49 Tuberculosis

Charles O. Thoen

Tuberculosis continues to cause significant economic losses to swine producers throughout the world. Although tuberculosis due to *Mycobacterium bovis* has been nearly eradicated in many developed countries, lesions continue to be reported in the cervical and mesenteric lymph nodes of swine during meat inspection. Available information indicates that 30–50% of the carcasses of slaughter swine from some large confined herds have granulomatous lesions from which *M. avium* complex serovars were isolated (Pritchard et al. 1977). The processing of tuberculous swine carcasses is costly and results in significant economic losses. Regulations of the Meat and Poultry Inspection Program of the USDA require that unaffected portions of swine carcasses with tuberculous lesions in more than one primary site, such as cervical and mesenteric lymph nodes, be cooked at 170°F (76.7°C) for 30 minutes before being approved for human food (National Archives and Records Services 1973). The value of a cooked carcass is only about 20–25% of the value of a carcass not cooked. In processing plants where facilities are not available for cooking, the carcass is condemned and there is no salvage value. The public health significance of *Mycobacterium avium* complex infections has been recognized. Of special interest are reports on the isolation of some of the same serovars of *M. avium* complex from patients with acquired immune deficiency syndrome and from swine (Chin et al. 1994; Komijn et al. 1999).

There has been no direct campaign to eradicate tuberculosis in swine. It was once believed that the campaign to eradicate bovine tuberculosis, which was started in 1917, would result in a reduction of the disease in swine in the United States. However, the percentage of swine with tuberculous lesions continued to increase for a number of years (Table 49.1).

ETIOLOGY

Swine are susceptible to infection with *M. avium* complex, *Mycobacterium tuberculosisc* complex, and *M. bovis*.

M. avium complex serovars 1, 2, 4, and 8 are the most common isolates from tuberculous lesions in swine in the United States (Mitchell et al. 1975; Thoen et al. 1975). At least 15 other *M. avium* complex serovars have been isolated from swine in the United States (Thoen et al. 1975) as well as in other countries: Australia (Tammemagi and Simmons 1971), Brazil (Pestana de Castro et al. 1978), Denmark (Jorgensen 1978), France, Germany (Meissner et al. 1978), Hungary (Szabo et al. 1975), Japan (Nishimori et al. 1995; Yugi et al. 1972), South Africa (Kleeberg and Nel 1973), and the Czech Republic (Matlova et al. 2004). These reports indicate the worldwide distribution of tuberculosis in swine due to *M. avium* complex. The similarity of *M. avium* and so-called *M. intracellulare* has led to the proposal that the latter be considered serovars of *M. avium* complex (*M. avium ss aviium–M. avium ss intracellulare*) (Wolinsky and Schaefer 1973; Thoen et al. 1984); this has been done in this chapter.

Molecular techniques including restriction fragment length polymorphism (RFLP) and serotyping have been shown to be reliable for identifying *M. avium* complex isolated from swine (Thorensen and Saxegaard 1993; Ritacco et al. 1998; Komijn et al. 1999; Pavlik et al. 2000). *Mycobacterium avium* complex (serovars 1, 2, and 3) occur mainly in birds but also in swine and humans, whereas serovars 4–6 and 8–11 are found in swine and humans. Molecular evidence supports a proposal to refer to human/porcine type of *M. avium* as *M. avium ss hominus-suis* (Mijs et al. 2002).

The decrease in prevalence of tuberculosis in swine in the United States is largely attributable to a lowering of the incidence of tuberculosis in poultry, which in turn is the result of the increasing practice of maintaining all-pullet flocks of chickens (Table 49.1). The control of tuberculosis in swine is thus incidental to and a beneficial but secondary effect of a changing practice of poultry husbandry. However, tuberculosis has been observed in large confined swine herds, in which the infection is caused by *M. avium* complex serovars 4, 6, and 8.

Table 49.1.   Prevalence of tuberculosis in swine in the United States as determined by inspection in abattoirs under federal supervision

Year	Number Slaughtered	Percent Tuberculosis[a]	Percent Condemned[b]
1912	34,966,378	4.69	0.12

1995	94,490,329	0.21	0.003

Sources: Data compiled from USDA 1922, 1973, 1979, 1984, 1990, 1996; Feldman 1963.

[a]Includes all carcasses with evidence of tuberculosis, varying in extent from only small foci in cervical lymph nodes to generalized involvement.

[b]Includes carcasses with evidence of generalized tuberculosis.

The problem has been associated with the use of sawdust and peat for litter contaminated with *M. avium* complex (Dalchow and Nassal 1979; Songer et al. 1980; Pavlick 2000).

EPIDEMIOLOGY

Because swine are not routinely tested with tuberculin, the only sources of information on the prevalence and geographic distribution of tuberculosis in this species are the data obtained from meat inspection records. On this basis an increase in the rate of infection occurred in the United States until 1922 (Table 49.1). During 1922, 16.38% of all swine slaughtered under federal supervision had tuberculous lesions; in 0.2%, the disease was so extensive that the entire carcass was condemned. Since 1922, there has been a gradual decline; by 1995, the prevalence had decreased to 0.21%, with only 0.003% having evidence of generalized tuberculous disease.

Data on the prevalence of tuberculosis in swine from meat inspection records may be misleading because the diagnoses are made on the basis of the macroscopic appearance of lesions (Figure 49.1). A certain number of tuberculous infections will escape detection because the lesions are not grossly visible. Avian tubercle bacilli have been isolated from tonsils (Feldman and Karlson 1940) and lymph nodes of apparently normal swine (Langenegger and Langenegger 1981).

In studies in the United States and Canada, where presumably tuberculous lymph nodes of swine were col-
49.1. *Tuberculous lesions in a mesenteric lymph node of a pig at slaughter (Thoen 1994).*

lected at abattoirs and examined bacteriologically, a varying percentage failed to yield tubercle bacilli (Table 49.2). Similar observations have been made by workers in Australia (Clapp 1956), Denmark (Plum 1946; Jorgensen et al. 1972), England (Cochin 1943), Finland (Vasenius 1965), France (LaFont and LaFont 1968), and Germany (Retzlaff 1966; Dalchow and Nassal 1979). The failure to demonstrate tubercle bacilli in lesions that appear grossly to be tuberculous may be due to inadequacy in present-day methods for isolating tubercle bacilli, occurrence of healed processes that contain no viable tubercle bacilli, or cause of the lesions by some microorganism other than tubercle bacilli, such as *Rhodococcus equi* or *R. sputi* (to be discussed later).

Sources of Infection and Their Control

Swine are susceptible to infection with serovars of *M. avium* complex*, M. tuberculosis,* and *M. bovis*. The occurrence of tuberculosis in swine, therefore, is in part related to the opportunity for direct or indirect contact with tuberculous cattle, humans, and fowl or the organism in the environment.

Mycobacterium bovis is not a frequent cause of tuberculosis in swine in localities where the disease in cattle is controlled by a campaign of eradication. In the United States and Canada, for example, *M. bovis* is rarely found in lesions of swine (Table 49.2). In Great Britain during 1952–1955, the bovine type of tuberculosis in swine gradually declined concurrently with the eradication of the disease in cattle. The percentage of avian-type infection increased from 44% during the first 5 years of the study to 92% for the last 5 years (Lesslie et al. 1968). However, the occasional finding of *M. bovis* in swine is a reminder that the disease in cattle is a constant threat. Efforts to eradicate bovine tuberculosis should not be diminished.

Where tuberculosis does occur in cattle, the infection may be transmitted to swine by the feeding of un-

[d]Garbage-fed swine.

pasteurized milk and dairy by-products. Feces of tuberculous cattle may contain viable tubercle bacilli; this provides an obvious hazard where swine and cattle are maintained in a common feedlot.

The practice of feeding swine the offal from abattoirs or uncooked garbage is obviously unwise, because such material may contain tuberculous material from beef carcasses. Fichandler and Osborne (1966) described an epizootic of tuberculosis in a herd of swine in Connecticut that was fed improperly cooked offal from tuberculous cattle. A serious outbreak of avian tuberculosis in a swine-feeding establishment in Denmark was traced to the improper cooking of offal from poultry plants (Biering-Sorensen 1959). *Mycobacterium tuberculosis* is occasionally isolated from tuberculous lesions in swine. No person known to have active tuberculosis should be permitted to have contact with swine or other animals.

Uncooked garbage is a potential means of transmitting tuberculosis to swine. Feldman (1939) recorded that 75 (28.4%) of 264 garbage-fed swine were found to have tuberculous lesions at the time of slaughter. Of these, 47 contained tubercle bacilli, of which 35 were avian type and 12 were human type. It was concluded that garbage may contain the offal of tuberculous chickens and that material from tuberculous human patients is not properly disposed of. The frequent occurrence of *M. avium* complex in lesions limited to the cervical and mesenteric lymph nodes in naturally infected swine indicates that infection usually occurs by ingestion. Janetschke (1963) found that the primary complex involved the alimentary tract in 97.3% of 1000 carcasses with tuberculous lesions; a pulmonary route of infection was noted in only 2.7%, as indicated by involvement of the bronchial lymph nodes.

Schalk et al. (1935) found that swine contracted tuberculosis when placed on ground that had not been occupied by tuberculous chickens for the previous 2 years. Viable and pathogenic avian tubercle bacilli were found in the soil and litter of a chicken cage after 4 years. Schalk and coworkers concluded that soil contaminated by feces of tuberculous fowl is the most important source of infection for swine. No success was obtained in controlling the disease merely by use of the tuberculin test and elimination of reactors, because the soil remained contaminated. They recommended that an ideal program to control avian tuberculosis is to rear young birds on clean ground and to dispose regularly of all fowl more than 1 year old.

Schliesser and Weber (1973) studied the survival of *M. avium* complex in sawdust. At 18–22°C, the survival time of two virulent strains was 153–160 days, and the survival time of two avirulent strains was 169–214 days. The survival times were greatly reduced when the contaminated sawdust was maintained at 37°C.

Wild birds may be incriminated as a source of *M. avium* infections in swine. Tuberculosis was found in starlings on a farm with a high incidence of tuberculosis in the swine but where no poultry had been kept for 8 years (Bickford et al. 1966). Tuberculosis due to *M. avium* has been found in various wild birds, some of which frequent feedlots (Thoen 1997).

The close contact of sows and slaughter pigs in yards and feeding pens provides opportunity for transmission of tuberculosis from animal to animal (Alfredsen and Skjerve 1993). The occurrence of intestinal lesions (Figure 49.2) allows spread of tubercle bacilli in feces. Feldman and Karlson (1940) and Pullar and Rushford (1954) demonstrated avian tubercle bacilli in the tonsils
49.2. Submucosal tuberculous lesion due to avian tubercle bacilli in the intestinal tract of the pig. The lesion appears to be extending toward the surface, where it may ulcerate and discharge bacilli into the lumen. Diffuse cellular proliferation with little necrosis is typical of avian tubercle bacillus infection in swine (H&E; ×50).

of pigs. The latter workers suggested that this may be a source of infection for other animals. Smith (1958) found *M. aviam* in apparently normal lymph nodes of 7% of swine, 5% of sheep, and 5% of cattle but was unable to find them in adult normal chickens; he suggested, therefore, that domestic mammals may contract *M. avium* from each other as well as from tuberculous fowl.

Pulmonary, uterine, and mammary tuberculous lesions in swine constitute sources of infection for other animals. Jorgensen et al. (1972) described an enzootic of pulmonary tuberculosis resulting from *M. avium* in pigs. Lesslie and Birn (1967) found *M. avium* in the udder or milk of 18 cows and concluded that such animals may be a source of *M. avium* in pigs. Bille and Larsen (1973) reported congenital infection in swine caused by *M. avium*, suggesting that infected pregnant sows may have a role in the transmission of this infection. Sigurdardottir et al. (1994) reported granulomatous enteritis due to *M. avium* in a pig.

Where sawdust is used for bedding, serovars 4 and 8 of *M. avium* complex have been isolated from lesions in swine as well as from the sawdust. Reactions to avian and bovine tuberculin have been reported in boars exposed to sawdust from which *M. avium* or other nonphotochromogenic mycobacteria were isolated (Fodstad 1977). Schliesser and Weber (1973) found that *M. avium* would

survive as long as 214 days in sawdust. In Hungary, Szabo et al. (1975) found that the incidence of tuberculous adenitis in swine was greater when sawdust was used as litter; when the use of sawdust was discontinued, the occurrence of such lesions decreased significantly. Dalchow and Nassal (1979) recorded that the same serovars of *M. avium* complex as found in swine could be isolated from sawdust. These workers also reported that sawdust could contain infectious mycobacteria even after 4 years of storage. Songer et al. (1980) investigated herds of swine in Arizona and found in at least one herd that the source was sawdust and wood shavings.

Investigations conducted in the Czech Republic and Slovakia indicate that *M. avium* complex serotype 8 may be spread by adult flies (Fischer et al. 2001).

PATHOGENESIS

The development of disease in swine depends on the ability of the tubercle bacillus to multiply within tissues of the host and to induce a host response. Although acid-fast bacilli initially encounter granulocytes and humoral components, activated mononuclear macrophages are considered to be more important in protection of the host against mycobacteria.

The capacity of *M. avium* to produce progressive disease may be related to certain complex lipids present in the cell wall, such as the glycopeptidolipids (previously referred to as C-mycosides) localized in the exterior portion of the cell envelope (Rastogi and Barrow 1994). However, it appears that the effect of these components alone or together on phagolysosome fusion cannot account for virulence. Available information suggests that a combination of toxic lipids and factors released by virulent tubercle bacilli may cause disruption of the phagosome, interfere with phagolysosome formation, alter the release of hydrolytic enzymes from the attached lysosomes, and/or inactivate the lysosomal enzymes released into the cytoplasmic vacuole (Thoen and Bloom 1995). Certain serovars of *M. avium* are susceptible to bactericidal mechanisms of macrophages; however, the importance of reactive nitrogen intermediates and oxygen radicals in macrophages of swine exposed to virulent tubercle bacilli remains to be elucidated (Thoen and Barletta 2004). Although the mechanisms by which mycobacteria produce disease in swine have not been clearly defined, experimental studies in piglets revealed that nonspecific esterase activity was elevated in mononuclear macrophages of lymph nodes 7 days following inoculation of *M. avium* complex serovar 8 (Momotani et al. 1980). Granulomas of varying stages were observed in mesenteric and mandibular lymph nodes and intestinal mucosa at 14 days postinoculation. In other investigations, sensitized lymphocytes and detectable mycobacterial antibodies have been reported to occur at 14–28 days post exposure to *M. avium* or *M. bovis* (Muscoplat et al. 1975; Thoen et al. 1979a).

LESIONS

Tubercle Bacilli

Detailed discussions of the pathological anatomy of tuberculosis in swine may be found in Pallaske (1931), Feldman (1938a), Francis (1958), and Kramer (1962). As seen in the abattoirs, tuberculous lesions in swine are usually limited to lymph nodes of the cervical and the mesenteric regions. The lesions vary in appearance from small, yellowish white, caseous foci a few millimeters in diameter to diffuse enlargement of the entire node (Figure 49.1). The disease may be localized in one group of nodes or may involve a number of lymph nodes along the digestive tract.

Gross differentiation between tuberculous adenitis caused by avian tubercle bacilli and that caused by mammalian tubercle bacilli is difficult, but in general, some features are characteristic of each. In an infection of avian origin the lymph nodes may be enlarged and firm with no discrete purulent foci, or there may be one or more soft caseous areas with indistinct borders. Calcification is seldom demonstrable. The cut surface of the lesion has a neoplastic appearance with a few caseous foci. Although there may be diffuse fibrosis, there is little tendency to encapsulation. Relatively large areas of caseation may be present and occasionally will involve the entire lymph node. The lesions due to tubercle bacilli of the avian type are generally not easily enucleated. In contrast, when the infection is due to *M. bovis or M. tuberculosis* the lesions tend to be well encapsulated and are relatively easy to separate from the surrounding tissue. In addition, calcification is usually prominent in lesions. The individual foci appear to be discrete and caseous. These distinctions are by no means absolute, and there are many variations in the gross appearance of tuberculous lesions in lymph nodes of swine.

Clapp (1956) examined, by bacteriological procedures, 420 lymph nodes (mostly submaxillary) designated as tuberculous upon meat inspection. There was some association between the gross appearance and the cause. Localized lesions that were not easily enucleated and large, dry calcareous processes involving an entire lymph node were usually due to *M. avium.* Indistinctly mottled and streaked lesions, large encapsulated purulent abscesses, and lesions that could be easily enucleated were usually not caused by tubercle bacilli. Some of these yielded *Corynebacterium equi*, now reclassified as *Rhodococcus equi* (Goodfellow et al. 1982), which Clapp considered important in producing tuberculosis-like lymphadenitis in swine. In the series of 420 specimens, only 5 were from swine with generalized tuberculosis, and all of these were associated with *M. bovis and M. avium.* Microscopically, the changes induced in swine tissues are characterized by diffuse proliferation of epithelioid cells and giant cells. There may be some necrosis and calcification, especially in older lesions, but cal-

cification is not usually prominent. Similar changes are observed in sows and slaughter pigs (Thoen et al. 1976b). Proliferation of connective-tissue elements accompanies the process. Lesions caused by mammalian tubercle bacilli have a tendency to become encapsulated by a well-developed zone of connective tissue (Figure 49.3). In addition, there is often early caseation and marked calcification (Karlson and Thoen 1971). However, consistent histopathological differentiation between lesions caused by mammalian and avian tubercle bacilli is not possible (Himes et al. 1983).

Generalized tuberculosis in swine is not commonly seen. In most instances it is from infection with *M. bovis,* but it may also result from the *M. avium* (Feldman 1938b; Jorgensen et al. 1972). The extent and character of generalized involvement vary from the occurrence of a few small foci in several organs to extensive nodular processes involving the liver, spleen, lungs, kidneys, and many lymph nodes. Generalized lesions from infection with *M. avium* tend to be diffuse. The cut surface is usually smooth, and there is no great tendency toward encapsulation by fibrosis. There may be foci of caseation, but calcification is not pronounced. Lesions resulting from infection with mammalian tubercle bacilli, however, are likely to be discrete, caseous, and well circumscribed by fibrosis. Calcification is prominent.

Bacteria Other than Tubercle Bacilli

Various species of mycobacteria other than tubercle bacilli have been isolated from swine and other animals in different countries, but reports of such are few and usually concern only sporadic cases (Schliesser 1976). The significance of finding *M. kansasii, M. xenopi, or M. fortuitum* is not clear. It may be important, however, to learn if animals and humans become infected from the same sources (Thoen and Williams 1994). Of potential importance is the recovery of *M. chelonei* from swine because this bacterium has been isolated from prosthetic heart valves that were prepared from swine (Thoen and Himes 1977).

In Norway, *M. avium paratuberculosis* was isolated by culture from lesions in the mesenteric lymph nodes of swine as well as from normal swine that were closely associated with a herd of cattle in which Johne's disease was present (Ringdal 1963). This microorganism was isolated in the United States from a slaughter pig (Thoen et al. 1975b). Jorgensen (1969) and Larsen et al. (1971) found that swine may be infected with *M. avium ss paratuberculosis* after oral administration of the organism. *M. xenopi* was isolated from tissues of slaughtered swine that originated in the southeastern region of the United States (Jarnagin et al. 1971). Another rare finding was the isolation of *M. microti,* from lymph nodes of three swine (Huitema and Jaartsveld 1967).

Mention must be made of the occurrence of *R. equi* in localized lesions that cannot be easily differentiated from tuberculous processes either macroscopically or
49.3. *Tuberculous changes in cervical lymph nodes of swine. (A) Mammalian tubercle bacillus infection. Peripheral fibrosis, necrosis, and calcification are typical of lesions due to bovine or human types of tubercle bacilli (H&E; ×40). (B) M. avium infection. Diffuse cellular proliferation with little necrosis (H&E; ×95).*

histologically (Feldman et al. 1940). Holth and Amundsen (1936) in Norway reported that of 162 tuberculous lymph nodes from swine, only 103 yielded tubercle bacilli (97 were typed, with 80 avian and 16 human strains and 1 bovine strain). Of the other 59, 38 contained a variably acid-fast "coccobacillus." The acid-fastness, however, was not constant and was lost on subculture. The presence of this microorganism in localized tuberculosis-like lesions in swine was soon confirmed by other Scandinavian workers. Ottosen (1945) has shown that *R. equi* occurs more frequently in the soil of hog pens than elsewhere. In Denmark, Plum (1946) studied a large number of tuberculous lymph nodes from swine and concluded that it is difficult for inspectors in abattoirs to differentiate between tuberculosis and *R. equi* infection. Barton and Hughes (1980) recorded 32 reports of *R. equi* infection in swine. *R. equi* expressing a 20 kDa antigen has been observed in all pig isolates, and 2 of 5 plasmids from pig isolates were the same as those from human isolates, suggesting that the source of infection for humans may be pigs or the pig environment (Takai et al. 1996).

Rhodococcus sputi has been isolated from tuberculosis lesions in the mesenteric lymph nodes of swine (Tsukamura et al. 1988).

DIAGNOSIS

A clinical diagnosis of tuberculosis in swine is presumptive at best. Generally, the tuberculous lesions are limited to small foci in a few lymph nodes of the digestive tract. It is difficult to conceive that such nonprogressive morbid changes may elicit signs detectable by physical examination. In extensive tuberculous infection, signs may be suggestive of an infectious disease, but the symptoms and changes are not sufficiently characteristic to establish a diagnosis of tuberculosis.

The necropsy and histopathological appearance of tuberculosis in swine has been described. Although the morbid changes are sufficiently characteristic to permit a tentative diagnosis of tuberculosis, they are not specific. The great similarity between localized tuberculous lesions and those associated with *R. equi* and other bacteria has already been discussed. Also, chronic granulomatous lesions may be difficult to differentiate grossly because of parasitic nodules and neoplasms.

Enzyme-linked immunosorbent assay (ELISA) has been described for detecting antibodies in swine infected with *M. avium* complex (Thoen et al. 1979a, b). Positive ELISA reactions were observed in pigs experimentally infected and in those naturally infected. The

ELISA is a rapid test that can be automated and may be of value in testing replacement breeding animals.

The mere demonstration of acid-fast bacilli in exudates or in lesions may be misleading. Some workers have recorded that *R. equi* is acid-fast in smears of necrotic material from lymph nodes of swine (Ottosen 1945). Acid-fast microorganisms other than tubercle bacilli have been isolated from swine (Karlson and Feldman 1940; Brandes 1961).

The characteristic pathological features of tuberculosis in swine and the presence of acid-fast microorganisms in such lesions provide important indications on which to base a diagnosis of tuberculosis. However, an unequivocal diagnosis can be made on the basis of bacteriological procedures designed for the isolation, identification by biochemical and seroagglutination tests, and/or by molecular techniques (Kaneene and Thoen 2004).

Tuberculin Test

The tuberculin test for the diagnosis of tuberculosis in swine appears to be a useful procedure on a herd basis. Of the various techniques described for this test in swine, the operator should select the method that proves by experience to be most suitable. Separate simultaneous tests with *M. avium and M. bovis* tuberculin must be made (Thoen and Karlson 1970). A number of investigators have found that some tuberculous swine may fail to react to the intradermal tuberculin test. Therefore, tests should be repeated in a herd in which animals with positive reactions have been found and excluded.

The intradermal test, usually on the ear or vulva, may be employed. Because swine are susceptible to infection with *M. tuberculosis* complex and *M. avium* complex, avian and mammalian tuberculin should be used. Fichandler and Osborne (1966) described an extensive outbreak of *M. bovis* in swine in which animals reacted to mammalian tuberculin by developing erythema and swelling of the ear, compared with slight reactions to the *M. aviam* tuberculin.

Feldman (1938a) recommended the use of 0.2 mL 25% Old Tuberculin applied into the dermis on the dorsal surface of the ear, slightly anterior to the base. A positive reaction is indicated in 24 hours by a flat, reddish swelling up to 3 cm in diameter, which in 48 hours reaches its maximal intensity. At this time the erythema and swelling are more pronounced; the central area becomes hemorrhagic, and ulceration may occur. McDiarmid (1956) described a means of testing swine in which restraint is not necessary. While the animals are feeding from a trough, 0.1 mL tuberculin is injected at a right angle into the skin at the junction of the ear and neck using a needle only 3.5 mm long. With this short needle, most of the tuberculin is deposited in the skin. Reactions are recorded in 48 hours. A positive reaction varies from "puffy" edema to inflammation, with purple discoloration and necrosis. McDiarmid used Weybridge purified protein derivative (PPD), which, according to Paterson (1949), has 3 mg protein/mL for mammalian tuberculin and 0.8 mg protein/mL for *M. aviam*.

Lanz (1955) recommended injecting the tuberculin in the skin of the back about 10–20 cm caudal to the shoulders and slightly to the right of the midline. This was easier and less time-consuming than trying to use the ear. A dose of 0.1 mL PPD (as used for cattle in Switzerland) is injected intradermally. A positive reaction reaches its peak in 72 hours and consists of a painful erythematous swelling 22–35 mm in diameter. As determined by necropsy, no false-negative or atypical reactions were found among 316 animals.

Lesslie et al. (1968), using Weybridge PPD, tested 84 White pigs from a herd known to have tuberculosis. The avian tuberculin was given in injections of 0.1 mL, each containing 2500 tuberculin units (TU); and the mammalian tuberculin was given in injections of 0.1 mL, each containing 10,000 TU. The injections were made simultaneously, each at the base on an ear; in 48–72 hours a positive reaction was recorded when the reaction consisted of edema and erythema. Guinea pigs experimentally sensitized with *M. avium* serovars 3, 4, 5, 6, 8, and 9 each reacted similarly to tuberculin prepared from serovars 2 and 7 (Anz et al. 1970). Swine experimentally infected with *M. avium* serovars 4 and 8 reacted well to the USDA avian Old Tuberculin and to PPD prepared from *M. avium* serovar 1 (Thoen et al. 1976a; Thoen et al. 1979b).

At present, intradermal injection of PPD tuberculin in the dorsal surface of the ear is the recommended procedure for applying the tuberculin test in swine. The injection site should be observed at 48 hours.

PREVENTION

The eradication of tuberculosis in swine, as well as in other species, is dependent on the availability of an economical and specific means of detecting infected animals. Additional information is needed to determine adequate measures for cleaning and disinfecting the premises where *M. avium* complex persists in the soil, in buildings, or on equipment. Also, we need to know how long these organisms will remain viable in the environment. Investigations also should be made to determine the sources and modes of transmission of the different serovars of *M. avium* complex.

50 Miscellaneous Bacterial Infections

David J. Taylor

Anthrax

Anthrax is relatively rare in swine compared to sheep and cattle, which are highly susceptible. Swine may become infected, however, along with other species of farm animals and may become important as a reservoir of infection.

Since anthrax is a zoonosis, infections in swine are a threat to human health. Infected swine represent a hazard to the farmworker and veterinarian, to the abattoir worker, and to those preparing and eating contaminated pig products. The importance of this relatively rare disease in swine is increased by the public health requirement for abattoir disinfection and the disposal of carcasses after the discovery of an infected animal at meat inspection. Meat processors are becoming unwilling to slaughter pigs from infected farms, retailers are increasingly concerned about their duty to consumers, and the safe disposal of manures can be a major problem. These factors add a wider importance to the disease.

Anthrax is present throughout the world, and the FAO-WHO report (1973) indicates that the disease occurred in swine in every continent during 1972. The incidence remains low and sporadic, but the disease presents a local problem in some areas.

ETIOLOGY

Anthrax is caused by *Bacillus anthracis,* a large gram-positive, aerobic, spore-forming, nonmotile rod. The individual bacilli are 1–5 μm in diameter and 3–8 μm long. When observed in tissue from an infected animal, the organisms are commonly in short chains surrounded by a well-developed capsule. Under suitable aerobic conditions, spores highly resistant to disinfectants, heat, and desiccation may be produced.

B. anthracis grows very luxuriantly on most common laboratory media. On blood agar plates, colonies can usually be detected within 12 hours. After 24 hours at 37°C, the colonies have a "ground glass" appearance, with irregular, wavy borders that give them the "medusa head" characteristic. No hemolysis is produced on blood agar; this is useful in distinguishing the colonies from those of certain nonpathogenic species of the genus (Norberg 1953). The colony of *B. anthracis* growing on blood agar on primary isolation possesses a stickiness that can be readily detected by touching with the bacteriological loop. The colonial growth tends to adhere to the loop and forms tenacious threads.

Bacteria in these colonies do not produce capsules unless grown on special media or in 5% carbon dioxide but do produce spores. *B. anthracis* may be distinguished from other members of the genus by biochemical tests. Those of use in differentiating the organism from related bacilli are listed in the section on diagnosis below. *B. anthracis* is pathogenic to laboratory animals and humans. Culture should not be attempted unless appropriate safety precautions such as safety cabinets and adequate disposal facilities are available. Personnel handling the organism should be vaccinated.

EPIDEMIOLOGY

Anthrax is generally considered a soilborne infection in cattle, sheep, and horses. Animal-to-animal spread does not commonly occur, but rather, *B. anthracis* is deposited in the soil or the environment by the infected animal at the time of or following death. Spores are formed by some of the organisms, and these highly resistant bodies may remain viable for years, even under adverse conditions. Subsequently, the spores may be ingested by susceptible animals and anthrax may develop.

Swine can presumably become infected in this manner; however, because of the small number of spores likely to be picked up and the higher degree of resistance in swine, infection probably occurs only rarely. Rather,

anthrax in swine generally occurs following ingestion of feed that contains a large number of *B. anthracis* or viable spores. Swine that are permitted to eat the carcass of an animal dead of anthrax may consume large numbers of organisms and may therefore become infected. The use of bonemeal or other animal products containing spores of *B. anthracis* in feed is the most common source of infection in swine. Davies and Harvey (1955) isolated *B. anthracis* from 5 of 41 cargoes of bonemeal shipped to England from the Near and Middle East. Direct cultural methods were unsuccessful, but the authors isolated the organism from guinea pigs that were first protected from the various anaerobic species common in bonemeal by means of clostridial antisera and antitoxins and that were then injected with a concentrated infusion from the bonemeal specimen.

The role of feed contaminated with spores of *B. anthracis* in the transmission of anthrax can be illustrated by a brief account of the 1952 outbreak that occurred in the midwestern United States (Ferguson 1986). Anthrax was confirmed on a farm in southern Ohio in February 1952, and further outbreaks occurred in rapid succession in widely separated areas. Within a week of the recognition of the first case, feed was incriminated as the source of infection. A number of feed companies were involved, but all had incorporated bonemeal obtained from a company in Columbus, Ohio, which had processed part of a shipment of 100 tons of raw bonemeal obtained from Belgium into a meat scrap concentrate. The companies purchased the concentrate and included it in many hundreds of tons of swine feed sold throughout Ohio and adjoining states. The organism was isolated from the raw bonemeal and from the meat scrap concentrate but not from any of the finished feeds.

The organism appears to be spread in wet-feed systems but rarely affects more than 1–2 animals in an infected herd. This was the classic picture, but accounts of continuing outbreaks exist (Jackson 1967; Jackson and Taylor 1989; Edgington 1990). The outbreak referred to by Jackson and Taylor (1989) and Edgington (1990) occurred in a 500-sow unit and persisted for 14 weeks, resulting in at least 18 cases in sows, suckling pigs, and weaned pigs. The development of disease in weaners may have been delayed by maternal immunity in this continuing outbreak. The origin of the outbreak was considered to be feed, but the disease persisted within the herd in spite of antimicrobial treatment. Persistence may have been in carrier pigs or as spores in slurry and housing. The role of flies in persistence and transmission was not clear, although recent studies in the United States indicate that biting flies (*Stomoxys calcitrans*) and mosquitoes (*Aedes aegyptii* and *A. taeniorhynchus*) transmit the disease experimentally 4 hours after feeding (Turell and Knudson 1987). Ticks (*Dermacentor marginatus*) were shown to harbor the organism for 76 days at 4°C and for 35 days at 22–25°C in the former Soviet Union (Akhmerov et al. 1982).

PATHOGENESIS

B. anthracis has two major sets of pathogenic determinants: a protective capsule composed of a polymer of d-glutamic acid and the complex exotoxin. Molecular biology studies have shown that toxin production results from the possession of a 110 MDa plasmid and that capsulation is related to the possession of a smaller 60 MDa plasmid (Uchido et al. 1985; Mikesell et al. 1983). The exotoxin (Smith et al. 1955; Harris-Smith et al. 1958; Davis et al. 1973) is composed of three fractions and is produced when bacteria reach 5–10×10^6 organisms per milliliter of blood. The toxins share the same binding unit—the protective antigen (PA)—and are binary toxins. PA binds to cell surfaces and is activated by a host protease, allowing edema factor (EF) and lethal factor (LF) to enter cells. EF is a calmodulin-dependent adenylate cyclase and affects neutrophils, preventing the respiratory burst and thus protecting the organisms. It is also responsible for the progressive hyperglycemia and the severe terminal hypoglycemia seen in animals with the septicemic form. LF appears to be a zinc-dependent protease affecting macrophages. All three toxins are needed to produce typical anthrax.

The organism appears to enter the pig through the gut or tonsil. Septicemic disease is rare, and the organism multiplies locally, resisting phagocytosis by means of the polyglutamic acid capsule. Edema is commonly produced locally. Neutrophils and other phagocytes are killed by EF, and organisms multiply until LF is produced, resulting in the death of the animal as a result of its effect on the mitochondria. Immunity against anthrax is associated with antibodies against the exotoxin (PA) (Sargeant et al. 1960; Thorne et al. 1960). Antibody to the cell wall may be produced but is not protective.

CLINICAL SIGNS

The first indications of an outbreak of the disease may be an increase in mortality. Investigation of these extra deaths may indicate the presence of anthrax and the clinical signs described below may be identified. Three forms of anthrax have been observed in swine: pharyngeal, intestinal, and septicemic. The usual portal of entry is the oral cavity, and invasion occurs in the tonsils or mucosa of the pharynx. In some cases the infection may remain localized in the lymph nodes of this region, and the disease is classified as pharyngeal. In other cases the organisms may pass into the intestinal tract, where primary invasion may also occur. When *B. anthracis* is not localized but gains access to the general circulation, the septicemic form of the disease develops.

The clinical signs commonly observed in pharyngeal anthrax are cervical edema and dyspnea. General depression, inappetence, and vomiting are commonly seen. Fever with temperatures to 41.7°C may occur, but it is not consistent, and in some affected swine the temperature

may be subnormal. Death follows in many of the swine within 24 hours after the cervical edema is noticed. It is not uncommon for swine to recover even in the absence of treatment. The swelling may disappear gradually, and complete recovery appears to occur; however, such animals may continue to remain carriers of *B. anthracis*.

Clinical signs of intestinal anthrax are not as obvious as those in the pharyngeal form. In severe cases an acute digestive disturbance may be evident, with vomiting, complete loss of appetite, and diarrhea with bloody feces. Death may follow in the most severely affected swine; however, recovery occurs in many affected with the milder forms (Brennan 1953). When 50 pigs were infected in an experimental study (Redmond et al. 1997), 33 developed anorexia, lethargy, dullness, shivering, constipation, loose feces, blood in the feces, and ataxia at some point between 1 and 8 days after infection. Only 2 died. Fever did not exceed 41.9°C, peaking 48 hours after infection.

Intestinal anthrax has been reported only rarely in the United States. Many cases may be unrecognized because of the usual practice of avoiding a complete necropsy of animals suspected of anthrax. It is possible that some of the animals dying of pharyngeal anthrax may also have had lesions in the intestinal tract. Brennan (1953) reported that intestinal anthrax was the most common form of the disease seen in the 1952 outbreak of anthrax in England.

Septicemic anthrax is the highly acute form that results from the entrance of *B. anthracis* into the bloodstream, followed by rapid reproduction of the organisms throughout the body. Death frequently occurs in animals so affected, without any period of illness being noticed by the owner. In swine it is the uncommon form of the disease. Walker et al. (1967) reported the presence of viable spores of *B. anthracis* in the lungs of dwarf swine for as long as 7 days following respiratory exposure. These authors suggested that resistance of swine may be related to some mechanism that inhibits germination of the spores. Of 30 swine examined at necropsy during the anthrax outbreak of 1952 in Ohio, only 3 had the enlarged, dark spleen so characteristically seen in cattle. It is possible that young pigs develop septicemia more frequently than older swine (Ferguson 1986).

LESIONS

In the interests of controlling anthrax, complete necropsy of animals is strongly discouraged. Pigs with anthrax may not be identified before necropsy because the disease is relatively rare. Large pigs which have died from the disease may have a bloody discharge from the nose (Edgington 1990), and small ones may appear very pale and dehydrated. The cervical region is edematous, but otherwise no superficial lesions are evident. Incision of the region reveals an extensive infiltration of the tissues with fluid, which is usually straw colored but may

appear pink or hemorrhagic. The tissue, containing large amounts of fluid, may appear to possess a gelatinous consistency. The tonsils are usually covered with a fibrinous exudate, or extensive necrotic changes may be evident. The pharyngeal mucosa is frequently inflamed and swollen.

The mandibular and suprapharyngeal lymph nodes are enlarged to several times their normal size. The cut surface of the affected node may vary in color from deep brick red to strawberry red. In more chronic cases the color may be grayish yellow, indicative of necrotic changes in the node. In cases of the septicemic and intestinal forms the carcass may be opened before anthrax is suspected. The intestinal form is more common and there is usually copious pinkish peritoneal fluid, which may clot on exposure to air. The small intestine is usually inflamed, with fibrinous adhesions on the serous surface. The mesenteric lymph nodes may be swollen, hemorrhagic, or necrotic, and edema of the mesentery is common. The intestinal mucosa is covered with a diphtheritic membrane and may be hemorrhagic. The intestinal wall may be grossly thickened. In the septicemic form little may be seen other than the presence of bloodstained fluid in the peritoneal cavity and local petechiation. In some cases the spleen is enlarged and there may be marked petechiation of the kidney. Small abscesses may be present in the lymph nodes of recovered pigs (Redmond et al. 1997).

Microscopic lesions in the lymph nodes usually consist of hemorrhage and necrosis with encapsulated bacilli. These may also be seen in the necrotic diphtheritic lesions of the intestinal mucosa and in the capillaries of any organ in septicemia.

DIAGNOSIS

Anthrax should be suspected when swine show cervical edema and dyspnea. However, erysipelas or malignant edema from *Clostridium septicum* may also provoke similar clinical signs. In malignant edema, the edema will often be more prominent in the shoulders or axillary spaces. The edematous fluid and enlarged cervical or mesenteric lymph nodes, as seen on necropsy, are very suggestive of anthrax. When the carcass has been opened, the presence of bloodstained fluid in the peritoneum, petechiation of the kidney or serosal surfaces, enlargement of the spleen, and thickening and inflammation of the small intestine should lead to suspicion of anthrax. A history of the type of feed products eaten by the affected swine is always of value.

The accurate diagnosis of anthrax is very important and in most cases is dependent upon the isolation and identification of *B. anthracis*.

Microscopic Examination
Impression smears and cultures should be made from the cut surfaces of the cervical lymph nodes, spleen,

mesenteric lymph nodes, intestinal mucosa, or kidney as appropriate, and peritoneal fluid should also be sampled when present. Smears should be fixed in Zenker's fluid, which kills spores, or by low heat, which does not, and then stained by polychrome methylene blue for 2 minutes and washed with water. The bacilli of anthrax appear as square-ended blue rods in a pinkish capsule. In smears made from decayed carcasses, other bacilli may be present, and where antimicrobial treatment has been given, the bacilli may be present only as capsules or in aberrant forms. The failure to find anthrax bacilli immediately should not rule out the disease, as up to 30 minutes' examination may be required. Peritoneal fluid is more often positive than splenic smears in septicemia. Slides and reagents used for diagnosis should be disposed of by incineration or formaldehyde fixation.

Spores are not observed in slides prepared from fresh tissue or from freshly cut surfaces. Spore-forming anaerobes are frequently encountered in tissues of animals that have been dead several hours prior to necropsy. Differentiation is important in such cases, and the following points are helpful. Spores are rarely seen in *B. anthracis* in fresh-tissue preparations, whereas spores are regularly seen in clostridia. In the latter organism the rod is usually slightly enlarged by the spore. Capsules are very rarely observed in the clostridia, and any capsules seen do not stain purple with polychrome methylene blue.

Cultural Studies

B. anthracis grows readily on many common media and is characterized by very rapid colonial development. Typical colonies can be observed after 12–18 hours of incubation. This rapid growth is useful in differentiating *B. anthracis* from other pathogens.

B. anthracis is readily cultured from the enlarged lymph nodes, and it may also be demonstrated from the surrounding connective tissue in some cases. In the occasional septicemic case the organisms can be isolated from the blood, spleen, or liver—in fact, from essentially any tissue of the body. Since *B. anthracis* grows more rapidly than most of the saprophytic bacteria likely to be encountered, except other species of *Bacillus,* one should always examine the cultures after incubation for 12–18 hours.

Suspect colonies can be identified as *B. anthracis* by their biochemical characters using API systems or by the absence of hemolysis, lack of motility, growth on chloral hydrate agar, and susceptibility to anthrax phage. Final confirmation of pathogenic *B. anthracis* depends on the inoculation of culture into scratches on the footpad of a guinea pig or mouse under strict containment. All cultures and any experimental animals should be fixed in formaldehyde and incinerated.

Serology

A competitive enzyme immunosorbent assay (EIA) has been described (Turnbull et al. 1986, 1992) to identify the presence of IgG antibody to PA, and PA may be assayed in serum in pigs which have died using the capture EIA (Turnbull 1990).

CONTROL

Control of the spread of anthrax differs significantly from control of most of the other important animal diseases. The highly resistant spore formed by *B. anthracis* accounts for this difference. Some swine may become inapparent carriers, but there is little evidence to indicate that this forms an important source of infection to susceptible animals. Otherwise, animals that become infected do show clinical signs and generally develop an acute disease that terminates in death within a few days. Transmission from animal to animal rarely occurs, but soil contaminated by the organisms serves as a source from which susceptible animals subsequently ingest the spores. Because of this common form of transmission, anthrax can be controlled by preventing susceptible animals from contacting viable spores of *B. anthracis*.

Van Ness and Stein (1956) pointed out the importance of soil types in the survival of anthrax spores. The principal areas of enzootic anthrax are regions characterized by soils high in nitrogen and with adequate calcium. Where such soil types are lacking (e.g., central and eastern United States), anthrax does not appear to persist.

The spores can survive for years under a variety of environmental conditions. In the unopened carcasses of animals dead of anthrax, few spores are formed except at the body openings. When the animal is opened for a complete necropsy or when carnivorous animals are permitted to eat the carcass, there is usually extensive spore formation as the heavily infected blood and viscera are exposed to the oxygen of the air. For this reason, the orifices and any cuts in a carcass should be covered with disinfectant-soaked cotton wool to prevent sporulation and spread of infection. The most productive control measures include the complete destruction of the carcasses of animals dead of anthrax by incineration or deep burial.

When an animal dies in the open, it is generally recommended that it be burned on the spot. If the animal must be moved, the carcass must be placed on a sled or some other vehicle that can be thoroughly disinfected and then hauled, not dragged, to an area for disposal. If burning is not an option, deep burial can be used. The carcass should be covered with lime and at least 4 feet (1.25 m) of soil. When carefully completed, these methods will minimize the chances of transmission of the infection.

Disinfection can be achieved with 5% freshly prepared sodium hydroxide or, more controllably, with 10% formaldehyde and the use of appropriate respirators. Only disinfectants capable of inactivating anthrax spores, such as those containing glutaraldehyde and

formaldehyde, should be used. Disinfectants should be used prior to clearing up infected premises, and contaminated articles should be burned. Exposed surfaces should be scrubbed or pressure washed with the disinfectant.

Edgington (1990) gives an account of the procedure adopted in depopulating and disinfecting a chronically infected 500-sow unit from which purchasers would no longer take pigs. All 5000 pigs were slaughtered and burned, all 300,000 gallons (1,364,000 L) of slurry were disinfected with 10% formaldehyde and disposed of in an approved toxic-waste site, and the buildings were formaldehyde-fumigated and cleaned—at a cost of £1,000,000 (US $1,700,000). Similar precautions may have to be adopted in contaminated meat plants to safeguard public health.

Following the outbreaks of anthrax in the midwestern United States in 1952, which were conclusively traced to imported bonemeal, regulations were established that prohibit the importation of raw bonemeal into the United States (Stein 1953). Comparable preventive legislation was adopted in Canada (Moynihan 1963). Bonemeal processed by an acceptable steam treatment may be imported under these regulations. In addition to this federal regulation, some states have laws pertaining to the operation of rendering plants and the use of animal products in feed. These regulations have proved effective. Similar regulations apply in most developed countries.

TREATMENT

Treatment of animals infected with *B. anthracis* is possible. Since swine may develop a chronic form of the disease, treatment can be successfully administered in some cases. In the outbreak in Ohio in 1952, penicillin in oil was used at a dosage level of 10,000 units/lb (22,000 units/kg) body weight. According to Ferguson (1986), pigs that were showing clinical signs of anthrax recovered completely after this treatment, and the losses were reduced considerably when the disease was recognized early in its course. Anthrax antiserum in doses of 20–75 mL was also used in treatment of a limited number of animals. The results were comparable to those following treatment with penicillin in that the pigs in the early stages of anthrax recovered promptly. Oxytetracycline is effective against *B. anthracis* and may be used parenterally in daily doses of 4.4–11.0 mg/kg body weight. Edgington (1990) reported the successful use of penicillin, oxytetracycline, and chlortetracycline:sulfonamide:penicillin combinations to treat or suppress infection but had to withdraw treatment from animals intended for slaughter. Following the study of Redmond et al. (1997), it is clear that infection may persist for up to 21 days after infection in a population, and this factor must be considered before carcasses are submitted for human consumption.

PREVENTION

Kaufmann et al. (1973) evaluated the Sterne strain anthrax vaccine, an avirulent spore vaccine, in an outbreak of the disease in Louisiana. The results supported the efficacy of the vaccine in swine, but the number involved was too small to provide significant data for this species. Similar findings were obtained by Jackson (1967) in a continuing outbreak in the United Kingdom. Immunization of swine would probably reduce incidence of infection when they are exposed to massive doses of *B. anthracis*. Immunization on a large scale has not been recommended, however, since swine possess a level of natural resistance adequate to prevent the disease except following heavy exposure to *B. anthracis*.

Human infection can be prevented by the safe disposal of all contaminated carcasses, articles, and fluids on the farm by the methods outlined above. Persons exposed to the infection can be given prophylactic antimicrobials such as penicillin and tetracyclines, and any cases can be treated with them. Where longer-term exposure is likely, vaccination should be carried out.

Melioidosis (*Burkoldaria pseudomallei* Infection)

Melioidosis is a chronic bacterial infection of pigs in tropical and subtropical regions such as those of Asia and northern Australia. Pigs may become infected by *Burkoldaria* (formerly *Pseudomonas*) *pseudomallei,* which is a short, gram-negative rod, 0.8 by 1.5 µm, that produces rough or mucoid colonies on a wide variety of laboratory media. It is present in water and soil in tropical and subtropical areas and may infect pigs when water supplies are contaminated. Infection is often clinically inapparent but has been associated with clinical signs (Olds and Lewis 1955; Omar et al. 1962; Laws and Hall 1964; Rogers and Andersen 1970; Veljanov et al. 1994). Clinical signs include a raised rectal temperature (40–42°C, 104–108°F) for up to 4 days, unsteady gait, lameness or weakness, slight nasal discharge, and subcutaneous swellings of the limbs. Deaths may occur but are rare in adults, in which abortions and uterine discharges have been recorded.

Lesions are found in slaughter pigs in which clinical signs have not been seen and in those that have died from the disease. They consist of large abscesses in the lungs, liver, spleen, kidney, and mesenteric and subcutaneous lymph nodes. The organism can be isolated from them. Melioidosis may be suspected on clinical grounds especially when prolonged raised rectal temperatures and unsteady gait are associated with subcutaneous swellings of the limbs. More frequently, diagnosis is based on the creamy abscesses found at slaughter or on the bacteriological results needed to confirm the presence of *B. pseudomallei* (Ketterer et al. 1986; Veljanov et al. 1994). A hypersensitivity test resembling a tuberculin test (the melioidin test) and serum-agglutination and complement-fixation tests have all been described and can be used to confirm a diagnosis in the live pig.

Treatment with tetracyclines has been described, and the disease can be prevented by use of clean or chlorinated water supplies and preventing access to contaminated soil. As the disease is of public health importance, infected carcasses should be disposed of safely.

Chlamydiae

Chlamydiae are small intracellular bacteria that cause disease in many mammalian species and are widespread in birds. They have been demonstrated in cases of conjunctivitis, enteritis, pneumonia, pleurisy, pericarditis, arthritis, orchitis, uterine infections, and abortion in pigs. Recent work on chlamydiae in pigs has shown that at least three species are involved (*Chlamydophila psittaci, C. pecorum, Chlamydia trachomatis*); the development of reliable tissue culture methods and the use of immunoperoxidase staining of tissue sections, DNA probes, and, more recently, polymerase chain reaction (PCR) methods have demonstrated that the organisms are relatively common

in pig populations. The literature prior to 1983 was reviewed comprehensively by Stellmacher et al. (1983), and the account in the present chapter draws on earlier work only where it is relevant to current knowledge.

ETIOLOGY

Chlamydiae are gram-negative bacteria that can multiply only inside living cells. They are unusual among bacteria in that they exist outside the cell only as an inactive, trypsin-resistant, infectious particle 0.2–0.3 μm (200–300 nm) in diameter known as an elementary body (Figure 50.1). This body has an electron-dense core packed with DNA and surrounded by a trilaminar cytoplasmic membrane, outside which lies a further trilaminar envelope and then a cell wall with projections that may be associated with attachment to cells. The outer-membrane proteins of the chlamydiae have been studied in considerable detail, and sequences of the genes coding for outer-membrane protein A (*ompA*) have been obtained (Kaltenbroeck and Storz 1992; Kaltenbroeck et al. 1993; Anderson et al. 1996). These sequences have contributed to the current species classification and are now widely used in diagnosis. *C. psittaci* contains a plasmid, and DNA sequences of it have also been identified in *C. pecorum*.

Within 6–9 hours after an elementary body has entered a cell, it forms a reticulate body 1 μm (1000 nm) in diameter. This body divides by binary fission to form further reticulate bodies in an inclusion within the host cell. At this stage the infected host cell may divide to give infected daughter cells, which may account for latent infections seen in animal hosts. Within 20 hours of the first division of the reticulate body, some begin to mature into elementary bodies. The chlamydial inclusions may occupy up to three-quarters of the cell volume and contain up to 10,000 elementary bodies. *C. trachomatis* produces glycogen inclusions in cells at this stage; *C. psittaci* and *C. pecorum* do not. Infected cells may lyse to release the elementary bodies or these may be budded from persistently infected cells.

Chlamydiae can be grown in the laboratory by inoculation of the yolk sac of 6- to 8-day-old embryonated hen eggs and in neonatal mice. Most laboratories now use cell cultures, usually McCoy or L929 cells, in which the chlamydiae grow readily. Some strains and species can be maintained in Vero cells. In some cases, isolation can be improved by treatment of the cells, using irradiation or cycloheximide (1 μm/mL), and by centrifugation of the chlamydiae onto the cells.

The different species of chlamydiae and biotypes within them can be distinguished by their differential growth in cell cultures in the presence of tissue culture medium supplemented with amino acids such as arginine, isoleucine, and methionine (Johnson 1984) and by the presence of inclusions or the time taken to develop in a particular cell line. The main methods of dif-
50.1. *Electron micrograph of elementary body (arrow) of* Chlamydophila *sp. in an aborted placenta (original magnification ×52,500).*

ferentiation are now (1) antigenic, based on differences between the outer-membrane proteins detected using monoclonal antibodies in immunoperoxidase, immunofluorescence, or ELISA methods, and (2) nucleic acid based, using genomic and *ompA* sequences for PCR (Anderson et al. 1996; Kaltenbroek and Storz 1992; Kaltenbroeck et al. 1993).

EPIDEMIOLOGY

The recent development of methods to differentiate the three species of chlamydiae present in pigs has raised a number of questions about the epidemiology of infections with these species in the pig. All three species are found in other animals or birds, and experimental infections show that *C. psittaci* from species such as sheep can be transmitted to pigs and sometimes produces lesions (Harris et al. 1984; Vasquez-Cisneros et al. 1994). *C. psittaci* occurs in many avian species and is particularly common in pigeons and doves but may occur in almost any bird. Some mammals such as sheep, cattle, and rodents may be infected. All these species may form a reservoir of *C. psittaci* infection for the pig. The relationship between *C. pecorum* and *C. trachomatis* infections of other mammalian species and the pig has not yet been explored in detail. All chlamydiae can survive for considerable lengths of time as elementary bodies in the environment, where they are resistant to drying. The

major routes of transmission of *C. psittaci* to pigs are by inhalation of aerosols of elementary bodies, either fresh or in dust, from respiratory, genital tract, or enteric infections; by ingestion of contaminated feed; and by contact, particularly venereal in the case of genital tract infections. The exact methods by which *C. pecorum* and *C. trachomatis* are transferred are not yet clear but are probably similar, with the fecal-oral route being of importance for enteric infections and transmission by flies or dust being involved in *C. trachomatis* conjunctivitis (Rogers et al. 1993).

Chlamydial infection in the pig has been reported from the United States (Willigan and Beamer 1955; Pospischil and Wood 1987), Britain (Wilson and Plummer 1966; Harris 1976), Rumania (Sorodoc et al. 1961), Germany (Stellmacher et al. 1983), and more recently from other countries. The early serologic surveys suggested that complement-fixing and microagglutinating antibodies were present in up to 23% of slaughter pigs (Wilson and Plummer 1966). Most antibody titers were low (1:8–1:128), but titers as high as 1:1024 were recorded (Wilson and Plummer 1966). More recent surveys using immunoperoxidase staining of histological sections of gut suggest that chlamydial inclusions can be found in up to 67% of piglets (Zahn et al. 1995) and 99% of finishing pigs (Szeredi et al. 1996). Serum antibody surveys of the same finishing animals using an ELISA method confirmed antibody in 82.6%, but the complement-fixation test (CFT) detected antibody in only 28.6%, a figure similar to that of Wilson and Plummer (1966). It is clear, therefore, that infection with chlamydiae is widespread among pigs.

Studies of the distribution of infection within infected herds suggest that infection can occur in animals of every age group. Samples from which chlamydiae have been isolated include semen samples from boars; fetuses, both live and aborted; sows; lungs, joints, and organs such as liver and spleen from piglets; store pigs; and pigs at slaughter. Enteric infection is uncommon in piglets of less than 4 weeks of age (6.9%) and more common (41.8%) in piglets aged more than 4 weeks (Zahn et al. 1995), and conjunctival infection was recorded by Rogers et al. (1993) as associated with clinical signs between 2 and 8 weeks of age. The presence of low levels of antibody in piglets may suggest maternal antibody transfer. The possibility of transmission of intestinal chlamydiae to humans from slaughter pigs was raised by Szeredi et al.(1996).

PATHOGENESIS

Experimental infections were carried out with "*C. psittaci*" or "chlamydiae" prior to the identification of the presence of three species of chlamydiae in pigs. The account which follows uses the term "*C. psittaci*" unless there is evidence that the organisms were of the other species.

Elementary bodies of *C. psittaci* enter by the respiratory, oral, or genital routes and enter epithelial cells, in which they multiply or are taken up by macrophages and distributed to lymph nodes. Infection may be local at the portal of infection and remain inapparent or latent; may cause local disease such as pneumonia, enteritis, or disturbances of reproduction; or may become generalized. *C. psittaci* isolates of avian, bovine, ovine, and porcine origin have been used in experimental infections; but strains of porcine origin appear to be most virulent for the pig, provided they have not become yolk sac or tissue culture adapted.

There appears to be some adaptation of strains to the method of transmission, in that strains of genital origin (Kielstein et al. 1983) do not appear to cause severe pneumonia, and parenteral inoculation was found necessary to reproduce arthritis with an arthritis isolate. Pneumonia has been consistently produced by intranasal or intratracheal inoculation with porcine strains (Kielstein et al. 1983; Martin et al. 1983; Stellmacher et al. 1983; Rogers et al. 1996), but infection was found to spread consistently to other organs. An acute exudative or interstitial pneumonia with peribronchiolar cellular cuffing and a lobular distribution occurs within 4–8 days of infection. Lesions are fully developed by 8–12 days postinfection and are largely resolved by 4 weeks after infection, although infection may still be present in the lungs. Similar lesions were produced in germfree pigs by Rogers et al. (1996) using a *C. trachomatis*–like isolate from a case of pneumonia. They identified mild multifocal rhinitis and diarrhea in addition to the pneumonic changes. Rogers and Anderson (1996) infected gnotobiotic piglets with isolates from diarrheic pigs to produce diarrhea after 4–5 days which lasted for 8 days. The apical part of the villus appeared to be colonized in the distal jejunum and ileum, with little or no infection in the colon. Villous atrophy developed and this was later followed (7–10 days postinfection) by mild focal serositis.

Contact infections suggest that natural infection is normally less severe and that reinfection after 3–4 weeks results in little or no further disease. This development of immunity is accompanied by development of complement-fixing antibodies to *C. psittaci*, which appear within 2 weeks and remain detectable for a variable period. Information on the time course of antibody detectable by ELISA and indirect immunofluorescence is lacking.

In genital infections, infected semen given to sows has resulted in the birth of weak piglets and continued shedding of chlamydiae for up to 20 months.

CLINICAL SIGNS

Many chlamydial infections are inapparent, but consistent features of respiratory tract and generalized infections include an incubation period of 3–11 days fol-

lowed by inappetence and a rise in rectal temperature to 39–41°C. Dyspnea, pneumonia and conjunctivitis may occur and may persist for 4–8 days. Evidence of pleurisy or pericarditis may be detected by auscultation, and articular involvement by lameness in one or more joints. In slaughter pigs, polyarthritis associated with synovitis has been reported. Other disturbances of gait include weakness in piglets and nervous signs in pigs of all age groups. Fatal infections are most commonly reported in younger animals.

Diarrhea has been reported to be associated with chlamydial infection (Pospischil and Wood 1987) and can be produced experimentally in gnotobiotic pigs with isolates from diarrheic animals (Rogers and Anderson 1996), but retrospective analysis of cases by Nietfeld et al. (1997) failed to confirm that infection (demonstrated by immunoperoxidase staining of the intestinal epithelium) was statistically associated with diarrhea. Many reports deal with genital tract infection and disturbances in reproduction. In the boar, infection is associated with orchitis, epididymitis, and urethritis; while infections in gilts and sows have resulted in late abortions and the birth of dead or weak piglets. Serologic and isolation studies suggest that many genital tract infections are clinically inapparent.

LESIONS

Lesions in which *C. psittaci* has been demonstrated often contain other agents, and many descriptions of the lesions found in field cases may not take into account the presence of agents such as mycoplasmas or viruses. The large body of work on respiratory disease suggests that lung lesions are distributed posteriorly in most cases, although occasional patches of pneumonia may occur in the anterior lobes (Harris et al. 1984).

Lesions are irregular and raised, are of firm consistency, extend deep into the lung tissue, are limited by lobular boundaries, and are clearly demarcated from adjacent grossly normal tissue. Early lesions are pale red, becoming grayish as they age. Enlarged bronchial lymph nodes may be present. The microscopic findings include thickening of the alveolar septae by capillaries, septal edema, and neutrophils in peribronchial and subepithelial sites. Neutrophils and macrophages are common in the alveolar lumina, and in some areas this exudate occludes terminal bronchioles. Edema and massive epithelial cell shedding have been reported in severely affected lung lobules (Martin et al. 1983). Foci of type II pneumocyte hypertrophy and hyperplasia and vacuolated pneumocytes and bronchial epithelium have been reported in *C. trachomatis*–like experimental infection (Rogers et al. 1996). Peribronchiolar accumulations of plasma cells, lymphocytes, and macrophages are also common. There appears to be no pleurisy in experimental infections, and no gross changes in other organs were reported beyond enlargement of the bron-

chial lymph nodes. Antigen can be demonstrated in bronchial and bronchiolar epithelial cells and in pneumocytes in experimental studies (Rogers et al. 1996) and in field cases (Done et al. 1992).

The other lesions reported to occur in field cases include pericarditis, pleurisy, hemorrhages of kidney and bladder, and enlargement of the spleen. There is little doubt that synovitis accompanies the arthritic changes and that orchitis in boars is accompanied by interstitial edema and tubular degeneration. Aborted piglets may be mummified; stillborn or weak piglets may have lung, liver, or enteric lesions. The organism has been isolated from pseudomembranous colitis in experimental *S. typhimurium* infections (Pospischil and Wood 1987), and extensive studies of pig intestines by immunoperoxidase (Zahn et al. 1995; Pospischil et al. 1996; Szeredi et al. 1996; Nietfeld et al. 1997) confirm the distribution of the inclusions in the small-intestinal villi in piglets and in the large-intestinal intercrypt epithelium in finisher pigs. Lesions in experimentally infected gnotobiotic piglets included watery colon contents with flakes of undigested curd, villous atrophy, lymphangitis, and multifocal necrosis of the apical portion of the villi (Rogers and Anderson 1996).

DIAGNOSIS

The clinical signs of chlamydial infection are not distinctive, but it must be considered as a possible cause of pneumonia, polyarthritis, enteritis, late abortion, stillbirths, mummified piglets, and orchitis. The gross lesions in the lung may be suggestive of chlamydial infection, but any firm diagnosis involves laboratory tests. These are serologic: complement fixation using heat-stable *C. psittaci* antigen, and ELISA using tissue culture antigen (Szeredi et al. 1996); microscopic agglutination (Wilson and Plummer 1966); and indirect immunofluorescence. Complement-fixing antibodies should ideally be found to rise in paired serum samples, but the presence of high levels of antibody (1:256) may be sufficient. As only low levels of complement-fixing antibodies may arise from infections in sites such as the respiratory, enteric, and genital tracts, the absence of high levels of complement-fixing antibody does not rule out chlamydiae as a cause of disease.

Chlamydiae may be detected in smears of discharges or postmortem specimens and in histological specimens after staining by Giemsa's method. The organisms are tiny (0.2–1.0 μm) and are present in large numbers in cells. A more satisfactory method is to use Koster's stain in which a fixed smear is stained for 5 minutes with carbol fuchsin, decolorized for 30 seconds with 0.25% acetic acid, and counterstained for 1 minute with 1% aqueous Loeffler's methylene blue. The chlamydiae appear as clusters of intracellular red dots against a blue background (Figure 50.2). Most specific of all is the
50.2. *Photomicrograph of elementary bodies of* Chlamydia *sp. (arrow) in aborted placenta (original magnification ×1200).*

immunofluorescence test using specific fluorescein-conjugated antibody to *C. psittaci* to demonstrate infected cells. Immunoperoxidase tests have been described (Chasey et al. 1981), and the immunoperoxidase staining of fixed tissue sections is now standard and appears to be the most sensitive method of detection (Szeredi et al. 1996) in tissue. Many laboratories are using PCR tests to confirm the presence of the three species in feces and tissue specimens. Primers include genomic DNA sequences, 16S rRNA gene sequences, *ompA* gene sequences, and plasmid sequences.

Isolation can also be carried out by the inoculation of young mice and of 6- to 8-day fertile hen eggs. More than one subculture may be necessary before infection can be detected. Cell cultures using L929 or McCoy cell lines treated with cycloheximide (1 µg/mL) may be inoculated by centrifugation (Farmer et al. 1982) in tissue culture medium at pH 7.0. Inclusions are at a maximum after 48 hours of incubation at 35–37°C.

Transport media for chlamydiae should contain streptomycin (50–100 mg/L) or gentamicin (10–20 mg/L) with vancomycin (100 µg/mL) and nystatin (25 mg/L). Samples can be stored at 4°C or at −70°C. Handling *C. psittaci* is dangerous, and severe human infections and death can result. Appropriate safety precautions should be observed.

TREATMENT

A number of antimicrobials have some effect on *C. psittaci* in vitro, but the most satisfactory compounds for treatment are the tetracyclines. Treatment for inadequate times may result in relapse; for complete elimination or suppression of infection to the latent state, 21-day treatment should be given at the therapeutic level. Tetracycline, oxytetracycline, and chlortetracycline can all be used in drinking water or feed. Long-acting oxytetracycline injections are useful for treating individual infected animals.

PREVENTION

Pigs should be prevented from coming into contact with infected pigs, other mammalian species, and bird droppings. Infected pigs should be maintained in separate air and drainage spaces from susceptible animals. Any infected breeding stock should be used only after tetracycline treatment or kept with other infected stock in isolation until sufficient uninfected animals are available to replace them. Disinfection with phenols and formalin fumigation will eliminate elementary bodies from buildings.

Actinobacillus suis

Septicemia and death caused by *Actinobacillus suis* and occasionally by *A. equuli* in suckling and recently weaned pigs have been reported sporadically from several pig-rearing countries (Van Dorssen and Jaartsveld 1962; Cutlip et al. 1972; Windsor 1973; Mair et al. 1974; MacDonald et al. 1976). *A. suis* outbreaks resembling erysipelas have been reported in older pigs and sows in Canada (Miniats et al. 1989), and the organism has also been the cause of disease resembling pleuropneumonia in older pigs in the United States (Yaeger 1996) and the United Kingdom. Most outbreaks occur as sudden death of one or several piglets in one, two, or, rarely, multiple litters in individual herds. Infection with *A. suis* is probably widespread but disease is seldom reported.

ETIOLOGY

A. suis is a gram-negative, nonmotile, nonencapsulated, aerobic, and facultative anaerobic coccobacillus, 0.5–3 μm long and about 0.8 μm in diameter. Filamentous forms occur. Grayish, adherent, circular, translucent colonies measuring 1–2 mm form on blood agar within 24 hours. On horse blood agar, colonies are surrounded by a narrow but distinct zone of alpha hemolysis, and on calf and sheep blood agars, by a wide zone of beta (complete) hemolysis. The organism grows on MacConkey agar. Biochemically, *A. suis* can be differentiated from other related bacteria isolated from pigs by its ability to produce catalase, oxidase, and urease; hydrolysis of esculin; and acid production without gas from arabinose, lactose, salicin, and trehalose, but not from mannitol or sorbitol. Its biochemistry and antigenicity have recently been studied by Bada et al. (1996). Distinction from isolates of *A. pleuropneumoniae* biotype II is difficult but can be achieved biochemically and using DNA analysis. *A.*

equuli differs from *A. suis* by being nonhemolytic; producing acid from mannitol but not from arabinose, cellulose, and salicin; and not splitting esculin. *A. suis* is pathogenic for mice; *A. equuli* is not. *A. suis* and *A. equuli* are killed within 15 minutes at 60°C and are sensitive to most disinfectants. They die out within a few days in culture and pathologic material.

EPIDEMIOLOGY

A. suis can be carried in the tonsils and nostrils of healthy pigs of any age and in the vaginas of apparently healthy sows (Ross et al. 1972). Clinical disease occurs in neonates and suckling pigs up to and just after weaning age, and less commonly in sows and mature swine (Miniats et al. 1989; Sanford et al. 1990). With the separation of pigs and horses in modern farming systems, infection in pigs by *A. equuli* seems to have diminished.

Outbreaks of clinical disease associated with *A. suis* infection occur more frequently in minimal-disease and other high-health-status herds (Miniats et al. 1989; Sanford et al. 1990), possibly because the lack of immunity in these pigs allows virulent *A. suis* organisms to express their pathogenic potential, but the organism can be recovered from herds in which disease is not apparent.

PATHOGENESIS

The pathogenesis of *A. suis* infection has not been defined. Infection probably occurs via the upper respiratory tract, and the disease has been reproduced by intranasal inoculation (Fenwick et al. 1996), although invasion through abrasions in the skin and mucous membranes is also likely. In susceptible animals, septic

emboli then spread rapidly to multiple organs and tissues throughout the body and either are trapped in vessels or adhere to vessel walls, forming microcolonies surrounded by areas of hemorrhage and necrosis. Virulence factors of *A. suis* have not been specifically determined, but lipopolysaccharide, polysaccharides in the cell wall, outer-membrane proteins, and, in some strains, a 104 kDa hemolysin (ApxI) are all potential virulence factors likely to be involved in pathogenesis. Antibodies to ApxI have been demonstrated in the sera of pigs which have recovered from experimental infection (Fenwick et al. 1996). Pigs may die within 15 hours of infection.

CLINICAL SIGNS

Sudden death of suckling piglets, 2 days to 4 weeks old, in one or more litters is often the first indication of an outbreak of actinobacillosis. Deaths in piglets are sometimes mistakenly attributed to crushing. Cyanosis, petechial hemorrhages, fever (up to 40°C, 104°F), and panting, sometimes accompanied by shaking and/or paddling, may be seen prior to death in suckling pigs. Congestion of extremities (leading to necrosis of feet, tail, and ears) and swollen joints may occur. In weaned pigs, anorexia, fever, a persistent cough, respiratory distress (Yaeger 1996) and pneumonia are reported; recovered animals may remain unthrifty. In outbreaks in mature animals, fever, round and rhomboid erythematous skin lesions, inappetence, and sudden deaths are characteristic, but mortality is usually low. Metritis, meningitis, and abortion have been reported in sows. The disease may be confused with erysipelas, especially when skin lesions develop, and with pleuropneumonia when respiratory signs are present.

LESIONS

The most striking gross lesions are petechial to ecchymotic hemorrhages in any of the following organs: lung, kidney, heart, liver, spleen, skin, and intestines. The lesions are especially prominent and most frequently seen in the lung, where lobular necrosis and serofibrinous exudates also occur (Figure 50.3). Increased serous or serofibrinous exudates may occur in the thorax and the pericardium. Pleurisy, pericarditis, and miliary abscesses in the lung, liver, skin, mesenteric lymph nodes, and kidney may be seen in older suckling or weaned pigs. The pneumonic lesions may resemble those of pleuropneumonia. Arthritis (Van Dorssen and Jaartsveld 1962; Odin 1994) and valvular endocarditis (Jones and Simmons 1971) have been reported. In mature animals, numerous round, rhomboid, or irregular skin lesions are common.

Histologically, bacterial thromboemboli with accompanying fibrinohemorrhagic necrosis in randomly scattered vessels in the lung, liver, kidney, skin, spleen, heart, pericardium, meninges, and brain are characteristic (Figure 50.4). Bacterial emboli may be surrounded by radiating eosinophilic clublike colonies. These are most obvious in the lung, where there may be large coalescing areas of necrosis.

DIAGNOSIS

Sudden mortality in suckling pigs in individual litters in herds with previous *A. suis* outbreaks usually indicates a new outbreak. The gross lesions of hemorrhages and necrosis in the lung and/or skin and kidney and splenic enlargement are suggestive of *A. suis* infection. In mature pigs, fever, inappetence, and skin lesions resembling erysipelas, especially in herds already vaccinated against erysipelas, should raise a suspicion of *A. suis*. Microscopic lesions consisting of bacterial emboli, necrosis, and inflammatory cells in the lung and other organs are also suggestive. Diagnosis, however, depends on isolation of *A. suis* or *A. equuli* from the lesions. *A. suis* infection should be considered when pleuropneumonia is suspected in herds thought to be free from that disease. In these herds it may cause mild or atypical lung lesions and give rise to antibody to ApxI but not to the cytotoxin of *A. pleuropneumoniae* or to its somatic antigens (Fenwick et al. 1996). *A suis* can usually be isolated from the tonsils of piglets aged 2–10 days in such herds.
50.3. *Lung of 3-day-old piglet with actinobacillosis. Note the hemorrhages.*
50.4. *Photomicrograph of a microabscess in the lung as shown in Fig. 50.3. Note the microcolonies of bacteria (H&E; original magnification ×110).*

TREATMENT

A. suis is sensitive to most commonly used antibiotics. Since outbreaks in suckling pigs are so acute and unpredictable, however, treatment is usually too late. In older pigs, responses to treatment with ampicillin (5 mg/kg) orally or parenterally, injectable benzathine-procaine penicillin G (2.25–3.0 × 10⁶ IU/kg) intramuscularly (IM), injectable procaine penicillin (1.8–2.4 × 10⁶

IU/kg) IM, or in-feed medication with oxytetracycline hydrochloride (550 g/ton) and/or streptomycin for periods up to 1 week have all been excellent.

PREVENTION

Autogenous bacterins have not been critically evaluated but have been used in herds with repeated *A. suis* outbreaks with apparent success.

Yeasts

Yeasts are fungi that are normally single celled but can form filaments (or pseudohyphae). Some can sporulate to produce resistant spores. They occur in the food of the pig and in dusts. Some species are commonly found on the skin and mucous membranes. In certain situations, yeasts of a number of species (but principally *Candida albicans*) may be isolated from inflammatory lesions of the oral cavity, gastrointestinal tract, urogenital tract, and skin. Their isolation from such lesions is often

associated with use of therapeutic antimicrobials, especially in piglets. Yeasts belonging to the genus *Malassezia,* possibly *M. pachydermatis,* are present in the ears and on the skin of pigs, but their role in disease at these sites is not known. They can reach high numbers when skin or ear lesions develop, but so little is currently known about them and their role in disease that they will not be considered further.

Yeasts may also form a major part of the diet of the

pig, as either yeast wastes from brewing or distilling or yeast grown and treated specifically as a component of rations. These yeasts can provide high protein and, in particular, high lysine. Traces of paraffin waxes have been found in the fat of pigs fed on yeasts grown on that substrate, and there are some reports of diarrhea and increased kidney weights in yeast-fed pigs. Most reports indicate that inclusion of yeasts in the ration does not adversely affect the health of pigs.

ETIOLOGY

Yeasts identified in infections in pigs belong to a number of genera. Those of the genus *Candida* are most commonly isolated, although species of *Torulopsis, Trichosporon, Rhodotorula, Pichia, Pityrosporum,* and *Cryptococcus* have been recorded. *Cryptococcus neoformans* has been isolated from cryptococcosis in pigs, but the disease is rare in this species and occurs only where the organism is commonly found in other livestock.

Candida albicans is the species of *Candida* most frequently reported; but *C. tropicalis, C. pseudotropicalis, C. brumptii, C. sloofii, C. rugosa, C. lipolytica, C. krusei,* and *C. scottii* have been isolated from lesions or feces of apparently healthy pigs. Since *C. albicans* is associated most frequently with specific lesions, both it and its relationship to these lesions will be described here.

Candida spp. are spherical cells, 2.5–6 μm in diameter. They reproduce by budding (blastospores) and chlamydospores, which bud from filaments (or pseudohyphae) on chlamydospore agar, particularly under reduced oxygen tension at 25°C (Carter 1979). Pseudohyphae and oval yeast forms are found in lesions. *Candida* spp. grow readily on Sabouraud agar, malt agar, and often on blood agar incubated aerobically. They form 1–2 mm, creamy white, opaque, circular colonies within 24–48 hours at 37°C and within 2–4 days at 25°C. *C. albicans* produces chlamydospores and germ tubes but no pellicle when grown in broth and ferments glucose, maltose, and galactose but not sucrose or lactose. It is not known to produce toxins, although there have been suggestions that it can produce keratolytic enzymes in the presence of glucose.

EPIDEMIOLOGY

C. albicans has been identified in the bedding, feed, and water supplies of pigs. It occurs on the skin and in the oral cavity, stomach, and intestines of normal pigs in small numbers. It can be shed in the feces and exhaled in droplets by animals with oral infections. It may be isolated from the feces of birds, rodents, and other animal species and may cause disease in those species, which may become sources of the organism for pigs. Organisms in the environment may multiply in moist conditions in the presence of suitable substrates such as spilled meal or garbage.

PATHOGENESIS

C. albicans appears to colonize debilitated skin surfaces and lesions on other mucous surfaces. The predisposing factors appear to include the effects of artificial rearing of piglets (Osborne et al. 1960) and chronic enteritis often associated with treatment with broad-spectrum antimicrobials. Gastric ulcers appear to be colonized by yeasts rather than initiated by them, and cutaneous candidiasis often results from exposure to continually warm moist conditions that are accompanied by poor hygiene and food residues (Reynolds et al. 1968).

Invasion of mucous surfaces appears to follow accumulation of yeast forms on the debilitated surface and develops with pseudohyphal invasion of the superficial layers of the epithelium. Systemic invasion is rare and the inflammatory response to infection is slight.

CLINICAL SIGNS

Yeasts have been implicated in chronic gastroenteritis in piglets, gastric ulceration, and cutaneous and oropharyngeal infections. Piglets are often 3–5 days old (more commonly, 7–14 days) before yeast infection complicates the underlying problem. The clinical signs of gastroenteritis complicated by yeasts are not specific, but there is often a history of dullness, inappetence, vomiting, and chronic diarrhea that may be grayish or blackish depending on the diet and has failed to respond to the use of broad-spectrum antibiotics such as tetracyclines. Piglets may die after 10–14 days of illness. In many cases there are characteristic yellowish white, circular, 2–5 mm lesions on the tongue and hard palate, which resemble colonies of *C. albicans* on artificial media. When scraped off, no macroscopic changes are seen beneath them. Cutaneous candidiasis often presents as a moist gray exudate on the surface of the skin of the abdomen with little or no effect on the hair in early lesions, but later resulting in hair loss and thickening of the skin. Affected animals are often kept in moist conditions and exposed to food residues.

LESIONS

Piglets with candidiasis are often in poor condition with chronic diarrhea. There may be lesions in the oral cavity and throughout the gastrointestinal tract. These consist of white specks and circular patches 2–5 mm in diameter on the dorsum of the tongue, less frequently on the pharynx, and sometimes on the soft or hard palate. These patches may coalesce to form larger areas of pseudomembranous material that may occlude the lumen of the esophagus. The lesions may extend down the esophagus and may be seen on the gastric mucosa. There may be small hemorrhages in the cardiac area and white pseudomembranous lesions in the esophageal area. Descriptions of the lesions distal to the stomach

are rarely published, but in heavily infected animals they resemble those of chronic enteritis, with villous atrophy and thickening of the mucosa. When the white pseudomembranous material is removed, congestion of the mucosal surface may be seen, but ulceration is rare. In older pigs, *C. albicans* may be isolated from gastric ulcers, but these do not differ grossly from uninfected ones. Gross lesions may be seen in cutaneous candidiasis and include a grayish surface deposit, thickening of the skin, and hair loss.

Microscopic lesions include the presence of numerous yeasts on the epithelial surface, with pseudohyphal filaments visible as 1.5–2.0 µm deeply staining threads in the epithelium. In lesions on the tongue, yeast cells and pseudohyphae may be seen in cavities beneath the papillae. They may also be present in large numbers in the periphery of infected gastric ulcers. Degenerative changes are frequently present in the infected epithelium. They include desquamation of epithelial cells, capillary dilation, edema of the submucosa or dermis (depending on the epithelial surface attached), and presence of inflammatory cells. These are neutrophils in the early lesions, later (in 4- to 5-day-old lesions) accompanied by eosinophils, macrophages, plasma cells, and lymphocytes.

DIAGNOSIS

In piglets the appearance of the white 2–5 mm lesions in the oral cavity may suggest that candidiasis is present, but diarrhea and association of infection with gastric ulceration may not be identified on clinical grounds. Skin changes may also suggest a diagnosis of candidiasis. A history of chronic enteritis and broad-spectrum antibiotic use or housing in moist conditions is often suggestive of candidiasis.

Confirmation of diagnosis is based on demonstration of the organism concerned in the lesions or, in life, isolation of large numbers from the feces. The presence of yeasts in lesions of the intestine may be established by their demonstration in Gram-stained smears in which oval or round, gram-positive, often budding, 2.5–6 µm cells may be seen (Figure 50.5). Similar bodies may be seen in histological sections stained by hematoxylin and eosin or, more easily, stained by periodic acid-Schiff or silver stains such as Grocott's (Figure 50.6). None of these allow the complete identification of the organism.

Yeasts may be isolated using Sabouraud's agar with or without chloramphenicol (Carter 1979). Some, such as *C. albicans*, will grow readily on horse blood agar. Incubation at 25°C yields colonies 1–2 mm in diameter after 3–4 days, but incubation at 37°C can allow colonies to be identified within 24–48 hours. The genera can be separated using characters such as shape of the cells, presence or absence of pseudomycelium, presence or absence of capsule, production of chlamydospores, ability to split urea, and other characters (Carter 1979). Many yeast species may be identified in culture using commercial biochemical strips such as the API Yeast series.

Isolation of large numbers of yeasts from lesions may confirm a diagnosis of candidiasis, but their isolation in small numbers from the skin, vagina, or feces and intestines of clinically normal pigs may not be significant.

50.6. *Photomicrograph of yeast cells and pseudohyphae adjacent to the ileal mucosa in a 10-day-old piglet (Grocott; original magnification ×400).*

TREATMENT

C. albicans and other yeasts are sensitive in vitro to a number of compounds such as nystatin, miconazole, and amphotericin B, but only nystatin and ampho-

tericin B have been used in treatment (Osborne et al. 1960). Nystatin suppressed the clinical signs but did not eliminate infection. Amphotericin B may be effective in young piglets given at a rate of 0.5 mg/kg twice daily. In many instances, correction of underlying disease or husbandry factors is sufficient. Cleaning up waste food and providing a dry environment caused resolution of cutaneous candidiasis (Reynolds et al. 1968). Treatment should also include discontinuation of the use of broad-spectrum antibiotics and their replacement with narrow-spectrum ones if they are a factor in yeast colonization. Animals with cutaneous candidiasis may also be scrubbed with suitable detergent or with hexetidine-based shampoos.

PREVENTION

Pigs should be maintained in warm, dry, clean conditions, and accumulations of moist fermenting food should be prevented. Enteric diseases in piglets should be treated with appropriate antimicrobials, and lengthy treatment with broad-spectrum antibiotics should be avoided. Disinfection of pens and pen fittings can be carried out using formaldehyde vapor or 2% formaldehyde; cleaning and drying of the pens will reduce levels of yeasts to normal background levels.

Yersinias

A number of species of *Yersinia* have been isolated from pigs, and reports of association between infection and clinical disease are increasing. *Y. enterocolitica* has increasingly become recognized as a cause of human food poisoning and enteritis since the late 1960s, and the pig is an important source. There are reports in the literature of many surveys of pig carcasses, offal, and feces for the presence of *Y. enterocolitica* (Doyle et al. 1981; Schiemann and Fleming 1981; Hunter et al. 1983). Results of these surveys show that infection is distributed worldwide in pigs, and serotypes considered pathogenic to humans are commonly present. This relationship to human disease has stimulated a number of reports of pathogenic determinants (Mosimbale and Gyles 1982) that have been demonstrated in *Y. enterocolitica* in both porcine and human isolates, and it seems

clear from the work of Kwaga and Iversen (1993) that the pig and human strains are identical. Further reports deal with the antigenic relationships between *Yersinia* spp. and *Brucella* spp., since infections with certain strains of the former can cause interference with serologic tests for both *B. abortus* and *B. suis*. This interference is described in Chapter 35.

