouck 1981; Lee and Yeo 2003a). The virus shows no hemagglutinating activity (Callebaut and DeBouck 1981).

There is no evidence of the existence of more than

one PEDV serotype. Polypeptide bands of a Korean isolate showed molecular weights similar to those of the prototype CV777 strain (Kweon et al. 1993). Genetic comparisons showed 96.5% homology of the N open reading frame (ORF) and 96.8% amino acid identity of the N protein between the Korean (Chinju99) and Belgian (CV777) isolates (Lee and Yeo 2003b). The entire S gene of the Korean strain showed 94.5% homology at the nucleotide level and 92.8% at the amino acid level (Yeo et al. 2003). Likewise, nucleotide sequences of the N gene of a Korean and two Japanese isolates were found to be almost identical (Kubota et al. 1999).

Propagation of PEDV was originally accomplished by orally inoculating piglets (DeBouck and Pensaert 1980). The adaptation of PEDV to laboratory conditions has been difficult. Numerous cell types were tested, but without success. Vero (African green monkey kidney) cells were later found to support the serial propagation of PEDV. Viral growth depends on the presence of trypsin in the cell culture medium. Cytopathic effects consist of vacuolation and formation of syncytia with up to 100 nuclei. Growth kinetics show virus titers peak at about $10^{5.5}$ plaque-forming units per ml 15 hours after inoculation (Hofmann and Wyler 1988, 1989; Lee and Yeo 2003a). PEDV was successfully grown in porcine bladder and kidney cells in Japan (Shibata et al. 2000). A Japanese isolate (P-5V) used as a vaccine strain was cultivated in swine cell lines KSEK6 and IB-RS2 (Kadoi et al. 2002).

EPIDEMIOLOGY

From 1982 to 1990, antibodies to PEDV were detected in swine populations in Belgium, England, Germany, France, the Netherlands, Switzerland, Bulgaria, and Taiwan (DeBouck et al. 1982; Hofmann and Wyler 1987; Möstl et al. 1990). In the northeastern part of India, 21.2% of 528 serum samples from pigs 2–6 months of age were positive for PEDV antibodies (Barman et al. 2003). The virus has been isolated in most swine-raising countries in Europe, as well as China (Qinghua et al. 1992), Korea (Kweon et al. 1993), and Japan (Takahashi et al. 1983). There are no reports of PEDV in North or South America.

In Europe, outbreaks of PED have become rare and there are few recent reports of serologic surveys or diagnostic studies.

In Belgium, a study was performed in 10 groups of multisource feeder pigs entering a fattening unit in September 1991, and none seroconverted. In contrast, the pigs in another 7 groups entering in February 1992 developed diarrhea and seroconverted to PEDV 4 weeks after arrival (Van Reeth and Pensaert 1994). Also in Belgium, a serological study on fattening farms showed 50% positive in 1990 and none in 1997, indicating that virus prevalence has markedly decreased in recent years (Pensaert and Van Reeth 1998).

In Spain, PED was identified as the cause of an epi-

demic of watery diarrhea in 7 of 15 farms, with the diarrhea becoming persistent in a small number of sows on one farm (Carvajal et al. 1995a). In a Spanish serosurvey conducted in 1992–1993, PEDV-specific antibodies were detected in 1,513 of 5,052 sows and positive animals were found in 55.0% of 803 breeding farms. (Carvajal et al. 1995c).

In the Netherlands, a clinical and virological study of an acute outbreak of PED in a herd with both breeding and finishing pigs was described (Pijpers et al. 1993). Diarrhea was most severe in fattening pigs and pregnant sows, and was mild or absent in suckling pigs and young weaners. The virus became endemic and persisted in 6–10-week-old pigs and in gilts newly introduced to the farm for at least 1.5 years after the original outbreak.

In Britain, a clinical PED outbreak was described in 1998 in 3 consecutive batches of 8–15-week-old pigs in a finishing herd over a 2-month period (Pritchard et al. 1999). In Hungary, 92 diarrhea samples from weaned pigs on 19 farms were examined in 1995 and 5.5% were positive for PEDV, with PED considered the most important cause of postweaning diarrhea (Nagy et al. 1996). In the Czech Republic, 27 of 219 fecal samples from diarrheic pigs less than 21 days old were positive for PEDV, often in combination with other enteric viruses (Rodák et al. 2004).

Distinct from the current situation in Europe, severe outbreaks of diarrhea with high mortality have been reported in Asia. These outbreaks are acute and so severe that they cannot be differentiated clinically from typical acute TGEV outbreaks.

In Japan, outbreaks between September 1993 and June 1994 resulted in 14,000 deaths, with mortality ranging from 30–100% in suckling pigs. During these epidemics, adult pigs showed only a transient inappetence with decreased milk production in sows (Sueyoshi et al. 1995). In the winter of 1996, a PED epidemic occurred in Japan on 108 farms, most of which were farrow-to-finish. Diarrhea was encountered in baby piglets and 39,509 of 56,256 died.

In Korea, PED has caused several outbreaks of diarrhea in swine of all ages. Of 71 viral enteric cases requested for diagnosis at the Veterinary Research Institute between January 1992 and December 1993, 56.3% were identified as PED. Piglets less than 10 days old were involved in 90% of the outbreaks (Hwang et al. 1994). Between August 1997 and July 1999, 50.4% of 1,258 enteric cases in 5 provinces were diagnosed as PED (Chae et al. 2000). A 1994 abattoir serosurvey in Korea of 469 sera from pigs in 7 provinces found seroprevalences of 17.6–79% (mean of 45%), suggesting that the virus had become endemic in some areas (Kweon et al. 1994).

There are suggestions that the PED situation in Asia has recently evolved to reflect a more endemic pattern of disease in a partially immune sow population.

Fecal-oral transmission is probably the primary, if not the only means of transmitting PEDV. Acute out-

breaks of PED on susceptible farms often occur 4–5 days after sale or purchase of pigs. The virus probably enters via infected pigs or on virus-contaminated fomites (trucks, boots, etc.). PEDV does not differ markedly from TGEV with regard to modes of transmission, but it appears to persist more easily on a farm once the acute infection has passed. After an outbreak has occurred on a breeding farm, the virus may either be eliminated from the herd or become endemic. An endemic cycle can be established if enough litters of pigs are produced and weaned so as to maintain virus circulation through infection of consecutive litters that have lost their lactogenic immunity at weaning. PEDV may be a cause of persistent postweaning diarrhea on such farms.

CLINICAL SIGNS

The main, and often the only, obvious clinical sign of PED is watery diarrhea. Outbreaks in susceptible breeding herds may show marked variation in morbidity and mortality. On some farms, pigs of all ages become sick, with morbidity approaching 100%. The disease is then very similar to TGE, except for a slower spread and a somewhat lower mortality in baby piglets. Piglets up to 1 week of age may die from dehydration after the diarrhea has lasted 3–4 days. Piglet mortality averages 50%, but may be as high as 100%. Older pigs recover after about 1 week. After the acute outbreak, diarrhea may be seen in pigs 2–3 weeks after weaning, and newly introduced pigs may routinely become sick. In recent years, typical acute outbreaks with high mortality in neonatal pigs are rare in Europe, but have been described in Japan and Korea (Chae et al. 2000; Sueyoshi et al. 1995).

When an acute PED outbreak occurs in multisource feeder pigs or during the fattening period, all the pigs in the unit will show diarrhea within a week. Animals are somewhat anorectic, depressed, and their feces are watery. Clinical PEDV infection towards the end of the fattening period may be more severe than TGEV. The animals appear to have more abdominal pain. As a rule, animals recover in 7–10 days. Mortality of 1–3% may be seen in such fattening pigs and they die acutely, usually in the early stages of diarrhea or even prior to the appearance of diarrhea. A common necropsy finding in these animals is acute necrosis of the back muscle. The highest mortality is found on farms with stress-sensitive pig breeds.

Compared to TGEV, PEDV spreads more slowly between the different units on closed breeding and finishing farms. It may take 4–6 weeks for the virus to infect different groups, and some units may even remain free of infection.

PATHOGENESIS

The pathogenesis of PED has been studied in hysterectomy-derived, colostrum-deprived piglets. Piglets were orally inoculated with the CV777 isolate at the age of 3 days (DeBouck et al. 1981b) and became sick 22–36 hours after inoculation. Viral replication, as demonstrated by immunofluorescence (IF) and transmission electron microscopy (EM), occurred in the cytoplasm of villous epithelial cells throughout the small intestine and also in the colon. Infected epithelial cells were observed as early as 12–18 hours postinoculation, with maximum involvement reached at 24–36 hours. Viral replication in the small intestine resulted in cell degeneration leading to villous shortening. A reduction in the villous height:crypt depth ratio from the normal 7:1 value to 3:1 was observed. No cell degeneration was seen in the infected colonic epithelial cells.

The pathogenic features of PEDV in the small intestine of piglets are very similar to those of TGEV. Since viral replication and progress of the infection in the small intestine with PEDV occurs at a somewhat slower rate, a longer incubation period is observed.

PEDV replication in piglets has not been detected in cells outside the intestinal tract. Shibata et al. (2000) showed that SPF pigs, inoculated with field PEDV between the age of 2 days to 12 weeks, developed age-dependent resistance and deaths occurred only in 2- and 7-day-old pigs.

The pathogenesis of PEDV in older swine has not been studied in detail, but fluorescence was found in the epithelial cells of the small intestinal and colonic villi of conventional fattening swine both after experimental and natural infection (DeBouck and Pensaert 1980). It is not clear how much the colonic infection adds to the severity of clinical signs. Also, no pathogenic explanation can be given for the sudden death with acute back muscle necrosis sometimes observed in finishing pigs and adult pigs.

Pathogenic features described in Korea and Japan are identical to those observed in Europe, except there is no evidence of viral replication in the colon by the Asian strains (Hwang et al. 1994; Kim and Chae 2003; Sueyoshi et al. 1995), and sudden deaths in fatteners have not been reported.

LESIONS

Lesions have been described both in experimentally infected and naturally infected piglets (Ducatelle et al. 1982a,b; Hwang et al. 1994; Pospischil et al. 1981; Sueyoshi et al. 1995).

Lesions are confined to the small intestine, which is distended with yellow fluid. Microscopically, vacuolation and exfoliation of enterocytes occur on the small-intestinal villi starting at 24 hours postinoculation and coinciding with the onset of diarrhea. From that time on, the villi rapidly shorten and enzymatic activity becomes markedly reduced. These findings were confirmed by scanning EM (Ducatelle et al. 1981a). This pathology is very similar to that described for TGEV. No

histopathologic changes have been observed in the colon.

Ultrastructural changes were first observed in the cytoplasm of enterocytes in which cell organelles had decreased, leaving electron translucent areas. Later, the microvilli and terminal web disappeared and parts of the cytoplasm protruded into the intestinal lumen. The cells became flattened, the tight junction was lost, and cell release occurred into the gut lumen. Intracellular virus formation was seen by budding through membranes of the endoplasmic reticulum (Ducatelle et al. 1981b; Horvath and Moscari 1981; Pospischil et al. 1981). In the colon, some cellular changes were observed in enterocytes containing virus particles, but no exfoliation was seen.

DIAGNOSIS

A diagnosis of PED cannot be made solely on the basis of clinical signs. Acute PED outbreaks involving pigs of all ages cannot be clinically differentiated from TGE. In Europe, outbreaks may appear as rapidly spreading, watery diarrhea in weaned pigs and older animals on the breeding farm, but without clinical signs in baby piglets.

An etiologic diagnosis can be made by direct demonstration of PEDV and/or its antigens or by detection of antibodies. A direct IF test and an immunohistochemical technique applied on sections of the small intestine of baby pigs are the most sensitive, rapid, and reliable methods. However, they can only be used on the intestines of pigs sacrificed during the acute phase of diarrhea, preferably within 2 days of onset. These techniques are often not reliable on pigs that die naturally, because of loss of enterocytes (Bernasconi et al. 1995; DeBouck et al. 1981a; Guscetti et al. 1998; Sueyoshi et al. 1995).

PEDV particles can be demonstrated in the feces of pigs by direct EM, although the virus particles are not easy to detect if the spikes on the virion are lost or not clearly visible. The highest percentage of positive fecal samples obtained from experimentally inoculated piglets was 73% in feces collected on the first day after the onset of diarrhea. Furthermore, immunoelectron microscopy has to be applied to differentiate PEDV from TGEV, since both viruses have the same morphology.

Isolation of field strains of PEDV in cell cultures from feces may need subpassages before cytopathology appears in Vero cells or in other cell types, but early detection can be done by IF (Hofmann and Wyler 1988; Shibata et al. 2000).

A number of ELISA techniques have been developed for detection of PEDV antigens in feces as well as for demonstration of specific antibodies in serum. They are sensitive and reliable for diagnosis, particularly on a group basis. For the antigen ELISAs, polyclonal and monoclonal antibodies were used with pig-cultivated virus (Callebaut et al. 1982; Carvajal et al. 1995a; van Nieuwstadt and Zetstra 1991). For the antibody ELISA,

antigen consists of semipurified virus, either pig- or cell-cultivated (Callebaut et al. 1982; Carvajal et al. 1995b; Kweon et al. 1994), or S and N viral proteins extracted from infected Vero cells (Knuchel et al. 1992). The antibody test has also been used for detection of immunoglobulins in sow's milk (de Arriba et al. 1995).

PEDV antigens can be demonstrated in rectal swabs from 3–11 days after experimental inoculation, with peak excretion being at 4–5 days (Carvajal et al. 1995a). Fecal material should be collected from several pigs, preferably during the acute phase of diarrhea. If proper and sufficient fecal samples are collected, the ELISA antigen test is of reliable sensitivity to detect the virus in pigs with endemic weaning diarrhea on breeding farms.

Other diagnostic tests for detection of PEDV in fecal material include reverse transcription-polymerase chain reaction (RT-PCR) (Ishikawa et al. 1997; Kubota et al. 1999) and in situ hybridization (Kim and Chae 2000). An RT-PCR was established for differential detection of TGEV and PEDV in intestines and stool samples of sick pigs (Kim et al. 2001).

Specific antibodies can be detected in sera from swine after natural or experimental infection with PEDV using ELISA, blocking ELISA, indirect IF, blocking IF, and seroneutralization in Vero cell cultures (Callebaut et al. 1982; Hofmann and Wyler 1989, 1990; Prager and Witte 1981; Shibata et al. 2000; Witte and Prager 1987). Demonstration of PEDV antibodies can be performed using the indirect IF test and the blocking IF test on PEDV-positive cryostat sections of pig intestine or on cell culture. Antibodies detected by blocking ELISA appear at 7 days postinoculation (Carvajal et al. 1995b). With all these tests, paired serum samples should be examined. The convalescent serum sample should be collected no sooner than 2 weeks after the onset of diarrhea.

PREVENTION AND CONTROL

Suckling pigs suffering from PED should have free access to water to diminish dehydration. In fattening swine, it is advisable to withhold feed. Since PEDV does not spread very quickly, preventive measures to temporarily prevent virus entrance into farrowing units with newly born piglets may be of help. Postponing the infection in these piglets until a later age may result in fewer deaths. Concurrently, exposure of pregnant sows to virus-contaminated feces or intestines will stimulate lactogenic immunity and shorten the outbreak on the farm. This approach is similar to that used with TGEV.

If the virus cycles in consecutive litters of weaned piglets, virus elimination can be attempted by removing pigs immediately after weaning to another site for at least 4 weeks. Simultaneously, introduction of new pigs should be stopped temporarily.

Oral administration of chicken egg yolk or cow colostrum containing PEDV immunoglobulins to neo-

natal pigs showed immunoprophylactic effect by preventing disease or reducing mortality (Kweon et al. 2000; Shibata et al. 2001).

In Europe, the disease is of insufficient economic importance to develop a vaccine. However, outbreaks in Asia have been so severe that attenuated virus vaccines are being developed.

Bernasconi et al. (1995) reported that cell culture adaptation of the CV777 virus made it strikingly different with regard to genomic sequences. Furthermore, the virulence of this cell culture-adapted virus was much lower for newborn cesarean-derived piglets and histopathological changes were decreased in severity. The Korean KPEDV-9 strain, when passaged 93 times in Vero cells, showed a reduction in pathogenicity for neonatal pigs and was found to be safe for pregnant sows. For that reason, the use of a cell culture-adapted virus as a vaccine has been proposed (Kweon et al. 1999), although its efficacy in the field needs to be determined. In Japan, a commercial, attenuated, live virus vaccine of cell-adapted PEDV (P-5V) has been used for prophylaxis in sows since 1997. The vaccine is considered efficacious, but not all sows develop solid lactogenic immunity (Usami et al. 1998).

23 Porcine Parvovirus

William L. Mengeling

Porcine parvovirus (PPV) causes reproductive failure of swine characterized by embryonic and fetal infection and death, usually in the absence of outward maternal clinical signs. The disease develops mainly when seronegative dams are exposed oronasally to the virus any time during about the first half of gestation, and conceptuses are subsequently infected transplacentally before they become immunocompetent. Porcine parvovirus is ubiquitous among swine throughout the world and is endemic in most herds that have been tested. Diagnostic surveys have indicated that PPV is the major infectious cause of embryonic and fetal death (Cartwright and Huck 1967; Mengeling 1978b; Mengeling et al. 1991; Thacker and Leman 1978; Vannier and Tillon 1979). In addition to its direct causal role in reproductive failure, PPV can potentiate the effects of porcine circovirus type II (PCV2) infection in the clinical course of postweaning multisystemic wasting syndrome (PMWS) (Krakowka et al. 2000; Opriessnig et al. 2004).

ETIOLOGY

PPV is classified in the genus *Parvovirus* (Latin *parvus* = small) of the family *Parvoviridae* (Bachmann et al. 1979; Siegl 1976). All isolates of PPV that have been compared are antigenically similar, if not identical (Cartwright et al. 1969; Johnson and Collings 1969; Johnson et al. 1976; Morimoto et al. 1972a; Ruckerbauer et al. 1978). PPV is also antigenically related to several other members of the genus (Cotmore et al. 1983; Mengeling et al. 1986, 1988). However, its identity can be established by relatively stringent serologic tests such as virus neutralization (VN) and hemagglutination inhibition (HI).

The biophysical and biochemical properties of PPV have been extensively studied (Berns 1984; Molitor et al. 1983; Siegl 1976) and are summarized as follows. A mature virion has cubic symmetry, two or three capsid proteins, a diameter of approximately 20 nm, 32 capsomeres, no envelope or essential lipids, and a weight of 5.3×10^6 daltons. The viral genome is single-stranded deoxyribonucleic acid (DNA) with a molecular weight of 1.4×10^6 (i.e., about 26.5% of the weight of the complete virion). Buoyant densities (g/ml in cesium chloride) of complete infectious virions, incomplete "empty" virions, and extracted virion DNA are 1.38–1.395, 1.30–1.315, and 1.724, respectively. Viral infectivity, hemagglutinating activity, and antigenicity are remarkably resistant to heat, a wide range of hydrogen ion concentrations, and enzymes.

Replication

Replication of PPV in vitro is cytocidal and characterized by "rounding up," pyknosis, and lysis of cells (Figure 23.1A). Many of the cell fragments often remain attached, eventually giving the affected culture a ragged appearance. Intranuclear inclusions develop (Cartwright et al. 1969) but they are often sparsely distributed (Rondhuis and Straver 1972). Infected cultures may hemadsorb slightly (Cartwright et al. 1969) (Figure 23.1B). Cytopathic changes are extensive when cell culture-adapted virus is propagated under appropriate conditions. However, on initial isolation, several serial passages of the virus (Cartwright et al. 1969) or, better, the infected culture may be necessary before the effects are recognized. The use of immunofluorescence (IF) microscopy greatly increases the likelihood of detecting minimally infected cultures (Lucas and Napthine 1971; Mengeling 1975).

Primary and secondary cultures of fetal or neonatal porcine kidney cells are most often used for propagation and titration of PPV, although other kinds of cultures are also susceptible (Pirtle 1974). Replication is enhanced by infection of mitotically active cultures (Bachmann 1972; Cartwright et al. 1969; Hallauer et al. 1972; Mayr et al. 1968). Many cells in such cultures are in the S phase (i.e., the DNA synthesis phase) of their cell cycle, wherein the DNA polymerases of cell origin needed for viral replication are available (Siegl and Gautschi 1973a, b; Tennant 1971).

If either fetal or adult bovine serum is incorporated
23.1. Cell cultures infected with PPV. (A) Cytopathic effect, secondary fetal porcine kidney cells, 120 hours after infection (×250) (Mengeling, 1972). (B) Hemadsorption, secondary adult porcine thyroid cells, guinea pig erythrocytes, 22 hours after thyroid cells were infected and then subcultured (May-Grünwald-Giemsa; ×100).

in the nutrient medium of cell cultures used to propagate PPV, it should be pretested for viral inhibitors (Coackley and Smith 1972; Johnson 1973; Pini 1975). The same may apply to sera of several other species (Joo et al. 1976d). Because replication of PPV is affected by mitotic activity, the effect of the serum on the cells is also especially important. In addition, cultures should be pretested for PPV contamination (Lucas and Napthine 1971; Mengeling 1975). Cultures are sometimes unknowingly prepared from infected tissues of fetal (Mengeling 1975) and postnatal (Bachmann 1969; Cartwright et al. 1969; Hafez and Liess 1979; Huygelen and Peetermans 1967) pigs. Moreover, PPV can be accidentally introduced into cultures in several ways (Hallauer et al. 1971), including the use of contaminated trypsin (Croghan and Matchett 1973; Croghan et al. 1973). If contamination is detected before all cells are infected, the virus can be eliminated by repeatedly subculturing the cells in the presence of nutrient medium containing PPV antiserum (Mengeling 1978a).

Several investigators have used immunofluorescence microscopy to follow the development of PPV in cell culture (Bachmann and Danner 1976; Cartwright et al. 1969; Lucas and Napthine 1971; Mengeling 1972; Siegl et al. 1972). In general, the sequence of events is as follows. Viral antigen is detected in the cytoplasm of cells soon after infection if the inoculum contains a high titer of virus and viral antigen. Most, if not all, of this early cytoplasmic fluorescence is the result of antigen phagocytized from the inoculum (Mengeling 1972; Mengeling and Cutlip 1975). By sequential examinations, such antigen can be demonstrated first on the external surface of the cytoplasmic membrane and later within the cytoplasm, often relatively concentrated in a juxtanuclear location. The first unequivocal evidence of viral replication is the appearance of nascent viral antigen in the nucleus (Figure 23.2A). In at least some infected cells, nascent antigen next appears in the cytoplasm in sufficient quantity that both cytoplasm and nucleus are brightly fluorescent. The infected cells commonly seen in the lungs of fetuses that develop a high titer of antibody for PPV probably represent this stage of replication (see Figure 23.8C). Affected cells subsequently round up, become pyknotic, and disintegrate with release of virus and viral antigen (Figure 23.2B). Other cells in the culture that are not at the appropriate stage to support viral replication continue to phagocytize and accumulate viral antigen in their cytoplasm (Figure 23.2C). A second wave of viral replication can be induced if these cells are stimulated to enter the S phase of the cell cycle as, for example, by the addition of fresh culture medium.

Hemagglutination

PPV agglutinates human, monkey, guinea pig, cat, chicken, rat, and mouse erythrocytes. Erythrocytes from other animal species that have been tested are relatively or completely insensitive, or the results have been equivocal (Cartwright et al. 1969; Darbyshire and Roberts 1968; Hallauer et al. 1972; Mayr et al. 1968; Mengeling 1972; Morimoto et al. 1972a). Several parameters of the hemagglutination (HA) test—such as the temperature of incubation (Mayr et al. 1968; Mengeling 1972), the species of erythrocyte used, and in the case of chicken erythrocytes the genetic composition (Cartwright et al. 1969; Pini 1975; Ruckerbauer et al. 1978) and age (Morimoto et al. 1972a) of the donor—may quantitatively affect results. The HA test is most commonly conducted at room temperature, at approximately neutral pH, and with guinea pig erythrocytes.
23.2. *Secondary cultures of fetal porcine kidney cells infected with PPV and examined by IF microscopy (×500). (A) 14 hours after infection, culture fixed and then reacted with fluorescent antibodies (FA). (B) 24 hours after infection, culture reacted with FA and then fixed; only extracellular antigen and antigen in cells with disrupted cytoplasmic and nuclear membranes are identified. (C) 48 hours after infection, culture fixed and then reacted with FA.*

Higher HA titers have been recorded when the diluent used in the test was veronal buffer rather than phosphate-buffered saline (Ruckerbauer et al. 1978). Elution of virus (the hemagglutinin is part of the virion) can be induced by suspending erythrocytes in alkaline buffer, pH 9 (Hallauer et al. 1972).

Infectivity Titrations

Infectivity titrations are conducted in a standard manner except that, because cytopathic changes at terminal dilutions are often vague, endpoints of infectivity are often determined either by examining cell cultures for intranuclear inclusions after appropriate staining or by examining cell culture medium for viral hemagglutinin (Cartwright et al. 1969). A titration procedure wherein infected cells are made evident by IF microscopy (Mengeling 1972) and a plaque assay (Kawamura et al. 1988) also have been described.

EPIDEMIOLOGY

Porcine parvovirus is ubiquitous among swine throughout the world. The most common routes of infection for postnatal and prenatal pigs are oronasal and transplacental, respectively.

In major swine-producing areas, infection is endemic in most herds and, with few exceptions, sows are immune. A large proportion of gilts are naturally infected with PPV before they conceive and develop an active immunity that probably persists throughout life. Collectively, the seroepidemiologic data indicate that exposure to PPV is common and that gilts that have not developed immunity before conception are at a high risk of infection and reproductive disease.

Pigs nursing immune dams absorb a high titer of an-

tibody for PPV from colostrum. Passively acquired serum antibody titers decrease progressively with time; both by dilution as pigs grow, as well as by biological degradation. Serum antibody titers usually decline to undetectable levels in 3–6 months, if sera are examined by the HI test (Etoh et al. 1979; Paul et al. 1982), but may persist for a longer interval. Levels of antibody too low to be detected by the HI test may be detected by the VN test (Johnson et al. 1976).

The primary significance of passively acquired antibody is that it interferes with the development of active immunity. High antibody levels can prevent infection and lower levels can minimize dissemination from infected pigs (Paul et al. 1980; Suzuki and Fujisaki 1976). Consequently, some groups of gilts are not fully susceptible to infection and dissemination of virus until either shortly before conception or during early gestation.

Contaminated premises are probably major reservoirs of PPV. The virus is thermostable, resistant to many common disinfectants (Brown 1981), and may remain infectious for months in secretions and excretions from acutely infected pigs. Experimentally, it was shown that pigs transmitted PPV for only about 2 weeks after exposure, but the pens in which they were initially kept remained infectious for at least 4 months (Mengeling and Paul 1986).

The ubiquity of PPV also raises the possibility that some pigs are persistently infected and, at least periodically, shed virus. Shedding beyond the interval of acute infection has not been demonstrated (Johnson et al. 1976), but the possibility of immunotolerant carriers of PPV as a result of early in utero infection has been suggested (Johnson 1973). When gilts were infected with PPV before day 55 of gestation, their pigs were born infected, but without antibody. Virus was isolated from

kidneys, testicles, and seminal fluid of such pigs killed at various times after birth up to 8 months of age, at which time the experiment was terminated (Johnson and Collings 1971). Likewise, a study in which dams were infected early in gestation and their pigs were born infected, but without antibody, also suggested immunotolerance (Cartwright et al. 1971). A possible example of an infected, immunotolerant, sexually active boar was reported (Johnson et al. 1976).

Boars may play a significant role in dissemination of PPV at a critical time. During acute infection, the virus is shed by various routes, including semen. The isolation of PPV from semen of naturally infected boars has been reported (Cartwright and Huck 1967; Cartwright et al. 1969; McAdaragh and Anderson 1975). Semen may also become contaminated externally, as for example with feces containing virus, or within the male reproductive tract. For example, PPV was isolated from the testicle of a boar 5 days after it was injected into the boar's prepuce (Lucas et al. 1974) and from testicles of boars killed 5 and 8 days after they were infected oronasally (Mengeling, unpublished data, 1976). Virus was also isolated from scrotal lymph nodes of boars killed 5, 8, 15, 21, and 35 days after oronasal exposure. After day 8, isolation was accomplished by cocultivating lymph node fragments with fetal porcine kidney cells (Mengeling, unpublished data, 1976). Irrespective of their immune status, boars can also function as a vector for mechanical dissemination of PPV among susceptible females.

CLINICAL SIGNS

Acute infection of postnatal pigs, including pregnant dams that subsequently develop reproductive failure, is usually subclinical (Cutlip and Mengeling 1975a; Fujisaki et al. 1975; Johnson and Collings 1969; Johnson et al. 1976; Joo et al. 1976a; Mengeling and Cutlip 1976). However, in young pigs, and probably in older breeding stock as well, the virus replicates extensively and is found in many tissues and organs with a high mitotic index. Viral antigen is especially concentrated in lymphoid tissues (Cutlip and Mengeling 1975a; Fujisaki et al. 1975) (Figure 23.3A, B).

Many pigs, irrespective of age or sex, have a transient, usually mild, leukopenia sometime within 10 days after initial exposure to the virus (Johnson and Collings 1969, 1971; Joo et al. 1976a; Mengeling and Cutlip 1976). PPV and other structurally similar viruses have been identified in the feces of pigs with diarrhea (Dea et al. 1985; Yasuhara et al. 1989). However, there is no experimental evidence to suggest that PPV either replicates extensively in the intestinal crypt epithelium or causes enteric disease, as do parvoviruses of several other species (Brown et al. 1980; Cutlip and Mengeling 1975a). PPV also has been isolated from pigs with lesions described as "vesicle-like." The etiologic role of PPV in such lesions has not been clearly defined (Kresse et al. 1985).

The major and usually only clinical response to infection with PPV is maternal reproductive failure. Pathologic sequelae depend mainly on when exposure occurs during gestation. Dams may return to estrus, fail to farrow despite being anestrus, farrow few pigs per litter, or farrow a large proportion of mummified fetuses. All can reflect embryonic or fetal death or both. The only outward sign in the dam may be a decrease in maternal abdominal girth when fetuses die at midgestation or later and their associated fluids are resorbed. Other manifestations of maternal reproductive failure—e.g., infertility, abortion, stillbirth, neonatal death, and re-
23.3. *Cryostat-microtome sections of tissues from PPV-infected 8-week-old pigs, examined by IF microscopy (×312.5). (A) Viral antigen in germinal center, tonsil. (B) Viral antigen in osteogenic layer of periosteum, rib: a = connective tissue, b = cortical bone, c = marrow cavity.*

duced neonatal vitality, have also been ascribed to infection with PPV (Cartwright and Huck 1967; Forman et al. 1977; Johnson 1969; Morimoto et al. 1972b; Narita et al. 1975). These are normally only a minor component of the disease. The presence of mummified fetuses in a litter can prolong both gestation (Narita et al. 1975) and the farrowing interval (Mengeling et al. 1975). Either may result in stillbirth of apparently normal littermates, whether or not they are infected.

There is no evidence that either fertility or libido of boars is altered by infection with PPV (Biront and Bonte 1983; Thacker et al. 1987).

PATHOGENESIS

Dams are susceptible to PPV-induced reproductive failure if infected anytime during about the first half of gestation. This interval of maternal susceptibility is indicated by the collective results of several experimental studies (Joo et al. 1976a; Mengeling 1979; Mengeling and Cutlip 1976; Mengeling et al. 1980a), by in-depth epidemiological investigations (Donaldson-Wood et al. 1977; Gillick 1977), and by estimates of the time of death of fetuses collected during epidemiological surveys (Mengeling 1978b; Mengeling et al. 1991). Consequences of maternal infection during this interval are embryonic and fetal death followed by resorption and mummification, respectively. Transplacental infection also follows maternal exposure after midgestation, but fetuses usually survive without obvious clinical effects in utero. The likely reason is that transplacental infection often requires 10–14 days (Mengeling et al. 1978, 1980a) or longer (Joo et al. 1976a), and by 70 days of gestation most fetuses are able to develop a protective immunologic response to the virus. In general, fetuses experimentally infected by transuterine inoculation of the virus died if infected before day 70 of gestation, but they have survived and produced antibody when infected later in gestation (Bachmann et al. 1975; Cutlip and Mengeling 1975b; Mengeling and Cutlip 1975; Redman et al. 1974). A strain of PPV of slightly greater virulence also has been reported (Choi et al. 1987). The usual consequences of infection at different stages of gestation are summarized in Table 23.1.

When only part of a litter is infected transplacentally, as is often the case, one or more littermates are fre-

quently infected by subsequent intrauterine spread of virus. The same would apply if initial infection were through contaminated semen. As a result, any combination or all of the sequelae indicated in Table 23.1 can develop in the same litter. Intrauterine dissemination is probably less common when early embryos are infected because they are quickly resorbed after death, effectively removing the intrauterine reservoir of virus (Mengeling et al. 1980a). In such cases there is no evidence at farrowing for the cause of fewer pigs per litter.

The effect, if any, of PPV on the ovum before ovulation is unknown. The virus adheres tenaciously to the external surface of the zona pellucida of the fertilized porcine ovum (Wrathall and Mengeling 1979a,b), and although it apparently cannot penetrate this layer, speculation is that it could pose a threat to the embryo after hatching (Wrathall and Mengeling 1979a).

Despite strong circumstantial evidence (Cartwright et al. 1971), a direct causal role of PPV-contaminated semen in reproductive failure has not been unequivocally established (Lucas et al. 1974). The zona pellucida could protect the early embryo while local immunity is developing. Conversely, the virus may cause uterine changes incompatible with gestation (Wrathall and Mengeling 1979c). In any event, a female infected through semen provides a focus of infection for others.

With the possible exception of the uterine changes alluded to in the preceding paragraph, PPV-induced reproductive failure is caused by the direct effect of the virus on the conceptus. In the absence of an immune response, the virus replicates extensively throughout these tissues. By the time the conceptus dies, most of its cells contain large quantities of intracytoplasmic viral antigen that can be demonstrated by IF microscopy. The relative lack of nuclear fluorescence at the time of death, compared to earlier stages of the disease, indicates that when the conceptus is severely affected, mitotic activity and the associated conditions necessary for viral replication are suppressed more than phagocytic activity.

Death of the conceptus probably results from the collective damage by the virus to a variety of tissues and organs, including the placenta (Cutlip and Mengeling 1975b). However, in the absence of an immune response, changes in almost any vital organ are probably sufficient to eventually cause death. One of the most striking features of viral distribution is the extensive in-

Table 23.1. Consequences of infection with PPV at different intervals of gestation

Infection of Dam	Interval of Gestation (days)[a] Infection of Conceptus[b]	Description of Conceptus	Consequences of Infection
≤56	10–30	Embryo	Death and resorption
	30–70	Fetus	Death and mummification
>56	70–term	Fetus	Immune response and usually survival in utero

volvement of endothelium. This seems to preclude further development of the vascular network of the conceptus. Preparation for cellular mitosis (i.e., the S phase) results in concomitant viral replication and cell death. Damage to the fetal circulatory system is indicated by edema, hemorrhage, and the accumulation of large amounts of serosanguineous fluids in body cavities. Necrosis of the endothelium is microscopically evident (Lenghaus et al. 1978).

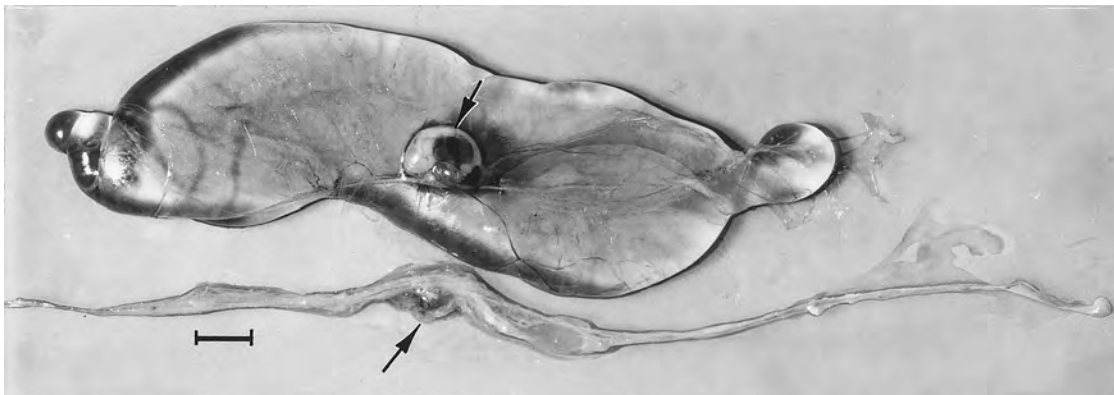
The mechanism of transplacental infection has been investigated by IF microscopy to identify infected cells in maternal and fetal tissues at progressively longer intervals after maternal oronasal exposure (Mengeling et al. 1978). Examination of tissues contiguous with the maternal-fetal junction revealed viral antigen in endothelial and mesenchymal cells of the chorion, with increasing involvement of these tissues at progressively later stages of gestation. Viral antigen was never detected unequivocally in either uterine epithelium or trophectoderm. Consequently, there was no evidence for maternal-fetal transfer of the virus by replicating through these tissues. However, this route cannot be excluded, since only a small part of the total area of contact was examined. Transfer of the virus within macrophages has also been considered (Paul et al. 1979). Whatever the route, maternal viremia seems a likely prerequisite for transplacental infection (Joo et al. 1976a; Mengeling and Cutlip 1976).

LESIONS

Neither macroscopic nor microscopic lesions have been reported for nonpregnant pigs (Brown et al. 1980; Cutlip and Mengeling 1975a). It is possible that cellular infiltrations subsequently described for fetuses could be induced by infection during the perinatal interval.

Macroscopic lesions have not been reported in pregnant dams; however, microscopic lesions have been seen in tissues of gilts killed after their fetuses were infected by transuterine inoculation of virus. Gilts that were seronegative when their fetuses were infected at 70 days of gestation had focal accumulations of mononuclear cells adjacent to the endometrium and in deeper layers of the lamina propria when they were killed 12 and 21 days later. In addition, there were perivascular cuffs of plasma cells and lymphocytes in the brain, spinal cord, and choroid of the eye (Hogg et al. 1977). When fetuses were infected earlier in gestation (35, 50, and 60 days) and their dams were killed 7 and 11 days later, the lesions were similar. However, uterine lesions were more severe and also included extensive cuffing of myometrial and endometrial vessels with mononuclear cells (Lenghaus et al. 1978). Only focal accumulations of lymphocytes were seen in uteruses of gilts that were seropositive when their fetuses were infected (Cutlip and Mengeling 1975b).

Macroscopic changes of embryos are death followed by resorption of fluids (Figure 23.4) and then soft tissues (Figure 23.5). Virus and viral antigen are widely distributed in tissues of infected embryos and their placentas (Mengeling et al. 1980a), and it is probable that microscopic lesions of necrosis and vascular damage, subsequently described for fetuses, also develop in advanced embryos.