Infection in pigs is usually inapparent, but *Y. pseudotuberculosis* and *Y. enterocolitica* have been isolated from pigs with fever, enteritis, and diarrhea.

ETIOLOGY

Yersinias are aerobic or facultatively anaerobic, gram-negative coccobacilli (or short rods), 1.2 μm in length and 0.5–1.0 μm in diameter. They are nonmotile at 37°C,

but some are motile at lower temperatures. Species isolated from pigs include *Y. pseudotuberculosis, Y. pseudotuberculosis* subsp. *pestis* (the plague bacillus), *Y. enterocolitica, Y. intermedia, Y. fredrikensii,* and *Y. kristensenii.* Only two species (*Y. pseudotuberculosis* and *Y. enterocolitica*) have yet been associated with clinical disease in pigs.

Yersinias may be isolated in routine media, upon which they appear as grayish 1–2 mm colonies within 24–48 hours and as similar-sized non-lactose-fermenting colonies on MacConkey agar. The species are distinguished by biochemical tests. *Y. pseudotuberculosis* is motile at 22°C, grows on citrate media at 22°C, splits urea, and does not ferment sucrose or raffinose but does ferment mannose. *Y. pseudotuberculosis* subsp. *pestis* is negative for all these characters. *Y. enterocolitica* is also motile and splits urea but ferments sucrose and does not grow on citrate or ferment mannose. Individual species can be divided into biotypes and serotypes. Capsules, attachment antigens, and enterotoxins have been described in organisms of this genus.

Y. enterocolitica has been subdivided into at least 46 O groups and at least 5 biotypes. Of these, most human infections are associated with biotype 2, O9 and biotype 4, O3. Biotype 1, O8 is also associated with some human infections. *Y. enterocolitica* organisms of a number of O groups have been recorded from pigs. The actual O groups isolated may vary from one part of a country to another (Schiemann and Fleming 1981) but include O3, O5, O6, O7, O8, O9, O13, O18, and O46.

EPIDEMIOLOGY

Y. enterocolitica is found throughout the world and has been recorded from pigs in many countries (Bockemuhl et al. 1979; Cantoni et al. 1979; Barcellos and Castro 1981; Doyle et al. 1981; Schiemann and Fleming 1981; Hunter et al. 1983). Infection may not be general, since not all herds are infected (Christensen 1980). It persists on the tonsils of infected pigs for long periods and is shed in the feces of infected pigs for up to 30 weeks. It has been shown to be transmitted to human food and elsewhere on farms by flies (Fukushima et al. 1979). Feed has been found to be infected, and studies of the dissemination of infection in pig facilities (Fukushima et al. 1983) indicate that infection is transmitted from contaminated pens, in which infection can persist for 3 weeks. Other studies suggest that feces can remain infected for up to 12 weeks and that, in suitable substrates, the organism may multiply at 20–22°C. It appears that transmission from pig to pig is via fecal contamination of accommodation, water, and feed.

Y. pseudotuberculosis is less commonly demonstrated in America than in Europe or Japan and is less commonly identified in pigs than *Y. enterocolitica.* It is commonly found in rodents, which probably represent the main source of infection for pigs.

Y. pseudotuberculosis subsp. *pestis* may infect wild pigs in California, presumably from infection present in rodents (Clark et al. 1983).

PATHOGENESIS

Y. enterocolitica has been shown to infect pigs orally, to multiply and be found in the feces within 2–3 weeks of infection, and to disappear from the feces within 30 weeks (Fukushima et al. 1984). No clinical signs or lesions were described and none were found following infection of 6 pigs with the isolate obtained from the clinical outbreak described above. Experimental studies by Nielsen et al. (1996) have confirmed that infection of the feces may be found between 5 and 21 days after infection and that tonsillar carriage persists longer. A serum antibody response develops by 19 days after infection and has disappeared by 70 days postinfection. Studies in suckling mice have indicated that 10 of the 12 pig isolates tested produced enterotoxin and that one isolate could produce fluid in piglet gut loops. The Sereny test for invasiveness was negative in typical pig strains (Mosimbale and Gyles 1982). Pig isolates harbor the virulence plasmid (Kwaga and Iversen 1993) and possess the capsular material considered essential for pathogenicity and detected using the Congo red magnesium oxalate test. Studies by Erwerth and Natterman (1987) suggest that oral infection is followed by establishment of infection in the tonsils and the development of enteritis in the ileum and large intestine. Similar colonization was reported by Schiemann (1988) and has also been reproduced by Shu et al. (1995a, b) and Shu et al. (1997), who demonstrated that small-intestinal infection in piglets led to microabscesses at the base of the villi and to reductions in the levels of intestinal lactases (Shu et al. 1997) and depressed growth (Shu et al. 1995b).

CLINICAL SIGNS

Clinical disease has been associated only with *Y. enterocolitica* and *Y. pseudotuberculosis. Y. pseudotuberculosis* subsp. *pestis* is clearly capable of producing serologic reactions (Clark et al. 1983), but no clinical disease has been described.

Y. enterocolitica was isolated in profuse culture from outbreaks of diarrhea in weaned pigs from which no other infectious agents could be recovered. Mild fever (to 39.4°C, 103°F) was present, and the diarrhea contained no blood or mucus and was blackish in color. Clinical signs resembling those described above have been seen in animals receiving tylosin or lincomycin. Bloodstained mucus may also be found in some diarrheic feces and on solid feces passed by penmates. The organism has been isolated from the rectal mucosa in cases of rectal stricture. Experimental infections in suckling piglets result in anorexia, vomiting, diarrhea, and reduction in weight gain (Shu et al. 1995a).

Y. pseudotuberculosis has been associated with clinical signs by Morita et al. (1968), who described an outbreak in Japan. Affected pigs were dull and showed inappetence; bloodstained diarrhea; and edema of eyelids, lower face, and dependent parts of the abdomen. Diarrhea was also observed by Barcellos and Castro (1981). Neef and Lysons (1994) were able to reproduce diarrhea in 4 of 9 pigs infected with a colitis isolate of *Y. pseudotuberculosis*. The organism has been isolated from pigs with the rectal stricture syndrome.

LESIONS

The lesions caused by *Y. enterocolitica* infection have been described in detail by Erwerth and Natterman (1987) and consist of catarrhal enteritis in the small and large intestines. Microcolonies of the organism can be seen in the disrupted intestinal epithelium, and in pigs with rectal lesions, bacterial penetration and inflammation reach the muscularis mucosae. Shu et al. (1995a) confirmed this finding for the small intestine and describe the presence of microabscesses at the bases of the villi.

Lesions of *Y. pseudotuberculosis* have been described (Morita et al. 1968). They resembled those of pseudotuberculosis in other species, with miliary gray-white spots on the liver and spleen and swollen gray-white mesenteric lymph nodes. A catarrhal and diphtheritic change was described in the colon and rectum, as edema and ascites also occurred. Microscopic lesions included necrotic foci containing masses of bacteria surrounded by a thin layer of granulation tissue in the lung, liver, spleen, mesenteric lymph nodes, and lymphoid follicles of the large intestine. Similar findings were made by Neef and Lysons (1994), who noted the penetration of the microabscesses into the lamina propria. *Y. pseudotuberculosis* was isolated from the liver, spleen, lungs, duodenum, rectum, and mesenteric lymph nodes by Morita et al. (1968). *Y. pseudotuberculosis* can also be isolated from inflammatory lesions of the rectal mucosa similar to those described above.

DIAGNOSIS

The clinical signs are not distinctive, but the occurrence of mild fever and blood and mucus on solid feces can indicate yersinia infection in the absence of swine dysentery. Where rectal stricture is common, the organism may be responsible for diarrhea in younger age groups, and the organism may be involved in the "colitis" syndrome of mild diarrhea in growing pigs. Diagnosis of infection with most *Yersinia* spp. in pigs depends upon isolation of the organism and its identification. Serology has been used to identify *Y. pseudotuberculosis* subsp. *pestis* (Clark et al. 1983), but most accounts of yersinia infections suggest that although agglutinating antibody may result from infection, isolation methods are ade-

quate for diagnosis. The indirect ELISA developed by Nielsen et al. (1996) for *Y. enterocolitica* O3 may be of value in the field but may not detect infections by other serotypes. *Y. pseudotuberculosis* can readily be isolated at 37°C on blood and MacConkey agar from lesions of the type described by Morita et al. (1968) and so may *Y. enterocolitica*. Most isolation methods for all yersinias involve use of a cold enrichment technique in which tissues or samples under investigation are placed in phosphate-buffered saline M/15 at pH 7.6 at 4°C for 6 weeks, with subculture at 3 and 6 weeks onto a selective medium (Hunter et al. 1983). The selective medium may be MacConkey agar incubated at 30°C or a specific medium for *Y. enterocolitica*. These methods may be used for direct isolation. Media are described by Hunter et al. (1983) and six are reviewed by Catteau et al. (1983). Recent studies by food microbiologists have resulted in a range of tests, such as the immunomagnetic separation and polymerase chain reaction technique of Rasmussen et al. (1995), which can detect as few as 200 cells per gram of feces.

TREATMENT

There is at present no general indication for the treatment of yersinia infections, since clinical signs are so rare. In vitro studies suggest that isolates are often sensitive to oxytetracycline, furazolidone, neomycin, sulfonamides, and spectinomycin. Tetracyclines have been used in feed to eliminate infection and clinical signs.

PREVENTION

Since spread of *Y. enterocolitica* from pig to pig appears to occur from contact with feces, hygiene coupled with housing groups of pigs in separate drainage areas will reduce infection. Control of flies and rodents and disinfection of pens before restocking will reduce transmission. Morita et al. (1968) found that pseudotuberculosis could be prevented by excluding birds and rodents. Current requirements for the control of *Y. enterocolitica* in pig meat concentrate on the removal of the tonsil at slaughter, so control programs have not been developed for the live animal. Control may be required when serologic cross-reaction in the brucellosis test is identified in herds selling breeding stock. The findings of Nielsen et al. (1996) suggest that serologic reactions peak at 33 days postinfection and have disappeared by 70 days postinfection, so pigs may be treated or managed at the time of infection to prevent the development of antibody or held and retested after antibody levels have declined.

Staphylococci

Staphylococci are ubiquitous. They are present on every pig farm and involved in a wide range of lesions in pigs of all ages. The most easily recognized are those of exudative epidermitis caused by *Staphylococcus hyicus* and described in Chapter 39. Few, if any, of the other lesions can be unequivocally identified as being staphylococcal on clinical grounds; in the majority, staphylococcal involvement must be confirmed by laboratory means. In addition to their association with pig disease, some of the staphylococci that infect the pig, notably *S. aureus*, may be involved in human food poisoning if carcasses are contaminated or abscesses are present.

ETIOLOGY

Staphylococci are gram-positive, 0.5–1.5 μm in diameter, forming grapelike clusters when grown in serum broth or seen in pus. They grow primarily in aerobic conditions but can also grow anaerobically, are oxidase-negative but produce catalase, and metabolize a wide variety of sugars. They produce a wide range of enzymes and some toxins. The species are distinguished by the presence of enzymes such as coagulase, DNAase, he-

molysins, and phosphatase and by the ability to utilize a variety of sugars. Major species reported from the pig are *S. aureus*, *S. hyicus*, and *S. epidermidis*, although *S. saprophyticus* has also been described.

S. aureus is the only species apart from *S. hyicus* to be consistently isolated from lesions in pigs. It forms yellowish-white, opaque, circular, domed colonies, 1–2 mm in diameter, on blood agar after 24 hours of incubation. These colonies may be surrounded by a zone of complete hemolysis, caused by alpha hemolysins, on horse blood agar. On sheep blood agar, the ring of complete hemolysis is surrounded by a wider area of incomplete hemolysis caused by beta hemolysins; this becomes complete on cooling of the plate. In addition to these hemolysins, the organism produces coagulase, DNAase, proteinases, hyaluronidase, and toxins that include the alpha toxin and the enterotoxins. Both have been demonstrated in strains of porcine origin (Engvall and Schwan 1983); protein A (Takeuchi et al. 1995) and polysaccharide capsules are also present. Isolates of *S. aureus* can be identified by phage typing and plasmid profiling, and those of public health significance may readily be traced. *S. aureus* is fairly resistant to drying but is readily inactivated by heat. It is sensitive to a wide

range of disinfectants, such as phenols, hypochlorites, iodine, and iodophors.

EPIDEMIOLOGY

S. aureus is widely distributed in the environment and has been recovered from pig feces, food, water following contamination of drinkers, pen floors and walls, and the air in pig facilities. The organism can be isolated from a wide range of hosts, including birds, rodents, dogs, cats, and humans. The extent to which isolates from lesions in pigs are of nonporcine origin is not yet known. Porcine strains capable of enterotoxin production have been identified on carcasses and represent a source of infection or possible food poisoning to humans (Engvall and Schwan 1983).

The pig is probably the major source of infection for other pigs; *S. aureus* can be isolated from the skin, oral cavity, upper respiratory tract, prepuce, vagina, and gut of healthy pigs on a very wide scale. Transmission of the organism may be by aerosol to the upper respiratory tract, directly by skin contact, or indirectly by contact with contaminated walls or fittings. Ingestion of *S. aureus* from food, contaminated water, or litter is common. Venereal contact may be responsible for some genital infections; local invasion of the mammary gland, navel, and skin lesions is common.

PATHOGENESIS

S. aureus appears to multiply on damaged mucosal surfaces or skin and can invade to cause bacteremia. In some cases, such as neonatal septicemia, animals may become fevered and die, but bacteremia usually leads to formation of multiple abscesses. These may occur in bones to give osteomyelitis; in joints; on the heart valves to give vegetative endocarditis; and in the liver, kidney, or lymph nodes. Vegetative endocarditis may give rise to septic emboli that cause abscess formation and infarction in the kidney. Most of these systemic infections occur in neonates or piglets and take 7–10 days to develop. They are also present in apparently normal pigs at slaughter. Abscesses contain neutrophils and microcolonies of bacteria in all stages of multiplication and heal by fibrosis.

Mastitis, vaginitis, and metritis appear to result from ascending infection. Abortion has been associated with the demonstration of serum antibody to alpha hemolysin in the sow (Kohler and Wille 1980), but the importance of this and other toxins in abortion is not known.

In enteric infection, experimental studies have shown that staphylococcal enterotoxin A will cause emesis within 90–180 minutes when given orally in doses of 40–50 μg (Taylor et al. 1982). Larger doses can cause behavioral changes, including inappetence, restlessness, and staggering. The piglet is clearly susceptible, but the ability of enteric staphylococcal infections to produce enterotoxin in vivo is not known.

CLINICAL SIGNS

The presence of *S. aureus* infection cannot readily be suspected on clinical grounds. *S. aureus* has been isolated from a wide variety of syndromes. Most of these occur in individual animals, and disease rarely spreads from animal to animal. It can cause neonatal septicemia and is often identified in small, hairy, stunted piglets of 7–10 days of age with umbilical abscesses, polyarthritis, and signs of cardiac enlargement due to vegetative endocarditis. It is a cause of subcutaneous abscesses associated with abrasions and foot lesions, especially in piglets. These often result in arthritis of the distal phalangeal joints, enlargement of the hoof, and sinus formation at the coronary band. Creamy pus is often seen to exude from the abscesses.

S. aureus has been isolated from enteritis in piglets and in older animals and from the rectal mucosa of animals with lesions of rectal stricture. No particular features of diarrhea are associated with staphylococci except that the enteritis is often chronic and antibiotic treatment may have been given. The organism is also present in a small percentage of cases of mastitis and has been isolated from pigs with metritis and agalactia. The only reason to suspect staphylococcal involvement may be the presence of a creamy white or bloodstained pus, but this often contains other organisms. It has also been isolated from aborted fetuses and placentas (Kohler and Wille 1980).

LESIONS

No gross lesions may be seen in piglet septicemia. In chronic infections, an inflamed mucosa may be associated with staphylococcal infection, but there is no specific feature that allows their identification with staphylococcal infection. Abscesses may occur in the umbilicus, liver, lungs, lymph nodes, spleen, kidneys, joints, and bones in osteomyelitis; bone abscesses may give rise to pathologic fractures, especially when in the vertebrae. Body cavities (peritoneal cavity, pericardial cavity, uterine lumen) may contain pus, especially in young animals, following umbilical infection. *S. aureus* is only one cause of such lesions. Both gross and microscopic lesions of mastitis may be found in the mammary glands, and in some cases fibrosis may be considerable. Occasionally, a granulomatous mass with fibrosis may be found in the abdominal cavity of piglets that have died after castration. In all cases, confirmation that the lesions are staphylococcal depends on demonstration of the organisms.

DIAGNOSIS

The clinical signs resulting from multiple abscess formation in individual pigs may be suggestive, and similar suspicions may arise from the postmortem findings.

Confirmation of involvement of staphylococci rather than *Arcanobacterium pyogenes* or streptococci in abscesses and arthritis is obtained from Gram-stained smears of the pus in which gram-positive cocci may be seen singly or in clusters. Only the isolation of staphylococci in culture confirms that they are involved. *S. aureus* can be isolated readily on blood and MacConkey agar, and its identity can be confirmed by coagulase and DNAase tests and by its ability to ferment mannitol. Isolates may be phage typed if this is considered relevant, and any toxins produced may be identified.

In most abscesses the absence of other bacteria must be confirmed before *S. aureus* is considered to be the sole cause; exclusion of other agents is even more important in diseases at mucous surfaces.

TREATMENT

Individual abscesses may be opened surgically after skin cleaning and disinfection, but most treatments rely on antimicrobial treatment. Since *S. aureus* infection is an individual-animal problem, there is usually no need to treat the whole group. Parenteral treatment with an ap-

propriate formulation and prompt treatment at any age can prevent the development of large and potentially extensive and fatal abscesses. The use of feed medication as a prophylactic cannot be justified unless a severe problem has been identified, since the development of antimicrobial resistance in staphylococci is likely to favor them over other organisms after a brief period during which they are suppressed. The use of bacterins has been described, but they are not widely available or extensively used.

Actinobaculum (Actinomyces-Eubacterium-Corynebacterium) suis

Soltys and Spratling (1957) isolated, anaerobically, a diphtheroid bacterium from the urine and diseased tissue of adult pigs in the United Kingdom affected with cystitis and pyelonephritis and named it *Corynebacterium suis*. Soltys (1961) described the characteristics of *C. suis* in more detail. *C. suis* was subsequently assigned to the genus *Eubacterium* (Wegienek and Reddy 1982), Actinomyces (Ludwig et al. 1992), and finally *Actinobaculum* Lawson et al. 1997).

A. suis infection associated with urinary tract disease in sows has been reported from Canada (Percy et al. 1966), Norway (Aalvik 1968), Holland (Dijkstra 1969; Frijlink et al. 1969; Narucka and Westendorp 1972), Denmark (Larsen 1970, 1973), Hong Kong (Munro and Wong 1972), Australia (Glazebrook et al. 1973), Switzerland (Schallibaum et al. 1976), Finland (Kauko et al. 1977), Malaysia (Too et al. 1985), Germany (Muller et al. 1986; Waldmann 1987), Brazil (De Oliveira et al. 1988), and the United States (Walker and MacLachlan 1989). Disease caused by *A. suis* occurs in small outbreaks or individual sows, but carriage is much more widespread. The main features of the organism and the disease are described below.

ETIOLOGY

A. suis is a gram-positive pleomorphic rod, 2–3 μm long and 0.3–0.5 μm wide; the organism tends to be larger in

tissues than in cultures. In tissues and cultures it occurs in the form of so-called Chinese letters and in a palisade fashion. It is nonmotile and does not form spores.

A. suis grows well on blood agar under anaerobic conditions. Colonies are evident at 2 days, having a diameter of 2–3 mm; they then begin to flatten and develop a characteristic dry, gray, opaque surface with a crenated edge; some colonies attain a size of 4–5 mm in 5–6 days. There is no hemolysis. Growth on nutrient agar, even after subculture, is poor. In liquid media such as cooked meat broth and brain-heart infusion, slight turbidity is produced in 2–4 days; growth is more luxuriant in trypticase soy broth and is further enhanced by the addition of urea to a final concentration of 1.2% (w/v). The addition of maltose to either solid or liquid media improves growth. Although *A. suis* has always been described as an anaerobic organism, prolonged aerobic incubation on blood agar results in the development of colonies within 5–10 days; on subculture, aerobically, colonies are evident in 1–3 days.

The organism is relatively inactive when subjected to conventional biochemical tests. Most strains ferment maltose and xylose and hydrolyze starch but do not attack other commonly used "sugars"; all produce urease. Catalase, methyl red, Voges-Proskauer, indole, and nitrate-reduction tests are negative. Coagulated serum and egg medium are not liquefied. A slight alkalinity is produced in litmus milk.

EPIDEMIOLOGY AND PATHOGENESIS

Most male pigs aged 6 months or more harbor *A. suis* in the preputial diverticulum, which may become colonized when pigs are only a few weeks old. Uninfected males are readily infected when they are housed with carrier males (Jones and Dagnall 1984). The organism may be found on the floors of pens occupied by male pigs. Carr and Walton (1990) have isolated *A. suis* from the footwear of handlers working with boars but not from those working in the farrowing area. Only rarely is it found in the vagina of healthy females, but it may be that existing cultural techniques are insufficiently sensitive to demonstrate its presence there. There are no reports of *A. suis* being isolated from any sites in the pig other than the urogenital tract.

Cystitis and pyelonephritis caused by *A. suis* mainly affect adult females. Infection of the bladder and kidneys is by the ascending route. Most cases occur within 1–3 weeks of mating, suggesting that predisposing factors are operating at this time. Wendt et al. (1994) suggest that these may include infection with other organisms, because of a requirement for erosion of mature vesical epithelial cells to allow attachment by *A. suis*. Water restriction and the presence of crystalluria may also predispose to infection (Wendt and Sobestiansky 1995). The disease may become clinically evident at any time in the breeding cycle of the sow (e.g., after parturition), and in such cases it is not always clear whether infection of the urinary tract is recent or whether there has been a recrudescence of previously existing disease.

Studies on the adhesive properties of *A. suis* have been reported by Larsen et al. (1986). They have demonstrated that some strains are heavily fimbriated and are able to adhere to the epithelial cells of the porcine bladder; their findings support the hypothesis that glycoconjugates are specific receptor sites for the attachment of *A. suis*. Infection of the ureters and kidneys follows infection of the bladder.

CLINICAL SIGNS AND LESIONS

Hematuria is the main sign in the acute phase. As the disease progresses, there is loss of weight. Some sows may die suddenly, apparently from acute renal failure.

Inflammatory reactions in the mucosa of the urethra, bladder, and ureters may be catarrhal, fibrinopurulent, hemorrhagic, or necrotic. Affected kidneys often have irregular yellow areas of degeneration in the parenchyma that are visible on the surface. The renal pelvis may be dilated and contain mucoid fluid in which flakes of necrotic debris and altered blood are present. The medullary pyramids often show yellow or dark green to black foci of necrosis. The ureters are often dilated and filled with reddish purulent urine. There are no related lesions elsewhere in the body.

DIAGNOSIS

Diagnosis is based on clinical signs and bacteriological examination of urine. *A. suis* is easily seen in Gram-stained films, often with other bacteria, notably streptococci. For cultural examination it is essential to incubate the medium (e.g., blood agar), which has been inoculated with urine or other appropriate material, anaerobically for 4 days. Results of cultural procedures should not be reported as negative before that time. Rapid diagnosis can be achieved by the use of immunofluorescent techniques (Schallibaum et al. 1976; Kauko et al. 1977). A selective medium for the isolation of *A. suis* has been described by Dagnall and Jones (1982). Wendt and Amstberg (1995) evaluated the possibility of using serology to detect infection and tested indirect immunofluorescence in diagnosis. They found that antibody did not appear until 3 weeks after hemorrhagic cystitis had occurred and that when a titer of ++ at 1/16 was used as an endpoint to give 100% specificity, the sensitivity was only 79%. There was no relationship between antibody level and the degree of renal damage.

TREATMENT AND PREVENTION

A. suis is sensitive in vitro to several antibiotics, including penicillin and tetracyclines. Administration of antibiotics is frequently effective, at least in the short term. However, relapses commonly occur, and often it is best to advise early slaughter of affected animals. Prolonged treatment for 20 days with ampicillin given at 20 mg/kg may be used (Wendt and Sobestiansky 1995), and enrofloxacin given for 10 days at 10 mg/kg may also be effective. In Wendt and Sobestiansky's studies (1995), pigs with lesions confined to the bladder recovered with antimicrobial treatment alone, but those with renal damage required infusion therapy for recovery.

There are no proven methods of prevention. *A. suis* may be transmitted from boars to sows at the time of mating. Culling of carrier boars has been suggested as a method of preventing infection of sows; this does not seem worthwhile, because replacement boars will almost certainly be infected. Culling might be of value if there are "pathogenic" and "nonpathogenic" strains of *A. suis*, but there is no evidence that such different strains exist. Currently, the only means of attempting prevention of the disease is to administer antibiotics to sows immediately after service or, if outbreaks of the disease are economically serious, to use artificial insemination.

Rhodococcus equi

Rhodococcus equi is associated with granulomatous lym-phadenitis affecting the lymph nodes of the head and neck of the pig. The lesions can be confused at slaughter with those of tuberculosis, and the organism is im-portant for this reason rather than as a cause of clinical disease.

ETIOLOGY

The organism was first isolated from the pneumonic lungs of a foal by Magnusson (1923) and was given the name *Corynebacterium equi*; it is now called *Rhodococcus equi*. This gram-positive coccobacillus is a member of the nocardioform actinomycete group (Goodfellow et al. 1982). In common with other members of *Rhodo-coccus, R. equi* produces pinkish colonies on solid media. The mycolic acids of *R. equi* have a chain length of 34–48 C, and the DNA base composition is 66–72 mol% gua-nine plus cytosine. Chemical properties used in defin-ing the species were summarized by Goodfellow (1987).

Isolation of *R. equi* from clinical samples is easily achieved by aerobic culture on routine media at 37°C, al-though the optimum temperature is 28–30°C. Selective media, such as that developed by Woolcock et al. (1979), are required for fecal isolation. Colonies are slow grow-ing, requiring 48 hours to reach a size of 2–4 mm. The typical colony is irregularly round, buff-pink, smooth, and mucoid, although colonial variation is common within and between strains (Mutimer and Woolcock 1981). *R. equi* is biochemically unreactive. It is not prote-olytic and does not ferment carbohydrates. *R. equi* is catalase positive, usually urease positive, and oxidase negative. The API ZYM system has been found helpful in bacterial identification (Mutimer and Woolcock 1982). *R. equi* is not hemolytic but, in conjunction with the phospholipase D of *Corynebacterium pseudotuberculosis* or the beta toxin of *Staphylococcus aureus,* produces com-plete hemolysis of sheep and cattle erythrocytes (Prescott et al. 1982). Semipurification of this factor, known as "equi factor," has indicated that cholesterol oxidase is the major constituent (Linder and Bern-heimer 1982).

R. equi possess an abundant acidic polysaccharide capsule, which is the basis for several serotyping schemes. Prescott (1981) has identified 7 serotypes, of which serotype 1 is the most frequently isolated in Canada, Australia, and India. Japanese workers have identified 27 serotypes, with the most common being equivalent to Prescott serotype 1 (Nakazawa et al. 1983). There is no relationship between capsular serotype and origin of the isolates. The capsular polysaccharides of 4 Prescott serotypes have been purified.

Recent studies of this species have confirmed that isolates from pigs possess a virulence-associated protein (vapA) that is encoded by a virulence plasmid. Takai et al. (1996) confirmed the presence of 79–95 kb plasmids coding for a 20 kDa virulence protein.

EPIDEMIOLOGY AND PATHOGENESIS

R. equi is primarily a soil resident. Environmental distribution favors soils enriched with herbivore manure, since fecal matter potentiates bacterial multiplication (Barton and Hughes 1984). *R. equi* is also a transient in the intestinal tract of many species, including pigs, cattle, deer, horses, sheep, goats, and wild birds (Woolcock et al. 1979; Carman and Hodges 1987). Being an obligate aerobe, *R. equi* is not likely to be a member of the normal flora. The bacterium is found in soil samples collected from arable land that has not pastured animals for many years, emphasizing its durability. *R. equi* is present in dust and even in cobwebs of farm buildings in areas where it occurs. *R. equi* is relatively resistant to chemical disinfectants, such as treatment with 2.5% oxalic acid and 0.5% sodium hydroxide over periods of 15–60 minutes (Karlson et al. 1940).

Little is known of the epidemiology or pathogenesis of the naturally occurring disease in swine. As in horses, *R. equi* infection is likely to be acquired from the environment (Woolcock et al. 1980). Ingestion is the normal mode of exposure in foals (Takai et al. 1986a), leading to the development of solid protective immunity in the majority of animals (Prescott et al. 1980; Chirino-Trejo et al. 1987). A similar situation probably occurs in swine housed on pasture or in yards contaminated with *R. equi*, as the bacterium is readily isolated from the feces of such pigs (Barton and Hughes 1984). Several slaughterhouse studies have also demonstrated recovery of *R. equi* from normal cervical and submaxillary lymph nodes at rates varying from 7% to 35% (Mutimer and Woolcock 1980; Takai et al. 1986b), although the organism may now be less common, as Takai et al. (1996) recovered it from only 3.1% of 1832 swine in Japan. However, no epidemiological studies have been carried out to correlate infection rates, disease prevalence, and environmental contamination of *R. equi* on pig farms, as has been done for horses. There have been suggestions that isolates from pigs differ somewhat from those from horses and that some pig isolates resemble those from humans.

Takai et al. (1996) speculated that some human cases may be of porcine origin.

The way in which *R. equi* causes granulomatous lymphadenitis of the head and neck in the pig is not clear. *R. equi* can be recovered from normal nodes, and there are accounts of failure to reproduce the nodal lesions experimentally (Karlson et al. 1940; Cotchin 1943). *Mycobacterium* spp. may also be recovered in some cases. It is possible that the severity of the lesions reflects the possession of the virulence-associated protein, which may vary from strain to strain, the degree of immunity present when infection took place, or the duration of the infection at sampling. However, *R. equi* typically produces a granulomatous tissue reaction in lymph nodes of other species, consistent with its action as a facultative intracellular pathogen (Yager 1987).

R. equi has been associated with serious clinical disease, including one outbreak of oral abscesses and one of pneumonia (Thal and Rutqvist 1959; Rao et al. 1982), but pigs are extremely resistant to experimental infection. Following aerosolization, *R. equi* is cleared from the lungs very slowly, but clinical signs and pathological lesions of pneumonia are minimal despite exposure to 107 organisms on 7 consecutive days (Zink and Yager 1987). Pneumonia has, however, been induced by intratracheal inoculation of fluid inocula (Thal and Rutqvist 1959).

LESIONS

Lymphadenitis causes no significant clinical signs; lesions are detected only at slaughter. Affected submandibular and cervical nodes are enlarged, containing multiple yellow-tan foci, often in a subcapsular location. Caseation and calcification of these foci sometimes occur. Histologically, the lesion is a granulomatous lymphadenitis. Similar lesions reported in the mesenteric lymph nodes have yielded *Rhodococcus sputi* on culture (Tsukamura et al. 1988).

DIAGNOSIS

Diagnosis is at postmortem. Microbiological identification of *R. equi* is necessary for it is not possible to differentiate the gross lesions of *R. equi*–induced lymphadenitis from those caused by *Mycobacterium* spp.

TREATMENT AND PREVENTION

R. equi–induced disease is not sufficiently important to necessitate antemortem diagnosis and treatment in swine. Therapy, which in foals requires long-term administration of rifampicin and erythromycin, is not feasible on economic grounds. While some economic loss may accrue from condemnation at slaughter, there are no studies that indicate the extent of this loss and there appears to be no incentive to institute control measures.

These would in any case be difficult; an effective vaccine is presently unavailable.

Arcanobacterium pyogenes

Arcanobacterium pyogenes, previously known as *Actinomyces pyogenes,* and even earlier as *Corynebacterium pyogenes,* is a common cause of suppurative lesions in pigs throughout the world. Infection is opportunistic, resulting from the invasion of skin or mucous membranes by resident *A. pyogenes*. Clinical disease can result from vertebral osteomyelitis, arthritis, pneumonia, endocarditis, mastitis, and subcutaneous and deep-tissue abscesses.

ETIOLOGY

A. pyogenes is a small gram-positive pleomorphic rod. There is marked morphologic variation between and within strains. Growth is enhanced by the addition of serum or blood to media and occurs under both aerobic and anaerobic conditions. The optimal temperature for growth is 37°C. Colonies are translucent and small, taking 48 hours to reach a diameter of 1 mm. *A. pyogenes* colonies are surrounded by a narrow zone of complete hemolysis after 24 hours on blood agar. Strains isolated from pigs are more hemolytic than those isolated from cattle. *A. pyogenes* produces a hemolysin and an exotoxin that is dermonecrotic in rabbits and guinea pigs and lethal following intravenous injection in rabbits and mice (Lovell 1944). Glucose is fermented by all strains, but other carbohydrate reactions are variable. In general, porcine strains are more biochemically active than bovine strains (Roberts 1968; Tainaka et al. 1983). *A. pyogenes* is proteolytic, a series of serine proteases with molecular masses of 69, 59, and 55 kDa being produced along with one of 108 kDa that is only produced by pig strains (Takeuchi et al. 1995).

A. pyogenes had been classified into the genus *Actinomyces* by Collins and Jones (1982), chiefly on the basis of cell wall composition. The guanine-cytosine content of DNA is 58 mol%. Identification of *Arcanobacterium pyogenes* is rapid and reliable with the API 20 Strep system (Morrison and Tillotson 1988). Recent studies of vaginal isolates have allowed the differentiation of *Arcanobacterium hyovaginalis* (Collins et al. 1993).

EPIDEMIOLOGY AND PATHOGENESIS

Arcanobacterium pyogenes is common on the mucous membranes of the upper respiratory tract and genital tract of several animal species, including the pig. Disease is therefore the result of endogenous infection and is sporadic, requiring some predisposing event, such as trauma, to initiate the process. For *A. pyogenes* to cause subcutaneous lesions, devitalized or inflamed tissue is an apparent prerequisite, since the inoculation of *A. pyogenes* subcutaneously does not, per se, lead to abscesses. Infection is often secondary. Tail biting may lead to abscessation and suppurative osteomyelitis, retention of the fetal membranes may lead to endometritis and infertility, lacerations of the mammary gland may lead to mastitis and arthritis, umbilical cord contamination may lead to omphalophlebitis, and iatrogenic abscesses may result from faulty injection or castration techniques. Local extension may produce pelvic lymphadenitis and peritonitis. *A. pyogenes* may act as a secondary invader in preexisting pneumonia.

Bacteremic spread from infective foci results in a variety of lesions, including embolic pneumonia, endocarditis, arthritis, and vertebral osteomyelitis. Experimental intravenous inoculation of *A. pyogenes* shows bacterial localization within the marrow of vertebral body epiphyses, initiating osteolysis, abscessation, and the formation of osteophytes (Vladutiu et al. 1982). Valvular endocarditis may result from bacteremia following tail-biting lesions (Van den Berg et al. 1981). *A. pyogenes* is occasionally recovered from fetuses and fetal membranes, but its role in abortion has not been established. Some of these isolates may be *A. hyovaginalis*.

A. pyogenes, as denoted by its name, causes suppurative lesions. Surprisingly little, however, is known of the virulence factors important in disease causation. Both the hemolytic protein exotoxin and protease have been proposed as toxic factors (Kume et al. 1983). *A. pyogenes* also binds alpha-2 macroglobulin (Lammler et al. 1985), a property that could interfere with local regulation of inflammation.

CLINICAL SIGNS AND LESIONS

The clinical signs are very variable, since *A. pyogenes* is responsible for a range of pathological lesions. Some, such as endocarditis and adhesive peritonitis, may be fatal. Others, such as vertebral osteomyelitis leading to posterior paralysis, may necessitate euthanasia. Suppurative osteomyelitis generally affects the vertebral bodies, leading to transverse pathological fractures, vertebral collapse, and compression of the spinal cord. Lameness results from polyarthritis or from cellulitis and periarthritis. However, many lesions, including subcutaneous and intramuscular abscesses, are clinically inapparent and are discovered only at postmortem or slaughter. Such abscesses vary from a few millimeters to several centimeters in size, usually have a thick fibrous capsule, and contain a yellow-green pus of variable consistency. Mastitis may be confined to one gland or may involve several.

DIAGNOSIS

Diagnosis in individual cases requires the demonstration of the organism in lesional material and confirmation by laboratory culture and identification. Carcass abscesses typically yield mixed cultures, including clostridia, *Bacteroides* spp., *Propionibacterium granulosum, Pasteurella multocida,* and unidentified anaerobes (Hara 1980; Jones 1980). Diagnosis of infection within a herd has been attempted serologically using an immunodiffusion test for antibody to *A. pyogenes* protease (Takeuchi et al. 1979). However, in a slaughterhouse survey, only 34.4% of pigs with abscesses had an antiprotease titer (Hara 1980).

TREATMENT

A. pyogenes is sensitive to a wide range of antimicrobial agents, including penicillin, tetracycline, and erythromycin. Some strains have been shown to be resistant to sulfonamides and trimethoprim. In vivo sensitivity does not necessarily reflect in vitro sensitivity, for the physicochemical properties of chronic abscesses tend to protect the bacteria from the action of antimicrobial drugs. Abscesses may be removed surgically.

PREVENTION

Surveys of serum antibodies to *A. pyogenes* protease show that approximately one-third of pigs are positive (Hara 1980). Antitoxin antibodies are also demonstrable and may increase with age. However, mice vaccinated with preparations of whole cells with or without toxoid or even given live organisms are not adequately protected against subsequent challenge (Derbyshire and Matthews 1963; Durner and Werner 1983). There is no effective vaccine available for swine. Prevention requires management of the environment to reduce or abolish the various conditions that predispose the development of *A. pyogenes* lesions. The treatment of sows with antimicrobials such as tetracyclines in the food prior to farrowing and throughout weaning can eliminate infection and reduce vulval discharges (Taylor 1984).

IV Miscellaneous Conditions

51 Behavioral Problems

P. H. Hemsworth and Greg M. Cronin

Most behavioral differences between wild and domestic animals, including farm animals, are quantitative rather than qualitative in character and best explained in differences in response thresholds (Price 2003). Once a species has become adapted to its captive environment, reproduction and growth efficiency are generally improved through better nutrition and health, reduced energy expenditure, and, in some cases, reduced stress in this captive or domestic environment. Behavioral problems by definition involve behavioral changes as a consequence of either environmental or genetic change that compromise the fitness of the animals, and thus in the case of farm animals, we can consider that behavioral problems compromise the animals' production efficiency, health, and welfare.

The term "abnormal behavior" in domestic animals often refers to behavior that either is not in the animal's natural repertoire of behavior or differs in its pattern, frequency, or context from what is considered normal. This issue of "what is natural or normal?" in domestic species is a contentious one, and it is simpler and perhaps less ambiguous to use the term *behavioral problem* and define it as a behavior that compromises the animals' production efficiency, health, and welfare. Such a definition incorporates implications for the animal, other animals, and the animal owner or caretaker. This review will focus on the major behavioral problems in commercial pigs, with the objective of recommending possible solutions to improve the productivity, health, and welfare of these pigs.

AGGRESSION

Agonistic behaviors are behaviors that occur in response to a conflict; may include offense, defense, submissive, or escape components (including dispersal, although this behavior is not possible in pig housing systems in which pigs are contained in pens or relatively small paddocks); and consist of contact (e.g., biting or pushing) or noncontact (e.g., body postures, gestures or vocaliza-

tions) behaviors. Aggressive behaviors strictly refer to attack and actual fighting and thus include parallel pressing, head-to-head knocks, levering, and bites in pigs (Fraser and Broom 1996).

An important behavioral trait that influenced the domestication of ungulate and galliform species was their social organization: these species had the ability to live in relatively large groups without marked year-round territoriality (Stricklin and Mench 1987). This trait has been further affected through artificial selection during domestication; the formation of social hierarchies and the tendency for subordinates to avoid dominant animals is considered an important mechanism that functions to control aggression in situations of limited resources (e.g., space and feed). Nevertheless social instability is an important social stressor for livestock. For instance, entire male pigs are reported to grow much less efficiently during the finisher phase of production than their genetic capability (De Haer and Merks 1992). The high level of aggression and social instability characteristic of entire boars in groups, was eliminated by application of an immuno-castration vaccine (Improvac), with concomitant improvement in feed intake and growth during the last few weeks of the finisher phase (Cronin et al. 2003).

In addition to aggression caused by competition over resources, such as feed, and meetings between unacquainted animals, some aggression in farm animals may function to maintain distance between individual animals (Fraser and Rushen 1987). Research on farm animals generally indicates that both increases in group size and decreases in space are associated with increased aggression, and high levels of aggression in pigs has been shown to lead to physical injury, including lameness, and acute stress and, if unresolved, chronic stress with consequences on immunity, disease, and productivity.

The results of growth studies on growing pigs generally indicate depressions in growth performance, either decreases in growth rate or increases in feed-to-gain ratio, with decreasing space allowance and increasing group

size (Kornegay and Notter 1984; Chapple 1993), with space allowance perhaps having the greater impact.

Reducing space in terms of either floor space or pigs per feeder will eventually reduce the growth performance of growing pigs (see Gonyou 2001), presumably through stress and/or access to feed. Reductions in space allowance may not be accompanied by changes in aggression since restrictions in space may restrict specific behavioral patterns, such as the species-specific motor patterns utilized in aggressive encounters. Indeed, Barnett et al. (1993) suggested that the reduced aggression observed in gestating gilts housed in narrow pens was due to insufficient space to fight using aggressive motor patterns such as parallel pressing. These adverse effects of space are generally a consequence of either stress or aggression and, in turn, injury and stress limiting growth in suboptimal social environments. Such effects also have obvious welfare implications. Since space requirements change with an animal's size, the following allometric expression has proven to be useful in estimating space allowance to maximize growth over a wide range of liveweights (Gonyou 2001): space allowance is calculated when the constant 0.035 is multiplied by body weight$^{0.667}$, with space allowance expressed as square meters and liveweight in kilograms.

Several studies have also examined the effects of space allowance on breeding female pigs (see Barnett et al. 2001). There is evidence of a chronic stress response and reduced reproductive performance if space allowance is insufficient. For example, elevated basal cortisol concentrations have been reported in breeding gilts in groups of six with a floor space allowance of 1 m^2/pig or less (Hemsworth et al. 1986a; Barnett et al. 1992). While the former study indicated that there may be reproductive performance advantages of housing at 3 m^2/pig rather than 2 m^2/pig, the physiological criteria indicated no differences between these space allocations. Weng et al. (1998) reported increased aggression and injuries in sows with decreasing space allowance and recommended a space allowance between 2.4 and 3.6 m^2/sow for groups of six pregnant sows.

While some research has indicated that increasing group sizes up to 80 will increase aggression and reduce growth in growing pigs (e.g., Petherick and Blackshaw 1987; Spoolder et al. 1999), other research has suggested no effect at least on growth if pigs are given ample space and the opportunity for ad libitum feed (e.g., Kornegay and Notter 1984; McConnell et al. 1987). Morrison et al. (2003) observed that growing pigs in groups of 200 on deep litter had a higher incidence of agonistic interactions per pig than pigs in groups of 20 on partially slatted concrete floors.

Mixing small groups of pigs results in vigorous fighting within the first 24 h, and by 48 h the dominance hierarchy can generally be identified (Meese and Ewbank 1973). Although olfactory, auditory, and visual cues have been suggested as important cues in individual pig recognition, it is still uncertain how the mechanism of individual animal recognition operates in pigs (Fraser and Broom 1997). Conventional thinking has been that small groups form stable social hierarchies and that as group size increases and individual animal recognition declines, aggression will increase. This has led to the widespread view in the literature that if animals regularly encounter unfamiliar animals in large groups in confined areas, aggression will increase with adverse effects on production and welfare. For instance, it is commonly believed that the total number of group members that can be recognized or remembered by each individual is 20 to 30 in pigs (Fraser and Broom 1997).

In contrast, there is recent evidence in laying hens and broiler chickens (Pagel and Dawkins 1997; Estevez 1998; Nicol et al. 1999) that aggression may actually decline as group size substantially increases with either total pen space or space per animal remaining constant. It is possible that the greater resources in very large groups, such as total and free space and availability of preferred lying areas, may reduce the need to form dominance hierarchies that function to control aggression in situations of limited resources. Pagel and Dawkins (1997) have also argued that if animals are able to adjust their behavior according to the size of the group, they may abandon all attempts to establish dominance hierarchies. Hughes et al. (1997) also suggested that animals might be more socially tolerant in large groups. While the effects of varying the size of small groups have been studied, neither maximal nor optimal group sizes have been identified for most livestock (Stricklin and Mench 1987).

There is some evidence that group size affects sow reproduction and welfare. Barnett et al. (1984, 1986) found that housing sexually mature gilts in pairs resulted in elevated basal cortisol concentrations compared to housing in groups of 4–8 with a similar space allowance. Both large group size (24 vs. 8 gilts) and small group size (3 vs. 9, 17, or 27 gilts) may reduce the expression of estrus (Christenson and Ford 1979; Christenson and Hruska 1984), while increasing group size and concomitantly decreasing space allowance may also reduce the expression of estrus in gilts (Cronin et al. 1983). Broom et al. (1995) compared sows in groups of 5 fed in stalls and a group of 38 sows with an electronic feeding station and while there was increased aggression in the larger group, particularly after initial mixing, any differences in aggression and stereotypies had disappeared by the fourth parity. Olsson et al. (1994) reported increased injuries as group size increased. Some limited research by Taylor et al. (1997) has shown varying group sizes, of 5, 10, 20, and 40 sows with a space allowance of 2.0 m^2/sow, had no effects on reproductive performance (farrowing rate and litter size). Although aggression immediately after mixing increased as group size increased, the number of lesions during gestation were similar across treatments. In the

same study, reducing space allowance for groups of 10 sows from 2.0 to 1.2 m^2/sow increased aggression. Further research is required to determine the optimum space allowance and group size for pregnant pigs. There are no data on space allowance and group size interactions for adult female pigs.

The design of the group pen will affect gilt and sow aggression. Petherick et al. (1987) have shown some advantages of partial stalls in reducing aggression around feeding in pens of group-housed pigs. However, whether the reduced aggression was due to individual feeding or the provision of escape areas was not determined. Barnett et al. (1992) subsequently demonstrated welfare advantages of partial stalls within group pens based on a reduction in aggression immediately after grouping unfamiliar pigs and in the longer term by feeding in the partial stalls. Feeding in the partial stalls also resulted in long-term benefits, based on lower free cortisol concentrations and a higher cell-mediated immunity. However, a subsequent study examining effects of pen design in reducing aggression in groups showed no benefits of partial stalls within pens either in the short term or subsequently (Barnett et al. 1993), although in that study the pigs were not fed in the stalls. Thus, it would appear that partial stalls may confer advantages in reducing aggression if the pigs are routinely fed in the partial stalls. Similar design modifications—that is, incorporating stalls into group pens—have also been reported (Edwards 1985). Pen shape has some effects on aggression (Barnett et al. 1993). Aggression was less in rectangular pens than square pens as a result of grouping unfamiliar pigs, provided the space allowance was 1.4.m^2/pig; the benefits were lost in larger pens providing 3.4 m^2/pig. However, Olsson et al. (1994) recommended against using long narrow pens with liquid feeding on the basis of competition and variable intakes.

Aggression among recently grouped unfamiliar gilts and sows has obvious welfare and reproductive disadvantages. In spite of the research to date on minimizing aggression when grouping unfamiliar pigs, there are few rigorous recommendations. In reviewing the literature, Barnett et al. (2001) suggested that aggression can be reduced in gilts by

1. Modifying pen size and shape on the basis that pigs require a minimum space in which to fight
2. Modifying pen design on the basis that the provision of escape areas reduces aggression
3. Preexposing pigs to their new pen
4. Grouping after dark, on the basis that it is the "normal" sleeping time, or providing feed ad libitum on the basis that restrictively fed pigs may prefer to feed than fight
5. Using masking odors on the basis that anosmic pigs show reduced aggression
6. Using "mood-altering" drugs on the basis of their positive effects in animal models

However, all or some of these methods may be effective in only postponing aggression rather than reducing it. There are few rigorous recommendations and this subject needs further research to allow industry to manage group housing of sows successfully, and thus minimize risks to welfare and reproduction. In particular, the effects of and interactions between factors such as space allowance, group size, pen shape, and features on pig welfare require thorough investigation.

As recognized by Barnett et al. (2001), both stall and group housing during gestation have advantages and disadvantages for the sow. A combination of these housing systems may optimize sow reproduction and welfare. For example, group housing of sows at mating and during mid-late pregnancy when social contact (Barnett and Hemsworth 1991) and space and exercise (Barnett et al. 2001), respectively, may be important, and individual housing of sows early in pregnancy when the control of nutrition may affect embryo mortality and aggression may affect conception (Barnett et al. 2001). There may also be opportunities to improve the design of these systems, such as "turning around" stalls for periods of individual housing (Barnett and Taylor 1995) and providing feeding stalls during the period of group housing (Barnett et al. 1992).

FEAR OF HUMANS

Stockperson interactions with livestock have been shown in a number of livestock industries to influence the welfare and productivity of farm animals (see Hemsworth and Coleman 1998). While many of these human interactions may appear mild and harmless, research in many livestock industries has shown that the frequent use of some routine behaviors by stockpeople can surprisingly result in farm animals becoming highly fearful of humans. Labor savings that have occurred through facility design and automation have generally reduced the human contact that pigs receive in modern production units. Consequently, opportunities for positive human contact are probably reduced and this, together with the fact that many routine husbandry tasks undertaken by stockpeople often contain aversive elements, may lead to the stockperson's interactions being biased toward negative ones.

Studies in the swine industry have shown, first, substantial variation between farms in the animals' fear of humans and, second, significant sequential relationships between the stockperson's attitudes and behavior toward their animals and the fear of humans and productivity of pigs farm animals (Coleman et al. 1998; Hemsworth et al. 1981; Hemsworth et al. 1989b). For example, negative attitudes to handling, such as beliefs that considerable verbal and physical effort is required to move pigs and that pigs do not require petting and stroking, were correlated or associated with a high percentage of negative behaviors used by stockpeople in

handling pigs. Negative tactile behaviors by stockpeople that were recorded included forceful hits and slaps as well as audible slaps and pushes while positive tactile behaviors included pats, strokes, and the hand of the stockperson resting on the back of the animal. Furthermore, a high percentage of negative behaviors used by stockpeople correlated with high fear levels in pigs. Surprisingly, high levels of fear of humans were best predicted at the farm when the classification of negative behaviors included not only forceful hits and slaps, but also negative behaviors used with less force, such as moderate slaps and pushes. This highlights the sensitivity of pigs to moderate negative interactions by humans, something that is not intuitively obvious to most of us.

Laboratory studies indicate that the likely mechanism responsible for the adverse effects of high fear on the productivity of pigs is a chronic stress response. Handling treatments that result in high fear levels, similar to those often seen in the swine industry, have been consistently shown to stress pigs as evidenced by a sustained elevation in the stress hormone cortisol (see Hemsworth and Coleman 1998). These stress effects of negative handling also accompany depressions in growth and reproductive performance (see Hemsworth and Coleman 1998).

Studies in the swine industry have shown that it is possible to improve the attitudinal and behavioral profiles of stockpeople and, in turn, reduce the level of fear and improve the productivity and welfare of commercial pigs (Hemsworth et al. 1994, Coleman et al. 2000). This approach in which cognitive-behavioral training is used to improve the attitudes and behavior of stockpeople has been described in detail by Hemsworth and Coleman (1998), but basically this type of training involves retraining people in terms of their behavior by, first, targeting both the attitudes that underlie the behavior and the behavior in question and, second, maintaining these changed attitudes and behavior. This process of inducing behavioral change is really a comprehensive procedure in which all the personal and external factors that are relevant to the behavioral situation are explicitly targeted. Clearly there is a strong case for introducing this training in the swine industry. A commercial multimedia training program called "ProHand," which targets the attitudes and behavior of the swine stockperson, is available and is currently used in Australia, New Zealand, and the U.S. (see website www.animal-welfare.org.au for details). A similar training program is also available for swine stockpeople at abattoirs.

Recent research has also shown the potential value of selecting stockpeople using screening aids to predict the performance of stockpeople. The results of research by Coleman et al. (2000) and Coleman (2001) have shown that a number of job-related characteristics, such as empathy and attitudes toward animals and toward aspects of work, may be useful in identifying inexperienced people who are likely to be good stockpeople. Therefore such tests could be assembled into a kit for use in selection in the swine industry. In addition to assisting in selecting stockpeople, assessing the key job-related characteristics of stockpeople may also provide the swine industry with a good opportunity to monitor the potential impact of individual stockpeople on animal welfare. Screening aids such as attitude and job motivation questionnaires may identify both weakness in individual stockpeople and specific training needs for these individuals.

There is a clear need to reduce the limitations that human-animal interactions impose on the productivity and welfare of commercial pigs. Appropriate strategies to recruit and train stockpeople in the swine industry will be integral in safeguarding the productivity and welfare of commercial pigs.

A crude assessment of differences in the level of fear of humans by pigs between units or farms can be made by observing in a standard manner the behavior of pigs in the presence of humans. For example, for units that house sows in gestation stalls, observation of the avoidance responses of sows to a human approaching in a standard manner and placing his or her hand in the front of the stall may provide consultants or managers with a useful technique to assess the relative fear levels across a number of units.

TAIL BITING

Although the incidence of tail biting appears to be highly variable, the problem is widespread with its incidence probably increasing with intensification of pig production (Smith and Penny 1986). The incidence of tail biting is generally lower in outdoor and straw-based housing systems (Schroder-Petersen and Simonsen 2001). The pathology of tail biting has been described by Smith and Penny (1986), and van Putten (1969) lists the possible consequences of tail biting as restlessness, poor growth, possible paralysis and mortality due to infections, and condemnation of the carcass. There have been few experimental studies conducted on tail biting because it is difficult to reliably induce, and consequently its cause(s) is poorly understood.

Outbreaks of tail biting have been attributed to numerous factors, including crowding, poor ventilation, interruption in feed or water supply, poor quality diets, absence of straw and breed type (Smith and Penny 1986; van Putten 1969, Fraser 1987a). The underlying causation of tail biting is poorly understood, but van Putten (1969) argues that an outbreak of tail biting originates from the chewing and rooting of penmates that generally occur with groups of pigs. These low-intensity behaviors are probably a result of the pig's natural tendency to root and chew on objects in its environment, but the behaviors are directed toward other pigs at least partly because of a lack of more suitable objects in a

commercial pig pen (van Putten 1969). Tail biting and aggression may occur when pen space is restricted (Jensen 1971; Bryant and Ewbank 1972; Randolph et al. 1981) and Beattie et al. (1996, 2000) showed that enriching the environment with the provision of straw reduced tail biting and persistent nosing of penmates, while increasing exploratory behaviors.

Since the tail is easy to chew and the chewing may not initially provoke an attack by the recipient because the distal half of the tail is relatively insensitive, it is the tail that is most likely to receive a wound. According to van Putten (1969), it is the vigorous tail waving, due to the irritation of a wound, that attracts further biting by other penmates as well as by the original biter. Fraser (1987b) has proposed that an attraction to blood from the wound may also lead to an escalation of tail biting. The large idiosyncratic differences between pigs in the degree of attraction to blood (Fraser 1987a, b) could explain the variable incidence of tail biting.

Removal of the distal half of the tail is a common industry practice: the remaining section of the tail is sufficiently sensitive to chewing to cause the recipient pig to respond (Fraser and Broom 1997). While clipping of the tail may reduce the incidence of tail biting, it may only mask the underlying problem. Attention to ventilation, temperature control, space allowances, feed trough space and drinking facilities may reduce the frequency of low-intensity chewing of penmates (Fraser 1987b; Fraser and Broom 1997), and the provision of distractions such as straw or other chewable objects may be beneficial (van Putten 1969). Injured animals obviously should be removed from the pen and the biter(s) should be identified if possible and housed separately from the group to avoid further occurrences of biting.

EAR AND FLANK BITING

As with tail biting, the cause(s) of outbreaks of these behaviors is poorly understood. However, the origins of outbreaks of ear and flank biting may be similar to those of outbreaks of tail biting: chewing and rooting penmates in an impoverished environment and reduced space may lead to a wound on the ear or a lesion on the flank, which in turn stimulates an outbreak of more biting by penmates. The pathology of ear and flank biting has been described by Smith and Penny (1986).

Treatment and control should be similar to that suggested for tail biting.

BELLY-NOSING

The nosing of the belly or the region between the hind legs of other pigs by weaned piglets, often in flat-deck cages, has been reported by a number of authors (see Fraser and Broom 1997). Belly-nosing for long periods may lead to inflammation of the nipples, umbilicus, penis or scrotum of the recipient.

Since access to straw has been shown to reduce its incidence (Beattie et al. (1996, 2000), the provision of straw or other chewable materials may reduce the incidence of belly-nosing in piglets. Early weaning is implicated in the incidence of belly-nosing (Fraser 1978; Gonyou et al. 1998).

PEN FOULING

The excretory behavior of penned pigs indicates that they have highly localized excretory habits (Baxter 1984), and although many pens are designed with specific excreting areas such as partly slatted areas or dung passages, this does not guarantee the use of these areas by pigs for excretion (Baxter 1989). Only limited research has been conducted on the excretory behavior of pigs; however, Petherick (1983) and Baxter (1984, 1989) have suggested that the main factors affecting the excretory behavior of pigs are security and the thermal environment.

Although objective data are limited, Baxter (1989) proposed a set of rules that can be utilized when designing a pig pen; those rules relating to excretory behavior can be considered when addressing a problem of pen fouling:

1. Pigs will choose a dry, warm, draft-free area in which to rest.
2. Pigs will not choose to rest in areas subject to commotion and disturbance such as around *ad libitum* feeders, drinkers, and grooming points.
3. Pigs will rarely excrete in the area chosen for resting, but they will excrete in any space that is left after the resting area has been established.
4. Pigs may choose to lie in wet, excretory areas if environmental temperatures are high enough to raise their body temperatures to their upper critical level.
5. Pigs will tend to defecate next to walls or corners of the excretory space where they have some protection when they adopt the somewhat unstable posture during excretion. Subordinates may be displaced from an overcrowded excretory area and may then excrete anywhere; this may give rise to a new focus for excretion.
6. A minimum of two drinkers should be provided in every pen, since competition for the drinker (as with feeders) may cause commotion, which in turn may encourage pigs to excrete away from the disturbance.

STEREOTYPIES

Stereotypic behavior can be defined as those behaviors that consist of morphological invariant movements that are regularly repeated, have no obvious function, or are unusual in the context of their performance (Cronin et al. 1986). Examples of these behaviors are bar biting, sham chewing, head weaving, chain chewing or rooting, and excessive drinking (Cronin and Wiepkema 1984).

Numerous authors have proposed explanations for stereotypies in pigs, and these proposed causes range from frustration of feeding to lack of environmental stimulation (Barnett and Hemsworth 1990). Stereotypies shown by pregnant sows in a range of housing systems have been studied by Vieuille-Thomas et al. (1995). The proportion of sows developing stereotypies did not differ between stall-housed and tethered sows (90 vs. 94%) but was lower in group-housed than stall-housed sows (66 vs. 93%). Stereotypies shown by tethered sows mainly involved actions directed against the physical environment, such as licking and rubbing, whereas group-housed and stall-housed sows mainly displayed biting and vacuum oral (self-directed) activities (e.g., vacuum chewing, sucking, and yawning/mouth stretching).

While the cause(s) of the stereotypies is unclear, the function is even less clear and indeed controversial. Some authors have proposed that the occurrence of stereotypies is indicative of poor welfare: it has been suggested that the welfare of the animal is at risk if the stereotypies occur for 10% of the animal's waking life (Broom 1983) and if they occur in more than 5% of all animals (Wiepkema 1983). In contrast, there is limited evidence that some stereotypies may be adaptive for the animal. For example, evidence of either associations between changes in stress physiology, indicative of reduced stress, and stereotypic behavior or that the prevention of stereotypies leads to changes in stress physiology, indicative of increased stress, suggests the adaptive value of these behaviors (Cooper and Nicole 1991). Furthermore, Loijens et al. (1999) reported a negative association between the intensity of stereotypy performance and the density of naloxone binding sites (evidence of opiate receptors) in the hippocampus of tether housed sows. This finding, together with the subsequent finding that individual differences in the density of opioid receptors in the hypothalamus and the hippocampus in sows were related to behavioral and heart rate responses of the pigs in stressful situations (Loijens et al. 2002), adds to the speculation that different individuals may have different coping strategies, and stereotypic behavior may be thus adaptive for some animals in stressful situations. While the latter findings support an association between stereotypies and endogenous opioid activity (e.g., Cronin et al. 1986; Kennes et al. 1988; Zanella et al. 1996), other authors do not support this coping hypothesis (see Dantzer 1991; Rushen 1993). Furthermore, not all stereotypies are a response to stress since Mason (1991) has shown that different forms of stereotypies may have different causes. As concluded by Rushen (1993), the adaptive value of many oral stereotypies may relate to their effects on digestive processes rather than in response to stress.

Therefore, with our present knowledge of the cause and function of stereotypies, there are substantial difficulties in interpreting the implications of stereotypies for the welfare and productivity of pigs, except for those stereotypies that result in physical damage—e.g., the development of lesions in stall-housed sows that persistently rub their tail roots from side to side against stall fittings (Ewbank 1978).

MATERNAL BEHAVIOR

A significant proportion of live-born piglets do not survive the lactation period and a number of factors, such as the physical and climatic environments, health, and nutrition appear to be responsible (see Chapter 62). While savaging and overlying of piglets by sows may account for up to a third of preweaning losses (Cutler et al. 1989), the contribution of changes in maternal behavior of sows to preweaning mortality has received surprisingly little research attention.

Savaging of piglets is more common in primiparous sows (Harris and Gonyou 2003) and the savaging attempt is often directed to only the first-born piglet (English et al. 1984; Spicer et al. 1985). Anecdotal observations suggest that the presence of multiparous (experienced) sows in the farrowing room in the vicinity of nulliparous sows helps calm the inexperienced sows and may contribute to a lower likelihood of savaging. Sows that savage their litters, however, are more likely to be those mated at low body weights (Spicer et al. 1985). Although the cause(s) of savaging is unknown, Pomeroy (1960) suggested that pain and fear predisposed gilts to savage their piglets, while Luescher et al. (1989) suggested that additional factors may be involved, such as the inability of sows to isolate themselves and perform nest-building activities, climatic stress, and human interference during parturition. Some nulliparous sows savage the entire litter. While savaging was responsible for increased mortality in piglets born outside the working hours of the piggery staff (Spicer et al. 1986), this could be reduced if farrowing rooms were continuously lit (Harris and Gonyou 2003). In cases in which the stockperson is on hand when savaging occurs, massage of the sow's udder by the stockperson, an injection of a suitable tranquillizer (e.g., Azaperone) (English et al. 1984) followed by separation of piglets from the sow until farrowing is complete is usually all that is needed to settle the sow.

While malnutrition or illness of piglets may be implicated in many cases of overlying (English et al. 1984), many overlain piglets show no evidence of preexisting illness (Spicer et al. 1985). If a high incidence of overlying is suspected, consideration should be given to the recommendations made by Cutler et al. (Chapter 62) for the provision of a suitable thermal environment for the sow and litter.

The possibility that piglet mortality may be affected by disturbances to the maternal behavior of sows has been demonstrated in an increasing number of studies. Cronin and van Amerongen (1991) found that the pro-

vision of straw to and a hessian cover over the farrowing crates of primiparous sows, in order to simulate a completed farrowing nest, reduced preweaning mortality. It is also of interest that the sows in this treatment were more responsive to distress vocalizations of their piglets. Similarly, Cronin et al. (1993) found the addition of small amounts of sawdust to the farrowing crates of young sows (parity 1–3) reduced both the incidence of intrapartum deaths (litter size alive of 10.5 vs. 10.0) and overlying during and 6 hours after parturition (2% vs. 21% of sows). The authors proposed that the provision of sawdust stimulated prepartum activity in younger sows which may have promoted the process of parturition and the development of maternal behavior. While Thodberg et al. (2002) reported that sows appeared calmer before parturition in farrowing pens in which prepartum "nesting" behavior was stimulated, Cronin et al. (1998) found that small, narrow farrowing pens appeared to interfere with the sows' prefarrowing nesting behavior, with consequent increases in sow restlessness during and after farrowing and piglet mortality. These limited results indicate that it may be possible to improve maternal behavior in order to reduce preweaning mortality by modifying the physical environment at parturition, and clearly further research is warranted on maternal behavior.

LOW LEVELS OF SEXUAL BEHAVIOR IN THE BOAR

While there is little documented evidence on poor sexual behavior in commercial boars, experience from artificial insemination centers and commercial piggeries indicate that up to 49% of culled boars are unable to copulate or copulate at sufficient frequency (Melrose 1966). This situation may not have changed much today. Low levels of sexual behavior result from either low sexual motivation or poor mating competency. The latter, if not too serious, may be overcome in some situations where matings are supervised and assisted by stockpeople. Poor mating competency leading to reduced mating success may lead in turn to poor sexual motivation.

Poor Mating Competency

Locomotor and penile injuries may not physically allow the achievement of copulation or may inhibit copulation because of pain (Christensen 1953), while injury sustained during copulation may produce a psychological effect for some time after physical recovery has occurred, again inhibiting copulation. Prevention of locomotor and penile injuries should include attention to the design and maintenance of the accommodation and mating areas, appropriate supervision and assistance at mating or semen collection, and selection for heritable conformational traits of the feet and legs. (See Physical Environment at Mating for a discussion on a suitable

arena for mating.) Poor orientation of the mounting response, such as head mounting, is often seen in the young boar. However, proper orientation is probably a learned response, and if the boar is of satisfactory sexual motivation, mating competency should improve with the positive reinforcement of copulation.

Social Environment

Research has shown that the social environment around the time of puberty can have long-term effects on the sexual behavior of the boar. Isolation of young postpubertal boars from 6–9 months of age from female pigs has been shown to depress their subsequent sexual behavior in a series of mating tests (Hemsworth et al. 1983). This has clear implications for boars used in natural mating but may also have implications for boars used for semen collection, although sexual motivation above a low level may be less critical because of the moderate collection frequency generally required. Housing young postpubertal boars within several meters of females should provide them with sufficient female contact to promote their subsequent sexual behavior. The effects on the sexual behavior of boars of housing near mature boars or near a semen collection area in which olfactory, visual, and auditory stimulation are provided are unknown. However, the interest in using exogenous hormones such as PGF2α to expedite the training of young sexually inexperienced boars for semen collection suggests the need to improve our understanding in this area (Kozink et al. 2002).

Isolation of mature boars from female pigs will also depress their sexual behavior (Hemsworth et al. 1977); however, this effect is not permanent, and housing these isolated boars near females will restore their sexual behavior within 4 weeks. The estrous status of the females does not influence the effectiveness of females in stimulating the sexual behavior of mature boars (Hemsworth 1982). It appears that olfactory and perhaps auditory stimuli from the female are most likely involved in stimulating the sexual behavior of mature boars in natural mating situations (Hemsworth 1982).

As with the social environment around puberty, the social environment during rearing also appears to exert a long-term and perhaps even permanent effect on the sexual behavior of boars. Young boars up to 30 weeks of age require social contact, particularly tactile contact with other pigs, in order to develop high levels of sexual behavior (Hemsworth 1982). Failure to provide young boars with this contact will depress their subsequent sexual behavior. It is recommended that prepubertal boars that may eventually be selected for breeding should be kept in groups for as long as practical, so that sexual behavior develops normally. Young boars kept in groups also display a fully coordinated mating response at an earlier age than boars reared individually (Thomas et al. 1979). If it is necessary to measure individual feed intake, separate feeding stalls could be provided in the

group pens. Alternatively, since limited tactile contact with neighboring pigs through wire-mesh walls is sufficient for boars to develop normal levels of sexual behavior (Hemsworth 1982), young boars can be reared in individual pens with wire-mesh or barred divisions.

Physical Environment at Mating

The implications of the physical environment at mating for the reproductive performance of the pig are often neglected. A common practice in intensive units is to mate pigs in the boar's accommodation pen, even though the physical conditions for mating may be far from ideal. For example, the pens are often small and the floors may be slippery, yet research has demonstrated the importance of physical conditions at mating on the sexual behavior of the boar. Hemsworth et al. (1989a) found that the percentage of mating tests that resulted in copulations was lower for pigs mating in the boar's accommodation pen than for those mating in a specific mating pen that had a large, dry, nonslip floor. The sexual behavior of the gilts in the two treatments was similar, but there was a consistent trend between treatments to differ in average time taken by the boars to mount suggesting that the low mating rate of pigs in the boar pen may have been mediated through an effect on the sexual behavior of the boar rather than that of the gilt. The authors concluded that the sexual motivation of the boars may have been adversely affected by the poor physical conditions at the time of mating when matings occurred in the boars' accommodation pens. This study highlights the importance of mating conditions for boars used for both natural matings and semen collection. It is recommended that natural matings should be conducted in separate, specially designed pens with a large floor area (minimum dimension of 2.5 m) to provide the boar with good access to the female's rear quarters; a nonslip floor surface, not abrasive to the animal's feet, that should be kept dry; and an area free of obstructions or other features, such as damaged or wire-mesh walls, that may trap the leg of an unbalanced boar. Similar principles should apply to the area for semen collection.

To minimize moving the pigs, it is useful to have an area adjacent to the boar pens that can be used for both estrus detection and mating. A group of females can be briefly held in this area while the back-pressure test (or riding test, see later) is conducted, and those in estrus can be separated and mated in this pen. Research indicates that gilts detected and mated in such an area have larger litters than those mated in the boar's accommodation pen (Hemsworth et al. 1991). If there is insufficient space available to build a mating pen, a number of these features of a mating pen can be incorporated into the boar pens. For example, pen floors should be properly maintained and a light application of sawdust or straw prior to mating may overcome a slippery floor.

In "hand-mating" systems, the stockperson has a

critical role in providing supervision and assistance at mating and in fact may be able to overcome the limitations of some mating systems. Stockpeople have an important role at the time of estrus detection and mating, particularly in terms of avoiding stress and injury to the sexually unreceptive female from a vigorously courting boar, providing the boar with good access to the rear quarters of the receptive female, assisting intromission to maximize the chances of mating, steadying the partners when there is a problem with their footing (e.g., slippery floor, slatted floor, etc.), and identifying those matings with a short duration of ejaculation (i.e., those where a repeat copulation should be attempted if the female is still sexually receptive).

An example of poor supervision that may compromise reproductive performance is found in observations on supervised matings in a large intensive piggery in Australia (Hemsworth, unpublished data). These observations found that one-third of the copulations by gilts and sows had mean durations of ejaculation of 2.5 and 3.2 minutes, respectively, and repeat copulations immediately following these copulations were not attempted. The number of sperm ejaculated during short copulations such as these may be insufficient to consistently achieve high fertility (Thiengtham 1991) and thus proper supervision in these cases may have enabled identification of most of these short copulations to allow a repeat copulation if the female was still receptive. Grigoriadis et al. (2000) has shown the importance of the quality of matings on the fertility of gilts in a dynamic group mating system.

Genetic and Climatic Factors

Evidence from other species (e.g., domestic fowl, McCollom et al. 1971), together with breed comparisons of boars (Einarsson 1968), suggests that the sexual behavior of the boar may have a heritable basis. Elevated environmental temperatures may reduce the sexual behavior of the boar, but this effect is generally only temporary (Winfield et al. 1981), and conducting matings during the cooler times of the day (e.g., early morning) should avoid this problem. Insulation, adequate ventilation, and sprinkler cooling in the mating shed should minimize the adverse effects of high external temperatures.

LOW LEVELS OF SEXUAL BEHAVIOR IN THE FEMALE PIG

Low levels of sexual behavior in female pigs will result in problems with estrus detection and sexual receptivity. It is generally recognized by pig producers that there is more difficulty in mating gilts than in mating sows (English et al. 1982), and thus this section concentrates on gilts; however, most of the principles considered apply to the sow. The literature indicates that in addition to delayed puberty, poor detection of estrus con-

tributes to mating difficulties in commercial gilts (Hemsworth 1982). The incidence and consequences of poor sexual receptivity in those gilts detected in estrus are unknown, although this condition does occur (Cronin et al. 1982). Nevertheless, problems with sexual receptivity and detection of estrus should be considered together, since receptivity or the standing response is generally the criterion used in the main procedures for detecting estrus (e.g., use of boars or the back-pressure test).

Boar Contact

The most common procedure for detecting estrus other than the use of boars is the back-pressure test (BPT) or riding test (Signoret 1970). Females reacting to pressure on their back by displaying the "standing" or lordosis response for at least 10 seconds are generally classified as being sexually receptive (Hemsworth et al. 1988). The efficiency of this procedure depends on the female receiving intense boar contact at the time of testing. Signoret (1970) reported that the maximum percentage of gilts displaying the standing response to the BPT in the absence of boars was 59% between 24 and 36 hours after the start of estrus. This percentage increased to 90% by providing the gilts with auditory and olfactory contact with boars and further increased to 100% with the addition of visual and tactile contact with boars. Similarly, Hemsworth et al. (1984) demonstrated the importance of intense contact with the boar at the time of conducting the BPT. Testing gilts at a distance of 1 m or more from the boar, which presumably reduced the amount of boar contact, reduced the efficiency of the test (52% of postpubertal gilts detected in estrus compared to 90% when gilts were tested adjacent to boars). Therefore, intense boar contact at the time of testing is vital in achieving a high efficiency with the BPT. Reducing boar contact at the time of detection will reduce sexual receptivity in estrous females. Langendijk et al. (2003) have shown the importance of boars in eliciting sexual receptivity, oxytocin release, and, in turn, uterine activity in estrous sows, and thus the stimulation from boars may be critical in situations that are suboptimal for fertilization, such as during seasonal infertility (Pena et al. 1998).

While it appears that boar contact has an important role in stimulating the female's sexual behavior, there are situations where continuous stimulation from the boar may adversely affect sexual behavior. Research (Hemsworth et al. 1984, 1986a, 1988) has shown that housing postpubertal gilts adjacent to boars, with a wire-mesh wall separating them, generally results in a low estrus detection rate with the BPT (e.g., 53% vs. 93% for gilts housed near but not adjacent to boars, Hemsworth et al. 1988). It has been proposed that habituation by gilts to the important boar stimuli (e.g., auditory and olfactory stimuli), which facilitate the standing response of the estrous female to pressure on her back (Signoret 1970), is responsible for this detection problem (Hemsworth et al. 1988). Housing gilts adjacent to boars, which is not uncommon in the industry, may also produce problems in detecting estrus when boars are used for detection (Hemsworth et al. 1987). The results of these studies indicate that housing postpubertal gilts adjacent to boars, with a wire-mesh or barred wall separating them, may adversely affect the sexual behavior of the gilts to the extent that there are difficulties in detecting estrus. Housing weaned sows adjacent to boars does not adversely affect the detection of estrus, possibly because there is insufficient time for habituation to the boar stimuli to occur before the onset of estrus (Hemsworth and Hansen 1990).

Another behavioral problem that may arise through excessive boar stimulation is prolonged boar stimulation at the time of detection. Observations on the sexual receptivity of estrous gilts exposed for an extended period to boars during estrus detection with the BPT indicate that many estrous females may become temporarily refractory to this stimulation, resulting in failure to display the standing response. Levis and Hemsworth, (unpublished data), in studying the behavioral responses of estrous gilts to repeated testing about every 5 minutes, found that the percentage of females standing for the BPT declined from 100% when initially tested to 65% when tested 21 minutes later. This reduction in the sexual receptivity of estrous gilts with frequent stimulation may be due to sexual refractiveness, similar to the sexual refractiveness that occurs in both males and females after copulation. This observation has implication for those situations where females may be tested with the BPT or a boar for estrus over an extended period, but mating or insemination is delayed. There is the possibility that repeated stimulation over an extended period at estrus detection may result in estrous females temporarily experiencing a decline in their sexual receptivity before they can be either detected in estrus or mated.

There is substantial variability in the industry in procedures that use a boar to detect estrous females and yet these procedures have received little research attention. Hughes et al. (1985) reported that 6- to 7-month-old boars provide female pigs with less sexual stimulation than older boars. They found that while only 38% of estrous gilts displayed an immediate standing response to the mounting attempts of young boars, the artificial provision of olfactory and auditory stimulation from older boars increased this percentage to 59%. When stockpeople rely on boars for estrus detection, it is therefore essential that the stockpeople adequately supervise the detection and promptly address any detection problems. Stockpeople need to be particularly vigilant when young boars are used, or when there is variation in the motivation of boars, distractions to the boar's courtship when testing occurs in an unfamiliar location for the boar, and insufficient time and opportunity for the boar to test each female when females are tested in groups. A

useful addition to procedures which directly rely on boars for estrus detection is for the stockperson to concurrently use the BPT.

Space Allowance and Group Size

As discussed earlier, there is limited evidence that space allowance and, to a lesser extent, group size of group-housed gilts may influence the efficiency of detecting estrus. Hemsworth et al. (1986b) examined the effects of housing groups of adult postpubertal gilts (6 pigs/group) with a space allowance of 1, 2, or 3 m^2/gilt on sexual behavior. A lower percentage of gilts was detected in estrus when housed with a space allowance of 1 m^2/gilt than with a space allowance of 2 or 3 m^2/gilt (88% vs. 100% and 100%). A significant sustained increase in plasma-free-corticosteroid concentrations in gilts housed with a space allowance of 1 m^2/gilt suggests that a chronic stress response may have reduced sexual receptivity. Clearly more comprehensive research is required, but in the meantime it is suggested that postpubertal gilts and weaned sows around the time of mating should be provided with at least 2 m^2/animal.

Several studies have examined the effects of group size, however the effects of group size on the sexual behavior of female pigs appear equivocal, perhaps because of suboptimal space allowances in these studies (Hemsworth and Barnett 1990). There are the suggestions from these results that there may be problems in detecting estrus in small groups (groups of 3, Christenson 1984), large groups (groups of 24, Christenson and Ford 1979), and groups of 50 or more (Cronin et al. 1983). The interaction between group size and space allowance must be examined to clarify the optimal social and spatial conditions for group-housed gilts.

Subordinate pair-housed sows show lower levels of sexual receptivity to boars than dominant pair-housed sows or individually housed sows (Pedersen et al. 2003). Although the number of animals studied was low, there were no adverse effects reported on the reproductive performance of these subordinate animals housed in groups. Nevertheless these results further highlight the need for vigilance by stockpeople in detecting estrus in situations in which social effects may impact on the sexual behavior of gilts and sows.

Climatic Environment

Several studies have reported seasonal variation in the rate of detecting estrus in gilts. Christenson (1981) observed that a higher proportion of ovulating gilts were undetected in late summer than in the remainder of the year (16.7 and 8.4%, respectively). Cronin et al. (1983) reported that in the spring there was a lower percentage of unmated postpubertal gilts at 35 weeks of age that had not been detected in estrus than at other times of the year (3.2 and 6.5%, respectively). The effects of photoperiod and temperature are confounded in these two studies.

There is some limited evidence that indicates that increased environmental temperatures may affect sexual behavior of gilts. In two of three trials, Warnick et al. (1965) reported that a total of 3 out of 13 gilts (23.1%) were not detected in estrus at an ambient temperature of 32°C although all had ovulated. In only one of a series of experiments reported by Godfrey et al. (1983), increased temperatures (38°C for 10 hours and 32° for 14 hours) reduced the percentage of gilts detected in estrus (21 vs. 4% for control); however, it was not determined whether ovulatory activity or detection of estrus was affected. Several studies reported that the duration of detected estrus was reduced by high temperatures (see review by Paterson and Pett 1987).

52 Coccidia and Other Protozoa

David S. Lindsay and J. P. Dubey

Coccidia (*Isospora suis* and *Eimeria* spp.)

Coccidia are obligatory intracellular protozoan parasites. *Eimeria*, *Isospora*, *Cryptosporidium*, *Toxoplasma*, and *Sarcocystis* are important genera of protozoal parasites of mammals and birds. Domestic animals may be infected with several species of coccidia but usually only a few species are pathogenic for a given host.

ETIOLOGY

The number of valid species of intestinal coccidia that infect swine is unknown because most are known only from the sporulated oocyst stage. Levine and Ivens (1986) list 13 named species of *Eimeria* and 3 species of *Isospora* from swine. *Isospora suis*, *I. almataensis*, and *I. neyrai* are the species of *Isospora* described from swine. *Isospora almataensis* and *I. neyrai* are known only from oocysts in the feces and have not been observed in the United States; they probably are not valid species. Neonatal coccidiosis caused by *I. suis* is the most important protozoal disease of swine. Although the causative agent, *I. suis*, was described from pigs in 1934 (Biester and Murray 1934), it was not until the middle 1970s that clinical coccidiosis was recognized as a disease problem in nursing pigs (Sangster et al. 1976). In 1978, it was demonstrated that *I. suis* was the cause of piglet coccidiosis in natural cases, and coccidiosis was experimentally reproduced in nursing pigs (Stuart et al. 1978). Neonatal piglet coccidiosis has a cosmopolitan distribution and is found anywhere pigs are raised in confinement.