There are numerous macroscopic changes in fetuses infected before they become immunocompetent (Figure 23.6). These include a variable degree of stunting and sometimes an obvious loss of condition before other external changes are apparent; occasionally, an increased prominence of blood vessels over the surface of the fetus due to congestion and leakage of blood into contiguous tissues; congestion, edema, and hemorrhage with accumulation of serosanguineous fluids in body cavities; hemorrhagic discoloration becoming progressively darker after death; and dehydration (mummification). Many of these changes also apply to the placenta. Microscopic lesions consist primarily of extensive cellular necrosis in a wide variety of tissues and organs (Joo et al. 1977; Lenghaus et al. 1978) (Figure 23.7A). Inflammation (Joo


23.4. *Embryos from a gilt experimentally infected oronasally immediately after breeding and killed 22 days later. Bar = 1 cm. (Top) Noninfected, clinically normal embryo (arrow) and associated extraembryonic membranes; (bottom) PPV-infected, dead littermate embryo (arrow) and associated extraembryonic membranes, recent death, no obvious resorption of soft tissues. (Mengeling et al. 1980a.)*

et al. 1977) and intranuclear inclusions (Lenghaus et al. 1978) also have been described.

In contrast, macroscopic changes have not been reported for fetuses infected after they become immunocompetent for PPV. Microscopic lesions are primarily endothelial hypertrophy (Hogg et al. 1977) and mononuclear cell infiltrations consistent with an immune response (Hogg et al. 1977; Joo et al. 1977). Meningoencephalitis characterized by perivascular cuffing with proliferating adventitial cells, histiocytes, and a few plasma cells was seen in the gray and white matter of the cerebrum and in the leptomeninges of PPV-infected stillborn pigs. These lesions were believed to be pathognomonic for PPV infection (Narita et al. 1975). Similar lesions have been observed in PPV-infected, live fetuses collected late in gestation (Hogg et al. 1977; Joo et al. 1977) (Figure 23.7B).

Both general types of microscopic lesions (i.e., necrosis and mononuclear cell infiltration) may develop in fetuses infected near midgestation (Lenghaus et al. 1978) when the immune response is insufficient to provide protection.

23.5. *Segment of uterus opened to show necrotic remnants of a partially resorbed PPV-infected embryo (arrows) and associated extraembryonic membranes of a gilt experimentally infected oronasally immediately after breeding and killed 22 days later; remnants are laden with virus and viral antigen. Bar = 1 cm. (Mengeling et al. 1980a.)*

23.6. *PPV-infected fetuses. Bars = −5 cm. (A) Litter of a gilt experimentally infected oronasally on day 47 of gestation and killed 34 days later; fetuses from left (L) and right (R) horn of uterus, numbered 1–4 from cervix toward ovary; fetuses L1 and L4 stunted but alive at necropsy, fetus L3 recently dead, others later stages. (B) Fetuses from litter of a naturally infected gilt, collected at about 114 days of gestation, advanced stage of dehydration (mummification). (Mengeling et al. 1975.)*
23.7. *Tissues of PPV-infected fetuses of gilts experimentally infected oronasally. (A) Necrotic focus in liver of live fetus of a gilt infected on day 40 of gestation and killed 42 days later; fetus had numerous macroscopic lesions (H&E; ×400). (B) Perivascular cuffing with mononuclear cells in cerebrum of live fetus, littermate of A; fetus had no macroscopic lesions (H&E; ×320). (Insert) Viral antigen associated with endothelium of cerebral vessel of fetus of a gilt infected on day 46 of gestation and killed 25 days later (IF microscopy; ×312.5). All fetuses were probably infected by intrauterine spread of PPV from transplacentally infected littermates. (Photographs A and B courtesy of T. T. Brown, Jr., National Animal Disease Center.)*

DIAGNOSIS

PPV should be considered in a differential diagnosis of reproductive failure of swine whenever there is evidence of embryonic or fetal death or both. A tentative diagnosis of PPV-induced reproductive failure can be made if gilts, but not sows, are affected, maternal illness was not seen during gestation, there are few or no abortions or fetal developmental anomalies, and the evidence suggests an infectious disease. The relative lack of maternal illness, abortions, and fetal developmental anomalies differentiates PPV from most other infectious causes of reproductive failure. However, a definitive diagnosis requires laboratory support.

Several mummified fetuses (<16 cm in length) or lungs from such fetuses, if sufficiently developed, should be submitted to the diagnostic laboratory. Larger mummified fetuses (i.e., more than about 70 days of gestational age) (Marrable and Ashdown 1967), stillborn pigs, and neonatal pigs are not recommended for submission unless they are the only samples available. If infected, their tissues will usually contain antibody that interferes with laboratory tests for either virus or viral antigen.

If females fail to farrow despite being anestrus and are sent to an abattoir, their uteruses should be collected and examined for affected fetuses. Sometimes only remnants of fetal tissues remain when fetuses die early in the middle third of gestation. Nevertheless, these are adequate samples if tested for viral antigen by IF microscopy (Mengeling 1978b; Mengeling and Cutlip 1975). However, the absence of affected fetuses or fetal remnants does not exclude PPV-induced reproductive failure. When all embryos of a litter die and are completely resorbed after the first few weeks of gestation, the dam may remain endocrinologically pregnant and not return to estrus until after the expected time of farrowing (Rodeffer et al. 1975).

Identification of viral antigen by IF microscopy is a reliable and sensitive diagnostic procedure. Sections of fetal tissues are prepared with a cryostat microtome and then reacted with standardized reagents (Mengeling et al. 1975; Mengeling 1978b). The test can be completed
23.8. *Cryostat-microtome sections of lungs of PPV-infected fetuses examined by IF microscopy. (A) Lung of mummified fetus reacted with FA plus nonimmune serum (×312.5). (B) Replicate section reacted with FA plus PPV-immune serum (i.e., blocking control) (×312.5). (C) Lung of live fetus with HI antibody titer of 640 reacted with fluorescent antibodies (FA) plus nonimmune serum, two infected cells (arrow) (×162.5). (Insert) Two similar infected cells in the same section as C (×500). (Mengeling 1978b.)*

within a few hours. In the absence of a fetal antibody response, antigen is seen throughout fetal tissues (Figure 23.8A, B). Even when antibody is present, infected cells usually can be detected in fetal lung (Figure 23.8C).

Detection of viral hemagglutinin also has been recommended as a diagnostic technique (Joo et al. 1976b; Joo and Johnson 1977a). Tissues are triturated in diluent and then sedimented by centrifugation. The supernatant fluid is tested for agglutinating activity for guinea pig erythrocytes. This test requires a minimum of laboratory equipment and is effective in the absence of antibody.

Virus isolation is less suitable as a routine diagnostic procedure than either of the aforementioned tests. Infectivity is slowly but progressively lost after fetal death (Mengeling and Cutlip 1975). As a result, isolation of virus from mummified fetuses that have died as a result of infection is sometimes unsuccessful (Mengeling 1978b). Moreover, the procedure is time-consuming, and contamination is a constant threat because of the stability of PPV in the laboratory (Cartwright et al. 1969) and because cell cultures are sometimes unknowingly prepared from infected tissues (Bachmann 1969; Cartwright et al. 1969; Hafez and Liess 1979; Huygelen and Peetermans 1967; Mengeling 1975). IF microscopy is often used to determine whether PPV has been isolated in cell culture (Cartwright 1970; Johnson 1973; Mengeling 1978b).

In addition to tests that depend on the detection of PPV antigen or antibody, polymerase chain reaction (PCR) assays for PPV been developed (Molitor et al.1991; Prikhod'ko et al. 2003; Soares et al. 1999). In addition, tissues can be directly examined for a portion of the PPV genome by in situ hybridization (Waldvogel et al. 1995).

Serologic Assays

The HI test is frequently used for detection and quantitation of humoral antibody for PPV. Antibody sometimes can be detected as early as 5 days after swine are exposed to live virus, and it may persist for years (Johnson et al. 1976). Sera examined by the HI test are usually pretreated by heat inactivation (56°C, 30 minutes) and by adsorption with erythrocytes (to remove naturally occurring hemagglutinins) and kaolin (to remove or reduce nonantibody inhibitors of HA) (Mengeling 1972; Morimoto et al. 1972a). Trypsin also has been used to remove nonantibody inhibitors of HA (Cartwright et al. 1969). Parameters of the HI test have been studied in detail (Joo et al. 1976c; Kim 1974).

The VN test is occasionally used for detection and quantitation of humoral antibody for PPV. Neutralization of infectivity is usually confirmed by the absence or reduction either of intranuclear inclusions or fluorescent cells in cultures or of viral hemagglutinin in the culture medium (Johnson 1973; Joo et al. 1975; Mengeling 1972). The VN test has been reported to be more sensitive than the HI test (Johnson and Collings 1971; Joo et al. 1975). A microtechnique for application of the VN test has been described (Joo et al. 1975).

Immunodiffusion (Joo et al. 1978), a modified direct complement-fixation test (Ruckerbauer et al. 1978), and enzyme-linked immunosorbent assay (ELISA) (Hohdatsu et al. 1988; Westenbrink et al. 1989) also have been used successfully to detect antibody for PPV.

In general, serologic procedures are recommended for diagnosis only when tissues from mummified fetuses are not available for testing. Results with maternal sera are of value if antibody is not detected, thus excluding PPV as a cause, and if samples collected at intervals reveal seroconversion for PPV coincident with reproduc-

tive failure (Mengeling et al. 1975; Morimoto et al. 1972b; Rodeffer et al. 1975). Because PPV is ubiquitous, the presence of antibody in a single sample is otherwise meaningless. However, a determination of relative amounts of antibody present as immunoglobulin M and G can suggest the time frame of infection (Joo et al. 1978; Kim 1974). Detection of antibody in sera of fetuses and stillborn pigs and in sera collected from neonatal pigs before they nurse is evidence of in utero infection, since maternal antibody does not cross the maternal-fetal junction (Cartwright et al. 1971; Chaniago et al. 1978; Johnson and Collings 1969, 1971; Mengeling 1972). When serum is not available, body fluids collected from fetuses or their viscera that have been kept in a plastic bag overnight at 4°C have been used successfully to demonstrate antibody (Cropper et al. 1976; Joo et al. 1976b).

PREVENTION AND CONTROL

There is no treatment for PPV-induced reproductive failure. Gilts should either be naturally infected with PPV or vaccinated for PPV before they are bred. To promote natural infection, a common practice is to arrange contact between seronegative gilts and seropositive sows, with the expectation that one or more of the sows will be shedding virus. Moving gilts to a potentially contaminated area, either currently or recently inhabited by seropositive swine, also can be recommended. Once infection is started, the virus spreads rapidly among fully susceptible swine. Just how effective these procedures are in increasing the incidence of natural infection is unknown. Infection is common, and probably well over one-half of all gilts in areas where PPV is endemic are infected before they are bred for the first time (Mengeling 1972).

The use of vaccine is the only way to ensure that gilts develop active immunity before conception. Both inactivated (Fujisaki 1978; Fujisaki et al. 1978b; Ide et al. 1977; Joo and Johnson 1977b; Mengeling 1977; Mengeling et al. 1979, 1980b; Suzuki and Fujisaki 1976) and modified live-virus (MLV) vaccines (Fujisaki and Murikami 1982; Paul and Mengeling 1980) have been developed. An inactivated vaccine has been tested under field conditions (Fujisaki 1978; Fujisaki et al. 1978a), and both types of vaccines were effective when tested under controlled laboratory conditions (Mengeling et al. 1979, 1980b; Paul and Mengeling 1980).

Vaccines should be administered several weeks before conception with the objective of providing immunity through the susceptible period of gestation. However, vaccines must be administered after the disappearance of passively acquired colostral antibody, which could interfere with the development of active immunity (Paul and Mengeling 1986). These limits may define a very brief interval for effective vaccination of gilts that are bred before 7 months of age. Although inactivated vaccine provides maximum safety, there is experimental

evidence that PPV can be sufficiently attenuated so that it is unlikely to cause reproductive failure, even if inadvertently administered during gestation (Paul and Mengeling 1980). The apparent safety of MLV vaccine may be due to its reduced ability to replicate in tissues of the intact host and cause the level of viremia needed for transplacental infection (Paul and Mengeling 1984). Moreover, it has been shown by transuterine inoculation of both virulent and attenuated virus that a much larger dose of attenuated virus is required to establish infection of fetuses (Mengeling et al. 1984).

Duration of immunity following vaccination is unknown; however, in one study antibody titers were maintained for at least 4 months after administration of an inactivated vaccine (Joo and Johnson 1977b). Low levels of antibody found to be protective allow speculation that, once the immune system has been primed with PPV, subsequent exposure to virulent virus during gestation is unlikely to result in transplacental infection, even if antibody from vaccination is no longer detectable (Mengeling et al. 1979).

Vaccination is also recommended for seronegative sows and boars. Seronegative sows are usually found only in PPV-free herds. In such cases, inactivated vaccine is indicated. Experience has shown that few herds can be expected to remain free of PPV, even if access is carefully controlled. Introduction of PPV into a totally susceptible herd can be disastrous (Donaldson-Wood et al. 1977). Vaccination of boars should reduce their involvement in dissemination of the virus.

Vaccines are used extensively in the United States and in several other countries where PPV has been recognized as an economically important cause of reproductive failure. All federally licensed vaccines marketed in the United States are inactivated.

24 Porcine Reproductive and Respiratory Syndrome Virus (Porcine Arterivirus)

J. Zimmerman, D. A. Benfield, M. P. Murtaugh, F. Osorio, G. W. Stevenson, and M. Torremorell

In the late 1980s, catastrophic outbreaks of a previously unrecognized disease were reported in U.S. swine herds (Keffaber 1989; Loula 1991). The clinical picture included severe reproductive losses, extensive postweaning pneumonia, reduction of growth performance, and increased mortality (Hill 1990). Initial efforts to identify the etiology of the outbreaks were unsuccessful and the name "Mystery Swine Disease" (MSD) came into common usage (Hill 1990; Reotutar 1989).

In Europe, outbreaks clinically similar to MSD occurred in Germany in November 1990 (OIE 1992). No common link was found between the outbreaks in Germany and MSD in the U.S. (Anon. 1991). Spreading rapidly, over 3,000 outbreaks were documented in Germany in May 1991 and across Europe in the following 4 years (Baron et al. 1992; Bøtner et al. 1994; Edwards et al. 1992; OIE 1992; Pejsak and Markowska-Daniel 1996; Plana Duran et al. 1992a; Valíček et al. 1997). In Asia, outbreaks occurred in Japan in 1988 (Hirose et al. 1995) and in Taiwan in 1991 (Chang et al. 1993).

The etiology of the disease was resolved in 1991 when Koch's postulates were fulfilled by researchers at the Central Veterinary Institute (Lelystad, the Netherlands) with a previously unrecognized RNA virus (Terpstra et al. 1991a; Wensvoort et al. 1991). Shortly thereafter, the virus was isolated in the U.S. (Collins 1991; Collins et al. 1992) and Canada (Dea et al. 1992a,b). The first virus isolates in the Netherlands and U.S. were designated Lelystad virus and Swine Infertility and Respiratory Syndrome (SIRS) virus (BIAH-001), respectively. European workers introduced the term "porcine reproductive and respiratory syndrome" (PRRS) into the literature in 1991 (Terpstra et al. 1991b). The term "swine arterivirus" is also found in the literature (Albina et al. 1998; Legeay et al. 1997) and is more in keeping with the spirit of the rules of virus nomenclature devised by the International Committee on Taxonomy of Viruses.

ETIOLOGY

PRRS virus (PRRSV) is a small, positive-strand RNA virus. Together with equine arteritis virus, lactate dehydrogenase-elevating virus, and simian hemorrhagic fever virus, PRRSV belongs to family *Arteriviridae*, which together with family *Coronaviridae* form the order *Nidovirales* (Cavanagh 1997). PRRSV is an enveloped virus with a diameter of 50–65 nm, a relatively smooth surface, and a cuboidal, nucleocapsid core with a diameter of 25–35 nm (Benfield et al. 1992) (Figure 24.1).

PRRSV is highly host restricted, growing primarily in porcine alveolar macrophages and in macrophages of other tissues (Pol et al. 1991). PRRSV can also replicate in testicular germ cells (spermatids, spermatocytes, multinucleated giant cells) in infected boars (Sur et al. 1997). In vitro, PRRSV grows in primary cultures of porcine alveolar macrophages, as well as MA-104 African green monkey kidney cells or its derivatives (Benfield et al. 1992, Kim et al. 1993). A cell line derived from cotton rat lung cells has also been reported to be highly susceptible to PRRSV (rat cell line, ATCC PTA-3930).

PRRSV enters the host cell by endocytosis. PRRSV particles have been visualized by electron microscopy at the cell surface or within small vesicles delineated by clathrin-like zones (Kreutz and Ackermann 1996). Meulenberg (2000) concisely described the complete process of morphogenesis: PRRSV is assembled through a process of nucleocapsid budding into the lumen of the smooth endoplasmic reticulum, the Golgi, or both. After budding, virions accumulate in vesicles and then move to the plasma membrane where release takes place through fusion. Under single-step growth conditions, the maximum output of PRRSV particles takes place between 10–20 hours, reaching titers of $10^{6.5}$ to $10^{7.5}$ $TCID_{50}$/ml (Meulenberg 2000).

Genomic Organization

The genomic organization of PRRSV is similar to that of other arteriviruses. The genome is approximately 15 kb
24.1. *A complete PRRSV particle (indicated by the open arrow) and an incomplete (coreless) PRRSV particle. The insert shows a complete PRRSV particle with the 35 nm nucleocapsid core (black arrow) surrounded by an envelope. Bars = 50 nm. (Courtesy of D. Robinson, South Dakota State University.)*

in length with eight open reading frames (ORFs). The complete genome sequence of Lelystad virus and several North American isolates has been published (Allende et al. 1999; Meulenberg et al. 1993; Nelsen et al. 1999; Wootton et al. 2000). A comparison of the amino acid sequences encoded by each PRRSV ORF indicates that PRRSV is more similar to lactate dehydrogenase-elevating virus than to equine arteritis virus.

ORFs 1a and 1b comprise 80% of the genome and encode the RNA replicase required for virus replication. ORFs 1a and 1b are translated as a single poly-protein, which is then processed into smaller nonstructural proteins (nsp). Nsp1-alpha, nsp1-beta, nsp2, and nsp4 are proteases that cleave the entire ORF1 polyprotein into 12 nsps (Snijder and Meulenberg 2001). The nsp10 region of ORF1b encodes a functional helicase (Bautista et al. 2002).

In addition to their functional role in PRRSV replication, the nsps have a potential role in diagnostics and in the host immune response. A significant number of epitopes exist on nsp2 and these are recognized by the immune system of the infected host (Oleksiewicz et al. 2001).

The six ORFs (2, 3, 4, 5, 6, and 7) located at the 3′ end of the genome encode the viral structural proteins. Of these, GP2, GP3, GP4, and GP5, are all N-glycosylated, whereas the nucleocapsid protein N (ORF 7 product) and the integral membrane (or matrix) M protein (ORF 6 product) are not (Dea et al. 2000). Recent evidence also suggests the existence of an additional nonglycosylated, small protein (73 amino acid, 10-kDa) encoded by a small ORF within ORF2 designated ORF2b (Wu et al. 2001).

Structural Proteins

PRRSV possesses a set of six or seven structural proteins. The three major structural proteins are GP5, M, and N.

The N protein is small (15 kDa), highly basic, and in-

teracts with the viral RNA in the assembly of infectious particles. The N protein is expressed at high levels in infected cells and represents 20–40% of the total protein content of the virion. It is active in nuclear shuttling and localization to the nucleolus and may influence nuclear processes during replication (Rowland and Yoo 2003), possibly through rRNA precursor processing and ribosome biogenesis (Yoo et al. 2003). The N protein is not important from an immunogenic or immunoprotective standpoint, but its abundant expression and antigenicity make it an ideal target for diagnostic assays.