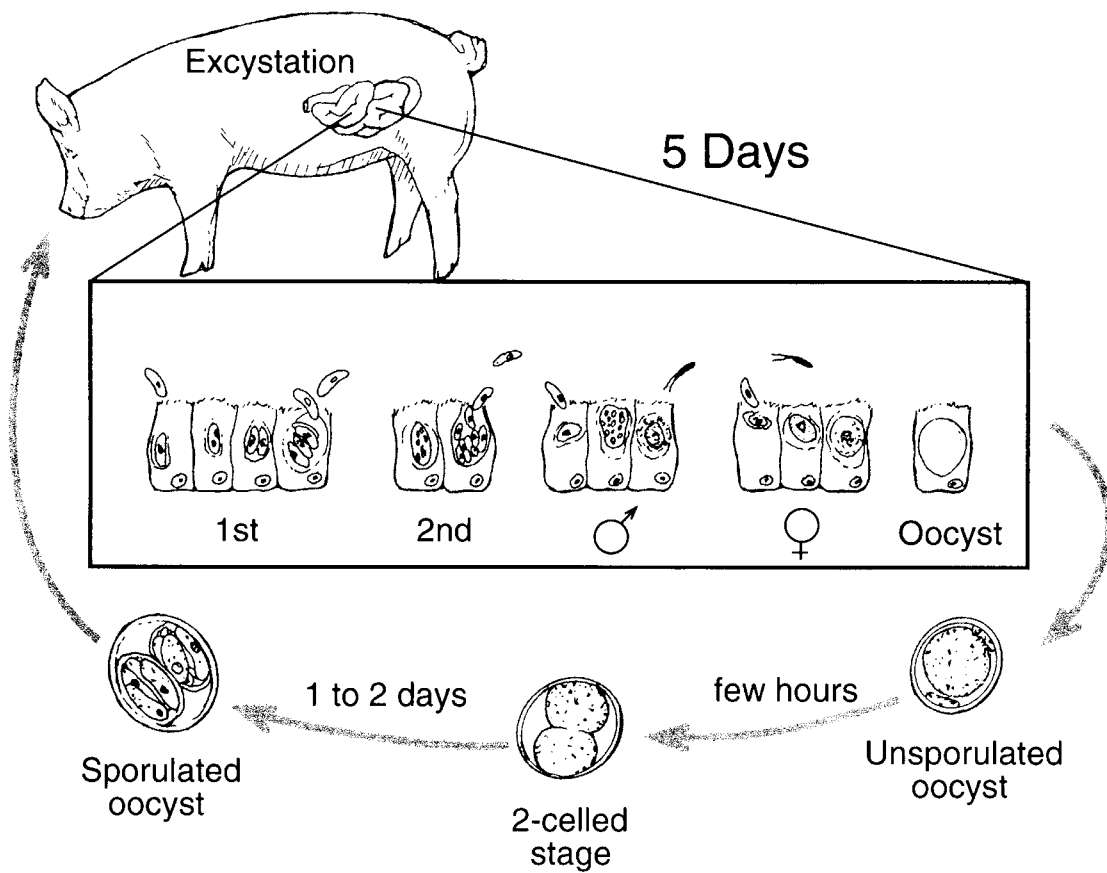
Life cycle of *I. suis*

Coccidial life cycles are divided into three phases: sporogony, excystation, and endogenous development (Figure 52.1). Each coccidial phase is unique for each species and knowledge of life cycle phases is important in diagnosis, treatment, prevention, and control of coccidiosis.

Sporogony is the process by which the oocyst (environmentally resistant stage) develops from the unsporulated noninfectious stage passed in the feces to the infective stage (Figure 52.2). Proper temperature and moisture must be present for sporulation to take place. The oocysts of *I. suis* sporulate rapidly at temperatures between 20°C and 37°C (Lindsay et al. 1982). The supplemental heat of between 32°C and 35°C provided by producers for newborn piglets favors rapid development (within 12 hours) of *I. suis* oocysts in the farrowing crate. Oocysts are most sensitive to killing when in the unsporulated state and during sporulation. Once the oocysts are sporulated, they are resistant to most disinfectants. When fully sporulated, the oocysts of *I. suis* and all other *Isospora* species contain two sporocysts, each with four sporozoites.

Excystation is the phase of the life cycle that occurs immediately after the infectious oocysts are ingested. Passage through the stomach alters the oocyst wall and allows bile salts and digestive enzymes to activate the sporozoites. The activated sporozoites leave the sporocyst and oocyst and are freed into the intestinal lumen. The sporozoites then penetrate enterocytes and begin the endogenous phase of parasite multiplication.

The endogenous stages of the life cycle of *I. suis* occur in cytoplasm of enterocytes throughout the small intestine, with most stages being present in the jejunum and ileum. Occasionally, in heavy infections, parasites can be found in the cecum and colon as well. Coccidial stages are usually located on the distal portions of the villi and are in a parasitophorous vacuole below the host-cell nucleus (Lindsay et al. 1980). In severe clinical or experimental cases, stages may also be located in crypt enterocytes.

There are two distinct types of asexual stages in the endogenous life cycle of *I. suis*. Sporozoites enter enterocytes and become binucleated type 1 meronts, which


52.1. *Life cycle of* Isospora suis.
52.2. *Oocysts of* Isospora suis *in fecal flotations. Bar = 10 μm. (A) Freshly excreted Unsporulated oocyst. Note the hazy bodies (arrows) and the sporont (SP). (B) Oocyst several hours after excretion. Note that 2 sporoblasts (SB) are present. (C) Sporulated oocyst approximately 1 day after excretion. Note the sporozoites (S) and residual body (arrow) in the sporocysts (Modified from Lindsay et al. 1982).*

divide by endodyogeny in about 24 hours; each meront produces two type 1 merozoites. The characteristic side-by-side appearance of these type 1 merozoites is useful in diagnosis because none of the swine *Eimeria* species divide by endodyogeny. Several divisional cycles by endodyogeny can occur and produce cells with many

type 1 merozoites. Type 2 meronts are multinucleated and form type 2 merozoites, which may be seen as early as 1 day postinoculation (PI). Type 2 merozoites are smaller than type 1 merozoites. Sexual stages consist of microgamonts, which produce biflagellated microgametes, and uninucleate macrogamonts. The microga-

metes fertilize the macrogamonts, and an oocyst is formed. These sexual stages also may be seen 4 days PI, whereas oocysts are first seen in the feces 5 days PI (rarely 4 days).

Immunity to *Isospora suis*

Pigs that have been infected with *I. suis* and recover are resistant to challenge infection (Stuart et al. 1982b). These challenged pigs excrete no or very few oocysts (in contrast to initial infection) and do not develop clinical signs. Administration of corticosteroids (methylprednisolone acetate) does not cause these previously exposed pigs to reexcrete oocysts, suggesting good immunity has developed. Colostral antibodies against *I. suis* do not protect piglets from developing clinical coccidiosis (Taylor 1984). Serum antibodies peak about 1 week after primary infection, and a secondary antibody response occurs following challenge infection. Serum antibodies against *I. suis* do not recognize sporozoites of *E. deblliecki, E. neodebliecki, E. scabra,* or *E. porci* from pigs in an indirect fluorescent antibody test.

Pigs have age-related differences in susceptibility to experimental infection and disease (Stuart et al. 1982a; Koudela and Kucerova 1999). Pigs that are 1–2 days old develop much more severe disease than do pigs inoculated with an identical number of oocysts at 2 or 4 weeks of age.

Clinical Signs

Signs of disease occur in formerly healthy nursing pigs between 7 and 11 days of age (Stuart et al. 1978). Yellowish to grayish diarrhea is the major clinical sign. The feces are initially loose or pasty and become more fluid as the infection progresses. Piglets become covered with the liquid feces, causing them to stay damp and have a rancid odor of sour milk. The piglets usually continue to nurse, develop a rough hair coat, become dehydrated, and have depressed weight gains (Lindsay et al. 1985). Litters within the farrowing house vary in the degree to which they demonstrate clinical signs, and not all piglets within a litter are equally affected. Morbidity is usually high but mortalities are usually moderate. Concurrent bacterial, viral, or other parasitic infections may lead to extreme mortalities and complicate diagnosis.

Occasionally *I. suis* oocysts are present in the feces of recently weaned pigs, some of which may have diarrhea. Although this indicates a patent infection, whether or not *I. suis* is the etiologic agent of the diarrhea is unknown because of complicating factors such as diet and other management changes that occur at weaning. There is a report that *I. suis* caused postweaning diarrhea in 5- to 6-week-old piglets (Nilsson 1988). Diarrhea began 4–7 days after the piglets were weaned. Morbidity was high (80–90%) but mortalities were rare. *I. suis* infections do not cause disease in finishing pigs or in breeding stock.

Pathologic Changes

Experimental studies have shown that the degree of disease is dependent on the number of sporulated *I. suis* oocysts that a piglet ingests (Stuart et al. 1980). Inoculation of 200,000 or more oocysts usually produces severe disease and moderate to extreme mortalities (Stuart et al. 1980; Lindsay et al. 1985). Inoculation of fewer oocysts generally produces clinical disease characterized principally by diarrhea but few or no mortalities.

Necropsy examination may demonstrate gross lesions of neonatal coccidiosis characterized by a fibrinonecrotic membrane in the jejunum and ileum, but this is seen only in severely infected piglets. Hemorrhage is not seen even in extreme cases of natural infections or in experimental infections where large numbers of oocysts are given.

Microscopic lesions consist of villous atrophy, villous fusion, crypt hyperplasia, and necrotic enteritis (Stuart et al. 1980). The usual tall columnar enterocytes at the tips of the villi may be destroyed, exposing the underlying lamina propria, or they may be replaced by flattened immature enterocytes. The functional ability for absorption is diminished in this altered epithelium, resulting in fluid loss and diarrhea. Immunohistochemical studies indicate that infection alters carbohydrate residues on the enterocystes (Choi et al. 2003). Lesions develop about 4 days PI and are associated with the presence of the asexual stages. In most natural cases few parasites are present in the sections and most of these parasites are asexual stages. In severe cases piglets may succumb to coccidiosis before the sexual stages are produced. The extent of microscopic lesions produced is dependent on the number of *I. suis* oocysts a pig ingests.

The role of viral and bacterial copathogens with *I. suis* has been examined experimentally (Baba and Gaffer 1985; Vitovec et al. 1991). The responses of gnotobiotic and conventional pigs to *I. suis* and rotavirus infection are similar (Vitovec et al. 1991). The degree of observed clinical disease is more severe when the two pathogens are administered concurrently than when either is given singly. Both the virus and the parasite prefer to develop in the enterocytes on the central and distal portion of the villi in the small intestine, and competition for a suitable host cell is believed to be the cause for the observed increase in clinical disease and microscopic lesions. An established *I. suis* infection will interfere with the establishment of a *Salmonella typhimurium* infection (Baba and Gaffer 1985). The increased gut motility and destruction of host cells probably interfere with the bacterium's ability to colonize the intestinal mucosa.

DIAGNOSIS

Diarrhea in nursing pigs 7–14 days of age that does not respond to antibiotic treatment is suggestive of neonatal *I. suis* infection. Other agents such as enteropatho-

genic *Escherichia coli,* transmissible gastroenteritis virus, rotavirus, *Clostridium perfringens* type C, and *Strongyloides ransomi* should be considered in the differential diagnosis.

Diagnosis of *I. suis* is best achieved by finding *I. suis* oocysts in the feces of clinically affected piglets (Figure 52.2A, B). This is the quickest method available for diagnosis. Fecal smears or fecal flotations should be made from several litters within the farrowing house that have been showing clinical signs for 2–3 days, because diarrhea starts about a day before oocysts are passed and peak oocyst production occurs about 2–3 days after clinical signs develop. Piglets excrete oocysts in several phases and may be negative during these phases. Pasty fecal samples are likely to contain more oocysts than are liquid samples. The oocysts of *I. suis* have characteristic structures called "hazy bodies" between the oocyst wall and the sporont (Figure 52.2A). These are diagnostic for *I. suis* because none of the oocysts of the swine *Eimeria* species have this structure (Lindsay et al. 1982). Additionally, some of the oocysts may be in the two-celled sporoblast stage (Figure 52.2B), which is also diagnostic for *I. suis*. Fecal fat may make identification of oocysts in Sheather's sugar flotation preparations difficult. A solution of saturated sodium chloride and glu-

cose (500 g of glucose in 1000 ml saturated sodium chloride solution) has been recommended as an alternative flotation medium (Henriksen and Christensen 1992).

Demonstration of developmental stages (Figure 52.3A–D) in mucosal smears can be used in the diagnosis of *I. suis* infection (Lindsay et al. 1983). The intestinal mucosa should be scraped with a scalpel or coverslip using just enough pressure to dislodge villi, and the scrapings should be prepared as a smear on a glass microscope slide. The smears are then stained with any of a number of routine blood stains.

The presence of paired type 1 merozoites (Figure 52.3D) is diagnostic. Other asexual stages (such as binucleated type 1 meronts or type 2 meronts and merozoites) and sexual stages (microgamonts and macrogamonts) will probably be present also, but their identification is more difficult and not needed for diagnosis.

Histologic diagnosis of *I. suis* in tissue sections is possible (Lindsay et al. 1983). As with mucosal smears, demonstration of paired type 1 merozoites is diagnostic (Figure 52.3E–H). The multinucleated type 2 meronts of *I. suis* are elongated and are often found in the same host cell. Finally, the macrogamonts of *I. suis* lack the characteristic eosinophilic wall-forming bodies seen in *Eimeria species.*
52.3. *Diagnostic stages of* Isospora suis *in Wright's Giemsa-stained intestinal smears (A–D: Bar = 5 μm) or hematoxylin- and eosin-stained histological sections (E–H: Bar = 10 μm). (A) Zoite with a single nucleus (n). (B) Type 1 meront, which has two nuclei (n). (C) Dividing type 1 meront. Note the nuclei (n). (D) Paired type 1 merozoites. Note that each has a single nucleus (n). (E) Zoite in a parasitophorous vacuole (arrow). (F) Type 1 meront. Note that two nuclei (arrows) are present. (G) Paired type I merozoites. (H) Host cell with a type 1 meront (arrows label nuclei) and a type 1 merozoite. (Modified from Lindsay et al. 1980.)*

PCR (Ruttkowski et al. 2001) and autofluorescence (Daugschies et al. 2001) of oocysts are other methods that can be used to diagnose *I. suis* infection. These methods are limited to use by diagnostic laboratories using specialized equipment.

EPIDEMIOLOGY

Eimeria Species

Eight species of *Eimeria* occur in swine in the United States (Vetterling 1965). Reports of coccidiosis in swine caused by *Eimeria* species are rare (Hill et al. 1985). Experimental studies have demonstrated that inoculation of 3-day-old nursing pigs with up to 5 million oocysts of *Eimeria debliecki* does not cause clinical disease and that inoculation of up to 10 million oocysts does not cause disease in 4-week-old weaned pigs (Lindsay et al. 1987). Similar results were obtained in 2- to 3-month-old pigs given 4 million oocysts of *E. debliecki* (Vitovec and Koudela 1990).

Eimeria spinosa is not pathogenic for pigs under experimental conditions (Koudela and Vitovec 1992). Reports of natural cases of *E. spinosa* associated disease in weaned pigs suggest that this species can cause disease under appropriate conditions in the field (Lindsay et al. 2002, Yaeger et al. 2003). Coccidia vary in their inherent abilities to cause disease, and it appears that the *Eimeria* species infecting swine are generally nonpathogenic.

Isospora suis

Once *I. suis* coccidiosis was recognized as a problem in nursing pigs, most veterinarians and researchers assumed that piglets were infected by ingesting *I. suis* oocysts from the sow's feces. However, studies have failed to confirm this assumption. Surveys of the swine population in the United States indicate that *Eimeria* infections are common (60–95%) in animals raised in lots or in the wild, but less than 3% of the animals sampled excrete oocysts of *I. suis* (Vetterling 1966; Lindsay et al. 1984). One study examined the species of oocysts excreted by sows on farms with and without a history of *I. suis* infections in nursing pigs; sows on all the farms underwent gestation on dirt lots (Lindsay et al. 1984). The study reported that 82% of the sows on farms with a history of coccidiosis had *Eimeria* infections but no detectable *I. suis* infections. The sows from farms with no history of neonatal coccidiosis had an infection rate of 95% with *Eimeria* species and less than 1% with *I. suis*.

In the United States, Stuart and Lindsay (1986) examined the transmission of *I. suis* on two farms in Georgia. Daily fecal samples were collected rectally from sows typically 1 week prior to farrowing, the day of farrowing, and for about 1 week after farrowing. Colostrum and placentas from several sows were examined microscopically for parasites. A coccidiostat (amprolium HC1, Amprol 25% feed grade) was given to half of the sows on each farm. *Eimeria* species were the only coccidia seen in the feces of sows. None of the sows given amprolium HC1 had oocysts in fecal samples at farrowing. No parasitic stages were seen in the colostrum or placentas examined. On Farm 1, 7 of 12 litters from nontreated sows and 9 of 12 litters from treated sows developed clinical coccidiosis. On Farm 2, all litters from nontreated sows and 11 of 12 litters from treated sows developed clinical coccidiosis. *I. suis* was the only species of coccidia seen in these piglets.

The results of these studies indicate that sows are not the primary source of *I. suis* infection for nursing pigs. It is still not known how *I. suis* becomes established on a farm; once it is established, it is probably transmitted through contaminated farrowing crates. The temperature (32–35°C) and moisture in the farrowing crate favor rapid sporulation of *I. suis*. High temperatures (32–35°C) may inhibit sporulation of the *Eimeria* species and could explain the absence of these species in nursing pigs.

TREATMENT AND CONTROL

Anticoccidials

Sows do not appear to be a major source of infection for nursing pigs; therefore, using anticoccidial drugs in the sow's ration is of little value in controlling neonatal coccidiosis. Early studies that reported success with treating sows probably are due to improved sanitation once the producers were made aware that their pigs had coccidiosis. Studies that demonstrate anticoccidial activity of drugs in weaned or finishing pigs are of no value in predicting the ability of these drugs to control disease in nursing pigs. Addition of anticoccidial drugs to the drinking water of piglets or mixing drugs in oral iron may be beneficial in treating coccidiosis, but there is no way to ensure that every piglet gets a therapeutic/preventive dose. There are no controlled studies that have documented the effectiveness of this type of treatment. Individual dosing is still the best way to ensure that each piglet gets a proper dose of anticoccidial drug.

Toltrazuril, a triazinon antiprotozoal not available in the United States, appears promising as an effective means of preventing coccidiosis in nursing piglets (Driesen et al. 1995). Toltrazuril (Baycox 5% suspension) was given orally at 20–30 mg/kg as a single dose to 3- to 6-day-old piglets on five farms with coccidiosis problems. Coccidiosis was reduced from 71% to 22% in treated litters. The severity of diarrhea and oocyst excretion was reduced in toltrazuril-treated piglets. Experimentally, toltrazuril was effective in reducing clinical signs and oocyst production at a single 20 mg/kg dose given to 5-day-old pigs that had been inoculated at 3 days of age (Mundt et al. 2003). Toltrazuril's excellent activity is probably based on its ability to kill asexual and sexual stages of coccidia and because it is slowly released from tissues of treated animals.

Controlled studies conducted to date in nursing pigs

have not identified other effective coccidiostats. Amprolium, furazolidone and monensin are not effective against neonatal procine coccidiosis.

Sanitation

Improved attention to sanitation has been the most successful method for reducing losses due to neonatal coccidiosis in pigs (Ernst et al. 1985; Stuart and Lindsay 1986). A good sanitation program entails thorough cleaning of the crates to remove organic debris, disinfection with bleach (at least 50%) or ammonia compounds for several hours or overnight, and steam-cleaning. Buildings should be empty of animals when disinfecting is being done. Ventilation should be adequate to prevent excessive exposure of workers to fumes of bleach or ammonia, or a chemical mask must be worn by workers. Producers should limit access to farrowing crates by workers to avoid crate-to-crate contamination with oocysts carried on boots or clothing. Likewise, pets should be prevented from entering the farrowing house and spreading oocysts from crate to crate on their paws. Rodent populations should be controlled to prevent these animals from mechanically transmitting oocysts.

Facilities need to be sanitized after every farrowing. Producers should be made aware that even though clinical disease is under control, the potential for future outbreaks is still present. In some cases, outbreaks of moderate clinical disease have developed in the first farrowing after sanitation was not done (Ernst et al. 1985).

Toxoplasmosis (*Toxoplasma gondii*)

Toxoplasmosis is caused by infection with *Toxoplasma gondii,* a protozoan parasite related to the coccidia. Infections are common in humans and animals. Postnatally, animals or humans become infected by ingesting food and water contaminated with sporulated *T. gondii* oocysts or by consuming meat containing tissue cysts. Cats (and other felines) are the only animals that can excrete resistant oocysts in their feces and are important in the transmission of *T. gondii* to pigs and other animals (Figure 52.4). Tissue cysts are found mainly in many edible tissues of infected animals, and they contain bradyzoites in various slowly multiplying stages (Figure 52.5B). Tissue cysts remain viable in the tissues for many years and probably the life of the animal. After ingestion, oocysts or bradyzoites can survive passage through the stomach. Once in the intestine of the host, sporozoites or bradyzoites change into a fast-multiplying stage called tachyzoites (Figure 52.5A). Tachyzoites multiply in the lamina propria of the intestine and eventually spread throughout the body. Prenatal infection may occur if the mother is infected during pregnancy. Tachyzoites from the mother's blood may cross to the fetus via the placenta. Tachyzoites cause tissue damage and eventually develop into the bradyzoite stage and form tissue cysts. Toxoplasmosis is a zoonosis, and pork is considered a major meat source of human infection in the United States (Dubey 1990).

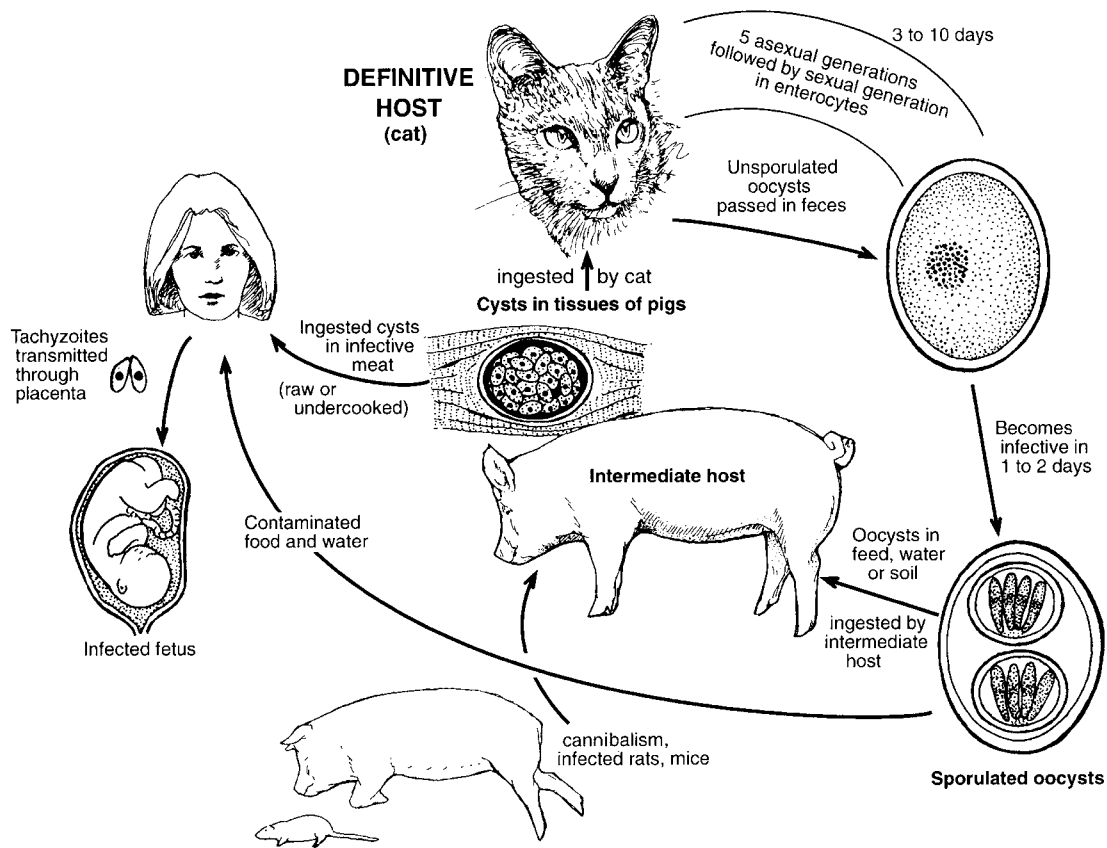
Clinical Signs

Most infections in swine are subclinical (Dubey 1986). Abortions due to *T. gondii,* although uncommon, may occur in sows infected during pregnancy. Transplacentally infected pigs may be born premature, dead, or weak, or they may die soon after birth. Pigs that live may develop diarrhea, incoordination, tremors, or cough. Few reports exist on clinical disease in pigs that acquire infection postnatally, but epizootics of clinical toxoplasmosis have been observed in both young and adult pigs (Dubey et al. 1979; Dubey and Beattie 1988). Experimental studies indicate that ingestion of *T. gondii* oocysts by pigs is more likely to produce clinical disease than ingestion of tissue cysts (Dubey 1986). Severity of disease is dependent upon the number of oocysts ingested. Older animals are less likely to develop clinical disease.

Pathologic Changes

Pathologic changes are associated with necrosis of host tissue caused by the rapidly multiplying tachyzoites (Figure 52.6). Ingestion of oocysts is more likely to give rise to intestinal lesions than is ingestion of tissue cysts. Enteritis, lymphadenitis, splenitis, hepatitis, pneumonitis, and less frequently myositis and encephalitis are seen in naturally infected pigs (Dubey 1986).

DIAGNOSIS

Methods of diagnosis include bioassays of tissues in cats or mice, serology, and histology. Bioassays are the most sensitive but are costly and time-consuming, and few laboratories perform these tests. Several serologic tests are available for determining antibodies to *T. gondii* in pigs. These include the Sabin-Feldman dye test (DT), indirect hemagglutination test, direct agglutination (DAG) test, latex agglutination test, indirect fluorescent antibody test, and ELISA. The DAG test is the most sensitive and specific for the detection of latent *T. gondii* infection in swine (Dubey et al. 1995a). Although finding *T. gondii* antibody in adult pigs only means exposure to *T. gondii*, finding antibody in a fetus indicates congenital infection because maternal antibodies are not transferred to the fetus in pigs. Histologic examination of tissues may be utilized for a presumptive diagnosis based


52.4. *Life cycle of* Toxoplasma gondii.

on lesion characteristics and parasite structure following routine histologic staining of tissue sections or identification of organisms in impression smears stained with Giemsa or other blood stains (Figure 52.5A). *Toxoplasma gondii* tachyzoites are lunate and about the size of a red blood cell. Tissue cysts are oval to round, up to 70 μm in diameter, and contain many bradyzoites (Figure 52.5B). For a definitive diagnosis if parasites are found in tissue sections, specific immunohistochemical tests (peroxidase-antiperoxidase test, avidin-biotin complex test) can be used.

EPIDEMIOLOGY

The prevalence of congenital *T. gondii* infection in pigs is less than 0.01%. Prevalence of *T. gondii* antibodies in feeder pigs (younger than 6 months) is much lower (3–5%) than in sows (15–20%) based on large-scale surveys in Illinois (Weigel et al. 1995; Dubey et al. 1995b). The presence of *T. gondii*-infected cats and infected rodents were identified as the main sources of *T. gondii* infection for pigs (Weigel et al. 1995). Cats become infected with *T. gondii* by ingesting infected animals (rodents, birds) soon after weaning. Therefore, infected juvenile cats are considered to be the main source of *T. gondii* for farm pigs. Cats generally acquire good immu-

nity to *T. gondii*, and cats that have excreted oocysts once are less likely to excrete oocysts again (Dubey et al. 1986*).

TREATMENT AND CONTROL

Because porcine toxoplasmosis is usually subclinical, little is known about the treatment of the disease (Dubey 1986). In general, drugs used to treat toxoplasmosis in humans have been effective. These include pyrimethamine or trimethoprim in combination with a systemically active sulfonamide.

Control of *T. gondii* infection in pigs is important because of public-health concerns over human infections. Toxoplasmosis causes mental retardation and loss of vision in congenitally infected children. Following experimental infection, viable tissue cysts of *T. gondii* can be found in most commercial cuts of pork, and studies have shown that the tissue cysts will be viable for at least 2.5 years (Dubey 1988). Freezing (−12°C) for 3 days or cooking pork until internal temperature reaches 60°C will kill tissue cysts in pork (Dubey et al. 1990). Low-dose gamma irradiation (0.5 kGy cessium 137) kills tissue cysts in pork.

Prevention of *T. gondii* infection in pigs can be achieved by practicing good husbandry. There is no vac-

cine. To prevent oocyst-induced infections, cats should never be allowed in buildings where pigs are housed or where feed is stored. Rodenticides should be used to control rodents and eliminate this possible source of tis-sue cysts. Any pigs that die should be removed promptly to prevent cannibalism. Wild-animal carcasses or un-cooked garbage should never be fed to pigs. Feed should be kept covered to prevent cats from defecating in it.

Sarcocystosis

Sarcocystis spp. are coccidia parasites that have a two-host life cycle (Figure 52.7). Three species use pigs as the intermediate host and form tissue cysts (sarcocysts) in the pig muscles. *Sarcocystis miescheriana* has a pig-dog life cycle and is the only species found in the United States. Dogs excrete infective stages (sporocysts) in their feces. The other species are *S. suihominis*, which uses the human as the definitive host, and *S. porcifelis*, which uses the cat as the definitive host (Dubey et al. 1989). Surveys indicate that from 3–18% of commercial breed-

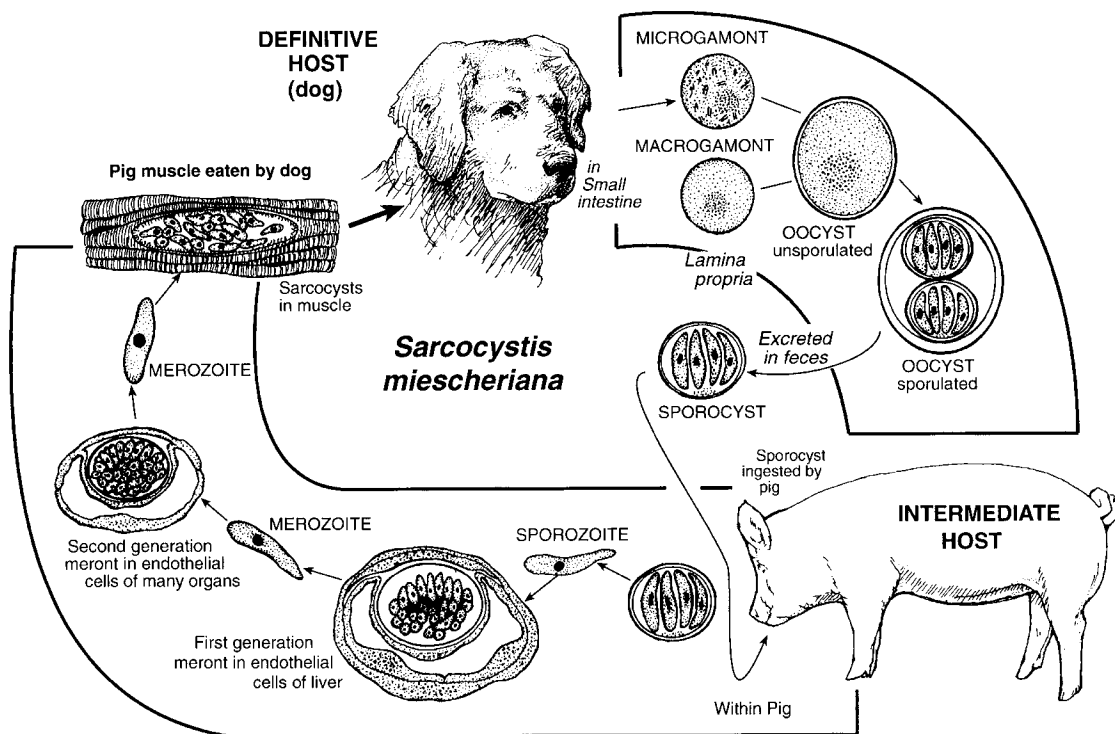
ing sows and 32% of wild swine examined in the United States have *Sarcocysitis* infection (Dubey and Powell 1994). There are no reports of naturally occurring clinical disease due to *Sarcocystis* infection in swine (Dubey et al. 1989). Experimental infections indicate that *S. mi-* *escheriana* can cause abortion, death, dyspnea, weight loss, muscle tremors, and purpura of the skin. *Sarcocystis* infection in swine can be prevented by eliminating their exposure to canine feces. To prevent exposure in dogs, they should not be allowed to consume pig carcasses.


52.7. *Life cycle of* Sarcocystis miescheriana.

Cryptosporidiosis

Members of the genus *Cryptosporidium* differ from conventional coccidia that infect animals in that they develop in the microvillous border of enterocytes rather than deep down in the host-cell cytoplasm (Figure 52.8). Additionally, oocysts of *Cryptosporidium* are completely sporulated when excreted in the feces and contain four sporozoites and no sporocysts (Upton and Current 1985).

Cryptosporidiosis is caused by infection with *Cryptosporidium parvum,* which is a recognized zoonosis. Recent molecular and animal infectivity studies indicate that pigs are host for other species of *Cryptosporidium* referred to as "pig genotypes" (Enemark et al. 2003; Ryan et al. 2003) that are different from *C. parvum*. The prevalence of *C. parvum* compared to pig genotype infections in pigs is not known. Human infections with pig genotypes are rare (Xiao et al. 2002), and pigs do not appear to be a major source of infection for humans.

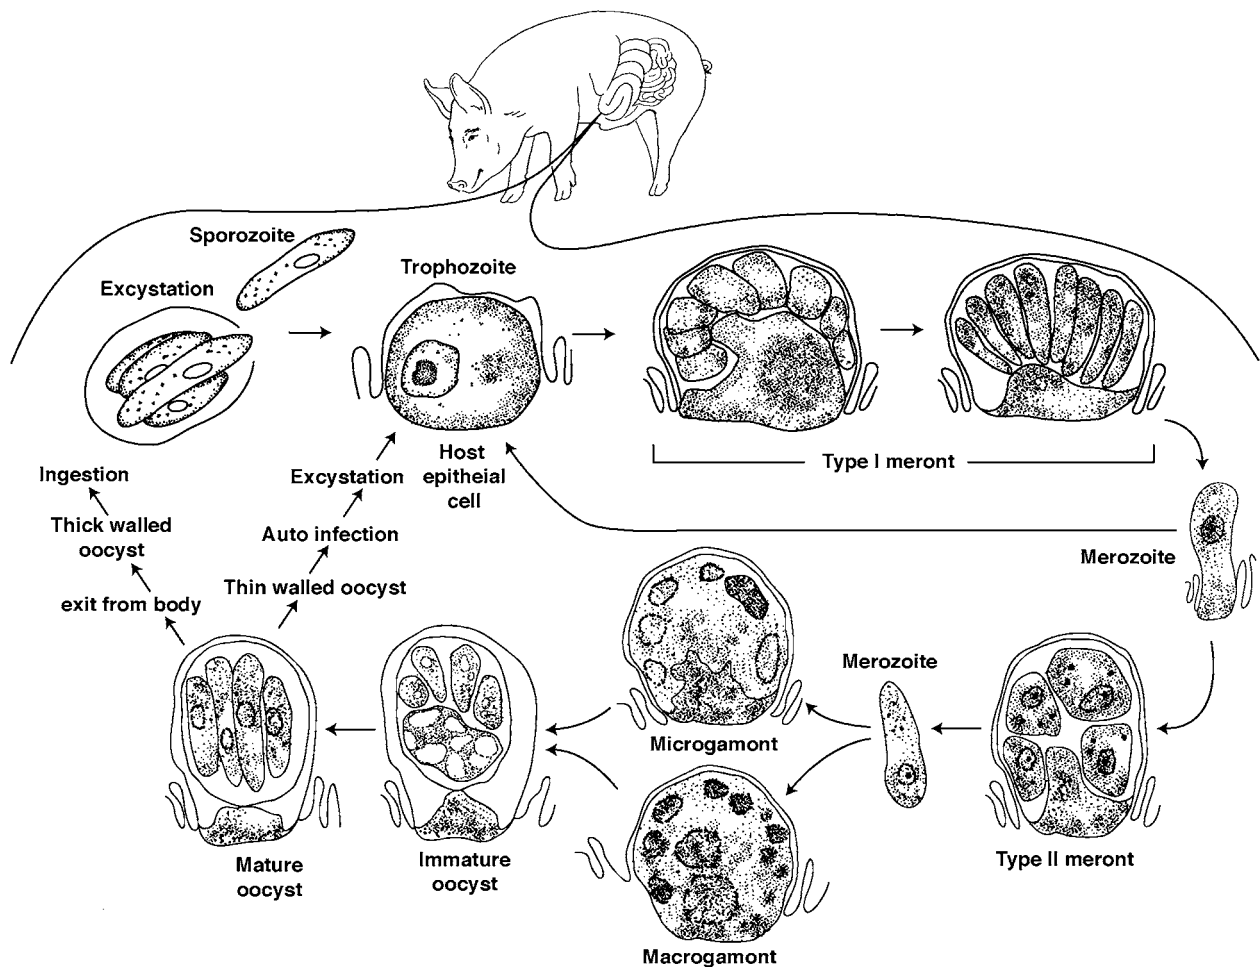
CLINICAL SIGNS AND PATHOLOGIC CHANGES

Porcine cryptosporidiosis is usually subclinical and not a major production problem (Sanford 1987). If clinical signs are present, they consist of nonhemorrhagic diarrhea, usually in pigs younger than 12 weeks (Sanford 1987).

Microscopic lesions associated with cryptosporidial infection in pigs are minimal or absent. The parasites are found in the jejunum, ileum, cecum, and colon, with most parasites being in the ileum. When lesions are present, they consist of mild villous atrophy and invasion of the lamina propria by large numbers of mononuclear inflammatory cells and fewer eosinophils (Sanford 1987). Microvilli in the area of the parasites may be displaced or hypertrophic.

EPIDEMIOLOGY AND DIAGNOSIS

Pigs are infected by ingesting oocysts in contaminated feed, from the environment, or in water. There is no seasonal pattern to the prevalence of infection (Sanford 1987).

Diagnosis can be achieved by finding the developmental stages of the parasite in histologic sections. The parasites are 2–6 µm and basophilic and appear to be embedded in the microvillous border of the enterocytes. Diagnosis can also be made by finding the characteristic oocysts in fecal flotations, but molecular methods are needed for speciation. The oocysts are small, 5.0 by 4.5 µm, and have a pinkish color and residual body when observed with light microscopy. Sheather's sugar solution is the flotation medium of choice; a microscope


52.8. *Life cycle of* Cryptosporidium.

equipped with good objectives is needed to identify the oocysts in flotations. It is important to remember that in fecal flotations, the cryptosporidial oocysts will be in a slightly higher plane of focus than other coccidial oocysts. Several methods of staining fecal samples and examining for oocysts have been developed but these are not practical for use in pigs. Several serologic methods such as enzyme-linked immunosorbent assay (ELISA) and indirect fluorescent antibody test (IFAT) have been developed for estimating the prevalence of cryptosporidial exposure, but these tests are not currently in widespread use.

TREATMENT AND CONTROL

There is no treatment for cryptosporidial infection. Sanitation methods used to control *I. suis* coccidiosis should also prove effective against cryptosporidial infections.

Other Protozoa of Minor Importance or Potentially Transmissible to Humans

GIARDIA

Giardia species are flagellated protozoan that cause fatty diarrhea in humans and companion animals. *Giardia* cysts contain four nuclei, median bodies, and are about 12 micrometers in length. These cysts can be found in the feces of many mammalian species, including pigs.

The trophozoites of *Giardia* live in the lumen of the small intestine, usually the upper small intestine. They have two nuclei and an adhesive disk by which they attach to enterocytes. They are not considered pathogenic for pigs (Koudela et al. 1991). Molecular analysis of *Giardia* isolates obtained from pigs indicates that

human infective *Giardia* may be found in pigs and that "Livestock" infective genotypes can be found in pigs (Ey et al. 1997). The role of pigs in the transmission of *Giardia* to humans is not presently known.

MICROSPORIDIA

Microsporidia are in the phylum Microspora. These organisms infect both vertebrates and invertebrates. They are intracellular pathogens and can be found in a variety of locations in the host's body. Human and animal infections with the well-known *Encephalitozoon cuniculi* were recognized prior to the AIDS pandemic. However, overall awareness of this phylum as important parasites of warm-blooded animals came about only after the advent of AIDS. Hosts are infected by ingestion of spores passed in the urine or feces. The polar tube penetrates a cell, and the sporoplasm, containing the nucleus, is passed through the tube into the host cell. Inside the host cell the parasite replicates asexually until the host cell bursts, releasing newly formed spores. Most microsporidia are small (1 to 4 micrometers) and resemble bacteria when examined unstained with light microscopy.

Clinical microsporidiosis has not been reported in pigs. Pigs are naturally infected with *Enterocytozoon bieneusi* (Breitenmoser et al. 1999), an important cause of chronic diarrhea in AIDS patients. Self-limiting diarrhea occurs in immuonocompetent patients. Several different genotypes of *Ent. bieneusi* occur in pigs and humans. An 18-month long survey of pigs from a slaughterhouse in Massachusetts revealed that 32% of the pigs were positive for *Ent. bieneusi* using a PCR test (Buckholt et al. 2002). Human infective genotypes were also isolated from the feces of these pigs.

Experimental infections of gnotobiotic pigs with *Ent. bieneusi* did not result in clinical signs (Kondova et al. 1998). Pigs excreted spores for at least 50 days. *Enterocytozoon bieneusi* was detected in enterocytes and feces of experimentally infected gnotobiotic pigs.

BALANTIDIUM COLI

Balantidium coli is the only important ciliate found in pigs and in humans. It is transmitted by cysts that are excreted in the host's feces. The cysts are 50 to 70 μm in diameter and contain a macronucleus and a micronucleus. No division occurs in the cyst. Trophozoites are covered in short cilia, are up to 100 μm in length, and also contain a macronucleus and a micronucleus. Trophozoites are usually found in the lumen of the large intestine. Most infections in swine and humans are subclinical. Individual infection rates approaching 100% can be found in weaned pigs and breeding stock on farms where *B. coli* is present (Hindsbo et al. 2000).

53 External Parasites

C. Cargill and Peter R. Davies

The importance of external parasites in swine production varies greatly among regions because of differences in climate and systems used to raise pigs. Unquestionably, the mite *Sarcoptes scabiei* var. *suis* is the most important external parasite of swine worldwide. Other external parasites include demodectic mites, lice, fleas, mosquitoes, flies, and ticks. Mites and ticks belong to the class Arachnida and are characterized by having four pairs of legs. Lice, fleas, flies, and mosquitoes belong to the class Insecta.

External parasites produce a range of clinical signs in pigs. Rubbing, scratching, and skin lesions, which are secondary to irritation, are the most common. Some parasites also cause significant economic effects due to reduced growth rate, reduced feed efficiency, and loss of carcass value at slaughter. The risk of chemical residues in meat is also increased because many products used to treat external parasites have a long withholding period and treatment of animals can complicate routine market and culling decisions. Furthermore, some external parasites are implicated in the transmission of pathogenic organisms.

SARCOPTIC MANGE

The mite *Sarcoptes scabiei* var. *suis*, the cause of sarcoptic mange, is the most important ectoparasite of swine throughout the world. Mange is considered the most detrimental skin disease affecting pigs, because of the economic losses from reduced growth rates and feed efficiency in growing pigs and decreased fertility in breeding sows (Zimmermann and Kircher 1998; Kessler et al. 2003). Its economic importance tends to be underestimated, especially by pig producers who fail to check for encrustations in the ears of sows and to recognize the importance of clinical signs in growing pigs.

Two clinical forms of the disease are recognized: a hyperkeratotic form (sometimes referred to as *chronic mange*) that most commonly affects multiparous sows and a pruritic or hypersensitive form that affects growing pigs. Earlier descriptions of sarcoptic mange referred to hyperkeratotic mange and described encrusted skin lesions from which mites were readily isolated (McPherson 1960; Sheahan 1970). More recent studies have shown that the hypersensitive form is the more common in growing pigs and is characterized by the development of delayed and immediate hypersensitive reactions to the mites. (Davis and Moon 1990a,b,c; Alonso de Vega et al. 1998; Cargill 2001, 2002).

Distribution

Sarcoptic mange mites are ubiquitous in swine herds, unless eliminated by specific eradication procedures (Yeoman 1984). Herd prevalence estimates of between 43% and 95% have been reported in numerous countries, including Australia, Belgium, Canada, the former Republic of Czechoslovakia, Denmark, France, Great Britain, Italy, Japan, Mexico, the Netherlands, Scotland, Spain, Sweden, and the United States (Wooten-Saadi et al. 1987b; Smeets et al. 1989; Horie 1990; McMullin et al. 1990; Davies et al. 1991a; Hasslinger and Resch 1992; Klopfenstein et al. 1992; McMullin et al. 1992; Mendez de Vigo et al. 1992; Garcia et al. 1994; Gualandi et al. 1994; Davies et al. 1996b). In many studies herd prevalences of 70–90% were recorded, with animal prevalences within herds ranging from 20% to 95%. As recently as 2003, herd prevalence in the U.S.A. and Canada was quoted at 29% and 38%, respectively (Melancon 2003).

Etiology and Life Cycle

Sarcoptes scabiei is a small, grayish-white, eight-legged arthropod, from the class *Arachnidia*, order *Acariana*, belonging to the family *Sarcoptidae* (Hill 1997). The mite is circular, approximately 0.5 mm in length, and just visible to the naked eye when placed on a dark background. When viewed under a dissecting microscope, the mite readily moves away from bright light. It has four pairs of short stumpy legs, some of which are provided with long unjointed pedicles that terminate in sucker like or-

53.2. Sarcoptes scabiei, *the sarcoptic mange mite. Male, ventral view. (From Belding 1952. Courtesy Appleton-Century-Crofts.)*

gans. These pedicles occur on the first two pairs of legs in the female and on the first, second, and fourth pairs in the male (Figures 53.1, 53.2).

Mites are permanent parasites in the epidermis, where eggs, larvae, nymphs, and adults all develop. The mites burrow by extra-oral digestion of the stratum corneum, and then consume cells of the stratum granulosum and stratum spinosum (Davis and Moon 1990a). After females mate, they lay 40–50 eggs in tunnels carved into the upper two-thirds of the epidermis and die approximately 30 days after maturity (Hill 1997). The eggs hatch in 3–5 days, larvae molt to nymphs, and then nymphs molt to adults, all within the tunnels. Mating occurs in the molting pockets or near the skin surface, after which the ovigerous females initiate new burrows. Reproduction can occur only on the host, and the entire cycle from egg to ovigerous female requires 10–25 days. Most studies in the pig suggest that most of the mite activity is confined to the inner surface of the ear (Walton 1967; Sheahan 1975; Davis and Moon 1990a, d). Although material from ear scrapings taken from an animal with an established infestation may contain very large numbers of mites, mites may be difficult to find on other parts of the body (Bogatko 1974; Cargill and Dobson 1979a). Using tissues dissected from mite-infested pigs, Magee (1974) demonstrated that mites burrow no deeper than the epidermis and make burrows parallel to the skin surface.

Epidemiology

Hyperkeratotic encrustations in the ears of multiparous sows are the main reservoir of mites within a herd. Boars, although less important with the increasing use of AI, can also be a source of infestation in breeding herds because they tend to be treated less often than sows. Although extensive hyperkeratotic lesions may occur on the body and hindlegs of adult animals (Martineau et al. 1984), only a small percentage of animals are affected in this manner. Hyperkeratotic lesions are

occasionally visible in the ears and on the body of growing pigs, especially where control measures for mange are poor. In most herds, mite populations are maintained within the ears of sows, and piglets become infested during suckling. Spread between sows and boars and between litters is mainly by direct contact between pigs, but according to Stegeman et al. (2000) the transmission of mites is slow. They estimated that the transmission of mange in housed pigs to be in the order of 0.06 new infestations for each infested pig per day. The newly fertilized adult female mite is thought to be the main means of spread and maximum opportunity for spread exists when groups of pigs huddle. Pig management practices such as group housing of sows, continuous-flow management systems for growing pigs, and current trends towards larger group sizes of growing pigs will facilitate the spread of mites.

Although environmental spread is much less important than direct contact between animals, pigs have become infested when placed in pens for as little as 24 hours immediately after infested pigs were removed from the pens (Smith 1986). Although mites have been kept alive for 3 weeks under optimum laboratory conditions (Soulsby 1968), survival of mites and eggs away from the host is limited. Their viability is reduced by desiccation and can be improved artificially by placing them in media such as mineral oil (Davis and Moon 1987). In our experience mites die within a few minutes in direct sunlight and after several hours in temperatures above 28°C. Even in colder climates mites do not appear to survive for more than 12 days in a piggery at temperatures of 7–18°C and relative humidity of 65–75% (Mikhalochkina 1975). In warmer climates, clinical evidence of sarcoptic mite hypersensitivity could not be demonstrated when noninfested pigs were exposed on repeated occasions to contaminated bedding vacated 3 days previously in either autumn or spring (Cargill and Dobson 1977). This was supported by laboratory experiments which demonstrated that mites did not survive longer than 96 hours at temperatures of less than 25°C, longer than 24 hours from 25–30°C, and less than 1 hour at temperatures above 30°C (Cargill and Dobson 1977). The prevalence and severity of sarcoptic mange have also been reported to increase in cooler months and decrease in warmer months (Davies et al. 1991b; Elbers et al. 1992; Davies et al. 1996b). Other species do not appear to play a role in porcine scabies (Magee 1974), and transmission from one herd to another usually occurs when pigs with subclinical infestations are moved.

The results of several studies indicate that only a small percentage of growing pigs will harbor significant numbers of mites on the internal surface of the pinna. In a study of 187 clinically healthy pigs (Bogatko 1974), mites could not be observed in skin scrapings from the head and neck region although 18% of skin scrapings from the luminal surface of the ears were positive. In

other studies, the prevalence of mites in the ears was five times higher in groups of pigs with hypersensitive skin lesions compared to pigs without lesions (Hollanders and Vercruysse 1990). Davies et al. (1996b) found that the number of pigs in a group with positive skin scrapings was positively correlated with the level of papular dermatitis in the group at slaughter. The prevalence of positive skin scrapings ranged from 3–63%. In a group of pigs where 47% had signs of hypersensitive mange and 5% had hyperkeratotic mange, mites were found in 33% of hypersensitive pigs but in 81% of pigs with hyperkeratotic mange (Kambarage 1993). Although the level of pruritus in groups of pigs appears to be positively correlated with the number of pigs that are positive for mites, the presence of mites on individual pigs appears to be negatively correlated with the degree of pruritus and hypersensitivity (Cargill et al. 1996a). The level of immune hypersensitivity in individual pigs appears to affect both the host behavior and the development of encrusted lesions (Davis and Moon 1990b). It would appear that within a group of pigs there are two populations. A smaller population of pigs harbors significant numbers of mites, but do not develop a severe form of hypersensitive mange, and a larger population of pigs harbors few mites, but develops a marked hypersensitivity reaction (Davies et al. 1996a). In this latter population the number of mites declines over time as the level of hypersensitivity increases (Cargill and Dobson 1979a; Cargill and Wegiel 2000; Davis and Moon 1990a). Regular exposure to mites from penmates maintains the allergic reaction and clinical signs in the hypersensitive animals (Cargill and Wegiel 2000).

Economic Importance

The production effects of sarcoptic mange have been previously reviewed by Davies (1995). Based on our current understanding of the pathogenesis of mange, deaths are unlikely in the absence of concurrent disease (Davies 1995), although mortalities may occur in cases with severe hyperkeratotic lesions (Pullar 1941). Field studies indicate that improved mange control will improve milk production, reduce piglet mortalities due to overlying, and increase weaning weights (Hewett and Heard 1982; Schultz 1986; Martelli and Beghian 1990). However, other studies have failed to confirm these findings (Dalton and Ryan 1988; Arends et al. 1990) but have demonstrated that feed utilization efficiency improved following prefarrowing treatment of sows. The variations in results could have been due to differences in the degree of infestation in the herds (Davies 1995). Other economic effects include downgrading and trimming of carcasses at slaughter and damage to pens and fixtures caused by rubbing pigs.

The most significant economic effect of sarcoptic mange is reduced growth rate and feed efficiency in growing pigs (Cargill et al. 1997); the level of economic loss may be underestimated by producers who fail to ap-

preciate the severity of clinical signs. The effect of sarcoptic mange on growth rate has been investigated in a number of studies, by comparing experimentally infested pigs with noninfested controls (Sheahan 1974; Cargill and Dobson 1979b; Wooten et al. 1986; Davies 1995) or by comparing treated with untreated pigs (Sheahan and Kelly 1974; Hewett 1985; Alva-Valdes et al. 1986; Wooten-Saadi et al. 1987a; Arends et al. 1990; Martelli and Beghian 1990). Although some results are conflicting, where growth rate was measured over a period of 12 weeks or greater, or from less than 20 to more than 60 kg liveweight, the majority of studies demonstrate growth rate suppression of between 4.5% and 12%. In one study, the growth rate in infested pigs was decreased by 8% (Wooten-Saadi et al. 1987a), and in another study (Davies 1995) reductions in growth rate in infested pigs ranged from zero up to 5.7% and were associated with the severity of papular dermatitis among groups. In a recent report by Elbers et al. (2000), infested pigs grew significantly slower, with a reduced feed efficiency of 2%, when compared with the control. Smets et al. (1999) also showed that breeding sows needed 5% less feed after eradication of mange. In the same herd, returns to estrus were reduced by 4.5%, pigs born alive increased by 0.33 piglets per litter, and pigs weaned increased by 1.34 piglets per sow per year. In addition to effects on production performance, financial loss is also incurred in treatment costs (acaricides and labor), carcass downgrading, and due to the risk of chemical treatment residues in meat products.

Interaction between sarcoptic mange and other diseases has also been suggested (Yeoman 1984; Gaafer et al. 1986) but no objective reports are available.

Clinical Signs, Pathogenesis, and Lesions

Pruritus is the most consistent clinical sign of sarcoptic mange. Following infestation, intermittent body scratching may be observed in piglets born to an infested sow or in older pigs coming into contact with mites for the first time. True generalized pruritus occurs from 2–11 weeks after infestation (Sheahan 1974; Cargill and Dobson 1979a). This variation is similar to that reported in human scabies, where the period between exposure and the development of pruritus ranges from 9–10 days to 4–6 weeks (Sheahan and Kelly 1974). Following exposure, pigs go through several phases, which include a nonresponse phase, a delayed-type hypersensitivity phase, a delayed- and immediate-type hypersensitivity phase, and finally an immediate-type hypersensitivity phase (Davis and Moon 1990a). The development of pruritus and the intensity of rubbing will depend on the number of mites in the initial exposure and the level of ongoing exposure. When pigs were exposed to either low (100) or high doses (1000) of mites, the development of delayed-type hypersensitivity, but not the development of immediate-type hypersensitivity, was found to be dose dependent (Davis and Moon

1990a). Desensitization has not been documented but field evidence suggests that it occurs.

The pattern and chronological order of clinical events are similar in both natural and experimental infestations (Sheahan 1974, 1975; Cargill and Dobson 1979a; Cargill and Wegiel 2000). Pigs develop encrusted lesions that are rich in mites, especially on the luminal surface of the pinnae (Figure 53.3). These plaquelike lesions may coalesce to cover up to 70% of the surface of the pinnae but will regress with time as hypersensitivity develops. The epidermal changes and sequence of events have been well documented by Morsy et al. (1989), using electron microscopy. It has been suggested that papular lesions of human scabies may result from unsuccessful burrowing of immature mites that fail to survive to adulthood (Green 1989).

Focal erythematous skin papules associated with hypersensitivity occur in most animals as encrustations regress. The papules occur primarily on the rump, flank, and abdomen (Cargill and Dobson 1979a). Histologically, they contain large numbers of eosinophils, mast cells, and lymphocytes but no evidence of mites. Immunoglobulin-secreting cells increase to a peak in the 2–5 weeks after infestation and then subside substantially after a few weeks (Morsy and Gaafar 1989). Repeated or multiple infestations result in only a small increase in immunoglobulin-secreting cells. The development of pruritus is signified by rubbing, which in severe cases results in the proliferation of connective tissue and keratinization, leading to hair loss, abrasions, and thickening of the skin, especially over the flanks of animals that rub frequently.

53.3. *Photograph of the ear of a sow with encrustation caused by sarcoptic mange mites.*

Lesions of hyperkeratotic mange are most common in mature animals. In growing animals they occur mainly in pigs that fail to develop the typical hypersensitivity response after infestation. The lesions, seen as thick asbestos-like scabs that are loosely attached to the skin, are very rich in mites and occur most frequently in the ears. The scabs may progressively cover the head, neck, and other parts of the body, although this is uncommon.

An interrelationship among immunity, inadequate nutrition, poor management, and hyperkeratotic sarcoptic mange has been noted. Hyperkeratotic mange has been described as a disease of poor management, and it is considered to be more common in poorly fed pigs. Studies have shown that low-protein diets and iron deficiency are associated with reduced hypersensitivity and a greater proportion of animals with hyperkeratotic mange (Sheahan 1974; Cargill and Dobson 1979a). The overall clinical picture is substantially influenced by the effectiveness of treatment and herd management. The influence of concurrent disease in the development of sarcoptic mange has not been elaborated.

Diagnosis

Sarcoptic mange is present in most herds unless they have been derived from specific pathogen free (SPF) sources or special measures have been taken to eradicate the parasite. Rubbing in growing pigs with small red papules on the body is the most obvious indication of sarcoptic mange. The small size of the parasite and its intracutaneous location, in combination with nonspecific signs (including pruritus), can make the diagnosis of scabies difficult to confirm (Smets and Vercruysse 2000). The majority of pigs in an infested herd may be subclinically infested and may not manifest obvious clinical signs of the disease (Kessler et al. 2003).

Diagnosis is confirmed by demonstrating the presence of mites within a herd, but the sensitivity of the methods available is low and the results depend on the location of the scrapings and the number of samples (Smets et al. 1999, Deckert et al. 2000). The best method is to use a flashlight to examine the luminal surface of the ears of breeding animals for encrusted lesions. About 1–2 cm^2 of the lesion can be removed and examined for mites. Mites can be observed by breaking the material onto a sheet of black paper and gently removing it after a few minutes, leaving mites adhering to the paper by the suckers on their feet. Mites can be observed directly or with a magnifying glass (Brakenridge 1958). A more sensitive technique is to break down scabs with 10% potassium hydroxide and observe them under a low-power microscope. Large numbers of mites can be collected from encrusted ear lesions by vibrating material in a petri dish over low heat for 6–24 hours. This will cause mites to emerge in great numbers and adhere to the bottom of the dish (Sheahan and Hatch 1975).

The severity of sarcoptic mange in a herd can be as-sessed by quantifying the level of pruritus in various groups of pigs. This is achieved by calculating a rubbing index (RI) (Pointon et al. 1995; Cargill et al. 1997; Cargill 2001). A group of 25–30 pigs is observed for 15 minutes and the number of rubbing and scratching episodes is divided by the number of pigs in the group to give the RI. An RI of greater than 0.1 indicates the need to review mange control programs. Increased stocking density will reduce the RI, whereas wetting pigs will increase the RI. Although other, confounding factors need to be identified before using an RI with confidence to compare pigs on different farms, it does provide a simple means of assessing mange control programs on individual farms (Cargill et al. 1997).

Examination of carcasses at slaughter for papular lesions also provides a simple and objective method for assessing the prevalence and severity of sarcoptic mange in growing pigs. The causal association between sarcoptic mites and papular dermatitis was first suggested by Flesja and Ulvesaeter (1979) and was confirmed by Davies et al. (1991a). The original method for scoring lesions was described by Pointon et al. (1987, 1992), and categories were defined according to the severity of dermatitis (Pointon et al. 1999). Although the specificity of score 2 and 3 lesions is greater than 0.98, the specificity of score 1 lesions ranges from 0.7 to 0.9 (Davies et al. 1996b). In order to improve specificity, a modified scoring system has been recently introduced in Australia where minor spotting, which may be caused by insect bites and bedding, is ignored. Score 1 lesions include mild dermatitis about the shoulders, underline, and rump up to a more generalized distribution of mild lesions over the back and moderately dense lesions about the shoulders, underline, and rump. Score 2 lesions include a generalized distribution of moderately dense lesions over the back and dense lesions over shoulders, underline, and rump, and worse. Hollanders et al. (1995) have also suggested modifying the scoring system in a similar way to improve specificity. However, it is also important to validate and quantify the association between skin lesions and sarcoptic mange on a regional and geographic basis and to ensure repeatability among the observers recording lesions (Cargill et al. 1997). This will allow interpretation of the lesions in a herd regardless of the system used to record lesions.

Recently, several enzyme-linked immunosorbent assays (ELISAs), which detect antibodies to *S. scabiei* in serum, have been used as diagnostic tools (Bornstein and Wallgren 1997; Bornstein et al. 2000; Deckert et al. 2000; Vercruysse and Smets 2000; Zalunardo et al. 2000). Although individual sensitivity varies from 29–64%, as a herd test, sensitivity approaches 95% (Deckert et al. 2000). Specificity of the antibodies in individual pigs ranges from 78–97% (Smets and Vercruysse 2000). Results of serological tests are affected by the stage of the disease process. Specific antibodies are not detectable until 5–7 weeks post-infestation or approximately 3–4

weeks following the onset of clinical signs of mange (Bornstein and Zakrisson 1993). Furthermore, following treatment and elimination of mites from heavily infested animals, detectable antibodies may persist for up to 9–12 months (Smets and Vercruysse 2000). Serological responses are also affected by the infective dose (Bornstein et al. 1994) and age of the pigs. Although antibodies can persist for at least 10 months in naturally infested sows following treatment (Bornstein et al. 1994), the half-life of specific antibody appears to be significantly shorter (less than 2 months) in younger pigs (Bornstein and Wallgren 1997). The ELISA has also been used to validate the efficacy of eradication programs (Jacobson et al. 1999; Cargill et al. 2004).

Differential diagnosis from other skin conditions is important. Conditions that can be confused with mange include parakeratosis, exudative epidermitis, niacin and biotin deficiencies, dermatomycosis, swinepox, sunburn, and photosensitization. The role of mosquitoes and other insects in the differential diagnosis of papular dermatitis must also be considered. Occasionally in mange-free herds, ear scrapings may reveal the presence of mites and mite eggs but not clinical disease. That may occur when old straw is used for bedding.

Treatment, Control, and Eradication

Failure to control sarcoptic mange is due in part to the covert nature of the disease and to a failure to understand the epidemiology of mange. Commonly farmers regard rubbing, the main clinical sign of hypersensitive mange, as normal. Several strategies are open to producers to reduce the economic effects of mange.

Establishment and Maintenance of Mange-Free Pig Populations. The establishment and maintenance of mange-free herds and populations is facilitated by three important facts. First, piglets are born free of mites and become infested through contact with infested sows or older growing pigs. Second, the mites are highly host-specific and survive poorly away from the pig. Third, modern acaricides are very effective. Mange-free herds can be established with cesarean-derived pigs, by depopulation and repopulation from mange-free stock, by segregated rearing of treated pigs, and by eradication using avermectins and other products. Biosecurity measures, which focus on careful scrutiny of, and minimization of, sources of incoming stock are usually adequate to prevent introduction of the parasite. In a number of countries, major breeding-stock suppliers maintain mange-free herds, and large populations of pigs in integrated production systems have been kept free of the parasite for many years. This should be the goal of most farms.

The Dutch mange-free certification scheme is an excellent example of how to eradicate sarcoptic mange from a large number of farms (Rambags et al. 1998, 2000). The scheme relies on treatment programs designed for individual farms, and freedom is validated using slaughter checks and serology.

Treatment. The key to the successful eradication and control of mange is correct use of acaricides. In our experience, the majority of registered acaricides will keep mange under control, and even eradicate it, provided the correct dosage and treatment schedules are used. The acaricides available for treating sarcoptic mange have received considerable attention. Older remedies include crankcase oil, diesel oil, and lime sulfur (Dobson and Davies 1992). Oil mixtures are more effective than water-soluble products because oil assists in softening the hard scab; oil mixtures are still useful either as an alternative treatment or in conjunction with insecticides. The first insecticides used were mainly sprays of either organochlorinated hydrocarbons (lindane and toxaphene) or organophosphate compounds (malathion, trichlorfon, and diazinon) (Table 53.1). Because of their toxicity, chlorinated hydrocarbons have been deregistered in many countries and should no longer be used. Although the organophosphates are not as effective, they have shorter withholding periods than the chlorinated hydrocarbons and are safer. More recently developed acaricides include phosmet, used as a pour-on, amitraz used as a spray, and the avermectins (ivermectin, doramectin, and moxidectin), which are given as injections or, in the case of ivermectin, can also be given orally in the feed. The precise products available depend on the legislation of the country in question. Instructions on dilutions, withholding periods, dangers, and any precautions given by the manufacturer must be followed carefully.

Amitraz, used as a 0.1% spray (Johansson et al. 1980) and phosmet formulated as a 20% oily pour-on and applied at the rate of 1 mL/10 kg body weight (Hewett and Heard 1982) have been shown to be effective. In the case of phosmet, it is recommended that a small amount of the product be placed in the inner aspect of each ear.

The avermectins are broad-spectrum antiparasiticides effective against most internal parasites, as well as lice and sarcoptic mange mites, with varying levels of persistence (Arends et al. 1999; Cargill et al. 2000). Ivermectin can be given orally at 300–500 µg/kg (Lee et al. 1980; Alva-Valdes et al. 1984), and all the avermectins can be given by either subcutaneous (SC) or intramuscular (IM) injection at 300 µg/kg body weight (Courtney et al. 1983; Martineau et al. 1984; Dalton and Ryan 1988; Ohba et al. 1989; Satyavir and Chhabra 1992; Seaman et al. 1993; Hollanders et al. 1995; Cargill et al. 1996a; Logan et al. 1996; Yazwinski et al. 1997). They are more efficient because of their systemic action and ease of administration.

Eradication. Eradication of sarcoptic mange is possible if a sound program is developed. Keller et al. (1972) eradicated sarcoptic mange from six SPF herds, which be-

Table 53.1.   Guidelines for chemical treatment of external parasites of swine

Chemical	Concentration	Parasites Affected	Directions for use
Amitraz	0.1% solution	Mites	Spray pigs and surroundings, repeat in 7 days.
Ciodrin	0.25%	Lice	Spray, repeat in 14 days.
Coumphos (Co-Ral)	0.06% solution	Lice, horn flies	Spray.
	0.12% solution	Ticks (*Amblyomma, Dermacentor, Ixodes*)	Treat wounds.
	0.24% solution	Mites	Apply to pigs; simultaneously apply 20g/m^2 to fresh bedding.
	1% dust	Screwworm, blowflies	Apply to ears and adjacent areas of head.
	5% dust	Lice Ear ticks	
Diazanon	0.05% emulsion	Lice, mites	Spray 3 times at 10–day intervals
Dioxathion (Delnav)	0.15% solution	Lice, Ticks (*Amblyomma, Dermacentor, Ixodes*)	Spray or dip. Do not treat sows within 2 weeks of farrowing or while lactating. Do not repeat treatment within a 2-week period.
Doramectin	IM injection	Lice, mites, fleas	300 µg/kg body weight
Ivermectin	SC injection	Lice, mites, fleas	300 µg/kg body weight
	Orally in feed		300–500 (g/kg body weight
Lindane	0.06% emulsion	Lice, sarcoptic mites	Dip or spray. Do not use benzene hexachloride.
	1% dust	Fleas	
	3% formulated in smear, paste, or pressurized aerosol	Fleas, screwworm, blowflies	Dust head, neck, and back. Treat all wounds.
Malathion	0.05% emulsion	Lice, ticks, mites	Spray.
	6% dust	Fleas, lice	Dust thoroughly.
	2.5% emulsion	Houseflies, stable flies, fleas,	Spray environment.
Moxidectin	SC injection, pour-on	Lice, mites, fleas	300 µg/kg body weight
Phosmet	20% oily solution	Mites	Pour 1ml/10kg body weight along back. Place some in each ear.
Polysulfide	2% solution	Sarcoptic mites	Spray.
Primiphos (Actelic 50 EC)	Powder	Control of fleas	Sprinkle through straw bedding (check withholding period).
Rabon	2% solution	Houseflies, stable flies, lice	Spray 4.5L/12–14g/m^2.
Ronnel (Korlan)	0.25% emulsion	Lice	Spray.
	5% granules	Lice	Apply to bedding 25g/m^2.
	5% pressurized aerosol	Screwworm, blowflies	Treat wounds.
Roteneone	1% powder	Fleas	Dust head, neck, and back.
Toxaphene	0.5% emulsion	Lice, ticks, mites	Spray.
Trichlorfon (Neguvon)	0.125% emulsion	Houseflies, stable flies, mites	Spray environs (avoid feed and water).

Note: It is important to follow the manufacturer's recommendations and observe the withholding period specified for each chemical.

came infested accidentally. All pigs were treated three to four times with diazinon and lindane at 9- to 15-day intervals, and the environment was sprayed. Dobson and Cargill (1979) achieved eradication by washing sows in oil and using two treatments of trichlorfon at 7-day intervals prior to farrowing and isolating progeny from untreated pigs. Courtney et al. (1983), Henriksen et al. (1987), White and Ryan (1987), Dalton and Ryan (1988), and Reddin (1997) eradicated sarcoptic mange from herds with a single SC injection of ivermectin, but Alva-Valdes et al. (1984) and Thomas et al. (1986) were unsuccessful with either a single oral treatment of ivermectin at 300 or 500 µg/kg or with three SC injections of 300 µg/kg within a month. Subsequently Ebbesen (1998) eradicated mange in three farrow to finish herds by medicating the breeding herd and all weaned pigs on the farm orally for 16 days with ivermectin and injecting

piglets twice 14 days apart. Prefarrowing treatment of sows will prevent the transmission of mites to their progeny (Firkins et al. 2001) and mites have been eliminated from pigs using single or double administrations of an avermectin (Jacobson et al. 2000), as well as a single injection of doramectin (Jensen et al. 2002). More recently Cargill et al. (2004) described three eradication programs based on treatment of the breeding herd only, using either oral or injectable formulations of ivermectin. Sows were treated twice prefarrowing and progeny were reared in isolation. Boars were treated whenever sows were medicated. Eradication was validated using slaughter checks and serology, as described in the Dutch eradication program (Rambags et al. 1998, 2000).

Eradication programs involve several key points. If the whole herd is to be treated, all marketable pigs must be sold before each treatment to reduce the cost, and the

withholding period for the chemical must be observed. All pigs are treated twice at the recommended interval for the acaricide used. If only the sow herd is to be treated, two options are available. All sows and boars can be treated at the recommended interval, or individual sows can be treated prefarrowing and moved to clean pens or crates. If the latter approach is taken, boars should be treated every 3 months, and the progeny of treated sows must be isolated from the progeny of untreated sows. Eradication is made easier in growing pigs by changing from a continuous-flow management system to an all-in/all-out system, such as age-segregated-rearing or multiple-site production. However, changing the management system must be combined with effective prefarrowing treatment of sows. All of these approaches can be effective and are justified economically.

Control. Mange control involves identification of animals with chronic mange so that they can receive systematic and regular treatment to protect the younger animals in the herd. All control programs must target the breeding herd. Mercier et al. (2002) demonstrated that a single dose of ivermectin (300 μg ivermectin/kg live weight) administrated to the sows 8 days before farrowing was very effective in preventing the transmission of mites to piglets. Any animals with extensive hyperkeratotic lesions in the ears and over the body should be culled, and the remainder of the sows treated either simultaneously or alternatively in segregated groups prior to farrowing. The boars should be treated every 3–6 months to prevent the spread of mites at mating. Piglets born to sows that are free of mites and housed in clean pens will remain free of mites unless they are exposed to infested pigs after weaning (Cargill et al. 2004). If mange is present in both breeding and growing pigs, the whole herd must be treated along with all introductions into the herd. Contaminated bedding should be removed and the environment sprayed with insecticide. Humans who handle infested pigs can also transfer mites to uninfested animals on their clothing (Mock 1997). Therefore, it is important that workers work with only one herd (infested or uninfested) or change clothes and shower before moving onto work with another herd.

DEMODECTIC MANGE

In contrast to sarcoptic mange, demodectic mange is relatively unimportant in pigs. It is a condition identified occasionally at meat inspection and is seldom reported as a clinical entity in the field.

Distribution throughout the world and in pig populations is not well documented. It has been reported in many countries, including Australia, the United States, Kenya, New Zealand, and several European and Pacific island countries.

The agent of swine demodectic mange is the mite *Demodex phylloides* (Figure 53.4). This spindle-shaped
53.4. Demodex phylloides, *the demodectic mange mite. Female, dorsal view (left) and ventral view (right). (From Hirst 1922. British Museum. Economic series 13.)*

mite measures about 0.25 mm in length and has four pairs of short, stumpy legs. It lives in the hair follicles, and for this reason the condition is often referred to as follicular mange. The life cycle of the mite is not well understood. The female lives in the hair follicle and lays spindle-shaped eggs, from which larvae with three pairs of legs hatch. The larval stage progresses through three nymphal instars to the adult (Soulsby 1968). Approximately 2 weeks are required to complete the life cycle, and the life span of the adult is 1–2 months.

Transmission of the mites is probably by direct contact of pigs, but it is difficult to produce artificial infestations. The parasites are able to survive for several days off the host in moist surroundings and up to 21 days under experimental conditions in pieces of skin kept moist and cool (Nutting 1976). However, the mites will live for only 1 or 2 days if removed from the host tissue and can be killed by desiccation in as little as 1 hour at 20°C on the skin surface.

Lesions observed are red pinpoint foci around the snout and eyelids, along the underside of the neck and abdomen, and inside the thighs (Walton 1967). Later, the lesions may take on a more scaly nodular appearance, particularly in the area of the mammary gland and flanks. These nodules resemble old pox lesions and when incised contain a thick, white, cheeselike material with innumerable mites (Harland et al. 1971). Mites

have been recovered in scrapings from the eyelids of swine that have shown no gross signs of infestation (Nutting et al. 1975) and most infestations are probably asymptomatic.

Diagnosis of the condition is confirmed by demonstration of *D. phylloides* in the lesions. Although there are no reports of successful treatment of pigs with any form of medication, either topical or systemic, both ivermectin and amitraz have been used successfully in dogs (Murthy et al. 1993). Severely affected animals should be culled from the herd.

LICE

Lice in pigs are readily observed and often blamed for damage due to mange because both conditions cause irritation and rubbing. Herds treated routinely to effectively control mange seldom carry significant lice populations, and many are probably free of lice. The sole species of lice that affects pigs (*Haematopinus suis*) belongs to the suborder Anoplura and has piercing and sucking mouthparts. It is grayish brown in color and has black markings. The females are about 6 mm long and the males slightly smaller (Figure 53.5). The pig louse is distributed almost worldwide. A survey of market pigs in Indiana in 1980–81 demonstrated lice in 22.5% of 821 herds surveyed (Wooten-Saadi et al. 1987b), but the parasite is likely to be much less prevalent in contemporary production systems.

The life cycle of *H. suis* was described by Florence (1921). The adult female lays 3–4 eggs (nits) each day, to a total of up to 90 over a period of about 25 days. Each egg is about 1–2 mm long and is attached by clear cement to the hair. Eggs hatch in 12–20 days. The nymphs develop through three instars, all of which feed on blood that is generally from a tender part of the body such as the inner surface of the ear. The third instar nymphs develop into adults. The whole cycle takes 23–30 days (Walton 1967) and epidemiology is uncomplicated. The pig louse is host-specific and cannot live for more than 2–3 days away from the host.

Lice are found on all parts of the body but particularly in the folds of the skin around the neck, jowl, and flanks, and on the inner surfaces of the legs. They often shelter inside the ears, where they are sometimes seen in "nests." The method of spread is by direct contact among pigs during huddling, although clean pigs placed in a yard just vacated by lousy pigs can become infested.

The economic importance of lice has not been critically evaluated to the same extent as sarcoptic mange has. However, it is known that heavy infestations result in anemia in young pigs and may affect growth rate and efficiency of food conversion. One estimate of reduced growth was 50 g/day (Hiepe and Ribbeck 1975), though Davis and Williams (1986) failed to demonstrate any such effect. Lice have always been considered vectors of
53.5. Haematopinus suis, *the pig louse. (From Whitehead 1942. Macdonald College Farm Bull 7.)*

swinepox. It has also been reported that hides from pigs with lice are rendered unsuitable for manufacture into high-grade leather (Hiepe and Ribbeck 1975).

Diagnosis

Lice should always be considered in the differential diagnosis of pruritus in pigs. Infestation can be confirmed by identifying adult lice on the body and nits attached to the lower parts of hairs. Examination inside the ears of a number of breeding animals will assist in finding lice if they are present and will enable differential diagnosis from sarcoptic mange.

Treatment and Control

Treatment and control of lice are readily achieved because the parasites live on the skin surface and can survive for only a few days away from their host.

Therapeutic agents may be applied to the pig in the form of sprays, pour-ons, and dusting powders. Control can also be assisted by placing granules containing insecticides in the bedding. Pour-ons and powders have the advantage that pigs do not have to be sprayed in cold weather.

The older treatments of diesel oil and crankcase oil applied to the pig either directly or from rubbing posts are of limited value and have been largely superseded by insecticides of the organochloride and organophosphorus compounds, which are effective and easier to apply. Several of the organophosphorus compounds, such as rabon, ciodrin, ronnel, coumaphos, and methoxychlor,

are suitable for lice control but are less commonly registered for treatment of sarcoptic mange (refer to Table 53.1). In addition, avermectins have been shown to be effective in controlling lice (Barth and Brokken 1980).

Control and eradication strategies listed for sarcoptic mange apply equally to the treatment of lice. These include special attention to the ears, treatment of the boars, multiple treatment of sows prior to farrowing, segregation of clean and untreated animals if all the herd is not treated at one time, and treatment of all introduced animals. Eradication of lice by thorough treatment of the whole herd is an achievable goal.

FLEAS

Fleas are not host-specific and will parasitize any convenient mammal or bird to obtain a blood meal. The two fleas most commonly associated with swine are *Pulex irritans*, the human flea, and the stickfast flea *Echidnophaga gallinacea*. *Ctenocephalides canis*, the dog flea and *C. felis*, the cat flea, also occasionally infest young swine. *Tunga penetrans,* the chigger flea, has been associated with pigs in Africa.

The distribution of fleas in nature is wide, but they are seldom a serious problem in the well-managed piggery. These wingless insects are 2–4 mm in length, have a thick, brown chitinous exoskeleton, and have powerful legs.

Life cycles are similar for all flea species. The female lays eggs about 0.5 mm long, which drop off the host into the animal bedding. Larvae hatch in 2–16 days and feed on dry blood, feces, and other organic material. With moderate temperature and high humidity, the larvae mature in 1–2 weeks and pass through a pupal stage. The whole life cycle takes as little as 18 days but may take in excess of 1 year depending on environmental conditions (Soulsby 1968).

Only the adult flea is parasitic in that it requires periodic blood meals. The stickfast flea differs from the others, spending most of its adult life on a host animal.

Fleas can survive for many months in the absence of a host. Survival is dependent on whether they are fed and the degree of moisture in the environment. Under optimal conditions the human flea can live for over 2 years.

Although fleas appear to be relatively unimportant in pig production, severe infestations have been reported recently in outdoor pig herds in New Zealand (Dobinson 2000). Clinical signs recorded were bright red discoloration of the skin, fleabite marks over the mammary glands, edema of the prepuce in boars, and sows spending more time in wallows. Because infestations occurred primarily over summer, it was difficult to determine whether production losses were flea- or weather-related. An allergic dermatitis similar to that described in dogs has also been described in pigs, and its signs resemble those seen in the allergic form of sarcoptic mange (Nesbitt and Schmitz 1978).

T. penetrans infestation has been reported as being associated with agalactia in sows in the Republic of Zaire (Verhulst 1976). Clinical examination showed that the ovigerous females (chiggers) were localized in the teats and obstructed the ducts. This produced agalactia and death of piglets. An outbreak of *T. penetrans* was also reported in Tanzania in which adult pigs were affected around the feet, snout, and scrotum (Cooper 1967).

Diagnosis and Treatment

Diagnosis of flea infestation is not easy, because adult fleas may leave the host, and larvae and eggs are difficult to find. The bites are not readily differentiated from those of mosquitoes, lice, and mites, so the presence of those other parasites should be carefully checked before a diagnosis is made. Infestation of humans during contact with pigs is also a good diagnostic aid (Dobinson 2000).

The range of chemicals used to treat and control fleas include many of the products listed for other external parasites. According to Dobinson (2000), amitraz, coumpaphos, maldison, doramectin, and ivermectin have all been used successfully to treat pigs and their bedding. However, although pigs are easily treated, ridding the environment of fleas is more difficult. Control is based on the location and treatment of the flea-breeding area, but it is important to use chemicals with published withholding periods so that pigs can be held in a chemical-free environment for the appropriate period before slaughter. Although litter, bedding, dirt, and manure should be removed and burned, this is not always practical until the pigs are moved. Environmental control has been achieved with primiphos and chlorpyrifos (Dobinson 2000) or 2.5% malathion.

MOSQUITOES

Mosquitoes, although considered primarily pests of humans, also attack livestock, causing discomfort and irritation. In some cases the affected carcasses of pigs must be skinned at slaughter.

Aedes spp. have been observed attacking swine in large numbers in Florida (Bennett 1975; Becker and Gross 1987). In South Australia the same species has bred in brackish pools of seawater left by high tides and has caused troubles in nearby piggeries (Dobson 1973). Lesions appeared on several or all the pigs within a pen in the form of raised edematous weals on the legs and abdomen. These tended to disappear spontaneously within 1–2 days but made pigs unacceptable for marketing at the time. Control was achieved by regular spraying with diazinon in the late evening. Mosquito screening and insect repellents are also helpful in minimizing the problem. Where possible, the breeding ground of the mosquitoes should be identified. The larvae can be destroyed by either draining water reservoirs or covering the surface with oil. A wide range of insecticides has been used successfully in breeding grounds.

Mosquitoes have a seasonal distribution, with populations disappearing in most temperate regions during winter. Mosquitoes are important vectors in the transmission of Japanese encephalitis virus, especially in rice-growing areas (Wada and Smith 1988). Vaccination has proved unsuccessful, and pigs must be separated from rice fields to prevent them from acting as amplifier hosts. Mosquitoes can also mechanically transmit porcine reproductive and reproductive syndrome virus (PRRSV), but do not serve as a biological vector of the virus (Otake et al. 2003a, 2002). The virus can also reside in the intestinal tract of the mosquito for up to 6 hours, but does not survive on the exterior surface of the insect. Mosquitoes also transmit *Mycoplasma haemosuis* between pigs (Prullage et al. 1993).

FLIES

Flies are important in pig production for several reasons, and they tend to be used as a measure of hygiene by local health authorities. Some flies annoy animals by their vicious bite, and others act only as a vehicle for transmission of infectious disease. Some species are associated with myiasis, that is, invasion of the tissues of animals by fly larvae.

The common housefly (*Musca domestica*) is ubiquitous and most active in summer. It prefers to breed either in the feces of animals or in decaying organic matter. The housefly is well known for its ability to transfer pathogenic bacteria mechanically via its hairy feet and legs or by regurgitation of fluid from its crop. It can also act as the intermediate host of several worm parasites of domestic animals, and it may act as a disseminator of the eggs of many others (Soulsby 1968). It has been demonstrated experimentally that it is capable of spreading hog cholera (HC) virus (Morgan and Miller 1976) and *Streptococcus suis* (Enright et al. 1987) from infected to susceptible pigs.