The nonglycosylated M (transmembrane) envelope protein is the most genetically conserved of all the structural proteins of PRRSV. As a matrix protein, M is important in virus assembly and budding. It accumulates in the endoplasmic reticulum, forming disulfide-linked heterodimers with the 25 kDa GP5 (Mardassi et al. 1996). These heterodimers are incorporated into the virus particles and are essential for interaction with cellular receptors and are vital for virus infectivity. Evidence for this is supported by the fact that M protein induces PRRSV-neutralizing antibodies (Bastos et al. 2002). The M protein and the M-GP5 complex contribute to PRRSV attachment to a heparin-like receptor on porcine alveolar macrophages (Delputte et al. 2002).

The envelope GP5 contains, after processing, an ectodomain 30 amino acids in length that carries 2 or 3 N-glycans. As the primary envelope protein, GP5 is involved in receptor recognition (Vanderheijden et al. 2003). GP5's role in receptor recognition is supported by the presence of a major neutralization epitope in the N-terminal ectodomain; thus, implying a role for the GP5 ectodomain in the infection process (Ostrowski et al. 2002; Plagemann 2004; Plagemann et al. 2002; Wissink et al. 2003).

The 29–30 kDa GP2 and the 31–35 kDa GP4 envelope proteins are minor constituents of the viral envelope and are typical class I membrane proteins (Meulenberg

2000). It is uncertain whether the 45–50 kDa GP3 protein is present on the structure of the virion, as described for European PRRSV isolates (van Nieuwstadt et al. 1996), or if it is secreted into the medium of infected cells, as reported in studies with a North American isolate (Gonin et al. 1998).

Genomic Diversity

PRRSV strains or isolates are exceptionally variable based on

1. Variation in the clinical presentation of the disease
2. Experimental evidence of differences in pneumovirulence and/or reproductive virulence
3. Antigenic differences as determined by reactivity with polyclonal and monoclonal antibodies
4. Differences in RNA sequences

Concomitant with improvements in the diagnostic assays has been an increased awareness of the genetic/antigenic diversity of PRRSV strains in the field (Meng 2000). In many laboratories, genetic sequencing has become routine in the diagnostic assessment of PRRSV infections.

With the increased use of genetic sequencing has come the realization that genetically diverse PRRSV strains may coexist on the same farm (Dee et al. 2001; Goldberg et al. 2003). Likewise, sequencing has led to the recognition of European genotype (Type 1) strains in areas previously considered to be exclusively populated by U.S. genotype strains (Type 2) (Ropp et al. 2004) and vice versa. Thus, in North America, Europe, and probably elsewhere, two distinct genotypes of PRRSV sharing only partial cross-protection may be found. This has great significance for vaccine strain selection and for the performance of diagnostic assays. Since recombination is likely an important genetic mechanism contributing to PRRSV evolution (Yuan et al. 1999), an additional concern is the possibility that recombination may occur between North American and European viruses coexisting in the same region. However, in vitro (cell culture) conditions indicate that RNA recombination is more likely to occur between two North American (Type 2) strains or two European (Type 1) PRRSV strains than between a Type 1 and Type 2 strain (van Vught et al. 2001).

Systematic application of sequencing has also contributed to concerns about the stability of attenuated vaccine viruses and their possible reversion to virulence. Evidence has suggested the reversion to virulence by attenuated vaccines (Key et al. 2003; Mengeling et al. 1999a; Nielsen et al. 2001; Opriessnig et al. 2002). On the other hand, a significant potential outcome of the study of the genomic structure of attenuated PPRSV strains is a better understanding of the molecular basis for virulence and attenuation in PRRSV. Several genomic pair studies of attenuated strains and their parental wild-type strains have provided an a priori indi-

cation of likely candidate virulence genes (Allende et al. 2000a; Grebennikova et al. 2004; Yuan et al. 2001). These studies are a precursor to studies of gene functions and the molecular basis of PRRSV virulence based on reverse genetics, e.g., infectious cDNA clones (Groot Bramel-Verheije et al. 2000; Meulenberg et al. 1998; Nielsen et al. 2003; Truong et al. 2004; Verheije et al. 2002a; Verheije et al. 2002b; Verheije et al. 2003).

EPIDEMIOLOGY

Geographic Distribution

As diagnostic assays became available during the 1990s, PRRSV was found to have spread nearly everywhere domestic pigs are raised. Retrospective serologic studies found that PRRSV was present in Canada by 1979 (Carman et al. 1995), the U.S. by 1985 (Zimmerman et al. 1997), and the former German Democratic Republic by 1987 (Ohlinger et al. 2000). In Asia, anti-PRRSV antibodies were retrospectively documented in serum from pigs imported into the Republic of Korea (South Korea) in 1985 (Shin et al. 1993), in serum samples collected in 1987 in Taiwan (Chiou 2003), and in samples collected in 1988 in Japan (Hirose et al. 1995). In all cases, the serologic evidence found that PRRSV was in the swine population well before the recognition of clinical PRRS.

Some regions are still free of PRRSV. In Europe, this includes Sweden (Elvander et al. 1997), Norway (OIE 1997), Finland (Bøtner 2003), and Switzerland. Likewise, in Oceania, New Caledonia (OIE 1996), New Zealand (Motha et al. 1997), and Australia (Garner et al. 1996, 1997) are PRRSV-free. In South America, Argentina (Perfumo and Sanguinetti 2003), Brazil (Ciacci-Zanella 2004), Cuba (Alfonso and Frías-Lepoureau 2003), and some areas of the Caribbean may be free of PRRSV.

Accurate estimates of the prevalence of infection with wild-type virus in specific countries or regions are not readily available, but within infected regions, 60–80% of herds are typically infected (Geue 1995; Hirose et al. 1995; Lu et al. 1999; Maes 1997; Mateusen et al. 2002; USDA 1997). The use of modified live virus (MLV) vaccines has made it difficult to estimate prevalence. Antibodies against vaccine virus are not easily differentiated from antibodies against PRRSV field strains. Furthermore, vaccine strain viruses are shed and transmitted in the field, further compounding the problem of identifying infection with wild-type virus (Astrup and Riising 2002; Bøtner et al. 1997; Christopher-Hennings et al. 1996, 1997; Mengeling et al. 1998; Sipos et al. 2002).

Susceptible Species

Presumably, PRRSV entered domestic swine from an as-yet-unidentified wildlife species. A number of species have been determined not to be susceptible to PRRSV, including mice, rats (Hooper et al. 1994), and guinea pigs (J. Zimmerman, unpublished data). Wills et al.

(2000) found no evidence of PRRSV replication in cats, dogs, mice, opossums, raccoons, rats, skunks, house sparrows, or starlings. Zimmerman et al. (1997) reported that mallard ducks (*Anas platyrhynchos*) were susceptible to PRRSV, but subsequent workers have not replicated these results (Trincado et al. 2004b).

Feral swine are susceptible to PRRSV infection, but according to serosurveys, infection in free-ranging feral swine animals is relatively rare (Albina et al. 2000; Lutz and Wurm 1996; Oslage et al. 1994; Saliki et al. 1998).

Even so, in areas where feral swine interact with domestic swine, they could conceivably serve as a source of PRRSV. Within superfamily *Suoidea* (*Sus* spp., peccaries, warthogs, and babirusa), the susceptibility of species, other than *Sus scrofa,* for PRRSV is unknown.

Routes of Shedding

Infected animals shed virus in saliva (Wills et al. 1997a), nasal secretions (Benfield et al. 1994; Christianson et al. 1993; Rossow et al. 1994a), urine (Wills et al. 1997a), semen (Swenson and Zimmerman 1993; Swenson et al. 1994a), and feces (Christianson et al. 1993). Pregnant susceptible females inoculated in late gestation shed virus in mammary secretions (Wagstrom et al. 2001).

Shedding of virus in semen is of particular concern because of the widespread use of artificial insemination. The duration of semen shedding varies widely among boars (Christopher-Hennings et al. 1996). Swenson et al. (1994a) found infectious virus in the semen of experimentally infected boars for up to 43 days following exposure. By PCR, Christopher-Hennings et al. (1995a) detected viral RNA in the semen of experimentally infected boars for up to 92 days postinoculation (DPI) and isolated PRRSV from the bulbourethral gland of a boar euthanized 101 DPI. Semen shedding of MLV vaccine virus occurred for up to 39 days in one study, but prior vaccination eliminated or reduced shedding upon challenge (Christopher-Hennings et al. 1997).

Transmission

Swine are susceptible to PRRSV by several routes of exposure, including intranasal, intramuscular, oral (Magar et al. 1995; Magar and Larochelle 2004; van der Linden et al. 2003b), intrauterine (Christianson et al. 1993), and vaginal (Benfield et al. 2000a; Gradil et al. 1996; Yaeger et al. 1993). Pigs are not equally susceptible to PRRSV by all routes of exposure. That is, the probability that a given dose will result in infection differs by route of exposure. Hermann et al. (2005) estimated the infectious dose$_{50}$ (ID$_{50}$)—i.e., the dose required to infect one-half of the exposed animals—for oral and intranasal routes of exposure to be $10^{5.3}$ TCID$_{50}$ and $10^{4.0}$ TCID$_{50}$, respectively. Based on data from Benfield et al. (2000a), the ID$_{50}$ for exposure via artificial insemination is approximately $10^{4.5}$ TCID$_{50}$. Yoon et al. (1999) reported that exposure to 20 or fewer PRRSV particles by intramuscular exposure resulted in infection.

Overall, the infectivity data indicate that pigs are extremely susceptible to infection via parenteral exposure (breaks in the skin barrier) and much less susceptible by all other routes investigated to date. In the field, potential parenteral exposures include standard husbandry practices, i.e., ear notching, tail docking, teeth clipping, tattooing, and inoculations with medications and biologics. Likewise, because PRRSV is present in saliva for weeks following infection, normal pig behavior commonly results in parenteral exposures, i.e., bites, cuts, scrapes, and/or abrasions that occur during aggressive interactions among pigs. Bierk et al. (2001) associated transmission with aggressive behavior between carrier sows and susceptible contacts. Other behaviors that result in exchange of blood and saliva, i.e., tail-biting and ear-biting, may also function in transmission. The significantly higher ID$_{50}$ estimates for oral and intranasal exposures imply that transmission by these routes is less common and more easily prevented.

Indirect transmission involves transmission by inanimate objects (e.g., equipment, instruments, clothing) or substances (e.g., water, food), living carriers (vectors), or aerosols. Otake et al. (2002b) confirmed needle-borne transmission of PRRSV under experimental conditions. Likewise, Otake et al. (2002a) showed that PRRSV was present on workers' coveralls, boots, and hands following 60 minutes of contact with acutely infected pigs. Importantly, elementary sanitation procedures, e.g., changing coveralls, changing boots, and washing hands, were sufficient to stop transmission (Dee et al. 2004a). Under experimental conditions, Dee et al. (2002, 2003) showed that PRRSV could be moved extensively on fomites in the field under winter conditions, i.e., below 0°C, but to a much lesser degree during warm weather, i.e., 10–16°C, again illustrating the importance of temperature in virus survival.

Preliminary reports suggest a possible role for arthropods in PRRSV transmission. PRRSV has been detected in, or on, wild-caught flies and mosquitoes (Otake et al. 2002c; Pringproa et al. 2004; Schurrer et al. 2004). Under experimental conditions, Otake et al. (2002c) demonstrated mechanical transmission of PRRSV by mosquitoes and house flies (*Musca domestica*) (Otake et al. 2003a). Overall, the current research data suggest that flies and mosquitoes might serve as mechanical vectors of PRRSV. However, the available data have not proven that PRRSV is an arthropod-borne infection. Typically, the ecologic relationships among host, infectious agent, arthropod, and environment in arthropod-borne infections are complex. Additional data are required to connect the current observations into a cohesive understanding of the role of arthropods in the transmission of PRRSV in the field.

Airborne virus was once considered the primary route of PRRS virus transmission. Airborne transmission, along with arthropod-borne transmission, could explain the apparent long-distance transmission (area

spread) of PRRSV in the absence of other sources of virus (pigs, inanimate objects, people). However, airborne transmission of PRRSV has been difficult to document. Under experimental conditions, transmission from infected to susceptible pigs over a space of 1.0–2.5 meters has been successful in approximately 50% of the attempts (Lager and Mengeling 2000; Otake et al. 2002d; Torremorell et al. 1997; Wills et al. 1997b). The one exception to this pattern of poor airborne transmissibility is a report by Kristensen et al. (2004). In three trials, approximately 50 acutely infected pigs transmitted PRRSV over a distance of one meter to approximately 50 susceptible pigs when 1%, 10%, or 70% of air was exchanged. In a field setting, airborne transmission did not occur over distances of 15 meters (Trincado et al. 2004a) and 30 meters (Otake et al. 2002d). The role of airborne transmission of PRRSV will not be understood until additional information is available; in particular, the quantity of virus excreted by pigs, the source of the virus, the rate of inactivation of aerosolized virus, and the infectious dose for pigs by aerosol exposure.

Vertical Transmission

PRRSV is transmitted from viremic dams transplacentally to fetuses, resulting in fetal death or birth of infected pigs that are weak or appear normal (Bøtner et al. 1994; Christianson et al. 1992; Terpstra et al. 1991a). Some pigs in affected litters may escape infection with PRRSV. PRRSV can replicate in fetuses 14 days of gestational age or older, but infection of fetuses during the first two-thirds of gestation is uncommon because most strains of PRRSV cross the placenta efficiently only in the last trimester of pregnancy (Christianson et al. 1993; Lager and Mengeling 1995; Mengeling et al. 1994; Prieto et al. 1996a,b). The reason for the difference in efficiency of maternal-placental viral transit at different stages of gestation and the mechanism(s) of viral transit are unknown. Transit is independent of the reproductive virulence of the virus strain. Park et al. (1996) showed that PRRSV strains of low and high virulence for fetuses cross the placenta with equal efficiency when sows are inoculated at 90 days of gestation.

Persistent Infection

PRRSV produces a chronic, persistent infection in pigs. Virus replicates in susceptible cells of clinically inapparent carrier animals for several months. This is the single most significant epidemiological feature of PRRSV infection. Persistent PRRSV infection has been documented through transmission experiments and by detection of virus in animals. Zimmerman et al. (1992) reported transmission of PRRSV from a sow infected 99 days earlier to susceptible sentinels. Following *in utero* exposure at day 90 of gestation, Benfield et al. (2000b) isolated virus from tonsil and lymph nodes from pigs for up to 132 days after farrowing. Wills et al. (1997c) isolated virus from one of 4 pigs at 157 DPI. Horter et al. (2002)

detected infectious PRRSV by virus isolation or swine bioassay in 51 of 59 (84%) animals necropsied between 63 and 105 DPI, including 10 of 11 (91%) of animals euthanized at 105 DPI. Allende et al. (2000b) detected infectious virus by bioassay in 2 of 5 pigs at 150 DPI.

Persistent infection is not a function of pig age at the time of infection. Persistence occurs regardless of whether the pig is exposed in utero (Benfield et al. 1997, 2000b; Rowland et al. 1999), as a young animal, or as an adult (Bierk et al. 2001; Christopher-Hennings et al. 1995a; Fairbanks et al. 2002; Zimmerman et al. 1992). The mechanism(s) by which the virus is able to persevere in the face of an active immune response has not been identified, but probably does not involve evasion of immunity through continual in vivo viral mutation. Chang et al. (2002) found relatively low rates of mutation in persistently infected animals.

Stability in the Environment

Shedding of virus in saliva, urine, and feces results in environmental contamination and creates the potential for transmission via fomites. PRRSV is fragile and quickly inactivated by heat and drying. At 25–27°C, infectious virus was not detected on plastic, stainless steel, rubber, alfalfa, wood shavings, straw, corn, swine starter feed, or denim cloth, beyond day zero (Pirtle and Beran 1996).

PRRSV can remain infectious for an extended time under specific conditions of temperature, moisture, and pH. PRRSV is stable for months to years at temperatures of −70°C and −20°C. Approximately 90% of PRRSV infectivity is lost within 1 week at 4°C, but low titers of infectious virus can still be detected for at least 30 days. In solution, PRRSV infectivity persists for 1–6 days at 20–21°C, 3–24 hours at 37°C, and 6–20 minutes at 56°C. The thermal stability of PRRSV in serum and tissues is similar to that described for virus stored in media. PRRSV was isolated from 47%, 14%, and 7% of porcine serum samples stored at 25°C for 24, 48, and 72 hours, respectively. When serum was stored at 4°C or −20°C, PRRSV was isolated from 85% of the samples after 72 hours (Van Alstine et al. 1993). PRRSV is stable at pH 6.5–7.5, but infectivity is rapidly lost at pH below 6 and above 7.5 (Benfield et al. 1992; Bloemraad et al. 1994).

Disinfection

PRRSV is inactivated by lipid solvents, e.g., chloroform and ether (Benfield et al. 1992). PRRSV is highly unstable in solutions containing low concentrations of detergents, which disrupt the envelope with concomitant release of the noninfectious core particles and loss of infectivity (Snijder and Meulenberg 2001).

Disinfection first requires removal of all organic material. Thereafter, infectious agents are inactivated in a temperature- and contact time–dependent fashion specific to the agent and the disinfectant. PRRSV is relatively labile in the environment and particularly suscep-

tible to drying (Pirtle and Beran 1996). At "room temperature," Shirai et al. (2000) reported complete inactivation of PRRSV with chlorine (0.03%) in 10 minutes, iodine (0.0075%) in 1 minute, and a quarternary ammonium compound (0.0063%) in 1 minute. The effects of temperature or pH were not explored. Dee et al. (2004b, c) reported that protocols involving cleaning, washing, disinfection, and drying were effective at inactivating PRRSV on transport vehicles.

Transmission within Herds

PRRSV tends to circulate within a herd indefinitely. Endemicity appears to be driven by persistent PRRSV infection in carrier animals and the continual availability of susceptible animals either through birth, purchase, or loss of protective immunity. The virus is perpetuated by a cycle of transmission from dams to pigs either in utero or postpartum, or by commingling susceptible animals with infected animals in later stages of production. Under conditions in which susceptible and infectious pigs are mixed, e.g., at weaning, a large proportion of the population may quickly become infected. Dee and Joo (1994a) reported 80–100% of pigs in 3 swine herds were infected by 8–9 weeks of age and Maes (1997) found 96% of market hogs sampled from 50 herds to be positive. However, marked differences in infection rates between groups, pens, or rooms of animals may be observed in endemically infected herds. Houben et al. (1995) even found transmission to vary within litters. Some littermates seroconverted as early as 6–8 weeks of age, but other individuals reached 12 weeks of age, the end of the monitoring period, still free of PRRSV infection. Likewise, Melnichouk et al. (2005) found differences in the pattern of transmission in farms. In 5 farms, approximately 50% of the pigs were infected at 5–7.5 weeks of age and at least 90% were infected by 8.5 weeks of age, but on 2 farms, only 20% to 40% of pigs were infected at 10–12 weeks of age.

Transmission between Herds

The role of infected pigs and virus-contaminated semen in herd-to-herd transmission is firmly established (Dee 1992; Mousing et al. 1997; Weigel et al. 2000). In a regional PRRSV control program in France, Le Potier et al. (1997) estimated that 56% (66 of 118) of herds acquired the infection through the introduction of infected pigs, 20% (23 of 118) through infected semen, 21% (25 of 118) through fomites/slurry, and 3% (4 of 118) through unidentified sources. Mortensen et al. (2002) found that PRRSV entered negative herds through the introduction of animals and semen and through area spread from neighboring farms, which they attributed to aerosol transmission. Dee et al. (2002, 2003) have demonstrated the ease with which PRRSV can be moved between farms on commonplace equipment and objects common to swine farms, e.g., insulated semen coolers, metal toolboxes, plastic lunch pails, and cardboard boxes, especially when wet and cold. Torremorell et al. (2004) attributed over 80% of new infections in commercial systems to area spread from neighboring units, the movement of pigs in PRRSV infected transports, the lack of compliance of the biosecurity protocols, or possibly, introduction via insects.

Proximity to infected herds is a well-recognized risk factor. The risk of a herd becoming PRRSV-positive increases with the density of PRRSV-positive neighboring herds, but decreased with distances (Zhuang et al. 2002). Le Potier et al. (1997) found that 45% of herds suspected to have become infected through area spread were located within 500 meters (0.3 miles) of the postulated source herd and only 2% were one kilometer from the initial outbreak.

Area spread is a major issue in the control and/or elimination of PRRSV. If area spread is to be prevented, it is essential that the mechanisms by which it occurs be firmly established. Area spread is often attributed to aerosols or insects. However, Goldberg et al. (2000) evaluated the ORF 5 gene sequences from 55 field isolates collected in Illinois (U.S.) and eastern Iowa (U.S.) and found that the genetic similarity of isolates did not correlate with their geographical distance. On that basis, they concluded that PRRSV was most commonly introduced into herds through animals or semen, as opposed to mechanisms associated with spread from neighboring herds.

PATHOGENESIS

The chronology of PRRS viral infection has been described in several key inoculation studies in germ-free, cesarean-derived/colostrum-deprived, or conventional pigs (Duan et al. 1997b; Halbur et al. 1995b, 1996a; Rossow et al. 1994a, 1995, 1996a). Following exposure, viral replication initially occurs primarily in local susceptible macrophages and then rapidly spreads to lymphoid organs, lungs, and, less consistently, to other tissues. Virulent strains of PRRSV cause viremia as early as 12 hours in some pigs, and in all pigs by 24 hours postinoculation along with viral infection of lymphoid tissues and lung. Viral titers increase rapidly and peak in serum, lymph nodes, and lung by day 7–14 with $10^2–10^5$ $TCID_{50}$ of virus detected per ml of serum or gram of tissue. The highest viral titers are consistently reported in lung.

PRRSV replicates primarily in well-differentiated subsets of monocyte-derived cells that display a 220 kDa glycoprotein receptor to which PRRSV binds and enters via receptor-mediated endocytosis (Duan et al. 1998; Kreutz and Ackermann 1996; Nauwynck et al. 1999; Wissink 2003a). Differentiated cells known to support replication include pulmonary alveolar macrophages (PAM) and intravascular macrophages (PIM) in the lung (Thanawongnuwech et al. 1997a; Wensvoort et al. 1991) and macrophages in lymphoid tissues (Duan et al.

1997b). Thus, the highest titers of PRRSV and most significant lesions are found in these tissues during acute PRRS.

Maturity and/or activation of PAM, and presumably other macrophages, is required for PRRSV replication (Duan et al. 1997a; Molitor et al. 1996, 1997; Thacker et al. 1998). PRRSV replicates in the subset of differentiated PAM with maximal ability to phagocytose bacteria and produce superoxide anion for bacterial killing in phagolysosomes (Molitor et al. 1996). Both PAM and PIM harvested from younger pigs replicate PRRSV to higher titers compared to older pigs (Mengeling et al. 1995; Thanawongnuwech et al. 1998b).

PRRSV will also replicate in microglia (Molitor et al. 1997), but will not replicate in all monocyte-derived cells, including peripheral blood monocytes, peritoneal macrophages, or bone marrow progenitor cells (Duan et al. 1997a,b).

The largest amount of PRRS viral antigen and/or nucleic acid is observed in lungs and lymph nodes, but is also consistently observed in perivascular and intravascular macrophages in heart, brain, kidney and elsewhere and is inconsistently observed in alveolar, bronchial, and nasal epithelium, endothelium, fibroblasts, spermatids, and spermatocytes (Halbur et al. 1995a,b, 1996a; Magar et al. 1993; Pol et al. 1991; Rossow et al. 1996a; Sirinarumitr et al. 1998; Sur et al. 1997; Thanawongnuwech et al. 1997a).

Generally, clinical disease and consistent lesions correspond to the time and place of highest viral titers, i.e. day 7–14 postinoculation in lung and lymph nodes. In contrast, in stillborn and congenitally infected live born pigs, viral antigen and nucleic acid is in largest amounts in lymphoid organs, but not lung (Cheon and Chae 2001).

After peaking, virus titers in serum decrease rapidly. Most pigs are no longer viremic by 28 DPI, although viral RNA has been detected in serum by rtPCR up to 251 DPI (Duan et al. 1997b; Wills et al. 2003). The duration of viremia may be slightly longer in congenitally infected pigs, being consistently demonstrated by virus isolation for up to 48 days after birth and infrequently by rtPCR for up to 228 days (Rowland et al. 2003).

Following viremia, congenitally- and postnatally infected pigs are persistently infected with virus in tonsil (Wills et al. 1997c) and/or lymph nodes, especially inguinal and sternal (Bierk et al. 2001; Xiao et al. 2004), for extended periods of time. Virus has been detected by virus isolation for as long as 132–157 DPI (Rowland et al. 2003; Wills et al. 1997c). Persistent virus is produced in lymphoid tissues by a low level of continuous replication (Allende et al. 2000b).

Mechanisms of Cell Injury

Replication of PRRS virus in macrophages in lung and lymphoid tissues, and to a lesser extent other tissues, in-

duces lesions and clinical disease by a variety of mechanisms. These include apoptosis of infected cells, apoptotic death of proximate noninfected cells (indirect or bystander apoptosis), induction of inflammatory cytokines, induction of polyclonal B cell activation, and reduction in bacterial phagocytosis and killing by macrophages that results in increased susceptibility to septicemia (also likely due to other forms of immunomodulation by PRRSV).

Direct and indirect (bystander) apoptosis is a major cause of cell death in PRRS. During acute infection when virus titers are high, only a small portion of macrophages in scattered foci are infected with PRRSV (Duan et al. 1997b; Mengeling et al. 1995), but there are large numbers of apoptotic mononuclear cells distributed diffusely (Sirinarumitr et al. 1998; Sur et al. 1998). Apoptotic cells rarely contain PRRSV and are in greatest numbers 10–14 days after PRRSV inoculation. This suggests that PRRSV induces apoptosis in noninfected cells in proximity to infected cells. Most apoptotic cells are morphologically typical of macrophages; fewer are typical of lymphocytes.

The gene product of PRRSV ORF5 (GP5) induces apoptosis when expressed in the simian COS-1 cell line in vitro and may be the cause of apoptosis in PRRSV-infected macrophages in vivo (Suárez et al. 1996). The cause of PRRSV-induced indirect apoptosis is unknown, but is likely due to substances released from, or secreted by, infected macrophages, e.g., p25, apoptogenic cytokines, reactive oxygen species, or nitric oxide (Choi and Chae 2002; Labarque et al. 2003; Suárez 2000).

Secretion of proinflammatory cytokines from PRRSV-infected macrophages likely results in effects that are both positive (recruitment of leukocytes, initiation of immune response, and reduction in viral replication) and negative (increased vascular permeability resulting in pulmonary edema and bronchial constriction). Studies demonstrated variable elevations in cytokine levels in broncho-alveolar lavage from PRRSV-infected vs. uninfected control pigs, including IFN-gamma, TNF-alpha, IL-1, IL-6, IL-10, and IL-12 (Choi et al. 2001; Suradhat and Thanawongnuwech 2003; Thanawongnuwech et al. 2003; van Gucht et al. 2003). Studies using in *situ* hybridization have also shown that production of these cytokines is predominantly by macrophages located in alveolar septa in foci of inflammation and also by lymphocytes positive for IFN-gamma (Choi et al. 2001; Chung and Chae 2003; Thanawongnuwech et al. 2003). Of these cytokines, TNF-alpha, IL-1, and IL-6 are proinflammatory and known to promote influx and activation of leukocytes, increased microvascular permeability (pulmonary edema), and induction of systemic effects such as pyrexia, anorexia, and lethargy. TNF-alpha and IL-1 can also cause bronchial hyper-reactivity and constriction with asthma-like symptoms.

PRRSV replication in lymphoid organs is also associ-

ated with polyclonal B cell activation. Grossly, this appears as nodular lymphoid hyperplasia and microscopically as follicular lymphoid hyperplasia (Lamontagne et al. 2001). Inoculation of neonatal gnotobiotic pigs with PRRSV results in lymphoid hyperplasia, extremely elevated levels of all classes of serum immunoglobulins (of which only 1% are specific for PRRSV), circulating immune complexes, immune complex deposition on glomerular basement membranes with associated cellular inflammation, and induction of auto-antibodies to Golgi antigens and dsDNA (Lemke et al. 2004).

CLINICAL SIGNS

Descriptions of the clinical signs of PRRS in swine herds are similar in North America (Bilodeau et al. 1991; Keffaber 1989; Loula 1991; Moore 1990; Sanford 1992), South America (Dewey 2000), Europe (Anon. 1992; Busse et al. 1992; de Jong et al. 1991; Gordon 1992; Hopper et al. 1992; Leyk 1991; Wensvoort et al. 1991; White 1992a,b), and Asia (Chiou 2003; Thanawongnuwech et al. 2003; Tong and Qiu 2003; Yang et al. 2003).

Clinical presentation of PRRS varies greatly between herds, ranging from asymptomatic to devastating. Clinical signs also vary greatly and may be masked or augmented by concurrent infection(s). The only completely consistent clinical feature of PRRS is that there is no consistent feature. For nearly every described clinical sign, there are exceptions. Clinical signs of PRRSV are influenced by virus strain, host immune status, host susceptibility, exposure to lipopolysaccharides (LPS), concurrent infections, and other management factors (Blaha 1992; White 1992a).

Clinical disease in a herd is primarily the consequence of acute viremia in individuals (Collins et al. 1992; Pol et al. 1991; Terpstra et al. 1991a) and transplacental transmission resulting in reproductive failure (Terpstra et al. 1991a). Because PRRSV isolates vary remarkably in virulence, low-virulence isolates can cause completely subclinical epidemic or endemic infections in herds (Morrison et al. 1992), whereas highly virulent isolates can cause severe clinical infections that appear differently, depending on the herd's immune status.

Clinical epidemics occur when PRRSV enters an immunologically naive herd or production site and all ages are affected. Endemic PRRS occurs in herds that have homologous immunity to the infecting strain of PRRSV. In endemic PRRS, clinical disease is observed in susceptible subpopulations, usually in nursery-grower pigs when maternal immunity decays, and/or in replacement gilts or sows that have previously escaped infection, as well as their congenitally infected progeny.

Antigenic variation is great enough among strains of PRRSV that entry of a new, relatively unrelated strain can cause an epidemic in an endemically PRRSV-infected herd.

Epidemic Infection

In PRRS epidemics, the first phase lasts 2 or more weeks and is characterized by anorexia and lethargy in 5–75% of animals of all ages as a result of acute viremia. It begins in one or more stages of production and quickly spreads in 3–7 or more days to all stages of production. Individuals are anorexic for 1–5 days. The spread of the disease through a segregated group of pigs usually requires 7–10 or more days, giving rise to the descriptive term "rolling inappetence." Clinically affected animals may also be lymphopenic, pyretic with rectal temperatures from 39–41°C (102–106°F), hyperpneic and dyspneic, or have transient "blotchy" cutaneous hyperemia or cyanosis on extremities.

The second phase may begin before the first phase of acute illness is completed and continues for 1–4 months, characterized by reproductive failure, primarily in sows that were viremic in their third trimester, and by high preweaning mortality in their live-born progeny. When reproductive performance and preweaning mortality return to near preoutbreak levels, endemic infection of most herds continues.

Sows. During the phase of acute illness, 1–3% of litters may be lost in sows that are from 21–109 days of gestation. This is recognized as overt abortions or, later, as irregular returns to estrus or nonpregnant sows (Hopper et al. 1992; Keffaber 1989; Loula 1991; White 1992a). Also observed inconsistently in acutely ill sows is agalactia (Hopper et al. 1992), incoordination (de Jong et al. 1991), and/or a dramatic exacerbation of endemic diseases, such as sarcoptic mange, atrophic rhinitis, or cystitis/pyelonephritis (White 1992a).

Mortality in sows is typically 1–4% during acute illness and is sometimes associated with pulmonary edema and/or cystitis/nephritis (Hopper et al. 1992; Loula 1991). A few cases of severe acute PRRS in sows have been described with 10–50% abortions, up to 10% mortality, and nervous signs such as ataxia, circling, and paresis (Epperson and Holler 1997; Halbur and Bush 1997).

Late-term reproductive failure begins at approximately 1 week and continues for up to 4 months. Not all affected sows are clinically ill during acute PRRS. Typically, 5–80% of sows farrow on day 100–118 of gestation and have litters composed of any combination of normal pigs, weak variably sized pigs, and dead pigs that are fresh stillborn (intrapartum death), autolytic (brown) partially mummified or completely mummified fetuses. Typically, pigs born dead comprise 0–100% of each affected litter and 7–35% of the total pigs born in a farrowing group. In time, there is a shift from predominantly stillborn pigs and large partially mummified pigs, to smaller more completely mummified pigs, to small weak-born pigs, to pigs of normal size and vigor (Keffaber 1989; Loula 1991; White 1992a). In some herds, the majority of abnormal pigs are born alive, pre-

mature, weak, and small, but few are born dead (Gordon 1992). Periparturient mortality in sows may be 1–2% (de Jong et al. 1991; Keffaber 1989). Surviving sows on the subsequent breeding often have delayed return to estrus and low conception rates.

Boars. During acute illness, in addition to anorexia, lethargy, and respiratory clinical signs, boars may lack libido and have variable reduction in semen quality (de Jong et al. 1991; Feitsma et al. 1992; Prieto et al. 1994). Changes in sperm occur 2–10 weeks after infection with virus and include reduced motility and acrosomal defects, but it is unclear whether conception rates are affected (Lager et al. 1996; Prieto et al. 1996a,b; Swenson et al. 1994b; Yaeger et al. 1993). However, of much greater significance is semen shedding of PRRSV that can result in venereal transmission to sows (Swenson et al. 1994b; Yaeger et al. 1993).

Suckling Pigs. During the 1- to 4-month phase of late-term reproductive failure, there is high preweaning mortality (up to 60%) in pigs born prematurely and at term associated most consistently with listlessness, emaciation/starvation, splay-legged posture, hyperpnea, dyspnea ("thumping"), and chemosis. Seen less commonly are tremors or paddling (Keffaber 1989; Loula 1991), slight doming of foreheads (Gordon 1992), anemia and thrombocytopenia with consequent hemorrhage from navels and elsewhere, and an increase in bacterial polyarthritis and meningitis (Hopper et al. 1992; White 1992a). Watery diarrhea was commonly reported in the United Kingdom (Gordon 1992; Hopper et al. 1992; White 1992a) and less commonly elsewhere (Keffaber 1989; Leyk 1991).

Weanling and Grower Pigs. Acute PRRSV infection in nursery or grower-finisher pigs is characterized most consistently by anorexia, lethargy, cutaneous hyperemia, hyperpnea and/or dyspnea without coughing, rough hair coats, and variable reduction in average daily gain creating uneven groups (Moore 1990; White 1992b). Frequently reported is a higher than usual incidence of endemic diseases and elevated mortality of 12–20% (Blaha 1992; Keffaber et al. 1992; Loula 1991; Moore 1990; Stevenson et al. 1993; White 1992a). Diseases most commonly reported include streptococcal meningitis, septicemic salmonellosis, Glasser's disease, exudative dermatitis, sarcoptic mange, and bacterial bronchopneumonia.

Endemic Infection of Herds
Once introduced into a herd, PRRSV becomes endemic in nearly all cases. In endemically infected herds, PRRS is most often seen as regular or occasional outbreaks of typical acute PRRS in susceptible nursery or grower-finisher pigs (Keffaber et al. 1992; Stevenson et al. 1993). Clinical signs are also observed in groups of susceptible gilts or replacement boars exposed to PRRSV after introduction into the herd (Dee et al. 1996; Dee and Joo 1994b; Grosse-Beilage and Grosse-Beilage 1992) but may also be seen in susceptible sows. Acute clinical disease in gilts or boars is as described for epidemics. The reproductive consequences depend on the number of gilts/sows infected and the stage of their reproductive cycle when infected, both of which may vary widely (Torrison et al. 1994). If few gilts are infected on an ongoing basis, there may be scattered abortions, irregular returns to estrus, nonpregnant gilts, and late-term reproductive failure with abnormal litters typical of PRRS. These may be recognized only if records are evaluated on a parity-specific basis (White 1992b). Alternatively, gilts may escape exposure to PRRSV until there is a significant subpopulation of susceptible gilts in various stages of gestation. In this situation, endemic PRRS in the breeding herd manifests as periodic mini-outbreaks of PRRS in gilts and, less commonly, sows, that are identical to those in an epidemic (Dee and Joo 1994b).

Factors Affecting the Severity of Disease
Differences in the expression of clinical disease are incompletely understood and affected by many factors, including virus strain, immune status (discussed elsewhere), host susceptibility, exposure to lipopolysaccharides (LPS), and concurrent infections. Management factors (pig flow, building design, temperature regulation, etc.) likely have impact, but are poorly defined.

PRRS virus strains differ genetically (Murtaugh et al. 1995), antigenically (Nelson et al. 1993; Wensvoort et al. 1992), in severity of induced respiratory disease and lesions (Halbur et al. 1995b, 1996a,b; van der Linden et al. 2003a) and in severity of induced reproductive disease (Mengeling et al. 1996a, 1998; Park et al. 1996). The specific virulence attributes that differ between strains are not known. High virulence strains, as compared to low virulence strains, are known to result in significantly more viral antigen in lung and lymphoid tissues (Halbur et al. 1996a), viremia of higher peak titer and of longer duration (Grebennikova et al. 2004; van der Linden et al. 2003a) and more pulmonary IFN-gamma producing cells (Thanawongnuwech et al. 2003).

A few PRRSV inoculation studies in purebred animals have demonstrated differences in disease between breeds. Halbur et al. (1998) reported significant differences in pulmonary lesions, number of pulmonary PRRSV antigen-positive cells, incidence of myocarditis, and incidence of encephalitis. Christopher-Hennings and others (2001) reported differences in duration of PRRSV shedding in semen of infected boars.

Bacterial LPS, also known as endotoxin, is a major component of bacterial cell walls and is known to be in high levels in dust in poorly ventilated swine buildings (Zejda et al. 1994). Intratracheal administration of LPS in PRRSV-inoculated pigs as compared to pigs given only PRRSV or LPS resulted in consistently more severe

clinical respiratory disease that was temporally associated with 10–100-fold elevations of IL-1, IL-6, and TNF-alpha, but not differences in gross and microscopic lung lesions or number of inflammatory -cells in broncho-alveolar lavage fluids (Labarque et al. 2002; van Gucht et al. 2003).