The stable fly (*Stomoxys calcitrans*) is about the size of the housefly, but it prefers to breed in moist, decaying vegetable matter such as straw and hay. Flies are most abundant in summer and prefer fairly strong light rather than dark stables or houses. Both male and female are bloodsuckers of humans and animals. When present in large numbers, the stable fly may become a source of annoyance, resulting in weight loss. However, Campbell et al. (1984) were not able to demonstrate reduced gain or feed conversion experimentally. The stable fly can also act as a vector of infectious organisms, including HC and *Mycoplasma haemosuis* (Prullage et al. 1993).

Horseflies of the Tabanidae family are large, robust flies with clear, powerful wings. The common breeding place is on the leaves of plants in the vicinity of water. Horseflies are active in summer, particularly on hot, sultry days. They attack animals, including pigs, by biting and feeding on blood (Tidwell et al. 1972). They are capable of transmitting infectious diseases, including HC (Tidwell et al. 1972).

Blackflies of the family Simuliidae, also known as buffalo gnats, occur in all parts of the world and can be troublesome in warm countries. They breed in streams below the surface of running water. They may cause inappetence and attack the legs, abdomen, head, and ears, resulting in vesicles and papules. Considerable numbers of stock have been killed in European countries. Grafner et al. (1976) reported the death of 3 sows and severe illness in another 27, together with reduced growth rate, in pigs in Germany.

Screwworm flies of the family Calliphoridae cause myiasis in humans and animals. *Cochliomyia hominovora* is present in Latin America, and *Chrysomya bezziana*, the Old World screwworm fly, occurs in Africa and southern Asia. The adult fly is 10–15 mm long and has a metallic green sheen to its thorax and abdomen. It has three longitudinal stripes on the thorax. It breeds in wounds on live animals, and each female lays 150–500 eggs at the edge of a wound. Larvae hatch in 10–12 hours and mature in 3–6 days, after which they leave the host to pupate in the ground. The pupal period lasts from 3 days to several weeks, depending on prevailing temperatures. Hibernation occurs most commonly in the pupal stage (Soulsby 1968).

Most cases of myiasis occur in rainy weather. Maggots penetrate the wound tissue, which they liquefy and thus extend the lesion. There is a foul-smelling exudate and deaths can occur. Loss can be prevented if surgical wounds are avoided during the fly season and prompt attention is given to lacerations and injuries. Wounds can be protected from myiasis by the application of a prophylactic wound dressing. Smear 62 (containing diphenylamine, benzol, turkey red oil, and lampblack) or, alternatively, EQ335 (containing 3% lindane and 35% pine oil) will protect wounds for at least 3 days (Bennett 1975). After wounds are invaded by larvae, they may be effectively treated with pressurized aerosols containing coumaphos, lindane, or ronnel (refer to Table 53.1). The larvae in wounds can be killed if penetration is not too deep.

Blowflies of the subfamily Calliphorinae differ from screwworm flies in that they deposit their eggs in necrotic wounds. Secondary blowflies deposit their eggs only on necrotic wounds that have been previously struck by either primary blowflies or screwworm flies. The damage caused by blowflies is similar to but less severe than that caused by screwworms. Treatment and prevention are similar.

Houseflies can also mechanically transmit PRRSV, but as with mosquitoes, do not serve as biological vectors of the virus. According to Otake et al. (2004, 2003b), the virus also resides in the intestinal tract of the housefly for up to 12 hours, but not on the exterior surface of the fly.

Control

Fly control in all piggeries must be a continuing exercise in summer months. The aim is to prevent flies from

breeding and to destroy adult flies. Breeding of flies can be prevented by regular removal of dung. At temperatures of 25°C or more, the life cycle of the housefly takes only 15 days; hence frequent cleaning is important. Manure should be removed at least weekly and spread thinly on soil to kill eggs and larvae by desiccation. Dung should be disposed of in the center of effluent ponds rather than at the edge, where flies can breed. A number of methods can be used to destroy flies within pig sheds. Insecticides are effective in the form of sprays, baits, or vapors strips (refer to Table 53.1). Some insecticides such as trichlorfon, given to pigs as a medication for internal parasites, are effective in destroying both the larvae and adult flies that settle on dung from treated pigs.

Sprays are applied to walls, ceilings, and pen partitions within sheds. With some insecticides, stock and feed may need to be removed first. Space or aerosol sprays (foggers) used twice daily with knockdown insecticides are also effective. Baits applied to clean concrete surfaces and pen divisions are effective and usually contain insecticides such as ronnel, diazinon, malathion, trichlorfon, and dichlorvos.

Fly electrocutors offer an automatic nonchemical method of controlling flies. Screens on openings help limit the number of flies entering buildings but can be impractical. Electric-light traps can be used as an auxiliary in fly control but are considered more efficient for midges rather than flies (Schmidt 1987).

TICKS

Ticks infest many species of mammals and birds and are generally not host-specific. Compared with grazing species, in which ticks and tick-borne diseases are of major economic importance, pigs are not commonly parasitized by ticks, and ticks essentially do not occur on pigs raised in confinement. The ticks of potential importance to pigs are of the suborder Ixodoidia, which includes two large families, the Ixodidae (or hard tick) and the Argasidae (or soft tick).

In the United States the following ticks have been reported as occurring on swine:

Ixodidae
- *Dermacentor andersoni* (Rocky Mountain spotted fever tick)
- *D. variabilis* (American dog tick or wood tick)
- *D. nitens* (tropical horse tick)
- *Amblyomma maculatum* (Gulf Coast tick)
- *Ixodes scapularis* (black-legged tick or shoulder tick)

Argasidae
- *Ornithodoros turicata* (relapsing fever tick)
- *Otobius megnini* (spinose ear tick)

In Australia, *I. holocyclus,* the dog paralysis tick, has been known to cause death in suckling pigs (Seddon 1968). In general, species of ticks are adapted to specific ranges of temperature and humidity, and the reader should seek local information to assist in identifying specific species.

Life cycles of ticks are characterized by the stages of egg, larva (seed tick), nymph, and adult. The six-legged seed tick, on hatching from the egg, climbs onto grass or shrubs, and waits until a suitable host passes. It attaches itself to the host and engorges with lymph and blood. It then molts and an eight-legged nymph emerges. This feeds on the host and molts to become an adult tick. After mating, the female drops off the host, lays her eggs, and dies.

The main economic importance of ticks for all species is their ability to act as vectors in disease transmission. Pathogens transmitted by ticks include protozoa, rickettsias, and viruses. African swine fever virus, when introduced experimentally to the tick *Ornithodoros moubata,* could be recovered 50 weeks after infection (Greig 1972). Therefore, ticks could be of significance in the spread of viral diseases from wild pigs to domestic animals.

Diagnosis

The diagnosis of tick infestation is based on the known location of ticks and the access of pigs to these areas. Ticks are readily seen by gross visual examination. Although found on any part of the body, they are more often seen around the ears, neck, and flanks. The tick differs from other arthropod parasites in that it is attached to its host. The size and appearance vary according to the degree of blood engorgement. A careful check should be made in the ear for the *Otobius* ear tick.

Treatment and Control

The treatment and control of ticks in pigs are seldom problems. If only a few ticks are present, these can be removed manually and the pigs confined away from infested pasture. Many insecticides are effective as a spray or dip. Toxaphene as a 0.5% spray is recommended because it will protect against reinfestation for 2 weeks or longer (McIntosh and McDuffie 1956). Other effective acaricides include coumaphos, dioxathion, and malathion (refer to Table 53.1). A 5% coumaphos dust has been used effectively in the ears to control the spinose ear tick.

54 Gastric Ulcers

Robert M. Friendship

This chapter focuses on ulceration of the pars oesophagea, the non-glandular region of the pig's stomach surrounding the esophageal entrance. This syndrome is distinct from ulceration of the fundic and pyloric regions. Often erosions in the glandular area of the stomach are associated with systemic diseases such as salmonellosis, erysipelas, or hog cholera infection. On the whole, ulceration of the pars oesophagea is the far more common and important of the two conditions and can lead to sudden death from acute intragastric hemorrhage or to chronic ill thrift. In addition to "gastric ulceration," various terms have been used to describe this condition, including "esophagogastric ulceration" (Driesen et al. 1987), "gastroesophageal ulceration" (Deen 1993), "proventricular ulcer" (Ito et al. 1974), and "ulcerative gastric hemorrhage" (Hannan and Nyhan 1962).

The first description of pars oesophageal ulceration was made in 1897 (McIntosh 1897), but little attention was paid to this condition until modern husbandry practices were adopted. Epizootic outbreaks of pars oesophageal ulceration began to occur in North America and Europe in the late 1950s (Thoonen and Hoorens 1961; Curtin et al. 1963; Griffing 1963; Muggenburg et al. 1964) concurrent with new developments in housing and feeding. Wherever in the world the introduction of confinement rearing and the use of grain-based processed rations have occurred, the problem of gastric ulcers has arisen. This syndrome is of economic significance, and its relative importance is increasing despite a growing knowledge of the risk factors and therapeutic procedures.

ETIOLOGY

The exact cause or causes of gastric ulceration is not completely understood, but many of the risk factors are well known. A list of some of the factors that have been reported to be associated with gastric ulceration in pigs are presented in Table 54.1.

There is considerable interaction between many of these factors, particularly in their effect on the fluidity of the stomach content, the speed of passage of ingesta through the stomach, and whether or not the stomach contains feed. Generally, factors that increase the firmness of the stomach content help prevent gastric lesions and factors that cause increased fluidity of the contents increases the risk of ulcers (Nielsen and Ingvartsen 2000).

Fine particle size of feed has been shown to increase the prevalence of gastric lesions (Mahan et al. 1966; Reimann et al. 1968; Maxwell et al. 1970, 1972; Hedde et al. 1985; Potkins and Lawrence 1989a; Wondra et al. 1995a; Ayles et al. 1996a). In addition, pelleting of feed may also increase the likelihood of ulcers developing (Griffing 1963; Chamberlain et al. 1967; Potkins and Lawrence 1989b). The prevalence and severity of ulcers vary with the cereal component of the diet. Generally, oats and barley appear to have a sparing effect (Reese et al. 1966) and corn and wheat tend to be more ulcerogenic (Smith and Edwards 1996).

The method by which the grain is processed affects the prevalence of ulcers. Grain that is ground using a hammer mill tends to be more ulcerogenic than if a roller mill is used (Wondra et al. 1995b; Nielsen and Ingvartsen 2000). Feed particle size is affected by grain component, milling procedure, and processing. Grains such as wheat are more likely to shatter during grinding and result in finer particle size compared to oats or barley. If grain is processed using a roller mill, there is less chance of the grain kernel shattering and creating "fines."

In addition, the pelleting process causes a further decrease in particle size. Neilsen and Ingvartsen (2000) showed that, in general, barley and rolling prevented stomach lesions while wheat grinding and pelleting increased the prevalence and severity of ulcers. The overall effect of a feed with very fine particle size is that the stomach content is very fluid and the emptying time is relatively rapid (Regina et al. 1999), and as a result, the pH gradient between the neutral proximal part of the stomach and the acidic distal region is lost.

Table 54.1. Risk factors associated with ulceration of the *pars oesophagea* in swine

Nutrition	Housing/Management	Other
Feed particle size	Confinement rearing	Season
Type of grain	Herd size	Concurrent disease
Milling	Mixing pigs	Parturition
Pelleting	Overcrowding	Heredity
Grinding vs. rolling	Holding and transport	Somatotropin
Heat processing	Feeding regimen	Histamine
Lack of fiber		*Helicobacter* infection
Vitamin E/Se deficiency		Porcine circovirus type II
Rancid fat		
Withdrawal of feed		

The method of feeding may be as important as feed processing and composition. A major risk factor of ulcer development is an interruption of feed intake (Henry 1996). Fasting of pigs has been a consistent method of experimentally producing gastric lesions (Pocock et al. 1968; Lawrence et al. 1998). Various workers have noted dramatic increases in ulcer severity and prevalence at slaughter in pigs examined after a 24-hour holdover period compared to pigs from the same herds slaughtered on the day of arrival at the abattoir (Chamberlain et al. 1967; Straw et al. 1992; Davies et al. 1994; Lawrence et al. 1998). There is at least one study that documented no association between a 24-hour feed withdrawal and an increased prevalence or severity of ulcers (Eisemann et al. 2002). Presumably, there is an interaction between factors affecting stomach emptying such as feed particle size and the effect of feed withdrawal that can explain the differences in findings between these studies.

Feeding regimen can influence ulcer development, although much of the work in this area is contradictory. For instance, Blackshaw et al. (1980) found fewer ulcer lesions in pigs fed twice daily than in pigs fed ad libitum, whereas Robert et al. (1991) found a similar prevalence of ulcers in pigs fed ad libitum and pigs fed twice daily but noted that ulcers were less severe in ad libitum–fed pigs. One can speculate that stability in the feeding regimen is critical and ultimately more important than whether pigs are routinely fed once a day, twice a day, or ad libitum.

Interruption of normal feed intake commonly occurs on almost all farms because of mechanical problems or human error. Periods of transition in feeding patterns such as when gilts are transferred to the breeding herd from a finishing barn or when sows approach the time of parturition, should be viewed as high risk for ulcerogenic events (Henry 1996). Hot weather resulting in dramatic reduction in feed intake is associated with gastric ulcer outbreaks (Deen 1993).

It is likely that factors such as acute infectious disease and season influence ulcer development in a similar manner to management practices that interrupt feed intake. Acute respiratory disease is associated with an increased likelihood of gastric ulceration (Dionissopoulos et al. 2001). In addition to respiratory disease causing inappetence, it is possible that increased levels of histamine as a result of infection could play a role, in that histamine is a powerful stimulant of gastric acid secretion. Injection of histamine has been shown to experimentally produce ulceration of the pars oesophagea (Muggenburg et al. 1966; Huber and Wallin 1965; Hedde et al. 1985). Experimental infection of gnotobiotic pigs with various viral pathogens, including porcine reproductive and respiratory syndrome virus, does not result in gastric ulceration; however, experimental infection of porcine circovirus type II has caused gastric lesions (Harms et al. 2001).

There has been considerable interest in finding an infectious cause of porcine gastric ulcers similar to the situation in humans. *Helicobacter*-like organisms have been identified in the glandular region of the stomach (Mendes et al. 1990) and appear to be widespread in the pig population (Grasso et al. 1996; Magras et al. 1999; Melnichouk et al. 1999). Whereas some workers have observed a correlation between the presence of these bacteria and the prevalence and severity of gastric ulcers (Barbosa et al. 1995; Queiroz et al. 1996), other researchers have not (Magras et al. 1999; Melnichouk et al. 1999).

Inoculations of *Helicobacter*-like organisms from pigs and *Helicobacter pylori* from humans have both been used to infect gnotobiotic pigs (Krakowka et al. 1995). These organisms colonize and cause irritation and lesions in the glandular region, but have not been shown to cause ulceration of the pars oesophagea. More work is necessary to clearly understand what significance these organisms have in the pig, but it is unlikely *Helicobacter* play such a significant role in ulceration of the para oesophagea of the pig compared to their importance in human peptic ulcer disease. It should be noted that the stomach ulcer problem in pigs is more like the human condition "oesophageal-gastric reflux disease" than peptic ulcer disease.

Before *H. pylori* became recognized as the main cause of gastric ulceration in humans, the accepted theory was that ulcers were caused by excessive acid secretion stimulated by stress. This theory has been examined exten-

sively in pigs. The onset of the first cases of porcine gastric ulcers occurred at the time of confinement rearing and increased intensification were first adopted. Certain studies have shown that the prevalence increases as herd size increases (Christensen and Cullinane 1990) and as stocking density increases (Pickett et al. 1969). However, there are other studies contradicting the belief that overcrowding is a risk factor (Driesen et al. 1987; Eisemann and Argenzio 1999a). It is likely that factors such as available feeder space and environmental temperature interact with stocking density to cause these contradictory results. Research clearly demonstrates that ulceration of the pars oesophagea is not mediated by glucocorticoids (Zamora et al. 1980). Chronic elevation of corticosteroids in response to stressful conditions has been shown under controlled trials to not result in an increase in ulcer prevalence or severity (Jensen et al. 1996).

Genetic susceptibility may play a role in ulcer development. Researchers have reported a link between fast growth rate and/or low backfat and a high prevalence of gastric ulcers (Berruecos and Robinson 1972; Grondalen and Vangren 1974). It has also been reported that injection of swine with porcine somatotropin causes an increase in prevalence and severity of ulcers (Smith and Kasson 1991).

In summary, many of the factors associated with an increased risk of ulcer development are closely tied to economic competitiveness such as the use of finely ground feed and fast-growing, lean genetics. Therefore, steps to reduce the prevalence of gastric ulcers need to be carefully balanced between economic considerations and welfare concerns.

EPIDEMIOLOGY

Gastric ulceration is common and widespread. Table 54.2 presents findings of various studies worldwide. Abattoir surveys demonstrate that the prevalence of stomach lesions, including parakeratosis, erosions, and ulcers, often approaches 90% when pigs are managed using modern confinement husbandry practices (Driesen et al. 1987). There is great herd-to-herd variation in prevalence and severity. Ulceration of the pars oesophagea can affect any age of pig but the highest rate of ulceration occurs in pigs 3–6 months of age. Mortality due to gastric ulceration among grower-finisher pigs has been reported to be about 1–2% on some farms, with much higher levels occurring sporadically (Deen 1993; Melnichouk 2002). Sows at the time of parturition are also a relatively high risk group. Examination of culled sows revealed 60% with stomach lesions and 10–15% with ulcerations (Hessing et al. 1992; O'Sullivan et al. 1996). Frequently, sow stomachs have extensive scar tissue, indicating previous severe ulcerative episodes. Gastric ulceration has been reported as a common cause of sow mortality (Sanford et al. 1994; Chagnon et al. 1991).

PATHOGENESIS

The pars oesophagea has a cornified stratified squamous epithelium and does not secrete protective mucus. It is generally assumed that chronic insult of this sensitive tissue results in hyperplasia of epithelial cells and thickening from layers of 10–20 cells to layers of 60–80 cells or more and keratinization (Driesen et al. 1987; Roels et al. 1997). Rapid cell development results in the production of immature cells, and the thickened layers of cells tend to outgrow their nutrient supply. As a consequence, the tight junctions between epithelial cells break down, allowing digestive juices access to underlying tissues. Initially, superficial layers of epithelium are lost, but if the insult continues, deeper erosions develop and affect the lamina propria and, eventually, the muscularis mucosa and submucosa. Erosion and damage can spread rapidly, destroying the entire pars oesophageal region. Ulceration ends abruptly at the junction of the glandular portion and the pars oesophagea,

resulting in a thick inflammatory ridge of edematous tissue separating normal and damaged areas.

There is still uncertainty as to the exact mechanism of insult that causes injury to the relatively unprotected pars oesophagea. In all likelihood there are several mechanisms that can cause tissue damage and various factors that might weaken the defensive barrier protecting the stratified squamous mucosa.

Because gastric ulceration is commonly associated with conditions that cause greater fluidity of the contents of the stomach and therefore a breakdown of the pH gradient between the distal and proximal portions, it is reasonable to assume that the increased acidity of the proximal stomach is a key factor in causing tissue damage. However, the stratified squamous mucosa of the pars oesophagea is relatively resistant to injury from HCl alone (Argenzio and Eisemann 1996). Studies have shown that pigs fed finely ground diets and/or are fasted tended to have high concentrations of bile acids in the proximal stomach (Lang et al. 1998). In vitro studies of pig tissue have shown that a combination of low pH and a conjugated bile salt concentration of ≥ 1 mmol/l can induce extensive tissue damage (Lang et al. 1998). Similarly, short chain fatty acids produced at relatively high concentrations by bacteria in the proximal portion of the stomach may be implicated in causing gastric ulceration, in that these acids can diffuse rapidly across tissue barriers as the luminal pH is reduced (Argenzio and Eisemann 1996).

It has been hypothesized that as HCl concentrations are increased, more of the short chain fatty acids would become undissociated, augmenting their rate of absorption. Lesions in the pars oesophagea were produced experimentally by feeding a carbohydrate-enriched diet to gnotobiotic pigs and inoculating the pigs with two different fermentative commensal bacteria, *Lactobacillus sp* and *Bacillus sp* (Krakowka et al. 1998). The importance of short chain fatty acids in causing gastric ulcers under farm conditions is uncertain. Generally, diets associated with producing the highest level of short chain fatty acids are the coarse-ground rations and nonulcerogenic finely ground diets (Argenzio 1999).

It is possible that in addition to the production of short chain fatty acids and the breakdown of the pH gradient caused by increased fluidity of the stomach contents and thus the combination of bile and HCl contacting the pars oesophagea, there may be other factors that interact with these agents. One obvious possibility is the hypersecretion of HCl which might occur with histamine release (Muggenburg et al. 1966) or by other mechanisms. It has been suggested that *Helicobacter sp* may play a role in ulcer development by somehow inducing excess acid secretion (Yeomans and Kolt 1996). However, hyperacid secretion has not been observed in trials using experimental *Helicobacter sp* infection (Krakowka et al. 1995 1998).

Diet may influence the defensive mechanisms of the pars oesophagea. Gastric ulcers have been observed in association with deficiencies of vitamin E or selenium (Van Vleet et al. 1970) presumably due to increased generation of reactive oxygen metabolites. In a recent study, focusing on the antioxidant defense system in stratified squamous mucosa, pigs fed a finely ground diet were found to produce higher levels of peroxides than pigs fed a coarse ration (Eisemann and Argenzio 1999a, b). These authors speculate that the generation of prooxidants and the antioxidant defense system may play a role in the predilection of gastric ulcers.

CLINICAL SIGNS

Ulceration occurs rapidly and the progression from normal pars oesophagea to complete ulceration may take less than 24 hours. Clinical signs tend to reflect the degree of blood loss associated with the gastric lesion. Frequently, a pig that had appeared to be healthy only a few hours earlier is found dead and the carcass is extremely pale. If blood loss occurs more slowly, signs associated with anemia will be apparent, such as paleness, lethargy, weakness, increased respiratory rate, and anorexia. In addition, black tarry feces may be noted, and some pigs show signs of abdominal pain by grinding their teeth and arching their backs. Vomiting may occur. Rectal temperatures of affected pigs are often below normal.

Sporadic outbreaks of gastric ulceration tend to occur among grower-finisher pigs, and frequently when one pig has suddenly died, careful observation will reveal others in the group that are showing signs of anemia. When ulceration occurs without significant blood loss, animals will generally appear to be in normal health. Evidence that subclinical ulceration reduces growth rate is inconsistent. Various researchers have attempted to correlate severity of stomach lesions at slaughter with growth performance during the grower-finisher phase. Certain studies have found no relationship (Pocock et al. 1969; Backstrom et al. 1981), whereas Elbers et al. (1995a) observed a 50–75 g per day decrease in growth rate for pigs with ulcers versus pigs with normal stomachs. This last result is in agreement with findings of a trial that followed pigs using endoscopic examination to measure gastric lesions (Ayles et al. 1996b).

Ulcers can occur rapidly and heal quickly, making it difficult to relate lesions at slaughter with performance during the grower-finisher stage. Evidence of past ulceration can sometimes be seen as cicatrization and a reduction in size of the pars oesophagea. In extreme cases, the pars oesophagea is entirely destroyed, and stenosis of the esophagus at its entry to the stomach occurs. Pigs afflicted with stenosis are observed to vomit shortly after eating but are hungry and therefore will immediately resume eating. These pigs tend to grow more slowly than penmates despite maintaining good appetites.

LESIONS

Lesions associated with ulceration of the pars oesophagea rarely extend into the contiguous esophagus or the glandular region of the stomach. Ulcerations and erosions of the pars oesophagea may involve only a small portion or all of the gastric squamous mucosa. The most common site for ulceration is at the junction of the pars oesophagea and the cardiac mucosa (Penny and Hill 1973). The normal epithelium of the pars oesophagea is smooth, white, and glistening and is easily distinguished from the surrounding glandular mucosa. It is believed that lesions usually progress from parakeratosis that causes a thickened, rough appearance to fissuring and peeling that result in erosion and eventually ulceration.

Frequently, the pars oesophagea is yellowish as a result of bile staining, particularly when the surface is rough and thickened due to parakeratosis. This type of corrugated surface may flake and peel off readily. When ulceration involves the entire pars oesophagea, the lesion has a punched-out or crater-like appearance with elevated ridges. The floor of the ulcer may be so smooth that it is misinterpreted as normal (Barker et al. 1993). The relationship between gross and microscopic lesions has been investigated by Embaye et al. (1990), who concluded that, generally, gross appearance was directly related to microscopic findings. However, these researchers found that in 155 apparently normal stomachs, 32% showed histologic evidence of parakeratosis, 30% had minor erosive lesions, and microscopically 23% had severe ulceration.

Gross evaluation of stomach lesions is commonly incorporated into an abattoir surveillance program to monitor disease status. To examine the pars oesophagea, the stomach should be incised along the greater curvature and inverted. Emptying the contents and rinsing the stomach before examination will improve the accuracy of the inspection. Various classification schemes have been used to grade stomach lesions at slaughter (Christensen and Cullinane 1990; Ayles et al. 1996a), and an example of such a system is presented in Table 54.3.

Histologically, the lesion is the result of thickening and parakeratosis, with nucleated cells present on the mucosal surface. Rete pegs and proprial papillae are elongated, and neutrophils and eosinophils are often present at the tips of the proprial papillae. Epithelial

separation and erosion usually occur beneath a band of cells with cytoplasmic pallor and nuclear degeneration (Embaye et al. 1990). Ulcers of the pars oesophagea usually involve only the submucosa, but they may advance to the muscularis externa and occasionally to the serosa (Barker et al. 1993).

In the case of a pig that has died acutely of gastric ulceration, postmortem diagnosis is usually straightforward. The carcass is typically pale but in good body condition. The stomach may contain clotted and unclotted blood and fibrinous exudate enclosing a variable amount of food. Blood may be found in the intestine as well. A blood clot may be adhered to the surface of the ulcer, which is generally deep and extensive in the case of a fatal hemorrhagic episode.

Gastric ulcers can heal by granulation and reepithelialization. Scarring can occur and, if extensive, may lead to occlusion of the esophageal opening into the stomach.

DIAGNOSIS

Often diagnosis is accomplished on the basis of gross postmortem findings and clinical history. Typically, only one or two animals in a large group of grower-finisher pigs are noticed to be ill or are found dead. Lesions in the stomach are readily observed and generally diagnostic. Determining the prevalence and severity of ulcer lesions in the remaining animals in a herd or group poses more of a diagnostic challenge. Mild to moderate blood loss occurring over a period of several days or weeks will result in anemia and poor performance. Various conditions causing anemia need to be considered, including blood loss from tail biting, abdominal bleeding from other organs, swine dysentery, proliferative ileitis, hemorrhagic bowel syndrome, and possibly dietary deficiencies.

Anemia associated with porcine reproductive and respiratory syndrome (PRRS) has been reported (Rathje et al. 1996). Slaughter checks (Elbers et al. 1995a) and necropsy information from pigs that die of various causes can help determine the extent to which ulceration of the pars oesophagea is a clinical problem in a herd. Care must be taken in interpreting necropsy data to determine disease prevalence in that an association exists between acute respiratory disease and gastric ulceration (Dionissopoulos et al. 2001).

Occasionally, swine practitioners are asked to make a diagnosis on an individual animal when sacrificing the animal in order to perform a postmortem examination is not an option, such as in the case of a valuable breeding boar or sow. Clinical signs of anemia and the presence of digested blood in the stool are suggestive of a gastric ulcer, but definitive diagnosis requires endoscopy (Kowalczyk et al. 1968; Mackin et al. 1997). Modern portable endoscopes are practical tools in the diagnosis of gastric ulcers in swine. They can be used to

Table 54.3.   Classification of stomach lesions at slaughter

Severity	Description
Grade 0	Normal, shiny, white, glistening surface over entire *pars oesophagea*
Grade 1	Evidence of parakeratosis such as thickening, roughened surface, corrugation, yellow color
Grade 2	Erosions of the epithelium, particularly at the border of the cardiac region
Grade 3	Active ulcers and cicatrization

determine the specific phase in production when ulceration is occurring without sacrificing pigs. Early erosive lesions are easily distinguished as red lesions against the white background of the pars oesophageal surface. At postmortem, these lesions are commonly overlooked because of the lack of contrast (Mackin et al. 1997).

TREATMENT

Early intervention is important for successfully treating pigs with gastric ulceration. This is usually hampered by the rapid onset of the problem and the difficulty in diagnosing subclinical disease in the live animal. Pigs that are observed to be pale and weak should be segregated from penmates to avoid injury from bullying. If severe blood loss has occurred, euthanasia should be a consideration.

If a specific risk factor can be identified as a probable contributing cause, then steps should be taken to change the factor. For instance, replacing finely ground pelleted feed with a moderately coarse mash feed has been shown to result in healing (Ayles et al. 1996a). Similarly, nutritional deficiencies such as vitamin E deficiency should be immediately corrected, and concurrent respiratory disease must be treated with appropriate medication.

In the case of expensive breeding stock, one might initiate more extensive treatment than mere pen separation and symptomatic care. Parenteral administration of glucose with electrolytes and vitamin K or 8% gelatin has been recommended as an initial response (Kowalczyk 1975). A blood transfusion (of 1–2 liters of blood in an hour for animals weighing 150–200 kg) should be performed as soon as possible. Parenteral preparations of iron and B-complex vitamins to stimulate hemopoiesis and appetite are generally administered to pigs recovering from severe blood loss.

Numerous pharmaceutical agents have been used in an attempt to neutralize acid, reduce gastric secretions, and/or promote ulcer healing. Various antacid preparations have been studied for their ability to neutralize gastric acid. Sodium bicarbonate is the most commonly used, but with conflicting results. Gamble et al. (1967) found no effect on ulcer severity by feeding 3% $NaHCO_3$, whereas Wondra et al. (1995c) demonstrated a slight improvement with inclusion of 1% $NaHCO_3$ in the ration. Southern et al. (1993) found an increase in stomach lesions when 1% $NaHCO_3$ was fed. The ingestion of sodium bicarbonate in small amounts over time can result in an increase in acid secretion, and this may nullify the advantages of its buffering capability. Nonabsorbable antacids such as aluminum hydroxide and magnesium silicate may be preferable to sodium bicarbonate because they act more slowly and with a more prolonged effect. If buffering agents are to be used, there is good rationale to add them to the water rather than the feed (Ange et al. 2000).

Reduction of acid production should be a goal in treating the individual pig with ulceration of the pars oesophagea. Histamine H_2-receptor antagonists, including cimetidine, ranitidine, famotidine, and nizatidine, have been considered potentially useful drugs. In addition to inhibiting histamine-evoked gastric acid secretion, cimetidine and ranitidine also appear to effectively control upper gastrointestinal bleeding in humans. Unfortunately, researchers (Hedde et al. 1985) have shown that histamine H_2-receptor antagonists do not reduce the incidence or severity of ulcers associated with finely ground feed. Likewise, ranitidine (150 mg per day) administered by injection, three times per day, does not alleviate ulcers in porcine somatotropin-treated swine (Baile et al. 1994). Intramuscular administration of cimetidine (4.3 mg/kg) or ranitidine (0.75 mg/kg) causes gastric pH to rise above 3.5 for only about 2 hours in swine, compared to a much longer time in humans (Sangiah et al. 1990), possibly explaining the poor response in pigs.

The inhibitors of H^+/K^+ ATPase (the proton pump in parietal cells) such as omeprazole (Friendship et al. 2000) and trioprazole (Adelstein et al. 1988) may be more useful agents in treating swine gastric ulcers. These benzinidazole compounds have been shown to successfully reduce severity and prevalence of ulcers in swine treated with porcine somatotropin (Baile et al. 1994). The E-type prostaglandins are widely used in human treatment. These drugs reduce acid secretion and promote mucus secretion. They have not been found to be effective in alleviating ulcer development in swine (Baile et al. 1994). However, other cytoprotectants may be more useful. Various inert and insoluble protectives such as bismuth subcarbonate, kaolin, and pectin have been used in an attempt to coat the ulcerated area and promote healing. Sucralfate, an aluminum salt of sulfated sucrose which adheres to ulcers and erosions and promotes healing while preventing further attacks, has been shown to prevent ulceration in bile duct–ligated pigs (Stapleton et al. 1989). However, the addition of 1 or 4 mg sucralfate per 3 kg of a finely ground pelleted diet fed to somatotropin-treated swine failed to alleviate ulcers of the pars oesophagea (Baile et al. 1994).

The role of *Helicobacter* spp. in swine gastric ulceration is unclear and may not be important. In humans, the recurrence rate of patients with *H. pylori* is 40–80% per year but is reduced to 0–4% when *H. pylori* is eradicated. The treatment for human *Helicobacter* infection is complex, involving the use of three or four pharmaceutical agents. For example, a patient may be prescribed a 1-week course of omeprazole (20 mg bid), bismuth subsalicylate (2 tabs qid), metronidazole (250 mg qid), and tetracycline (500 mg qid) (Chiba 1996). It is not likely appropriate to consider this regimen in swine practice. Even if it can be proven that infection with *Helicobacter* spp. is a factor in swine disease, reinfection from environmental sources may make eradication an impractical

approach in preventing the recurrence of gastric ulcers under farm conditions.

PREVENTION

Treatment for the most part is prohibitively expensive, laborious, and often unsuccessful. In addition, early diagnosis of gastric ulcer disease is difficult. Therefore, prevention of stomach lesions is generally considered the most appropriate approach to handling this problem. A cost-benefit analysis of the prevention program is important in determining what action should be taken to reduce losses from gastric ulcers on a particular farm. The risk factors and the losses from disease will vary from herd to herd, and each case needs to be considered separately. In general, it is very easy to overreact to the loss of one or two animals and institute changes that reduce overall herd performance and result in economic losses that far outweigh the benefits of reduced ulcer prevalence. For example, changing feed particle size from fine to coarse, decreasing the stocking density, and removing growth promotants from the ration are all common recommendations (Kowalczyk 1975), but each will have a significant effect on growth rate and/or feed efficiency.

On the other hand, the swine industry needs to be concerned about the welfare implications of a high level of stomach lesions and must take steps to decrease the prevalence if possible. Many causative factors and complex interactions of nutrition, environment, and management contribute to the expression of this disease, but a coordinated effort—although difficult by feed providers, owners, production personnel, and herd veterinarians—can result in feed preparation standards and management that limit gastric ulceration as a swine production problem without reducing animal performance (Henry 1996). The use of roller mills instead of grinding feed appears to be one of the best methods of reducing ulcers (Nielsen and Ingvartsen 2000).

The feed industry must endeavor to produce a pellet that contains grain particles of a uniform and appropriate size, prepared at a proper temperature. Feed production practices that incorporate flour or "fines" in pellets increase the risk of ulcers. Likewise, high temperatures during pelleting might result in gelatinization of starches and therefore be more ulcerogenic. The addition of fat to the diet, if allowed to become rancid, can also contribute to an ulcer problem. Addressing these concerns can lead to better feed efficiency and reduce the incidence of gastric ulcers.

Feeding practices must be carefully monitored. An interruption of feed intake appears to be a major contributing factor to ulcer formation. Blocked feeders or waterers, heat stress, unpalatable feed, or the presence of vomitoxin in the feed can lead to ulcer problems. Good management practices can minimize the occurrence and influence of these factors.

Various attempts have been made to incorporate protective substances in swine feeds to prevent ulcer development. Increasing levels of antioxidants such as vitamin E and selenium beyond physiological requirements does not appear to be useful (Davies 1993). There is some evidence to suggest that the inclusion of vitamin U (methylmethionine sulphonium) reduces the prevalence and severity of ulcers (Hegedus et al. 1983; Elbers et al. 1995c). Alfalfa has been used at levels of up to 9%, because it is high in vitamins E and K, as well as a source of increased fiber. Alfalfa was not effective in reducing the level of severity of ulcers in pigs treated with porcine somatotropin (Baile et al. 1994). The production of sunflower hulls to diets was shown to be effective in reducing lesions (Dirkzwager et al. 1998).

Products that reduce gastric emptying have been examined and found somewhat effective, at least in an experimental setting. Melatonin has been reported to slow gut motility and when included at levels as low as 2.5 g/ton results in less ulcer development (Ayles et al. 1996b). Similarly, diets containing sodium polyacrylate are retained for longer periods of time in the stomach of swine, and gastric ulceration is reduced (Yamaguchi et al. 1981). There may be circumstances in which various therapeutic agents are useful for treatment or prevention, but because of the many contributing factors and the interactions of these factors, it is unlikely that a single pharmaceutical product or management technique will be found that completely prevents gastric ulceration caused by various combinations of factors in different herds.

Internal Parasites

T. Bonner Stewart and Phillip G. Hoyt

Internal parasites are ever present and must be considered in the economic production of pork. Infectious diseases are spread quickly through a herd and are often easily recognized by the presence of moribund or dead pigs. The internal nematodes, more specifically the worms, can also kill, but loss of appetite, reduction in rate of gain, poor feed utilization, and the potentiation of other pathogens that may be present are the more common results of parasitism. The less-than dramatic performance problems cannot be easily related directly to parasite infection or measured in terms of economic losses. Condemnation of parts of and even entire carcasses due to parasites can be dramatic and is easily documented; however, the more important losses come from insidious depressant effects of parasites on feed intake, daily gain, and feed conversion.

Controlled trials with single-species infections with the more common parasites of swine have shown that all of the nematode infections resulted in a reduction in average daily gain (ADG) of infected pigs compared to their controls. Similarly, the feed to gain ratio (F/G) for the infected pigs increased compared to control pigs. Differences at low levels of infection ranged from 2% to 21% reduction in ADG and from 3% to 6% increase in F/G for the infected pigs compared to their controls. At higher levels of infection, deaths occurred (Stewart 1996) Losses vary greatly in relation to geographic region, type of housing, management, nutrition, pig breed and strain, and species of parasite. The impact of swine parasites and the need for research have been reviewed (Stewart et al. 1985a), as well as the economic losses in production (Stewart and Hale 1988; Kennedy et al. 1988)

In a survey in the United States, based on examination of fecal samples from 84 hog farms judged to have good management in 15 states, the prevalence of *A. suum* was 70% (Kennedy et al. 1988). Utilizing available statistical data (U.S. Department of Agriculture) and calculating performance data on the basis of experimental low ascarid infections, the estimated loss in 1994 from ascarid infections was $174 million (Stewart 1996).

Most schemes for parasite control have been aimed at reducing condemnation of livers caused by *A. suum* or *Stephanurus dentatus*: for example, the "McLean County" system developed in the midwestern United States (Raffensperger and Connely 1927), the "Profit" program in North Carolina (Behlow and Batte 1974), and the "Gilt-Only" system developed in Georgia (Stewart et al. 1964). These systems incorporated sanitation, anthelmintics, and management, singly or in combination, to reduce condemnation and production losses. All anthelmintics introduced for swine since the 1950s have been highly efficacious against *A. suum,* yet it is still the most prevalent swine worm parasite in the world. Incidently, this is also true of *A. lumbricoides* of humans.

More recently, biological systems of control have been researched. For example, daily doses of 5×10^4 units of chlamydospores of the microfungus *Duddingtonia flagrans* fed in feed over a 2-month period to pastured pigs infected with known number of *Oesophagostomum dentatum* and *Hyostrongylus rubidus* resulted in lower herbage numbers of infective larvae of both species compared to the control pigs not receiving the microfungus (Nansen et al. 1996).

The organization of this chapter is by anatomic system infected by the important cosmopolitan parasites, beginning with the stomach. Other parasites are discussed in the section on miscellaneous parasites. The distribution, morphology, life cycle, pathology, and diagnosis of each parasite and, where appropriate, other special effects such as immune response, public health significance, and economic importance are discussed. Separate sections are included on prevention and on anthelmintic compounds currently being used and those under development.

STOMACH

Hyostrongylus rubidus
The trichostrongyloid nematode *Hyostrongylus rubidus*, the red stomach worm of pigs, becomes concentrated in

the lesser curvature in the fundic area of the stomach of pigs. The adult worms are less than 10 mm in length and are bright red when first removed from the host. They are essentially parasites of pastured animals.

Morphology. These slender red worms have cuticular striation (Figure 55.2). Males are 4–7 mm and females 5–9 mm in length. Males have a pair of short spicules and a bursa. The female vulva is located on the midposterior half of the body. Cervical papillae are present. The eggs are typical strongyle type and are in the 16- to 32-cell stage when passed in the feces. They are thin-shelled and measure 60–76 by 30–38 μm (Figure 55.1F).

Life Cycle. Eggs develop on the ground into infective larvae (L_3) in about 7 days. After ingestion, the infection becomes patent in about 21 days. The L_3 enter pits of the gastric glands, where they remain for about 2 weeks as they go through two molts, returning to the lumen as L_5, young adults. Larvae can remain in the mucosa for several months in a histotrophic stage similar to that of *Ostertagia* of cattle and sheep and cause formation of small nodules.

Pathology. Infections usually are not pathogenic, but if enough worms are present, hyperemia, catarrhal gastritis, submucosal edema, hyperplasia of the gastric gland area, erosion of the mucosa, and ulcer formation may result (Porter 1940; Kendall et al. 1960; Stockdale et al. 1973). *H. rubidus* is a bloodsucker; and in herds with clinical hyostrongylosis, emaciation and pallor of the skin and mucous membranes may be apparent in adult animals (Davidson et al. 1968; Appert and Taranchon 1969). Clinically inapparent infections can lead to reduced weight gains, feed conversion, and N balance (Dey-Hazra et al. 1972; Stewart et al. 1985b).

Diagnosis. The eggs are almost indistinguishable from those of *Oesophagostomum* spp. in both size and morphology, although *H. rubidus* eggs are more advanced in development. Larval culture is a better method of differentiation (Homer 1967).

SMALL INTESTINE

Strongyloides ransomi

Strongyloides ransomi, the small-intestinal threadworm, is a rhabditoid nematode of cosmopolitan distribution. Its prevalence and importance are greater in the warmer climatic regions, where it is an important parasite of suckling pigs.

Morphology. Only parthogenetic females are present in the parasitic generation. Adults are practically microscopic, measuring 3.3–4.5 mm in length. The filariform esophagus occupies about a third of the total body length. The vulva is located near the middle of the body.

The thin-shelled eggs passed in the feces contain larvae and measure 45–55 by 26–35 μm (Figure 55.1A).

Life Cycle. Larvated eggs that pass in the feces hatch in a few hours into L_1 rhabditiform larvae. These may develop either directly into infective larvae (homogonic cycle) or into males and females (heterogonic cycle), which in turn will produce infective larvae. In the homogonic cycle, infective larvae can appear in a little more than a day. In the heterogonic cycle, infective larvae can appear in 2.5 days. Different routes of infection have been proven for *S. ransomi*: percutaneous, oral, transcolostral, and prenatal.

Percutaneous penetration by larvae produces patency in 6–10 days after infection. Larvae enter the bloodstream, proceed to the lungs, undergo tracheal migration, and are swallowed. Oral infections are possible when the ingested larvae penetrate the mucous membranes and migrate to the lungs, L_3 being killed by gastric juices.

Transcolostral infection may also occur, by 4 days after birth. This is considered the primary means of infection of neonates in the southeastern United States. Larvae in the sow colostrum differ physiologically from L_3 and pass through the stomach and develop into adults in the small intestine without migration. Larvae responsible for infection of the neonates are sequestered in the mammary fat of the sow and apparently are mobilized and included in the colostrum (Moncol 1975; Stewart et al. 1976).

Prenatal infection producing patency in suckling pigs as early as 2–3 days after birth can occur. Larvae from the sow accumulate in various tissues of the fetus during the latter part of pregnancy, and complete migration to the small intestine of the newborn rapidly after birth.

Pathology. Diarrhea followed by progressive dehydration is the usual sign. In heavy infections, death generally occurs before pigs are 10–14 days old, but stunting and unthriftiness are the more usual sequelae of *S. ransomi* infection. No pathognomonic lesions are associated with field cases of strongyloidosis (Stewart et al. 1968). Larvae apparently can be distributed widely in most tissues of the body and lesions are dependent on the number of larvae and host response (Stone and Simpson 1967).

Immune Response. Breed differences in susceptibility to *S. ransomi*, which appear to be genetic (Johnson et al. 1975), have been reported. Duroc pigs were less susceptible to effects of infection than Hampshire pigs, and the F_1 cross of the two breeds was intermediate in response. Murrel and Urban (1983) showed that enteral exposure of pigs infected with milk larvae produced protective immunity to subsequent subcutaneous inoculation with *S. ransomi* L_3.
55.1. *(A)* Strongyloides *egg, thin-shelled, lacking one of three layers, and larvated; (B)* Ascarops *egg, larvated and similar morphologically to those of* Physocephalus *and* Gongylonema*; (C) the* Ascaris *egg has an outer proteinaceous layer, often missing; (D)* Metastrongylus *egg; (E)* Oesophagostomum *egg; (F)* Hyostrongylus *egg; (G)* Globocephalus *egg; (H)* Stephanurus dentatus *egg passed in the urine; (I)* Trichuris *egg; (J)* Macracanthorhynchus *egg. (All eggs photographed and printed at the same magnification.)*
55.2. *Scanning electron micrograph of anterior of* Hyostrongylus ru-bidus *showing cuticular striations.*

55.3. *The three lips of* Ascaris suum. *Note sensory papillae and den-ticles on edges of lips.*

Diagnosis. Identification of eggs in feces or finding the adults in the small intestine at necropsy, with a history of diarrhea and unthriftiness, confirms a diagnosis of strongyloidosis; however, care must be taken because clinical disease can be confused with colibacillosis and coccidiosis.

Ascaris suum

Ascaris suum, the large roundworm of swine, is an ascaridoid (ascarid) nematode of cosmopolitan distribution. It is the most common gastrointestinal worm parasite in pigs, with a prevalence of 50–75%. It is more common in growing pigs than in mature pigs. Although now recognized as a separate species, the large roundworm of humans, *A. lumbricoides*, was thought to be the same as that in pigs.

Morphology. Ascarids are large, stout-bodied, pinkish-yellow nematodes with three prominent lips surrounding the mouth (Figure 55.3. Females are 20–40 cm long, and the males 15–25 cm. The male tail is conical and bent ventrally. Males have two stout spicules. The female vulva is anterior to the middle of the body. Eggs are thick-shelled and brownish yellow with a mammillated proteinaceous coating on the exterior, and they measure 50–80 by 40–60 μm. The eggs are unsegmented when passed in feces (Figure 55.1C)

Life Cycle. The life cycle is direct and involves a hepatotracheal migration route. Eggs are laid in the intestine of the pigs and pass out in the feces. At room temperature the L_1 appeared in the egg at 17–22 days; the L_2 appeared at 22–27 days; and the L_3 first appeared on day 27 (Geenen et al. 1999). Additional time is needed for eggs to become infective, and they may remain infective for 7 years or longer in protected areas of lots and pastures.

When ingested, infective eggs hatch in the digestive tract. The liberated L_3 penetrate the intestinal wall and generally pass via the hepatic portal system to the liver. A few, however, may pass via the lacteals to the mesenteric lymph nodes; others may even be found in the peritoneal cavity and other locations. Most larvae are in the liver by the first or second day after ingestion and in the lungs by days 4–7. From day 8 to day 10 after infection, larvae leave the lungs by penetrating the bronchioles, are coughed up into the trachea, and are swallowed. By 10–15 days after infection the L_3 have returned to the small intestine and molted to L_4. At this time, some L_4 are spontaneously eliminated from the small intestine into the cecum and colon. L_4 molt to young adults (L_5) 21–30 days after ingestion of eggs. The prepatent period is 40–53 days. Female ascarids are phenomenal egg producers capable of laying hundreds of thousand to nearly 2 million eggs per day. The eggs are sticky and are easily transported by cockroaches and other arthropods, birds, boots, etc. Most disinfectants have no effect on the eggs, but heat (steam) and direct sunlight are effective in destroying their viability.

Most adults live in pigs only about 6 months, at which time they begin to be expelled, but pigs may continue to carry a light infection for a year or longer. In foreign hosts as in humans or domesticated and laboratory animals, larvae may migrate but are generally unable to develop to adults in the intestine and are expelled in the feces if they reach the digestive system.

55.4. Ascaris *emerging from a tear in the gut wall. (Photo by Mark Martinez.)*

Pathology. The larvae migrate through the liver and cause hemorrhagic foci which microscopically show mild eosinophilic infiltration and a few, small lymphoid nodules in portal areas. On repeated exposure to larvae, there is an increase in connective tissue, infiltrating eosinophils, and dilation of lymphatics, which grossly appear as whitish spots, commonly referred to as "milk spots." Such lesions disappear within 25 days. In the lungs, migrating larvae cause verminous pneumonia, which may result in death if large numbers of larvae are involved. Clinical signs are those of pneumonia. Pigs have an asthmatic cough ("thumps") and may breathe with difficulty. Hemorrhagic foci of various sizes are present. There may be an exudate, edema and emphysema with secondary bacterial pneumonia. Migration of *A. suum* larvae markedly enhances the pathogenicity of swine influenza as well as viral pneumonia.

Adult worms compete with the host for nutrients and interfere with absorption of nutrients by the host. They may occlude and rupture the small intestine (Figure 55.4). In addition, adults may migrate into the common bile duct and occlude it, causing icterus.

Immune Response. Acquired resistance can be induced in pigs by oral inoculation with infective eggs or L_3 pulmonary larvae (Eriksen 1982: Stewart et al. 1985c). The presence of adults or late larval ascarids can prevent development of additional larval stages (Stewart and Rowell 1986). High levels of protective immunity based on the number of lung larvae recovered after challenge with 10,000 larvae following repeated experimental or natural exposure was shown by Urban et al. (1989). Protective immunity was not altered by strategic anthelmintic treatment that prevented growth retardation of pigs constantly exposed to natural infection. Sterilizing immunity is transitory, and periodic boosting or anthelmintic treatment is necessary to eliminate both intestinal worms and lesions during the growing-finishing period (Urban et al. 1988, 1989). The intestine

is considered important as a defense mechanism in preventing larval penetration of the gut mucosa (Bindseil 1970), and it has been shown that the intestinal phase of ascarids can induce circulating antibodies without prior somatic migration (Leigh-Brown and Harpur 1974). Protective immunity is characterized by antibody in serum and in intestinal washings (Urban et al. 1984).

Economic Importance. Ascariasis is undoubtedly the most important parasitism of pigs worldwide. The effects of ascarids on the performance of pigs were detailed by Spindler in 1947 and by many others since then. Controlled experimental single infections at different levels with the ubiquitous *A. suum* showed that low levels of infection depress feed intake and daily gain with a concomitant increase in maintenance cost; at higher levels of infection, depression in feed conversion also occurs. Periodic analyses of metabolic functions during the prepatent period showed a significant effect on nitrogen (N) metabolism on days 33–37, coincident with rapid growth of the immature worms in the small intestine. The average number of worms recovered at slaughter ranged from 13–18, although the infecting doses in the studies ranged from 600–60,000 (Hale et al. 1985). Such lack in correlation between infecting numbers and establishment of adults has been observed many times (Schwartz 1959; Andersen et al. 1973). Losses from condemnation of parts and lowered performance of pigs in the United Sates were calculated at more than $385 million annually (Levine 1980). More recently, losses due solely to lowered feed conversion from low-level *A suum* infections were estimated at $155 million for 1987 in the United States (Stewart and Hale 1988). There are no estimates of the value of losses incurred from the potentiation or exacerbation of other diseases by migrating ascarid larvae, or the effect of different management practices or nutritional levels (Underdahl 1958; Zimmerman et al. 1973).

Diagnosis. Typical eggs in fecal flotation or "milk spot" liver lesions at necropsy are diagnostic. In heavy infections the adult worms can be seen and felt in the intact intestine. In areas where the kidney worm is endemic, liver lesions must be differentiated because early *S. dentatus* lesions can be confused with those produced by *A. suum.*

Trichinella spiralis

Probably all mammalian species are susceptible to *Trichinella spiralis* infection, although natural cycles seem climatically based. In the Temperance Zone the usual cycle has swine and bears as natural hosts (Schad et al. 1984), and in the Arctic Zone polar bears and grizzly bears (Kim 1983) and walrus (MacLean et al. 1989) are natural hosts. Other species, including humans, are involved incidently. Trichinellosis is found less frequently in the Tropics. Regulation of garbage feeding to

swine, public health programs, and recently improved trichinoscopic and serodiagnostic techniques have reduced the incidence of this infection.

Morphology. The life stage most frequently observed is the encysted (L_1) in muscle fibers. These cysts are 400–600 µm long and 250 µm in diameter. Prior to skeletal muscle fiber penetration, (L_1) may be found in the circulatory system. Adult females occur in the lamina propria of the small intestine, have a stichosome type esophagus, produce larvated eggs in utero and are 3–4 mm long and 60 µm in diameter. Adult males are rarely seen but are about one-half the size of females.

Life Cycle. Muscle cysts are ingested and digested in the stomach and small intestine, and L_1 are liberated into the small intestine. Molting from L_1 to L_5 then occurs in 2–6 days. Intracellular infection of enterocytes with adults was demonstrated in mice by electron microscopy (Wright 1979). Males die soon after mating and females burrow into lymph spaces, depositing larvae. Larvae are numerous in the blood from 8–25 days post infection; these L_1 penetrate the sarcolemma of skeletal muscle fibers throughout the body and become encysted by 3 months. Although calcification of cysts begins at 6–9 months, L_1 remain viable for up to 11 years, demonstrating the symbiotic relationship between L_1 and host muscle fiber, the "nurse cell" (Despommier 1990). Modes of transmission in swine herds include cannibalism, tail biting, scavenging on carcasses of dead farm cats (Hanbury et al. 1986), feeding on raw garbage, the presence of hog lots on covered garbage dumps (Zimmerman et al. 1962), and eating wild animal carcasses such as raccoon and fox (Kazacos 1986; Campbell 1988).

Pathology. *Trichinella* is much less pathogenic for swine than for rats and humans. Experimental infections in pigs caused decreased weight gains and intense muscle pain, but most of these infected pigs recovered with rapid weight gain (Scholtens et al. 1966); in experimentally infected miniature pigs, eosinophilia and hypergammaglobulinemia were observed (Beck and Anfinson (1965). Clinical illness has not been described for natural infection with the muscle fiber cyst and infiltration of eosinophils is often the lesion observed.

Immune Response. Experimental inoculation of pigs with *T. spiralis* excretory-secretory products induced moderate but variable degrees of immunity to subsequent challenge per os with doses of 2500–2700 L_1. These pigs harbored fewer adult worms, and the fecundity of female worms recovered (measured by shedding of newborn larvae) was significantly lower than that of females recovered from control pigs (Gamble et al. 1986). Prospects for potential use of targeted vaccine in an integrated control program for swine trichinosis are being investigated (Murrel 1985).

Diagnosis. Federal, until recently state, meat inspection regulations have not included examination for *Trichinella*, but procedures for diagnosis would be by digestion of muscle at slaughter or by enzyme-linked immunosorbent assay (ELISA) for serologic detection of *Trichinella*-specific antibodies (Gamble et al. 1983). A pooled-sample digestion method using 5–6 g diaphragm samples from lots of 20 pig carcasses has been adopted by several European countries but not by the U.S. Department of Agriculture (Zimmerman 1967). These pooled samples are digested and homogenized using 1% pepsin/1% HCL and a mixing action which simulates peristaltic motion of the stomach (using a stomacher device). Analysis of pooled samples can be accomplished in 1.5 hours (Oliver et al. 1985).

An ELISA test using an excretory antigen for diagnosis of trichinosis was evaluated in the field with sera from herds with ongoing transmission of *T. spiralis* (Murrell et al. 1986). Results showed a high sensitivity of 93–96% with sera from infected pigs. Of those that were false-negative, five-sixths had fewer than 5.0 larvae per gram (LPG). This should prove to be a major technique for antemortem diagnosis in herd screening.

Public Health. In Europe, trichinoscopic examination of pork appears to have practically eliminated *T. spiralis* from domestic swine. Incidence of swine trichiniasis in the United States was 0.125% in 1966–1970 (Zimmerman and Zinter 1971). Pork, mainly prepared sausage, apparently is the major source of human trichinellosis, accounting for 73.2% of 254 cases for which source was identified (USDHHS 1976). There are close to 40 million potential exposures each year based on the estimated number of infected pigs, the estimated number of human cases is 300,000, the majority of which cases cause no symptoms of infection (Leighty 1974). Non-pork products included meat from walrus, black bear, and horses and ground beef (James 1989), with beef likely adulterated with pork. Small custom slaughterhouses are important epidemiologically, for these often prepare fresh, whole dressed pork for social occasions where one animal is consumed by many persons (Schad et al. 1985). There have been several recent small epidemics among Indo-Chinese immigrants in the United States (USDHHS 1982); an update on trichinosis surveillance in the United States appeared in 1988 (USDHHS 1988).

In the United States, educating the public to recognize the hazard and to cook pork adequately to kill the organisms, and requiring freezing of manufactured pork products that need cooking have been the two principal patterns used by federal and state meat inspection programs (Leighty 1974). A more concerted effort to identify herds with active infections in order to provide a "safe" product was initiated by the state of Illinois with the introduction of a Trichinosis Control Act in 1986. The pooled-sample digestion and ELISA technique are

employed to identify and subsequently to quarantine, depopulate, and indemnify those herds found infected. Other states, such as North Carolina, are following suit with use of a semiautomatic ELISA to screen hogs in a packing plant at the rate of 400/hour; all recorded positives then are screened by the diaphragm technique.

For chemotherapy, ivermectin was confirmed as having no antiparasitic activity, whereas excellent efficacy was reported for albendazole. Calf thymus extract, cyclosporin A, and the experimental compound luxabendazole have also been proven efficacious (James 1989).

CECUM AND COLON

Trichuris suis

Pigs and wild boars are considered the natural hosts of *Trichuris suis*, although primates, including humans, may be infected with *T. suis*. Whipworms are distributed widely and are a fairly common problem in swine.

Morphology. Adult females measure 6–8 cm long and males half that length. This trichuroid has a unique morphology, with the anterior or esophageal portion 0.5 mm in diameter and extending two-thirds of the body length. The esophagus is a stichosome-type consisting of a column of spiraling stichocytes, one cell layer in thickness. A microscopic lancet protrudes from the stoma in all stages. Glandular and muscular components are interspersed along the esophagus. The posterior third of the body is thicker, 0.65 mm, protrudes into the lumen and contains the midgut of the worm and its reproductive tract. Bipolar thick-shelled eggs may be seen in the uterus of the female, and a single copulatory spicule in the male. Eggs are 60 by 25 μm, yellow to brown, and in the one-cell stage (Figure 55.1I).

Life Cycle. The eggs passed in the feces require 3–4 weeks to reach infectivity, still in the L_1 stage, and can remain infective for as long as 6 years. Infective eggs hatch in the small intestine and cecum, with the released L_1 penetrating cells lining the crypts. A histotrophic phase persists for 2 weeks with gradual larval migration from the deeper lamina propria to the submucosa. Luminal development begins the third week post infection with the posterior body coming into view and the anterior end remaining buried in the mucosa (Figure 55.5). Meanwhile, four molts have occurred, prepatency is 6–7 weeks, and life span 4–5 months (Beer 1973).
55.5. Trichuris *worm. Note intracellular penetration (Batte et al. 1977.)*

Pathology. *Trichuris* infections cause enterocyte destruction, ulceration of the mucosal lining, loss of capillary blood, and probably secondary bacterial infection. Thus, trichuriosis must be considered in the differential diagnosis of swine dysentery complex that does not respond to antibiotic therapy. The spectrum of gross lesions may be edema with formation of nodules containing exudates surrounding portions of worms to formation of a fibrinonecrotic membrane. Erosion of capillary beds and vasodilation results in hemorrhage, anemia, and hypoalbuminemia. Clinical signs include anorexia, mucoid to bloody diarrhea, dehydration, and death.

Immune Response. Susceptibility with accompanying clinical signs is up to 6 months of age, although mature hogs may show clinical infection when stressed. Light infections persist, allowing intermittent shedding of eggs. Infection of pigs with *Trichuris suis* was shown to induce suppression of mucosal immunity to resident bacteria and is linked to the pathogenesis of necrotic proliferative colitis (Mansfield and Urban 1996).

Diagnosis. Clinical signs, including bloody scouring, are presumptive. Eggs in stools and whipworms at necropsy are confirmative. Trichurids are sporadic egg layers therefore, little significance can be given to number of eggs per gram (EPG).

Oesophagostomum spp.

Oesophagostomum spp. are strongyloid nematodes, of which *O. dentatum* and *O. quadrispinulatum* are the most common in occurrence. *O. brevicaudum* occurs in the southeastern United States and other areas with similar climates. Two other species, *O. granatensis* in Europe and *O. georgianum* in the southeastern United States, are probably morphovariants of *O. dentatum* (Raynaud et al. 1974; Stewart and Gasbarre 1989).

Morphology. Adult *Oesophagostomum* have stout, slightly curved bodies; females are 1–2 cm long and males are slightly shorter. Species differentiation is by shape of esophagus, shape of buccal capsule, and length of tail and spicules (Figure 55.6). Eggs are 70 by 40 μm, morulated when passed, thin-shelled, and typically strongyloid (Figure 55.1E).

Life Cycle. The preparasitic cycle is of the strongylid type, with L_1 emerging from eggs and ensheathed L_3 appearing by 1 week. Larvae can survive on pastures for up to 12 months. Swine are infected by ingesting L_3 from contaminated pastures, by mechanical transmission by psychodid flies (midges), or from rats with encysted larvae (Jacobs and Dunn 1968). The L_3 enter the mucosa of the cecum and colon and molt to L_4, remain for 2 weeks, causing small nodules, and emerge into the lumen, molt to L_5, and reach patency in 3 weeks after ingestion.
55.6. Scanning electron micrograph of anterior of Oesophagostomum *brevicaudum.*

Pathology. Formation of nodules from the cecum to the rectum is the major change (Taffs 1966). The sequelae are petechiation at the point of entry of the L_3 (Jacobs 1969); focal thickening of the mucosa consisting of lymphocytes, macrophages, and esosinophils; and then presence of luminal nodules by day 4. Encysted larvae may be found in the muscularis mucosa (McCracken and Ross 1970). By 1 week, nodules are up to 8 mm in diameter and plugged with yellow to black necrotic debris. Walls of the cecum and colon become edematous from extensive thrombosis of lymphatics; there is possibly a localized fibrinonecrotic membrane. Resolution begins the second week with some remnants of nodules and scarring. Secondary infection may occur and enhance clinical signs of depression, anorexia, and scouring.

Immunity. There is no apparent age immunity (Taffs 1956), but pigs over 3 months seem more susceptible (Haas et al. 1972). A periparturient rise of EPG is maintained through lactation with a subsequent expulsion of worms (Connan 1967; Haas et al. 1972).

RESPIRATORY TRACT

Metastrongylus spp.

Species include *M. apri (elongatus), M. pudendotectus* and *M. salmi*, which occur in the bronchi and bronchioles, especially in the diaphragmatic lobes, and exclusively in swine. Although *M. apri* is the most common, all occur worldwide and natural infections occur more often with two species present.

Morphology. Adults are slender and white, with females 50 mm in length and males 25 mm; males have paired spicules, Mucoid deposits around these adults makes it
55.7. *Cluster of* Metastrongylus *worms in a terminal bronchiole of the diaphragmatic lobe of the lung. (Photo by Blaise Brazos.)*

difficult to separate individuals. Eggs are larvated, thick-shelled, and measure 40–50 μm (Figure 55.1D).

Life Cycle. Larvated eggs are coughed up, swallowed, and passed in feces. Earthworms ingest these eggs, which then hatch, and L_1 migrate to the heart. Infective larvae appear in 10 days and hogs rooting in the soil eat the infected worms. These L_3 penetrate the wall of the intestine and are transported to the mesentery lymph nodes, where they molt to L_4. These L_4 are then swept through the right heart to the lungs (Figure 55.7) and molt to L_5, with patency in 4 weeks.

Pathology. Dissecting the bronchioles reveals mucoid plugs in the diaphragmatic lobes of the lungs; these are adults and eggs. Parasites, mucus, and cellular exudate cause occlusion and induce atelectasis, observed as coughing or "thumps." Apparently *Mycoplasma hyopneumoniae* is not transmitted with *Metastrongylus* via earthworms (Preston and Switzer 1976). Fewer parasites seem to occur in breeding stock.

Diagnosis. It is difficult to find *Metastrongylus* eggs in a fecal exam, but it is important to look for "fuzzy" areas in which eggs are held in mucus. At necropsy, lungworms can be extruded by clipping the posteroventral margins or the tip of the diaphragmatic lobes of the lungs.

URINARY TRACT

Stephanurus dentatus

The kidney worm is a strongyloid nematode of swine. Domestic and feral pigs raised on soil in warm climates are most often infected. In the United States, endemicity is from the Carolinas to southern Missouri, with interstate transport accounting for the worm's appearance as far north as Canada (Smith and Hawkes 1978).

Morphology. Adults are thick-bodied with black and white mottling from contents of the reproductive and intestinal tracts showing through the cuticle; they are 1–3 cm long by 2 mm in diameter. The strongylid eggs are ellipisoidal, thin-walled, morulated, and measure 120 by 70 μm (Figure 55.1H).

Life Cycle. Kidney worms are found in cysts in perirenal fat with fistulous openings into the ureters, in the kidney, and in ectopic sites such as the pancreas, lumbar muscles, spinal cord, and lungs. Eggs are voided, with the greatest numbers found at first urination from overnight accumulation in the bladder. Eggs may hatch in 1–2 days; molt to infective L_3 in 3–5 days; and survive for several months in warm, moist, shaded conditions. They are invasive by ingestion, skin penetration, and infected earthworms (Tromba 1955; Batte et al. 1960). Prenatal infection also has been reported (Batte et al. 1966).

Infective L_3 migrate from the small intestine to the mesenteric lymph nodes and molt to L_4, which move through portal veins to the liver (Lichtenfels and Tromba 1972). Bronchiole lymph nodes, lungs, pancreas, and spleen also may be infected by L_3 (Waddell 1969). In the liver, L_4 increase from 0.4 to 6.0 mm, molt to L_5 in 2–4 months, and then leave the liver (Lichtenfels and Tromba 1972). They migrate through the body cavity to perirenal and mesenteric fat. Patency is uncommon before 9–12 months, and eggs are shed for 3 years after initial infection (Batte et al. 1966).

Pathology. Gross pathological changes may be found where there is migration. Mesentery lymph nodes are edematous and swollen; liver changes include inflammation, eosinophilia, abscessation, and extensive fibrosis, making this infection easily differentiated from ascarid migration. Similar lesions can be seen in other organs. Nodules are formed in perirenal fat, and fistulous tracts are present along the ureters. Posterior paralysis has been associated with migration around the spinal cord.

Diagnosis. Worms, abscessation, and liver scarring can be seen at necropsy. Eggs in urine are confirmatory antemortem.

Economic Consideration. At least 95% of liver condemnations are due to kidney worms and ascarids in hogs in the southeastern United States (Batte et al. 1975). Marked reduction in growth rate and feed efficiency was shown in pigs infected experimentally (Hale and Marti 1983).

MISCELLANEOUS PARASITES

Three spiruroid nematodes that require dung beetles as intermediate hosts infect pigs: *Ascarops strongylina* and

Physocephalus in the stomach and *Gongylonema pulchrum* under the epithelial layer of the esophagus and tongue. The two thick stomach worms cause a gastritis if present in large numbers. For aesthetic reasons, tongues for human consumption should be scalded and the skin peeled off to remove *G. pulchrum*. The eggs of these spiruroids are thick-shelled. Eggs of *Ascarops* measure 34–40 by 18–22 µm (Figure 55.1B); eggs of *Physocephalus* measure 31–39 by 12–17µm; and eggs of *Gongylonema* measure 57–59 by 30–34 µm.

The hookworm of swine, *Globocephalus urusubulatus*, of cosmopolitan distribution, is more common in the southern part of the United States in feral and pastured swine. It apparently is not as common or pathogenic as hookworms of carnivores and has received little attention. The eggs are typically strongyloid and measure 52–56 by 26–35 µm (Figure 55.1G). *Macracanthorhynchus hirudinaceus,* the thorny-headed worm of swine, is an acanthocephalan. It attaches to the ileal portion of the small intestine and causes nodular lesions, which are sometimes invaded by secondary organisms. Occasionally the gut wall is perforated by the proboscis, and peritonitis results. Eggs measure 110 by 65 µm, are brown, and have a three-layered shell (Figure 55.1J). A beetle is the required intermediate host.

Two trichostrongylid nematodes, commonly parasites of ruminants, can be found in pigs: *Trichostrongylus axei* in the stomach and *T. colubriformis* in the small intestine.

Of public importance, *Taenia solium* (*Cysticercus cellulosae*) has humans as the host for the adult tapeworm as well as the potential host for the cysticercus. Swine are the natural intermediate host. Humans are usually infected with a single worm; the adult measuring 3–5 m long, and with an armed rostellum. Gravid proglottids are 12 by 6 mm, have a single, lateral genital pore, and contain taeniid eggs 42 µm in diameter. Following ingestion of proglottids by swine, cysticerci develop in skeletal and cardiac muscles, measuring up to 18 mm in diameter. These are infective by 2–3 months and remain so for 2 years; prepatency in humans is 2 months. Cysticercosis in swine and taeniasis in humans are usually of no clinical significance, but cysticercosis in humans is life threatening, because cysticerci become space-occupying lesions in the central nervous system and have unrestricted growth with no outer limiting membrane (racemose).

Swine may also be infected with *Fasciola hepatica* and *Echinococcus granulosus* in the liver but with no apparent clinical problems. These infected swine are found in endemic areas where there is common pasture use with sheep.

The ciliated protozoan *Balantidium coli* is found primarily in the cecum and anterior colon of swine as a commensal. The motile form is pleomorphic, 30–150 µm by 25–120 µm, and 45–65 µm in diameter. Reproduction is by binary fission, resistant cysts are formed. *B. coli* feeds on starch, bacteria, and ingesta, including nematode eggs. It is a secondary invader into mucosal lesions by other invaders and produces hyaluronidase, which enlarges lesions. Humans, other primates, and dogs have been found clinically affected in zoos and in areas near hog farms. *B. coli* may cause an explosive bloody diarrhea in these species.

PREVENTION

Parasite control methods may be broadly categorized as either preventive or therapeutic. Those parasites requiring an intermediate host can be successfully prevented by removing pigs from contact with the intermediate hosts—for example, dung beetles and earthworms. Therefore, maintaining pigs on concrete will prevent infection with the spiruroids, acanthocephalans, and metastrongyloids. An added benefit would also be the reduction or prevention of infection by other parasites, such as *Hyostrongylus*, *Globocephalus*, and *Trichostrongylus*, that require pasture conditions for transmission.

Good sanitation is a critical element in controlling parasitic infections. The major mode of transmission of internal parasites is through contamination of food, soil, or bedding with feces or urine. Since parasite eggs need moisture and warmth to develop and survive, direct sunlight or dry conditions shorten egg and larval survival. Thorough cleaning of buildings, pens, and equipment with detergent and steam is the best way to control parasite eggs and larvae Steam penetrates cracks and crevices and kills the tiny eggs and larvae. The common disinfectants used on the farm do not kill eggs of parasites such as ascarids.

Since parasites compete with the host for available nutrients, adequate nutrition aids in reducing the adverse effects on feed efficiency and average daily gain. It has been shown that increasing the protein and vitamins in the feed affects the performance of parasitized pigs by increasing the average daily gain and feed efficiency (Stewart et al. 1969).

A management system in which only gilts are used as breeders has been shown to be effective in eradicating kidney worms. This is possible because of the lengthy prepatent period of 6 months or longer and the fact that only animals 2 years old or older pass kidney worm eggs in significant numbers. Selling breeders as soon as first litters are weaned and maintaining boars separately or replacing them with young stock will prevent contamination of the premises. Eradication can be achieved in 2 years or less by using the "gilt-only" system (Stewart et al. 1964).

TREATMENT

Therapeutic treatment of pigs with anthelmintics may present only a temporary solution, unless the conditions under which the parasites were acquired are altered. No drug is effective against all parasites, and the

tissue damage prior to patency results in slower growth rates and increased nutrient requirements. A good management system will incorporate practices, such as sanitation, genetic selection, and nutrition, to prevent infections and will not use treatment as the sole method of controlling parasites. The choice of anthelmintic is dependent on the parasite species present and the relative cost of the products. Routine surveillance and strategic treatment for parasites is advisable on farms with a previous history of clinical disease. Treatment reduces the number of egg-producing parasites and keeps further premise contamination to a minimum.

The use of chemical agents such as pyrantel tartrate fed for several weeks can be helpful under lot or pasture conditions to control infections and reduce lesions from ascarids and nodular worms. Prophylactic use of pyrantel or repetitive treatments with fenbendazole reduces worm populations and also appears to stimulate immunity against *Ascaris suum* (Southern et al. 1989; Stankiewicz and Jeska 1990).

Treatment of sows 10–14 days before farrowing with ivermectin has been shown to be effective in preventing transmission of *Strongyloides ransomi* from sows to their piglets. Such treatment of sows is also beneficial in preventing transmission of *Sarcoptes scabiei*.

Anthelmintics

From 1960–1996 several new classes of anthelmintic compounds were developed, approved by the Food and Drug Administration for use in swine, and marketed in formulations for administration in water or feed and by injection. The spectrum of activity varies by compound, with some effective against a few target species and others broader in effect.

Macrocyclic Lactones. Avermectins are derived from fermentation products of *Streptomyces avermitilis*. The mode of action is to stimulate the release of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) in target organisms. This inhibits neuromuscular transmission, leading to paralysis and death. The spectrum of activity includes internal and external parasites, including *Ascaris*, *Oesophagotomum*, and *Metastrongylus*, with less effect on *Trichuris* and excellent effect on *Haematopinus* (sucking lice) and *Sarcoptes*.

Ivermectin is available as an injectable formulation and as a feed additive. The injectable formulation is approved for the control of *A. suum*, *Hyostrongylus rubidus*, *Oesophagostomum* spp., *S. ransomi* (adults and somatic larvae), *Metastrongylus* spp., *Haematopinus suis*, and *Sarcoptes scabiei* var. *suis*. It has an 18-day slaughter withdrawal. The feed formulation is approved for the control of *A. suum*, *Ascarops strongylina*, *H. rubidus*, *Oesophagostomum* spp., *S. ransomi* (adults and somatic larvae), *Metastrongylus* spp., *Stephanurus dentatus*, *Haematopinus suis*, and *Sarcoptes scabiei* var. *suis*. It has a 5-day slaughter withdrawal.

In a series of controlled trials doramectin, which is available in an injectable form, was shown to have an efficacy of 98% or greater against *H. rubidus*, *A. suum*, *S. ransomi*, *Oesophagostomum dentatum*, *Oesophagostomum quadrispinulatum*, *Stephanurus dentatus*, and *Metastrongylus* spp., but its efficacy against *Trichuris suis* varied (Logan et al. 1996). In two controlled studies the efficacy of doramectin against *T. suis* was 54% in mixed-species infections and 95% in single-species infections. In both types of population, efficacy was greater for female than for male worms (Stewart et al. 1996a). The efficacy of doramectin against *S. dentatus* was 100% against worms in all locations (Stewart et al. 1996b). It is approved for the control of *A. suum*, *O. dentatum*, *O. quadrispinulatum*, *S. ransomi*, *H. rubidus*, *Metastrongyulus* spp., *S. dentatus*, *S. scabiei* var. *suis*, and *H. suis*. It has a 24-day slaughter withdrawal.

Moxidectin, a milbemycin related to the avermectins, has experimentally been shown to have efficacy as a pour-on against *A. suum*, *Oesophagostomum* spp., and *Metastrongylus* spp. with a variable efficacy against *Trichuris* (Stewart et al. 1999). Currently there is no approved formulation for swine in the United States.

Benzimidazole Carbamates. There are several efficacious compounds among the benzimidazole carbamates, but only fenbendazole (FBZ) is approved for use in swine in the United States. The progenitor of this class of anthelmintics is thiabendazole (TBZ), which has been available since the early 1960s. At 50 mg/kg body weight, TBZ had a greater than 95% efficacy against *Hyostrongylus*, *Strongyloides*, and *Oesophagostomum* but much less activity against ascarids and whipworms. Commercially, it was used in a paste form given therapeutically in a single oral dose for *Strongyloides* infections in baby pigs. Its pharmacologic action is to block nematode fumarate reductase activity. Absorption is a passive diffusion through the cuticle of the worm. TBZ has little solubility in water; therefore, only a small amount is rapidly absorbed from the intestinal tract. Its metabolites are excreted completely in feces and urine within 3 days. There is negligible mammalian toxicity, with 20 times the therapeutic dose producing no adverse effects.

FBZ was approved for use in swine in the United States in 1984. It is known to be effective against ascarids, whipworms, nodular worms, lungworms, and larval and adult kidney worms (Batte 1977). It is more potent than TBZ, especially against ascarids. Pharmacologic activity is inhibition of glucose uptake from luminal fluid of the nematode gut, which results in an inability of the parasite to produce adenosine triphosphate (ATP). Parasites are expelled over a 2- to 3-day period following treatment. FBZ may also affect fumarate reductase. It is administered in feed over a 3-day period (Corwin et al. 1984). It is approved for the control of *A. suum*, *O. dentatum*, *O. quadrispinulatum*, *H. rubidus*,

Metastrongylus apri, *Metastrongylus pudendotectus*, *T. suis*, and *S. dentatus*. No slaughter withdrawal is required. Although approved for *T. suis*, its efficacy is variable (Marti et al. 1978).

Imidazothiazoles. Levamisole was introduced in the late 1960s and demonstrated a broad range of activity in the removal of gastrointestinal, respiratory, and urinary tract nematodes. It has good efficacy against *Ascaris*, *Strongyloides*, *Hyostrongylus*, and *Oesophagostomum* and low efficacy against *Trichuris* (Marti et al. 1978). It has also demonstrated efficacy against *Stephanurus* (Stewart et al. 1977).

Levamisole has a paralyzing effect by blocking ganglionic transmission, with a rapid expulsion of living worms. It also blocks the metabolic pathway responsible for formation of ATP at the site of fumarate reduction and succinate oxidation. Parasites expelled from the proximal gut are decomposed and may not be apparent in the feces.

Only the hydrochloride form is approved for use in swine and is administered in the feed or water at 8 mg/kg body weight. Levamisole hydrochloride is marketed in a pelleted ready-to-use form with a dehydrated alfalfa carrier or as a powder for use in drinking water. It is intended to be consumed within a 24-hour period. It is highly soluble in water and is rapidly absorbed from the gastrointestinal tract, with 40% excreted in the urine in 12 hours and 41% in the feces over 8 days. It is approved for the control of *A. suum*, *Oesophagostomum* spp., *Metastrongylus* spp., and *S. ransomi*. It has a 72-hour slaughter withdrawal.

Resistance to levamisole and cross-resistance to pyrantel in swine *Oesophagostomum* spp. has been reported in Denmark (Bjorn et al. 1990).

Organophosphate Compounds. Dichlorvos is the only organophosphate compound approved for use as a swine anthelmintic. It was the first broad-spectrum compound for use in swine, with good efficacy against *Ascaris*, *Oesophagostomum*, *Trichuris*, and *Hyostrongylus* with slightly lower efficacy against *Strongyloides* (Marti et al. 1978).

Dichlorvos inhibits nematode cholinesterase, leading to interference with neuromuscular transmission (Knowles and Cassida 1966). Nematode cholinesterase is removed by complexing with the organophosphate, whereas host cholinesterase may fail to complex, thus providing a margin of safety for the treated host. Dichlorvos is rapidly absorbed from the gastrointestinal tract and detoxified by the liver. Metabolites do not persist as tissue residues. Dichlorvos should not be given within a few days of other organophosphates, other anthelmintics, or modified live virus vaccines. There apparently are no adverse effects upon conception or gestation. The compound causes increased intestinal peristalsis.

Dichlorvos is a unique organophosphate in that it can be incorporated into polyvinyl chloride pellets which allow for slow release of the volatile active ingredient from these undigestible units during passage along the intestinal tract. Slow release allows for continued effect in the cecum, thereby producing the desired removal of whipworms. This also provides greater safety for an otherwise toxic compound, since the host can then detoxify dichlorvos as it is absorbed over a 2- to 3-day period. Dichlorvos is administered in the feed, mixed with one-third the regular ration. The recommended dose is 11.2–21.6 mg/kg body weight. It is approved for the control of *A. suum*, *Oesophagostomum* spp., *T. suis*, and *Ascarops strongylina*. There is no slaughter withdrawal when used at the recommended dosages.

Tetrahydropyrimidines. Pyrantel tartrate is the only tetrahydropyrimidine approved for swine and was introduced as a broad-spectrum anthelmintic compound in 1966. It is efficacious in the removal of adult and infective larval stages of *Ascaris*, *Oesophagostomum*, and *Hyostrongylus*.

Pyrantel acts as a neuromuscular blocking agent by depolarization of synapses. The musculature contracts irreversibly. The powdered premix is given at a single therapeutic dose level of 22 mg/kg body weight with an overnight fast or as a prophylactic measure at 96 g/ton of feed. For maximum effect against luminal forms, it is administered dry in the feed to minimize absorption. It is most commonly used as a continuous dewormer in feed for starter and growing pigs and is given in combination with carbadox, which promotes growth. It has a great margin of safety and can be used concurrently with organophosphate insecticides. It is not recommended for use in severely debilitated animals because of more pronounced nicotinic activity. It is approved for the control of *A. suum* and *Oesophagostomum* spp., an aid in the prevention of larval migration and establishment of *A. suum*, and an aid in the prevention of establishment of *Oesophagostomum*. There is a 24-hour slaughter withdrawal. Resistance of swine *Oesophagostomum* spp. has been reported in Denmark (Roepstorff et al. 1987).

Piperazine Salts. An older generation of antiparasitic drugs includes piperazine salts. Piperazine compounds are still widely used, being efficacious in removal of ascarids and nodular worms. Up to 100% of the lumen-dwelling stages may be eliminated with a single treatment, but mature worms are more susceptible than earlier stages. A second treatment is recommended 2 months later to remove emerging larval stages.

Piperazine is a diethylenediamine, with the hexahydrate formed in water. It is readily absorbed from the proximal region of the gastrointestinal tract. Some of the base is metabolized in tissues, with 30–40% excreted in the urine. The pharmacologic effect is an anticholin-

ergic action at the myoneural junction, producing a neuromuscular block. In addition, succinic acid production is inhibited. These combined activities produce an overall narcotic effect. Affected parasites are passively removed by intestinal peristalsis and voided live in the host feces. There are no known contraindications, and the compound can be given to animals with gastrointestinal distress.

Piperazine salts are administered in the feed or water. For example, piperazine citrate is given as a 1-day medication in feed, and the hexahydrate form is used in drinking water because of its suitability for storage in solution. Medicated feed or water should be consumed in an 8- to 12-hour period; therefore, withholding feed or water the previous night is beneficial. The recommended dosage is 275–440 mg/kg body weight. It is approved for the control of *A. suum* and *Oesophagostomum* spp. There is a 21-day slaughter withdrawal.

56 Occurrence of Mycotoxins in Grains and Feeds

G. D. Osweiler

Mycotoxins are secondary metabolites of mold growth in grains or forages. They result from stress or altered conditions of fungal growth related to a variety of plant and environmental factors. Most mycotoxin problems in veterinary medicine involve the feed grains (e.g., corn, wheat, milo, cottonseed). Fungal growth requires a readily available carbohydrate (supplied by grains), adequate moisture, oxygen, and appropriate temperatures (often 12–25°C; Wilson and Abramson 1992). Plant or fungal stressors (e.g., drought, high ambient temperatures, insect damage, mechanical harvest damage, and reduced plant vigor) predispose crop plants to infestation by toxigenic fungi with subsequent mycotoxin production (Richard and Cole 1989; Ominski et al. 1994). Environmental and plant stress factors are sometimes used by plant pathologists to predict mold infestations and probable mycotoxin production.

Although specific fungi are associated with mycotoxin formation, simple visual or cultural examination of grain or feed cannot be used to determine safety for animals. Many toxigenic strains of molds can occur in grains without the production of mycotoxins, and there is little correlation between spore counts or degree of fungal growth and presence of mycotoxins. Conversely, absence of molds does not mean that a feed is safe from mycotoxins, since high temperature and pressure during milling may reduce fungal populations so that mold growth is not apparent. However, the common mycotoxins are resistant to the temperatures that kill molds and may persist in feeds when there is no evidence of fungal contamination (Osweiler et al. 1985).

Two general categories of fungi recognized are field fungi and storage fungi (Christensen and Kaufmann 1965; Wilson and Abramson 1992). Field fungi grow in crops prior to harvest. Fusarium spp. are recognized as a source of common mycotoxins. They require high relative humidity (>70%) and grain moisture (>23%) for growth. Field fungi often cause death of ovules, shriveling of seeds or kernels, and weakening or death of embryos. The grading term for this effect is "weathering."

The field fungi grow poorly after harvest because storage to prevent spoilage precludes these conditions, and growth and toxin production appear not to occur readily if dry grain is remoistened (Christensen and Kaufmann 1965).

Storage fungi include the genera Aspergillus and Penicillium, which account for several mycotoxins important in swine production. These fungi may grow and produce mycotoxins even when moisture content ranges from 14–18% and at temperatures that vary from 10–50°C. Aspergillus flavus, normally considered a storage fungus, often produces significant concentrations of aflatoxin in crops prior to harvest.

Mycotoxins occur sporadically both seasonally and geographically (Pier 1981). Certain geographic regions are considered at high risk for specific mycotoxins. This regional predilection may be strongly influenced, however, by local conditions such as early frost, drought, and insect damage. In addition, long-distance transport of grains and finished feeds, as well as blending of grains, damage in transit, and improper storage, can obscure regional differences.

Environmental and management conditions may influence mycotoxin production and animal exposure to mycotoxins. Mycotoxin concentrations are higher in grain that is damaged, light, or broken, which occurs, for example, in screenings. When screenings are fed on the farm or sold locally at harvest time, there may be increased exposure to high concentrations of mycotoxins; grain producers who also have a farrowing operation may give lower-quality grain to sows for short periods of time during harvest. Grain that is slightly above optimum moisture for storage may continue to respire and produce water; eventually a portion of the storage bin will achieve free-moisture levels supportive of mold growth and toxin production. Alternating warm and cool temperatures during fall and spring may favor moisture migration and condensation within a storage bin. Each time a fungal-contaminated grain is cracked or ground, the protective seed coat is broken and the

Table 56.1. Conditions for Fungal Growth and Synthesis of Common Mycotoxins

Fungal Source	Grains Most Affected	Optimal Temperature	Moisture Requirements	Mycotoxin Produced	Agronomic Influences
Aspergillus flavus *A. parasiticus*	Corn, peanuts, cottonseed, milo	24–35°C	ERH 80–85% EMC 17%	Aflatoxin	Drought, insect damage increase risk
Fusarium roseum	Corn, wheat, barley	7–21°C	EMC 24%	Deoxynivalenol	Alternating warm and cool growing season
Claviceps purpurea	Rye, wheat, triticale, oats, barley	Likely moderate to cool during seed formation	Moist, humid conditions favor production	Ergot	Warm humid conditions, wind and insects favor spread of ergot infection
Fusarium moniliforme *F. proliferatum*	Corn	Likely moderate temperatures <25°C	Probable EMC> 20%	Fumonisin	Dry and hot growing conditions followed by moist autumn
Aspergillus ochraceus *Penicillium viridicatum*	Corn, wheat, barley, rye	12–25°C Can produce toxin at 4°C	ERH 85% EMC 19–22%	Ochratoxin	Lower temperatures favor increase toxin yield
Fusarium sporotrichoides	Corn, barley, milo, wheat,	8–15°C	EMC 22–26%	T-2 Toxin	Alternating cool and warm conditions; overwintered crops.
Fusarium roseum	Corn, wheat	7–21°C	EMC 24%	Zearalenone	Alternating high and low temperatures during maturation

ERH = Equilibrium Relative Humidity; EMC = Equilibrium Moisture Content.

grain is susceptible to molding. Feed stored in warm, humid conditions such as a nursery may mold and produce mycotoxins within only a few days. Table 56.1 shows the fungi and their growth conditions that favor production of specific mycotoxins.

INTOXICATION BY MYCOTOXINS

The most important factor in toxicosis is access to contaminated grain by a susceptible animal. Dietary deficiencies of protein, selenium, and vitamins have been suggested as predisposing factors in mycotoxicosis, but well-documented examples are rare. Drugs that reduce or enhance foreign-compound metabolism could influence response to mycotoxins, since most common mycotoxins are metabolized to intermediate or final products that differ in toxicity from the parent mycotoxin (Osweiler et al. 1985; Beasley et al. 1986). This type of drug interaction is more likely with aflatoxins and ochratoxin than with the trichothecenes.

Combinations of some mycotoxins may potentiate the action of one another, or at least exert an additive effect. One example of this is the combination of aflatoxin and ochratoxin (Huff et al. 1988; Harvey et al. 1989a). Currently there is little evidence that common mycotoxins act synergistically. Fortunately, conditions for production of several mycotoxins concurrently in the same grain appear to be relatively uncommon.

Some mycotoxins are reported to alter immune function under certain conditions. Aflatoxins, some trichothecenes, and ochratoxin A have been demonstrated to be immunosuppressive in domestic or laboratory animals. Common diseases influenced by aflatoxin under experimental conditions include swine erysipelas,

swine dysentery, and salmonellosis. Generally, immunosuppressive effects of aflatoxins and trichothecenes are seen only at concentrations that cause subtle or chronic changes typical of the mycotoxin. Marin et al. 2002, reported that 4 weeks feeding of 280 ppb aflatoxin reduced weight gain in swine while also increasing leukocyte count and raising serum gamma globulin. This same study demonstrated that immune response to *Mycoplasma agalactiae* was reduced and that cytokine mRNA expression in phytohemagglutinin-stimulated blood cells was associated with decreased proinflammatory factors, IL-1 beta and TNF-alpha, but increased antiinflammatory IL-10 cytokine expression. Because the mycotoxin interaction is usually expressed as the infectious disease, mycotoxin-facilitated disease is difficult to detect or confirm. Normal immune function is expected to return after exposure to the toxin ends (Pier 1981; Panangala et al. 1986; Richard and Cole 1989).

CLINICAL MYCOTOXICOSES

Clinical response of swine to mycotoxins may be acute, subacute, or chronic and is both dose and time dependent, similar to other chemical toxins. For known mycotoxins of clinical importance, response is usually subacute or chronic and the presenting signs are often subtle and vague. Many times problems are expressed only as alterations of the reproductive cycle, reduced feed intake, slow growth, or impaired feed efficiency. Nevertheless, an understanding of the range of effects for specific mycotoxins is important in differential diagnosis and evaluation of clinical prognosis for mycotoxin diseases. Common mycotoxins affecting swine are summarized in Table 56.2.

Table 56.2. Major Features of Mycotoxins That Commonly Affect Swine

Mycotoxin	Most Susceptible	Clinical Effects	Lesions	Diagnostic Specimens and Tests	Therapy and/or Prevention	Residue Concerns
Aflatoxin	Piglets, feeder pigs	Reduced growth, hepatotoxicosis Immune dysfunction	Hepatic necrosis, bile duct hyperplasia	Aflatoxin in feed; AF M1 in liver or urine	Vitamin E and selenium supplements Aluminosilicate in diet	Residues occur in liver and milk for <3 weeks
DON	Feeder pig, Finishers Sows	Feed refusal, reduced growth	Weight loss	DON >1 ppm in diet	Change feed	Not likely to cause residues
Fumonisin	All	Pulmonary edema, dyspnea, cyanosis, 2–4 hrs to death. Abortion in sows. Hepatic damage	Pulmonary edema, hepatosis	Histological lesions of pulmonary edema or hepatosis; FB1 in feed	Change feed; treat for liver damage; avoid grain screenings in diet	Residues brief, most likely in liver and kidney
Diacetoxy-Scirpenol or T-2 Toxin	Feeder pig, Finishers Sows	Feed refusal Diarrhea Leucopenia Oral ulceration Immune suppression	Oral ulcers, gastric ulcers, lymphoid and thymic depletion	Histological lesions of ulceration, lymphopenia, leucopenia, feed analysis	Change feed and treat for diarrhea/ulcers	Not likely to cause residues
Ergot	Sows Nursing pigs	Agalactia with piglet starvation Peripheral gangrene	Piglet starvation Peripheral gangrene	Ergot bodies or alkaloids in urine or diet; peripheral vascular lesions	Avoid ergot in grain	Residues brief, not likely to be significant
Ochratoxin	All	Reduced growth Polydipsia, polyuria, renal failure	Gastric ulcers Pale swollen kidneys	Histological evidence of gastric ulcers and renal tubular damage or fibrosis	Change feed; low protein diet for kidney damage recovery	High probability of persistent residues
Zearalenone	Prepuberal gilts Cycling sows Young boars	Hyperestrogenism in young gilts Pseudopregnancy, delayed cycling, early embryonic death Reduced libido	Vulvovaginitis, Vaginal keratinization Retained Corpora lutea Reduced testicular size	Histological lesion of vaginal keratinization; Elevated serum progesterone; Zearalenone in feed	Change feed; treat gilts for prolapse Administer 10 mg PGF2α to pseudopregnant sows	Rapidly excreted in urine; low residue probability

Aflatoxins

Aspergillus flavus and *A. parasiticus* produce aflatoxins in grains and oilseeds both in storage and before harvest. Although many areas of North America have conditions supportive of aflatoxin production, conditions leading to aflatoxin production often occur in the southeastern United States (Richard and Cole 1989).

Aflatoxins B_1, B_2, G_1, and G_2 occur in grains. When Aflatoxin B_1 (AFB$_1$) is metabolized by mammals, it occurs in milk or urine as aflatoxin M_1. Aflatoxin B_1 is the most abundant and most toxic fraction under natural contamination (Jelinik et al. 1989; Richard and Cole 1989).

Aflatoxin B_1 is metabolized by liver microsomal mixed-function oxidases to form at least seven metabolites. The major metabolite of aflatoxin is an epoxide, which binds covalently to nucleic acids and proteins and is believed to be responsible for causing hepatic cancer as well as toxic signs and lesions. Impairment of protein synthesis and subsequent inability to mobilize fats result in characteristic early lesions of hepatic fatty change and necrosis, as well as reduced growth rate. Animals on protein-deficient diets are more susceptible to aflatoxin, and increased dietary protein will protect against aflatoxin effects on weight gain (Coffey et al. 1989).

Toxicity of aflatoxin is affected by dosage, length of exposure, animal species, and age of animal. Acute toxicosis is uncommon. The single oral dose LD50 for swine is 0.62 mg/kg body weight; dietary levels of 2–4 parts per million (ppm) are associated with acute fatal toxicosis, while rations containing 260 ppb for several weeks were associated only with reduced growth rate (Allcroft 1969). Exposure to low or moderate concentrations in feed for several weeks is a common circumstance of exposure. Combined evidence from experimental reports, field cases, and my personal experience suggests that concentrations of naturally occurring aflatoxins above 300 ppb fed for a period of several weeks will likely cause reduced growth and feed efficiency (Allcroft 1969; Cook et al. 1989; Harvey et al. 1988, 1989c; Richard and Cole 1989; Dilkin et al. 2003).

The experimental threshold dietary concentration for clinical effects varies widely. Young swine are more susceptible to aflatoxins than finishing hogs or adults, and mitigating factors may include dietary protein level, vitamin A deficiency, and inadequate selenium intake. Effects of aflatoxins may be both time and dosage dependent. Liver lesions have been reported caused by concentrations as low as 140 ppb fed for 12 weeks in 18–64 kg swine, and 690 ppb was associated with mild liver lesions in 64–91 kg finishing hogs (Allcroft 1969). In my experience, prolonged feeding of aflatoxin at concentrations above 400 ppb can cause microscopic liver lesions. Dilkin et al. 2003, fed 50 (ppb) of Aflatoxin B_1 to weaned piglets for 28 days. Body weight gain and feed consumption were not affected, and there were no gross or microscopic lesions found. In addition, no evidence of changes in complete blood count or clinical chem-

istry were detected. Marin et al. (2002) fed Aflatoxin B_1 (AFB$_1$) to weanling pigs at 140 and 280 ppb for 28 days. AFB$_1$ at 280 ppb caused significant decrease in weight gain, but caused no effect on total red blood cell count, differential leukocyte count, total globulin, albumins, or total protein concentration in serum. However, gamma globulin was significantly increased at both 140 ppb and 280 ppb. The lower concentration of AFB$_1$ (140 ppb) resulted in reduced average daily gain that was not statistically significant ($P < .05$). Aflatoxin at 50 ppb when fed concurrently with 30 ppm Fumonisin B_1 (FB$_1$) caused decreased feed consumption and reduced feed conversion (Dilkin et al. 2003), but effects were attributed mainly to FB$_1$. Much higher dietary concentrations of FB$_1$ have resulted in significant clinical and pathological effects. Harvey et al. (1995a, b) fed 2.5 ppm AFB$_1$ to 17.5 kg barrows for 35 days. Body weight, gain, and feed consumption were significantly ($P < 0.05$) decreased by AF. Aflatoxin increased serum gamma glutamyl transferase (GGT) activity and total iron concentration and decreased urea nitrogen concentration and unsaturated iron-binding capacity. Aflatoxin increased relative liver weight and resulted in liver that was pale, rubbery, and resistant to cutting. Characteristic hepatic necrosis and degeneration, accompanied by bile duct proliferation resulted from aflatoxin feeding. When 100 ppm of Fumonisin B_1 (FB$_1$) was fed with 2.5 ppm AFB$_1$, mitogen-induced lymphoblastogenic stimulation index was decreased by aflatoxin and FB$_1$ diets, and the combination diet significantly decreased cell-mediated immunity compared to single toxin diets. Thus AFB$_1$ and FB$_1$ in culture material, singly or in combination, can adversely affect clinical performance, serum biochemical, hematologic, and immunologic values and induce lesions in growing barrows. One should remember that the dosages of this study were very high and do not commonly occur under natural conditions.

Clinical signs of acute to subacute toxicosis are depression and anorexia. Anemia, ascites, icterus, and hemorrhagic diarrhea may develop. Coagulopathy characterized by hypoprothrombinemia may occur. Enzymes associated with hepatocellular damage are elevated, including aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, and gamma glutamyl transferase. Other serum clinical chemistry changes observed have been decreases in serum total iron-binding capacity, total protein, albumin, cholesterol, blood urea nitrogen, and glucose (Harvey et al. 1989c). Total bilirubin, icterus index, sulfobromophthalein clearance, prothrombin time, and partial thromboplastin time are also elevated in clinical aflatoxicosis (Panangala et al. 1986).

Gross lesions associated with porcine aflatoxicosis include pale tan or clay-colored liver with centrilobular hemorrhages, subserosal petechial to ecchymotic hemorrhages, and intestinal and colonic hemorrhages. As the course of aflatoxicosis progresses, the liver becomes

yellow and fibrosis develops, characterized by a firm, hard liver with accentuated lobular pattern. The yellow discoloration of icterus occurs at serosal and mucosal surfaces (Cook et al. 1989; Harvey et al. 1989b).

Microscopic alterations are useful for diagnostic purposes and generally include hepatocyte vacuolization, necrosis, and fatty change, which is more predominant around central veins. As disease progresses to subacute or chronic, hepatomegalocytosis, including multiple nuclei is seen. Interlobular fibrosis and characteristic biliary hyperplasia develop in chronic cases (Cook et al. 1989; Harvey et al. 1988). Full evaluation and diagnosis of aflatoxicosis should include a search for the characteristic lesions.

Significant reproductive effects of aflatoxin in swine have not been documented. Sows fed aflatoxin have maintained normal reproduction through four successive gestations at dietary concentrations of 500 and 700 ppb. Although gestation and farrowing were normal, piglets nursing these sows had reduced growth rate due to aflatoxin excretion in the milk (Armbrecht et al. 1972; McKnight et al. 1983).

Aflatoxins are recognized as immunosuppressive agents in many species. Aflatoxin is an immunomodulating agent that acts primarily on cell-mediated immunity and phagocytic cell function (Bondy and Pestka 2000). Piglets nursing on sows exposed to AFB_1 may be immunocompromised. Sows fed diets containing either 800 or 400 ppb purified AFB_1 throughout gestation and lactation had B_1 and M_1 residues in milk 5 and 25 days after parturition, at approximately 1000-fold lower than that in the feed and with increases during the 25 days after parturition. Lymphoproliferative response to mitogens was reduced and monocyte-derived macrophages failed to efficiently produce superoxide anions after oxidative burst stimulation in vitro. Ability of macrophages to phagocytose red blood cells was not compromised, but granulocytic cells showed a reduction of chemotactic response in vitro to chemoattractant bacteria factor and casein (Silvotti et al. 1997).

Residues of aflatoxin M_1 occur in tissues, milk, and urine of swine but are not persistent. Dietary concentrations of 400 ng/g resulted in tissue residues of 0.05 ppb or less, and these rapidly disappeared when aflatoxin feeding stopped (Trucksess et al. 1982).

Diagnosis of aflatoxicosis should be considered when acute icterus, hemorrhages, or coagulopathy are not explained by other causes. Chronic signs of slow growth, malnutrition, and persistent low-grade infectious diseases should also suggest investigation for aflatoxicosis. Characteristic liver lesions and clinical chemistry changes would strongly suggest aflatoxicosis. Chemical analysis of the ration and grain supply may identify aflatoxin, but sometimes the grain that initiated a chronic problem is no longer available or representative. Any grain sampling should be representative (see the section Prevention and Management of Mold and Mycotoxin Problems for sampling procedure). Examination of suspect grain sample under ultraviolet light has long been a screening approach. This simple procedure identifies kojic acid, a metabolite produced by aflatoxin-producing fungi. However, it may falsely implicate some samples and should never be relied upon without a confirmatory chemical analysis for AFB_1.

Aflatoxicosis is generally a herd problem and not amenable to individual animal treatment. Specific practical antidotes for affected animals are not available. Work in poultry has shown some benefit from increased dietary selenium. Increased dietary levels of high-quality protein and supplementation with vitamins (A, D, E, K, and B complex) are recommended (Coppock and Swanson 1986; Coffey et al. 1989). Hydrated sodium calcium aluminosilicate (HSCAS) at 0.5% in the diet provided substantial protection against loss of gain and occurrence of lesions induced by dietary aflatoxin in swine (Harvey et al. 1989c). Treatment of grain with anhydrous ammonia for 10–14 days has reduced aflatoxin concentration in grain. Swine accept ammoniated grain and their growth is comparable to controls. Presently, this method of treatment has not been cleared by the U.S. Food and Drug Administration.

Since aflatoxin may compromise the immune system, animals with concurrent infectious diseases should be aggressively treated with appropriate antimicrobial therapy and passive immunization if appropriate. However, specific studies with the antibiotics lincomycin and tylosin added to aflatoxin-contaminated diets neither decreased or enhanced the detrimental effects of aflatoxicosis in growing swine (Harvey et al. 1995b).

Ochratoxin and Citrinin

Ochratoxin is a fungal nephrotoxin produced by *Aspergillus ochraceus* and *Penicillium viridicatum*. Citrinin, also a nephrotoxin, is produced by *P. citrinum*. Based on clinical and pathologic effects in swine, both toxins can be considered together. Toxins are associated with corn, barley, rye, and wheat, most commonly from eastern and northern Europe, Canada, and the northern United States (Jelinik et al. 1989; Juszkiewicz et al. 1992). Significant concentrations of ochratoxin can occur at temperatures as low as 4°C. Ochratoxin A has been prevalent in Denmark and is associated with the feeding of barley and oats (Carlton and Krogh 1979). In the United States, at least one case has been documented in swine fed contaminated corn (Cook et al. 1986). A survey of Romanian slaughter pigs revealed that 98% of serum samples were positive for ochratoxin A (OTA) at concentrations as high as 13.4 ng/g, although 85% of samples contained less than 5 ng OTA per ml. Measurable levels of OTA occurred in 75–80% of swine liver and kidney. (Curturi et al. 2001).

Toxicity appears related to binding of OTA in specific receptors for organic ion transporters of the renal tubule (Huessner et al. 2002). The mechanism of action appears

Table 56.3. Clinical guide to mycotoxins in swine

Toxin	Category of Swine	Dietary Level	Clinical Effect
Aflatoxins	Growing-finishing	<100 ppb	No clinical effect
		200–400 ppb	Reduced growth and feed efficiency; possible immunosuppression
		400–800 ppb	Microscopic liver lesions, cholangiohepatitis; increased serum liver enzymes; immunosuppression
		800–1200 ppb	Reduced growth; decreased feed consumption, rough hair coat; icterus, hyproproteinemia
	Brood sows and gilts	>2000 ppb	Acute hepatosis and coagulopathy; deaths in 3–10 days
		500–750 ppb	No effect on conception; deliver normal piglets that grow slowly due to aflatoxin in milk
Ochratoxin and Citrinin	Finishing	200 ppb	Mild renal lesions seen at slaughter; reduced weight gain
		1000 ppb	Polydipsia; reduced growth; azotemia and glycosuria
		4000 ppb	Polydipsia and polyuria
	Sows and gilts	3–9 ppm	Normal pregnancy when fed first month
Trichothecenes T-2 and DAS	Growing-finishing	1 ppm	No effect
		3 ppm	Decreased feed consumption
		10 ppm	Decreased feed consumption; oral/dermal irritation; immunosuppression
		20 ppm	Complete feed refusal, vomiting
Deoxynivalenol (DON, vomitoxin)	Growing-finishing	1 ppm	No clinical effect; minimal (10%) reduction in feed consumption
		5–10 ppm	25–50% reduction in feed consumption; taste aversion to same diet
		20 ppm	Complete feed refusal
Zearalenone	Prepuberal gilts	1–3 ppm	Estrogenic; vulvovaginitis, prolapse in prepuberal gilts
	Cycling sows and gilts	3–10 ppm	Retained corpora lutea; anestrous; pseudopregnancy
	Pregnant sows	>30 ppm	Early embryonic death when fed 1–3 weeks post mating
Ergot	All swine	0.1%	Reduced weight gain
	Sows last trimester	0.3%	Gangrene of ears, tail, feed
		3.0%	Decreased feed consumption
		0.3%	Agalactia, reduced piglet birth weight; piglet starvation
Fumonisins	All swine	25 ppm	Minimal changes in clinical chemistry – increased AST, AP
		50–75 ppm	Minimal reduction in feed intake; possible mild hepatosis
		75–100 ppm	Reduced feed intake, reduced weight gain; hepatosis with icterus and increased bilirubin and GGT
		>100 ppm	Acute pulmonary edema after 3–5 days consumption; survivors develop hepatosis

to result from a combination of inhibition of phenylalanine metabolizing enzymes, inhibition of adenosine triphosphate (ATP) production, and accumulation of lipid peroxidation (Marquardt and Frohlich 1992). Resulting effects on protein synthesis may be related to inhibition of phenylalanine metabolism. Immunosuppressive effects are associated with a combination of suppressed lymphocyte proliferation and interference with the complement system (Bondy and Pestka 2000).

In swine, principal effects are manifest on proximal renal tubules. Ochratoxin A at 1 mg/kg body weight is lethal in 5–6 days. Concentrations of 1 ppm in the diet for 3 months cause polydipsia, polyuria, reduced growth, and lowered feed efficiency. Levels as low as 200 ppb for several weeks cause detectable renal lesions. Additional clinical signs are diarrhea, anorexia, and dehydration. Sometimes no clinical signs are noted and the only effect observed is the appearance of pale, firm kidneys at slaughter, commonly associated with ochratoxin in endemic areas such as Denmark and Sweden.

Clinical pathology changes include increases in blood urea nitrogen, plasma protein, packed-cell volume, aspartate aminotransferase, and isocitric dehydrogenase, as well as increased urinary glucose and protein.

Citrinin, ochratoxin, and penicillic acid are synergistic and primarily produce nephrosis characterized by necrosis of the proximal convoluted tubules, followed by interstitial fibrosis. Liver damage, characterized by fatty change and necrosis, may be present but is less severe than for other primary hepatoses. Gastric ulceration is a characteristic and consistent lesion in prolonged clinical cases (Szczech et al. 1973; Carlton and Krogh 1979). Boars given 20 μg OTA per os for 6 weeks had reduced ejaculation volume, initial viability, and progressive motility. Viability, initial forward motility, and motility after 24 hours were significantly reduced during a 24-hour storage period (Biro et al. 2003).

Diagnosis should include demonstration of the toxin and/or its metabolite, ochratoxin alpha, in feed or fresh kidney. A simple HPLC method recently reported can detect from 0.3–3 ng ochratoxin A or B (Curturi and Gareis 2001). The approximate half-life for ochratoxin A in swine tissue is 3–5 days, and little or no ochratoxin can be found in kidneys 30 days after ochratoxin exposure ceases (Carlton and Krogh 1979). Mildly affected animals may recover if removed promptly from the contaminated feed. However, if the clinical course is prolonged, recovery is slow.

Trichothecenes

The trichothecenes include at least 148 structurally related compounds. Those of known veterinary importance are produced by Fusaria, especially *F. graminearum* and *F. sporotrichioides*. This group of sesquiterpene toxins has an epoxide group that is responsible for most toxic effects. The three receiving most attention world wide are T-2 toxin, diacetoxyscirpenol (DAS), and deoxynivalenol (DON, vomitoxin). Even though much work has been done with the macrocyclic trichothecenes, T-2 and DAS, in swine, they rarely occur at toxic concentrations in North American grains.

Trichothecenes are metabolized in two phases. Initially (phase 1) oxidation and hydrolysis create transformation products that are then conjugated with glucuronic acid. In phase 2 the epoxide ring of trichothecenes is cleaved by gastrointestinal microflora (Bauer 1995; Beasley et al. 1986). Deoxynivalenol undergoes no extensive metabolism; only deoxynivalenol glucuronide and the de-epoxide product are produced. Serum, bile, and urine may contain DON after experimental feeding of as little as 4.3 ppm dietary DON. However, de-epoxy DON is found only in urine (Doll et al. 2003). The glucuronide is rapidly excreted, mainly in urine, and does not accumulate in plasma (Eriksen et al. 2003).

Trichothecenes can cause direct skin irritation and necrosis, profound lymphoid depletion, gastroenteritis, diarrhea, shock, cardiovascular failure, and death from experimental direct dosing. Chronic administration causes hematopoietic suppression and eventual pancytopenia. In addition, they are immunosuppressants (Coppock et al. 1985; Beasley 1993; Lundeen et al. 1986). Although T-2 and DAS are potent toxins, their strong tendency to induce feed refusal and/or vomiting in swine makes them somewhat self-limiting as toxins, except as potential causes of reduced feed consumption.

DON has great economic importance in world wide feed grain use because it is established as a common mycotoxin of corn, barley and wheat and is well documented as a cause of feed refusal or reduced feed intake in swine (Trenholm et al. 1984; Russell et al. 1990; Bohm 1992; Bergsjo et al. 1993; Rotter et al. 1996). In corn, DON occurs at low levels during some harvest seasons, with an incidence as high as 50%. Grain contamination in other grains and in other parts of the world also occurs (Hietaniemi and Kumpulainen 1991). Swine begin to reduce voluntary feed consumption at DON concentrations of 1 ppm or more, and feed refusal may be complete at concentrations in excess of 10 ppm (Young et al. 1983; Pollman et al. 1985; Bohm 1992; Bergsjo et al. 1992; Rotter et al. 1996).

Many studies have demonstrated only feed refusal with concurrent health effects in swine that are consistent with effects of reduced nutrient intake (Lun et al. 1985). Among a variety of blood chemistry parameters in pigs fed DON, only alpha-globulin and possibly cortisol were altered in animals fed diets containing DON. Other sporadic differences appeared to be due to differences in feed intake; hematologic and blood chemistry tests are of limited value in diagnosing low-level dietary DON in swine (Prelusky et al. 1994a). At low dosages of DON, hematological, clinical, and immunological changes are transitory and decrease as compensatory/adaptation mechanisms are established (Rotter et al. 1994). Effects of a 3.5 mg DON/kg diet included increased liver weights, decreased serum proteins and albumin, and a temporary fall in packed-blood-cell volume, serum calcium, and serum phosphorus. No other effects on hematological, biochemical, or immunological parameters occurred (Bergsjo et al. 1993). Diets containing 3.0 mg DON/kg fed for 28 days appeared associated with increased skin temperature, depressed feed intake, reduction in thyroid size, and apparent hyperplasia and increased mucosal folding of the esophageal portion of the stomach. Serum T4 (thyroxine) levels were increased at 7 and 28 days of exposure. Other changes reported were elevated serum albumin levels, decreased alpha-globulin levels, increased albumin/globulin ratio, and delayed titer response to immunization with sheep red blood cells. An increase in the segmented neutrophil count was observed (Rotter et al. 1994).

Recent work has shown that DON in swine causes conditioned taste aversion, and flavoring agents will be ineffective in inducing swine to consume contaminated grain (Osweiler et al. 1990). Others have shown that T-2 toxin, closely related to DON, may affect brain neurotransmitters, such as serotonin or dopamine, contributing to feed refusal and lethargy (MacDonald et al. 1988). A number of studies have implicated changes in brain neurochemistry as a factor in feed refusal and/or vomiting induced by DON or T-2 toxin. Central serotoninergic (5-hydroxytryptamine [5HT]) pathways are believed to be involved in the mechanisms of anorexia and/or emesis evoked by DON (Prelusky et al. 1992). Low-level DON exposure (30 µg/kg intragastric [IG]) caused a rapid and sustained increase in cerebrospinal fluid 5-hydroxyindoleacetic acid (5HIAA) for up to 20 hours post dosing, indicating that elevated brain serotonin turnover related to DON exposure is important in the decreased feed intake of animals fed DON (Prelusky 1993, 1996). DON causes elevated norepinephrine and depressed dopamine concentrations, while levels of 5HT increase initially and then drop significantly at 8 hours. However, DON has only weak affinity for 5HT receptors, suggesting that relatively high concentrations of the toxin are needed for this effect, and there may be other mechanisms of interaction with serotoninergic receptors at the central level. Feeding grain contaminated with 5.5 ppm DON and 0.5 ppm 15-acetyl DON, 26.8 ppm Fusaric Acid, and 0.4 ppm zearalenone caused an expected reduction in feed intake and weight gain (Swamy et al. 2002). In addition, there were significantly

reduced concentrations of dopamine in the hypothalamus and pons as well as concentration of dihydroxyindoleacetic acid and norepinephrine in the pons. Prelusky (1997) found that infusion of DON by intraperitoneal osmotic pump caused a more prolonged and sustained decrease in weight gain than an equivalent dietary exposure. Pigs fed DON tend to recover weight gain significantly after the initial 3 days of exposure to dietary DON. This was interpreted as evidence that the effect of DON on weight gain is due to more than just reduced feed intake. Although several neurochemical changes caused by DON are compatible with known neurochemical changes for chemical-induced anorexia, the feed refusal effects of acute DON exposure need further clarification.

Diagnosis of mycotoxin-related feed refusal presents a difficult problem to the clinician. Other toxins, drugs, concurrent disease, inclement weather, and reduced water intake may contribute to feed refusal. There is no apparent detectable effect of DON on plasma levels of brain neurotransmitters at DON doses that cause vomiting in swine. Thus, sampling of peripheral blood would not predict the central serotoninergic effects associated with DON toxicosis (Prelusky 1994). Since trichothecenes are rapidly metabolized, diagnosis by analysis of tissue or blood samples is rarely possible or practical. Fortunately, due to rapid metabolism and excretion, significant residues of trichothecene mycotoxins in edible swine tissues are unlikely (Bauer 1995). Often the DON concentration detected chemically in feed is insufficient to fully explain feed refusal. One should remember that feed concentrations are approximations, that sampling is never completely representative, and that many factors in the herd and environment may not be apparent to either the clinician or the producer.

Treatment of DON toxicosis with drugs has been studied very little. Antiemetics that are specific serotonin (5HT)-receptor antagonists (ICS 205-930, BRL 43694 A) have been shown to prevent DON-induced vomiting in swine. Anticholinergic compounds were moderately effective at high dosages by acting directly at the emetic center. However, antihistaminic and antidopaminergic antiemetics without anticholinergic activity were not effective anti-emetics against DON (Prelusky and Trenholm 1993).

Attempts to prevent DON effects have centered on feeding adsorbents or on chemical or physical means of detoxification. These have included calcium aluminosilicate, bentonite, and sodium bisulfite. None of these have been successful in an economic and practical way. Recently, Avantaggiato et al. (2004) have shown in an in vitro gastrointestinal model significant reduction in intestinal absorption of DON and Nivalenol. With 2% activated carbon (charcoal) there was a reduction of absorption from 51% to 28% for DON and from 21% to 12% for Nivalenol. If the in vitro model is confirmed effective in feeding trials, this could offer another alternative to adsorption prophylaxis against DON. Feeding of yeast cell wall polymer (a glucomannan polymer, GM polymer) prevented some of the known effects of trichothecenes on brain neurochemistry and serum Ig concentrations (Swamy et al. 2002). Another novel detoxification method was described in which contents of the large intestine of chickens (CLIC) incorporated into swine diets reduced the feed refusal effects of 2.1 ppm dietary DON (He et al. 1993). Anaerobic incubation of swine colonic contents with DON demonstrated degradation of the epoxide ring of DON (Kollarczik et al. 1994). Additional data (Eriksen et al. 2002) has shown that different gastrointestinal microfloras of swine have different capacities to metabolize trichothecenes. They found that intestinal de-epoxidation ability is common on some Swedish swine farms, and that this characteristic may be transferred between pigs in a herd. These studies may suggest future means for management or prevention of the feed refusal effects from DON. Physical decontamination of deoxynivalenol from barley was recently demonstrated by use of an abrasive pearling procedure, which removed 66% of DON with loss of only 15% of the grain mass (House et al. 2003). This method could provide a practical means for reducing DON contamination to a manageable level in years of widespread crop contamination.

Zearalenone (F-2 Toxin)

Fusarium graminearum (F. roseum) produces zearalenone, an estrogenic mycotoxin in corn, milo, and wheat. *Fusarium roseum* can produce either zearalenone or deoxynivalenol (Diekman and Green 1992). High moisture (23–25%) is required for growth. Under laboratory conditions, optimum production of zearalenone occurs when *F. graminearum* is incubated at a water activity ($a[w]$) = 0.97 for 2 weeks at 28°C followed by 4 weeks at 12°C (Jimenez et al. 1996). Poorly dried ear corn and alternating high and low ambient temperatures favor zearalenone production (Christensen and Kaufmann 1965). Often it is produced in the field prior to harvest.

Zearalenone is a substituted resorcyclic acid lactone similar in structure to the anabolic agent zearanol used in cattle. As an estrogen, zearalenone binds competitively to estrogen receptors of the uterus, mammary gland, liver, and hypothalamus. It will cause hypertrophy of the uterus and cornification of vaginal epithelium. Zearalenone is rapidly absorbed from the intestine and is metabolized to alpha- and beta-zearalenol and alpha- and beta-zearalanol and then conjugated with glucuronic acid for excretion in bile and urine (Gajecki 2002; Meyer et al. 2000).

Clinical signs vary with dosage and age of swine exposed. In prepuberal gilts, concentrations as low as 1–5 ppm in the ration cause vulvovaginitis, which is characterized by tumescence and edema of the vulva and vagina and precocious mammary development. Tenesmus is common, occasionally with resultant rectal pro-

lapses (Osweiler 2000). Zearalenone at clinically effective dosage in sexually immature gilts is reported to have caused ovarian follicle atresia and apoptotic-like changes in granule cells. Intensified cell proliferation was observed in both uterus and oviduct (Obremski et al. 2003). Prepuberal gilts fed 2 ppm for up to 90 days attained normal sexual maturity with no adverse effects on subsequent reproductive function (Green et al. 1990; Rainey et al. 1990).

Reproductive effects of zearalenone on mature cycling sows are quite different from the effects seen in prepuberal gilts. As with other estrogens, zearalenone is luteotropic in swine, and dietary concentrations of 3–10 ppm can induce anestrus in sows if consumed during the middle portion of the estrous cycle. Since estrogens are luteotropic in swine, the probability of abortion in the last two trimesters of gestation appears very unlikely. Anestrus and elevated serum progesterone persist for several months; long after exposure to zearalenone has stopped (Edwards et al. 1987).

Fewer pigs per litter are seen in sows given high dietary concentrations of zearalenone. The susceptible period for reduced litter size appears to be in the preimplantation stage at 7–10 days post-mating (Long et al. 1983; Diekman and Long 1989). Zearalenone fed at 1 mg zearalenone/kg body weight (equivalent to approximately 60 ppm dietary zearalenone) on days 7 through 10 after mating resulted in mild blastocyst degeneration by day 11 and advanced degeneration by day 13. Viability of individual embryos is apparently not maintained beyond 21 days. During this time period zearalenone did not cause morphologic changes in the endometrium that could be associated with hyperestrogenism (height of the endometrial luminal epithelium and morphology of secretory vesicles in the endometrial glandular epithelium) (Long et al. 1992). Zearalenone at 22.1 ppm in the ration of breeding gilts caused a decrease in the number of corpora lutea, a decrease in ovarian weight, a decrease in the number of live embryos, and an increase in the number of dead-born piglets and abortions (Kordic et al. 1992).

Piglets born to sows receiving zearalenone may have enlarged external genitalia and uteri. Zearalenone and its metabolites, alpha and beta zearalenol, are present in milk of exposed sows and may contribute to estrogenic effects in piglets (Palyusik et al. 1980; Dacasto et al. 1995). A perinatal hyperestrogenic syndrome reported in swine herds and by experimental verification included lower conception rate, increased numbers of repeat breeders, decreased litter size, and increased numbers of stillbirths. Clinical signs in neonatal gilts were swelling of the vulva and teats and edematous infiltration of the perineal region, ventral abdomen, and umbilicus, usually accompanied by exudative, crusted inflammation and necrosis of the teats. An increase in splayleg and trembling piglets has been reported. Lesions of hyperestrogenism included enlargement of the ovary and uterus, ovarian follicle maturation, glandular proliferation of the endometrium, and epithelial proliferation in the vagina (Vanyi et al. 1994). Swine diets containing 2 ppm zearalenone from day 30 of gestation through weaning did not adversely affect reproduction in sows. Estrogenic effects on testes and on uterine and ovarian weights were observed in the piglets at 21 days of age, but subsequent breeding performance was not affected (Yang et al. 1995).

Preputial enlargement may occur in boars exposed to zearalenone. Young boars may have reduced libido and decreased testicular size, but mature boars are unaffected by concentrations of zearalenone as high as 200 ppm (Ruhr et al. 1983; Young and King 1983).

Differential diagnosis of zearalenone toxicosis should include estrogenic feed additives and natural estrogens such as coumestrol in mature alfalfa. Suspect rations of corn should first be analyzed for the presence of zearalenone, then for other estrogens. Feed samples available at the time of anestrus or return to service may not represent the contaminated feed that initiated the problem.

Treatment of zearalenone toxicosis depends on the nature of the effect and the age and reproductive status of swine. Removal of the feed from prepuberal gilts will allow regression of signs within 3–7 days. Medical and surgical treatment of vaginal and rectal prolapse may be necessary. For mature, nongravid sows with anestrus, administration of one 10 mg dose of prostaglandin $F_{2\alpha}$ or two 5 mg doses on successive days is useful in eliminating retained corpora lutea (B. N. Day, personal communication, 1982; Green et al. 1991). Dehydrated alfalfa has experimentally shown some protection from zearalenone-induced enlargement of the uterus of gilts (James and Smith 1982; Smith 1992), although the high concentrations needed (>20%) are not considered practical in swine diets. Activated charcoal or cholestyramine has been used at 2% in an in vitro gastrointestinal model system to evaluate its binding effect on zearalenone. Both activated charcoal and cholestyramine reduced absorption of zearalenone from 32% to 5% and 16%, respectively (Avantaggiato et al. 2003). The dramatic reduction caused by activated charcoal could be useful for contaminated grain if feeding trials are also effective.

Ergot

Ergot, *Claviceps purpurea,* is a parasitic fungus that affects cereal grains, especially rye, oats, and wheat. The fungus invades the grass ovary, forming a dark elongated body (sclerotium), which produces alkaloids that cause gangrene and reproductive interference. Major toxic alkaloids include ergotamine, ergotoxine, and ergometrine; total ergot alkaloid content commonly ranges from 0.2–0.6% of sclerotia weight. The U.S. Department of Agriculture has set a tolerance of 0.3% ergot in grain (Christensen and Kaufmann 1965).

Gangrenous ergotism is the result of a combination of vasoconstriction and endothelial damage, leading to prolonged ischemia of appendages and eventually gangrene. Because venous and lymphatic drainage remains intact, the gangrene is "dry" in nature. Signs occur over a period of days or weeks and include depression, reduced feed intake, rapid pulse and respiration, and general ill thrift. Lameness may occur, most commonly in rear limbs, and in advanced cases necrosis and sloughing of the tail, ears, and hooves can occur. Signs may be exacerbated by cold weather.

Ergot alkaloids affect reproduction indirectly by causing agalactia. Pregnant gilts fed either 0.3% or 1% sclerotia during gestation had low piglet birth weights, low piglet survival, and poor piglet weight gains. Agalactia occurred in 50% of gilts fed 0.3% sclerotia in the gestation and lactation rations (Nordskog and Clark 1945; Wiernusz and Schneider 1984). The agalactia induced is noninflammatory and results from the well-known ability of ergot to inhibit prolactin release in late gestation (Whitacre and Threlfall 1981). Both experimental and clinical evidence indicates that ergot in rations of pregnant sows is not generally a cause of abortion, and swine exposed to ergot during late gestation routinely suffer agalactia but rarely abortion (Osweiler et al. 1985).

Reduced weight gain may be caused by as little as 0.1% ergots in the ration. Higher levels (3.0%) have been implicated in feed wastage and slow growth (Roers et al. 1974).

Differential diagnosis should include zearalenone or other estrogenic factors, bacterial infections, and mastitis-metritis-agalactia syndrome. If the clinical signs suggest ergotism, grains should be examined for the presence of significant amounts of ergot sclerotia. In the case of ground or processed feeds, feed microscopy or chemical analysis for ergot alkaloids may be necessary to confirm the diagnosis.

Treatment of ergotism is general and supportive. Gangrenous areas should be cleaned and treated locally and secondary infections controlled with broad-spectrum antibiotics. Removal of the feed is followed by improvement within 2 weeks for gangrenous effects. When agalactia has occurred, milk production returns 3–7 days after feed is changed. In the interim, supplemental nutrition and milk replacers may be used to save the piglets.

Fumonisins

Fusarium moniliforme and *F. proliferatum* fungi are ubiquitous in white and yellow corn worldwide (Bezuidenhoudt et al. 1988; Steyn 1995; Shephard et al. 1996; Gelderblom et al. 1988). Recently, these fungi have been identified as the source of the fumonisin mycotoxins. Swine consuming fumonisins have been affected by the disease generally known as porcine pulmonary edema (PPE). Corn screenings contaminated with the fumonisin mycotoxins are the most likely source of fumonisin toxicosis (Harrison et al. 1990; Ross et al. 1991; Osweiler et al. 1992; Ross et al. 1992).

Fumonisins appear to be produced when corn is stressed by moderate drought followed by persistent rainfall or high humidity late in development, but full knowledge of the inciting conditions remain to be determined. Since corn screenings contain the highest concentrations of fumonisins, producers should be advised to clean poor-quality corn to remove damaged kernels before feeding.

Fumonisins commonly present in corn are fumonisin B_1 (FB_1), fumonisin B_2 (FB_2), and fumonisin B_3 (FB_3). They are water-soluble, heat-stable, and alkaline-resistant aliphatic hydrocarbons with a terminal amine group and two tricarboxylic acid side chains (Steyn 1995). The number and position of hydroxyl groups on the aliphatic hydrocarbon determine the structure as FB_1, FB_2, or FB_3; the first two are of approximately equal toxicity, while FB_3 is much less toxic.

In South Africa, fumonisin-contaminated corn is associated with esophageal cancer in a well-defined geographic area (Bezuidenhoudt et al. 1988). The fumonisins are known tumor promoters leading to precancerous liver nodules after appropriate initiation. Chronic fumonisin consumption by swine has experimentally caused esophageal hyperplasia and hepatic neoplasia (Casteel et al. 1993, 1994).

Acute PPE has been associated with increases in pulmonary intravascular macrophages and increased pulmonary arterial pressure (Smith et al. 1996). These responses have been hypothesized to lead to pulmonary edema either by increased pulmonary hydrostatic pressure or by pulmonary capillary endothelial cell damage.

Fumonisins are poorly absorbed orally (3–6% of ingested dose), and most ingested fumonisins remain in the gastrointestinal tract. Once absorbed, they are excreted readily and rapidly in both bile and urine (Prelusky et al. 1994b). Persistent tissue residues after toxicological or accidental exposure appear unlikely, but more work is needed to clarify the toxicokinetics of fumonisins.

Mechanism of Action and Toxicity. Fumonisins inhibit the enzyme-mediated conversion of sphinganine to sphingosine, thus raising the sphinganine/sphingosine (SA/SO) ratio and potentially interfering with cell cycle control and cell function (Norred et al. 1992; Riley et al. 1993; Ramasamy et al. 1995). FB1 affects several cell signaling proteins including protein kinase C (PKC), a serine/threonine kinase involved in a number of signal transduction pathways that include cytokine induction, carcinogenesis, and apoptosis (Gopee and Sharma 2004). Fumonisin B1 appears also to inhibit ceramide synthase in the sphingolipid signaling pathway on the ascending aortic impedance spectrum of pigs. This is associated with inhibition of myocardial L-type calcium

channels with a decrease in cardiac contractility, left heart failure, and pulmonary edema (Constable et al. 2003). The result clinically in pigs is massive pulmonary edema and hydrothorax. Smith et al. (2000) concluded that fumonisin-induced pulmonary edema is caused by left-sided heart failure and not by altered endothelial permeability. Interestingly, Zomborszky-Kovacs et al. (2002) reported that very low concentrations of FB_1 fed for 8 weeks resulted in chronic pulmonary changes of connective tissue proliferation, in the subpleural and interlobular connective tissue of lungs and in peribronchial and peribronchiolar areas. Whether there is a relationship ranging from more acute to chronic low dose studies relative to porcine pulmonary edema is not clear from current literature.

More than 120 ppm dietary fumonisins for 4–10 days produces acute PPE (Haschek et al. 1992; Osweiler et al. 1992; Colvin et al. 1993). Surviving swine develop subacute hepatic toxicosis in 7–10 days. Dietary levels of more than 50 ppm cause hepatosis within 7–10 days. Although 25 ppm or less causes no apparent clinical effects, mild microscopic hepatic lesions are documented for dietary levels as low as 23 ppm (Moetlin et al. 1994). The serum SA/SO ratio has been altered experimentally by diets with as low as 5 ppm fumonisins, although the clinical relevance of this change is not known (Riley et al. 1993; Moetlin et al. 1994). FB_1 and FB_2 are similarly toxic to swine, and they appear to occur at a relatively constant ratio in field-contaminated corn (P. F. Ross, personal communication, 1996). FB_3 appears to be nearly nontoxic to swine (G. D. Osweiler, unpublished data).

Fumonisins have been evaluated for their potential interactions with aflatoxins and deoxynivalenol (DON). Effects of aflatoxins and fumonisins were found to be additive when fed together, except for the variables cholinesterase and alkaline phosphatase, which showed a synergistic response to aflatoxins and FB_1 (Harvey et al. 1995). For a combination of FB_1 and DON, the effect on most variables was additive. However, for body weight, weight gain, hepatic weight, and mean corpuscular hemoglobin concentration, the responses were interactive in a greater-than-additive manner (Harvey et al. 1996).

Clinical Signs and Lesions. Dietary concentrations of fumonisins greater than 120 ppm are likely to cause acute interstitial pulmonary edema and hydrothorax, with attack rates up to 50% and case fatality rates of 50–90%. Initially there is lethargy, restlessness, depression, and dermal hyperemia. Mild salivation, dyspnea, open-mouth breathing, posterior weakness, recumbence, and moist rales develop rapidly, followed by cyanosis, weakness, and death. Initial signs begin after 4–7 days of continuous fumonisin consumption (Colvin and Harrison 1992; Osweiler et al. 1992). Once signs appear, death usually occurs in 2–4 hours. Sur-

vivors may develop hepatic disease. Feeding fumonisins at concentrations from 75–100 ppm for 1–3 weeks, without development of pulmonary edema, causes hepatic disease characterized by icterus, anorexia, ill thrift, and weight loss (Osweiler et al. 1993).

Serum chemistry analyses show elevated concentrations of gamma glutamyl transferase (GGT), aspartate amino transferase (AST), alkaline phosphatase (ALP), lactate dehydrogenase (LDH), cholesterol, and bilirubin. Early increases in the serum enzymes and cholesterol are followed by increased GGT and serum bilirubin accompanied by clinical icterus (Osweiler et al. 1992; Colvin et al. 1993; Moetlin et al. 1994).

Based on current evidence, fumonisins are not considered potent immunosuppressants in swine. One study has shown transient reduction in lymphocyte blastogenesis and delayed titer response to pseudorabies vaccine (Osweiler et al. 1993). Others have also reported decreased lymphoblastogenesis (Harvey et al. 1995, 1996). Tornyos et al. (2003) determined humoral and cell-mediated immune response to FB_1. Pigs were fed a high dose (100 mg/animal/day for 8 days) or in a low concentration for a longer period (1, 5, and 10 ppm for 3–4 months), and then vaccinated against Aujeszky's disease with inactivated vaccine. Specific and nonspecific in vitro cellular immune response was measured by the lymphocyte stimulation test (LST) induced by PHA-P, Con A, LPS, and inactivated suspension of the Aujeszky's disease virus. Humoral immune response—e.g., specific antibody titer—was measured by virus neutralization (VN). None of the immunological parameters examined showed significant differences between groups. They concluded that fumonisin B_1 had no significant effect on the humoral and cellular specific and nonspecific immune response.

The characteristic lesion of PPE is pulmonary edema and hydrothorax with 200–350 mL of clear, cell-free, straw-colored thoracic transudate. Lungs are heavy and wet with wide seams (3–10 mm) of interlobular edema. Bronchioles, bronchi, and trachea are relatively clear with little alveolar edema (Haschek et al. 1992; Osweiler et al. 1992; Colvin et al. 1993; Moetlin et al. 1994; Palyusik and Moran 1994). Acidophilic, fibrillar material is found in alveoli and interlobular lymphatics, and hyalinized alveolar capillary thrombi may be present. Increased numbers of pulmonary intravascular macrophages (PIM) filled with osmiophilic material have been reported by electron microscopy. This response is hypothesized to result from phagocytosis of damaged cellular components. Pancreatic necrosis and hepatosis with disrupted hepatic architecture, increased mitotic figures in hepatocytes, apoptosis and single-cell hepatic necrosis are typical lesions of subacute fumonisin toxicosis (Haschek et al. 1992). Chronic exposure can include fibrosis, hepatic hyperplastic nodules and medial hypertrophy of small pulmonary arteries.

Abortions are common 1–4 days after onset of acute

signs (Osweiler et al. 1992; Becker et al. 1995), presumably due to fetal anoxia caused by severe pulmonary edema in the dam. Concentrations of 100 ppm FB_1 fed in the last 30 days of gestation did not cause abortion, fetal abnormalities, or infertility in sows (G. D. Osweiler, unpublished data). Persistent clinical signs or continuing reproductive problems after exposure is stopped have not been reported.

Diagnosis. Clinical signs of acute respiratory distress with high mortality and lesions of interstitial edema and hydrothorax suggest fumonisin toxicosis. A history of consumption of corn screenings or poor-quality corn is typical. Serum chemistry changes and elevated serum SA/SO ratios are expected, and the acute liver enzymes usually peak at from 4–7 days after initial exposure, while bilirubin and GGT continue to increase for 1–2 weeks if sublethal exposure continues. Serum SA/SO ratio is the most sensitive indicator of fumonisin exposure and appears unique to the fumonisins (Riley et al. 1993; Moetlin et al. 1994). However, this assay is currently not widely available as a diagnostic test. Many diagnostic and commercial laboratories can detect and quantitate fumonisins in corn and feeds, but routine chemical analysis to detect fumonisins in tissues is not available, and the metabolism and excretion rate of fumonisins from oral exposures are unknown but likely very rapid (Prelusky et al. 1994a).

Treatment and Management. There is no antidote to the toxin itself. The very acute and massive changes of PPE do not allow for effective symptomatic and supportive therapy. Because clinical signs appear after days to weeks of exposure, oral detoxification is usually not useful. Liver damage from fumonisin toxicosis may be lessened by appropriate supportive care.

Analysis of corn or feeds for fumonisins can identify a source and help in estimating the risk from a specific feedstuff (Ross et al. 1991). Contaminated corn should be cleaned and the good-quality grain analyzed to demonstrate that a safe level of fumonisins has been reached.

Fumonisins are potential human and animal carcinogens, and their eventual regulation in foodstuffs seems likely.

PREVENTION AND MANAGEMENT OF MOLD AND MYCOTOXIN PROBLEMS

When mycotoxicosis occurs or is suspected, the first action should be to change the source of feed. This may be beneficial, even when a specific mycotoxin cannot be identified. A thorough inspection of the grain storage bins, mixing equipment, and feeders may reveal caking, molding, or musty odors. All contaminated feed should be removed and the equipment cleaned. Additionally, walls and containers should be washed with a dilute solution of hypochlorite (laundry bleach) to reduce contaminating fungi. All equipment should be completely dry before fresh feed is added.

Any suspect feed should be analyzed to determine if known mycotoxins were present. Although spore counts or fungal cultures alone do not confirm a diagnosis, they may give some indication of the potential for mycotoxin production. With this information, the swine producer can better formulate a preventive program.

If storage conditions are adverse or if grain moisture is too high, use of a mold inhibitor may be advisable. Most commercial mold inhibitors are based on an organic acid such as propionic acid and are effective in reducing or delaying mold growth. Mold inhibitors do not destroy preformed toxins, which commonly may have formed in the field prior to harvest. Except for ammoniation (not yet approved by the Food and Drug Administration) to destroy aflatoxin, there are no practical commercial treatments that effectively destroy preformed mycotoxins.

Dilution of contaminated grain with clean grain is commonly used to reduce mycotoxin effects; this is not an approved procedure for aflatoxin. For any mycotoxin problem, dilution may reduce exposure initially, but care must be taken that wet or contaminated grain does not introduce new fungi and conditions that eventually lead to the entire mixture being contaminated.

Mycotoxin contamination may not be suspected until most or all of a contaminated feed is consumed. A prudent practice is to save a representative sample of all grains and feeds purchased and hold them in stable condition until swine are marketed or at least a month past when the feed was consumed. When questions about feed quality arise later, these samples may be valuable in documenting whether specific feeds were involved in a problem.

Samples of feeds or grain should be representative of the entire supply. Representative sampling can best be done after feed is ground and mixed by passing a cup through the moving auger stream at frequent intervals, mixing these samples thoroughly, and saving a 4.5 kg (10-pound) sample for analysis (Davis et al. 1980). Alternatively, probe sampling of large bins may give some idea of contamination levels. Bins should be probed in at least 6–10 perimeter locations and 2–4 central locations for each 1.8 m (6 feet) of bin height. High-moisture samples should be either dried to 12% moisture or stored frozen. Long-term storage is recommended in paper bags permanently marked with the date and source of the feed or grain, and samples should be held in a dry, clean location.

Mycotoxins present formidable challenges to the swine producer and veterinarian. Diagnosis is sometimes difficult and effective therapy is virtually lacking. A sound and practical preventive program should be a part of every swine management system.

57 Nutrient Deficiencies and Excesses

D. E. Reese and P. S. Miller

Proper nutrition is the foundation for sustained economic and environmental viability of any pork producing operation. Pigs perform best and excrete less manure nutrients when they consume diets that contain the correct amount and balance of essential nutrients. Occasionally pigs consume diets that contain insufficient or excessive amounts of one or more nutrients. The effects range from mild (slight, unnoticed reductions in weight gain and feed efficiency) to marked (obvious clinical and subclinical symptoms, including death).

The relationship between a nutrient deficiency and excess varies among nutrients (Figure 57.1). The absolute difference (the range of tolerance) between the nutrient intake associated with overcoming a deficiency (i.e., requirement) and the intake associated with a toxicity may be large (e.g., water-soluble vitamins) or small (e.g., selenium). This observation is critical in as much as it represents the window of safety for a particular nutrient.

This chapter presents clinical symptoms (outwardly apparent) and subclinical symptoms (evident only by necropsy or clinical methodology) of nutrient deficiencies and excesses that have occurred in pigs. Although it is rare today to observe symptoms of a single nutrient deficiency or excess, the recognition of faulty nutrition should be part of an overall approach to solving problems in swine operations.

The information presented herein was derived from research results with pigs and, in most instances, obtained by varying the intake of one nutrient at a time. However, nutrient interactions occur and it is unclear if the information would apply when multiple deficiencies or excesses of nutrients exist (e.g., when a vitamin and trace mineral mix is not added to the diet properly).

On farms today, vitamin and mineral deficiencies are less likely to occur than excesses. This is because diets are routinely fortified with vitamins and minerals. Also, it is important to consider that many of the nutrient deficiency symptoms reported here were observed in pigs fed purified or semipurified diets. This was necessary in order to provide a diet that contained a very low level of the nutrient of interest so deficiency symptoms could be observed. Ingredients used in practical swine diets contain a variety of essential nutrients (NRC 1998) which, even without recommended nutrient fortifications, would prevent the appearance of some symptoms.

CAUSES OF NUTRIENT DEFICIENCIES

Reduced Feed Intake

Pigs should consume a certain quantity of essential nutrients daily for optimum performance. Because diets are often formulated on a concentration basis, lower-than-expected feed intake by pigs could result in a nutrient deficiency. This situation is most commonly observed in gestating sows and breeding boars when feed intake is restricted to control weight gain, and in lactating sows, because they may consume less feed than needed for optimum performance. Furthermore, growing pigs with a high genetic capacity for lean-tissue accretion sometimes have reduced feed intake.

Low Nutrient Bioavailability in Ingredients

Nutrients present in ingredients are not fully available to the pig for maintenance, growth, and(or) lactation. The portion of the nutrient in the ingredient that is absorbed in a form utilizable by the pig is said to be bioavailable. The amount of that nutrient that is bioavailable depends primarily on the nutrient source. For example, the phosphorus in dicalcium phosphate is much more bioavailable than the phosphorus in grain and plant protein supplements. In these ingredients, the phosphorus is bound in a phytate complex and is not fully released during digestion. Thus, a phosphorus deficiency could occur if bioavailability is not considered in diet formulation. On the other hand, some feed ingredients contain nutrients that have a low bioavailability but that still release sufficient amounts of nutrients to meet the animal's requirement. It should be

931
57.1. *Idealized relationship between pig performance (e.g., average daily gain) and nutrient intake.*

noted that estimates of bioavailability are relative to a reference ingredient or ingredients; therefore, one should closely examine the nature of the reference ingredients.

Variability in Nutrient Content of Ingredients

Deviations in the nutrient content of ingredients from expected or "book" values can result in nutrient deficiencies if not taken into account in diet formulations. For example, samples of corn from 15 states in the USA contained between 0.24% and 0.31% lysine; for soybean meal the range was from 2.7%–3.0% (NCR-42 1992). More variability has been reported for vitamins, and this has been attributed to agronomic, harvest, storage, and processing conditions (Hoffman-La Roche 1991).

Diet Formulation and Preparation Errors

There are a number of possible mistakes in diet formulation and preparation that can result in nutrient deficiencies. These include using the incorrect quantity or the wrong ingredients in the diet and not cleaning the mixer properly between batches. In addition, nutrient deficiencies can occur when commercial feed products that are not designed to complement each other are used to prepare the diet. Haphazard additions of an extra package of minerals to a diet already adequately fortified may cause certain minerals to interfere with the utilization of others, resulting in deficiencies. Furthermore, according to Traylor et al. (1994), cutting short the time the feed mixer runs can cause significant variation in the nutrient content of the final diet and reduce pig performance.

Variation in Nutrient Requirements of Pigs

Pigs have varying potentials for lean growth and reproduction and therefore have different nutrient requirements. For example, a given level of dietary lysine may be seemingly adequate for diseased, low-lean-gain pigs but deficient for high-health, high-lean-gain pigs (Williams et al. 1997). Stahly et al. (1991) also demonstrated that increasing the dietary lysine density improved performance to a greater extent as the lean-growth capacity of different genotypes increased, indicating a genotype by lysine density interaction. Moreover, within a contemporary group of pigs, some may show deficiency symptoms while others do not (Cunha 1977), indicating the need to carefully observe individual pigs for symptoms of nutrient deficiencies.

Nutrient Excesses

All essential nutrients must be digested and utilized by the pig to avoid deficiencies. To facilitate this process, it is important to maintain a proper balance of nutrients in the diet. There are common absorption sites for many nutrients in the small intestine. Thus, a high dietary concentration of one nutrient can impair the passage of another nutrient through the absorption sites and cause a deficiency. In addition, an excess of one nutrient can cause the formation of certain chemical complexes which are poorly absorbed. The more frequent nutrient interactions that can cause problems in practical situations are between calcium and phosphorus, calcium and zinc, and copper, iron, and zinc. In some cases, a nutrient excess can be associated with the deficiency symptom of the interacting nutrient it is .

SYMPTOMS OF NUTRIENT DEFICIENCIES

Clinical and subclinical deficiency symptoms for several nutrients are presented in Tables 57.1, 57.2, and 57.3. There is wide variation in the amount of time that elapses before symptoms of nutrient deficiency begin to appear. For example, it takes 4–6 months for pigs fed a vitamin D–deficient diet to develop symptoms of a deficiency (NRC 1998), whereas a salt deficiency will be evident in a few days (Patience and Zijlstra 2001).

Nutrient requirements for swine were published by the NRC (1998). These can serve as a guide in formulating swine diets to minimize the occurrence of nutrient deficiencies. Because several factors are known to influence nutrient requirements (NRC 1998), it is prudent to add a margin of safety to these requirements to ensure optimum animal performance (Reese et al. 2000).

CAUSES OF NUTRIENT EXCESSES

Excessive Feed Intake

Sometimes gestating females and breeding boars are given more feed than they need for optimum performance. Consequently, they consume too much energy and get excessively heavy and fat, which reduces reproductive performance and longevity.

Diet Preparation Errors

The same mistakes in diet preparation that can cause nutrient deficiencies can also cause nutrient excesses.

Poor Water Quality

Water may contain large amounts of several minerals, some of which may be contributed to the water by industrial wastes and other sources of pollution (NRC 1980) and by natural mineral deposits. Few studies have been conducted to investigate nutrient excesses caused by consuming poor-quality water. However, it appears pigs can tolerate water containing high levels of total dissolved solids (5000 ppm) after a period of adaptation (Reese et al. 2000).

Contaminated Mineral Supplements

Mineral supplements, such as dicalcium phosphate and defluorinated rock phosphate, are added to swine diets to correct the deficiencies in diets formulated with grains and protein supplements. Often these mineral supplements contain elements other than those of primary interest. For example, defluorinated rock phosphate contains 3.27% and .84% sodium and iron, respectively (NRC 1998). In addition, some phosphorus sources may contain high levels of aluminum and fluorine, and some sources of calcium contain large amounts of magnesium and iron. Also, some zinc and copper sources may be contaminated with lead and cadmium (D. A. Hill, personal commmunication, 1997). These "extra" elements will not normally pose a prob-

lem to the pig if their contribution to the diet is accounted for during formulation. The type and amount of the "other" elements the mineral supplement contains depend on the raw material from which the supplement was made and the type of processing (NRC 1980).

SYMPTOMS OF NUTRIENT EXCESSES AND TOLERANCE LEVELS

Symptoms of excessive nutrient intake and estimated tolerance levels for several nutrients are presented in Tables 57.4, 57.5, and 57.6. Because many minerals interact with each other during the digestive and utilization processes, a high intake of one mineral (e.g., calcium) can result in a deficiency of another mineral (e.g., phosphorus or zinc). To solve this kind of problem, either reduce the dietary level of calcium, for example, or increase the level of phosphorus and(or) zinc in the diet.

Copper (at 250 ppm as copper sulfate) and zinc (at 3000 ppm as zinc oxide) are unique in that they promote additional growth in young growing pigs at dietary concentrations which far exceed the nutritional requirement for these nutrients (Hill and Spears 2001). However, like other minerals, too much copper or zinc in the diet will produce deleterious effects (see Table 57.5).

According to Lewis (2001) the deleterious effects of consuming incorrect amounts of amino acids have been classified into at least two main types: toxicity and imbalance. Toxicities result from the consumption of a large excess of an individual amino acid. Imbalances are also caused by excessive intake(s) of (an) amino(s), but in this case the excess exacerbates a deficiency of the most limiting amino acid in the diet. An imbalance is corrected by the appropriate addition of that amino acid. Under practical conditions, toxicities and imbalances would be caused only by mistakes in formulation or manufacturing of a diet with crystalline amino acids. The only amino acids currently available in feed-grade form are lysine, tryptophan, threonine and methionine.

With the exception of the study by Wahlstrom and Libal (1974) where supplemental lysine and methionine were evaluated, the effects of excess levels of amino acids reported in Table 57.6 were observed when the amino acid of interest was added to a basal diet considered to be adequate in all essential amino acids. In other words, a constant level of soybean meal was maintained in the basal and amino acid–supplemented diets.

Wahlstrom and Libal (1974) added DL-methionine (0.2%) to a diet that contained less soybean meal than the basal diet. They observed a reduction in pig performance at a lower level of added methionine than other researchers have reported because they exacerbated a lysine deficiency (i.e., caused an amino acid imbalance). Nevertheless, according to Baker (1977), pigs appear to be particularly sensitive to excess methionine in the diet. It is important to recognize that there is probably a

Table 57.1. Signs of vitamin deficiencies in swine

Nutrient	Clinical Signs	Subclinical Signs	Reference
Vitamin A	Incoordination; lordosis; paralysis of rear limbs; night blindness; congenital defects; reduced weight gain; respiratory disfunction; roughness of skin; tilting of head; eye discharge; stillborn pigs; aborted fetuses with cleft palate, harelip, and deformed hind legs; impaired spermatogenesis; increased embryonic mortality	Retarded bone growth; increased cerebrospinal fluid pressure; degeneration of sciatic and femoral nerves; minimal visual purple; atrophy of epithelial layers of genital tract; decreased plasma vitamin A	NRC 1979, 1998; Ullrey 1991; Darroch 2001
Vitamin D	Rickets; osteomalacia; tetany; reduced weight gain; stiffness and lameness; posterior paralysis	Lack of bone calcification and proliferation of epiphyseal cartilage; rib and vertebra fracture; low plasma calcium, magnesium, and inorganic phosphorus; elevated serum alkaline phosphatase	NRC 1979; Cunha 1977; Crenshaw 2001
Vitamin E	Lactation failure; reduced litter size; extended parturition time; weak pigs at birth; sudden death (fast-growing pigs); postweaning diarrhea	Liver necrosis (hepatosis dietetica); cardiac muscle degeneration (mulberry heart); increased fluid in pericardial sac; gastric ulcers; anemia; yellow discoloration of fat tissue; skeletal degeneration; increased serum glutamic oxalo-acetic transaminase and glutamic pyruvic transaminase; reduced prothrombin time, serum vitamin E, and immune response; testicular degeneration	NRC 1998; Mahan 1991, 2001
Vitamin K (menadione)	Pale newborn pigs with loss of blood from umbilical cord; massive subcutaneous hemorrhage; hematomas in ears; enlarged, blood-filled joints; sudden death following dicoumarin intake; blood in urine	Increased prothrombin and blood-clotting time; internal hemorrhage; anemia due to blood loss	NRC 1979, 1998; Fritschen et al. 1971; Crenshaw 2001
Biotin	Excessive hair loss, skin ulcerations, and dermatitis; exudate around eyes; inflammation of the mucous membranes of the mouth; transverse cracking of the hooves; cracking and bleeding of footpads; spasticity of hind legs; diarrhea; reduced litter size	Reduced serum biotin	NRC 1998; Dove and Cook 2001
Choline	Reduced weight gain, litter size, and farrowing rate; rough hair coat; unbalanced and staggering gait	Fatty infiltration of liver and kidney; reduced red blood cell count, hematocrit, and hemoglobin; increased plasma alkaline phosphatase	NRC 1998
Folic acid	Reduced weight gain and litter size; fading hair color	Normocytic and macrocytic anemia; leukopenial thrombopenia; reduced hematocrit; bone marrow hyperplasia	NRC 1998; Dove and Cook 2001
Niacin	Anorexia; reduced weight gain; rough hair coat; hair loss; severe diarrhea; dermatitis; vomiting	Buccal mucosa ulcerations, ulcerative gastritis; inflammation and necrosis of cecum and colon; normocytic anemia	NRC 1998
Pantothenic acid	Anorexia; reduced weight gain; dry skin; rough hair coat; hair loss; unusual gait (goose-stepping); impaired sow reproductivity	Edema and necrosis of intestinal mucosa; increased connective tissue invasion of the submucosa; loss of nerve myelin; degeneration of dorsal root ganglion, fatty liver; enlarged adrenal glands; atrophic ovaries; infantile uteri; reduced immune response; intramuscular hemorrhage	NRC 1998; Dove and Cook 2001
Riboflavin	Reduced weight gain; cataracts; seborrhea; stiffness of gait; vomiting; hair loss; reduced farrowing rate; anestrus; higher piglet mortality	Increased blood neutrophil granulocytes; discolored liver and kidney tissue; fatty liver; collapsed follicles; degenerating ova; degenerating myelin of the sciatic and brachial nerves; elevated blood erythrocyte glutathione reductase activity coefficient; reduced immune response	NRC 1998; Dove and Cook 2001
Vitamin B_1 (thiamin)	Anorexia; reduced weight gain; occasional vomiting; sudden death	Cardiac hypertrophy; bradycardia; increased plasma pyruvate; reduced body temperature; myocardial degeneration; flabby heart	NRC 1998; Dove and Cook 2001

Table 57.1.   (*continued*)

Nutrient	Clinical Signs	Subclinical Signs	Reference
Vitamin B$_6$ (pyridoxine)	Anorexia; reduced weight gain; convulsions; exudate development around eyes; ataxia; vomiting; coma; death	Microcytic hypochromic anemia; elevated serum iron and gamma globulin; fatty infiltration of liver; reduced albumin, hemoglobin, red blood cells, lymphocytes	NRC 1998; Dove and Cook 2001
Vitamin B$_{12}$	Anorexia; reduced weight gain, litter size, and pig birth weight; hypersensitivity; rough hair coat; dermatitis; hind leg incoordination	Normocytic anemia; increased neutrophil and reduced lymphocyte count; enlarged liver	NRC 1998; Dove and Cook 2001
Vitamin C (ascorbic acid)[a]	None documented	None documented	Dove and Cook 2001

[a]Synthesized from d-glucose and related compounds in pigs. No deficiency signs have been observed; however, reports of improved pig performance from vitamin C additions to practical diets exist.

greater tolerance level of feed-grade forms of amino acids when they are added to a diet which contains an adequate quantity of the 10 essential amino acids than when they are added individually to a low-protein diet.

For some nutrients, no documentation was found to indicate a tolerance level, because no adverse effects from an excessive intake have been reported in swine. Thus, when "none documented" appears in the tables, one should not assume that the nutrient is completely safe for swine. There are reports of magnesium and potassium toxicity in other species (NRC 1980), as well as for niacin, vitamin K, vitamin E, and pyridoxine (NRC 1987). In general the vitamins that have not been observed to cause adverse reactions in swine are relatively safe at dietary concentrations much greater than the requirement. This is especially true for the "B vitamins" (e.g., riboflavin, folic acid), which are not extensively stored in the body and excesses are readily excreted in the urine.

Estimated tolerance for a nutrient is defined as the dietary concentration, when fed for a limited time, that is not likely to impair pig performance and should not produce unsafe residues in pork (NRC 1980). Although the tolerance level will vary with the age and physiological condition of the animal (NRC 1980), only one tolerance level is given in the tables for each nutrient, except where information was deemed sufficient to give more. The tolerance values listed may not represent the actual tolerance levels for production situations. Many of the research trials on which the tolerance levels were based were conducted for a limited time period using nutrient sources that may have different bioavailabilities from those used in practical swine diets. "Not determined" in the tables means insufficient data were available to suggest a tolerance level.

INVESTIGATING A POSSIBLE FEED-RELATED DISORDER

Good production records combined with close, daily observation of animals are important in identifying problems caused by faulty nutrition. Monitor gain, feed intake and feed efficiency, because they are typically impacted by many feed-related disorders. After it is apparent that growth performance is impaired or several animals appear abnormal, it is important to consider what aspects of feeding and nutrition could be a problem. Generally, feed-related disorders are caused by inadequate feed intake or impaired feed quality.

Feed Intake

Many feed-related problems on farms occur because pigs do not consume enough feed. For example, access to feed by lactating sows and growing pigs is too often restricted. Feed access is often restricted because of human error, feed bridging in the bins or feeders, or equipment failure. Other reasons for inadequate feed intake are water quantity or quality problems, overcrowding, and poor feeder space and design. Eliminate the possibility that inadequate feed intake may be causing suspected feed-related disorders before investigating feed quality.

Feed Quality

If a feed-related disorder can not be explained by inadequate feed intake, look for possible feed quality problems. Observe for evidence of foreign contamination such as dirt, stones, rodent droppings, and other indicators such as color and odor. A significant change in color may indicate a change in ingredients (which is not necessarily a problem) or it may suggest improper processing such as overheating. Beware of moldy or mycotoxin-contaminated feed. Also, feed quality may be impaired because it contains too little or too much of one or more nutrients.

Nutrient deficiencies and excesses are seldom severe enough on farms to cause clinical or subclinical signs in pigs; however, some have occurred under practical conditions. Selenium/vitamin E, amino acid, biotin (in sows), zinc, phosphorus, and salt deficiencies have been observed. Problems with excess amounts of selenium, vitamin A and D, copper, and zinc have been seen.

Table 57.2. Signs of mineral deficiencies in swine

Nutrient	Clinical Signs	Subclinical Signs	Reference
Calcium	Rickets; osteomalacia; low calcium tetany; humped back or camelback syndrome; reduced weight gain; stiffness of gait; lameness; enlarged and painful joints; spontaneous fractures; posterior paralysis (downer sow syndrome)	Reduced bone breaking strength; low plasma calcium level; elevated serum phosphorus and alkaline phosphatase; reduced bone mineralization	NRC 1979; Peo 1991; Crenshaw 2001
Chromium[a]	None documented	None documented	Hill and Spears 2001
Copper	Anorexia; reduced weight gain; bowing of legs; spontaneous fractures; ataxia	Microcytic, hypochromic anemia; leucopenia; reduced serum ceruloplasmin; reduced erythrocyte life span; aortic rupture; cardiac hypertrophy	Miller 1991; NRC 1998; Hill and Spears 2001
Iodine	Goiter; sows farrow weak, hairless pigs	Enlarged, hemorrhagic thyroid; hyperplasia of follicular epithelium of thyroid; reduced plasma protein-bound iodine	Hill and Spears 2001
Iron	Reduced feed intake, weight gain, and feed efficiency; rough hair coat; pallor; wrinkled skin; labored breathing; death	Hypochromic, microcytic anemia; enlarged heart and spleen; enlarged fatty liver; ascites; reduced serum iron, percent transferrin saturation and hemoglobin (≤ 7 g/100 mL); thin, watery blood; reduced disease resistance	NRC 1979, 1998; Miller 1991; Hill and Spears 2001
Magnesium	Hyperirritability; muscular twitching; reluctance to stand; weak pasterns; loss of equilibrium; tetany; death	Low serum magnesium and calcium; reduced bone magnesium	NRC 1979, 1998
Manganese	Lameness; enlarged hock joints with crocked and shorten legs; increased fat deposition; resorbed fetuses; small, weak pigs born; reduced milk production; irregular or absent estrous cycles; delayed post-weaning estrus	Replacement of cancellous bone with fibrous tissue; early closure of distal epiphyseal plate; low serum manganese and alkaline phosphatase	NRC 1979, 1998; Hill and Spears 2001
Phosphorus	Reduced weight gain and feed efficiency; rickets; osteomalacia; spontaneous fractures; posterior paralysis (downer sow syndrome)	Reduced bone breaking strength and mineralization; elevated serum calcium and alkaline phosphatase; enlarged costochondral junction (beading); reduced serum inorganic phosphorus	NRC 1979; Koch and Mahan 1986; Hall et al. 1991; Crenshaw 2001
Potassium	Anorexia; reduced weight gain; rough hair coat; emaciation; ataxia; inactivity	Reduced heart rate; increased PR, QRS, and QT intervals on electrocardiogram; multifocal myocardial necrosis	Van Vleet and Ferrans 1986; NRC 1998; Patience and Zijlstra 2001
Selenium	Sudden death; reduced milk production; prolonged farrowing time; weak progeny; postweaning diarrhea; lower sperm production and motility; sperm tail abnormalities	Liver necrosis (hepatosis dietetica); cardiac muscle degeneration (mulberry heart); increased fluid in pericardial sac; gastric ulcers; skeletal degeneration; increased serum glutamic oxalo-acetic transaminase and glutamic pyruvic transaminase; reduced prothrombin time and immune response; reduced serum and skeletal muscle selenium; reduced glutathione peroxidase activity	Ullrey 1987; NRC 1998; Mahan 2001
Sodium and chloride	Reduced feed intake, weight gain, and feed efficiency; low water intake; unthriftiness; reduced pig birth weight and litter size; extended weaning-to-estrus interval; increased attraction to blood and possibly tail-biting	Reduced plasma sodium and chloride (sodium deficiency); elevated plasma potassium (sodium deficiency); elevated plasma urea nitrogen (sodium and chloride deficiency); elevated plasma total protein and albumin (sodium deficiency)	Honeyfield et al. 1985; Fraser 1987; Cromwell et al. 1989; Seynaeve et al. 1996; Patience and Zijlstra 2001
Zinc	Anorexia; reduced weight gain and feed efficiency; parakeratosis; extended parturition time; increased stillbirth rate; reduced litter size and pig birth weight; alopecia; poor wound healing	Reduced serum, tissue, and milk zinc; reduced serum albumin and alkaline phosphatase; reduced thymus weight; retarded testicle development; deleted fat depots; serous atrophy of fat; depletion of thymocytes; keratinization of tongue and esophagus; cardia of stomach; reduced immune response	Kalinowski and Chavez 1986; Miller 1991; NRC 1998; Hill and Spears 2001

[a]Supplemental chromium (from chromium tripicolinate, chromium propionate, or chromium-L-methionine) has improved growth performance, muscling, and litter size (Southern and Payne 2003).

Table 57.3. Deficiency signs for other nutrients and dietary components in swine

Item	Clinical Signs	Subclinical Signs	Reference
Energy	Weakness; low body temperature; reduced weight gain and loss of body weight; impaired sow reproductivity; coma; death	Hypoglycemia; loss of subcutaneous fat; elevated hematocrit and serum cholesterol; reduced blood glucose, calcium, and sodium	NRC 1979; Pettigrew and Tokach 1991
Fat (linoleic acid)	Dermatitis; hair loss; necrosis of skin	Small gallbladder; elevated triene/tetraene in tissue lipids	NRC 1979; ARC 1981
Protein/amino acids	Reduced feed intake, weight gain, and feed efficiency; unthriftiness; impaired sow and boar reproductivity; increased carcass backfat, feed wastage, and attraction to blood (possibly tail-biting)	Kwashiorkor-like symptoms in baby pigs, including reduced serum protein and albumin, anemia, gross edema, and increased liver lipids; increased plasma urea; reduced resistance to bacterial infection	NRC 1979, 1998; Baker and Speer 1983; Pettigrew and Tokach 1991; Fraser et al. 1991; Lewis 1992
Water	Reduced feed intake and weight gain; dehydration; possible salt poisoning; increased respiration; diarrhea in piglets; death	Elevated hematocrit and plasma electrolytes; loss of temperature regulation; tissue dehydration; crystalluria; proteinuria; bacteriuria; cystitis	NRC 1979; Madec et al. 1986; Thacker 2001

To facilitate identification of the nutrient(s) to focus on when troubleshooting suspected feed-related problems, use Table 57.7 as an initial screen. In this table the clinical symptoms presented in Tables 52.1–52.6 are arranged in alphabetical order. Locate the clinical symptom observed and determine the nutrient(s) that may be involved. For example, if pig feed intake is impaired, find "anorexia/reduced feed intake" in Table 57.7 for a list of nutrients that may be involved in decreased feed intake. If additional clinical symptoms are observed, use them to help narrow the list to fewer nutrients. Subsequently refer to the subclinical symptoms in Tables 57.1–57.6 to help make a more definite diagnosis. It is important to remember that some of the clinical symptoms in Table 57.7 may be caused by factors other than faulty nutrition (i.e., environment, infectious disease, etc.). Finally, collect a sample of the feed and analyze it for the nutrient(s) suspected to be involved.