Infection with PRRSV renders pigs more susceptible to some bacterial and viral diseases and has an additive or synergistic effect with some other bacteria or viruses to create more severe disease than either agent alone. Postnatal and congenital infection with PRRSV renders pigs more susceptible to development of septicemia with *Streptococcus suis* (Feng et al. 2001; Galina et al. 1994). Elegant studies have demonstrated that a likely mechanism is replication in and killing of pulmonary intravascular macrophages (PIMS) and alveolar macrophages (PAMS) as well as reduction in ability of virus-infected PIMs and PAMs to phagocytose and kill bacteria (Thanawongnuwech et al. 1997b; 1998a,b; 2000a,b). This mechanism may be operative in rendering pigs with acute PRRS more susceptible to septicemia by other bacteria, but experimental proof is lacking. Infection of weanling pigs with PRRSV also renders them more susceptible to development of bronchopneumonia due to *Bordetella bronchiseptica* (Brockmeier et al. 2000). This might be due to PRRSV infection of PAMs and resulting reduction in ability to kill bacteria (Thanawongnuwech et al. 1997b). Acute PRRS increases incidence and severity of clinical disease following inoculation with *Salmonella choleraesuis* (Wills et al. 2000). Infection with PRRSV also significantly enhances replication of porcine circovirus type 2 (PCV2), resulting in more severe PRRS viral pneumonia as well as lesions of PCV2-associated porcine multisystemic wasting syndrome (Allan et al. 2000; Harms et al. 2001). Attempts to experimentally confirm field observations of increased susceptibility in PRRSV-infected pigs to diseases caused by *A. pleuropneumoniae*, *Pasteurella multocida*, or *Haemophilus parasuis* have been unsuccessful (Cooper et al. 1995; Pol et al. 1997; Segalés et al. 1999). Other studies have demonstrated an additive or potentiating effect between PRRSV and some bacterial and viral agents. That is, dual infection causes more severe disease than either single infection. These include *Mycoplasma hyopneumoniae*, porcine respiratory corona virus, swine influenza virus, and Aujeszky's disease virus (Shibata et al. 2003; Thacker et al. 1999; van Reeth et al. 1996, 2001). No potentiation was observed between PRRSV and classical swine fever virus (Depner et al. 1999).

LESIONS

Postnatal Lesions

Postnatal virulent PRRSV produces consistent gross lesions of interstitial pneumonia and enlarged lymph nodes in all ages of swine. These lesions are suggestive of PRRSV, but are not diagnostic since a variety of other viral and bacterial diseases can cause similar lesions. Typical microscopic lesions of PRRSV sometimes allow a strong presumptive diagnosis. However, a definitive diagnosis always requires demonstration of PRRSV.

Similar lesions are described in all ages of pigs with PRRSV infection. The severity and distribution of lesions varies with the virulence of virus strain (Done and Paton 1995; Halbur et al. 1996b). Most inoculation studies in which lesions have been described were in suckling or weaned pigs 1–70 days of age (Collins et al. 1992; Dea et al. 1992c; Halbur et al. 1995b, 1996a,b; Pol et al. 1991; Rossow et al. 1994a, 1995). Gross and microscopic lesions are consistently observed from 4 to ≥28 DPI in lung and lymph nodes, where most viral replication takes place. Later, only microscopic lesions are inconsistently observed, beginning at approximately 7 to 14 DPI, in kidney, brain, heart, and elsewhere where there is much less virus; mostly in perivascular and intravascular macrophages and endothelial cells. Microscopic lesions are also in the uterus of dams following reproductive failure and in the testicles of boars. Lesions unique to pigs inoculated at ≤13 days of age include periocular edema on days 6–23 postinoculation, scrotal edema on days 11–14 postinoculation, and subcutaneous edema on days 2–7 postinoculation (Rossow et al. 1994a, 1995).

Lungs have interstitial pneumonia from 3 to ≥28 DPI that is most severe 10–14 DPI. Mild lesions are in cranial lungs or diffuse. Affected parenchyma is resilient, slightly firm, noncollapsing, mottled gray-tan, and moist. Severe lesions are diffusely distributed, and parenchyma is mottled or diffusely red-tan, noncollapsing, firm and rubbery, and very moist. Microscopically, alveolar septa are expanded by macrophages, lymphocytes, and plasma cells and may be lined by hyperplastic type II pneumocytes. Alveoli may contain necrotic macrophages, cell debris, and serous fluid. Lymphocytes and plasma cells form cuffs around airways and blood vessels. Rarely, PRRSV antigen is described in few bronchial epithelial cells with cell swelling and loss of cilia (Done and Paton 1995; Pol et al. 1991). In field cases of PRRS, especially in nursery and grower/finisher pigs, PRRS pulmonary lesions are often complicated or obscured by lesions of concurrent bacterial and/or viral diseases.

Lymph nodes have lesions from 4–28 or more DPI (Dea et al. 1992c; Halbur et al. 1995b; Rossow et al. 1994a,b, 1995). Many lymph nodes in most pigs are enlarged from 2–10 times normal. Early postinoculation, enlarged nodes are edematous, tan, and moderately firm. Later, nodes are firm and white or light tan in a nodular or diffuse pattern. Uncommonly, there are multiple fluid-filled 2–5 mm diameter cortical cysts. Microscopic lesions are predominantly in germinal centers. Early in the course of infection, germinal centers are necrotic and depleted. Later, germinal centers are very large and composed of blast-type lymphocytes. The

cortices may contain small cystic spaces that are variably lined by endothelium and contain proteinaceous fluid, lymphocytes, and multinucleate prokaryocytes (Rossow et al. 1994b, 1995). Microscopically, there may be mild lymphoid necrosis, depletion, and/or hyperplasia in the thymus, in periarteriolar lymphoid sheaths of the spleen, and in lymphoid follicles in tonsil and Peyer's patches (Halbur et al. 1995b; Pol et al. 1991).

Mild to moderate multifocal lymphohistiocytic vasculitis and perivascular myocarditis may develop in the heart ≥9 DPI (Halbur et al. 1995a, 1996b; Rossow et al. 1994a, 1995). Less commonly, mild myocardial fibrillar necrosis and lymphocytic cuffing of Purkinje fibers is described (Rossow et al. 1995).

Mild lymphohistiocytic leukoencephalitis or encephalitis involving cerebellum, cerebrum, and/or brainstem may develop ≥7 days PI (Collins et al. 1992; Halbur et al. 1996b; Rossow et al. 1995; Thanawongnuwech et al. 1997a). There is segmental cuffing of blood vessels by lymphocytes and macrophages and multifocal gliosis. Necrotizing vasculitis was also described in one field case of PRRS with neurologic clinical disease (Thanawongnuwech et al. 1997a).

Kidneys occasionally have mild periglomerular and peritubular lymphohistiocytic aggregates from 14–42 DPI (Cooper et al. 1997; Rossow et al. 1995). Cooper and others (1997) described mild to severe segmental vasculitis that was most severe in the pelvis and medulla. Affected vessels had swollen endothelium, pooled subendothelial proteinaceous fluid, fibrinoid medial necrosis, and intramural and perivascular aggregates of lymphocytes and macrophages.

By 12 hours postinoculation, the nasal mucosal epithelium may have clumped or absent cilia and epithelial cell swelling, loss or squamous metaplasia (Collins et al. 1992; Halbur et al. 1996b; Pol et al. 1991; Rossow et al. 1995). By 7 DPI, lymphocytes and macrophages are in the epithelium and propria-submucosa.

Microscopic lesions are frequently in the uterus of pregnant sows with natural or experimental PRRS (Christianson et al. 1992; Lager and Halbur 1996; Stockhofe-Zurwieden et al. 1993). The myometrium and/or endometrium is edematous with lymphohistiocytic perivascular cuffs. Less commonly, there is segmental lymphohistiocytic vasculitis in small vessels and microseparations between endometrial epithelium and placental trophoblasts that contain eosinophilic proteinaceous fluid and cell debris.

Atrophy of seminiferous tubules is seen in 5- to 6-month-old boars 7–25 days PI (Sur et al. 1997). Atrophic tubules have PRRSV antigen and nucleic acid in germinal epithelial cells, giant cells with 2–15 nuclei, and apoptosis and depletion of germ cells.

Fetal Lesions

PRRS reproductive failure should be suspected when litters are delivered at ≥100 days of gestation but before term and are composed of variable proportions of clinically normal pigs, small or normal-sized weak pigs, dead variably autolyzed pigs, and mummies. Lesions in fetuses and stillborn pigs are uncommon and rarely contribute to a definitive diagnosis of PRRS. An absence of lesions in fetuses does not rule out PRRS.

PRRSV-infected litters contain variable numbers of normal pigs, small weak pigs, and dead pigs that are either fresh stillborn (intrapartum deaths), autolytic stillborn (prepartum deaths), or partially mummified/completely mummified fetuses. Dead pigs are commonly coated with a thick brown mixture of meconium and amnionic fluid; a nonspecific finding that suggests fetal stress and/or hypoxia (Lager and Halbur 1996; Stockhofe-Zurwieden et al. 1993). Most lesions in fetuses are non-specific and due to sterile in utero autolysis.

PRRSV-specific gross and microscopic lesions are few and inconsistent. These are best observed in fetuses with little or no in utero autolysis (Bøtner et al. 1994; Collins et al. 1992; Done and Paton 1995). Lesions are more commonly seen in live-born PRRSV-infected littermates that die or are sacrificed within a few days after birth. Gross fetal lesions include perirenal edema, edema of the splenic ligament, mesenteric edema, ascites, hydrothorax, and hydroperitoneum (Dea et al. 1992c; Lager and Halbur 1996; Plana Duran et al. 1992b). Microscopic lesions are mild and nonsuppurative and include segmental arteritis and periarteritis in lung, heart, and kidney (Lager and Halbur 1996; Rossow et al. 1996b), multifocal interstitial pneumonia with occasional hyperplasia of type II pneumocytes (Plana Duran et al. 1992b; Sur et al. 1996), mild periportal hepatitis (Lager and Halbur 1996), myocarditis with loss of myocardial fibers (Lager and Halbur 1996; Rossow et al. 1996b), and multifocal leukoencephalitis (Rossow et al. 1996b).

An uncommon, but diagnostically discriminating lesion is segmental hemorrhagic enlargement of the umbilical cord up to three times normal diameter that is caused by segmental necrosuppurative and lymphohistiocytic vasculitis (Lager and Halbur 1996).

IMMUNITY

The difficulty of achieving consistent and reliable control and prevention of PRRS with live, attenuated vaccines emphasizes our incomplete understanding of PRRS immunology. Serious deficits exist in our knowledge of the events initiating immunity at the time of infection, of key immunologic targets for both antibody and cytotoxic T cell-directed protection, of the molecular and cellular mechanisms regulating induction and maturation of the immune response, of the consequences of genetic diversity in PRRSV on immune pro-

tection, and of host genetic variation in pig populations on immune resistance to PRRSV.

The immune response to PRRSV begins with an attenuated innate antiviral response in the cytoplasm of an infected macrophage. Interferon (IFN) and inflammatory cytokine responses are weak (Albina et al. 1998; Buddaert et al. 1998; van Reeth et al. 1999). The downregulation of IFN-alpha production facilitates PRRSV replication since IFN-alpha mediates inhibition of PRRSV replication. PRRSV also blocks IFN-alpha production after super-infection with TGEV, a strong inducer of IFN-alpha. This weak innate response may compromise the subsequent initiation and elaboration of antigen-specific adaptive immunity. In addition, suppression of innate antiviral immune mechanisms may increase the risk of secondary infections.

Humoral Immune Response

In serum, PRRSV-specific IgM appears 5–7 days after infection and wanes to undetectable levels after 2–3 weeks. Anti-PRRSV IgG antibodies are detected 7–10 days after infection, peak at about 4 weeks, remain constant for a period of months, and then decline to low levels by 300 days.

The kinetics of anti-PRRSV antibody isotypes in bronchoalveolar lavage (BAL) fluid are similar to those in serum, indicating that these antibodies extravasate from the vasculature. The antibodies in BAL may contribute to the clearance of PRRSV from the lung but are unable to eliminate the virus completely.

Antibodies directed against the nucleocapsid (N) protein are most abundant and are used diagnostically to detect infected animals, but are not neutralizing.

Virus neutralizing (VN) antibodies appear in serum about 3 weeks after infection and are maintained for long periods, but at low levels. There is substantial variation in the VN antibody responses of individual pigs, including lack of response, the kinetics of their appearance, and in the level of titers (Loemba et al. 1996; Nelson et al. 1994; Yoon et al. 1995b). Neutralizing antibodies are produced against glycoproteins GP4 and GP5 and against the matrix (M) protein. A linear epitope on the ectodomain region of GP5 has been identified as the target of neutralizing antibodies, but the characteristics of the specific amino acid sequence involved in neutralization are not fully resolved (Ostrowski et al. 2002; Pirzadeh and Dea 1997; Plagemann et al. 2002; Wissink et al. 2003b).

Antibody responses also are elicited to nonstructural proteins (nsp) of the replicase complex, particularly the nsp2 polypeptide (Oleksiewicz et al. 2001). These antibodies may have diagnostic value and the proteins may be important targets for T cell responses.

The humoral immune response is presumed to play an important role in resistance to reinfection and in prevention or reduction of viral spread from animal to animal since neutralizing antibodies have the potential to clear virus from the circulation. However, the concurrent detection of neutralizing antibodies and infectious PRRSV in blood suggests that the role of neutralizing antibodies in protection against infection may be complex (Loemba et al. 1996; Molitor et al. 1997). Since viremia may occur in the presence of VN antibodies, the level of neutralizing antibodies normally generated against PRRSV may not be sufficient to control the replication of the virus and may even constitute a deleterious, nonprotective response (Yoon et al. 1996).

The kinetics of neutralizing antibody appearance in lung and serum are delayed relative to the changes in viral load in lung and serum. Viral loads peak in the lung at 7–9 days after infection and in serum at 4 days after infection (Labarque et al. 2000; Greiner et al. 2000; Samsom et al. 2000); that is, 2 weeks before VN antibodies first appear. Thus, it appears that neutralizing antibody plays a secondary role in adaptive immune responses to PRRSV.

Cell-Mediated Immune Response

PRRSV titers in the lung peak 7–9 DPI and decline to near zero by day 20, although virus still may be isolated from lung fluids for an extended period. During and subsequent to the decrease in PRRSV, total CD8+ T lymphocyte numbers in the lung may either remain low and constant or increase substantially (Labarque et al. 2000; Samsom et al. 2000). PRRSV-specific T cell responses are transiently induced 2–8 weeks after infection (Bautista and Molitor 1997; Lopez Fuertes et al. 1999; Xiao et al. 2004). T cell responses have been detected against all viral proteins that have been tested, including the products of ORFs 2, 4, 5, 6, and 7 (Bautista et al. 1999). The circulating T cell phenotype is reported as PRRSV-specific CD4+CD8+ memory or CD8+ gamma-delta+, and constitutive CD4+ natural killer (Lopez Fuertes et al. 1999).

The T cell response to PRRSV is highly variable and transient, ranging from insignificant to a high response that occurs after the peak or in the absence of viremia (Xiao et al. 2004). Xiao et al. (2004) found that the abundance of virus-specific T cells in both acutely and persistently infected pigs was highly variable and showed no correlation with the amount of virus. No significant difference in antigen-specific T cell abundance was observed in secondary lymphoid tissues in either acute or persistent infection, except for tonsil, in which the number of responding cells was extremely low. CD4+ and CD8+ T cell frequencies did not change after PRRSV infection, although a decrease in gamma-delta T cells was observed. Macrophages, the permissive cell type for PRRSV, were present in all tissue preparations at various levels that were not in proportion to local virus load. The weak T cell response probably contributes to prolonged PRRSV infection and suggests that PRRSV suppresses T cell recognition of infected macrophages. Meier et al. (2003) also observed that the initial T cell re-

sponse to PRRSV was weak and transient, but increased steadily for 1–2 years after infection.

Protective Immunity

PRRSV persists for weeks or months in lymphoid tissue (Chang et al. 2002; Horter et al. 2002; Wills et al. 1997c). Persistence in lung and lymph nodes despite the presence of neutralizing antibodies and cell-mediated immunity argues that other factors, such as alteration in macrophage permissiveness to infection and innate immunity, may be important in control of PRRSV infection. The broad genetic and antigenic variation in PRRSV and the presence of multiple viral genotypes circulating on farms or within production systems simultaneously also has an unknown effect on the efficacy of humoral and cell-mediated immune responses.

Nevertheless, pigs infected or vaccinated with live PRRSV are resistant to the reproductive effects of PRRSV upon reexposure to homologous PRRSV (Lager et al. 1997b). Exposure to PRRSV therefore establishes some form of immunological memory that restricts or limits the second infection. The level of protection may be profound; Foss et al. (2002) observed the complete absence of PRRSV following challenge of vaccinated pigs, even though there was no change in specific antibody by two separate measures. Partial-to-high levels of protection may also be achieved against reinfection of immune pigs with heterologous PRRSV strains (Lager et al. 2003; Mengeling et al. 1999b, 2003a, b).

Whether neutralizing antibodies or cytotoxic T cells are essential for protection or even play a key role under natural conditions of reinfection is not known. It is possible that protection against PRRSV is afforded primarily by something other than adaptive immunity, such as a change in the permissiveness of macrophages to infection. Lactate dehydrogenase elevating virus, the arterivirus of mice, elicits ineffective neutralizing antibody and cytotoxic T cell responses, but is controlled primarily by a reduction in macrophages permissive for infection (Plagemann and Moennig 1992). In pigs, the infection in the lung begins to subside before there is evidence of an effective adaptive immune response and more than 98% of macrophages do not become infected (Duan et al. 1997b). Primary prevention and control of PRRSV infection by deletion of permissive macrophages would mean that neutralizing antibody and T cell responses are secondary and are more likely to play a role in the final elimination of virus.

CROSS-PROTECTION

PRRSV is continuously evolving and, therefore, vaccine strains will always be different from current field isolates. Therefore, cross-protection against heterologous field isolates is a key issue in disease prevention strategies that include vaccination.

Experimental studies consistently demonstrate a high level of protection for sows against reproductive losses upon rechallenge with strains homologous to an immunizing virus (Lager et al. 1997a, , 1999; Mengeling et al. 1999b). Attenuated live vaccines also have been effective in reducing disease severity, duration of viremia, virus shedding and the frequency of heterologous PRRSV infection (Christopher-Hennings et al. 1997; Dee and Molitor 1998; Lager et al. 1999, 2003; Mavromatis et al. 1999; Mengeling et al. 1999b, 2003a,b; Nielsen and Bøtner 1997; van Woensel et al. 1998). Still, episodic field observations of chronic and endemic PRRS and of "vaccine failure" suggest that protective immunity may be a variable feature of the immune response to heterologous PRRSV isolates.

MATERNAL IMMUNITY

No specific study has evaluated the effect of maternal immunity on piglet susceptibility to PRRSV infection, but indirect inferences suggest that immune sows provide maternal protection to piglets. Anti-PRRSV antibodies are present in colostrum at the same concentration as in blood (Eichhorn and Frost 1997) and PRRSV infections increase in pigs as maternal antibodies decline (Albina et al. 1994; Chung et al. 1997; Houben et al. 1995; Melnichouk et al. 2005). Maternal immunity appears to be of relatively short duration. In a study of seven commercial herds in Canada, Melnichouk et al. (2005) estimated that 12–44% of pigs had maternal antibodies at 3 weeks of age, but only 2–16% by 5 weeks of age. In the dam, prior immunity does not prevent transplacental infection (Lager et al. 2003) and neutralizing antibodies, particularly at low concentrations, may exacerbate PRRSV infection by antibody-dependent enhancement (ADE) (Yoon et al. 1996). At present, the role of maternal immunity in protection of piglets against PRRS is not known.

DIAGNOSIS

A diagnosis of PRRSV is based on subjective (history, clinical signs, gross and microscopic lesions) and objective (herd production records, detection of virus, and serology) information (Benfield et al. 1999). Table 24.1 summarizes the various diagnostic assays and their recommended use.