Sampling Procedures

When sampling feeds for laboratory analysis, it is essential to get a representative sample; otherwise, the results may be misleading. The sampling technique will be most accurate by using a grain probe; it allows deep penetration into feeders, bags, and other containers while sampling. If a probe is not available, use your hand or a cup on a pole.

Obtain samples from feeders to maximize the chance of identifying a feed quality problem. Take a sample from at least one out of every two feeders, inserting the probe at two different locations. If you use your hand for sampling, be sure to insert your arm to elbow depth to obtain a sample. When sampling directly from the mixer or unloader, grab 10 single handfuls of feed per ton at various intervals as the feed is unloaded, except for the initial and final outputs. Collect the samples in a large, clean container and mix thoroughly. Obtain two

.5 kg samples and seal each in individual, clearly marked and dated containers. Heavy plastic bags, plastic containers with lids and clean, widemouthed jars are excellent for storing samples. Submit one sample to the laboratory and keep the other in the freezer until the analysis is complete.

Interpreting Laboratory Results

Even if the feed sampled was made to perfection, there are errors in sampling and laboratory analyses that at best can only be minimized. These errors can cause differences in nutrient levels between what the laboratory reports and producer expects. Generally there is no need for concern as long as analyzed nutrient values are not significantly different from the calculated nutrient content of the diet. Comparing analyzed values to the calculated nutrient content of the diet is an essential step in interpreting laboratory results.

Calculate the nutrient content of the finished feed from the diet formula, appropriate feed labels, and nutrient contents of ingredients. Compare those values to the "as-fed," "as-is," or "as-received" values from the laboratory report.

How much difference can there be between the calculated and analyzed values before it is appropriate to conclude there is a feed quality problem? The expected amount of variation associated with sampling and laboratory analyses for some nutrients is shown in Table 57.8 (for phosphorus, 13%). From these values and the calculated nutrient content of the diet, an expected range for the amount of that nutrient in the diet can be estimated. For example, assume the calculated phosphorus content of a diet is .65%. To allow for normal sampling and laboratory variation, the acceptable range of phosphorus levels in the diet will be from .57 to .73%:

$.65\% \times .13 = .08; .65\% - .08\% = .57\%; .65\% + .08\% = .73\%$

Table 57.4. Signs of vitamin excess and estimated tolerance level in swine

Nutrient	Clinical Signs	Subclinical Signs	Estimated Dietary Tolerance Level[a]	Reference
Vitamin A[b]	Reduced feed intake and weight gain; skeletal malformation; rough hair coat; hyperirritability; incoordination; blood in urine and feces; joint pain and swelling; skin thickening; death	Bone lesions; internal hemorrhage; bone fractures; reduced spinal fluid pressure, liver and serum tocopherol and uronic acid in joint cartilage; increased blood clotting time	20,000 IU/kg (growing pig) 40,000 IU/kg (breeding herd)	NRC 1987; Blair et al. 1992, 1996; Darroch 2001
Vitamin D[c]	Reduced feed intake, feed efficiency and weight gain; rough hair coat; lameness; stiffness; arching of the back; paralysis; vomiting; death	Reduced liver, radius, and ulna weight; calcification in aorta, heart, kidney, and lung; hypercalcemia; hyperphosphatemia; osteoporosis; hemorrhagic gastritis	22,000 IU/kg (<60 days)[d] 2,200 IU/kg (>60 days)[d]	Long 1984; Hancock et al. 1986; NRC 1987, 1998; Crenshaw 2001
Vitamin E	None documented	None documented	Not determined[e]	Mahan 2001
Vitamin K (menadione)	None documented	None documented	500 mg/kg	NRC 1998; Crenshaw 2001
Biotin	None documented	None documented	0.2–0.5 mg/kg	NRC 1998; Dove and Cook 2001
Choline	Reduced feed intake and weight gain[f]	None documented	Not determined	Dove and Cook 2001
Folic acid	None documented	None documented	Not determined	Dove and Cook 2001
Niacin	None documented	None documented	Not determined	Dove and Cook 2001
Pantothenic acid	None documented	None documented	Not determined	Dove and Cook 2001
Riboflavin	None documented	None documented	Not determined[g]	Campbell and Combs 1990a; Dove and Cook 2001
Vitamin B$_1$ (thiamin)	None documented	None documented	Not determined[h]	Dove and Cook 2001
Vitamin B$_6$ (pyridoxine)	None documented	None documented	Not determined[i]	Dove and Cook 2001
Vitamin B$_{12}$	None documented	None documented	Not determined	Dove and Cook 2001
Vitamin C (ascorbic acid)	None documented	None documented	Not determined[j]	Dove and Cook 2001

[a]When higher dietary levels were provided certain clinical and subclinical signs were either observed or could appear under experimental conditions. These levels may not represent actual tolerance levels in production situations and they generally apply to growing pigs allowed ad libitum access to feed.

[b]Increased dietary levels of vitamins D, E, and K may reduce vitamin A toxicity.

[c]Toxicity is reduced when the diet is low in calcium or high in vitamin A.

[d]Applies to vitamin D$_3$. Vitamin D$_2$ is significantly more toxic.

[e]Feeding ≤1000 IU/kg of feed has not caused any ill effects in growing swine.

[f]Observed when 2000 mg/kg choline was fed throughout the nursery, growing, and finishing phases (Southern et al. 1986)

[g]No ill effects were observed when 37 kg pigs were fed diets supplemented with 0.1, 0.3, 0.5, and 0.7% riboflavin for 70 days.

[h]100 mg/kg has been fed to young pigs with no ill effects.

[i]No detrimental effects were observed when a diet containing 9.2 mg/kg was fed to early weaned pigs.

[j]No adverse effects were observed when a diet containing 10 g/kg was fed to young pigs.

If the analyzed value falls within the acceptable range (e.g., between .57% and .73%), a feed quality problem associated with that nutrient probably does not exist. However, if the level of all or any one of the nutrients falls outside the acceptable range and proper sampling procedures were used, submit a portion of the retained sample to the same or another laboratory for a repeat analysis. If the results from the second analysis also fall outside the normal range, a feed quality problem may exist. Review the causes of nutrient deficiences and excesses presented earlier in this chapter to help determine an explanation for the quality problem. Again

it is important to remember that a nutrient deficiency may be manifested by the antagonism or excess of another nutrient. Therefore, deficiency symptoms may be observed in the presence of seemingly adequate dietary nutrient concentrations. This situation is most likely to occur between zinc and copper and calcium and zinc.

PREVENTING NUTRIENT DEFICIENCIES AND EXCESSES

Emphasis should be placed on reducing the opportunity for pigs to consume diets with inadequate or excessive

Table 57.5. Signs of mineral excess and estimated tolerance level in swine

Nutrient	Clinical Signs	Subclinical Signs	Estimated Dietary Tolerance Level[a]	Reference
Calcium	Reduced feed intake, weight gain and feed efficiency; parakeratosis[b]	Elevated plasma calcium; increased prothrombin clotting time[c]	1.0%	NRC 1980; Foley et al. 1990; Hall et al. 1991; Crenshaw 2001
Chromium	Anorexia; diarrhea; depression; inactivity; labored breathing; tremors[d]	None documented	3,000 ppm (oxide) 1,000 ppm (chloride)	Vishnyakov et al. 1985; Hill and Spears 2001
Cobalt[e]	Anorexia; reduced weight gain; stiff-legged; humped back; incoordination; muscle tremors	Anemia	10 ppm	NRC 1980, 1998; Hill and Spears 2001
Copper	Anorexia; reduced weight gain; bloody feces; jaundice; death	Anemia; yellow appearance to liver; internal hemorrhage; ulceration of esophageal zone of stomach; pulmonary edema; elevated liver and kidney copper; reduced hemoglobin	250 ppm[f]	NRC 1980, 1998; Cromwell et al. 1983; Miller 1991; Hill and Spears 2001
Iodine	Reduced feed intake and weight gain	Decreased blood hemoglobin and liver iron	400 ppm	NRC 1980; Miller 1991; Hill and Spears 2001
Iron	Reduced feed intake, weight gain, and feed efficiency; profuse diarrhea; incoordination; shivering; tetanic convulsions; labored breathing; coma; dyspnea; drowsiness; death; rickets[g]	Edema of stomach wall; hyperemia; extensive mucosal necrosis; pallor of skeletal muscles; swollen kidneys; epicardial hemorrhage; hypopericardium; hydrothorax; severe degeneration of muscle and nephrosis; necrosis of liver; reduced disease resistance	3,000 ppm <100 mg[h]	NRC 1980, 1998; Miller 1991
Magnesium	None documented	None documented	0.3%	NRC 1998
Manganese	Reduced feed intake and weight gain; stiffness	Reduced hemoglobin	400 ppm	NRC 1980, 1998
Phosphorus	Reduced weight gain and feed efficiency	Urinary calculi; osteodystropia fibrosa; metastic calcification in soft tissue	0.9%[i]	Hall et al. 1991; Crenshaw 2001
Potassium	None documented	Abnormal electrocardiogram	3%	Patience and Zijlstra 2001
Selenium[j]	Anorexia; reduced feed intake and weight gain; hair loss; separation of hoof and skin at coronary band; reduced conception rate and litter size; pigs small, weak, or dead at birth; labored breathing; vomiting; prostration; frothing at month; abnormal staggering movement; muscle twitching; squeal when approached; spinal paralysis; death	Degenerative changes in liver and kidney; pulmonary edema; elevated serum selenium and glutamic oxaloacetic transaminase; high liver selenium; fatty infiltration of liver	0.5 ppm[k]	Mahan 1991, 2001; NRC 1998; Kim and Mahan 2001
Sodium and chloride	Anorexia; weight loss; edema; nervousness; weakness; staggering; diarrhea; epileptic seizures; paralysis; death		8%[l]	NRC 1998; Pretzer 2000; Patience and Zijlstra 2001
Zinc	Reduced weight gain, feed intake, feed efficiency, litter size, and pig weight at weaning; arthritis; lameness; depression	Hemorrhage in axillary spaces; gastritis; osteochondrosis in sows; increased liver zinc; decreased liver iron and copper	3,000 ppm (weanling pigs)[m] 1,000 ppm (carbonate)	Poulsen 1995; NRC 1998; Hill and Spears 2001

[a]When higher dietary levels were provided certain clinical and subclinical signs were observed under experimental conditions. These levels may not represent actual tolerance levels in production situations and they generally apply to growing pigs allowed ad libitum access to feed.

[b]With limited dietary zinc.

[c]In the absence of supplemental vitamin K in the diet.

[d]Trivalent chromium given via stomach tube (3g/kg body weight) to 60-day-old pigs.

[e]Selenium, vitamin E, and cysteine have provided some protection against excessive levels of cobalt.

[f]250 ppm has resulted in symptoms of excess when fed throughout the starter, growing, and finishing phases and when dietary iron, zinc, and sulfur intake was limited. Nursery pigs can tolerate diets with 500 ppm as copper sulfate for 28 days.

[g]Increasing dietary phosphorus has alleviated the rickets.

[h]As iron dextran administrated IM to pigs born from vitamin E-deficient dams.

[i]The amount of calcium in the diet is important. A deficiency of calcium may lower the tolerance level.

[j]Chronic selenosis can be treated by supplementing the diet with 40 ppm arsenic or 50–100 ppm arsenilic acid (Osweiler et al. 1985).

[k]Tolerance may be higher, but less than 5 ppm.

[l]Assumes ample water supplies are available. Water restriction will lower the tolerance level.

[m]As zinc oxide for a maximum of 35 days.

Table 57.6. Symptoms of excess and estimated tolerance level for other nutrients and dietary components in swine

Nutrient	Clinical Signs	Subclinical Signs	Estimated Dietary Tolerance Level[a]	Reference
Energy	Reduced sow feed intake in lactation[b]; increased carcass backfat; reduced embryo survival[c]	Impaired development of mammary secretory tissue; elevated plasma nonesterified fatty acid level; reduced plasma insulin	Variable	Kirkwood and Thacker 1988; Weldon et al. 1991, 1994a, 1994b; Australian Agricultural Council 1987
Fat	Increased carcass backfat	Soft carcass fat[d]	Variable	Wood et al. 1994; Azain 2001
Protein	Reduced weight gain, feed efficiency, and carcass backfat; mild diarrhea	Increased plasma urea	Not determined	Hansen and Lewis 1993; Dewey 1993; Chen et al. 1995; NRC 1998
Lysine	Reduced weight gain and feed efficiency[e]	None documented	Not determined[f]	Wahlstrom and Libal 1974; Edmonds et al. 1987; Goodband et al. 1989; Campbell and Combs 1990b.
Methionine	Reduced weight gain, feed intake and feed efficiency	None documented	Variable[g]	Wahlstrom and Libal 1974; Edmonds et al. 1987; Edmonds and Baker 1987; Campbell and Combs 1990c; Van Heugten et al. 1994
Threonine	Reduced feed intake and weight gain	None documented	1%	Edmonds et al. 1987; Edmonds and Baker 1987
Tryptophan	Reduced feed intake, weight gain, and feed efficiency; diarrhea	None documented	1% (100 kg pigs) 2% (10 kg pigs)	Edmonds et al. 1987; Edmonds and Baker 1987; Chung et al. 1991

[a]When higher dietary levels were provided, certain clinical and subclinical signs were observed under experimental conditions. These levels may not represent actual tolerance levels in production situations and they generally apply to growing pigs allowed ad libitum access to feed. Variable indicates tolerance levels are generally known, but they are too situation-dependent to describe here.

[b]Result of excessive energy intake during gestation.

[c]Result of excessive energy intake during rearing, the estrus cycle, and early pregnancy.

[d]Occurs when high iodine number (highly unsaturated) fat(s) is present in the diet.

[e]When provided as L-lysine acetate (4% of the diet) to 28-day-old pigs for 16 days.

[f]L-lysine≃HCL (0.7% of the diet) provided to 31 kg pigs for 85 days did not affect performance. In addition, L-lysine≃HCL (1.03% of the diet provided to 61 kg pigs for 50 days did not affect performance.

[g]Tolerance level appears to be impacted by pig age and dietary amino acid concentration and ingredient composition. The tolerance level is less than 0.2% added DL-methionine in finishing pigs fed a lysine-deficient diet. However, no ill effects were observed in nursery pigs fed diets containing 1 or 1.08% DL-methionine.

levels of nutrients. Proper nutrition ensures that the goals of economy, performance, health, and environmental stewardship are realized.

Meet The Pigs' Nutrient Requirements

Several factors, including gender, age, season, and genotype affect nutrient requirements of pigs. Therefore, it is important to monitor pig performance (e.g., rate of lean gain, feed intake, etc.) on individual farms and formulate diets based on observed production rather than using a general set of nutrient recommendations. In addition, as pigs grow their nutrient requirements decrease when expressed as a percentage of the diet. Thus, as pigs approach market weight they should be fed diets that contain a lower density of nutrients. This is commonly called "phase feeding." In typical phase-feeding programs, pigs growing from 25–120 kg would be fed four or more different diets. Also, because barrows consume more feed than gilts during the growing-finishing

period, amino acid requirements (percent of the diet) for barrows are lower. Thus, it is recommended that barrows be separated from gilts and fed diets containing different amino acids densities (Reese et al. 2000). Nutrient recommendations for various classes of swine were provided by NRC (1998) and Reese et al. (2000). Typically, separate requirements for barrows and gilts relative to other nutrients are not provided.

Implement a Quality Control Program

Monitor the nutrient content of ingredients and finished feeds on a periodic basis to help prevent problems associated with faulty nutrition. Collect samples carefully to ensure they are representative and submit them to a reputable laboratory for analysis. It is not practical to analyze ingredients and diets for all the nutrients pigs require. Instead, analyze for the major nutrients provided by an ingredient or contained in the diet. In general, these include crude protein, calcium, and phos-

Table 57.7. A summary of clinical signs associated with nutrient deficiencies and excesses in swine

Clinical Signs	Caused by a Deficiency of:	Caused by an Excess of:
Aborted fetuses	Vitamin A	. . .
Anestrus	Riboflavin, manganese, energy, protein/amino acids	. . .
Anorexia/reduced feed intake	Niacin, pantothenic acid, vitamin B_1, vitamin B_6, vitamin B_{12}, copper, iron, potassium, sodium and chloride, zinc, protein/amino acids, water	Vitamin A, vitamin D, chromium, cobalt, copper, iodine, iron, manganese, selenium, zinc, calcium, sodium and chloride, energy (in gestation sows), methionine, threonine, tryptophan
Ataxia	Vitamin B_6, copper, potassium	. . .
Blood-filled joints	Vitamin K	. . .
Blood, increased attraction to	Sodium and chloride, protein/amino acids	. . .
Bloody feces	. . .	Copper
Bloody urine and feces	. . .	Vitamin A
Breathing, labored	Iron	Chromium, iron, selenium
Coma	Vitamin B_6, energy	Iron
Congenital defects	Vitamin A	. . .
Death	Vitamin B_6, magnesium, energy, water, iron	Vitamin A, vitamin D, iron, selenium, sodium and chloride, copper
Death, sudden	Vitamin E, selenium, vitamin B_1	
Dehydration	Water	. . .
Depression	. . .	Chromium, zinc
Dermatitis	Biotin, niacin, linoleic acid, vitamin B_{12}, pantothenic acid	. . .
Diarrhea	Niacin, biotin, selenium, vitamin E, water	Chromium, iron, protein, tryptophan, sodium and chloride
Embryo survival, reduced	Vitamin A	Energy
Epileptic seizures	. . .	Sodium and chloride
Eye discharge	Vitamin A, biotin, vitamin B_6	. . .
Farrowing rate, reduced	Choline, pantothenic acid, riboflavin, energy, protein/amino acids	Selenium
Feed efficiency, reduced	Iron, phosphorus, sodium and chloride, zinc, protein/amino acids	Calcium, phosphorus, iron, zinc, vitamin D, protein, lysine, methionine, tryptophan
Fractures, spontaneous	Calcium, copper, phosphorus	. . .
Frothing at mouth	. . .	Selenium
Gait, goose-stepping	Pantothenic acid	. . .
Gait, stiff and stilted	Riboflavin, calcium	Cobalt, manganese
Goiter	Iodine	. . .
Hair coat, rough	Choline, niacin, pantothenic acid, vitamin B_{12}, iron, potassium	Vitamin A, vitamin D
Hair loss (alopecia)	Biotin, niacin, pantothenic acid, riboflavin, linoleic acid, zinc	Selenium
Hemorrhage, subcutaneous	Vitamin K	. . .
Hoof cracks	Biotin	. . .
Hoof, skin separate at coronary band	. . .	Selenium
Humped back	Calcium	Cobalt, vitamin D
Hypersensitivity/irritability	Vitamin B_{12}, magnesium	Vitamin A, sodium and chloride
Inactivity	. . .	Potassium, chromium
Incoordination/staggering movement	Vitamin A, vitamin B_{12}, choline	Vitamin A, cobalt, iron selenium, sodium and chloride
Joints, enlarged	Calcium, manganese	Vitamin A
Lactation failure	Vitamin E, selenium	. . .
Lameness	Vitamin D, manganese, calcium	Vitamin D, zinc
Legs, bowed	Copper, manganese	. . .
Litter size, reduced	Vitamin A, vitamin E, biotin, choline, folic acid, pantothenic acid, vitamin B_{12}, sodium and chloride, selenium, zinc, manganese, energy, protein/amino acids	Selenium, zinc
Milk production, reduced	Manganese, selenium	. . .
Night blindness	Vitamin A	. . .
Osteomalacia	Vitamin D, calcium, phosphorus	. . .
Pallor	Iron	. . .
Parakeratosis	Zinc	Calcium
Paralysis	Vitamin A, vitamin D, calcium, phosphorus	Vitamin D, selenium, sodium and chloride
Parturition time, extended	Vitamin E, selenium, zinc	. . .

(continued)

Table 57.7. *(continued)*

Clinical Signs	Caused by a Deficiency of:	Caused by an Excess of:
Piglets, born weak and small	Vitamin E, riboflavin, vitamin B_{12}, manganese, zinc, selenium, protein/amino acids	Selenium
Piglets, born hairless and weak	Iodine	. . .
Piglets, born pale and bleeding	Vitamin K	. . .
Prostration	. . .	Selenium
Rickets	Vitamin D, calcium, phosphorus	Iron
Skeletal malformation	. . .	Vitamin A
Sperm motility, reduced	Selenium	. . .
Sperm tail abnormalities	Selenium	. . .
Sperm production, reduced	Selenium, protein/amino acids, vitamin A	. . .
Stillbirths, increased	Vitamin A, zinc	. . .
Tail-biting	Sodium and chloride, protein/amino acids	. . .
Tetany	Vitamin D, calcium, magnesium	Iron
Tremors, muscle	. . .	Chromium, cobalt, selenium
Ulcers, gastric	Vitamin E, selenium	. . .
Vomiting	Riboflavin, niacin, vitamin B_6, vitamin B_1	Vitamin D, selenium
Water intake, reduced	Sodium and chloride	. . .
Weaning to estrus interval, extended	Sodium and chloride, manganese, energy, protein/amino acids	. . .
Weight gain, reduced	Vitamin A, vitamin D, choline, folic acid, niacin, pantothenic acid, riboflavin, vitamin B_1, vitamin B_6, vitamin B_{12}, calcium, copper, iron, phosphorus, sodium and chloride, zinc, potassium, energy, protein/amino acids, water	Vitamin A, vitamin D, choline, calcium, cobalt, copper, iodine, iron, manganese, phosphorus, selenium, zinc, protein, lysine, methionine, threonine, tryptophan

Table 57.8. Analytical variations[a]

Item	Variation, %	Example	
		Calculated level	Normal range
Crude protein	±3	16%	15.5–16.5%
Lysine	±20	.7%	.56–.84%
Calcium	±26	.70%	.52–.88%
Phosphorus	±13	.65%	.57±.73%
Copper	±25	250 ppm	188–313 ppm
Zinc	±20	100 ppm	80–120 ppm
Selenium	±25	.3 ppm	.23–.38 ppm
Vitamin A	±30	5,500 IU/kg	3,850–7,150 IU/kg

[a]Adapted from AAFCO 2004.

phorus for complete diets. Analyze protein supplements for crude protein and refer to NRC (1998) for coefficients to estimate amino acids from crude protein content. Analyze for calcium, phosphorus, at least one trace mineral (e.g., zinc), and vitamin A or E in base mixes and premixes. Compare the analyzed values to the expected nutrient content of the ingredient or diet when interpreting the results.

In situations where animals are not performing as expected, it is sometimes appropriate to collect a water sample for chemical analysis. Some commercial laboratories offer a "livestock suitability" test which includes an analysis for various minerals. Minerals from water should not substitute for quantities recommended in the feed. Furthermore, when water contains a higher-than-normal mineral content, always compare the pig's daily requirement for that mineral to that which would

be consumed through the water. Then decide whether the mineral content of the diet should be adjusted to prevent a problem with mineral excess. Often the mineral contribution from water is minute compared to the pig's requirement, and thus no adjustment in the mineral concentration of the diet is warranted.

Adopt Good Feed-Manufacturing Practices

These include using products according to the manufacturer's directions, operating the mixer properly, and using a reliable set of scales to weigh feed ingredients. The bulk density or test weight of ingredients is variable; thus, adding ingredients to the diet on a volume basis is not recommended (Reese and Brumm 1992). In addition, be sure all feed ingredients are clearly labeled and that the mill area is kept clean. Monitor ingredient purchases and

usage to ensure feed is being prepared according to specifications. Also, use feed within 30 days of manufacture.

Maximize Nutrient Intake and Minimize Nutrient Excretion

Only a portion of the nutrient content of a feed ingredient and(or) diet is available to the pig. The inefficiencies of digestion and metabolism are associated with nutrients excreted in the feces and urine, respectively. Therefore, to account for the variability of nutrient availability among feedstuffs (especially by-product feedstuffs), diets should be formulated based on digestible nutrient content (i.e., apparent digestibility or true ileal digestibility). In addition, nutrient concentration for amino acids, minerals, and vitamins can be corrected according to estimates for relative bioavailability (see Ammerman et al. 1995). Relative bioavailabilities of nutrients from several ingredient sources have been reported by NRC (1998).

Blend Adulterated Feed

Feed that contains higher-than-intended levels of a nutrient(s) is sometimes identified before it is offered to pigs. Often the adulterated feed can be handled as a new ingredient and used to manufacture other diets.

CONCLUSION

Pigs will exhibit certain symptoms when they are not provided optimum nutrition. The challenges for producers and their advisors are to ensure that pigs continually receive the correct balance and amount of all essential nutrients and effectively monitor for and recognize symptoms of faulty nutrition.

58 Porcine Stress Syndrome

P. J. O'Brien and Ron O. Ball

Porcine stress syndrome (PSS) is a well-known concern in the swine industry. The genetic mutation responsible for PSS is widespread and commercially important and produces dramatic features. In swine homozygous for the gene causing PSS, effects are conspicuous: heavy muscling and leanness (decreased fat deposition), predisposition to postmortem muscle deterioration, and a susceptibility to stress and anesthetic agents that may produce death and severe loss of pork quality. The PSS mutation was first captured in Pietrain swine in Belgium by selection and development for extreme muscularity, formerly referred to as "double-muscling" or *culard.* In the early 1950s, the PSS gene began to spread rapidly throughout the intensive swine industry worldwide until it reached near-epidemic proportions. Its spread was fueled by the demand for increased lean-meat production and decreased fat deposition but disregard for poor meat quality.

The heavy muscling is associated with other economically beneficial traits (leanness and increased growth efficiency) but also with economically deleterious traits: stress susceptibility and predisposition to development of inferior pork quality. The expression of the deleterious susceptibilities, however, is highly variable since it can be modified by environmental and managemental factors.

There is reasonably good understanding of the pathophysiological basis of the abnormalities associated with the PSS gene (O'Brien 1987, 1995; O'Brien et al. 1990a). They reflect inappropriate and excessive metabolic and contractile responses to all forms of stimulation of skeletal muscle. This includes stimulation associated with exertional, thermal, and social stressors—especially during transport and mixing of swine—and the electrical, mechanical, and anoxic stimulation occurring with stunning and exsanguination at slaughter. PSS is the first genetic disease for which the molecular basis is known and the mutation identified and for which a DNA-based diagnostic test is used on a wide, international, and commercial scale. The PSS mutation occurs in the *ryr-1* gene (first known as the *Hal* gene) coding for the calcium-release channel (ryanodine receptor) of sarcoplasmic reticulum of skeletal muscle.

CLINICAL SIGNS

Ludvigsen (1953, 1954) first reported an often fatal syndrome, occurring in Danish swine, characterized by increased temperature, dyspnea, muscle twitches, and light cyanosis. It was also associated with the exertional, thermal, and social stress of transporting and processing swine for slaughter. The syndrome resulted in pale, "juicy," sour-smelling pork, which he called *muskeldegeneration.* In the late 1950s this condition was recognized in other countries and described as *la myopathie exudative dépigmentaire du porc* in France (Henry et al. 1955), pale, soft, and exudative (PSE) pork in the United States (Judge et al. 1959; Briskey et al. 1959a; Briskey 1964), "back muscle necrosis" in Belgium (Thoonen and Hoorens 1960), and "white muscle condition" in England (Lawrie 1960).

The condition was found to be associated with pigs that were "stress-susceptible" (Judge et al. 1967, 1968; Forrest et al. 1968). When excited in a warm environment, they developed marked metabolic and respiratory acidosis, oxygen desaturation of venous blood, and tachycardia and tachypnea which progressed to cardiac and respiratory failure. Postmortem, their muscle was extremely PSE. The clinical syndrome was further described and named "porcine stress syndrome" (PSS) (Topel et al. 1968). In Europe, it was referred to as "acute stress syndrome" (Allen et al. 1970a), "malignant hyperthermia syndrome" (Eikelenboom and Minkema 1974), or "acute back muscle necrosis" (Thoonen and Hoorens 1960; Bickhardt et al. 1975; Bradley et al. 1979). PSS was also noted to occur on-farm and to be associated with other social stressors, including mixing, fighting, and mating. Topel et al. (1968) noted that rapid tail tremors were often the first sign, followed by dyspnea progressing to open-mouthed breathing, hyperthermia, irregu-

lar skin blanching and erythema, reluctance to move, collapse, and death within as little as a few minutes of the stress, and rigor mortis occurring almost immediately postmortem.

Pharmacologic induction in pigs of a fatal syndrome with a genetic basis was first recognized during anesthesia of Landrace pigs for experimental surgery using depolarizing muscle relaxants such as succinylcholine (Hall et al. 1966; Harrison 1994) and volatile anesthetics such as halothane (Harrison et al. 1968). Malignant hyperthermia rapidly developed, characterized by muscle rigidity, "blotchy blueness" of the skin, and circulatory failure with gross metabolic and respiratory acidosis. The similarity of this malignant hyperthermia syndrome to PSS was soon recognized (Eikelenboom and Sybesma 1969; Sybesma and Eikelenboom 1969; Allen et al. 1970a), and a halothane challenge test was developed as a field test for identification of swine with susceptibility to PSS (Christian 1974) and formation of PSE pork (Eikelenboom and Minkema 1974) and gained widespread, international use (Webb 1980). Induction of malignant hyperthermia has also been reported using α-adrenergic agents $5HT_{2A}$ serotonin receptor agonists (Hall et al. 1977b; Löscher et al. 1990; Fiege et al. 2003) and high doses of ryanodine receptor agonists such as 4-chloro-m-cresol (Wappler et al. 1999).

EPIDEMIOLOGY

Origin

Occurrence of PSE pork was reported in the German literature in the early twentieth century (Wismer-Pedersen 1969). It was associated with inbreeding, the stress of management and transport, and acute heart failure (Hupka 1939). The mutation was first recognized and concentrated in swine near the small village of Pietrain in the province of Brabant in Belgium about 1920 (Ollivier 1980; Porter 1993). It was used to create the Pietrain breed, which was based on crossings of swine of the local (Normand) and Berkshire breeds (Porter 1993). With the development of demand for high-quality fresh meat, the leanness (decreased fat deposition) and muscularity of the Pietrain gained greater importance, and it was recognized as a breed, with a Belgium herd book being established in 1953 (Porter 1993). Recent haplotype DNA sequence analyses (Fujii et al. 1991) and extensive DNA testing throughout the world (O'Brien et al. 1993; Vögeli et al. 1993, 1994; McPhee et al. 1994; Lackovic et al. 1997; Yun et al. 1998; Bastos et al. 2000; Morioka 2002; EuiKyung and YeonSoo 2002; Sabre et al. 2003) confirm that PSS arose from a single founder pig.

Spread

The PSS mutation apparently spread from Belgium to adjacent Germany, France, and the Netherlands, and to other European countries. It may have spread to the United States via Danish Landrace, which were imported into the United States in 1934, released to the public in 1950, and became important in establishing the American Landrace herd (Porter 1993). In the United States, the PSS gene first became well known in Ohio's Poland China breed, where the mutation might also have been introduced from its Berkshire ancestry (Lynch 1914), which it has in common with the Pietrain breed. During the Second World War, due to the development of vegetable fats and consequent decrease in demand for lard, the Poland China began to be bred for a leaner carcass (Porter 1993). By the late 1950s this breed was recognized for its high incidence of PSE pork (Judge et al. 1959; Briskey 1964), by the mid-1960s for its associated high prevalence of stress susceptibility (Judge et al. 1967, 1968; Briskey 1969; Forrest et al. 1968), and soon afterward for its high prevalence of halothane sensitivity (Jones et al. 1970, 1973; Nelson et al. 1972). In the 1970s, the pattern of spread of the PSS mutation was indicated by national prevalences within the Landrace breed of reactors in the halothane challenge test: approximately 90% in Belgium; 70% in West Germany; 20% in France and the Netherlands; 15% in Sweden, Switzerland, and South Africa; 10% in Britain, Denmark, Finland, and French Canada; and 5% in Norway, Ireland, Australia, and English Canada (Jensen 1979; Webb 1980, 1981; DeRoth et al. 1981; Mitchell and Heffron 1982; Seeler et al. 1984; Kallweit 1985).

Prior to the early 1980s, in marked contrast to the Pietrain, Landrace, and Poland China breeds, positive responders to the halothane challenge test were not reported for Duroc, Large White, and American Yorkshire swine, and Hampshires and Dutch Yorkshire had fewer than 3% responders (Webb 1981).

The rapid spread of the PSS mutation was based on a number of factors other than the conspicuous increase of muscularity and leanness in PSS gene homozygotes. Propagation was, and still is in North America and many other countries, facilitated by pork-packing plants providing financial incentives for carcasses with high lean yields. Consequently, swine breeders emphasized selection for decreased backfat and for increased lean carcass weight. Spread was further propagated by the lack of penalty for production of inferior-quality pork, especially in countries such as Belgium, Germany, Great Britain, and the United States, which were primarily importers of pork, compared with countries that were primarily exporters of pork, such as Denmark and the Netherlands (Kallweit 1985). The speed and pervasiveness of the spread were facilitated by the pyramidal structure of the modern swine industry, which amplifies the genetics of a small proportion of the population into a large proportion of slaughter hogs, and by the rapid national and international exchange of breeding stock. The major impetus for its spread was the intense selection pressure for leanness that began in the mid-1950s and intensified through the early 1970s, resulting in PSS achieving near-epidemic proportions.

There is a noteworthy implication of the rapid spread of the PSS mutation from a single founder animal across numerous breeds in many countries. Crossbreeding must have occurred between supposedly purebred breeds of swine. This is especially evidenced by the high frequency of the PSS gene that developed in Yorkshire, Duroc, and Hampshire breeds (O'Brien 1995), which in the 1970s had been considered to be free of PSS susceptibility (Webb 1981). Furthermore, local swine breeds raised for pork production in areas where modern intensive selection programs have not been used may be free of the PSS mutation, such as in Siberia (Knyazev et al. 1996) or the Guanling pigs in Guizhou, China (ShanHua 1997), or Manchado de Jabugo pig of Portugal (Ramos et al. 2000).

In the 1970s, the relationships of PSS and muscularity and PSE, and the adverse economic impact of mortality and severe PSE pork in homozygotes for the PSS gene, became widely recognized (Topel 1981a; Kallweit 1985). This, and the availability of the halothane challenge test (and blood-typing tests in Europe), led to intense selection against homozygotes for the PSS gene and a rapid and substantial decline in their numbers from the late 1970s and early 1980s (Topel 1981a; Webb 1981; Kallweit 1985; Vögeli et al. 1985), especially in countries with a national swine selection program. From 1978, the percentage of halothane test reactors dropped from 18% to 1% in 1982 in Swiss Landrace; from 18% to 5% in 1984 in French Landrace; from 12% to 5% in 1984 in Finnish Landrace; and from 6% to 2% in 1983 in Norwegian Landrace. In the early 1990s in North America and England, DNA tests of breeding stock indicated that 1–2% of swine, especially Landrace swine, were homozygous for the PSS mutation and therefore likely to be halothane test responders (O'Brien 1995).

Prevalence

Estimates of the prevalence of the PSS mutation in 25,000 swine of various breeds used in breeding programs were made using a DNA-based blood test (O'Brien et al. 1993; O'Brien 1995). Blood was submitted from 200 American swine breeders, of which 50% were from Illinois, Indiana, and Iowa; from 150 Canadian swine breeders, of which 50% were from Ontario; and from 5 British farms. The percentage of swine heterozygous for the PSS mutation varied in different breeds and countries but was highest in England and in the Landrace: in England, 40% of Landrace, 20% of Large White, and 30% of all pigs; in the United States, 40% of Landrace, 35% of Duroc, 25% of Hampshire and of all swine; and in Canada, 30% of Landrace and 15–20% of Yorkshire, Hampshire, Duroc, and all swine. The percentage of swine homozygous for the PSS mutation was 1% in Canada and 2% in the United States and England. In Canada, selection against swine with the PSS mutation over the last 10 years has apparently decreased the incidence of PSS gene heterozygotes by up to 75% (Du 2003).

Mortality is the most conspicuous and dramatic effect of the PSS mutation but is uncommon, typically occurring in substantially fewer than 0.5% of North American and European swine (Tarrant 1993). However, prior to selection against PSS gene homozygotes and improvement of transport conditions (Tarrant 1993), mortality in transported swine was as high as 4–10% (Devloo et al. 1971; Lendfers 1971; Korolija 1979). Mortality from PSS occurs at rates of up to 10–15% of homozygotes for the PSS mutation (Webb and Jordan 1979; Rundgren et al. 1990; McPhee et al. 1994). These deaths may be largely eliminated by not using PSS gene homozygotes as slaughter pigs and by "stress"-free management practices (Topel 1981b). Finnish studies showed that reduction of the prevalence of halothane reactors from 12% to near 0% resulted in a decrease in mortality rates during transport from 0.8% to 0.1% (Kuosmanen and Puonti 1993). In Denmark, where the PSS gene has been largely eradicated, transport death rates are less than 0.02% (Barton-Gade et al. 2003).

The average frequency of PSS gene heterozygotes in North America was approximately twofold higher in tested breeding stock, 20–25% (O'Brien et al. 1993; O'Brien 1995), than in pigs used for slaughter, 11–15% (Pommier et al. 1992; Goodwin 1994a, b; Goodwin and Burroughs 1995; Gibson et al. 1996). This difference probably reflects use of the gene in breeding stock, especially in terminal sire lines, but removal of PSS gene homozygosity from slaughter hogs.

Introduction of the DNA-based test for the PSS mutation has enabled more recent estimates of the frequency of heterozygotes to be made in additional countries, including 28% in Brazil (Bastos et al. 2000), 6% in Japan (Morioka 2002), 9% in Estonia (Sabre et al. 2003), 15% in Korea (EuiKyung and YeonSoo 2002), 28% in Taiwan (Yun et al. 1998), and 11% in Croatia (Lackovic et al. 1997).

Because of possible negative commercial effects, few estimates of the prevalence of PSE pork are published, especially in countries exporting pork (Cassens et al. 1980). Estimates vary depending on the criteria used for defining PSE. In Europe, in the early 1960s, PSE pork was reported in high proportions, in up to 40% of Danish Landrace and 90% of Belgium Pietrain carcasses (Briskey 1964). As previously indicated, the proportion of Landrace swine testing positive in the halothane challenge test was high, and 80% of these swine developed PSE pork (Eikelenboom 1985; Jensen and Barton-Gade 1985). In some countries, such as Switzerland and Finland, where there was intense selection pressure against halothane reactors and where meat quality was used in breeding selection programs, the incidence of PSE pork has decreased. Frequency of PSE pork in Swiss Landrace decreased from 33% in 1978 to 7% in 1983 (Vögeli et al. 1985). In 1998, the incidence of PSE, based on an initial postmortem measurement of semimembranosus pH of less than 6, was reported to be 69% for

Portugal, 23% for the Netherlands, 8% for Italy, and only 2% for Denmark. (Warriss et al. 1998). In contrast, the incidence of PSE pork increased over this time period in Great Britain: in 1964 and 1972–73, 6% of 5000 carcasses were found to have PSE pork as defined by a pH of less than 6 occurring 45 minutes after slaughter; but in 1983, the figure was 13% (Kempster and Cuthertson 1975; Chadwick and Kempster 1983). In two surveys reported in 1981 of 10,000 hogs in Canada, 20% and 22% were found to have PSE pork based on this pH measurement (Thompson 1981). Subjective determinations on swine carcasses of PSE pork scores based on color, firmness, and wetness are apparently little changed in the United States since the early 1960s. A survey of 15,000 swine indicated a prevalence of 18% PSE pork (Briskey 1964). Assessment of more than 10,000 hams at 14 different slaughterhouses in the early 1990s found PSE pork prevalence to average 16% but to vary widely from 6% to 33% (Kauffman et al. 1993; Bäckström and Kauffman 1995). In Ireland in the late 1990s the annual average PSE prevalence was estimated at 26%, although the frequency varied substantially over the year, depending in part on the weather but also on slaughtering rates and variation in resting periods before slaughter (O'Neill et al. 2003).

PATHOGENESIS

The PSS gene causes increased sensitivity and responsiveness of swine and of their isolated skeletal muscle to pharmacologic, neural, anoxic, endocrine, and physical stimulation (Lister et al. 1970; Gronert et al. 1980; Ahern et al. 1985). This muscle hypersensitivity is associated with abnormal intracellular calcium release from the sarcoplasmic reticulum, the organelle primarily regulating intracellular calcium concentration and, therefore, muscle activity. When loading calcium into isolated sarcoplasmic reticulum to study calcium release, release occurred prematurely, especially in the presence of caffeine (Ohnishi et al. 1983; Nelson 1983). Calcium was released in abnormally greater amounts and at faster speeds (Kim et al. 1984). Specifically, the sarcoplasmic reticulum's calcium-release channel, which plays a critical role in the biochemical coupling of muscle stimulation and activity (Ogawa 1994), was activated by lower concentrations of agonists and inhibited by higher concentrations of antagonists than for controls (O'Brien et al. 1985a; O'Brien 1986a). This hypersensitivity of the calcium-release channel causing calcium release at greater speeds and in higher amounts than normal was proposed to result from a submolecular defect that facilitated the opening of the channel or else inhibited its closure (O'Brien 1985; O'Brien 1990). The channel defect arises from a DNA point mutation of cytosine to thymine at the 1843rd nucleotide of the *ryr-1* gene near the centromere of chromosome 6. This causes replacement of arginine by cysteine at the 615th amino acid of

the channel (Fujii et al. 1991). This gene was first referred to as the *Hal* gene in swine, based on linkage studies of halothane sensitivity and blood types (Andresen and Jensen 1977).

Various forms of muscle stimulants activate the hypersensitive calcium-release channel by different mechanisms (O'Brien 1986a; Ogawa 1994). Caffeine and calcium itself are calcium-release channel agonists. Neural and electrical stimulation and depolarizing muscle relaxants depolarize the muscle surface membrane and thereby activate a voltage sensor (itself a vestigial calcium channel) that is coupled to, and regulates, the calcium-release channel. Activation may also occur due to an increased intracellular influx of calcium down its steep concentration gradient into the cell. Nonspecific membrane-perturbing agents, such as volatile anesthetics, increase membrane permeability to calcium (O'Brien 1986a). Stimulation of surface-membrane α-adrenergic or serotonin $5HT_{2A}$ receptors triggers inositol phosphate formation and opening of an associated calcium channel (Scholz et al. 1991, 1993; Gerbershagen et al. 2003). During anoxia, several factors operate to increase calcium influx, including energy depletion, acidosis, free-radical formation, and activation of membrane-degradative enzymes and loss of calcium-sequestration activity by sarcoplasmic reticulum (O'Brien 1986b; O'Brien et al. 1991).

Stress Susceptibility

Stress susceptibility (PSS) is largely restricted to swine homozygous for the PSS gene (see below) and can be attributed to the inappropriate and excessive metabolic and contractile responses of skeletal muscle to stimulation. Hypermetabolism results in accelerated oxygen and muscle glycogen consumption, with release of excessive heat, acids, potassium, carbon dioxide, and muscle proteins into the blood (Berman et al. 1970; Clark et al. 1973; Gronert and Milde 1976; Hall et al. 1980a). Thermogenesis, in conjunction with peripheral vasoconstriction, leads to hyperthermia (Clark et al. 1973; Hall et al. 1976). Rapid rates of aerobic metabolism desaturate venous oxygen, leading to cyanosis (Hall et al. 1976; Gronert 1980). Developing metabolic and respiratory acidosis causes tachypnea and dyspnea. Marked activation of the sympathetic neuroendocrine system causes tachycardia and enhanced cardiac output, but with the developing hypercatecholemia, hyperthermia, hyperkalemia, acidosis, and hemoconcentration, this rapidly progresses to cardiac arrhythmia and eventually arrest (Gronert and Theye 1976; Gronert et al. 1977). The rapid depletion of intramuscular glycogen and adenosine triphosphate (ATP) results in almost immediate onset of rigor mortis (Briskey 1964).

Although sympathetic neuroendocrine responses in PSS-susceptible swine are exaggerated and prolonged, they are clearly consequences and aggravators, rather than initiators, of the exaggerated and prolonged re-

sponses of muscle to stimulation (Gronert et al. 1977, 1980). The PSS reaction may be aggravated by sympathetic enhancement of muscle glycogenolysis, facilitation of neuromuscular transmission, vasoconstriction in skin or muscle, leading to decreased heat loss or muscle ischemia (Lister et al. 1970; Gronert et al. 1980) and to direct stimulation of skeletal muscle by alpha-adrenergic receptor activation (Lister et al. 1976; Hall et al. 1977b). Serotonin may also have a secondary role in PSS. Its release in the brain and its serum concentration are increased by stress, may facilitate motor neuron transmission, have a vasoconstrictive effect that impairs oxygenation of ischemic muscle (Komiyama et al. 2004), and directly stimulate skeletal muscle (Löscher et al. 1990, 1994; Gerdes et al. 1992).

Inferior Meat Quality (PSE Pork)

Muscle Characteristics. Formation of PSE pork is due to postmortem glycogenolysis and glycolysis generated by the sudden anoxia and catecholamine, motor nerve, and mechanical stimulation that occur with stunning and exsanguination at slaughter (Lawrie 1960; Briskey 1964; McLoughlin 1971). The combined effects of the resultant increases in acid and heat production cause denaturation of sarcoplasmic and myofibrillar proteins and contraction of the intermyofilament fluid compartment as negative electrostatic repulsion between filaments decreases (Bendall and Swatland 1988). These changes result in loss of water-binding capacity, increased light scattering, altered refractive indices, and sarcomere lengthening, which collectively produce PSE pork (Bendal and Swatland 1988; Swatland 1989, 1993). Furthermore, during the early hypermetabolic state, osmotically active end-products cause a transient influx of water from the extracellular space into the sarcoplasmic fluid compartment (Berman et al. 1970; Frøystein et al. 1984; Janzen et al. 1994).

The PSE pork develops primarily in muscles of the hams and loins, especially the longissimus dorsi, semimembranosus, and gluteus muscles (Ludvigsen 1953; Briskey et al. 1959b; Lawrie 1960; Thoonen and Hoorens 1960). These muscles have a higher proportion of "white" fibers with high glycolytic capacities: 70–85% in the longissimus dorsi, 79–93% in the white semitendinosus, and 81% in the gluteus (Gallant 1980; Rahelic and Puac 1981; Essén-Gustavsson and Lindholm 1984).

Selection for increased muscularity has resulted in domestic swine having skeletal muscle with increased susceptibility to PSE, which is further increased if they have the PSS gene. Compared to wild pigs, their skeletal muscle has more fast-twitch (type II) fibers, and more of these fibers have a high capacity for glycolysis but poor fatigue resistance (Szentkuti et al. 1981; Rahelic and Puac 1981; Essén-Gustavsson and Lindholm 1984). Swine with PSS susceptibility have increased muscle fiber diameter (Dildey et al. 1970; Sair et al. 1972) in association with decreased numbers of capillaries and

oxidative capacity (Essén-Gustavsson et al. 1992; Fiedler et al. 1999), although proportions of fiber types do not differ (Gallant 1980; Heffron et al. 1982; Essén-Gustavsson and Lindholm 1984), or are mildly increased for fast twitch glycolytic fibers (Fiedler et al. 1999), from those of nonsusceptible swine of the same breed. Apparently because of their hypersensitivity to stimulation, muscle fibers from PSS-susceptible swine frequently are supercontracted in histologic preparations (Ludvigsen 1953; Henry et al. 1955; Lawrie 1960), especially the type II fibers (Palmer et al. 1977). Swine with PSS susceptibility also have increased numbers of fibers with internal nuclei and increased numbers of angular fibers and of giant fibers, which may represent accumulation of mild muscle injury (Cassens and Cooper 1969; Palmer et al. 1977; Dutson et al. 1978; Handel and Stickland 1986; Fiedler et al. 1999).

Environmental and Managemental Factors. Because muscle affected by the PSS mutation is hypersensitive to stimulation, postmortem development of PSE pork is more frequent and severe than in normal muscle. However, there are several environmental and swine/carcass management factors that modify the degree of development of PSE pork in swine with the PSS mutation. These factors exert their effect primarily by affecting the degree of muscle stimulation and the amount of muscle metabolic substrate, glycogen. Since the speed and duration of the postmortem glycolytic reaction, and the associated production of acid and heat, are primarily dependent on glycogen content, then preslaughter factors that decrease glycogen concentration will limit the development of PSE pork (Briskey et al. 1959b). If muscle glycogen is substantially reduced prior to slaughter, and the animal given time to normalize any perturbations in acid-base balance, then muscle from PSS swine does not develop PSE. If the glycogen depletion is severe, as with exhaustion or excessive fasting, the opposite to PSE pork may develop, namely, dry, firm, and dark (DFD) pork (Briskey et al. 1959b; Lundström et al. 1989; Bäckström and Kauffman 1995; Gispert et al. 2000). Since swine with the PSS mutation are more sensitive and reactive to muscle stimulation and therefore to initiation of glycogenolysis, they may be more sensitive to development of DFD.

Specific environmental and swine management factors shown to enhance the development of PSE pork are preslaughter transport more than 500 km, high stocking density during transport; increased ambient temperatures of summer and autumn, and stress immediately before slaughter. Factors known to decrease the development of PSE pork are preslaughter transport of 50–300 km; preslaughter fasting for 12–22 hours; preslaughter lairage holding times of 2–3 hours to allow recovery from stresses prior to the abattoir; rubber-textured floor surface allowing stable footing; and preconditioning to stressors such as handling, mixing, and crowding

(Ludvigsen 1954; Scheper 1969, 1976; Lendfers 1969; Barton 1971; Nielsen 1979; Korolija 1979; Grandin 1980b, 1986, 1996; Tarrant 1993; Bäckström and Kauffman 1995; Berg 1998; Guardia et al. 2004). Incidence of PSE was substantially decreased by reduction of stress immediately before slaughter in a French study (Franck et al. 2003). The traditional use of electrical prods and restrainers to drive pigs in single file to the stunning maching was replaced with an automated system of driving small groups of pigs with a sliding door from the piggery to the machine.

Compared with using captive-bolt instruments, carbon dioxide, or low-voltage for stunning for slaughter, muscle stimulation was thought to be reduced and development of PSE pork decreased with the use of short-duration stunning with high voltage (300 V) followed within 30 seconds by bleeding (van der Wal 1971a, b; Ratcliff 1971; Grandin 1980a, 1982; van der Wal and Eikelenboom 1981). Conversely, several more recent studies suggest that high-voltage stunning may produce more PSE pork than when pigs are stunned without restraint and with low voltage or, especially, with carbon dioxide (Bäckström and Kauffman 1995). In a Spanish study, PSE was reduced from 36% to 5% and the incidence of petechiae, ecchymosis, and hematomas was substantially reduced by replacing electrical stunning with carbon dioxide stunning (Velarde et al. 2001). Drip loss was reduced from 7.3% to 5.8% in an Australian study by use of carbon dioxide rather than electrical stunning (Channon et al. 2000).

High rates of postmortem glycolysis stimulated by slaughter and leading to PSE pork are reduced by prior inhibition of neuromuscular transmission with curare (Bendall 1966), nondepolarizing muscle relaxants (Hallund and Bendall 1965), magnesium (Sair et al. 1970; Lahucky et al. 2004), or by prior administration of dantrolene (Yang et al. 1983); whereas rates of postmortem glycolysis are increased by preslaughter administration of epinephrine (Althen et al. 1979). Liquid nitrogen chilling prevents formation of PSE (Borchert and Briskey 1964). Use of rapid chilling within the first half hour postmortem causes decreased rates of pH drop and decreased incidence of PSE, with heterozygotes having normal drip loss (Maribo et al. 1998). However, too rapid a chilling rate is associated with cold shortening of muscle fibers with loss of water binding capacity and development of tough pork (Rosenvold and Anersen 2003).

Hampshire swine have a high prevalence of the *RN* gene, which causes a 70% increase in glycogen content of white muscle (Sair et al. 1963; Monin and Sellier 1985; Le Roy et al. 1990). Consequently, postmortem glycolytic metabolism is prolonged—although at a normal rate—the final pH is abnormally low, and the meat quality is decreased. Carcasses with both the *RN* and *ryr-1* genes are especially susceptible to developing severe PSE pork, because of increased duration and rate of postmortem glycogenolysis (Gibson et al. 1996).

Environmental and swine/carcass management factors may play a more important role than genetic factors in determining the prevalence and severity of PSE pork. Although it has long been known that PSE pork develops in swine without the PSS gene (Mitchell and Heffron 1982), the proportion of PSE pork caused by the PSS gene may be highly variable, depending on the PSS gene frequency, definition of PSE pork used, the severity of the preslaughter stress, and the extent of control over postmortem carcass deterioration. Jensen and Barton-Gade (1985) reported that inclusion of pork of doubtful quality into the category of PSE pork increased the incidence of PSE pork from 5% to 15%, 27% to 38%, and 81% to 90% in swine without, heterozygous for, and homozygous for the PSS gene, respectively. Kauffman et al. (1993) introduced the terms RSE (red, soft, and exudative) and RSN (red, soft, and normal) to classify non-PSE pork of questionable quality and of optimal quality, respectively. Only 15% of pork was considered ideal, with more than 50% being of questionable quality because of exudation despite acceptable color. Barton-Gade found that an increase in preslaughter stress increased the incidence of PSE pork from 0% to 33%, 13% to 33%, and 79% to 100% in swine without, heterozygous for, and homozygous for the PSS gene, respectively (Lundström et al. 1989). The development of the DNA test for PSS allowed a recent study of a slaughterhouse with a high (20–30%) incidence of PSE and revealed that nongenetic causes of PSE pork were twice as important as the PSS gene (Pommier and Houde 1993). Loins deemed by visual appraisal to be PSE pork were objectively assessed for PSE pork using a surface colorimeter. Swine normal, heterozygous, and homozygous for the PSS gene, respectively, had PSE pork frequencies of 54%, 80%, and 91% and produced 68%, 29%, and 4% of the PSE pork at that slaughterhouse. In a Spanish study, meat quality assessed by measuring electrical conductivity in the semimembranosus muscle was unaffected by the heterozygous state (Gispert et al. 2000). However, lack of effect of the heterozygous gene in this study may be related to the slower postmortem rate of decrease in pH in semimembranosus than in longissium muscle for heterozygotes (Fernandez et al. 2002).

Revenue loss related to PSE muscle is caused by increased drip loss during storage, transport, and processing of the carcass and pork. This increased water loss from pork causes shrinkage and weight loss, which decrease its dollar value (Kauffman et al. 1978). Additionally, PSE muscle may be rerouted for processing into less-valuable pork products, such as sausage. Shorter shelf life and, especially, decreased consumer acceptance of PSE pork appearance and taste cause retail loss to the swine and pork industries (Buchter and Zeuthern 1971; Topel 1976; Smith and Lesser 1982; Goodwin 1994a, b; Casteels et al. 1995; Jeremiah et al. 1996). For the swine and pork industries of the United States, estimates of revenue loss due to PSE pork exceed $50 million annually (see below).

Superior Muscularity, Leanness, and Growth Efficiency

The calcium-release channel defect caused by the PSS mutation can plausibly explain the associated muscularity, leanness, and increased growth efficiency, although the physiological mechanisms have not been defined. For the same amount of stimulation as for muscle without the PSS mutation, activity of muscle with the PSS mutation is more frequent, intense, and longer lasting. Because contractile activity is a stimulus for muscle hypertrophy, swine with the PSS mutation develop greater muscularity. This increased demand for muscle growth must also result in increased demand for conversion of feed into lean muscle than into adipose tissue, resulting in greater leanness. And, because the energy content of muscle is lower than that of adipose tissue, less feed is required per unit body weight.

Although a calcium-release channel defect may plausibly explain the phenotypic changes associated with the PSS mutation, it is not implausible that expression of other genes linked to this mutation might modify these phenotypic traits. Several genes with trophic or regulatory effects on skeletal muscle and adipose tissue have been linked to the PSS mutation, including apolipoprotein E, hormone-sensitive lipase, transforming growth factor ß-1, and the extended black (E) locus for the melanocortin 1 receptor for α-melanocyte-stimulating hormone (Vögeli et al. 1993; Mariani et al. 1996). In this regard, it is interesting to note the relationship of the black-spotting phenotype associated with the e-locus and the black coloration of Pietrain and Poland China swine, which have had the highest incidence of PSS, and of their common ancestor, the Berkshire. Recently, the increased muscle mass and decreased fat deposition of the Pietrain compared to Large White pigs has been attributed to similar but separate and noninteractive effects of the PSS mutation and a polymorphism in an imprinted gene linked to the locus for insulin-like growth factor 2 and expressed exclusively from the paternal allele (Nezer et al. 1999). Use of Pietrain lines free of the halothane gene as terminal sires has been reported to decrease incidence of PSE and increase pork quality compared to use of Pietrain sires homozygous for the PSS mutation (Fabrega et al. 2004).

Extramuscular Tissue Effects

Tissues other than skeletal muscle that might be directly affected by the PSS mutation can be deduced from the tissues that express the *ryr-1* gene. Although cardiac and smooth muscle, adipose tissue, and viscera do not express it, the *ryr-1* gene is expressed in the brain, particularly in the thalamus, hippocampus, striatum, and cerebellum, and especially in Purkinje cells (Furuichi et al. 1994; Giannini et al. 1995). Although the physiological relevance of brain *ryr-1* expression is unknown, it may be related in part to the observation of regional abnormalities of neurotransmitter concentrations in brains

from swine with the PSS mutation (Altrogge et al. 1980; Adeola et al. 1993). This interpretation is supported by the association of the mutation of *ryr-1* in swine hippocampus with decreased expression of *ryr-1* and the calcium-binding protein, calsequestrin (Weaver et al. 2000). Alternatively, these alterations in catecholamine and serotonin concentration may be secondary to stress susceptibility. Stress increases the brain release and serum concentration of serotonin, which is a mediator of psychological stress by facilitation of motor neuron excitation, and has a vasoconstrictive effect that impairs oxygenation of ischemic muscle (Komiyama et al. 2004), and directly stimulates muscle (Löscher et al. 1990, 1994; Gerdes et al. 1992).

The increased sensitivity of lymphocytes from individuals with the PSS mutation to halothane-induced increases in intracellular calcium (Klip et al. 1987; O'Brien et al. 1989; O'Brien et al. 1990b) has recently been attributed to the B lymphocyte expressing the *ryr-1* gene (Girard et al. 2001; Sei et al. 2002). There was increased sensitivity to other triggers of *ryr-1*-mediated calcium signaling, including caffeine, and 4-chloro-*m*-cresol. The physiological significance of this lymphocyte hypersensitivity is unknown and has not been associated with any pathophysiology of the immune system or inflammatory response. It is noteworthy, however, that B cells produce inflammatory cytokines, which may elicit a pyrogenic response that could contribute to abnormal temperature regulation in PSS.

In addition to primary involvement of tissues expressing the *ryr-1* gene, there is secondary involvement of other tissues. As described above, the amount and distribution of fat deposition are decreased in swine with the PSS mutation, probably because of their enhanced muscle growth. Also, as described above, PSS is characterized by marked stimulation of the sympathetic neuroendocrine system, causing cardiac arrhythmia and arrest (Gronert et al. 1977). Mild erythrocyte membrane abnormalities (Harrison and Verburg 1973; O'Brien et al. 1985b) and increased sensitivity platelets (Miller et al. 1991; Fink et al. 1992) to halothane-induced increases in cytoplasmic calcium also occur in swine with the PSS mutation. These abnormalities may be secondary to altered muscle metabolism, although a direct effect of the mutation cannot yet be definitively excluded.

Secondary Degenerative Effects

In addition to calcium's role in metabolic and contractile activities, it activates degradative processes, including proteolysis by neutral proteases and free-fatty-acid release from phospholipids by calmodulin-dependent phospholipase A_2 (Cheah et al. 1986; Sensky et al. 1999). Furthermore, as a side-product of increased mitochondrial activity, free radicals are formed and cause lipoperoxidation and further damage (Duthie and Arthur 1993). These processes likely contribute to the postmortem deterioration of pork quality.

INHERITANCE OF THE PSS GENE AND ITS EFFECTS IN THE HETEROZYGOUS STATE

Historically, definition of the pattern of inheritance of the various traits associated with the PSS gene has been controversial. However, with refinement and improved accuracy of methods for detection of the heterozygote, patterns have become more clear. The appearance of the inheritance pattern is dependent upon a number of factors, including nature of the trait being considered, gene dosage needed for the trait to be exhibited, sensitivity and precision with which the trait is measured, presence of exacerbating or obscuring modifying factors, variability in the trait due to other genetic factors, and accuracy with which the genotypes can be separated. Finally, as attention focuses on the heterozygote, it is becoming apparent that there are breed and strain effects modifying the expression of the gene in various live-performance and carcass traits.

Halothane Sensitivity and Stress Susceptibility

Breeding experiments by Christian (1974) and Mabry et al. (1981) using American Yorkshire and Poland China swine first indicated that the pattern of inheritance of reactivity in the standardized halothane challenge test was monogenic and autosomal recessive. This was confirmed in studies of Pietrain (Ollivier et al. 1975; Reik et al. 1983), Pietrain-Hampshire (Smith and Bampton 1977; Webb and Smith 1977), and Dutch (Minkema et al. 1977) and Australian Landrace (McPhee et al. 1979). The average penetrance estimate was high, near 90%, but ranged from 64–130%. Lowered penetrance estimates were caused by false-negative test results (Gallant and Rempel 1987), which in turn were due to various causes, including testing pigs that were less than 8 weeks old (Carden and Webb 1984; Fay and Gallant 1990), in poor body condition, or with poor muscularity (Mabry et al. 1981); using suboptimal halothane exposure (McGrath et al. 1984); and the inherent inaccuracy of the test (Webb and Jordan 1979). Accurate definition of the pattern of inheritance depended on knowledge of the genotype of breeding swine testing negative, which could be determined after mating them with positive responders. Otherwise, offspring from matings of positive with negative responders would frequently yield positive responders and the pattern of inheritance would be confounded (Carden et al. 1983; O'Brien et al. 1985b). Understanding of the pattern of inheritance was further confused by the finding of dominant inheritance when the challenge test was made more vigorous by prolongation of halothane exposure (Williams and Lasley 1977; Britt et al. 1978) or by coadministration of succinylcholine (Webb et al. 1986; Seeler et al. 1984), resulting in identification of heterozygotes.

The pattern of inheritance of susceptibility to PSS has not been well studied but appears recessive. Stress-induced mortality was approximately tenfold higher in halothane test reactors than nonreactors (Eikelenboom et al. 1980a, b). In one study, deaths occurred in none of the PSS gene heterozygotes but occurred in 15% of PSS gene homozygotes (Rundgren et al. 1990). Transport of swine in tropical Australia caused the death of 14% of PSS gene homozygotes, 2.6% of heterozygotes, but only 1.4% of normal swine (McPhee et al. 1994). The adverse effect of the PSS gene on mortality was almost twofold higher in swine selected for rapid lean-growth rates.

Beneficial and Deleterious Carcass Traits

Ollivier (1967, 1980) studied backcrosses of offspring (F1) of Pietrain and Large White matings and was the first to report that increased muscularity in association with the PSS gene was inherited in an autosomal, monogenic, dominant pattern. Heterozygotes had intermediately greater conformation scores for increased muscling, shorter carcass length measurements, and increased ham and loin yields. After the discovery of the halothane test, further studies confirmed these results and showed that positive reactors had shorter carcasses, lower backfat thicknesses, greater ham and loin yields, and increased dressing compared with nonreactors (Eikelenboom and Minkema 1974; Webb and Jordan 1979; Gerwig et al. 1979; Monin et al. 1981) and that heterozygotes typically had intermediate values (Eikelenboom et al. 1980a, b; Kukoyi et al. 1981).

Detection and quantification of the effects of the PSS gene in heterozygotes on carcass characteristics were further facilitated by the development of linked blood markers and the DNA test for the PSS gene. Using these tests, heterozygotes, compared with normal swine, were typically shown to be shorter, leaner, more muscular, and slower but more efficient growers. The effects of the gene varied substantially according to breed and strain but produced up to 4–5% slower daily weight gain, 0.5–0.9% shorter carcasses, 0.5–1% increased carcass weights, 0.5–1.2% increased dressing percentage, 2–6% increased lean yield, 2.5–4% increased daily gain of lean tissue, 2–6% increased ham yield, 3–15% increased loin-eye area, 0–8% decreased backfat, 10–36% decreased marbling, and 2–9% decreased feed consumption per liveweight gain (Jensen and Barton-Gade 1985; Rundgren et al. 1990; Pommier et al. 1992; De Smet et al. 1993; O'Brien et al. 1994; McPhee et al. 1994; Goodwin and Burroughs 1995; Leach et al. 1996; Fabrega et al. 2002). Although these advantageous effects were found in swine heterozygous for the PSS gene in both purebred and various crossbred lines of Hampshire, Berkshire, Duroc, Landrace, Pietrain, Large White, and Yorkshire origin, they were not found in some strains of Yorkshire, Large White, Duroc, and spotted swine. Data from three large studies, each including 1000–3000 swine of various breeds, and in which breeds were not separated, indicated that the only consistent effects of the heterozygous gene in all swine were 0.5–0.6% increased dressing

percentage, 8–11% decreased marbling scores, and 2–9% increased loin-eye area (Goodwin 1994a, b; Goodwin and Burroughs 1995; Gibson et al. 1996). A Spanish study of 1300 genotyped swine found that the gene in the heterozygous state increased loin depth by 6% and mean lean content by 1.5%, although other unidentified factors across abattoirs could cause up to 2.5% difference in lean content (Gispert et al. 2000).

Early studies on the inheritance of adverse meat quality due to the PSS gene were inconsistent. MacDougall and Disney (1967) found in crossbreeding studies of Pietrain and British Landrace swine that heterozygotes had intermediate-quality pork, although it was closer to that of normal swine than to that of the PSS homozygous Pietrains. Studies of Dutch Landrace by Eikelenboom et al. (1980a, b) indicated that poor meat quality was a recessive trait; heterozygotes and normal swine carcasses were indistinguishable by subjective scoring. Later studies, in which genotypes could be more accurately distinguished, indicated that heterozygotes for the PSS gene had meat quality characteristics that were intermediate between those of normal and PSS gene homozygotes, but closer to normal. In Danish Landrace, heterozygotes had intermediate meat quality, although it was significantly closer to normal than to that of PSS gene homozygotes (Jensen and Barton-Gade 1985). The frequency of PSE pork in these Danish carcasses was 81% for PSS gene homozygotes, 5% for normal swine, and 27% for heterozygotes. In Spanish commercial swine, incidence of PSE was 25% for heterozygotes and 8% for normal swine (Velarde et al. 2001). Numerous studies found drip loss after 24 hours at 4°C was increased by 5–50% in heterozygous compared with normal loin muscle. Also, intermediate scores for muscle color, firmness, and pH were found in heterozygotes (Jensen and Barton-Gade 1985; Lundström et al. 1989; De Smet et al. 1993; Pommier and Houde 1993; Goodwin 1994a, b; Goodwin and Burroughs 1995; Casteels et al. 1995; Leach et al. 1996; Gibson et al. 1996). Scores for sensory characteristics, such as tenderness and juiciness of cooked pork, and for retail appearance were also found to be intermediate for heterozygotes but closer to normal than to PSS gene homozygotes (Goodwin 1994a, b; Goodwin and Burroughs 1995; Casteels et al. 1995; Jeremiah et al. 1996; Monin et al. 1999; Van Oeckel et al. 2001; Moelich et al. 2003). Untrained consumers, however found no differences in tastiness of pork from heterozygous compared to normal swine (Van Oeckel et al. 2001). Sensory traits of cured-cooked ham, in contrast to fresh meat, was unaffected by heterozygosity for the PSS gene (Fernandez et al. 2002 a, b).

As for beneficial live-performance and carcass traits, the effect of the heterozygous gene on pork quality varied substantially according to breed and strain. All strains were affected at least partially, with Berkshire less affected than other swine, Hampshires more affected than other swine, and Yorkshires more affected than Landrace (O'Brien et al. 1994; Goodwin and Burroughs 1995; Gibson et al. 1996).

Abnormal physiological and biochemical responsiveness of skeletal muscle to stimulation is also inherited in a dominant fashion. Dose-response relationships for heterozygotes are intermediate between those of the homozygotes and those of normal swine for agonist-induced calcium release from isolated calcium-release channels, caffeine-induced contracture of isolated skeletal muscle, and high-energy phosphate depletion and acid production of muscle biopsy specimens (O'Brien 1986a, 1987; Lundström et al. 1989; Fujii et al. 1991; Shen et al. 1992; Geers et al. 1992).

DIAGNOSIS

Visual Appraisal
Visual appraisal by an experienced swine handler may be 40–80% accurate in identification of homozygotes for the PSS gene. The homozygote can frequently be identified by its shorter body, bulging oval hams, thin layer of body fat, and rapid tail tremor when excited.

Necropsy
Postmortem findings after fatal PSS are nonspecific. There may be lesions of acute heart failure, including pulmonary congestion and edema with froth in trachea and bronchi, hepatic congestion, and hydrothorax. In a fresh carcass, rapid onset of rigor mortis and dark blood, due to oxygen desaturation, may be observed. The muscle is pale or gray, watery, and soft-textured with a sour smell (Ludvigsen 1953). Histopathologic examination of muscle frequently reveals hypercontracted fibers, occasional myofiber degeneration, and separation of fibers by edema, especially in longissimus dorsi and semitendinosus muscles (Ludvigsen 1953; Henry et al. 1955; Lawrie 1960). Cardiac muscle may show multifocal myofiber degeneration and fragmentation (O'Brien et al. 1987).

Halothane Challenge Test
In the typical halothane challenge test, 2- to 3-month-old swine are physically restrained and forced to inhale 3–6% halothane in oxygen (2–5 liters/minute) through a face mask for 3–5 minutes or until the development of extensor muscle rigidity (Webb and Jordan 1979; Webb 1981). Those developing rigidity are considered to have a positive response. Rigidity in responders typically starts after 1–3 minutes of exposure (Reik et al. 1983; McGrath et al. 1984; O'Brien et al. 1985b). Halothane exposures of less than 3% for 4 or 5 minutes may cause false-negative responses, whereas exposures of 4% or more only slightly increase frequency of reaction and decrease time of onset but may increase mortality (Webb and Jordan 1979; McGrath et al. 1984). The potency of inhalant anesthetic used is also critical to obtaining an accurate test result, with potency decreasing

in the order halothane, isoflurane, enflurane, desflurane, and methoxyflurane (McGrath et al. 1981b; Wedel et al. 1993).

Sensitivity to halothane is increased by prior exertional (Van den Hende et al. 1976), thermal (Ørding et al. 1985), or pharmacologic stimulation of muscle by caffeine, succinylcholine, and α-adrenergic and serotoninergic agents (Hall et al. 1977b; Chapin et al. 1981; Seeler et al. 1984; Löscher et al. 1990). Halothane sensitivity can be reduced, but not prevented, by poor body condition or muscularity (Mabry et al. 1981), prior tranquillization (Ahern et al. 1977; McGrath et al. 1981a), administration of nondepolarizing muscle relaxants (Gronert and Milde 1981) or magnesium (Flewellen and Nelson 1980), and epidural blockade (Kerr et al. 1975; Gronert et al. 1977; Gronert 1980). However, the reaction can be prevented by administration of dantrolene (Harrison 1975; Gronert and Milde 1976; Hall et al. 1977a) or its analog azumolene (Dershwitz and Sreter 1990).

Responsiveness in the halothane test is also affected by the age of the pig. Pigs homozygous for the PSS gene but less than 8 weeks old had positive tests less frequently, with only 50% of the pigs reacting at age 3 weeks and 75% reacting at 5 weeks (Webb 1981; Carden and Webb 1984). Although the younger pigs did not always develop muscle rigidity, they did develop a nonrigid form of malignant hyperthermia, with increased body temperature and metabolic and respiratory acidosis (Fay and Gallant 1990).

Mortality, occurring within 24 hours of a positive reaction, is an important disadvantage of the halothane test. Rates of mortality among reactors in the halothane test are variable and apparently breed and strain dependent: 0.5% of approximately 360 Dutch Landrace reactors (Eikelenboom et al. 1978) to 9% of 229 Pietrain-Hampshire reactors (Webb and Jordan 1979) and 9% of French and Belgium strains of Pietrain and Landrace (Ollivier et al. 1976). Mortality rates are substantially increased if a more severe challenge is given, such as by prolonging anesthesia or additionally using succinylcholine (Williams and Lasley 1977; Britt et al. 1978; Seeler et al. 1984; Webb et al. 1986). In one Minnesota study of swine of Pietrain or Yorkshire parentage, mortality over an 18-month period averaged 10% of 200 reactors but varied from 4% to 40%, with Pietrain swine dying more often and in hot, humid weather (O'Brien et al. 1985b).

Although the standard halothane challenge test identifies only homozygotes for the PSS gene, used in combination with either progeny testing or bloodtyping it has been highly effective at identification of heterozygous swine. However, such time-consuming, labor-intensive tests have been largely replaced with the more accurate and precise DNA-based test, which can be used to identify the PSS genotype in the absence of any pedigree information or ancillary tests.

Serum Enzymes

Early studies of PSS/PSE pork demonstrated that susceptible swine had two- to tenfold greater than normal activities of muscle enzymes in the blood, especially 10–20 hours following stress. These enzymes included the skeletal muscle isozymes of lactate dehydrogenase and creatine kinase (CK), aldolase, aspartate transaminase, malate dehydrogenase, and pyruvate kinase (Hessel-De Heer 1969; Allen et al. 1970b; Woolf et al. 1970; Bickhardt 1971; Duthie and Arthur 1987). Various "CK-tests" for PSS-susceptible swine were subsequently developed, based on measurement of plasma CK activity after a standardized exercise or thermal or pharmacologic stress (Bickhardt et al. 1977; Hwang et al. 1978; Hallberg et al. 1979). Although blood CK activity gained widespread use in screening for PSS susceptibility, its variability and relatively small difference from normal make it inaccurate. Blood CK activity is increased by numerous other factors, including rapid growth phase, increased muscle mass, mild physical injury occurring during routine handling, unaccustomed exertion, and even intramuscular injections (Mitchell and Heffron 1975; Allen et al. 1976). The test was found to be unreliable, especially when the frequency of susceptible swine was low or for identification of heterozygotes (O'Brien et al. 1985b; McDonell et al. 1986).

Clinical Chemistry

Clinical chemistry changes associated with PSS reflect the increased metabolic rate of skeletal muscle (Berman et al. 1970; Gronert and Theye 1976; Hall et al. 1982; Löscher et al. 1994). In a fulminating syndrome, there are marked increases in serum concentration of side-products of metabolism, including phosphate by 3-fold, lactic acid by 25-fold, venous carbon dioxide by 2-fold, potassium by 2- to 3-fold, glucose (from glycogenolysis) by 3-fold, adenosine (vasodilator) by 5-fold, glycerol (from muscle lipolysis) by 2-fold, magnesium by 2-fold, and body temperature by 4–6°C. Blood pH may decrease to 6.6. Because aerobic metabolism is stimulated in addition to anaerobic metabolism, oxygen uptake by muscle is increased 2- to 3-fold and venous blood is two-thirds desaturated of oxygen. Release of potassium and glucose due to glycogenolysis occurs from liver as well as muscle (Hall et al. 1980b). As metabolic end-products accumulate within the muscle cell, its osmotic activity is increased. The resulting influx of water from the extracellular space produces a 30% hemoconcentration (Berman et al. 1970; Frøystein et al. 1984). Due to muscle membrane injury, there may be 20-fold increased leakage of CK into blood. Up to 80-fold increases in epinephrine and norepinephrine develop in association with the endocrine response.

Blood-Typing

Inheritance of PSS susceptibility can be traced through family lines with almost 90% accuracy by haplotype

analysis of marker loci linked to the PSS gene, in conjunction with the halothane test (Gahne and Juneja 1985; Vögeli et al. 1985). This method was used extensively in Europe in national breeding selection programs. The locus for the halothane sensitivity gene (*Hal* or *ryr-1*) is closely linked to genes for the H blood group system (H; Rasmussen and Christian 1976), suppressing effect on the A-O blood group system (S; Rasmussen et al. 1980), erythrocyte phosphohexose isomerase (Phi; Jorgensen et al. 1976) and 6-phosphogluconate dehydrogenase (6-Pgd; Jorgensen et al. 1976), and serum postalbumin (Po-2; Juneja et al. 1983), which are close to the centromere of chromosome 6 (Davies et al. 1988; Harbitz et al. 1990). However, this accuracy is too low for reliable application of the test to an individual, requires knowledge of the genotypes of the parents, and is substantially more labor intensive and less cost effective than the DNA test. It has poor accuracy when the frequency of halothane responders is low. Furthermore, it requires the halothane challenge test, which may be inaccurate and fatal. Thus, use of blood-typing for diagnosis of PSS susceptibility has been largely replaced by the DNA test.

DNA Testing

Identification of the defective protein responsible for PSS (O'Brien et al. 1985a; O'Brien 1986a, 1987), studies of the molecular biology of this protein in the rabbit by muscle biologists (Takeshima et al. 1989; Marks et al. 1989; Zorzato et al. 1990), and its recognition as a candidate for predisposition to the human form of PSS (McCarthy et al. 1990; MacLennan et al. 1990) precipitated the sequencing of the PSS gene (O'Brien et al. 1990a). Identification of the precise mutation site (Fujii et al. 1991) for PSS defined a now-patented, DNA-based test (MacLennan and O'Brien 1992), which allowed, for the first time, the specific, unequivocal, and direct diagnosis of PSS susceptibility on a wide, cost-effective scale for the eradication or control of PSS (O'Brien et al. 1993).

In this definitive test for PSS susceptibility, DNA is isolated from a small amount of tissue, usually blood collected into a sterile heparinized tube or dropped onto absorbent paper, although hair roots or muscle and adipose tissue have been used. The sequence immediately surrounding the mutation site is copied approximately one million times via the polymerase chain reaction. This amplified DNA is then subjected to restriction fragment length polymorphism (RFLP) analysis, in which it is cut at two sites by a restriction endonuclease enzyme: the mutation site and a site common to both mutated and nonmutated DNA. The number and size of the resulting fragments are determined via agarose gel electrophoresis and a fluorescent stain. The staining pattern unambiguously identifies the PSS genotype (O'Brien et al. 1993).

A patent has been issued in several countries (MacLennan and O'Brien 1992) for the detection of the PSS mutation, and a trademark has been registered for the classification of the PSS genotype of tested animals or their progeny. The trademark is based on the (former) name for the gene locus of the PSS mutation (*Hal*), on the nucleotide number identifying the site of the single-point mutation (1843), and on additional descriptors that indicate whether the animal is unaffected by the PSS mutation (Hal-1843 nm [nonmutant]), heterozygous for the mutation (Hal-1843 mm [monomutant]), or homozygous for the mutation (Hal-1843 dm [dimutant]).

TREATMENT, PREVENTION, AND CONTROL

In addition to use of the muscle relaxant dantrolene (Harrison 1975) or its analog azumolene (Dershwitz and Sreter 1990), symptomatic treatment of acidosis, hyperthermia, hyperkalemia, hypoxia, and cardiac arrhythmia is necessary (Gronert and Milde 1976). Cooling and intravenous administration of bicarbonate have been effective components of treatment.

Several factors must be considered in developing an optimum strategy for use of the PSS mutation. Whereas it is clear that swine homozygous for the PSS mutation have too high a risk of developing PSS and severe PSE pork to make them economically viable as slaughter pigs, heterozygous swine may offer significant economic advantage under certain conditions. The occurrence of PSE pork in heterozygous swine is not a major deterrent if there is no demerit for pork quality or if swine/carcass management practices are optimized so as to substantially reduce PSE pork in normal and heterozygous swine. Since technology is presently unavailable for rapid online determination of pork quality and for discrimination between genetic and management causes of PSE, producers cannot be penalized for inferior pork quality. In contrast, producers may be paid premiums for decreased backfat, or increased lean yields, which are conferred by the PSS gene. Premiums on lean yield, which may be increased up to several percent in heterozygous swine, significantly increase producer profits because of the narrow profit margins in the swine industry.

Although the producer is not penalized for PSE pork, its occurrence is economically important to the swine industry. Abnormal shrinkage, rerouting to sausage and other less valuable products, and decreased consumer acceptance reduce the value of ham and loin yield by approximately 5%, or $5 per pig ($2 per pound for 50 pounds of ham and loin) (Hall 1972; Kauffman et al. 1978; Brown 1981; Holland 1981; Smith and Lesser 1982). Assuming a PSE pork incidence of 16% (Kauffman et al. 1993) and 90 million pigs slaughtered, PSE pork causes an annual loss of $70 million. Annual losses in each of the U.K. and Australia for the late 1980s were estimated at $20 million (Cassell et al. 1991; Guise 1987). However, less than one-third of heterozygotes usually

produce PSE pork (Jensen and Barton-Gade 1985; Lundström et al. 1989), and even when the PSE pork prevalence is high, heterozygotes have produced less than one-third of it, with most of the remainder arising due to effects of management practices on normal swine (Pommier et al. 1992). In comparison, the economic gain from the PSS gene is a 2–6% increase in ham and loin yield, or $2–$6 per pig, depending on breed and strain. Assuming that one-third of heterozygotes develop PSE, the net economic benefit of the PSS gene to the swine and pork industries ranges from approximately $0.3–$4.3 per pig, although benefit to the swine producer, in the present absence of penalties for PSE, is $2–$6 per pig (Pommier et al. 1992; De Smet et al. 1993; O'Brien et al. 1994; McPhee et al. 1994; Goodwin 1994a, b; Goodwin and Burroughs 1995; Gibson et al. 1996).

Accordingly, it may be more advantageous to reduce PSE pork by optimizing management practices than by eradication of the PSS gene and its associated economic benefits. The combination of preslaughter feed restriction to reduce muscle glycogen, reduction of other pre- and perimortem stressors, and rapid chilling of carcasses may dramatically reduce the incidence of PSE pork to an acceptable level in swine with or without the PSS mutation (Borchert and Briskey 1964; Topel 1981b; Grandin 1986, 1996; Tarrant 1993). Short-term dietary supplementation with magnesium oxide may also reduce incidence and severity of PSE (Sair et al. 1970; Ludvigsen 1985; Lahucky et al. 2004), although a study of supplementation with magnesium aspartate (Caine et al. 2000) indicated the effects of magnesium on pork yield and quality were dependent upon diet and genotype. If PSE pork was controlled by such management practices, the prevalence and profit of PSS gene heterozygotes could be increased substantially.

Occurrence of the PSS gene is highly controlled and used to economic advantage in several countries on a wide scale, including Belgium, Germany, Austria, and Norway (Porter 1993; Knap 1996; Burlot and Naveau 2003). An effective strategy for using the PSS gene is to limit it to the sire line to boost performance and carcass quality in the slaughter generation. This strategy requires knowledge of the PSS genotype of replacement breeding stock and payment for testing or royalty costs of the patented testing procedure. However, this should be cost effective given that a breeding boar may produce thousands of slaughter offspring, with each having up to several dollars of added value.

Alternatively to maintaining and controlling the expression of the PSS mutation, it could be eradicated from herds. With the current high prevalence of PSE pork from nongenetic factors, this may be an advantage to the pork-packing and pork-retailing industries and the consumer, although it may be a disadvantage to the swine producer. However, since nearly three-quarters of the top North American breeding stock is free of the PSS mutation, it is clearly not a prerequisite for good muscu-

larity and leanness. Furthermore, as genetic selection for leanness, growth rate, and feed efficiency has continuously improved performance of normal swine, the magnitude of the beneficial effects of the PSS gene may have diminished. This point is made by recent findings for Pietrain swine, in which breed a polymorphism affecting the insulin-like growth factor 2 gene confers increased lean muscle equivalent to that of the PSS gene (Nezer et al. 1999). In use of Pietrain terminal sires, exclusion of the PSS mutation may maintain high yield of lean muscle but decrease PSE in the progeny (Fabrega et al. 2004).

Attempts at eradication of the PSS mutation have been undertaken in some countries, such as Switzerland (Vögeli et al. 1985) and Finland (Kuosmanen and Puonti 1993), with good success and without long-term deleterious effects on swine carcass quantity and pork quality. In the late 1990s, some countries, such as Denmark, and international breeding companies removed the PSS mutation from their selection lines (Rosenvold and Anersen 2003; PIC 2003). In Denmark, the swine population is largely free of the PSS mutation; the percentage of heterozygotes was only 2% (Aaslyng and Barton Gade, 2001). In Canada, the percentage of heterozygotes in Canadian swine has dropped from approximately 20% in the early 1990s (O'Brien 1995) to 5% in 2003 (Du 2003). Eradication has been promoted by the National Pork Producers Council (NPPC: Miller 1996) and is being implemented by the National Swine Registry (NSR 2004) in the United States. However, Germany, Belgium, and Austria use heavily Pietrain boars homozygous for the PSS gene (Burlot and Naveau 2003) and in France, Pietrain and Pietrain crossed (with Large White) boars are still used in some terminal boar production programs (Burlot and Naveau 2003). Elimination of the PSS gene may cause the loss of an easily accessible, predictable, and cost-effective selection criterion for favorable carcass and live-performance characteristics.

59 Prolapses

W. J. Smith and Barbara E. Straw

The rectum and vagina are held in place by a complex matrix of fascia, collagen fibers, muscles, and ligaments. This support mechanism may become heavily infiltrated with fat in some animals. In theory, rectal prolapse will occur if the support mechanism is either overcome by pressure or is weakened for some reason. Pressure on the support mechanism may be brought about by straining (proctitis, urethritis, constipation, coughing, and farrowing) or by physical pressure (excessive slope on the floor or increase in abdominal pressure for any reason). Brockman et al (2004) produced rectal prolapse in 10 49–74 kg pigs by insufflating the abdominal cavity with water at pressures of 222–343 mmHg (mean 292 mmHg). In humans, lifting from a flexed position causes intraabdominal pressure to increase to 187 mmHg. Weakness of the support mechanism may be brought about by edema (including that due to mycotoxins), fat infiltration, tumor infiltration, certain drugs, and genetic susceptibility. In most animals, and especially growing pigs, rectal and/or vaginal prolapse is almost an all-or-nothing phenomenon, with the early stages rarely being observed. The prolapse in the growing pig usually protrudes about 10–13 cm. This relatively constant degree of prolapse is probably due to anchorage by the short mesorectum and muscles of the pelvic diaphragm (Hindson 1958; S. H. Done, personal communication, 1990). Although the stockperson is usually presented with a complete rectal prolapse, some pigs have a temporary protrusion of a portion of the rectal mucosa on defecation. This phenomenon is also seen during coughing, and one might conjecture that such pigs might be prime candidates for complete rectal prolapse at a later stage.

The comparative anatomy of the pelvic and perineal regions of several species, including the pig, has been studied by Bassett (1971).

INCIDENCE

Most swine production units experience cases of rectal or vaginal prolapse in swine of various ages. Correction of rectal prolapse is the most commonly performed gastrointestinal surgical procedure in swine (Welker and Modransky 1991). Cases are nearly always sporadic in nature, and most often the cause is not determined. However, outbreaks do occur and may occasionally be prolonged. Kjar (1976) noted that the incidence of rectal prolapse was highest in pigs 6–12 weeks of age and concluded that the cause was unknown but that the incidence, which varied from 1–10%, increased during a change from cold to damp weather.

In a study of one finishing herd over 7 years (total throughput: 56,363 pigs), Garden (1988) noted that the incidence varied from 0.7%–4.7% on an annual basis. In another study in one herd over 6 months, Gardner et al. (1988) noted that 30 (1%) of 2862 pigs of 12–28 weeks of age suffered from rectal prolapse, with a peak incidence between 14 and 16 weeks of age. Becker and Van der Leek (1988) noted an estimated 10–15% prevalence of rectal prolapse over a 12-month period in pigs of 2–4 months of age in a herd of 125 sows (farrow to finish). Perfumo et al (2002) found that rectal prolapse was responsible for 7.7% of deaths that occurred in pigs from weaning to market. In a herd with 8.62% annual emergency-culling mortality, Baumann and Bilkei (2002) found that rectal stricture and rectal prolapse were responsible for 7.5% and 5.9% of the deaths.

Smith has noted (unpublished data) that rectal prolapse was most common in pigs 3–5 months of age; the incidence in three herds of 1000, 600, and 120 sows (all in confinement) was 0.7%, 0.9%, and 0.6%, respectively. The affected pigs ranged from 45 to 180 days of age and from 10–90 kg in weight. Swine were not observed to be ill before prolapse occurred, and the only common factor was mild constipation. Straining was not observed in any of these pigs before prolapse of the rectum occurred, but this clinical sign may have been missed due to the intensity of confinement.

Daniel (1975) noted that rectal prolapse in sows could occur in all sizes of units and that the incidence varied from 0.5%–1%. Two-thirds of the cases occurred

965

around the time of parturition. Although prolapse of the rectum and vagina and/or cervix was not mentioned as a specific reason for culling sows from U.K. pig herds (Anonymous 1964), Jones (1967) reported an 8.9% frequency of culling for rectal prolapse in one herd. In Australia 7.1% of sows culled in a 2500-sow unit were cases of rectal or vaginal prolapse (Penny 1972).

Schulz and Bostedt (1995) noted that vaginal prolapse affected 33 of 523 farrowing sows and was a significant cause of dystocia. Information regarding the incidence of vaginal and uterine prolapse is sparse, apart from outbreaks of vulvovaginitis associated with mycotoxins, when vaginal prolapses can occur in 30% of affected females (McNutt et al. 1928).

CAUSES AND PREDISPOSING FACTORS

Inflammation

Vaginal prolapse is very rare in suckling swine. However, rectal prolapse is sometimes associated with enterocolitis caused by viral, bacterial, parasitic, or mycotic infection (Pfeifer 1984; Straw 1987). In cases where the inflammation is severe and irritation of the rectum occurs, tenesmus results and rectal prolapse may be a sequel. Outbreaks of prolapse have been seen in association with swine fever, although fewer than 0.1% of piglets with diarrhea will suffer from rectal prolapse. Although many outbreaks of colitis, both infectious and noninfectious, have been observed in Scotland, rectal prolapse was not noted as a sequel. In older swine, urethritis and vaginitis from any cause may lead to straining, which may in turn lead to prolapse of the rectum or vagina or both.

Nutritional Factors

P. L. Shanks (personal communication, 1955) observed an outbreak of rectal prolapse in a group of pigs that had been fed waste food material from the floor of a feed mill. He concluded that unusual constituents in the diet led to straining, with resultant prolapse. Morbidity was approximately 30%. More recently, E. N. Wood (personal communication, 1979) described an outbreak of rectal prolapse in early weaned pigs between 2 and 6 weeks of age. Thirty-one of 235 piglets (13.2%) died during the outbreak and all were males. Subsequent investigation revealed the cause of death to be uremia from blockage of the urethra with calculi—a sequel to an unusually high level (2.25%) of calcium in the diet. Partial or complete obstruction of the urethra had caused excessive straining and subsequent prolapse of the rectum. During the outbreak, the piglets fed for short periods only, making frequent visits to the automatic drinker. The food consisted of a mixture of denatured skim milk, dried whey, fish meal, and soya meal.

Sudden changes in the diet (e.g., from meal to whey) may lead to occasional cases of rectal prolapse. Chronic shortage of water will lead to constipation with rectal

prolapse as a sequel. Diets that are low in fiber (e.g., those without bran or wheat feed) may also lead to constipation. Constipation produced by this means may also be aggravated by lack of exercise (e.g., sows confined in farrowing crates or dry sow stalls). A higher incidence of rectal prolapse is therefore to be expected in confinement, although the daily feeding of a little straw may help prevent the condition.

In a 250-sow, breeding-to-finishing unit, the author found the number of rectal prolapses in the growing pigs decreased from five to one a week when the barley in the ration was replaced by a variety with a higher fiber content. Reintroduction of the lower-fiber barley and its removal repeatedly worsened or improved the situation, respectively.

In a 300-sow, breeding-to-finishing unit, 15 kg weaners were randomly divided and placed into strawed kennels or second-stage flat decks, both units being contained in the same large general-purpose building. The pigs were fed the same ration and the stocking density in both types of housing was almost identical. Prolapse of the rectum was a chronic problem only in the pigs in the strawed kennels. When the barley straw was replaced with wheat straw from a neighboring farm, the prolapse problem disappeared during the time the wheat straw was used. As soon as the barley straw was reintroduced (three times), the prolapse problem reappeared (Anonymous 1985). It was later postulated that the barley straw might have contained mycotoxins.

Prolapse of the rectum and vagina was a chronic problem in a 400-sow herd in Spain. The sows were housed in level, partly slatted stalls and fed brewers' grains as part of the ration. The grains were kept in an outside pit, which held enough to last about 3 weeks. Prolapses increased toward the end of the 3-week period, by which time the contents were heavily contaminated with fungi. No mycotoxin assays were carried out (E. Marco, personal communication, 1990).

Sudden outbreaks of rectal and vaginal prolapse were noted by the author in pigs over 30 kg every time whey feeding was reintroduced after a few days of absence. The pigs in this 2000-sow herd were normally fed a mixture of meal and whey without access to water. When whey was unavailable (e.g., Christmas holidays), the pigs were fed meal and water, which they did not like and intake dropped markedly. As soon as whey was reintroduced (on a restricted basis), the hungry pigs gorged themselves and the incidence of prolapse rapidly rose to about 1.5% for a short period. Deaths due to torsion also rose.

Muirhead (1989) investigated a chronic problem of rectal prolapse in finishing pigs. The incidence varied from 4–6% at 12–18 weeks of age. Reducing the density of the diet reduced the incidence of prolapse to less than 1%, but this measure also reduced growth rate significantly. In this particular herd most of the prolapses occurred within 1–2 hours of the lights being switched on

at 7 a.m.; this observation might be of some significance. Amass et al. (1995) noted that an experimental ration containing a high lysine level was 6.73 times more likely to cause rectal prolapse than a controlled diet. Casper et al. (1991) noted rectal prolapses in sows as a sequel to lupin bean meal toxicosis.

It has to be admitted that many outbreaks of rectal prolapse respond to a change in diet, but the reason for this response is rarely found.

Physical Factors

Injury to the rectum or urethra from service by the boar may also lead to tenesmus and prolapse. In addition, gradual weakening of the pelvic diaphragm may arise as sows age or during pregnancy as the abdominal contents become heaviest. Rupture of one or more of the supporting structures may then occur, with prolapse of either rectum or vagina or both as a sequel.

Outbreaks have been observed when sows are confined in stalls or in tethers with an excessive slope to the floor. When the fall is greater than 1 in 20, increased intraabdominal pressure may overcome the resistance of one or more structures of the pelvic diaphragm, especially as the abdominal contents increase in weight as pregnancy progresses (S. M. Richmond, personal communication, 1979). An outbreak of rectal and vaginal prolapse was also observed in a herd where the dry sows were tethered in stalls with solid floods that were shorter than usual and there was a 13 cm drop from the solid lying area to the dunging passage; the rear end of the sows hung over the dunging passage. Partial or complete rectal or vaginal prolapse was seen in 14%. Sometimes the rectum prolapsed, sometimes the vagina, and in a few cases both. When the sows were recumbent, the first clinical sign was an outward bulging of the vaginal mucous membrane (partial prolapse). In the standing position the prolapse usually disappeared, but as pregnancy progressed and the uterine load increased, the prolapse became more evident when the sow was lying down. Eventually, bacterial contamination occurred, inflammation gradually became more severe, and the partial prolapse became complete. Complete prolapse was prevented by removal of affected animals to a spacious pen with a level, solid floor.

Physical damage to the vaginal tract may also occur during parturition, either by natural means or by human interference. This may damage some of the structures of the pelvic diaphragm or may lead to inflammation, which will cause excessive straining. In either case, vaginal prolapse may result.

Le Bret (1980) noted that sows in five herds from the same origin were most likely to suffer from rectal prolapse at farrowing. These sows were characterized by a particular pelvic conformation shown by measuring different pelvic angles. The larger the angle between the coccygeal vertebrae and the pelvis, the higher the risk of rectal prolapse.

Guise and Penny (1990) noted that rectal prolapses occurred when pigs were transported at high stocking density; no prolapses were noted in the low-stocking-density treatment groups. These authors also reported that haulers had observed prolapses occurring as pigs struggled up steep ramps. V. R. Fowler (personal communication, 1980) noted a high incidence of rectal prolapse in weaner pigs shortly after being tethered in metabolism cages. These cases may have been a sequel to increased abdominal pressure during episodes of struggling.

Drugs

The repeated use of estrogens or any estrogenic substance to stimulate estrus in sows or gilts may lead to excessive swelling of the vulva, with vulvovaginitis and prolapse as sequels. Rectal prolapse has been described in growing pigs fed therapeutic levels of tylosin in the diet. It is not known why this occurs (J. D. Mackinnon, personal communication, 1979), but A. Hogg has suggested (personal communication, 1979) that tylosin may alter the normal bacterial flora of the gut, with overgrowth of fungi such as *Monilia* spp. as a sequel. Moniliasis may cause proctitis and straining, leading to prolapse. Smith has noted (unpublished data) that when Tylasul (tylosin/sulfadimidine) was added to the diet (5 kg/ton) of 10 experimental feeder pigs, 3 suffered from rectal prolapse within 10 days. It was noticeable that the pigs in this group seemed to suffer from a form of anal irritation, manifested as frequent episodes of rapid tail shaking.

Rectal prolapse due to edema has been noted when pigs were medicated with lincomycin. This reaction is frequently observed when swine are first placed on the drug, but clinical signs usually subside within 72 hours (Kunesh 1981).

Genetic Factors

A. Hogg (personal communication, 1979) reported a severe problem characterized by vaginal and uterine prolapse in a large breeding herd in the United States; uterine prolapse occurred both before and after farrowing. Apparently inbreeding had emphasized a recessive genetic factor.

In a commercial swine herd in California, pigs sired by Yorkshire boars were 3.3 times more likely to suffer from rectal prolapse; one Yorkshire boar in particular was 9.4 times more likely to sire affected pigs. In the same herd, sows of low parity (1, 2, and 3) were likely to farrow pigs more susceptible to rectal prolapse, but it was not possible to determine if this was a genetic effect (Gardner et al. 1988). In their studies, Hindson (1958) and Saunders (1974) concluded that hereditary factors were involved. Becker and Van der Leek (1988) concluded that genetic factors were strongly implicated in an outbreak of rectal prolapse in a commercial 125-sow, farrow-to-finish herd.

Environmental Factors

It is generally agreed that rectal prolapse occurs more commonly during winter months; and there is some evidence to support this (Kjar 1976; Wilson 1984; Gardner et al. 1988; Prange et al. 1987). However, in one study over 7 years in a finishing herd (throughput: 56,363 pigs; average incidence: 2.9%), Garden (1988) found no evidence of seasonal effect. It has been suggested that cold weather causes pigs to pile, thus increasing the likelihood of prolapses; no objective data have been produced to support this hypothesis.

Muirhead (1989) reported a problem of rectal prolapse in recently weaned pigs on flat decks. The problem resolved when the climatic environment was improved, particularly temperature and ventilation. Perramón and Muirhead (1998) reported similar findings in another herd in which rectal prolapses were associated only in the winter with a specific building housing 30–60 kg pigs.

Mycotoxicosis

Rectal and/or vaginal prolapse is a common sequel to vulvovaginitis caused by mycotoxicosis (see Chapter 56 for further details).

Other Factors

In a study in one commercial herd, Gardner et al. (1988) noted that male pigs were more likely to suffer from rectal prolapse than females. However, in a study of one herd over a much longer period and with a higher incidence of prolapse, Garden (1988) could find no evidence of a sex effect. In another, very small experimental study, Smith (1980) observed that 6 (32%) of 19 randomly acquired pigs with rectal prolapse were males. On the other hand, Perramón and Muirhead (1998) found 73% of prolapses in females.

Gardner et al. (1988) noted that pigs of low birth weight (less than 1000 g) were more likely to suffer from rectal prolapse later in life. It was hypothesized that low-birth-weight pigs that have fewer muscle fibers at birth have an inherently weaker rectal support mechanism, which may fail when a period of rapid growth occurs. Muirhead (1989) noted that a behavioral aberration, anal nuzzling, in recently weaned pigs led to a rectal prolapse problem (4–6% incidence). Improvement to the climatic environment prevented further cases from arising. An outbreak of anal nuzzling was reported by van Sambraus (1979).

When pigs cough, the rectal mucosa often protrudes temporarily. As with piling, it has been suggested that coughing may precipitate rectal prolapse, but again there are no objective data to support this hypothesis. Indeed, Gardner et al. (1988) could find no relationship between coughing and the prevalence of rectal prolapse. In another study, the prevalence of rectal prolapse was dramatically reduced from 4.7% to 0.7% when weaners (30–35 kg) were placed in a strawed yard for 3 weeks be-

tween being held in the second-stage flat decks and the fully slatted finishing accommodation (Garden 1985).

Diarrhea is not a common precursor of rectal prolapse, and in one herd studied by Gardner et al. (1988) an outbreak of transmissible gastroenteritis did not increase the prevalence.

Henry (1983) suggested that lack of anal sphincter control due to infection or trauma of pelvic nerve centers such as might occur after docking (especially short docking) or tail biting could lead to rectal prolapse.

Jennings (1984) noted that a significant number of sows with hypocalcemia suffered from uterine prolapse.

In a survey of sow mortality, Chagnon et al. (1990) noted that uterine prolapse was the cause of death of 6.6% of sows. The average parity was 6.0, and it is possible that some weakness of the support mechanism may have been the main determinant (see Chapter 63).

RECTAL STRICTURES

In the United States, rectal strictures were first reported in Illinois (Gibbons 1967); later outbreaks were observed in Indiana (Lillie et al. 1973) and those authors reported more cases during the coldest months, although in Argentina, the incidence was 10% in the summer months for all-age pigs and in September and December for nursery and grower pigs, respectively (Perfumo et al 2002). Outbreaks have also been noted in the United Kingdom (D. G. Taylor, personal communication 1988). Rectal stricture is considered to be a sequel to rectal prolapse (Saunders 1974; Van der Gaag and Meijer 1974; Häni and Scholl 1976; Von Muller et al. 1980; Prange et al. 1987; Becker and Van der Leek 1988; Jensen 1989). Perfumo et al (2002) reported a mean age for rectal prolapse of 115.8 ± 4.2 days, and that for rectal stricture was 164.2 ± 6.1 days.

In a more detailed study of 25 pigs with rectal prolapses that were allowed to heal naturally without treatment, Smith (1980) noted that 3 developed complete rectal stricture and died; the remainder grew normally, but in every case there was evidence of partial rectal stricture at slaughter (Figure 59.1).

Harkin et al. (1982) considered that a strong genetic component was implicated in the etiology of rectal stricture. Lillie et al. (1973) and Perfumo et al. (2002) reported that routine microbiological procedures failed to demonstrate an infectious agent, and Harkin et al. (1982) failed to detect any salmonellae. However, Wilcock and Olander (1977a) noted that many cases of rectal stricture were preceded by severe enteric disease. *Salmonella typhimurium* was frequently isolated, and ulcerative proctitis, a possible precursor of rectal stricture, was also noted. In later studies Wilcock and Olander (1977b) produced rectal strictures experimentally by injecting chlorpromazine into the cranial hemorrhoidal artery and suggested that rectal prolapses may be a sequel to ischemic proctitis induced by thrombosis associated with salmonellosis.

TREATMENT AND CONTROL

Apart from treatment and noting any factors peculiar to each case, it is not considered worthwhile to implement any specific control or preventive measures for sporadic cases of rectal prolapse. If an outbreak occurs, however, attempts should be made to identify the causes and predisposing factors. Whatever conclusion is reached, measures taken must be cost effective; for example, if the lack of exercise in farrowing sows is the main factor, the cost of providing that exercise in confinement may be greater than the cost of the disorder. Treatment should also be cost effective. In the United Kingdom it is now common practice to deal with rectal prolapse in feeder pigs by isolation only. No surgical treatment is carried out, and the prolapse is simply left to resolve naturally in 10–14 days. However, this practice is not good welfare, and a simple nonsurgical amputation technique such as described by Douglas (1985) should be considered. Many surgical procedures for treating rectal prolapses have been described (Hindson 1958; Chalmin 1960; Daniel 1975; Ivascu et al. 1976; Kjar 1976; Vonderfecht 1978; Schon 1985; Moore 1989; Kolden 1994; Grosse-Beilage and Grosse-Beilage 1994).

It should be noted that amputation of the uterus often results in high mortality. Prolapse of the uterus is best treated by surgical replacement; a laparotomy technique, which ensures that each horn of the womb can be properly repositioned, has been successful. Surgical techniques for treating the general prolapse have been described by Toth and Huszenicza (1983). Nonsurgical intervention is greatly assisted by general anesthesia and hoisting the hindquarters of the sow with a block and tackle or similar device.

Treatment of rectal stricture is rarely cost effective, but a surgical technique has been described (Boyd et al. 1988).

60 Toxic Minerals, Chemicals, Plants, and Gases

Thomas L. Carson

Although modern confinement facilities, accurately formulated rations, and improved management practices have reduced some risks of poisoning associated with outdoor swine production, cases of poisoning in swine still occur. The occurrence of swine toxicoses associated with the environment, feed, or management practices is frequent enough to warrant their inclusion in differential diagnostic considerations for swine health problems. The following discussion summarizes the impact of potentially toxic agents to which swine may be exposed.

MINERALS

Trace Minerals

Most swine formula feeds are properly fortified with trace elements. However, some trace minerals are deliberately added in excess for various reasons. They include copper (Cu), selenium (Se), and occasionally iron (Fe) and zinc (Zn). The existence of concentrated premixes of these minerals raises the risk of feed mismixes resulting in the accidental feeding of high, potentially toxic levels of these elements.

Copper. Dietary requirements of 5–6 ppm Cu have been established for swine. A dietary level of 250 ppm is generally considered the maximum tolerable level (MTL) of Cu for swine, and ration levels ranging from 300–500 ppm cause reduced growth and anemia. The tolerance to Cu is related positively to dietary levels of Fe and Zn. For example, animals consuming feed containing 750 ppm Cu are essentially normal if also supplemented with 750 ppm Fe and 500 ppm Zn. Icterus, anemia, hemoglobinuria, and nephritis associated with a hemolytic crisis may be observed in swine, although not as commonly as in sheep. Diagnosis can be suggested by clinical signs and a history of feeding excess Cu. Liver and kidney Cu levels greater than 250 and 60 ppm, respectively, on a wet-weight basis are diagnostically supportive.

Iron. The recommended dietary levels of Fe range from 40–150 ppm, the highest requirements being in the youngest pigs. Many factors influence the risk of Fe toxicosis. Elemental Fe and iron oxides are relatively nontoxic, whereas iron salts are more toxic. Dietary phytate, phosphate, cobalt (Co), Zn, Cu, manganese (Mn), and disaccharides competitively depress Fe absorption. Ascorbic acid, sorbitol, fructose, and several amino acids improve Fe absorption, which is facilitated by being chelated with citric, lactic, pyruvic, and succinic acids; Fe chelated by desferrioxamine is poorly absorbed.

Pigs fed 1100 ppm Fe as a salt have shown reduced weight gains. Animals fed 5000 ppm have displayed depressed feed intake and rates of gain as well as rickets characterized by hypophosphatemia and reduced bone ash. The condition has not been prevented by providing 0.92% dietary phosphorus (P). Injections of Fe, usually as the dextran, have caused intoxications characterized by cardiovascular shock and death within hours after administration as well as staining at injection sites and in regional lymph nodes, liver, and kidneys. The incidence of this acute toxicosis appears to be decreasing. High single doses of iron salts will cause gastroenteritis, followed by apparent recovery and then, frequently, collapse and death within 2 days. Diagnosis may be facilitated by consideration of history, clinical signs, and necropsy changes. Feed and serum should be analyzed for Fe. Normal serum Fe levels are approximately 100 mg/dL and will increase during toxicosis. Iron toxicosis should be differentiated from other forms of rickets. There is no practical individual treatment for Fe toxicosis. Desferrioxamine (Desferal) may be used in selected cases. Dietary imbalances should obviously be corrected.

Selenium. The recommended dietary level of Se varies from 0.1 to 0.3 ppm. Selenium, as the selenate or selenite, is approved for addition to swine feeds at up to 0.3 ppm.

Accidental oversupplementation of swine feeds with selenium premixes has been a sporadic problem. When

Se levels of 5–8 ppm have been fed to growing swine, anorexia, alopecia, separation of hooves at the coronary band, and degenerative changes in the liver and kidney have occurred. Liver changes may look remarkably like those seen with vitamin E–Se deficiency. A level of 10 ppm fed to breeding sows has caused retarded conception and pigs dead or weak at birth. Misformulated feeds containing from 10 to 27 ppm Se produced a paralytic disease in growing swine characterized by quadriplegic or posterior paralysis while the pigs remained mentally alert and continued to eat and drink. Focal symmetrical poliomyelomalacia was found in affected swine (Harrison et el. 1983; Casteel et al. 1985).

Several injectable products containing varying concentrations of Se are currently available for treatment or prevention of Se-responsive diseases. Death losses have approached 100% when Se overdose occurred from the mistaken use of a more concentrated product or from miscalculation of the recommended dosage. The minimum lethal dose of injectable Se is about 0.9 mg/kg body weight, with pigs that are Se deficient being the most susceptible to toxicosis (Van Vleet et al. 1974). Weakness and dyspnea progressing to irregular gasps and death occur within 24 hours of the parenteral overdose.

Diagnosis of Se toxicosis in swine can be made by consideration of a history of Se supplementation, clinical signs, necropsy findings, and chemical analysis of tissues and feeds. Liver and kidney Se concentrations greater than 3 ppm (wet weight) are seen with toxicosis.

Zinc. Recommended dietary levels of Zn for swine vary from 15–100 ppm based on age, sex, stage of production, and other ration components. A level of 2000 ppm Zn produced growth depression, arthritis, intramuscular hemorrhage, gastritis, and enteritis. The MTL is probably less than 300 ppm, possibly because zinc salts in large concentration are unpalatable. Zinc interacts competitively for absorption with Fe, Ca, and Cu. Pigs fed 268 ppm Zn developed arthritis, bone and cartilage deformities, and internal hemorrhages. However, feeding 3,000 ppm Zn as zinc oxide for 14 days has shown increased weight gains and reduction of postweaning scours without adverse signs. Diagnostic considerations should include clinical signs, history, and chemical analyses of feed and tissues. Normal kidney and liver levels of Zn are 25–75 ppm (wet weight) and may increase during toxicosis. However, excretion is quite rapid.

Nonessential Minerals

Arsenic. Inorganic arsenicals, which are distinctly different from the phenylarsonic feed additives discussed later, have been used in antiquated ant baits, herbicides, insecticides, and some animal medications. Pigs are relatively resistant to inorganic arsenic (As) poisoning with 100–200 mg/kg body weight of sodium arsenite being a lethal oral dose. This is equivalent to about 2000–4000 ppm in the feed. However, pigs have refused to consume 1000 ppm in the feed. Clinical signs of acute As poisoning colic, vomiting, diarrhea, dehydration, collapse, convulsions, and death within hours to days. Prominent necropsy findings are dehydration and severe hemorrhagic gastritis and enteritis with sloughing of mucosa and edema. Diagnostic considerations should include history, clinical signs, lesions and chemical analyses. Kidney and liver tissues levels of 10 ppm (wet weight) are significant. Prognosis is generally poor and depends on the degree of tissue damage and dehydration.

Fluorine. Fluorosis may be observed in animals consuming water or forages contaminated by nearby industrial plants or eating crops raised on soils high in fluorine (F). A common source is consumption of minerals high in F. Feed-grade phosphates by law must contain no more than one part F to 100 parts P. It is recommended that swine be fed feeds containing no more than 70 ppm F during their lifetime to prevent fluorosis. Sodium fluoride has been used as an ascaricide at levels of 500 ppm; higher levels have caused vomiting. Other signs of acute toxicosis are diarrhea, lameness, tetany, collapse, and death. A tentative diagnosis of chronic fluorosis may be difficult, since the lameness may appear similar to rickets, mycoplasmosis, and erysipelas. Normal bone F levels in swine are 3000–4000 ppm. Higher levels are associated with fluorosis. Normal urine F levels are 5–15 ppm; higher levels are diagnostically significant. Necropsy findings may reveal exostoses on the long bones and tooth mottling. Treatment should be aimed at reducing dietary F and feeding aluminum or calcium (Ca) mineral supplements.

Lead. Swine are quite resistant to elevated lead (Pb) exposure. Consequently, field cases of lead poisoning in swine are extremely rare. Experimentally, pigs fed 35.2 mg lead (as the acetate)/kg body weight for 90 days did not die from lead poisoning despite blood lead concentrations of up to 290 µg/dL (Lassen and Buck 1979). If toxicosis is suspected, a thorough diagnostic workup including kidney and liver analyses should be performed.

Mercury. Mercury (Hg) has been used in paints, batteries, paper, and fungicides, but most uses have been restricted. All mercurial compounds are toxic, but organic forms are the most toxic to all species. Mercury is cumulative, and toxicity depends on form, dose, and duration. Swine have been poisoned after consuming seeds treated with organic mercurial fungicides. Initially, signs of gastroenteritis may be evident, followed by uremia and central nervous system (CNS) disturbance, including ataxia, blindness, aimless wandering, paresis, coma, and death. Mercury toxicosis may be confused with erysipelas, cholera, or poisoning by pigweed or phenylarsonics. Clinical signs, history, necropsy find-

ings, and chemistry should aid in the diagnosis. Kidney and liver normally contain less than 1 ppm Hg but will contain much higher levels following Hg toxicosis. Treatment is usually disappointing.

FEED ADDITIVES

Adverse effects of drug additives are rare except in cases of misuse or misformulation of rations (Lloyd 1978). Details of specific drug effects have been reviewed recently (Adams 1996).

Phenylarsonic Compounds

The phenylarsonic compounds, occasionally referred to as organic arsenicals, have at times been used as growth promotants and to treat swine dysentery and eperythrozoonosis. Arsanilic acid and roxarsone (3-nitro-4-hydroxyphenylarsonic acid) have been approved for use in swine rations, and their sodium salts have been used in drinking water. Arsanilic acid was approved for continuous use in complete swine rations at levels ranging from 50–100 ppm (45–90 g/ton).

Clinical signs of arsanilic acid toxicosis will start within a few days at levels of 1000 ppm, 2 weeks at 400 ppm, and 3–6 weeks at 250 ppm and include ataxia, posterior paresis, blindness, and quadriplegia. Paralyzed animals will continue to live and grow if provided food and water. Swine that receive lower doses for extended periods are prone to develop goose-stepping (a chronic posterior nerve affliction) and total blindness from optic nerve damage. Swine that receive very large doses, for example, 10,000 ppm in the ration, may exhibit a gastroenteritis resembling poisoning by inorganic arsenic compounds.

Roxarsone is approved for continuous use in swine rations at levels of 25–37 ppm and at 200 ppm for 5–6 days. Poisoning may result with feed roxarsone levels of 250 pp or more for from 3–10 days. Clinical signs include uncontrolled urination and defecation as well as muscle tremor and convulsive seizures, all of which are induced by physical stimulation. Ataxia may be observed, although not as severe as the "drunken sailor" incoordination of arsanilic acid toxicosis. In advanced stages, pigs show paraparesis and paraplegia, but will continue to eat and drink.

Clinical signs and a history of administration of arsenicals in feed or water may be the best basis for suspecting phenylarsonic toxicosis. Necropsy findings are generally nonproductive, but histopathologic examination of peripheral nerves, especially the sciatic, may reveal a demyelination.

Chemical analysis of tissues for the specific phenylarsonic compounds may not be helpful, since the compounds are excreted within a few days after withdrawal. However, analysis of kidney, liver, muscle, and feed for As may assist in the diagnosis. Elemental arsenic levels (wet weight) greater than 2 ppm in kidney and liver and 0.5 ppm in muscle are illegal and indicative of excess As intake. Further analyses of feed for the specific phenylarsonic compound will provide more diagnostic evidence.

Deficiencies of B-complex vitamins, especially pantothenic acid and pyridoxine, may cause a similar demyelination of peripheral nerves. Chronic phenylarsonic toxicosis may also resemble rickets. Although water deprivation, organic mercurial poisoning, and viral diseases affect the CNS primarily, they may be confused with phenylarsonic compound toxicosis. Toxicoses are reversible if arsenicals are promptly removed from the feed and water.

Carbadox

Carbadox (Mecadox, Pfizer) is incorporated in feed at 11–27.5 ppm as a growth promotant or at 55 ppm to control swine dysentery or enteritis. A feed level of 100 ppm has caused decreased feed consumption and growth retardation. Higher levels have caused feed refusal and emesis. Mild lesions in the glomerular zone of the adrenal cortex are reported with 50 ppm carbadox in the feed for 10 weeks, while more extensive lesions are seen at feed levels of 100–150 ppm after 5 weeks of consumption (Van der Molen 1988).

When fed a ration containing from 331 to 363 ppm carbadox, recently weaned pigs refused to eat and showed poor weight gains, posterior paresis, the passing of hard, pelleted feces, and death in 7–9 days (Power et al. 1989).

Dimetridazole

Dimetridazole is listed as an antihistomoniasis drug used in turkey rations and for treatment and prevention of swine dysentery in some countries. A level of 1500 ppm has caused no toxicosis, but 17,000 ppm have caused diarrhea in swine. Large overdoses of dimetridazole would cause ataxia, bradycardia, dyspnea, salivation, muscle spasms, prostration, and death. Death or recovery would be rapid.

Monensin

Monensin is marketed as Rumensin for cattle supplements or as Coban, a poultry coccidiostat. Use levels are up to 120 ppm for poultry and 30 ppm in cattle feeds, although some premixes may contain up to 1320 ppm. Swine may be fed monensin by mistake, but the drug is not highly toxic to them. Pigs fed levels ranging from 11 to 120 ppm in the feed for 112 days were not affected as far as feed consumption and weight gains were concerned. Gilts fed 110–880 ppm had a transient anorexia for 14 days; thereafter, only weight gains were depressed. The LD50 of monensin in swine is 16.8 mg/kg. Pigs suffering from monensin toxicosis showed open-mouth breathing, frothing around the mouth, ataxia, lethargy, muscle weakness, and diarrhea. These signs were visible within 1 day of exposure and persisted for about 3 days. Myocardial and skeletal muscle necrosis was present in

pigs receiving 40 mg monensin/kg (Van Vleet et al. 1983).

The greatest risk of poisoning from monensin in swine appears to be with the concurrent administration of tiamulin, an antibiotic approved for use in treatment of swine dysentery that potentiates the effect of monensin (Van Vleet et al. 1987). Swine poisoned from this combination show acute massive necrotizing myositis of the skeletal muscles, myoglobinuria, and acute death.

Lasalocid

Lasalocid is a polyether antibiotic marketed as Bovatec for feedlot cattle to improve feed efficiency and weight gains. Swine fed lasalocid at 2.78 mg/kg and 21 mg/kg showed no adverse effects. However, transient muscle weakness occurred at a dose of 35 mg/kg (equivalent to about 1000 ppm of lasalocid in the feed), and death occurred at 58 mg/kg when fed for 1 day.

Sulfonamides

The sulfonamide drugs are antibacterials commonly used in swine medicine. Overdoses will cause crystalluric nephroses. Pigs are not likely to be intoxicated from drinking water containing sulfonamides because of the lack of palatability, but overdosing in the feed, coupled with low water intake, may cause nephrosis and uremia. Nephrotoxic mycotoxicoses such as those caused by citrinin and ochratoxin will predispose sulfonamide toxicoses. Sulfonamide residues in pork are related to persistence of the drugs in feed and excreta and are not a toxicosis.

Urea and Ammonium Salts

Swine may be fed cattle feeds containing nonprotein nitrogen compounds such as urea and ammonium salts. Urea is relatively nontoxic for swine, a level of 2.5% causing only reduced feed intake and growth rate, elevated blood urea nitrogen (BUN), polydypsia, and polyuria. Higher levels of urea should not cause signs of acute toxicosis. Ammonia and ammonium salts are toxic for swine, however, with individual doses of 0.25–0.5 g/kg body weight causing intoxication and doses of 0.54–1.5 g/kg being lethal. Considering that growing swine consume feed equal to 5–10% of their body weights, the expected toxic and lethal levels of ammonium salts are 0.25–1% and 1.5–3%, respectively. Pigs poisoned with ammonia and ammonium salts would be expected to become depressed, have tonoclonic convulsions, and either die or recover within a few hours.

PESTICIDES

Insecticides

Concurrent production of both livestock and crops on the same premises may provide a unique opportunity for exposure of swine to agricultural chemicals. Among the chemicals presenting the greatest potential hazard of poisoning are the organophosphorus (OP), carbamate, and the older chlorinated hydrocarbon insecticides.

Poisoning may occur when insecticides are accidentally incorporated into swine feed. Discarded or unlabeled portions of granular insecticides can be mistaken for mineral mixes or dry feed ingredients and added to swine feeds. When farm equipment used for feed handling is also used for insecticide transportation, contamination of this equipment may result in insecticides being inadvertently mixed into animal feeds. In addition, swine may have accidental access to insecticides when they are stored or spilled on the farm premises. Improperly operating back rubbers and oilers may provide an additional source of these insecticides for livestock.

Miscalculation of insecticide concentrations in spraying, dipping, and pour-on procedures may also result in toxicosis. Re-treating animals with OP or carbamate preparations within a few days' time may result in poisoning.

Organophosphorus and Carbamate Insecticides. The OP and carbamate insecticides are discussed together because of their similar mechanisms of action.

Cholinergic nerves utilize acetylcholine as a neurotransmitter substance. Under normal conditions, acetylcholine released at the synapses of parasympathetic nerves and myoneural junctions is quickly hydrolyzed by cholinesterase enzymes. When the hydrolyzing enzymes are inhibited, the continued presence of acetylcholine maintains a state of nerve stimulation and accounts for the clinical signs observed with poisoning from these insecticides.

Clinical Signs. The clinical syndrome produced by OP and carbamate insecticides is characterized by a rapidly progressing overstimulation of the parasympathetic nervous system and skeletal muscles. Earliest clinical signs of acute poisoning frequently include mild to profuse salivation, defecation, urination, emesis, stiff-legged or "sawhorse" gait, and general uneasiness. As the syndrome progresses, signs observed include profuse salivation; gastrointestinal hypermotility resulting in severe colic, vomiting (especially common in swine), and abdominal cramps; diarrhea; excessive lacrimation; miosis; dyspnea; cyanosis; urinary incontinence; muscle tremors of the face, eyelids, and general body musculature; and acute death. Hyperactivity of the skeletal muscles is generally followed by muscular paralysis, as the muscles are unable to respond to continued stimulation. Swine may exhibit increased CNS stimulation but rarely, if ever, convulsive seizures. More commonly, severe CNS depression occurs.

Death usually results from hypoxia caused by excessive respiratory tract secretions, bronchoconstriction, and erratic, slowed heartbeat. The onset of clinical signs

of acute poisoning may appear within a few minutes in severe cases to several hours in milder ones.

Lesions. Lesions associated with acute OP or carbamate toxicosis are usually nonspecific but may include excessive fluids in the respiratory tract as well as pulmonary edema.

Diagnosis. A history of exposure to OP or carbamate insecticides associated with clinical signs of parasympathetic stimulation warrants a tentative diagnosis of poisoning with these compounds.

Chemical analyses of animal tissues for the presence of insecticides are usually unrewarding because of the rapid degradation of OP and carbamate insecticides, resulting in low tissue residue levels. However, finding the insecticide in the stomach contents and the feed or suspect material can be quite valuable in establishing a diagnosis. In addition, the degree of inhibition of cholinesterase enzyme activity in the whole blood and tissue of the suspected animal should be assessed. A reduction of whole-blood cholinesterase activity to less than 25% of normal is indicative of excessive exposure to these insecticides. The cholinesterase activity level in the brain tissue of animals dying from these insecticides will generally be less than 10% of normal brain activity.

Whole-blood and brain samples should be well chilled but not frozen for best laboratory results. Samples of stomach contents as well as the suspect feed or material should be submitted to a laboratory for chemical analysis.

Treatment. Treatment of animals poisoned by OP or carbamate insecticides should be considered on an emergency basis because of the rapid progression of respiratory distress in the clinical syndrome. Initial treatment for poisoned swine should be the intramuscular use of atropine sulfate at approximately 0.5 mg/kg body weight. One-quarter of this dose may be given intravenously for a quick response in especially severe cases. Atropine does not counteract the insecticide-enzyme bond but blocks the effects of accumulated acetylcholine at the nerve endings. Although a dramatic cessation of parasympathetic signs is generally observed within a few minutes after administration of atropine, it will not affect the skeletal muscle tremors. More atropine at approximately one-half the initial dose may be required but should be used only to control recurring parasympathetic signs. Although the use of atropine alone is generally adequate, especially if vomiting has occurred, specific cases may warrant the use of pralidoxime chloride or activated charcoal.

Oral activated charcoal is recommended for treatment of any ingested insecticide to reduce continued absorption of the insecticide from the gut. Although a useful treatment, the need for activated charcoal in swine may be reduced when vomiting helps empty the gut and thereby reduces further absorption of the insecticide.

The use of the oximes (e.g., TMB-4, 2-PAM, pralidoxime chloride) in large animals, although efficacious, may be economically unfeasible. If used, pralidoxime chloride is recommended at a dose of 20 mg/kg body weight. The oximes are of no benefit in treating carbamate toxicoses.

Dermally exposed animals should be washed with soap and water to prevent continued absorption of these compounds.

Morphine, succinylcholine, and phenothiazine tranquilizers should be avoided in treating OP poisoning.

Chlorinated Hydrocarbons. The chlorinated hydrocarbon (CH) insecticides (e.g., toxaphene, chlordane, aldrin, dieldrin, and lindane) produce toxicosis in swine by acting as diffuse but powerful stimulants of the CNS. Even though these are old products that have been restricted from the market for over 30 years, improperly discarded leftover products may become available to animals when older barns or storage areas are cleaned out.

Clinical Signs. Clinical signs often appear 12–24 hours after exposure. Initially, animals may appear apprehensive. A period of hyperexcitability and hyperesthesia characterized by exaggerated responses to stimuli and spontaneous muscle spasms is usually observed. The spontaneous tremors and fasciculation are usually in the facial region and involve lips, muscle, eyelids, and ears, progressing caudally to involve the heavy muscles of the shoulder, back, and hindquarters. These spasms may progress into a tonoclonic convulsive seizure. Abnormal posturing, elevation of the head, and chewing movements may be observed. Varying degrees of respiratory paralysis occur during the seizures, with periods of depression and inactivity between successive seizures.

The rapidity of onset and severity of clinical signs provide a poor index of the prognosis of the episode in individual animals. Occasionally, animals will die during seizures, while others may completely recover following several severe episodes.

Lesions. Specific lesions other than those from the physical trauma of the seizures are not observed.

Diagnosis. Clinical signs of hyperexcitability and tonoclonic convulsive seizures with a known exposure to CH insecticides should yield a tentative diagnosis of toxicosis.

The presence of significant levels of CH insecticide in liver, kidney, and brain tissue is essential for confirming a diagnosis. Samples of these tissues as well as stomach contents and suspect material such as feed or spray should be submitted to a laboratory. Avoid contamination of specimens with hair or gut contents to prevent erroneous analytic results.

Laboratory tests are usually required to differentiate this toxicosis from pseudorabies, water deprivation, or gut edema.

Treatment. Treatment is essentially symptomatic, since there is no specific antidote for the CH insecticides. Animals should be sedated with long-acting barbiturates to control convulsive seizures. Animals with dermal exposure should be washed with warm, soapy water to remove the chemical and prevent continued contact. If the chemical is orally ingested, activated charcoal in a water slurry may be used to prevent further absorption. Oil-based cathartics should be avoided, as they may hasten absorption of the chemicals. Intravenous fluids plus glucose may be needed in protracted cases.

Residues. Because of the persistence of CH insecticides and their concentration in fat deposits of the body, the carcasses of animals dying from CH insecticide toxicosis are a source of contamination for feed ingredients such as tankage, meat and bone meal, and fats. Therefore, proper disposal of contaminated carcasses is very important. Tissue residues of these chemicals in swine surviving an episode of insecticide exposure should be an important consideration in market animals. In some cases the time required for excretion of these residues is too long to make decontamination economically feasible.

Synthetic Pyrethroids. Several synthetic pyrethroids (e.g., permethrin, fenvalerate) are commercially available for fly and external-parasite control. As a class, the synthetic pyrethroids are relatively nontoxic to mammals and are unlikely to produce poisoning in swine.

Formamidines. Amitraz is a formamidine pesticide with insecticidal and acaricidal properties. It is available in the United States as Taktic for control of lice and mange on swine. This compound has low mammalian toxicity and is unlikely to produce toxicosis in swine.

Fungicides
Captan. Captan has been widely used as a seed treatment although some newer fungicides are now being employed. Field corn seed produced commercially in the United States has generally been treated with captan at a level of approximately 1000 ppm. Consumption of captan-treated seed corn represents little hazard of poisoning, as the acute lethal dose of captan for livestock is greater than 250 mg/kg body weight.

Organomercurials. The organomercurials include phenyl mercuric chloride, phenyl mercuric acetate, various aliphatic compounds such as ethyl mercuric chloride, and complex aromatic derivatives like hydroxy mercuric cresol. The toxicoses associated with mercury-based seed treatments are discussed above, in the section on mercury.

Pentachlorophenol. Pentachlorophenol (PCP) has been employed for over 45 years as a wood preservative and fungicide. PCP- or "penta"-treated wood has found application in livestock handling and housing facilities, where wood is in contact with soil, manure, or moisture. Acute poisoning is not a major problem from PCP-treated wood, although toxicosis, including stillborn pigs, may occur when livestock have contact with surfaces that have been freshly treated with PCP preparations (Schipper 1961). A single oral dose of 80 mg/kg was not fatal to a weanling pig. If toxicosis occurs, depression, emesis, muscular weakness, accelerated respiratory rate, and posterior paralysis are clinical signs that may be observed. A problem of greater concern may be the recognition of blood and tissue PCP residues in swine that have been in contact with PCP-treated facilities. Finding from 10 to 1000 ppb PCP in whole blood is apparently unrelated to manifestations of toxicosis.

Chromate–Copper Arsenate. Chromate–copper arsenate (CCA) is widely used as a wood preservative in consumer lumber intended for outdoor use. CCA-treated wood generally presents a negligible hazard to swine, as the metallic salts are bound in the wood fibers. However, the residual inorganic arsenic in the ashes of burned CCA wood can produce poisoning in swine.

Herbicides
Phenoxy Herbicides. 2,4-D; 2,4,5-T, MCPA; and silvex are selective herbicides widely used in crop production and pasture and range management. Because the toxic dose of 2,4-D and 2,4,5-T is greater than 300 mg/kg body weight for several days, the hazard of poisoning by these compounds under normal conditions of use is low. When large doses have been administered experimentally, depression, anorexia, weight loss, muscular weakness, and incoordination have been observed.

Dipyridal Herbicides. Paraquat, a plant desiccant type of herbicide, has found widespread application in no-till farming technology. Accidental, as well as malicious, poisoning of swine with paraquat has resulted in toxicosis. An approximate lethal dose of paraquat for swine is 75 mg/kg.

Acute effects involving necrosis and erosion of the oral and gastric mucosa are attributed to the carrier solvent. The more classic effects, however, occur 7–10 days after ingestion and are characterized by pulmonary congestion and edema. The pulmonary lesions progress to a severe diffuse interstitial pulmonary fibrosis. Initial clinical signs include emesis and diarrhea, and the later stages are characterized by respiratory distress. Once clinical signs suggesting pulmonary involvement develop, therapeutic measures are usually futile.

Rodenticides
The rodenticides are used to control rat and mouse populations in or around farmsteads, feed storage areas, and

swine production facilities. Accidental access to these compounds constitutes the usual route of exposure, although malicious poisoning of swine with rodenticides has also occurred.

Anticoagulant Rodenticides. The anticoagulant rodenticides (e.g., warfarin, diphacinone, chlorophacinone, bromadiolone, brodifocoum, pindone) compose the largest group of rodenticides available through retail outlets. Swine are quite susceptible to this class of compound, as evidenced by toxicosis occurring after a single oral dose of warfarin at 3 mg/kg body weight. Repeated oral doses of only 0.05 mg/kg per day for 7 days also produced toxicosis in swine (Osweiler 1978). These rodenticides produce lowered prothrombin levels by interfering with vitamin K utilization. The physiologic result is increased blood-clotting time, which is manifested clinically as mild to severe hemorrhage. The clinical signs—including lameness, stiffness, lethargy, recumbency, anorexia, and dark tarry feces—are related directly to extravasation of blood. Observed lesions include hematoma, articular swelling, epistaxis, intermuscular hemorrhage, anemia, and melena.

A diagnosis of anticoagulant rodenticide toxicosis should include demonstration of a defect in the clotting mechanism as evidenced by increases in clotting time, one-stage prothrombin time, or activated partial thromboplastin time. The chemical detection of the rodenticide in samples of blood, liver, or suspect baits is also helpful.

Injectable vitamin K and oral vitamin K supplements are included in a successful treatment regime. Whole-blood transfusions may be utilized successfully in special cases.

Strychnine. Strychnine, an indole alkaloid, is widely available commercially, often as either a green- or red-dyed pellet or grain or as a white powder. This alkaloid acts by selectively antagonizing certain types of special inhibitory neurons, thereby allowing uncontrolled and relatively diffuse reflex activity to proceed unchecked. The approximate oral lethal dose of strychnine for swine varies from 0.5 to 1 mg/kg body weight. Clinical signs appear within 10 minutes to 2 hours after ingestion and are characterized by violent tetanic seizures that may occur spontaneously or in response to external stimuli such as touch, light, or sound. The intermittent seizures are usually separated by periods of relaxation. Death occurs from anoxia and exhaustion during the seizures, often in less than 1 hour. Diagnosis is best confirmed by detection of the strychnine alkaloid in either the stomach contents or urine. Treatment consists of controlling seizures with long-acting barbiturates and other muscle relaxants.

Cholecalciferol. Rodenticides containing cholecalciferol (vitamin D_3) are commercially available as Rampage, Quintox, or Ortho Rat-B-Gone. Toxic doses of these products produce vitamin D poisoning with hypercalcemia, mineralization of soft tissues, and clinical signs of depression, weakness, nausea, anorexia, polyuria, and polydipsia.

Bromethalin. Bromethalin-based rodenticides, marketed as Assault, Vengeance, or Trounce, produce cerebral edema and signs of rear-leg ataxia and/or paresis and CNS depression. Hyperexcitability, muscle tremors, and seizures may be seen with higher doses of bromethalin in the dog (Dorman et al. 1990).

TOXIC PLANTS

Amaranthus retroflexus (Redroot Pigweed)

A distinct disease syndrome of swine called perirenal edema occurs during the summer and early fall months. Its onset is associated with sudden access to pastures, barn lots, or fencerows containing moderate amounts of *Amaranthus retroflexus* (redroot pigweed).

Clinical signs appear suddenly 5–10 days after access to the pigweed. Initial signs are weakness, trembling, and incoordination. The disease progresses rapidly to knuckling of the pastern joints and finally to almost complete paralysis of the rear legs. Affected pigs usually lie in sternal recumbency, and if disturbed, attempts to walk will be in a crouching gait or with the rear legs dragging. The body temperature is usually normal and the eyes are bright. Coma and death generally occur within 48 hours of the onset of clinical signs, but affected swine may live from 5 to 15 days, with progression from signs of acute nephrosis to those of chronic fibrosing nephritis. In affected herds, new cases may appear for as long as 10 days after removal from the source. Morbidity ranges from less than 5% in some herds to 50% in others, and the mortality is usually about 75–80% in those showing clinical signs.

Gross necropsy findings are dramatic and characterized as edema of the connective tissue around the kidneys. The amount of fluid in the perirenal area varies, at times occupying the greater portion of the abdominal cavity. The edematous fluid may contain considerable blood, although the kidney itself is usually of normal size and pale. Edema of the ventral body wall and perirectal areas as well as ascites and hydrothorax may be observed. Histologic lesions of affected swine are characterized by hydropic degeneration and coagulative necrosis of both proximal and distal convoluted tubules. Glomeruli may be shrunken, with dilation of Bowman's capsules. Proteinaceous casts are numerous in distal and collecting tubules.

As a consequence of severe renal disease, there are elevations in BUN, serum creatinine, and serum potassium. The electrocardiograph of affected swine is characteristic of hyperkalemic heart failure (Osweiler et al. 1969). The changes include bradycardia, a wide and

slurred QRS complex, and an increase in magnitude and deviation of the T wave. The probable cause of death is hyperkalemic heart failure.

Immediate removal of affected pigs from the source of the weeds is the only definite therapeutic recommendation that can be made at this time.

Xanthium spp. (Cocklebur)

Cockleburs, including *Xanthium strumarium* and other species, are annual herbs that reproduce only from seed. They may be found throughout the world in cultivated fields, fencerows, and ditches and may heavily infest pastures as a result of being washed in from adjacent cropland.

The greatest potential for cocklebur poisoning arises when the more toxic two-leaf seedling stage or ground seeds are ingested. The unpalatable more mature plant contains less of the toxic principle, carboxyatractyloside. Within 8–24 hours after ingestion, swine develop signs of depression, nausea, weakness, ataxia, and subnormal temperature. Spasms of the cervical muscles, vomiting, and dyspnea may occur. Death occurs within several hours after the onset of symptoms. Lesions typically include ascites with large fibrin strands on the surface of the liver and other viscera and congestion and centrilobular accentuation of the liver. Microscopically acute centrilobular hepatic necrosis is observed (Stuart et al. 1981).

Treatment includes mineral oil per os to delay absorption of the carboxyatractyloside. Intramuscular injection of 5–30 mg physostigmine may produce a dramatic response in some cases (Link 1975).

Solanum nigrum (Black Nightshade)

Even though black nightshade is easily recognized and found in woods, permanent pastures, and fencerows, actual cases of poisoning are rare. The alkaloid solanine is found principally in the leaves and green berries, but the plant is generally not palatable and is usually consumed under conditions of its abundant growth and lack of other suitable forage.

Affected animals display anorexia, constipation, depression, and incoordination. Poisoned swine may vomit. Dilation of the pupils and muscular trembling are neurologic signs observed. Animals may be seen lying on their sides and kicking with all feet, progressing then to coma and death. Necropsy may reveal some degree of gastrointestinal irritation. The toxic alkaloid is rapidly eliminated through the urine (Kingsbury 1964).

Nitrates and Nitrites

As monogastric animals, swine are relatively resistant to the effects of nitrate, especially when compared with cattle. Nitrate or nitrite toxicosis occurs most commonly when these ions accumulate in either plants and/or water sources. Some fertilizers, such as ammonium nitrate or potassium nitrate, may also be a source

of nitrate for animals. Several different plants may accumulate nitrate, depending on varying climatic and soil fertility conditions. Nitrate may accumulate in the lower stalk and perhaps leaves of corn and other plants, but not in the fruit or grain.

The nitrates from both water (see the section on water quality below) and plant sources are additive and should be evaluated together in particular field cases. The nitrate ion (NO3) itself is not particularly toxic and may produce no more than gastrointestinal irritation. However, nitrite (NO_2), the reduced form of nitrate, is quite toxic. The nitrite ion oxidizes ferrous iron in hemoglobin to the ferric state, forming methemoglobin, which cannot accept and transport molecular oxygen. The result is tissue hypoxia from poorly oxygenated blood.

Pigs given single oral doses of greater than 10–20 mg nitrite-nitrogen (as potassium nitrite)/kg body weight developed clinical signs of poisoning but recovered, whereas those given doses greater than 20 mg nitrite-nitrogen/kg body weight died within 90–150 minutes after ingestion (London et al. 1967). Clinical signs became apparent when approximately 20% of the total hemoglobin was present as methemoglobin; death was associated with methemoglobin levels of approximately 80%. Clinical signs observed with acute nitrite toxicosis include increased respiratory rate, salivation, miosis, polyuria, weakness, ataxia, and terminal anoxic convulsive seizures. The blood and tissues are a chocolate brown color from the methemoglobin. Treatment of acute nitrite toxicosis consists of intravenous injection of 10 mg methylene blue/kg body weight in a 4% solution (Link 1975).

WATER QUALITY

Water is one of the most important nutrients for swine. The availability of adequate quantities of good-quality water is essential for successful swine production. Even though it may be easy to incriminate water as the cause of poor performance and vague disease conditions in swine, water evaluation should be part of a thorough diagnostic investigation. A detailed history of the animals as well as the water source, careful clinical evaluation, and submission of representative animal and water specimens should be included in the investigation. Results of water tests should be evaluated in view of existing standards for livestock water quality. Some general guidelines for evaluating water quality parameters for livestock are presented in Table 60.1.

Information about the source of the water should be recorded. Ponds, wells, and regional rural water systems are the most common water sources, and each may influence the quality of the water supplied. The depth of wells may also be helpful, as deeper wells tend to have a higher mineral content, while shallower wells are more likely to have higher nitrate levels and coliform counts.

Table 60.1.   Water quality guidelines for livestock

Item	Maximum Recommended Limit (ppm)
Major ions	
Calcium	1000
Nitrate + nitrite	100
Nitrite alone	10
Sulfate	1000
Total dissolved solids	3000
Heavy metals and trace ions	
Aluminum	5.0
Arsenic	0.5[a]
Beryllium	0.1[b]
Boron	5.0
Cadmium	0.02
Chromium	1.0
Cobalt	1.0
Copper (swine)	5.0
Fluoride	2.0[c]
Iron	No guideline
Lead	0.1
Manganese	No guideline
Mercury	0.003
Molybdenum	0.5
Nickel	1.0
Selenium	0.05
Uranium	0.2
Vanadium	0.1
Zinc	50.0

Source: Canadian Task Force on Water Quality 1987.
[a]5.0 if not added to feed.
[b]Tentative guideline.
[c]1.0 if fluoride is present in feed.

Sometimes the age of the well and type of pumping device may suggest certain mechanical problems, including a cracked casing or defective sanitary seal. Estimates of the amount of water consumed may also be helpful when investigating potential water problems.

Microbiologic Standards

Microbiologic examination of water samples determines the general sanitary quality of the sample and indicates the degree of contamination of the water with waste from human and animal sources.

In general, these examinations do not attempt to isolate pathogenic bacteria but detect the presence of indicator organisms. The coliform group of bacteria has traditionally been the indicator used to assess the degree of water pollution and thus the sanitary quality of the particular sample. As an advance in the microbiologic examination of water, the differentiation of fecal coliforms as a subgroup within the general category of coliforms is encouraging. The U.S. Environmental Protection Agency (1973) proposed that acceptable levels for water to be used directly by livestock should not exceed 1000/100 mL. Many believe, however, that as long as animals are allowed to range freely and drink surface waters, these proposed limits will be unenforceable and of doubtful value.

The standard plate count, which enumerates the number of bacteria multiplying at 35°C, is of doubtful significance in evaluating livestock water sources other than helping to judge the efficiency of various water treatment processes.

Salinity

Salinity, or total dissolved solids (TDS), generally expressed in milligrams per liter, is an expression of the amount of soluble salts in a particular water sample and is one of the most important parameters used to evaluate water quality. The ions most commonly involved in saline waters are calcium, magnesium, and sodium in the bicarbonate, chloride, or sulfate form. Hardness is sometimes confused with salinity, but the two are not necessarily correlative. Hardness is expressed as the sum of calcium and magnesium reported in equivalent amounts of calcium carbonate. Although hardness of water may affect the mechanical function of valves and waterers because of the formation of mineral deposits, hardness itself has a minimal impact on animal performance.

Water containing less than 1000 mg soluble salts/L should present no serious hazard to any class of swine. Water containing between 1000 and 5000 mg soluble salts/L may cause mild temporary diarrhea or be refused at first by swine not accustomed to it, although health or performance should not be greatly affected (NRC 1974; Anderson and Strothers 1978; Paterson et al. 1979). Water containing 5000–7000 mg soluble salts/L may present a health risk for pregnant, lactating, or stressed animals. Water containing more than 7000 mg soluble salts/L should be considered unsafe for swine.

In some regions, sulfates are a major portion of the TDS in water. A recent study (Fleck Veenhuizen et al. 1992) demonstrated that except for an increase in fecal moisture content, water containing up to 1800 mg of sodium, magnesium, or a combination of sodium and magnesium sulfate per liter had no effect on nursery pig performance. An epidemiologic study of water on swine farms did not find an association between sulfate concentrations and prevalence of diarrhea, although water sulfate levels increased with the depth of the wells tested (Fleck Veenhuizen 1993). A recent study of water quality on 173 Iowa swine farms found a mean TDS of 343 mg/L (range 100–2,500), but measured no significant effects of elevated TDS on several performance parameters (Ensley 1998).

Nitrates and Nitrites

Nitrates and nitrites are water soluble and thus may be leached from the soil or soil surface into groundwater. Animal wastes, nitrogen fertilizers, decaying organic matter, silage juices, and soils high in nitrogen-fixing bacteria may be sources of contamination through surface-water runoff to adjacent poorly cased, shallow, or low-lying wells or reservoirs.

The upper limit for nitrate in human drinking water is 45 mg nitrate/L (USEPA 1975). This level has the intent of preventing the methemoglobinemia of "blue baby" syndrome in human infants who receive formulas made from high-nitrate waters. Although it has been suggested that neonatal swine are also quite susceptible to elevated nitrates, evidence to support this theory is unavailable. Emerick et al. (1965) concluded, however, that 1-week-old pigs are no more susceptible to nitrite-induced methemoglobinemia than older growing swine. A review of water quality for livestock (NRC 1974) proposed 440 mg nitrate/L as the maximum nitrate that could safely be allowed in livestock water.

Reports of experimental production of a chronic or low-level nitrate-poisoning syndrome in livestock have been extensively reviewed (Turner and Kienholz 1972; Emerick 1974; Ridder and Oehme 1974). The bulk of the evidence indicates that sublethal or chronic effects are extremely rare and difficult to verify. London et al. (1967) fed growing pigs up to 18.3 mg nitrite-nitrogen/kg body weight for 124 days without serious effects developing. No effect on the performance of growing-finishing swine or on reproductive performance of gilts was observed when the drinking water contained 1320 ppm nitrate (Seerley et al. 1965).

MISCELLANEOUS TOXICANTS

Sodium Ion Toxicosis

Sodium ion toxicosis, also called water deprivation or salt poisoning, is a common problem in swine. The occurrence of sodium ion toxicosis is inversely related to water intake and is almost always related to water deprivation caused by inadequate water supply or to changes in husbandry. The likelihood of toxicosis will also increase with increased dietary salt, but the condition may occur when rations contain normal levels of added salt, for example, 0.25–1%. It has also been associated with the feeding of whey and other milk by-products. Sodium ion toxicosis may occur after water deprivation of only a few hours, but in most cases the time exceeds 24 hours.

The initial clinical signs are thirst and constipation, followed by CNS involvement. Intermittent convulsions start within 1 to several days after water deprivation and may be exacerbated by rehydration. The frequency of characteristic tonoclonic convulsions with opisthotonos, often starting from a sitting position, increases. Affected animals may also wander aimlessly and appear to be blind and deaf. Moribund pigs become comatose, often lying on their sides with continuous paddling. Most affected animals die within a few days. Some pigs that appear to be unaffected may succumb later to a subacute polioencephalomalacia. Salt poisoning, from eating excess salt or consuming brine, usually causes vomiting and diarrhea.

Diagnosis is best accomplished by establishing that water deprivation occurred, which may be difficult in some cases. If water deprivation is not evident, other means must be used to aid the diagnosis. Necropsy findings may reveal a gastritis, gastric ulcers, constipation, or enteritis. Chemical analysis of serum and cerebrospinal fluids may confirm a hypernatremia with levels of Na above 160 mEq/L (Osweiler and Hurd 1974). However, after rehydration, normal values of 140–145 mEq/L may exist. Brain sodium levels above 1800 ppm (wet weight) are consistent with a diagnosis of sodium ion toxicosis. Histologic examination of brain tissue, especially cerebrum, will usually reveal the presence of a pathognomonic eosinophilic meningoencephalitis characterized by cuffing of meningeal and cerebral vessels with eosinophils. However, when pigs live several days, the eosinophils may disappear or be replaced by mononuclear cells. Brains of pigs affected subacutely may have a laminar subcortical polioencephalomalacia. Analysis of feed for sodium is usually of limited value. Differential diagnosis should include viral encephalitic diseases such as pseudorabies and hog cholera, chlorinated hydrocarbon insecticide poisoning, and edema disease. In known cases of water deprivation, rehydration should be gradual, but the prognosis is poor.

Coal Tar Pitch

Coal tars are a mixture of condensable, volatile products formed during the destructive distillation of bituminous coal. The phenolic portions of these products have the greatest acute toxicity. Sources of these substances for swine are clay pigeons, lignite tar flooring slabs, tar paper, and tar used in waterproofing and sealing. Because of the rapid clinical course, sudden death is often the first physical sign observed. Weakness, depression, and increased respiratory rate can be observed in animals that may live for several hours or even days. Icterus and a secondary anemia may develop. Necropsy of pigs poisoned by coal tar pitch reveals a greatly enlarged friable liver. The hepatic lobules are very distinct grossly; some are darkened in color, and others are yellowish orange. Microscopically, this lesion is observed as severe centrilobular necrosis with subsequent intralobular hemorrhage. Ascites and large turgid kidneys may also be observed.

There is no specific treatment for this condition. Removal of animals from the source of the coal tar is important to prevent recurrence of poisoning.

Ethylene Glycol

Most permanent antifreeze/coolant mixtures for liquid-cooled engines contain approximately 95% ethylene glycol. A hazard of poisoning exists when animals have accidental access to antifreeze solutions during periods of engine maintenance or when these solutions are used in plumbing systems to prevent freezing. Swine may be poisoned by ingesting 4–5 mL ethylene glycol/kg body weight. Ethylene glycol toxicosis is exhibited in two

clinical phases. Initially the glycol may enter the cerebrospinal fluid, producing a narcotic or euphoric state of intoxication. Subsequent clinical signs of acidosis and renal failure are associated with the highly toxic metabolites of the glycol and formation of calcium oxalate crystals in the kidney tubules. Renal tubular blockage with development of uremia is observed 1–3 days after ingestion. Clinical signs generally include emesis, anorexia, dehydration, weakness, ataxia, convulsions, coma, and death. The entire course of illness may be as short as 12 hours following consumption of large quantities of ethylene glycol. Oxalate nephrosis can be demonstrated histopathologically and is characterized by finding pale yellow birefringent oxalate crystals in the tubules. Polarizing filters greatly aid in the detection of oxalate crystals in kidney sections or in impression smears of freshly incised kidney.

Once clinical signs of renal failure are evident, treatment is usually of no avail. If treated within the first 6–12 hours after ingestion, reasonable response has been achieved in ethylene glycol–poisoned dogs by using 5.5 mL/kg body weight of 20% ethyl alcohol intravenously and 98 mL/kg body weight of 5% sodium bicarbonate intravenously.

Gossypol

Cottonseed meal (CSM), a by-product of the cotton fiber and cottonseed oil industries, is an important protein supplement for livestock rations in cotton-producing regions. Its use as a protein supplement for swine, however, is limited by gossypol content, which varies with the strain of the cotton plant, its geographic location, climatic conditions, and the oil extraction procedure used. Gossypol, a polyphenolic binaphthalene, is a yellow pigment in glands of decorticated cottonseed. The toxic "free" gossypol becomes partially inactivated (bound) during the extraction and milling processes, as well as spontaneously in the prepared meal. Toxicity of gossypol depends on the species and age of the animal and on various components of the diet, particularly the protein, lysine, and iron concentrations (Eisele 1986).

Toxicosis only follows prolonged feeding (weeks to months) of CSM with a high content of free gossypol and may be manifested simply as ill-thrift or as an acute respiratory problem followed by death. The main pathologic changes are cardiomyopathy, hepatic congestion and necrosis, skeletal muscle injury, and severe edematous changes throughout the animal. A decrease in hemoglobin total serum, protein concentration, and packed-cell volume is seen in pigs fed a diet containing $\geq$200 mg of free gossypol/kg (Haschek et al. 1989).

Recommendations for growing and fattening swine include feeding no more than 9% CSM in the diet, with less than 100 mg (0.01%) of free gossypol/kg, in a 15–16% protein diet. Tolerance to gossypol can be induced by adding $FeSO_4$ ($\geq$400 mg/kg) at a 1:1 weight ratio with free gossypol. Increasing the amount of crude protein or supplementing with lysine can also induce tolerance (Pond and Maner 1984).

VENTILATION FAILURE AND TOXIC GASES

Confinement of swine in closed structures increases the risk of potential gas toxicosis and other dynamics dependent upon mechanical ventilation. Fortunately even at relatively low ventilation rates used during cold weather, concentrations of ammonia and hydrogen sulfide, the two most potentially dangerous gases associated with manure decomposition, usually remain below toxic levels. Unfortunately, however, accidents, poor design, and improper operation may result in insufficient ventilation and the concentration of poisonous gases to toxic levels.

The most important gases released by the decomposition of urine and feces either in anaerobic underfloor waste pits or in deep litter or manure packs are ammonia and hydrogen sulfide. Carbon dioxide and methane are also produced but seldom reach significant concentrations. A number of vapors responsible for the odors of manure decomposition are also produced. These include organic acids, amines, amides, alcohols, carbonyls, skatoles, sulfides, and mercaptans. Concentrations of toxic gases are usually expressed as parts of the gas per million parts of air (ppm) by volume.

Ventilation Failure

Even more common than the accumulation of toxic gases are swine deaths associated with failure of a mechanical ventilation system. The failure of ventilation may occur in whole confinement buildings and result in high death losses at any time of the year. Similar dynamics and death losses occur in tightly sealed insulated trucks used to transport young pigs. When ventilation stops because of storms, power outages, or mechanical failure, the dynamics of air, heat, and moisture in the confined space may become critical. The retention of heat and moisture leads to high relative humidity and poor evaporative cooling and consequently hyperthermia as the most critical factor in these confined swine. Death losses may approach 95% under these circumstances. Although there is no method to specifically confirm hyperthermia as a cause of death, a history of ventilation failure, rapid carcass decomposition, a pale "cooked" appearance to the muscles, and blood-tinged foam in the trachea are usually seen.

Ammonia

Ammonia (NH_3) is the toxic air pollutant most frequently found in high concentrations in animal facilities, and production is especially common where excrement can decompose on a solid floor. This gas has a characteristic pungent odor that humans can detect at approximately 10 ppm or even lower. The NH_3 concentration in enclosed animal facilities usually remains

below 30 ppm even with low ventilation rates; however, it may frequently reach 50 ppm or higher during long periods of normal facility operation.

Ammonia is highly soluble in water, and as such will react with the moist mucous membranes of the eye and respiratory passages. Consequently, excessive tearing, shallow breathing, and clear or purulent nasal discharge are common symptoms of aerial NH_3 toxicosis.

At concentrations usually found in practical animal environments (<100 ppm), the primary impact of this gas is as a chronic stressor that can affect the course of infectious disease as well as directly influence the growth of healthy young pigs. The rate of gain in young pigs was reduced by 12% during exposure to aerial NH_3 at 50 ppm and by 30% at 100 or 150 ppm (Drummond et al. 1980). Aerial NH_3 at 50 or 75 ppm reduced the ability of healthy young pigs to clear bacteria from their lungs (Drummond et al. 1978). At 50 or 100 ppm, aerial NH_3 exacerbated nasal turbinate lesions in young pigs infected with *Bordetella bronchiseptica* but did not add to the infection-induced reduction in the pigs' growth rate (Drummond et al. 1981a). In another study, aerial NH_3 at 100 ppm reduced the rate of gain by 32% and ascarid infection by 28%; however, effects of the NH_3 and infection, when imposed on the pigs at the same time, were additive, and the rate of gain was reduced by 61% (Drummond et al. 1981b). More extensive reviews of aerial NH_3 and its effect on animal production are provided by Curtis (1983) and the National Research Council (1979a).

Hydrogen Sulfide

Hydrogen sulfide (H_2S) is a potentially lethal gas produced by anaerobic bacterial decomposition of protein and other sulfur-containing organic matter. The source of H_2S which presents the greatest hazard to swine is liquid manure holding pits. Most of the H_2S, which may be continuously produced, is retained within the liquid of the pit. However, agitation of waste slurry to resuspend solids prior to being pumped out causes the rapid release of much of the H_2S that may have been retained within it. Hydrogen sulfide is heavier than air and consequently is found in, and will move to, pits, tanks, and other low areas of a facility. The concentration of H_2S usually found in closed animal facilities (less than 10 ppm) is not toxic, but the release of gas upon agitation may produce concentrations of H_2S up to 1000 ppm or higher within the facility.

Acute H_2S poisoning is directly responsible for more deaths in closed animal facilities than any other gas, with the possible exception of carbon monoxide. Additionally, several human deaths are recorded each year from H_2S accidents associated with animal facilities.

Humans can detect the typical "rotten egg" odor of H_2S at very low concentrations (0.025 ppm) in air. Exposures to these low concentrations have little or no importance to human health, and thus the olfactory re-

sponse is a useful warning signal of its presence. However, at higher concentrations (greater than 200 ppm), H_2S presents the distinct hazard of a paralyzing effect on the olfactory apparatus, thus effectively neutralizing the warning signal (NRC 1979b).

Hydrogen sulfide is an irritant gas. Its direct action on tissues induces local inflammation of the moist membranes of the eye and respiratory tract. When inhaled, the action of H_2S is more or less uniform throughout the respiratory tract, although the deeper pulmonary structures suffer the greatest damage. Inflammation of the deep lung structures may appear as pulmonary edema. If inhaled at sufficiently high concentrations, H_2S can also be readily absorbed through the lung and can produce fatal systemic intoxication (O'Donoghue 1961).

At concentrations in air exceeding 500 ppm, H_2S must be considered a serious imminent threat to life; between 500 and 1000 ppm, it produces permanent effects on the nervous system. If spontaneous recovery does not occur and artificial respiration is not immediately provided, death results from asphyxia.

Management is the most important part of preventing animal deaths from H_2S. When manure stored in a pit beneath a building is agitated, animals should be moved out of the building if at all possible. When movement of the animals is not possible, other steps should be taken to protect the animals during agitation. In mechanically ventilated buildings, the fans should run at full capacity, even during the winter; in naturally ventilated buildings, manure pits should not be agitated unless there is a brisk breeze blowing. Immediate rescue of affected swine should not be attempted for the rescuer may quickly become a victim of H_2S toxicosis.

Carbon Dioxide

Carbon dioxide (CO_2) is an odorless gas present in the atmosphere at 300 ppm. It is given off by swine as an end product of energy metabolism and by improperly vented, though properly adjusted, fuel-burning heaters. It is also the gas evolved in the greatest quantity by decomposing manure. Despite all this, CO_2 concentration in closed animal facilities rarely approaches levels that endanger animal health (Curtis 1983).

Methane

Methane (CH_2), a product of microbial degradation of carbonaceous materials, is not a poisonous gas. It is biologically rather inert and produces effects on animals only by displacing oxygen in a given atmosphere and thereby producing asphyxiation. Under ordinary pressures, a concentration of 87–90% CH_2 in a given atmosphere is required before irregularities of respiration and eventually respiratory arrest due to anoxia are produced. The chief danger inherent in this material is its explosive hazard as concentrations of 5–15% by volume in air are reached (Osweiler et al. 1985).

Carbon Monoxide

Carbon monoxide (CO), which is produced from the inefficient combustion of carbonaceous fuel and is present in the exhaust fumes of gasoline-burning internal-combustion engines, is also potentially lethal to swine. Poisoning occurs when improperly adjusted and improperly vented space heaters or furnaces are operated in tight, poorly ventilated buildings such as farrowing houses.

Ambient background levels of CO are 0.02 ppm in fresh air, 13 ppm in city streets, and 40 ppm in areas with high vehicular traffic.

Carbon monoxide acts by competing with oxygen for binding sites on a variety of proteins, including hemoglobin, with which most of the compound is associated in the body. The affinity of hemoglobin for CO is some 250 times that for oxygen. When CO becomes bonded to the heme group, forming carboxyhemoglobin, the molecule's oxygen-carrying capacity is reduced. This results in tissue hypoxia.

High concentrations of CO (>250 ppm) in swine farrowing houses can produce an increased number of stillborn piglets. Clinical history generally associated with these stillbirths reveals (1) nonexistent ventilation, (2) inadequate ventilation due to blocked apertures of natural systems or reduction to minimal winter rates for mechanical systems, (3) use of unvented or improperly vented LP gas-burning space heaters, (4) a high percentage of near-term sows delivering dead piglets within a few hours of being put in an artificially heated farrowing facility, (5) sows that appear clinically normal but that produce whole litters born dead, and (6) negative laboratory results for the detection of infectious causes of abortion (Carson 1990).

Exposure to high levels of CO can be confirmed by actually measuring the CO level in the air or by measuring the percentage of carboxyhemoglobin in the blood of the affected animal. In addition to these two parameters, carboxyhemoglobin concentration of greater than 2% in fetal thoracic fluid may be used as an aid in diagnosing CO-induced stillbirth in swine (Dominick and Carson 1983).

Anhydrous Ammonia

On occasion, swine may be exposed to anhydrous ammonia (gas-NH_3) used as an agricultural fertilizer nitrogen source. This gas presents a unique risk of exposure to both animals and people because of its presence on farms and the fact that it is stored, transported, and applied under high pressure. Poisoning with gas-NH_3 is associated with gas release from broken hoses, failure of valves, and errors in operating transport or application equipment. Once released, gas-NH_3 rapidly combines with water and forms caustic ammonium hydroxide. The cornea, mouth, and respiratory tract are high in moisture and especially susceptible to the resulting strong alkali burns. Acute death from laryngospasm and

accumulation of fluid in the lungs can occur within a matter of minutes. Blindness from corneal opacity and sloughing epithelium in the respiratory tract may be seen in swine surviving initial exposure. Residual respiratory damage and secondary bacterial invasion may not allow affected animals to regain full productive status.

Genetic Influences on Susceptibility to Acquired Diseases

Kin-Chow Chang and Michael J. Stear

The use of genetic information in pig breeding to improve productivity is a successful and an expanding area of research and development, as exemplified by the routine genetic screening, in breeding stock, for the mutant ryanodine receptor allele in malignant hyperthermia (Fujii et al. 1991). The main areas of genetic applications have been on muscle production and reproductive performance (Rothschild et al. 1996; Bidanel and Rothschild 2002). In recent years, there has been increasing focus on the development of genetic markers to be used for enhancement of resistance to porcine diseases in breeding stock. This chapter reviews the current knowledge of porcine genetics and genomics that is relevant to infectious diseases. A consequence of its commercial importance has been the limited amount of publicly available information on specific diseases. Nonetheless, it is anticipated that DNA markers for disease resistance will be in regular use in pig breeding in the not too distant future.

Infectious diseases are realities of pig farming. The demand for improved standards of animal welfare and food safety, as well as farming economics, require that the incidence of disease be minimized. However, modern trends may be increasing the impact of specific diseases. The shift toward more intensive systems of production will reduce soil-transmitted infections such as gastrointestinal nematodes but may exacerbate other conditions like respiratory diseases. With the ban of growth-promoting antibiotics in several countries, there has been some deterioration in animal health, in particular, a rise in the number of gastrointestinal infections in early postweaning piglets, with a concomitant increase in the use of therapeutic antibiotics, which could have the inadvertent and paradoxical effect of promoting antibiotic resistance (Casewell et al. 2003).

Methods to control disease include good management to reduce exposure to pathogens and parasites as well as increasing the ability of animals to resist infection by vaccination and improved nutrition. Genetics also has a role to play in disease control. The identifica-

tion of resistant or susceptible animals for selective breeding could reduce or prevent outbreaks of disease. A quantitative genetic analysis can indicate how much of the variation among animals in disease incidence is genetic in origin, whereas a study of molecular genetic variation can help identify the mechanisms underlying resistance and susceptibility to disease. Arguably without knowledge of genetic variation, our understanding of the disease process is meager and unsatisfactory. At the very least, genetic studies can target future research more effectively.

DEFINING DISEASE RESISTANCE

In any study of disease, the definition of resistance requires careful consideration. A variety of traits can be used alone or in conjunction, and the most appropriate traits to define disease resistance may vary with the type or nature of disease. Pathogens with different predilection sites of infection (e.g., intestine or lung) will present different clinical signs. However, their systemic effects could be similar, such as pyrexia, inappetance and emaciation (Taylor 1999). With the same pathogen, host responses could vary between individuals, in clinical severity (asymptomatic to peracute), in duration of infection (transient to chronic), and in transmission of infection (no to high infectivity). Hosts could vary in exposure to the disease agent because of differences in behavior. Variation among hosts could also be due to variation in response to infection. The distinction between disease resistance (the ability to prevent infection establishing) and disease resilience (the ability to prevent the infection producing clinical signs or reducing performance) has long been recognized (Albers et al. 1987). However, these terms are commonly used interchangeably. An animal could show disease resistance, in comparison with its exposed cohorts, if it shows no or mild clinical signs, recovers rapidly, or blocks transmission to other pigs. A subclinical infection, compared with a full-blown acute state, with little effect on production could

be desirable. Likewise, a clinically affected animal that is able to prevent or reduce horizontal transmission could be regarded as disease resistant and would confer resistance at the herd level. Variation in clinical symptoms could be due to failure of the pathogen or parasite to establish, to rapid clearance by the host innate response, or to effective acquired immune response. Clinical, biochemical, or immunological parameters that can distinguish resistant animals from the rest of the population are phenotypic indicators of disease resistance.