A presumptive diagnosis of PRRS is suggested in any herd with reproductive problems in breeding swine and respiratory disease in pigs of any age. Production records in clinically active PRRS herds usually reveal evidence of increased abortions, early farrowings, stillbirths, preweaning mortality, and nonproductive sow days. However, the lack of these signs does not indicate that a herd is free of PRRSV infection. Differential diagnoses include parvovirus, pseudorabies virus, hemagglutinating encephalomyelitis virus, porcine circovirus type 2, enterovirus, swine influenza virus, classical swine fever

Table 24.1. Summary of the use of diagnostic assays for the diagnosis of PRRSV

Assay	Sensitivity	Specificity	Preferred Diagnostic Specimens by Stage of Infection (Days Post Infection (DPI))				Optimum Window of Detection (DPI)
			In Utero Infection	1–28 DPI	30–90 DPI	90–300 DPI	
VI	medium	high	Collect samples from live pigs. Stillborn pigs or mummies are of limited diagnostic value. Refer to list of tissues for acute infection (1–28 DPI). Umbilical cords and umbilical cord blood also appropriate samples.	Serum, lung, tonsil, lymph nodes, lung lavage, heart, kidney, spleen, thymus	Tonsil, oropharyngeal scrapings, serum, lung lavage	Tonsil, oropharyngeal scrapings. Success rate rare to very low.	Serum and most tissues positive through 28–35 DPI. Lymphoid tissues through 157 DPI in limited number of pigs.
FA	medium	Depends on strain of PRRSV used in the test	Lung from live pigs	Lung or macrophages in lung lavage	Lung lavage and direct culture of macrophages from lavage sample.	Not recommended	4–14 DPI
IHC	medium	high	Most tissues from live pigs	See list for VI	Limited success with lymphoid tissues from 30–70 DPI	Not recommended	4–14 DPI
PCR	high	high	Limited success with thoracic fluid and tissues from stillborn fetuses. Most tissues from live pigs.	See list for VI	Good success with tonsil, oropharyngeal scrapings, and lung lavage	Tonsil, oropharyngeal scrapings, and lymph nodes. Success rate low.	Reports of detection by PCR up to 257 DPI.
ELISA	high	high	Can detect antibodies in umbilical cord blood.	serum	serum	serum	Variable from 9–13 DPI to at least 10 months post infection
IFA	high	Depends on strain of PRRSV used in the test	Can detect antibodies in umbilical cord blood.	serum	serum	serum	Variable from 9–14 DPI to 5 months pi
VN	low	Depends on strain of PRRSV used in the test	Not detected in stillborn fetuses or live pigs	serum	serum	serum	Variable from 9–28 DPI, usually 28–46 DPI for appearance and persists up to 12 months

VI=virus isolation; FA=fluorescent antibody on frozen samples; IHC = immunohistochemistry using formalin fixed tissues; PCR=reverse-transcriptase polymerase chain reaction; ELISA= HerdChek 2XR PRRS ELISA, IDEXX Laboratories Inc., Westbrook, Maine; IFA=indirect fluorescent antibody; VN=serum-virus neutralization. Contents of table based on references used in the "Diagnosis" section.

virus, cytomegalovirus, and leptospirosis (Halbur 2003). Co-infections with bacteria and other viruses also complicate the differential diagnosis (Halbur 2003; Zeman 1996). Thus, a definitive diagnosis requires either detection of PRRSV or antibodies in infected pigs.

Pathological Evaluation

There are no pathognomonic gross or microscopic lesions for PRRSV and aborted fetuses and stillborn pigs rarely have lesions of diagnostic value. Gross lesions of interstitial pneumonia and enlarged lymph nodes can be observed in infected pigs of all ages (Lager and Halbur 1996; Stevenson et al. 1993). Microscopically, interstitial pneumonia is the primary lesion. The virus replicates in alveolar macrophages and in macrophages and dendritic cells in germinal centers of lymphoid tissues, vascular endothelial cells, and the intra- and perivascular macrophages of blood vessels in the heart, brain, kidney and other tissues (Halbur et al. 1995; Rossow et al. 1996; Thanawongnuwech et al. 1997b). Lung, lymph nodes, heart, brain, thymus, spleen, and kidney may be fixed in 10% neutral buffered formalin and submitted to the diagnostic laboratory for microscopic evaluation and immunohistochemistry (IHC). The combination of IHC and histopathology allows visualization of cells containing PRRSV antigens in the cytoplasm within or contiguous to microscopic lesions (Halbur et al. 1994; Magar et al. 1993). Tissues should be processed for IHC within 48 hours of fixation to avoid degradation of PRRSV antigens and loss of IHC-positive cells (Van Alstine et al. 2002). Lesions and viral antigens are best observed during acute infection (4–14 DPI), when viral titers in tissues are high and sufficient quantities of viral antigen are present in the cytoplasm of infected cells.

Laboratory Confirmation

Detection of either PRRSV or antibodies is dependent upon proper sample selection and handling. Specimens for virus isolation and detection of viral RNA must be refrigerated (4°C) immediately after collection (freezing may degrade viral RNA for PCR) and shipped to the diagnostic laboratory within 2 days (Yoon et al. 2003). The virus is degraded by heat and has a narrow pH stability. Thus, maintain sterility to avoid pH alterations caused by bacterial contamination and always submit fresh tissues (Benfield et al. 1992, 1999; Bloemraad et al. 1994; Van Alstine et al. 1993). Generally, PRRSV is detected in higher amounts and for longer periods of time in younger, compared to older, pigs. Virus persists longer in tonsil and lymph nodes relative to serum, lung, and other tissues. Virus replicates in most tissues during the acute phase of the disease, reaching peak levels at 4–7 DPI before declining to undetectable levels by 28–35 DPI. Viremia can persist for 28–42 DPI in suckling, weaned, and grower pigs (Mengeling et al. 1996c) and for 7–14 DPI in sows and boars (Christopher-Hennings et al. 1995; Mengeling et al. 1996c). Infectious virus and viral RNA can be demonstrated in pulmonary lung lavages, tonsil, and lymph nodes for several weeks after cessation of viremia (Benfield et al. 1999; Horter et al. 2002; Mengeling et al. 1995; Rowland et al. 2003; Wills et al. 2003).

Virus Isolation (VI)

Virus isolation is done using either porcine alveolar macrophages (PAMs) or sublines (CL-2621, MARC-145) of the African monkey kidney cell line MA-104 (Benfield et al. 1992; Kim et al. 1993). Isolation of PRRSV on these cell lines followed by fluorescent antibody (FA) or IHC staining of cells to detect viral antigens is the gold standard for detection of infectious virus. Results can be obtained within 1 day after inoculation of cultures, but may take several weeks, depending on the amount of virus in the clinical specimen. PAMs are reported to be more sensitive than MARC-145 cells for VI and the presence of Fc receptors on PAMs enhances the success of isolating PRRSV in the presence of antibodies (Yoon et al. 2003). Use of MARC-145 cells may also bias VI for recovery of modified live vaccine viruses because they are adapted to this cell culture (Benfield et al. 1999; Yoon et al. 2003). Not all PRRSV strains replicate in all cell types (Bautista et al. 1993), suggesting that at least two cell types should be used for VI whenever possible (Yoon et al. 2003). Use of PAMs is required for successful isolation of most European-like strains of PRRSV (Christopher-Hennings et al. 2002; Wensvoort et al. 1991).

Virus can also be detected by VI, FA, and PCR in direct cultures of PAMs from pulmonary lavage collected either from live infected pigs or at necropsy (Mengeling et al. 1995).

The most sensitive assay for detection of PRRSV is the swine bioassay. In this assay, a homogenate of sample suspected to contain PRRSV is injected into a young pig. Presence of PRRSV in the sample is confirmed by seroconversion or detection of replicating virus in the bioassay pig (Horter et al. 2002; Swenson et al. 1994a,b).

Virus isolation is most successful using serum, lung, lymph nodes, and tonsil collected between 4–28 DPI. In late-term abortion and early farrowings, similar tissue samples from liveborn pigs are preferred, because mummies or stillborn fetuses rarely yield positive VI results due to tissue autolysis. For persistent infections, tonsil, oropharyngeal scrapings, and lymph nodes are better samples than serum and lung. Under experimental conditions, virus has been isolated from the tonsil and oropharyngeal scrapings at 130 and 157 DPI, respectively (Rowland et al. 2003; Wills et al. 2003).

Detection of Viral Antigens

Viral antigens are detected by immunohistochemistry (IHC) using formalin fixed tissues (Halbur et al. 1994; Magar et al. 1993; Van Alstine et al. 2002) and fluorescent antibody (FA) using frozen tissue sections (Benfield et al. 1992). Lung, heart, kidney, lymph nodes, spleen,

thymus, and tonsil are typically used for IHC, whereas lung is the primary sample for FA (Halbur et al. 1996a; Rossow et al. 1999). Both assays use the SDOW17 or SR30 monoclonal antibodies, either singly or in combination (Nelson et al. 1993; Yoon et al. 1995a), to detect viral nucleocapsid antigen in the cytoplasm of infected cells. The IHC is more sensitive than the FA test and can be done using formalin fixed tissue. The FA test is more rapid and more economical, but requires fresh tissue. Results from both tests are influenced by technician skill, so diagnostic laboratories usually confirm positive IHC and FA tests by VI or PCR. Viral antigens are best detected during peak viral replication (4–7 DPI).

Detection of Viral Nucleic Acid

PCR-based assays detect viral nucleic acid in tissue homogenates, serum, semen, oropharyngeal scrapings, and pulmonary lavage fluids. These assays are highly sensitive and specific (Benson et al. 2002; Horter et al. 2002). While VI amplifies infectious virions, PCR converts viral RNA to DNA using a reverse transcriptase and then exponentially amplifies the DNA to a detectable level. PCR offers several advantages over VI, IHC and FA: (1) Higher sensitivity and specificity; (2) Detection of viral RNA in both acute and persistently infected pigs; (3) Detection of viral RNA in autolyzed fetuses and in samples, such as semen and feces, that are toxic to cell cultures; (4) Rapid turnaround time, with results available in 1–3 days compared to days-to-weeks with other diagnostic assays; and (5) PCR products can be utilized for sequencing, thus expanding the diagnostic utility of this assay. The main disadvantage of PCR is that it does not differentiate between infectious and noninfectious virus. However, under experimental conditions, 94% and 81% correlation was reported between positive PCR results and detection by swine bioassay of infectious virus in semen and oropharyngeal scrapings, respectively (Christopher-Hennings et al. 1995b; Horter et al. 2002).

PCR assays are validated within, and occasionally between, diagnostic laboratories. Results may vary among diagnostic laboratories depending on the PCR assay and the method used to amplify and detect the viral genome (Christopher-Hennings et al. 2002; Kleiboeker et al. 2002). Nested PCR tests are as sensitive as conventional VI techniques, but require stringent controls to avoid false positive results. PCR-based assays are in a period of change and improvement. Several automated PCR methods have recently been developed that are less prone to false positive results, better adapted to screening multiple samples and more economical than nested PCR. These tests target ORF6 and ORF7, i.e., the ORFs with the most consistent nucleotide sequences between different strains of PRRSV. If sequencing is used to monitor viral evolutionary changes within herds, the ORF5 gene is targeted. Recently, a real time PCR assay that uses a primer to the 3'UTR sequence of the PRRSV genome to detect PRRSV nucleic acid in semen and sera was commercially released. Once licensed for diagnostic use, the industry will have a standardized PRRSV PCR assay (Wasilk et al. 2004).

In acute infections, serum and the tissues recommended for VI are also the preferred diagnostic samples for PCR. During persistence, oropharyngeal scrapings and PCR are the most sensitive combination of sample and assay for detection of PRRSV (Horter et al. 2002). PRRSV nucleic acid has been detected up to 86 DPI in lymph nodes (Bierk et al. 2001), 92 DPI in semen (Christopher-Hennings et al. 1995), 105 DPI in oropharyngeal scrapings (Horter et al. 2002), and 251 DPI in serum and tonsil homogenates (Wills et al. 2003).

Sequencing

Sequencing is commonly done on ORF5 and ORF6 with direct PCR products from diagnostic samples to avoid the potential bias of selection, mutation, or nucleotide changes by passage in cell culture. ORF5 sequences are highly variable and there is an extensive databank of sequences available for comparison. ORF6 is highly conserved and serves as a sequencing control. Sequencing is best used to show the relatedness of strains over time and within a herd. Computer programs compare all possible pairs of sequences and a phylogenetic tree or dendogram is constructed. A phylogenetic tree depicts similarity among genomic sequences like a family lineage. This type of analysis may be used to

1. Determine whether the reappearance of PRRS on a farm is due to the reemergence of a previously existing or a new virus strain.
2. Determine whether PRRS outbreaks on farms are due to a single clone or multiple clones of virus.
3. Track introduction of virus into a swine operation.
4. Monitor spread of PRRSV strains within and between herds.
5. Differentiate vaccine and field viruses (Christopher-Hennings et al. 2002; Roberts 2001, 2003a).

Restriction Fragment Length Polymorphism

Prior to the advent of sequencing, restriction fragment length polymorphism (RFLP) of ORF5 was developed to differentiate a PRRSV modified live vaccine strain from other North American field strains. The ORF5 PCR product is digested using three restriction endonucleases. These enzymes always cleave a nucleic acid chain at a predetermined sequence of nucleotides; thus viruses with the same RFLP pattern contain the same restriction cleavage sites and have similar sequences. Each digest was assigned a three-digit code based on the pattern of digestion (Umthun and Mengeling 1999; Wesley et al. 1998). RFLP patterns are now based on computer-generated digestion patterns from an ORF5 sequence. Experience has shown that RFLP characterizations do not accurately reflect similarity or differences among isolates.

Indeed, many genetically dissimilar PRRSV isolates share the same RFLP pattern. RFLP data were previously used to determine the introduction of a new PRRSV isolate into a herd, monitor spread of an isolate, and differentiate vaccine from field viruses (Christopher-Hennings et al. 2002). Most of the applications of RFLP have been replaced by sequencing and phylogenetic analysis (Roberts 2003a).

Serology

Serological diagnosis is still favored by many practitioners because serum is easily collected in quantities for multiple tests and easily stored for future reference. The demonstration of seroconversion (negative to positive) using acute and convalescent serum samples is the most definitive method to diagnose PRRSV infection serologically. Increasing titers of PRRSV specific antibody demonstrated by FA or rising ELISA S/P ratios in a group of infected animals can also indicate PRRSV infection.

Serology is not a valid approach for diagnosis of PRRSV in previously infected or vaccinated herds, because serologic assays do not differentiate among antibodies resulting from the initial infection, reinfection, or vaccination. Single serum samples are of limited use because of the high prevalence of PRRSV in herds. For that reason, a single positive serologic result does not prove a causal role for PRRSV in a clinical diagnosis. Detection of antibodies in nursing and nursery pigs may be due to the presence of maternal antibodies, which usually persist until pigs reach 3–5 weeks of age (Melnichouk et al. 2005).

Five serological tests to detect antibodies to PRRSV have been described: indirect fluorescent antibody (IFA), ELISA, blocking ELISA, serum-virus neutralization (VN), and immunoperoxidase monolayer assay (IPMA). The proper use of these assays, interpretation, and limitations has been reviewed elsewhere (Christopher-Hennings et al. 2002; Yoon et al. 2003).

The IFA detects IgM and IgG antibodies as early as 5 and 9–14 DPI, respectively (Joo et al. 1997; Zhou et al. 2002). The IgM antibodies persist for 21–28 DPI, whereas IgG antibodies peak at 30–50 DPI and are undetectable 3–5 months after infection. Test sensitivity is impacted by the technical skill of laboratory personnel and antigenic differences between the PRRSV isolate used in the IFA and the field strain that induced antibodies in the pig. Little or no cross reaction between North American and European-like isolates of PRRSV is demonstrated by IFA (Christopher-Hennings et al. 2002). This assay is generally used to confirm a suspicious positive ELISA result.

The commercial ELISA (HerdChek® 2XR PRRS ELISA, IDEXX Laboratories Inc., Westbrook, Maine) is the "gold standard" for detection of antibodies to PRRSV. The assay is sensitive, specific, standardized, and rapid. The test putatively targets antibodies to the nucleocap-

sid antigens for both North American and European-like strains of PRRSV. Antibodies can be detected as early as 9 DPI, peak at 30–50 DPI and then decline to negative levels 4–12 months after infection. ELISA results are interpreted as positive (S/P ≥0.4) or negative (S/P <0.4). Practitioners have attempted to use ELISA S/P ratios to differentiate animals on the basis of their susceptible, infectious, and resistant immune status. However, this is an overinterpretation of the assay because the response of individual pigs on the ELISA is highly variable (Roberts 2003a).

Interpretation of ELISA negative and positive samples collected at a single point in time can be difficult. Negative ELISA samples have several possible interpretations:

1. Pigs were not infected.
2. Pigs were recently infected and have not yet seroconverted.
3. Pigs are persistently infected, but have become seronegative.
4. Pigs have cleared the infection and reverted to seronegative.
5. Pigs are negative due to low test sensitivity (Roberts 2003a; Yoon et al. 2003).

Pigs negative for antibodies on ELISA can be persistently infected, as demonstrated by recovery of virus or detection of virus or viral RNA in tonsil tissues or oropharyngeal scrapings (Dee et al. 2004a; Horter et al. 2002; Kleiboecker et al. 2002).

False positive (ELISA-positive reactors in expected negative herds) reactions occur at a rate of 0.5–2.0% (Ferrin et al. 2004; Keay et al. 2002; O'Connor et al. 2002; Torremorell et al. 2002a). Both IFA and blocking ELISA are used as confirmatory tests in cases of suspected false positive ELISA results. The blocking ELISA is as sensitive and specific as the commercial ELISA and IFA (Ferrin et al. 2004).

The serum-virus neutralization (VN) assay detects antibodies capable of neutralizing a constant amount of PRRSV in cell culture. The test is highly specific, but antibodies do not develop until 1–2 months after infection; thus the assay is less sensitive than the IFA and ELISA (Benfield et al. 1992). These antibodies typically peak 60–90 DPI and persist up to 1 year after infection. Like IFA, the magnitude of the VN response is highest when homologous virus is used in the assay. Laboratories have not developed standardized VN tests and it is typically used as a research rather than a diagnostic test.

Application of Diagnostic Assays to Herd Monitoring

Herd monitoring is typically done using ELISA and PCR as screening assays and PCR, IFA, and blocking ELISA to confirm suspicious positive results in herds expected to be negative for PRRSV (Dufresne et al. 2003). Issues in herd monitoring are complex and are extensively re-

viewed elsewhere (Dee 2004; Dufresne et al. 2003; Roberts 2003a,b).

PREVENTION AND CONTROL

Prevention

The objective of PRRSV prevention programs is either to stop the introduction of PRRSV into negative herds or the introduction of new strains into PRRSV-infected herds (Dee et al. 2001). Animals and semen have been considered the primary sources of PRRSV (Le Potier et al. 1997), but the importance of other sources of infection has become evident (Desrosiers 2004). Torremorell et al. (2004) found that over 80% of new infections occurring in commercial systems in the U.S. were not due to pigs or semen, but to area spread from neighboring units, the movement of pigs in PRRSV infected transports, the lack of compliance of the biosecurity protocols, or the possible introduction via insects.

Under ideal conditions, biosecurity starts with the establishment of the production units in isolated areas, but regardless of the herd location, biosecurity efforts should place particular emphasis on all procedures involving the movement of inputs and outputs from the farms, e.g., pigs, supplies and materials, feed, water, personnel, removal of manure, and reclaims. Because PRRSV persists in cold and wet conditions (Dee et al. 2002), all equipment and material used at the farm or for transport of pigs must be cleaned and dried (Dee et al. 2004b,c). All units should also exclude the entry of pests such as rodents, insects, and birds from all buildings.

All replacement breeding stock entering a negative herd should originate from sources known to be PRRSV-negative by a regular schedule of herd testing. In addition, all breeding stock should be properly isolated in isolation/quarantine facilities for a minimum of 30 days and then tested prior to introduction into the herd.

Semen for artificial insemination should come from PRRSV-negative boar studs. Boar studs should be routinely monitored for PRRSV infection. In order to detect early infections, it is recommended that serum or semen from stud boars be tested with a PCR-based assay prior to use in order to detect early infection. Although PCR testing allows for early detection of infections (Christopher-Hennings et al. 1995b; Wasilk et al. 2004), it may not fully prevent infection downstream should an infection in the stud occur (Torremorell and Conroy 2003).

Control

Specific treatments for PRRS are not available. Therefore, the objective of PRRS control is to limit the effects of the virus in the various stages of production. Even so, consistent PRRS control is problematic.

PRRSV cycles in endemically infected herds because, at any given time, animals are in various stages of infection and immunity (Dee et al. 1996). Circulation of the virus in the breeding herd results in PRRSV-infected piglets (Albina et al. 1994). Therefore, the first step in breaking virus circulation in the breeding herd is to use replacement animals that have been exposed to PRRSV and developed immunity prior to their introduction into the herd (Dee 2003). Consistent acclimatization of incoming breeding stock to PRRSV results in the stabilization of clinical signs, improvements in production parameters, and the production of PRRSV negative piglets at weaning.

Gilt introduction is the key to PRRSV control (FitzSimmons and Daniels 2003). This is primarily achieved through management steps involving the gilt pool. Serologically negative replacements are exposed to PRRSV in the acclimatization or isolation unit and are allowed to recover from infection. These animals are then introduced into the breeding herd after they become immune, i.e., when they are no longer viremic and do not constitute a source of infection to herdmates. Different methods for gilt acclimatization have been described (Dee et al. 1994; FitzSimmons and Daniels 2003). It is generally accepted that early exposure (2–4 months of age) will result in protection of the exposed animals and introduction of the replacement animals at a time when shedding has stopped. The exposure methods described in this section utilize PRRSV-negative gilts as the starting point. Regardless of the method of exposure, a major challenge is achieving consistent PRRSV infection.

Continuous-flow gilt development units that rely on contact exposure from previously infected PRRSV positive replacements to newly incoming PRRSV negative animals do not always yield consistent results. In some systems, weaned pigs and culled sows are also used as donor sources for infectious material. However, over time and as the breeding herd becomes immune, virus transmission within the breeding herd stops and the production of PRRSV negative animals at weaning increases. Therefore, incoming gilts may not become exposed to PRRSV when they are commingled with weaned pigs.

Additional exposure methods in replacement gilts may include methods such as feedback with tissues from weak-born piglets and stillbirths in the face of outbreaks, the use of modified live and killed vaccine products, and inoculation of negative replacement animals with serum collected from viremic pigs from the same farm (Batista et al. 2002; Dee 2003; FitzSimmons and Daniels 2003; Thacker et al. 2003).

Modified live virus (MLV) vaccines are used to develop protective immunity and bring consistency to the procedures. The main limitation attributed to PRRSV vaccines is the limited cross-protection that may exist among PRRSV strains. When using MLV vaccine products, the entire population housed in the same air space should be vaccinated at one time. Killed vaccine products may be used in gilt acclimatization protocols as a complement to MLV vaccine products or following exposure with field virus.

The use of planned exposure using serum containing viable field virus has recently increased due to the increased genetic heterogeneity among PRRSV strains and the perception that commercial vaccines do not induce enough protective cross-protection among newly identified PRRSV strains. This method has inherent risks and requires thoughtful application and high quality control standards.

Breeding-Herd Control. The consistent application of acclimatization protocols for incoming replacement animals results in the stabilization of the breeding herd and the production of PRRSV negative animals; therefore, additional procedures directed at breeding/gestating animals may not be required. However, MLV vaccines have also been used in the breeding herd in order to reduce the presence of susceptible animals (Dee 1996; Gillespie 2003), expedite the production of PRRSV-negative pigs (Gillespie 2003; Rajic et al. 2001), and, in the face of outbreaks, to limit field virus replication (although success of the latter measure is still under discussion). Currently, some products are approved for use in nonpregnant females; others are not. Producers and veterinarians should read the product label and understand its application. Vaccination of negative pregnant sows during the third trimester of gestation has been reported to result in fetal infection (Mengeling et al. 1996a).

Planned exposure based on inoculating pigs with serum collected from acutely affected pigs has also been used in the face of acute outbreaks. This procedure should be considered experimental at this time and veterinarians should be cautious in its use. Although it has inherent risks and very little documented information, planned exposure is thought to shorten the duration of the clinical outbreak and speed the recovery of the PRRSV negative weaned pig production. Overall losses expected to be incurred through planned exposure are believed to be similar to a naturally occurring outbreak.

An additional measure to minimize the effects of PRRSV infection in the face of a recent infection or in an effort to accelerate production of PRRSV-negative weaned pigs is the temporal interruption in the introduction of replacement animals (temporal herd closure) (Dee et al. 1994; Torremorell et al. 2003). By discontinuing the introduction of younger, recently infected, replacement animals, a level of herd stabilization is achieved. Periods of 2–4 months may be sufficient to minimize the effects of the virus, but not to eliminate it.

Weaned-Pig Management. Control of chronic PRRS in the weaned-pig population is one of the most frustrating challenges that veterinarians face. The cycle of transmission within the nursery or finishing stage is maintained through transmission of the virus to recently weaned piglets from older, infected pigs. Partial depopulation is a control strategy that consists of a strategic adjustment in the pig flow to prevent the lateral spread of PRRSV within chronically infected populations. Results of partial depopulation have shown highly significant improvements in average daily gain, mortality, and the overall economic performance of the nursery (Dee et al. 1993; Dee et al. 1997). Limitations to this strategy include the logistics involved in depopulating large nurseries and the fact that it may need to be repeated periodically to maintain improvements in performance.

An alternate strategy to eliminate the virus from the infected population is mass MLV vaccination of the growing pig population and unidirectional pig flow (Dee and Phillips 1998). This strategy has been used in commercial settings to displace PRRSV when emptying a site is not a possibility.

Control measures in the weaned pig population should also include the control of concurrent infections aggravated by PRRSV infection, e.g., *Haemophilus parasuis*, *Streptococcus suis*, etc. Appropriate vaccination and medication protocols need to be determined for the individual infections.

If the suckling piglet population is acutely infected, a series of management strategies may be required (Henry 1994; McCaw 2000, 2003). Management practices should limit the movement of piglets between litters to the initial 24 hours of life, humanely destroy chronically infected offspring prior to weaning, and maintain strict all-in/all-out animal flow of the nursery.

Eradication. Spontaneous elimination of PRRSV from a herd has been described (Freese and Joo 1994), but this is considered a rarity for current production systems. Over the last few years major advances have been made to define protocols that can successfully eliminate PRRSV from infected farms (Dee 2004; Torremorell et al. 2003). These include total depopulation/repopulation, partial depopulation, segregated early weaning, test-and-removal, and herd closure.

Successful PRRSV elimination in the breeding herd relies on the introduction of negative nonexposed replacement animals at a time when virus is no longer circulating. Successful control strategies, as described earlier, will prepare the population for eradication since eventually an immune, virus-free, population is developed. A successful elimination plan also requires the implementation of strict biosecurity measures in order to prevent the herds from becoming reinfected (Torremorell et al. 2004).

Total herd depopulation and repopulation is a very successful technique, but it is costly and may be justifiable only if the elimination of other concurrent diseases is desired. This strategy may be the only feasible alternative for farrow-to-finish herds where ongoing replication of PRRSV in the growing population does not allow for the elimination of the virus through other measures.

Partial depopulation, described above, has also been

used for the elimination of PRRSV (Dee et al. 1993; Dee et al. 1997). This measure is indicated for the elimination of the virus from growing pigs when shedding from the breeding population has completely stopped. This technique may be sufficient to eliminate the virus from small-sized farms. However, when used in large units (>500 sows), it requires the application of additional strategies, e.g., herd closure or test-and-removal, to eliminate the virus from the breeding herd prior to attempting elimination in the pig flow.

Segregated early weaning has also been used to produce PRRSV-negative pigs from infected sows. Depending on the level of PRRSV activity in the sow herd, production of PRRSV-negative batches may not be consistent (Donadeu et al. 1999; Gramer et al. 1999). All-in/all-out segregated production of batches of weaned pigs is needed to maximize the success of this technique. In addition, the establishment of PRRSV negative herds from positive sources is possible when negative piglets are produced by the combination of several of these techniques (Torremorell et al. 2002b).

PRRSV elimination through herd closure is based in the fact that PRRSV cannot persist in an immune population (Torremorell et al. 2003). This strategy mimics the principles followed for TGE eradication, whereby all animals are exposed to the virus and no replacement animals are introduced while there is a possibility that they could be exposed to the virus (Harris et al. 1987). In the case of PRRSV, longer periods of herd closure with no introduction of new replacement animals are required. Exposed animals will eventually eliminate the virus from their tissues, although because of the ability of PRRSV to establish persistent infection, this will require a long time. As a rule of thumb, a period of 6 months is recommended, but variations may be needed depending on the status of the farm and pig flow. Introduction of negative replacement animals should be followed by attrition or scheduled culling of the previously infected animals. This strategy will develop a negative population of breeding animals over time. The success rate using this strategy is above 90% for farms with segregated production. Production management practices, such as off-site breeding projects and others, can minimize the economic effects of herd closure.

PRRSV elimination through the test-and-removal technique has also showed promising results (Dee 2004). Elimination of PRRSV by test-and-removal consists of blood-testing the entire breeding herd, identifying PRRSV-infected animals using tests both for antibody and virus, and removing positive animals from the farm. Candidate herds for test-and-removal include herds with segregated production and more than 12 months since the last clinical episode of PRRSV, as well as herds with an estimated prevalence below 25%. Test-and-removal is recommended for herds where there is no indication of virus recirculation in the breeding herd and where the presence of persistently infected animals is considered a potential risk for failure of the program.

Vaccines. Several studies have established that vaccination against PRRSV can result in protective immunity (Gorcyca et al. 1995; Hesse et al. 1996; Mengeling 1996b; Plana Duran et al. 1995). A variety of MLV and inactivated products are available, depending upon the geographic region. In general, it is accepted that MLV vaccines induce a more efficacious immune response, although there are concerns regarding the safety of some of the products. Inactivated vaccines are also available, but in general they are considered less efficacious when used in naive animals. However, when used in combination with attenuated products or in previously infected animals, they may induce a higher production of neutralizing antibodies than when used alone.

When used in the field, vaccines have met with variable degrees of success. These differences may be due to differences in the commercial products available and in how the products are utilized. Likewise, the results may reflect differences in the virus strains circulating in different regions and/or they may relate to the question of cross-protection. In addition, field reports raise the possibility of reversion virulence by attenuated vaccine virus (Nielsen et al. 2001). Vaccine virus behaves very similarly to field PRRSV strains in terms of transmission, persistence, transplacental transmission and congenital infection, shedding in semen, and the length of time required to induce protective immunity. Research to provide safer and more efficacious products is needed in order for practitioners and producers to have a reliable tool to control the devastating effects of PRRSV.

25 Aujeszky's Disease (Pseudorabies)

Z. K. Pejsak and Marian J. Truszczyński

Pseudorabies (PR) was first described in 1813 in cattle suffering with extreme pruritus. Based on the clinical signs, the disease was called "mad itch" (Baskerville et al. 1973). The term "pseudorabies" was first used in Switzerland in 1849 because the clinical signs in cattle were considered similar to those of rabies. Aladar Aujeszky, the Hungarian for whom the disease is named, determined that the etiologic agent was filterable, i.e., not bacterial, and also conducted research on the disease in the dog and cat. The agent was first recovered from swine in 1909 by Weiss and from sheep in 1910 by Schmiedhoffer (Wittmann and Rziha 1989). Schmiedhoffer also confirmed Aujeszky's findings that the agent was filterable, i.e., that it was viral. In 1934, Sabin and Wright identified the virus as a herpesvirus, later called swine herpes virus 1 (SHV-1) or pseudorabies virus (PRV).

The primary host of PRV is the pig. The pig is the only species able to survive a productive infection and, therefore, serves as the reservoir host (Kretzschmar 1970). Prior to the 1960s, PR was of some importance in pig production, but only in Europe (Wittmann and Jakubik 1979). Beginning in the 1970s, PR achieved global importance (Kluge et al. 1999). The transformation of PR from a sporadic, fatal disease of cattle to a swine disease of major economic significance on a worldwide basis was driven by changes in swine production. Specifically, over a period of 50 years, swine production became concentrated into large farms located relatively close to each other. In addition, intensified international trade led to greater movement of animals, particularly swine and their by-products (Müller et al. 2003; Pensaert and Kluge 1989; Wittmann 1985). At present, PR causes serious losses to swine producers in many parts of the world, both as a result of the disease and because of movement restrictions related to controlling PRV and its impact on trade (Andersson et al. 1997; Bech-Nielsen et al. 1995; Müller et al. 2003; Vannier 1988; Waston 1986).

Significant progress in molecular biology and ge-netic engineering, most notably by Van Oirschot et al. (1990) and Mettenleiter (1994a, 2000), led to major improvements in diagnostic methods and vaccines and resulted in vast improvements in the prevention and control of the disease in the last 15 years.

ETIOLOGY

PRV belongs to subfamily *Alphaherpesvirinae* of the family *Herpesviridae* (Mettenleiter 2000). Comparison of deduced amino acid sequences of homologous proteins showed PRV to be closely related to bovine herpesvirus 1 (BHV-1), equine herpesvirus 1 (EHV-1), and varicella-zoster virus (McGeoch and Cook 1994). On this basis, it was assigned to the genus *Varicellovirus* of subfamily *Alphaherpesvirinae*.

Alphaherpesviruses are characterized by rapid lytic growth in cell culture, neurotropism, latency in neurons, and a broad host range. All of these features are particularly pronounced in PRV. Numerous strains of PRV have been described, and differences in the severity of clinical signs have shown that strains differ in their infectivity and virulence. Strains also differ in the quantity and duration of virus shedding during infection (Maes et al. 1983). Genomic differences believed to influence virulence have been identified (Gielkens et al. 1985; Lomniczi et al. 1984; Lomniczi and Kaplan 1987).

PRV particles have the typical architecture of a herpes virion. They are quasispherical in shape, with an overall diameter of 150–180 nm (Nauwynck 1997). Mettenleiter (2000) demonstrated that PRV, like all herpesviruses, is composed of a nucleoprotein core that contains the genome, an icosahedral capsid of 162 capsomers, a proteinaceous tegument layer, and a lipid bilayer envelope derived from cellular membranes that contain virus-encoded (glyco) proteins. Figure 25.1 shows an electron micrograph of a PRV virion attached to a bovine kidney cell (Granzow et al. 1997).

Studies on capsid architecture have primarily been done on herpes simplex virus (HSV-1). However, the
25.1. *Electron micrograph of a PRV virion attached to a bovine kidney cell (MDBK) in culture. Bar: 150 nm (from Mettenleiter 2000).*

morphological similarity of herpesvirus capsids and the homology of capsid components indicate that they share common features.

Little is known about the composition and possible structure of the tegument. In electron micrographs it appears as an electron-dense amorphous structure that lies between capsid and envelope. Several proteins of HSV-1 have been identified as tegument components, and homologues have been found in PRV.

The PRV envelope is derived from intracellular membranes of vesicles in the trans-Golgi area (Granzow et al.

1997). It contains eleven glycoproteins (Table 25.1). All glycoproteins are constituents of the viral envelope, except gG, which is abundantly produced during PRV infection in cell culture and released into the medium. Other putative nonglycosylated membrane proteins are the products of the UL3, UL11, UL20, UL34, and UL43 genes (Mettenleiter 2000).

Genomic Organization and Gene Expression

The PRV genome consists of double-stranded, linear, DNA composed of approximately 150 kilobase pairs (Figure 25.2). Around 90% of the genome has been sequenced. Based on available information from the fully sequenced herpesvirus genomes and partial sequence information from PRV, the only major sequence gap that remains probably contains the homologues of HSV-1 genes UL31 to UL37.

The genome consists of a unique long (UL) region and a unique short (US) region, the latter being bracketed by inverted repeats. So far, three origins of replication which conform to the alphaherpesvirus consensus sequence have been mapped in the repeats (2x) and middle of the unique long region (Klupp and Mettenleiter 1991). Another replication origin with apparently unique features resides at the left end of the genome (Kupershmidt et al. 1991).

Virulence-determining proteins can be divided into viral membrane glycoproteins, virus-encoded enzymes, and nonessential capsid proteins (Mettenleiter 2000). Virus-encoded enzymes involved in nucleic acid metabolism are major determinants of herpesvirus virulence. Their inactivation leads to attenuation of the virus. Deletion of the nonessential envelope glycoprotein gE also leads to a significant decrease in the virulence of some PRV strains. Glycoprotein gE seems to play a prominent role in the spread of PRV within the nervous system, both in the trigeminal and olfactory pathways.

Table 25.1. Properties of PRV glycoproteins (from Mettenleiter 2000; reprinted with permission)

Designation (a)	Gene (b)	Essential	Virion Component	Attachment	Penetration	Cell-to-Cell Spread	Neuronal Spread
gB (gII)	UL27	+	+	-	+ (c)	+	+
gC (gIII)	UL44	-	+	[+] (d)	-	-	-
gD (gp50)	US6	+	+	[+]	+	-	-
gE (gI)	US8	-	+	-	-	[+]	[+]
gG (gX)	US4	-	-	-	-	-	-
gH	UL22	+	+	-	+	+	+
gI (gp63)	US7	-	+	-	-	[+]	[+]
gK	UL53	+	+	-	-	+	? (e)
gL	UL1	+	+	-	+	+	?
gM	UL10	-	+	-	-	[+]	-
gN	UL49.5	-	+	-	[+]	-	-

(a) The old nomenclature of PRV glycoproteins has been added in parentheses.
(b) Gene designation according to the HSV-1 homologue.
(c) + indicates an essential function.
(d) [+] indicates a nonessential or modulating function.
(e) ? indicates no information available.
25.2. *The PRV genome. In (A) the division of the genome into a unique long (UL) and unique short (US) region by inverted repeats (open boxes) is shown. Arrows denote identified origins of replication. In (B) the Bam HI restriction fragment map of the PRV strain Ka is depicted. Those areas of the viral genome for which sequence information is available are designated in (C) by closed boxes. Shaded areas denote parts of the genome in which sequence information is present. Only one gap remains, indicated by the hatched area, which contains the open reading frames homologous to the UL31 to UL37 genes of HSV (from Mettenleiter 2000).*

Absence of gE leads to a restricted neural infection (Cheung 1995; Rauh and Mettenleiter 1991; Schang et al. 1994; Van Oirschot et al. 1990).

Replication

The PRV replication cycle is diagrammed in Figure 25.3. Infection of cells is initiated by attachment of free virions to target cells, followed by fusion of the virion envelope and the cellular cytoplasmic membrane (Mettenleiter 1994b). The interaction between viral envelope glycoproteins and cellular surface components that act as virus receptors is critical in both attachment and fusion.

The first contact between PRV and the target cell involves the interaction of glycoprotein gC with heparan sulfate proteoglycans at the cell surface. In addition, gD and two cellular groups of receptors, heparan sulfate proteoglycans and poliovirus-receptor related proteins, are involved in PRV attachment. Entry requires fusion between the cellular cytoplasmic membrane and the viral envelope. The fusion process involves at least four viral glycoproteins: gB, gH/gL, and gD. Absence of any of these glycoproteins in engineered virus mutants renders the virus incapable of fusion. After translocation of the nucleocapsid into the cytoplasm of the cell, it is transported to the nuclear membrane and locates adjacent to nuclear pores. This transport most likely occurs along microtubules. The capsid is invariably oriented toward the nuclear pore so that one vertex is juxtaposed to the pore complex (refer to Figure 25.3). The DNA presumably leaves the virion and enters the nucleus through this vertex. Subsequent intranuclear events and the egress of the virion are described by Mettenleiter (2000).

Laboratory Cultivation