The relationship between disease resistance and production traits is unpredictable and will vary among different environments, diseases, herds, and intensities of infection (Stear et al. 2001). A rational approach to improving disease resistance would be to genetically target improvement of host responses to selected diseases of major economic importance. Any improvement in recovery time and in reduction in mortality, clinical signs, and pathogen shedding in the face of a serious challenge is welcome.

GENETIC CONTRIBUTION TO DISEASE RESISTANCE/SUSCEPTIBILITY

Essentially every disease that has been seriously investigated has shown genetic variation among hosts in disease resistance (Nicholas 1996). Genetic variation could be shown in immune response traits as well as in host responses to direct pathogen exposure. The challenge is to use such information most effectively.

Geneticists divide diseases into different categories depending upon the nature of the genetic variation. Diseases that are entirely caused by the presence or absence of a single abnormal gene are classified as Mendelian diseases. These are subdivided into four categories depending upon the nature of inheritance: autosomal dominant, autosomal recessive, sex-linked dominant, and sex-linked recessive. There are a large number of different Mendelian diseases in pigs, although many are noninfectious (www.morgan.angis.su.oz.au). They are due to mutations in specific genes, either in the coding or regulatory regions. They can be recognized by examining the pedigree of affected animals.

Autosomal dominant diseases are caused by a single copy of a defective gene on one of the autosomes (non-sex chromosomes). They have three characteristic features: They affect approximately equal numbers of males and females. Breeding an affected sire with an affected dam can produce unaffected offspring. If the pedigree of an affected individual is traced back, the disease is present in every generation until the original mutation. Dominant diseases are rare in pigs because breeders do not usually breed from obviously diseased animals. This is an example of deliberate selection. Natural selection will also reduce the frequency of autosomal dominant disorders.

Autosomal recessive diseases occur when both copies of an autosomal gene are defective. They have three characteristic features. They occur in approximately equal numbers of males and females. Crossing an affected sire with an affected dam gives only affected offspring. The disease can also skip generations when tracing the inheritance back to an affected individual, since the offspring is unaffected, although being a carrier, when at least one parent is not a carrier of the defective gene. Autosomal recessive diseases are much more common than autosomal dominant diseases because carriers with only one copy of the disease appear normal.

Sex-linked dominant diseases are caused by a mutation on the X chromosome. The small Y chromosome carries relatively few genes, which include those involved in sex determination. Sex-linked dominant diseases are rare and none are known in pigs. Sex-linked recessive diseases are relatively common and include some hemophilias. They occur at a greater frequency in males than females. All offspring of two affected parents are affected and as with autosomal recessives the disease may skip generations.

If a disease is suspected of being inherited in a Mendelian fashion, the most useful strategy is often to draw up a pedigree and check inheritance against the simple rules outlined above. It can be useful to check whether a similar disease has been shown to be inherited in the same or other species. The simplest way to avoid dominantly inherited diseases is to avoid breeding with affected individuals. The strategy to avoid recessive diseases is to ensure that at least one parent is not a carrier. For many diseases, carriers or noncarriers can be identified among potential parents. Where DNA tests do not exist, crossing a sire with a number of known carriers (females that have given birth to diseased individuals) can indicate whether the sire is a carrier.

Many important diseases are complex: influenced by more than one gene and the environment. A multifactorial model of liability with a threshold describes these diseases. Here statistical methods that utilize the similarity among relatives can indicate what proportion of the variation among individuals in disease prevalence is genetic in origin. This is known as the *heritability* (Nicholas 1996). The heritability is the ratio of the variation due to the average effects of genes divided by the total variation. If the heritability is close to 0 most of the variation is due to nongenetic forces. Conversely, if the heritability is close to 1, most of the variation is genetic in origin.

GENETIC VARIATION IN DISEASE RESISTANCE

Controlling complex diseases by genetic methods is possible and uses the same methods developed by breeders to enhance production traits. A crucial decision is deciding whether to breed for resistance to one disease or for resistance to a range of diseases. For dairy

cattle the most economically important disease is mastitis; for sheep the dominant problem is nematode infection. Selective breeding has therefore concentrated on controlling these diseases. For pigs, there is no single overwhelmingly important disease worldwide and research has concentrated on identifying pigs with superior immune responses (Wilkie and Mallard 1999). It may not be possible to breed an animal that is completely immune to all known infectious diseases, but results certainly indicate that animals with enhanced resistance to a variety of important diseases can be identified.

Selection strategies are unlikely to be solely based on clinical symptoms. Selection based on host responses to specific disease challenge is the most direct route to identify resistant animals but is inconvenient and risky in intensive pig production. A sensible approach would be to target responses to diseases of major economic importance. Ideally, phenotypic markers that predict resistance should be detectable in the live animal to facilitate subsequent breeding.

Variation in Immune Responsiveness

Several studies have demonstrated differences in immune traits between individual pigs reared under the same conditions (Edfors-Lilja et al. 1994; Hessing et al. 1995; van Diemen et al. 2002). Immune parameters that were found to vary between individuals included total white blood cell count, neutrophil number and phagocytic capacity, CD2 and CD4 lymphocyte numbers, lymphocyte proliferation rate, antibody level and interleukin-2 (IL-2) production (Edfors-Lilja et al. 1994; Mallard et al. 1998). Differences in immune parameters were also detected between breeds. Several immune traits, like leucocyte number and concanavalin-A induced cell proliferation, were quantitatively different between Large White and Duroc pigs (Nguyen et al. 1998), and C3 complement activity showed breed differences between Duroc and Berlin Miniature pigs (Mekchay et al. 2003). High immune activity is not necessarily a predictor of better protection from disease (Mallard et al. 1998; Visscher et al. 2002).

Variation in Response to Specific Diseases

There are breed differences in neutralization antibody response to vaccination against Aujeszky's disease (Rothschild et al. 1984); Yorkshire and Chester White pigs were found with higher postvaccinated antibody titers than Duroc and Landrace pigs. The humoral response is only part of the immune response, and, as suggested earlier, high postvaccinated titres on their own do not inevitably mean greater resistance to Aujeszky's infection. However, this finding does serve to demonstrate a genetic basis for variation in humoral immune response to vaccination against Aujeszky's disease.

Sarcocystis miescheriana is a coccidial parasite that accumulates as cysts in the skeletal muscle of pigs acting as intermediate hosts. Experimental infection with *S. miescheriana* showed breed differences in host response (Reiner et al. 2002a). Pietrain pigs displayed greater clinical severity and parasite load in skeletal muscles than Meishan pigs.

Finally, a challenge experiment with *Salmonella choleraesuis* was conducted on a reference family bred from full-sister F1 gilts and four selected boars from two commercial lines (van Diemen et al. 2002). Infected pigs showed significant variation in bacterial recovery from liver and spleen, pyrexia response, weight gain, and several immune parameters. The most resistant pigs, as evidenced by low bacterial recovery from liver and spleen and better growth performance, had higher neutrophil numbers and better neutrophil functions (oxidative burst and intracellular killing of *S. choleraesuis*) but lower proliferation rate of lymphocytes and lower antibody response. In this study, it appears that the innate response is more critical than the acquired immune response in deciding on the outcome of *S. choleraesuis* infection.

The above viral, protozoal, and bacterial examples of infection illustrate the range of host response to different types of infection and the genetic contribution to variation in disease response for each type of infection. There is therefore considerable opportunity for genetic improvement of immune capacity since immune traits show wide genetic variation between pigs and moderate heritability (Visscher et al. 2002). However, as exemplified by the *Salmonella* infection experiment (van Diemen et al. 2002), the difficulty lies in the determination of the effective set of innate and/or acquired immune traits to be used as selection markers that are critical in alleviating the severity of a particular disease.

SELECTIVE BREEDING FOR DISEASE RESISTANCE

Unlike muscle and fat traits, which are relatively straightforward to select in breeding programmes (Rothschild 2000; Guldbrandtsen et al. 2002), breeding for disease resistance is more challenging but, in recent years, there has been a noticeable rise in research into porcine disease resistance, conducted in both academia and industry.

Phenotypic Markers

There has been success in selecting pigs for enhanced immunity. Pigs were selected over eight generations for high and low responses in general IgG antibody production and in certain cell-mediated functions (Mallard et al. 1998). Following *Mycoplasma hyorhinis* infection, high responder pigs had reduced pulmonary damage but more severe arthritis, the latter probably due to accumulation of immune complexes. Although protection was incomplete, high responder pigs appeared better equipped than the low responders to deal with *M. hyorhinis*. Additionally, the high response pigs grew

more rapidly. As cited earlier, in *S. choleraesuis* infection, the innate immune parameters of neutrophil number and performance seemed able to predict relative resistance (van Diemen et al. 2002).

Genetic Markers

Postweaning Diarrhea: Resistance to Fimbriated F18 *Escherichia coli.*

With few exceptions, susceptibility to infectious disease seldom follows a simple pattern of Mendelian inheritance. One such exceptional example of single-gene control of resistance is found in the condition of postweaning diarrhea associated with F18 *E. coli.*

The permissive expression of *E. coli* F18 receptor by the host on its gut lining leads to susceptibility to fimbriated F18 colonization and is controlled by a dominant allele (Meijerink et al. 1997). The gene responsible for F18 bacterial susceptibility has been recently identified as $\alpha(1,2)$-fucosyltransferase (*FUT1*), which exhibits $\alpha(1,2)$fucosylation of glycolipid and glycoprotein acceptors, and is involved in the formation of blood group antigen structures on cell membranes, structures that determine the adherence of F18 bacteria. The causal mutation within *FUT1* has been narrowed to a point mutation at nucleotide position 307 where the residue guanine ($M307^G$), corresponding to a codon for alanine, is replaced by the residue adenine ($M307^A$), coding for threonine (Meijerink et al. 2000). There is a high correlation between the single-nucleotide polymorphism and F18 *E. coli* susceptibility, such that the dominant F18 susceptibility genotypes are homozygous $M307^{GG}$ and heterozygous $M307^{GA}$, where at least one allele has the alanine codon, whereas the recessive F18 resistant genotype is homozygous $M307^{AA}$, where both alleles house the threonine codon (Frydendahl et al. 2003). It should be mentioned that pigs with the resistant $M307^{AA}$ genotype are more, but not completely, resistant to F18 *E. coli* infection as other, as yet undetermined, factors are likely to be involved in the pathogenesis of the disease. Meanwhile, other fimbriated enterotoxigenic *E. coli* will continue to pose a threat for postweaning diarrhea syndrome.

Neonatal Diarrhea: Resistance to Fimbriated F4 *E. coli.*

The *E. coli* fimbrial types that are responsible for neonatal diarrhea are F4 (K88), F5 (K99), F6 and F41, of which most is known about type F4. There are three F4 antigenic variants: F4ab, F4ac and F4ad (Python et al. 2002). Like fimbriated F18 in postweaning diarrhea, adherence of F4 *E. coli* to the small intestinal epithelium, leading to host susceptibility, is a dominant trait (S), inherited in a Mendelian manner. Only pigs with the homozygous recessive *ss* genotype are resistant to F4 bacteria challenge (Sellwood 1979). By linkage analysis, a candidate locus, designated *F4bcR*, has been identified that relates to F4ab and F4ac bacteria colonization (Python et al. 2002). The locus is located on chromosome 13, and the putative receptor gene involved may be related to a type of transferrin. To date, the gene responsible for the pathogenicity of F4 *E. coli* has not been formally identified, but it is likely to be established in the not too distant future. It would then be interesting to determine the effects of the causal gene at *F4bcR* on the differential binding of the three F4 antigenic variants. Like *FUT1*, its effect is likely to be fimbrial type specific. In the future, there is the real prospect of producing pigs that are resistant to both F18 and F4 fimbriated *E. coli*, which should have a dramatic effect on piglet diarrheas.

Salmonella Resistance: Nramp1.

Nramp1 (Natural resistance-associated macrophage protein) is an integral membrane protein that resides in late endocytic vacuoles of macrophages where it removes divalent ions (Fe^{2+} and Mn^{2+}) from the vacuolar compartment (Boyer et al. 2002; Dangl 2003; Kehres and Maguire 2003). An environment deficient in Mn^{2+} and Fe^{2+} is detrimental to bacterial growth, and hence an effective Nramp1 would render greater host resistance to intracellular pathogens, like *Salmonella*. Its function in resisting disease is evident in several animal species. Inbred mice susceptible to infections are associated with a single substitution of aspartic acid for glycine at position 169 of the protein (Vidal et al. 1993). Polymorphisms found in human and poultry Nramp1 are associated with susceptibility to tuberculosis and *Salmonella enteritidis*, respectively (Kramer et al. 2003; Abe et al. 2003). Porcine *Nramp1* has been mapped to chromosome 15 (Sun et al. 1998) and cloned (Zhang et al. 2000). No association study between porcine Nramp1 polymorphism and *Salmonella* resistance has been reported. However, genetic variation in porcine resistance to *Salmonella* infection was recently demonstrated (van Diemen et al. 2002), and a causal relationship between Nramp1 and *Salmonella* resistance may well be found in the near future.

Swine Influenza: Porcine Mx Genes.

Swine influenza, caused by influenza A virus, an orthomyxovirus, is a major cause of respiratory disease, and together with porcine reproductive and respiratory syndrome (PRRS) significantly contribute to the problem of postweaning respiratory disease. Additionally, swine influenza has wider significance in the evolution of human and avian influenza viruses. Human and avian influenzas are effectively species specific due to species differences in cell surface sialyoligosaccharides. The pig, however, is potentially susceptible to both human and avian influenzas and could act as an intermediate host to the emergence of new viral strains with the potential to cause devastating epidemics, in the animal or human population (Wentworth et al. 1997). Measures that can reduce the incidence of swine influenza will promote pig welfare as well as carry substantial indirect benefits to human and avian health. One strategic approach to re-

ducing swine influenza in pig herds is to identify and breed from animals that display enhanced resistance to the disease.

The best-documented innate antiviral protein that specifically inhibits influenza virus is encoded by the α/β interferon-inducible *Mx* gene family, whose GTPase protein products are localized either in the nucleus (e.g., murine *Mx1*) or cytoplasm (e.g. human *MxA*). The specific antiinfluenza activity of *Mx1* protein is dependent on its GTPase activity (Melen and Julkunen 1994; Toyoda et al. 1995), but independent of a functioning immune system (Horisberger 1995). Murine *Mx1* protein neutralizes influenza infection by blocking viral mRNA synthesis within the nucleus, probably by interaction with the viral polymerase subunit PB2 (Huang et al. 1992; Stranden et al. 1993). *Mx* proteins also have a broader spectrum of antiviral activity, against vesicular stomatitis virus (VSV), dhori virus, and thogoto virus (Zürcher et al. 1992; Haller et al. 1995; Thimme et al. 1995; Frese et al. 1996). In mice, resistance is inherited as an autosomal dominant trait, conferred by the functional allele *Mx1*+. The recessive allele *Mx1*⁻ is nonfunctional, as a result of a deletion or non-sense mutation. The cDNA and genomic DNA of porcine *Mx1* and *Mx2* have been cloned (Müller et al. 1992; Horisberger 1992). The two porcine genes are arranged in tandem on chromosome 13 (own unpublished data). Early work on the in vitro induction of porcine *Mx* proteins correlated with inhibition of influenza virus and VSV (Horisberger 1992). Three porcine *Mx1* polymorphisms, comprising a silent mutation and a deletion-frame shift mutation, have been identified from several pig breeds (Morozumi et al. 2001; Asano et al. 2002). It will be interesting to see if polymorphisms in *Mx1* or *Mx2* gene are related to differences in influenza susceptibility.

QUANTITATIVE TRAIT LOCI (QTL) AND MARKER-ASSISTED SELECTION

The genetic markers listed above are examples of QTL because they are genetic loci that contribute to variation in the analyzed quantitative (complex) trait of the chosen population. QTL can also be identified by whole genome scans as well as targeted searches on specific areas of the genome. The strength of this approach is that we do not need to make many assumptions about physiological mechanisms. The disadvantage is that preexisting knowledge is not taken into account in the study. Chromosomal regions harboring QTL can be detected by linkage or association analyses, but further work is usually necessary to identify the causative mutation and here a knowledge of physiological mechanisms can be very useful (Segal and Hill 2003). A variety of QTL for disease resistance have been identified including resistance, as assessed by rectal temperature and neurological signs, to the neurological syndrome of Aujeszky's disease (Reiner et al. 2002b). Although all infected pigs

developed fever and nearly all Large White pigs showed neurological signs, none of the Meishans was neurologically affected. QTL for leucocyte counts, neutrophil phagocytosis, lymphocyte proliferation, IL-2 production, virus-induced IFN-α production, and antibody response to F4 *E. coli* vaccination (Edfors-Lilja et al. 2004) were found in 200 F2 wild pig-Swedish Yorkshire crosses.

In summary, in the struggle to minimize the effects of infectious diseases in pig production, there is increasing attention given to the genetic development of disease-resistant animals. The prospects of breeding pigs that are resistant to specific diseases are real and, given current research efforts, many more genetic markers for porcine diseases can be expected in the not too distant future.

62 Preweaning Mortality

Ross S. Cutler, V. Anthony Fahy, Greg M. Cronin, and E. Murray Spicer

Preweaning mortality is a major cause of wastage in pig production. On the best farms with young herds as few as 7% of those born alive die before weaning. Throughout the world on commercial farms preweaning mortality rates generally fall between 10 and 20% (Table 62.1).

In the U.K. the Meat and Livestock Commission (2003) reported a preweaning mortality rate for liveborn piglets of 12.2% in indoor herds and 9.9% in outdoor herds. Some data (MLC 1986) suggested that as litter size born alive has increased, so too has preweaning mortality, but, in 2002 litter sizes in the MLC (2003) study were about 0.5 pigs higher than they were in 1986 and preweaning mortality rates remained steady.

Over half the preweaning deaths occur in the first 4 days of life, and most of these occur in the first 36 hours. The majority of sows successfully rear their litters, but aged sows, sows with large litters, litters with unevenly sized pigs, and sick sows have disproportionately high preweaning mortality (Friendship et al. 1986; Pettigrew et al. 1986; Spicer et al. 1986a, Holyoake et al. 1995).

Although some disease outbreaks have a profound impact on neonatal pig survival, the resolution of day-to-day preweaning mortality problems relates to the attitude, diligence, and skill of the farrowing-house staff in supervising farrowing, providing weak pigs with colostrum, and making sure the piglets are warm. Contributing factors also include the distribution of creep heat, farrowing-crate and farrowing-pen design, the thermal comfort of the sow, disease control, and sow nutrition. Some studies (Dyck and Swiestra 1987) conclude that an inadequate milk supply is the primary factor contributing to piglet deaths and may account for in excess of 85% of the losses.

FACTORS AFFECTING PREWEANING MORTALITY

Birth weight

Birth weight is the single largest predictor of survival in pigs (Stanton and Carroll 1974). It is directly correlated with the energy intake of the sow during pregnancy but there is a considerable variation in response and it is often quite small. Baker et al. (1969) and Libal and Wahlstrom (1977) found that weights of newborn pigs increased as sow gestation energy intake increased but leveled out at about 26.4 MJDE/day. Feeding levels that increase net sow body weight by about 30 kg during gestation will be sufficient to sustain acceptable birth weights.

As litter size increases from ≤11 to ≥16, birth weight decreases from 1.59 to 1.26 kg, or about 35 g for each piglet born. In these large litters the number of pigs weighing less than 1 kg increases from 7% to 23% of total born. Below 1 kg more than 11% of pigs are stillborn and thereafter more than 17% die in the first 24 hours, compared with 4% and 3%, respectively, in pigs weighing more than 1 kg at birth (Quiniou et al. 2002). Uterine blood flow per fetus and hence fetal nutrition decreases as litter size increases (Pere et al. 1997), so within-litter variation in birth weight is already established by 35 days of pregnancy (van der Lende et al. 1990). In litters of low average birth weight, it is the high variation in birth weight that contributes to reduced survival (Milligan et al. 2002).

Low birth weight pigs have an increased risk of dying from asphyxia during delivery (Herpin et al. 1996). This was directly responsible for the deaths of 5.5% of the liveborn pigs. Nonetheless it does not necessarily follow that pigs of low birth weight will always have higher mortality rates. For example stillbirths and preweaning mortality rates for Jan Xin and Large White breeds are similar, yet the Jan Xin average birth weight is only 50% that of the Large White (0.7 kg vs. 1.4 kg) (Le Dividich citing Bidanel personal communication 1999). Biensen et al. (1998) argued that the growth of Meishan fetuses between day 90 and term depends on a combination of increases in placental size and density of placental blood vessels, whereas Yorkshire fetuses relied exclusively on placental growth to increase the surface area for nutrient exchange between the sow and her litter.

Table 62.1.   Preweaning mortality rates from published studies

Country	Author	Data Set	Number Weaned per Litter	Preweaning mortality Rate* (%)
Australia	Cleary et al. 2003	22,000 sows	9.2	13.5
Canada	Friendship et al. 1986	30 farms	8.2	18.6
Canada	PigChamp[1]	69 farms	9.3	12.2
France	Quéméré et al. 1993	53 farms	9.2	14.0
Netherlands	Anon. 1986	36,000 farms (national survey)	8.7	14.2
United Kingdom	MLC 1986	270 farms	9.6	11.5
	MLC 2003		9.7	10.8
	PIC UK 1996	360 indoor herds	9.6	12.2
		122 outdoor herds	9.2	13.3
United States	Cromwell et al. 1989	1080 litters	8.2	16.8
United States	PigChamp[1]	515 farms	9.3	12.2
Venezuela	Gonzalez et al. 1987	461 litters	8.0	12.1

*Rate of pigs born alive.
[1]www.pigchamp.com/overview6.asp and www.pigchamp.com/overview5.asp

Fetal weight gain is most rapid in the last 10 days of pregnancy. More than 50% of fetal energy reserves are deposited in the last month. Moser and Lewis (1981) concluded that supplemental fat in sow diets increased the fat content of milk and colostrum and decreased the preweaning mortality from 18% to 15.4%. Pettigrew (1981) indicated that it was necessary to feed 1 kg/day of fat to the sow in the last 10 days of gestation to demonstrate an effect on the piglets. Improvement in survival is unlikely if the average piglet birth weight is normal (i.e., 1.3–1.4 kg) and preweaning survival is more than 85%.

Although the value of feeding fat in the last 10 days of gestation is equivocal, higher energy intakes for longer periods may be worthwhile. Cromwell et al. (1989) demonstrated that feeding an extra 1.36 kg/day of a maize or sorghum diet (14% protein) from day 90 of gestation resulted in greater sow weight gain to term, more piglets born alive, and, as a consequence, more pigs alive at 21 days. Pigs born to high–feeding-level sows were heavier both at birth and at 21 days of age.

Unlike most newborn mammals pigs do not possess brown adipose tissue so the maturity and hence capacity of skeletal muscle to shiver and preserve body temperature is critical. Indeed explanations for increasing neonatal survival are likely to be found in a higher degree of maturity or fetal development during late gestation (Leenhouwers et al. 2002). Heavier pigs at birth have a lower critical temperature (LCT) and can more readily mobilize their fat or glycogen reserves. Pettigrew et al. (1986) were unable to increase survival solely by feeding corn oil to baby pigs, indicating survival is due more to environmental factors than individual-pig nutrition

Farrowing Crate Design

Where sows are closely confined, neonatal mortality from trauma has generally been reduced compared to sows farrowing in unconfined conditions. The farrowing crate is that portion of the pen that confines the sow. Jones et al. (2003) assessed seven different farrowing systems including nonrestraint systems. They found

that the best and most consistent system was a crate with a fully slatted floor, with a preweaning mortality rate (PWMR) of 11.81%. A nonrestraint system with fully slatted floors and a hinged gate, which when opened allowed the sows to turn around five days postpartum, performed next best (PMWR 15.11%). Nonrestraint systems with straw performed worst (PMWR 20.22%). The research of Weber (1997) indicates that piglet production and survival can be as good in loose pens with straw bedding as in crates, provided genetic selection for careful behavior by sows has occurred and the environmental conditions of the farrowing room are correct.

Spatial Arrangements

Environmental factors influence neonatal mortality. In farrowing pens, two zones can be identified: a safe zone for the piglets, where they can rest free from the sow; and an interaction zone, where the sow and the piglets occupy a common space. The safe zone (creep area) must be attractive and large enough for suckling pigs of all ages, and the piglets must find it comfortable (and prefer it) for resting.

The space requirements of piglets are relative to the thermal environment. In cool conditions piglets huddle and use about 60% of the space they would in warm conditions. Under hot conditions, rectangular creep areas of about 1.3 m^2 will provide adequate space for about 10 pigs of 3 weeks of age (Baxter 1989).

The interaction zone is the most dangerous area in the farrowing pen. For the piglet, the greatest risk occurs when the sow changes posture (to stand, sit, lie down, or move about), especially during feeding, and when the pen is being cleaned (Svendsen et al. 1986). The danger is compounded because piglets prefer to lie against walls or close to the sow even when the temperatures in the pen are very high.

Danger increases if the sow acts suddenly; gentle, deliberate movements are readily tolerated provided there is enough space within the crate for the sow to change posture. However, movement is often restricted due to the length of the crate, in which case sows adapt their

posture or movement but often at the risk of injury to themselves or their piglets (Baxter 1989).

Heating

Curtis (1970) demonstrated that although newborn piglets can mobilize carbohydrate energy reserves in response to cold stress, they utilize it poorly due to physiological immaturity. By 2 days of age the pig can mobilize and use efficiently both glycogen and lipids in response to cold. Thus, the 2-day-old pig has a much better response to cold stress. Protecting the newborn pig is the key priority.

Sows and piglets have different heat requirements. The newborn pig has a LCT of about 30–34°C, whereas the sow's LCT is 15–19°C (Baxter 1989). When the deep body temperature is 39°C at the LCT (34°C), the piglet can generate heat through increased metabolism and conserve heat to a limited degree by piloerection and vasoconstriction. When the environmental temperature falls below 34°C, the single newborn pig is subjected to cold stress and must utilize glycogen and fat reserves to maintain body temperature. Coldness impairs the development of thermostability and induces hypothermia. In farrowing rooms maintained at 17°C, as many as 72% of newborn pigs have rectal temperatures below 37°C. If deep body temperature is reduced by 2°C, piglet vigor is severely reduced. Sucking is less vigorous, and, hence, less colostrum is consumed. As a result, serum IgG levels are lower than in piglets kept warm (Le Dividich and Noblet 1981; Kelley et al. 1982).

Due to their higher surface-area-to-mass ratio, light pigs experience a larger body temperature decrease soon after farrowing than do heavier pigs, further emphasizing the importance of warmth for neonates (Ahlmann et al. 1983). In the creep area, overhead heaters are better than heated pads for lightweight pigs because of the pigs' higher surface area.

Electric or gas heaters are the most common methods of providing warmth for young pigs, but additional comfort factors are required to attract the neonate away from the sow toward the creep area. Large amounts of straw bedding have been the traditional method, but heated floors or heat pads, covered creeps, insulated or heated creep boxes, and carpet have replaced straw on many farms for convenience and safety. Good-quality, deep bedding (sawdust, shredded paper, wood shavings) raises the effective environmental temperature relative to concrete floors by 8°C and is attractive to piglets (Welch and Baxter 1986).

The Importance of Properly Applied Heat. Following birth the piglet has an instinctive desire to remain close to the udder for the first 24–48 hours of life. An extra heat source needs to be provided for this period (Morrison et al. 1983).

With creep areas on both sides of the sow, piglets spent less time lying in the danger zone and mortality was reduced from 19.3% to 6.9% in the first week of life.

Svendsen et al. (1986) reduced mortality in the first week from 7.0% to 1.1% by providing a movable heat source. The addition of a third heat source behind the sow (100 W light bulb) did not further reduce piglet mortality (Ogunbameru et al. 1991). Xin et al. (1996) reported a 19% reduction in piglet mortality for 175 W (5.0%) compared with 250 W radiant heat lamps (6.2%). Piglets subjected to the 250 W heat lamp tended to avoid staying directly under the lamp, an indication of excessive heat. By contrast, piglets under the 175 W heat lamp spread more evenly. In addition, the 175 W heat lamps saved 21% on energy costs and had a 45% lower failure rate than the 250 W lamps. The lower wattage lamps may also benefit the sow, keeping her cooler, due to a narrower radiant beam spread. Where heat sources go unchecked or uncontrolled, very high temperatures have been recorded, as high as 60°C under some heat lamps (Prime et al. 1989).

The effectiveness of electrically heated floor mats (110 W) for piglets after the first day of lactation was compared with 250 W infrared heat lamps by Rousseau et al. (1994). Litters in the heat mat treatment were reported to have a lower level of piglet mortality (6.1% vs. 9.2%), however, 250 W heat lamps were supplied in both treatments: behind the sow during farrowing, then beside the udder for the first day of lactation.

Morrison et al. (1983) also demonstrated the effect of farrowing-house temperature on survival. As farrowing-house temperature was increased from 13.6°C to 20.5°C, liveweight gain to 7 days increased (135 g/day vs. 169 g/day) and 7-day mortality fell (15.1% vs. 10.7%). Ziron and Hoy (2003) tested the effect of a warm flexible piglet nest heating system. Piglets reared in this system weighed 7.72 kg, 0.46 kg heavier at 28 days of age than piglets reared in concrete floored pens with gas heating systems. Pigs reared in the warm nest also had fewer skin lesions than the pigs in the other systems.

Interaction of People and Pigs

Prime et al. (1989) demonstrated how training staff had a positive effect on pigs weaned and how it reduced neonatal mortality. Spicer et al. (1987) described how the successful operation of a crib care system for neonates depended heavily on the diligence of the individual operator. Two operators supervised the care of 600 farrowing sows and their progeny over a 4-week period. Operator A obtained 6.1% mortality (range, 5.5–7.0%) in the first week of life, whereas operator B achieved a piglet mortality of 1.3% (range, 0.95–1.65%) over the same period. Hemsworth et al. (1999) found some moderate correlations between the withdrawal response (as an indicator of fear of humans) of lactating sows at days 16–18 of lactation to an experimenter and stillbirth rate. Sows that were apparently more fearful of humans were more likely to have a higher stillbirth rate. This behavioral variable accounted for about 18% of the variance in stillbirth rate at the farm.

Ravel et al. (1996b) examined personality profiles on independent and integrated farms in Canada. On both

types of farm stock people were more reserved, emotionally stable, serious, conscientious, unsentimental, controlled, introverted, and less anxious than the average person in the general population. High levels of self-discipline in the stockperson were associated with high preweaning performance on both integrated and independent farms, whereas poor preweaning performance was associated with exaggerated self-assuredness and boldness (Ravel et al. 1996a).

Tooth Clipping

Sibling fights occur during establishment of the teat order in the first few days and subsequently as piglets defend their teat-order position against littermates (Fraser 1975; Hartsock et al. 1977). Injury may be inflicted to the faces of littermates or the sow's udder and although the occurrence of the latter is generally reported as low to negligible (Robert et al. 1995; Weary and Fraser 1999), serious udder and teat damage occasionally occurs (Wilkinson and Blackshaw 1987). In addition, clipping *per se* can result in injury to gums or infection (Weary and Fraser 1999; Hay et al. 2004).

Piglets are born with eight very sharp, fully erupted "needle teeth" (the deciduous canines and the corner incisors) (Weary and Fraser 1999). To avoid potential problems, on many farms all eight needle teeth are routinely clipped for all piglets during the first 1–2 days after birth (Robertson and Arey 1998).

The tooth consists of a crown (encased in enamel) and a root, with the gum forming a living seal between the crown of the tooth and the root. During tooth clipping, the crown is fractured close to the gum leaving a cross-section of tooth which contains exposed regions of dentine and pulp. Pulp is connective tissue containing numerous nerves. It is therefore sensitive and a potential route of infection to reach the tooth socket and enter the blood stream. In addition, when force is applied to the tooth during the clipping process, there is potential for significant movement in the area where the gum meets the tooth. Poorly performed teeth clipping can result in serrated or splintered teeth and gum damage, which could greatly increase the risk of infection and contribute to morbidity and mortality (Robertson and Arey 1998). The literature is equivocal that tooth clipping is associated with increased incidence of arthritis and mortality (Hay et al. 2004). Nevertheless, care and hygiene are critical factors during the tooth clipping process.

Concern over the potential adverse impacts of tooth clipping on piglet health and welfare has led to questioning of routine tooth clipping and stimulated investigation of alternatives such as selective clipping, partial clipping, and tooth grinding.

Partial clipping was examined by Weary and Fraser (1999). Three clipping treatments were compared: intact, clipped to the gum line, or partial, in which about one-third of the visible tooth was removed. All piglets of a litter received one treatment on one side of the mouth and a different treatment on the other side, with the three treatments balanced over the two sides in different litters. Facial lesions were negligible on the side facing either partially clipped or fully clipped teeth, while lesions on the side facing intact teeth were greater. In the first week after birth, piglets with fully clipped teeth gained the least, those with partially clipped teeth were intermediate and those with intact teeth gained most. There was no effect of treatment however, on later weight gain or the number of piglet deaths.

Fostering

English and Smith (1975) reported that a major factor affecting preweaning mortality was the degree of variation in birth weight. They argued that piglets of average birth weight were not competitive when mixed with larger piglets. Marcatti Neto (1986) found that piglets with a birth weight of 800 g had a preweaning mortality of 62.5% if left on their dam, compared with 15.4% if fostered into groups with equivalent birth weights. Piglets fostered according to weight also grew faster and had half the mortality of piglets fostered without regard to weight.

Straw (1997) cautions against fostering and questions its value, particularly for older piglets. She argues that fostered pigs grow less rapidly than pigs that remain with their dams. Straw's data indicated that although litter weight variation was reduced by fostering, it came at the expense of individual pig performance. Price et al. (1994) reported that 6 hours after being moved to their new dam, fewer than half the pigs fostered after 2 days of age had suckled. Robert and Martineau (1997) reported increased levels of fighting in fostered litters and an increase in lacerations in fostered piglets, in sow aggressiveness, and in nonproductive milk letdowns. Horrell and Bennett (1981) found that piglets fostered at 7 days had reduced weight gains. McCaw and Desrosiers (1997) demonstrated the success of fostering systems if the pigs were fostered only on the first day, only available teat space was filled, pigs were not moved between different rooms, severely sick piglets were euthanized, and no pigs that were doing poorly were moved back to younger age groups. Their program was targeted at porcine reproductive and respiratory syndrome (PRRS) control, but the recommendations apply equally to herds where PRRS is not present. In contrast Kirkwood et al. (1998), in a study of 120 sows, found no advantage in creating litters of uniform bodyweight. They found that mortality rates were always highest in the smallest pigs regardless of uniformity. Nonfostered pigs always had better survival and the light pigs always had higher mortality rates (20%) than heavy pigs (8.7%).

If fostering is to be applied, it must be done on the first day of life. Creating teat space by weaning a good litter early and then filling the teat space with pigs of the same size will alleviate the concerns of those cautious

about fostering and those wanting to safeguard small pigs. Fostering piglets after teat order has been established, after a day of age, or from older litters to younger litters is contraindicated.

Hygiene

Good shed hygiene is important in reducing preweaning mortality. It may spell the difference between a microbial challenge that the piglet can cope with and an overwhelming infection. Thorough cleaning and disinfecting of empty sow crates help to reduce environmental microbial burdens and more specifically to reduce pathogens that may be exclusive to newborn piglets. Svendsen et al. (1975) demonstrated that both morbidity and mortality associated with gastrointestinal disease were higher in herds with poor hygiene standards. The prevalence of diarrhea fell from 28 to 5% during the year an organized hygiene program was developed. Ravel et al. (1996a) showed that high preweaning performance was associated with routine washing of farrowing crates between litters. Sanitation programs based on thorough cleaning followed by application of disinfectants effective in the presence of organic matter are preferred.

Field data on litters of unvaccinated gilts indicate that piglets born early in the week take 3–4 days before commencing to scour, whereas piglets born later in the week, when the environmental microbiological load is heavy, may show profuse diarrhea within 24 hours of birth (V. A. Fahy 1997, unpublished data). Studies on coccidiosis in pigs reveal that as hygiene measures lessen in intensity, coccidiosis emerges in herds where it had earlier been controlled, indicating that the severity of the disease reflects the intensity of the challenge dose (Stuart and Lindsay 1985).

SOW FACTORS AFFECTING PREWEANING MORTALITY

Prefarrowing Behavior

Studies investigating the effects of manipulating the environment of the young sow have suggested that, apart from affecting prefarrowing behavior, the environment may also affect the course of parturition, postfarrowing behavior of the sow, and piglet survival (Cronin and Smith 1992; Cronin et al. 1993, 1994, 1998; Thodberg et al. 1999, 2002a, b).

Cronin et al. (1993), McGlone et al. (1996), and Thodberg et al. (2002a) demonstrated that by stimulating nesting behavior in young sows, the sows appeared calmer before parturition, had shorter intrabirth intervals or fewer stillborns. Further, Cronin et al. (1998), who investigated sow behavior and piglet survival in loose farrowing pens, reported that small, narrow farrowing pens appeared to interfere with the sows' prefarrowing nesting behavior, with a consequent increase in sow restlessness during and after farrowing and a reduction in piglet survival.

Litter Size

Litter size increases with parity. Although preweaning mortality increases in numerical terms, more pigs are weaned from the larger litters, including those of older sows, until a plateau is reached between four and six litters. As litter size increases, the number of deaths during parturition increases, birth weight decreases, and the number of small pigs per litter increases (Table 62.2) (Spicer et al. 1986a; Dyck and Swiestra 1987).

Sow Health

Spicer et al. (1986a) indicated that 15% of overlain pigs that died were associated with sow illness. An assessment of sow health using the checklist below is an important part of farrowing-house management.

1. Assess water availability. Sows require up to 40 L/day during hot summer days (R. H. King 1997, personal communication). To consume this amount, they need a drinker flow rate of 1.5–2.0 L/minute.
2. Assess feed intake. The target is an average of 6–7 kg/day (80 MJDE/day) between farrowing and weaning.
3. Observe fecal consistency, urine (color and pus), vulval discharge, vomiting, skin pallor, skin wounds, udder condition, abdominal bloat, and lameness.

Table 62.2.   Effects of litter size on stillbirth and birth weight

Litter Size	Number of Litters	Total Born	Preparturient Deaths	Parturient Deaths	Number Weaned	Birth Weight (kg)	Piglets/ Litter <0.8 kg	% Litters with Pigs <0.8 kg	Length of Parturition (minutes)

4. The normal rectal temperature is 39°C ± 0.5°C, but it may exceed 40°C during hot weather.
5. The normal resting respiration rate is 12–30 breaths per minute. Observers should allow for an increase during hot weather.
6. Consider past history, including genetic susceptibility to stress.

Stillbirths

Stillborn pigs represent about one-quarter of all deaths between parturition and weaning. The percentage of pigs born dead varies from 4% to 10%; veterinary intervention is suggested when stillbirths exceed 8%. Approximately 70% of pigs classified stillborn are alive at birth. Although the heart is beating, the piglets are severely anoxic and die within minutes of birth. The anoxia can be related to compression or premature rupture of the umbilical cord during farrowing (Randall 1978). In general, stillborn pigs weigh less than normal pigs and are born after a longer interpig interval (Spicer et al. 1986a) (Table 62.3); however, up to 9% of stillborn pigs may be heavier than average (Evangelista et al. 1996).

Pigs are relatively neurologically mature at birth; hence, a period of anoxia can be serious. As the duration of farrowing increases beyond 4–5 hours, or after 80% of the pigs have been born, the number of stillbirths increases. Most stillbirths occur among the last three pigs born. Svendsen and Andreasson (1980) found that sows kept in stalls during gestation had higher stillbirth rates than sows kept in pens, the difference due to the longer farrowing time in stalls. In fact, the duration of farrowing has a greater impact on stillbirths than parity. Long farrowing times also reduce neonatal survival.

Cutler and Prime (1988) found that about 60% of sows farrowed litters without stillbirth pigs; a small percentage of the sows farrowed most of the stillborn pigs. Sows farrowing two or more stillborn pigs per litter delivered 70% of the total number of stillborn pigs, whereas these sows composed only 17.5% of the farrowings. Bilkei-Papp and Papp (1994) found an increase in stillbirths in fat sows in addition to a greater mortality during the first 3 days postpartum.

Parity. As sows age, the duration of parturition increases, and, consequently, the percentage of stillborn pigs farrowed increases. An exception occurs for parity 1 sows, which have a higher percentage of stillbirths than might be expected if the relationship between parity and stillbirths was linear. Parity 1 sows and aged sows (parity 7–10) have the greatest risk of farrowing multiple stillbirths.

Previous History of Stillbirth. It is unusual for a sow to repeatedly farrow stillborn pigs. However, sows that had multiple stillbirths at the previous farrowing have an increased chance of farrowing multiple stillbirths at the next.

Season. The percentage of stillbirths is higher for sows farrowing during summer (7.3%) than winter (6.4%), although the number of affected sows remains the same.

Strategies available to farrowing-house staff to reduce stillbirths include cooling sows in summer, inducing parturition in old sows, and providing close supervision of high-risk sows, including manual assistance after the seventh pig has been delivered and interpig intervals exceed 30 minutes. Attempting to influence stillbirth rates by chemotherapy is generally unrewarding.

Induction of Parturition

Effective supervision of farrowing can reduce stillbirths and preweaning mortality on farms (Holyoake et al. 1995). Several techniques exist for manipulating the timing and duration of parturition. Although parturition can be induced 3 days on either side of the average gestation length for the herd, piglet survival and vigor are highest when farrowing is induced on the due date for the sow. Farrowing sows earlier than day 112 or after day 118 generally results in increased numbers of stillbirths.

Early farrowings can be prevented by daily injections of progesterone (100 mg) from day 112 to 114 or the use of altrenogest (Regumate) at a dose rate of 20 mg from day 110 (Guthrie et al. 1987). Farrowing is most commonly initiated with an intramuscular injection of natural prostaglandin $F_{2\alpha}(PGF_{2\alpha})$ or a synthetic analog

(Dial et al. 1987). Sows farrow 2–44 hours following injection of $PGF_{2\alpha}$, with a mean time of 22–26 hours. This technique has proved valuable where all-in/all-out systems are practiced to ensure that all farrowings occur within a week.

Several authors have used $PGF_{2\alpha}$ injection followed by 20–30 IU oxytocin 18–24 hours later in an attempt to more closely control the time of parturition (Welp et al. 1984; Wilson 1984). This amount of oxytocin can induce uterine spasms in some sows, which increases the number of stillbirths and the number of manual interventions required (Welp et al. 1984). Holtz and Welp (1984) achieved reliable induction of parturition by combining 5 IU oxytocin with 1.5 mg of carazolol, a beta-blocker that effectively blocks adrenaline receptors in the uterus and allows a lower level of oxytocin to initiate parturition. Carazolol shortens farrowing time and can reduce stillbirths, especially in older sows (Bostedt and Rudloff 1983).

Despite attempts to control the time of parturition with $PGF_{2\alpha}$, many sows still farrow overnight, making supervision difficult. To overcome this, Zerobin and Kundig (1980) injected 150 μg of clenbuterol during labor but before the birth of the first piglet and delayed parturition for up to 15 hours. Zerobin (1980) showed that clenbuterol-induced uterine relaxation could be overridden with higher doses of oxytocin (20–40 IU) without uterine spasms. The following schedule using $PGF_{2\alpha}$ to initiate parturition followed by clenbuterol and carazolol/oxytocin has been successful for farrowings needing special supervision: 9:00 a.m., the sows are dosed with 10 mg $PGF_{2\alpha}$; sows not farrowed by 4:00 p.m. are injected with 150 μg clenbuterol to reduce the chance of overnight farrowing; parturition is reinitiated the following morning using 10 IU oxytocin plus 1.5 mg carazolol (Spicer et al. 1986b).

The success of these regimes in improving piglet survival relies heavily on the quality and assistance of the staff during and soon after farrowing. Some caution with oxytocin administration is indicated. Mota-Rojas et al. (2002) found that although oxytocin-treated sows had a significant decrease in farrowing time and expulsion intervals, they also had significantly more stillbirths than the controls.

CAUSES OF PREWEANING MORTALITY ON INTENSIVE PIG FARMS

Several papers have documented the causes of piglet mortality (Nielsen et al. 1974; English and Smith 1975; Glastonbury 1976). These studies have been based mainly on the autopsy of dead piglets. English and Smith (1975), Spicer et al. (1986a), and Dyck and Swiestra (1987) supplemented autopsy findings with case histories or piglet weights so factors predisposing to illness and death could be documented. The causes of preweaning mortality (Table 62.4) are discussed in the light of the authors' experience, from veterinary diagnostic laboratory submissions, and from the documentation of other investigators.

Enteritis

Enteritis is the most common infectious cause of mortality in suckling pigs. Whereas Glastonbury (1977) found that 5% of all deaths were due to enteritis, the Veterinary Investigation Service (Anoymous 1959), Svendsen et al. (1975), and Spicer et al. (1986a) put the figure at 15%. All these data were recorded before the advent of vaccines to control neonatal colibacillosis and effective coccidial chemotherapy. The causative agents of enteritis in suckling pigs are transmissible gastroenteritis virus, porcine adenovirus, porcine epidemic diarrhea virus (coronavirus), rotavirus, calicivirus, Aujeszky's disease virus, enterotoxigenic *Escherichia coli*, *Clostridium perfringens* types A and C, *Salmonella* spp., *Candida* spp., coccidia, and *Strongyloides ransomi*. The

reader is referred to specific chapters on each agent in this text. On a worldwide basis the organisms most commonly causing diarrhea are *E. coli*, *Isospora suis*, and rotavirus. *Clostridium perfringens* and transmissible gastroenteritis, while not cosmopolitan, are nonetheless important causes of enteritis.

Risk Factors. The following factors associated with an increasing risk of enteritis are drawn from Svendsen et al. (1975).

1. *Parity.* Diarrhea was more prevalent in gilt litters, suggesting a lack of specific antibodies.
2. *Litter size.* The incidence of diarrhea increased with litter size, suggesting lack of access to protective milk antibodies. Similarly, there was an increase in enteritis in litters where the sow was ill or dysgalactic.
3. *Season.* There was a higher incidence in winter, probably due to the effect of cold stress, particularly on small piglets.
4. *Hygiene.* A significantly higher level of mortality was associated with low levels of hygiene.
5. *Age.* More than 60% of deaths occurred during the first week of life, with 10.5% occurring in the second week and 1.3% each week thereafter until weaning. The mortality is inversely proportional to age at onset and directly proportional to the duration of diarrhea (Table 62.5). Deaths from enteritis occurring during the first 5 days of life are usually due to colibacillosis. Deaths associated with enteritis from day 5 to weaning are more likely associated with coccidial infection (Driesen et al. 1993) and enterotoxigenic *E. coli* (F4) (Fahy et al. 2003).
6. *Intercurrent disease.* Fifty-three percent of animals that died with enteritis had intercurrent disease or disabilities, such as polyarthritis, respiratory disease, were small or starved pigs, or had been overlain.

Prevention. Immunity to enteric infections is acquired primarily from passive antibodies, which bathe the intestine and prevent attachment and multiplication of pathogens. Piglets must receive adequate antibodies from colostrum and milk. Parenteral vaccination of the dam is effective against neonatal colibacillosis and clostridial infections occurring in the first 5 days of life. Enteric infections occurring after the first week of life are not well controlled by parenteral vaccination as the IgG levels of colostrum have plummeted to about 10% of their original levels by day 7. Oral vaccination of the dam is the most effective way to stimulate lactogenic IgA antibodies, which will protect the pig for the duration of lactation. In this regard oral vaccination of breeders at around 11 weeks of gestation with F4 hemolytic *E. coli* has proven highly effective at preventing diarrhea and death in suckling pigs (Fahy et al. 2003). Supplementary feeding of fostered and small pigs with colostrum will prevent them from scouring and contaminating the en-

Table 62.5. The association between age at onset and duration of diarrhea and preweaning mortality

Piglets	Number of Deaths[a]	Number of % Deaths	Duration of diarrhea (days)
No diarrhea[b]	1648	103	6.3
1	275	24	8.7
2	90	11	12.2[c]
3	93	15	16.1[c]
Age at onset of diarrhea (days)			
1	125	7	5.6
2–4	123	27	22.8[c]
5–7	77	12	15.6
8–11	64	4	6.3
12	64	2	3.1

[a]Includes deaths from all causes.
[b]Excludes piglets that died before 2 days of age.
[c]Significantly (P <0.05) different from no diarrhea.

vironment. In addition to adequate immunity, both warmth and hygiene play pivotal roles in the prophylaxis of neonatal diarrhea. With the advent of vaccination to control fimbriated enterotoxigenic *E. coli*, it is highly unusual to find these strains as a cause of neonatal scour, or indeed to isolate any common enteric pathogens of suckling pigs. The only thing in common with farms that have this problem is inadequate creep heating for newborn pigs. Invariably when this is corrected the problem disappears.

Treatment. Piglets with diarrhea die when they lose approximately 10% of their total body fluid. In addition to specific antimicrobial therapy, piglets should be rehydrated. Although parenteral rehydration can be given by subcutaneous or intraperitoneal injection, oral rehydration via a stomach tube is the preferred method. The volume to be given daily is 10% of total body water, which is 75% of body weight. A 1 kg pig requires 75 ml/day. Piglets will drink water within a few hours from birth, so the provision of electrolytes in troughs is warranted. These troughs should be wall mounted to prevent them becoming contaminated with feces.

Overlay/Trauma

Overlay, the most common noninfectious cause of death for suckling pigs, accounts for the death of up to 20% of all pigs born alive. Most deaths occur within 4 days of birth (see Table 62.4).

Overlays occur more often in larger litters; in sow, rather than gilt, litters (Svendsen et al. 1986); and in free stall crates rather than crates with modifications such as finger-bars, hydraulic rails, and bowed bottom bars (Walker et al. 1996). The risk of overlay is directly proportional to the number of times a sow stands or sits. Edwards et al. (1986) found from video recordings of overlay incidents that even relatively minor movements by the sow, such as sitting up and lying down again, can

result in the crushing of healthy, viable piglets. Factors that cause sows to be restless increase the chance of overlay: inadequate water supply, sore teats, too many piglets for the number of active teats, and fear of humans. Highly fearful sows are likely to be restless in the presence of stockpersons.

An increased incidence of postural changes (i.e., from standing to lying and vice versa) and increased time spent standing led, in one set of observations, to a higher incidence of overlays for those sows farrowing during, compared with after or before, the stockpersons' work time (G. M. Cronin 1997, unpublished data). This increased overlay rate may be the direct result of the two feeding sessions that occurred during the stockpersons' work time. Olsson and Svendsen (1989) found that 80% of overlay incidents occurred when the sow was standing or changing posture and that almost 30% of these incidents occurred around feeding times. Since the stockperson may be present during feeding, it is not possible to separate the possible effects of feeding per se from the presence of the stockperson in these studies. Vieuille et al. (2003) found that in outdoor herds, crushing occurred in the evening or at night in the first 12 hours after farrowing.

Spicer et al. (1986a) reported that 44% of deaths due to overlay were secondary to illness in the sow or piglet. Sow illness was associated with overlay in 15% of cases. The illnesses included mastitis, agalactia, purulent vulval discharge, rectal prolapse, and inappetence.

Piglet illness or defect was associated with 26% of overlays. These included enteritis, anemia, splayleg, weakness, and pneumonia. Inadequate creep heating is a common risk factor for overlays. Creep heaters that are too hot or too cold result in piglets lying next to the sow, with consequent risks. It is a common mistake for farrowing house staff to try to make up for inadequate creep heating by raising the temperature of the farrowing house. This may exacerbate the problem by making the sow uncomfortable and hence more restless; it will certainly decrease the lactating sows' feed intake (Muirhead and Alexander 1997.)

Necropsy Findings. Overlain pigs display gross deformity and marked bruising. The pigs are flat sided, with the tongue protruding. Death is caused by suffocation or internal hemorrhage. In the former case there is often extensive bruising and edema of the subcutaneous tissue and muscles, particularly of the head and neck. The lungs are usually edematous and petechial hemorrhages may be present in the upper respiratory tract. In those animals that die of internal hemorrhage, the former lesions may be present in addition to the thoracic or abdominal cavities containing extravasated blood. Skull fractures may be evident.

Prevention. Sows should be monitored closely for the first 48–72 hours after farrowing for signs of illness or restlessness, evidence of mastitis, udder edema, and vulval discharge. Check to determine whether the sow is eating and is passing feces. If there is inappetence, make sure that the water supply is adequate and not overly hot, as can happen when plumbing is exposed to direct sunlight. Conversely, frozen pipes will prevent delivery of water.

Since a disproportionate number of traumatic injuries occur during feeding, particular diligence should be applied at these times. Where splayleg pigs are fostered, the foster mother should be a gilt, for they seem more attentive to the shrieking sounds of an overlain piglet, are more agile, and will stand up to release it.

Walker et al. (1996) identified certain combinations of farrowing-crate design and floor type that were associated with higher incidences of piglet overlay. Producers should therefore consider avoiding the following combinations to prevent overlay: either free stall or finger-bar crate with tri-bar metal floor, and bow-bar crate with either polygrate plastic or rubber-coated expanded metal.

Very Small Pigs

The newborn pig is very susceptible to cold stress and hypoglycemia. Coldness impairs the development of thermostability and induces hypothermia. Glycogen and fat reserves are used as major energy substrates for heat production within the first 24 hours of life (Close 1992). Piglets have no brown fat for thermogenesis (Le Dividich and Noblet 1983). They rely first on an increased metabolic rate and then shivering to maintain warmth (Mellor and Cockburn 1986). In the shivering process muscles initially use glycogen stores. Once these are depleted, they use blood glucose, which in turn is replenished from liver glycogen. However, the liver contains a limited supply of glycogen. In addition, glycogenolysis and glycolysis are poorly developed and cannot keep pace with the demand. To avoid hypoglycemia and hypothermia, the piglet needs an exogenous source of energy. They obtain this from colostrum, which provides lactose and fat. Both play a major role in the supply of energy and in glucose homeostasis in the neonatal pig (Le Dividich et al. 1994). Colostrum supplies 60% of the energy required for heat production.

Piglets feed about 15 times in the first 12 hours of life. They take in 15 ml per feeding (Werhahn et al. 1981) and consume about 7 g of lactose, 16 g of fat, and 19 g of immunoglobulin during this time. Not only does colostrum provide lactose but it also has an enhancing effect on the hormonal and metabolic mechanisms controlling blood glucose levels. A fasting newborn piglet can resist hypoglycemia for 18 hours under favorable conditions (28–32°C). However, this is reduced to 12 hours if the temperature is low (18–26°C) (Mellor and Cockburn 1986). Cold stress of the neonate reduces its acquisition of colostral immunoglobulins and results in increased mortality (Blecha and Kelley 1981). Additionally, a delay

in the intake of colostrum after birth will affect the absorption of immunoglobulins: A 4-hour delay in access to colostrum results in 15% of piglets having very low levels of serum immunoglobulin (Coalson and Lecce 1973). Low serum immunoglobulin is associated with higher mortality (Werhahn et al. 1981).

It is against this background that the fate of small pigs weighing less than 800 g is considered. There are two problems: There is a tendency for them to be born weak, and they cannot compete with larger littermates. In the study of Spicer et al. (1986a) pigs less than 800 g had a higher stillbirth rate (25% vs. total stillborn rate of 8.3%), and 62% of those born alive perished, compared with the average of 11.3%. These pigs were assessed as being unable to survive under standard husbandry conditions because they were too weak or small. There was a relationship between birth weight and vitality as determined by the time taken to achieve an adequate first suck (see Table 62.3). The number of small piglets increased markedly in litters with more than 11 piglets; 67% of the litters with more than 13 piglets had some pigs weighing less than 800 g (see Table 62.2). This may reflect a degree of fetal growth retardation due to a small placenta for some of the piglets (Mellor and Cockburn 1986).

The number of mammary glands per pig varies between 8 and 18, with an average of 12. However, 95% of sows have between 10 and 14 glands (Schmidt 1971). The small pig born in a large litter will be the one most likely to miss out. Even if there are enough teats, in older, higher-parity sows with large udders, the top row of teats tends to point upward when the sow is lying down. The small piglet is often unable to reach such teats and will starve to death in the midst of plenty. Because the little pig may be hungry, it is continually at the teat and therefore at a significantly greater risk of being overlain.

Necropsy Findings. Spicer et al. (1986a) found the average age of these small weak pigs at death was 2.3 days; those pigs that survived to that time appeared emaciated and dehydrated. At autopsy there was little, if any, food in the stomach. Glastonbury (1977) found that 17% of 538 dead suckling pigs had empty alimentary tracts. Bille et al. (1974) described a characteristic red-brown color of the striated muscle, which they considered almost pathognomonic for pigs dying of starvation. Often in pigs less than 24 hours of age there are no gross abnormalities, but the size of the pig and absence of food in the stomach prompt a diagnosis of hypoglycemia or hypothermia. Nielsen et al. (1975) reported that 65% of cases of death from septicemia were secondary to low birth weight and starvation and presumably low levels of serum antibody.

Prevention and Treatment. There is much controversy about whether small pigs that are not in excess of func-

tional teats should be fostered. However, where the small pig is in a litter with insufficient functional teats available, it needs to be transferred to a foster sow which has farrowed on the same day and which has an entire litter made up of small pigs. The foster dam also should have a teat line that is accessible to small piglets, hence gilts are favored as foster dams. If a piglet is splaylegged as well as small, a special crate or crib may be required where extra heating is provided. The crib is essentially a temperature-controlled box (30–32°C) where ill or disadvantaged piglets are kept for a limited period of time (usually less than 24 hours) to prevent them from being overlain or dying from hypoglycemia or hypothermia. While they are in the crib, piglets are fed colostrum milked from a sow during farrowing or a commercially available powdered colostrum. Svendsen et al. (1990) found that underweight pigs, both those apparently normal and weak ones, had a greater capacity for absorption of macromolecules, including colostral antibodies, than did apparently normal pigs over 1 kg. The piglets are fed 20 ml of colostrum every 1.5–2 hours using a standard human baby bottle and teat during the period staff are available. Le Dividich et al. (1994) suggested a colostral intake of 12 ml/kg/hour during the first day of life. An electrolyte and a colostrum solution is provided for the piglet to drink overnight. If they do not have a swallowing reflex (or will not drink), they can be fed using a human infant nasogastric tube (French Gauge 8, 40 cm in length). Colostrum can be obtained from the sow by injecting 1–2 ml of oxytocin intramuscularly after one or two pigs have been born; after a few minutes, colostrum can be milked into a wide-necked container and stored at 4°C or frozen until needed.

Piglets selected to be placed in the crib—for example, the small, weak, or splayleg pigs—are those with a high risk of perishing if left in the farrowing pen. Piglets that have survived overlay also respond well to a period in the crib. The rule is, "if in doubt, do not hesitate, place them in the crib." Piglets suffering from hypothermia should be warmed in a bucket of warm water (43°C) for 5–10 minutes, dried, given 20 ml of colostrum via a stomach tube, and placed in the crib.

After receiving nourishment and warmth for 24–48 hours, most piglets can be fostered back to a sow selected for having small nipples and a low teat line to ensure they can readily gain access to milk. Using these approaches small, weak piglet mortality can be reduced to 10–20%, compared with 40–60% under normal husbandry practices.

Neonatal Hemorrhagic Anemia

Spicer et al. (1986a) reported that of 2224 live-born piglets from 238 litters, 4.8% were born anemic (as determined clinically by skin pallor) or became anemic shortly after birth as a result of navel cord bleeding. The preweaning mortality of anemic piglets was 35%, compared with 10% for the remainder of the population.

Anemia was the primary cause of death in 75% of cases and was a major predisposing factor in the death of the remainder. In subsequent studies, using packed-cell volume (PCV) as an indicator, it was found that 6.8% of piglets were anemic (PCV <20%), and 30% of litters had at least one anemic piglet. Statistical analysis indicated that there was a familial effect (Connaughton et al. 1986; Spicer et al. 1986a). Factors contributing to piglet anemia include deficiency of vitamins K or C; toxicity due to mycotoxins, pentachlorophenol, and warfarin; isoimmune thrombocytopenic purpura and isoimmune hemolytic anemia; eperythrozoonosis; and anemia in the sow. Muirhead and Alexander (1997) report that periparturient anoxia will result in excessive retention of blood in the placenta at birth. Martelli et al. (1989) reported that the propensity to bleed is due to a hypofibrinogenemia. Penny (1980) cited data showing that some pale pigs have below-normal levels of platelets. These effects may follow blood loss and the consequent platelet dilution, which accompanies movement of extracellular fluid into the vascular compartment.

Necropsy Findings. Often the umbilical cord is large and fleshy. The skin, muscles, mucous membranes, and internal organs are pale. There is no evidence of internal bleeding, which allows differentiation from pale overlain pigs. PCVs as low as 5% have been recorded.

Treatment. Piglets at risk of bleeding can be identified by their large fleshy umbilical cords; there is also excessive blood on the floor of the farrowing pen. The umbilical cord should be ligated as soon as possible in these pigs. Because they appear to bleed for longer than normal pigs, tail docking and ear notching should be left until 10–14 days of age. Iron is best given orally or in drinking water because excessive bleeding from the injection site follows intramuscular injection. Physical stress of handling should be avoided, for this may greatly increase the tissue demand for oxygen and acute cardiac failure may ensue.

Splayleg
Piglets with splayleg assume a posture in which the hindlimbs or all four legs are laterally extended (Ward 1978). Splayleg is usually evident within 2–4 hours of birth, and the problem has resolved in piglets that survive to 5 days of age. One or several pigs in a litter are usually affected but on occasions the whole litter may be affected. According to van der Heyde et al. (1989), splayleg occurred more often in large than in small litters, with a remarkable breakpoint at eight piglets, and was more than twice as common in male as in female piglets.

Spicer et al. (1986a) demonstrated that splayleg occurred in 5.5% of piglets born alive, and 24% of these died. This is higher than the 0.5% incidence reported by Ward (1978). In the former study afflicted piglets were unable to compete with littermates and died of starva-

tion, hypoglycemia, hypothermia, or overlaying. The death rate was higher (66% vs. 24%) in pigs with both fore- and hindlimbs affected. The average age at death (2.6 days) was similar to that of small weak pigs (2.3 days). There was a greater incidence of splayleg from older sows (0.8/litter) than gilts (0.1/litter).

Splayleg piglets were generally lighter than average (1.20 ± 0.07 kg) and took longer than average to obtain a first suck. Those that survived to weaning had a reduced growth rate to weaning. Offspring from Landrace boars had a 13.7% incidence of splayleg, compared with 4.5% for Large White boars and 3.4% for hybrid boars (P <0.01). Ward (1978) states that in Britain the disease is particularly prevalent within the Landrace and Large White breeds. Identical matings do not always result in splayleg piglets being born (Dobson 1968). The etiology of splayleg is multifactorial, comprising genetic and environmental components (Ward 1978). Slippery floors are an important predisposing environmental factor in the development of splayleg (Kohler et al. 1969). Deficiencies of choline and thiamine may result in splayleg, as does the presence of zearalenone mycotoxin in sow feed, but correction of these problems does not universally eliminate the abnormality.

Treatment and Prevention. The standard treatment for splayleg is to tape (electricians insulating tape) the legs 2–3 cm apart so that they cannot abduct further than in the normal standing position. Where the hindlimbs extend forward beneath the animal after taping, a strip of tape is attached to the middle of the first tape and taken back over the tail to join to a third strip encircling the body in the flank region. A variation of this favored by Gadd (2003) is to tape the hindlimbs in normal position, but to then tape the legs to the body, slightly to one side by placing the tape around the body and the legs just anterior to the pelvis. The animal is left like this for 3–4 hrs and the body tape removed. The theory is that in struggling to get free the muscles regain function much faster than if they are not body-taped. This method will most probably require use of a hospital crib or a creep box in the farrowing pen.

If an animal can move adequately after taping, it can be left with the sow. If, however, they still have difficulty in walking, as is often the case with small piglets that are splayed or piglets splayed in both front and back legs, they need to be transferred to a crib to avoid starvation and crushing. Provision of sows' colostrum is important. Burrin et al. (1995) detected a nonnutrient component of colostrum that has an effect on muscle protein synthesis. By 3–4 days of age the problem has usually resolved. This coincides with the disappearance of histological signs of myofibrillar hypoplasia.

Savaging
Spicer et al. (1986a) found that savaging accounted for 11% of mortalities and was confined predominantly to

gilt litters. This is consistent with the finding that a high proportion of gilts attempt to savage at least their first piglet (English et al. 1977). A survey by Harris and Gonyou (2003) of 7 newly constructed pig farms that had exclusively gilt herds recorded that savaging deaths represented 11.2% of preweaning mortality. The proportions of gilts that savaged piglets and piglets that died from savaging varied widely between farms. Some gilts savage the entire litter. Savaging was responsible for increased mortality in piglets born outside the working hours of the piggery staff (13.7% compared with 9.7%) and was the only significant factor in this mortality difference; only 2 of the 27 piglets savaged were born during working hours (Spicer et al. 1986a). The incidence of mortality due to savaging could be reduced outside working hours of the piggery staff, if farrowing rooms were continuously lit (Harris and Gonyou 2003). During savaging the gilt will snap at any piglet that wanders into reach, behavior similar to that of savage sows toward stock people. Cronin and Smith (1992) and Cronin et al. (1994) reported that the level of savaging in gilt litters was higher when animals farrowed in a large pen without straw bedding than when animals farrowed in a standard farrowing crate (with or without straw bedding) or pen with straw bedding.

Necropsy Findings. The lesions of savaging are essentially caused by the crushing effect of the sow's teeth and jaw. In some cases savaged piglets may be difficult to distinguish from overlain pigs. However, the lesions are more focal and the skin is often broken.

Prevention. Little can be done to prevent savaging in the absence of staff. Therefore, if savaging is a problem, induced farrowing will ensure that the majority of gilts farrow when staff is present. Savage gilts may be tranquilized (1–2 mg/kg of azaperone). Piglets can be placed in a small cage in the creep area as they are born. Once farrowing is over, the piglets can be removed from the cage, and the gilt usually makes no further attempt to savage. The birth weight of savaged piglets was significantly lower than the average birth weight of pigs that survived to weaning (see Table 62.4). Gilts that savage their litters were likely to be those mated at lower body weights (Spicer et al. 1985). The lower weights at mating were due to inadequate feed intake between selection and mating of submissive pigs penned in groups of 20. The problem was overcome by periodically drafting off those animals that appeared to be losing weight. It is unusual for dams to savage more than one of their litters; therefore, there is no valid reason to cull them. However, Knap and Merks (1987) and van der Steen et al. (1988) indicate that it is possible to select against aggressiveness in sows. The selection of boars and gilts from mothers with normal behavior will probably be the most efficient procedure.

Pneumonia

Pneumonia is responsible for the death of around 1% of all live-born piglets (Fahmy and Bernard 1971; Bille et al. 1975; Spicer et al. 1986a). The pneumonia is primarily a bronchopneumonia, and gilt litters are more often affected than sow litters. Bille et al. (1975) found a higher incidence in winter, but the pneumonia was unrelated to the indoor climate or level of hygiene. In most cases, only one pig per litter was affected, with an average incidence of 10% per litter. Organisms isolated include *Streptococcus* spp., *Bordetella bronchiseptica*, *Pasteurella* spp., *Moraxella* spp., *Escherichia coli*, and *Arcanobacterium pyogenes* (Bille et al. 1975), and *Staphylococcus aureus, Pasteurella multocida, Pseudomonas aeruginosa,* and *Citrobacter freundii* (Spicer et al. 1986a).

In a study of pneumonia in 55 baby pigs, Kott (1983) isolated *Haemophilus parasuis, Mycoplasma hyorhinis,* and *Bordetella bronchiseptica*. Pleuropneumonia due to *Actinobacillus pleuropneumoniae* has been reported by Bille et al. (1975) and Cameron and Kelly (1979). Septicemia due to the same organism has been reported in suckling pigs (Thomson and Ruhnke 1965).

Although *Mycoplasma hyopneumoniae* infections are commonly thought to begin in weaned pigs, the organism has been reported from pneumonic suckling pigs; however, microbiological evidence that it is common in such lesions has not been forthcoming (Ross 1986).

Treatment and Prevention. With low mortality levels treatment is probably not a practical procedure due to the difficulty of identifying the affected animals. However, where the problem exceeds a 1% level of mortality, injecting gilts at farrowing with an appropriate antibiotic to lower excretion rate may be warranted. Ensuring piglets adequate access to colostrum is recommended, for the low incidence of the disease and its occurrence in predominantly gilt litters suggest that lack of specific antibodies is a major contributing factor.

Generalized Infections and Septicemia

Field data indicate that as many as 2% of the piglet population die of septicemia (Driesen 1990). Affected piglets were all less than 48 hours of age. Nielsen et al. (1975) surveyed 28,000 live-born pigs and found that 2.1% died from septicemia, 37% of which were primary septicemias, and the remainder were secondary to low-birth-weight starvation or preceding illness; 44% of mortalities occurred before 3 days of age. In a study by Spicer et al. (1986a), septicemias in the first week of life were a secondary manifestation of other causes of mortalities. However, generalized infection was responsible for most deaths in the second and third week of life. Organisms isolated and associated conditions included *Actinobacillus suis*: septicemia, arthritis, peritonitis, and meningitis; *Citrobacter freundii*: septicemia, meningitis, alpha-hemolytic streptococci septicemia: arthritis and meningitis; *E. coli*: septicemia and peritonitis. Glaston-

bury (1977) and Nielsen et al. (1975) found that *E. coli* and beta-hemolytic streptococci were the most common causes of septicemia in dead suckling pigs.

A major predisposing factor in generalized infection would appear to be the quantity and specificity of maternal antibodies absorbed by piglets. In this regard Nielsen et al. (1975) found (1) a significantly higher incidence in piglets of sows with mastitis and agalactia, (2) an increase in mortality from septicemia with larger litters, (3) a higher incidence in open versus closed herds, and (4) a higher incidence in winter.

Necropsy Findings. Often excess fluid and small amounts of fibrin are found in the serous cavities. Lungs may be edematous and fail to collapse. Jaundice, subserosal petechial hemorrhage, and mild dehydration may be seen.

Treatment and Prevention. The most common isolates are *Streptococcus* spp. and *E. coli*; thus broad-spectrum antibiotics may be of use. Therapeutically the success rate is low (Driesen 1990), but prophylactic treatments are worthwhile. Prevention should be aimed at ensuring adequate intake of colostrum for all piglets and providing adequate heating.

Miscellaneous Causes of Death

This group includes anal atresia, cleft palate, renal hypoplasia, hydrocephalus, and accidental death and accounts for 1.2% of all pigs born alive (Spicer et al. 1986a). A summary of the prevalence of specific congenital defects of pigs is provided by Edwards and Mulley (1999). A summary of their prevalence and etiologies is presented in Table 62.6.

REDUCING PREWEANING MORTALITY

Cutler et al. (1989) reported farm studies where preweaning mortality rates were reduced by paying attention to staff training and attention to detail in the farrowing house. After an intensive period of "hands-on" staff training and demonstration, farrowing-house performance was monitored and preweaning deaths fell by 5–7%. Holyoake et al. (1995) in a study of 250 sows were able to decrease both stillbirths and preweaning deaths by inducing sows to farrow with cloprostenol (250 µg) combined with constant staff supervision from three hours before farrowing to 3 days after. Through supervision, stillbirths were decreased from 0.68 to 0.26 per litter, preweaning deaths per litter decreased from 1.26 to 0.86 and numbers weaned increased from 9.44 to 10.17 per litter. White et al. (1996) reduced preweaning mortality, including stillbirths, by approximately 44% (about a pig per litter) and increased weaning weight in pigs through attending farrowing and implementing a piglet care protocol involving provision of oxygen, drying the pigs, tying the umbilicus, bovine colostrum supplements, and placing the newborn piglets on a teat. In addition to increasing the intensity of staff training and staff awareness, the following measures provide a basis for decreasing neonatal mortality:

1. Provision of written instructions about piglet survival for staff.
2. Thorough hygiene programs for the farrowing house and processing equipment.
3. Creep areas that are draft free and comfortable. Sawdust, wood shavings, shredded paper, or straw are suitable bedding materials.

Table 62.6. Common developmental defects of swine

Defect	Prevalence	Etiology	Diagnosis
Micrencephaly	0.07%	Heat stress midpregnancy	History of heat stress
		Unknown (most cases)	An agent affecting development in early or midpregnancy
Microphthalmia		Vitamin A deficiency	Multiple defects in affected litters; heavy neonatal mortality; history; diet analysis; serum and liver vitamin A analysis
		Hog cholera (HC) infection	HC infection in herd; virus isolation; fluorescent antibody test; serology; congenital tremor AI present in herd
		Heritable	Mode of inheritance uncertain; dominant gene (?)
		Unknown	An agent affecting embryos at 12–16 days of development
Neural tube defects (anencephaly, encephalocele, hydrocephalus, spina bifida)	0.04%	Unknown	An agent affecting embryos at 12–16 days of development
		Vitamin A deficiency (hydrocephalus)	Multiple defects in affected litters; heavy neonatal mortality; history; diet analysis; serum and liver vitamin A analysis
Congenital tremor	0.20%	HC virus (type AI)	HC infection in herd; virus isolation; fluorescent antibody test; serology; affects piglets of all breeds and both sexes; hypomyelinogenesis; cerebellar hypoplasia; neurochemical analysis of myelin lipids of spinal cord; small cross-sectional area of the spinal cord
		Type AII (unidentified virus)	Hypomyelinogenesis of spinal cord; analysis of myelin lipids of spinal cord; small cross-sectional area of the spinal cord
		Type AIII	Monogenic sex-linked gene mutation in Landrace affecting only males and associated with defect in myelin sheath

(continued)

Table 62.6. Common developmental defects of swine (*continued*)

Defect	Prevalence	Etiology	Diagnosis
		Type IV	Autosomal recessive gene in Saddleback affecting both sexes
		Pseudorabies (PR) virus	PR infection in herd; virus isolation; serology
		Neguvon (metrifonate, trichlorfon)	History of dosing sows in midpregnancy; hypoplasia of cerebrum and cerebellum; Purkinje-cell loss; changes in neurotransmitters
Arthrogryposis	0.10%	Tobacco stalks, jimsonweed, poison hemlock, wild black cherry	History of exposure to plants in early to midpregnancy
		Vitamin A deficiency	Multiple defects in affected litters; heavy neonatal mortality; history; diet analysis; serum and liver vitamin A analysis
		HC attenuated vaccine virus	History of vaccination during early pregnancy
		HC infection	HC infection in herd; virus isolation; fluorescent antibody test; serology; congenital tremor AI in herd
		Paramyxovirus infection	Menangle virus infection during pregnancy
		Heritable	Recessive gene (?); autosomal recessive in Yorkshire pigs
		Unknown (most cases)	An agent affecting development in early or midpregnancy
Micromelia	0.10%	Unknown	Possibly caused by limb vascular defects in early pregnancy
Cleft palate/harelip	0.07%	Heritable	Possibly a recessive gene; cleft palate in Poland China pigs probably genetic
		Unknown (most cases)	An agent affecting development in early or midpregnancy
Deformed tail	0.08%	Possibly heritable	Mode of inheritance uncertain; occasionally urogenital defect associated
		Unknown	Often associated with motor defects in hindlimbs; vertebral defects
Myofibrillar hypoplasia	1.05%	Heritable	Most common in Landrace, less in Large White; probably polygenic mode of inheritance; incidence modified by maternal stress, slippery floor, birth weight, maternal nutrition
		Fusarium toxin	Higher mortalities than other forms; feed analysis
Inguinal hernia	0.40%	Heritable	Mode of inheritance uncertain; incidence modified by environment
Umbilical hernia	1.00%	Unknown	Possibly polygenic mode of inheritance
Anal atresia	0.40%	Heritable	Possibly polygenic inheritance or an autosomal recessive or autosomal dominant form of transmission
Hypotrichosis		Heritable in some breeds	Mode of inheritance uncertain
		Iodine deficiency	Stillbirths and high neonatal mortality; enlarged thyroids; skin edematous; feed analysis
Epitheliogenesis imperfecta	0.05%	Heritable	Possibly autosomal recessive gene; hydronephrosis associated
Dermatosis vegetans		Heritable	Autosomal recessive; associated with fatal giant-cell pneumonia
Pityriasis rosea		Probably heritable	Mode of inheritance uncertain; affects young pigs, especially Landrace; benign and self-limiting
Von Willebrand's disease		Heritable	Recessive gene in Poland China pigs; excess bleeding from minor wounds; decrease in factor VIII and platelet retention time
Navel bleeding	0.14–1.2%	Unknown	Cord is edematous, familial linkage
Cardiac defects	0.03%	Unknown	Most cases recognized at 4–8 weeks; mostly males
Cryptorchidism	0.39%	Probably heritable	Polygenic transmission; left testicle most commonly involved
Female genital hypoplasias, duplications	0.68% 0.06%	Probably a heritable component	Mode of inheritance uncertain; genital tract incomplete or duplicated
Male pseudo-hermaphroditism	0.2–0.6%	Heritable	Mode of transmission uncertain; testicles in abdomen together with female tubular tract
True herma-phroditism		Heritable	Mode of inheritance uncertain; testicular and ovarian tissues usually with female tubular tract

4. An additional heat lamp provided toward the rear of the sow during the farrowing period and for 24 hours afterward to reduce the chance of chilling newborn pigs and to provide an extra (lateral) creep area. At birth pigs can be positioned under the heater.

5. Freeing newborn pigs from placenta, drying them, clearing airways of mucus.

6. A heated crib for the care of sick pigs and to house temporarily small pigs (<800 g bodyweight) or pigs from large litters during split suckling sessions.

7. Supervision of pigs to ensure access to colostrum, or supplementation with colostrum substitutes (up to 100 ml/day) or milk replacer by bottle or stomach tube especially for small or weak pigs or for pigs in large litters.

8. An active fostering program based on cross-fostering within 48 hours of birth.

9. Regular inspection of sows and prompt treatments

10. A vaccination program against neonatal colibacil-losis.

63 Longevity in Breeding Animals

Sylvie D'Allaire and Richard Drolet

Poor sow longevity in commercial breeding herds can lead to economic inefficiency and animal welfare concerns. Thus effective culling strategies should be an essential part of herd health management. Culling policies influence herd economic performance in many different ways. A high sow turnover is generally associated with a shift toward younger females, which are less productive, and with an increase in the number of nonproductive sow days. A high removal rate requires larger replacement gilt pools, which will increase disease risks and the cost of production. Difficulty in supplying replacement animals may also lead to a suboptimum population that will decrease the herd output and disrupt pig flow. On the other hand, an excessively low removal rate, will be associated with a higher proportion of older sows, which are more prone to certain diseases and may have lower production levels.

Evaluation of a culling program should include determination of the average longevity in the herd, reasons for culling and death, nonproductive days associated with removal, lifetime productivity, and risk factors for poor longevity.

MEASURES OF LONGEVITY

Determining the average longevity of animals is the first step in assessing a herd culling program, and several measures have been used to define sow longevity: removal rate, culling rate, replacement rate, percent gilts in the herd, mean parity of females in inventory, and mean parity at removal. Others have proposed the use of more economic indicators, such as pigs weaned per day of life or number of herd days per pig weaned (Culbertson and Mabry 1995; Lucia 1997).

The term "removal rate" covers all types of removal, including culling, natural death, and euthanasia. This rate is defined as the number of animals removed from the herd during a year, divided by the average inventory, and multiplied by 100. Culling and death rates should be analyzed separately; in some instances, the number

of euthanasias, which are usually included in the mortality, should also be assessed. Annual removal rates of 35–55% for sows have been reported in different surveys (Dagorn and Aumaitre 1979; Pattison et al. 1980a; Friendship et al. 1986; D'Allaire et al. 1987; Dijkhuisen et al. 1989; Marsh et al. 1992; Paterson et al. 1997a; Boyle et al. 1998).

Because these values represent average rates, higher or lower rates may be found on individual farms, ranging from 20% to 70%. However, high removal rates seem to be more frequent than excessively low rates. A target of 39–40% is recommended: 35–36% for culling and 3–5% for death (Muirhead 1976; Dial et al. 1992). Target values should be adjusted for individual farms, because the removal rate is influenced by many factors, such as herd size, genetic turnover desired, breeds, definition of the average inventory, and population dynamics. Higher rates are to be expected for seed stock herds to ensure genetic improvement and to reduce the genetic lag for commercial producers. Market trends and economic conditions also influence a producer's culling decision and timing (Brandt et al. 1999; Stalder et al. 2004).

A breed difference in longevity has been observed by some authors, with Yorkshire and Large White sows having longer lifetimes than Landrace sows (Dagorn and Aumaitre 1979; Kangasniemi 1996). Others have found no difference between these breeds (Cederberg and Jonsson 1996). In general, purebred sows are less robust than hybrid sows (Kangasniemi 1996; Sehested and Schjerve 1996; Jorgensen 2000); however, this finding might be confounded by the genetic selection occurring in nucleus herds. Nevertheless, several researchers have reported heritability estimates for longevity ranging from 0.05–0.27 (Tholen et al. 1996; Lopez-Serrano et al. 2000; Yazdi et al. 2000; Fortin and Cue 2002). A difference of almost one parity at removal was observed between some genetic lines (Rodriguez-Zas et al. 2003). Collectively these results indicate that selection of a source of breeding stock might impact the producer's ability to improve sow longevity.

1011

Comparisons of sow removal rates between herds or studies are often difficult because the definition of "average female inventory" may be different. The inventory may refer to sows only or to sows and gilts, with gilts being introduced at different times in their production cycle. For a better standardization of terminology, it has been suggested that only mated females be considered in the calculation of the annual removal rate. On some farms, however, culling of gilts introduced into the breeding herd but not yet mated is very high and may require more investigation.

The annual removal rate for the herd is also influenced by specific circumstances, such as a change in the inventory, a change in the culling policies, and the average length of the lactation period. A decrease in the inventory will increase the culling rate for the corresponding year; conversely, an increase in the inventory may decrease the rate if the producer culls less extensively in order to increase the number of females. On some farms, an involuntary cycle is established in culling patterns. For example, a producer realizes that the herd is getting older and reacts by culling more extensively that year. The following year, the rate may be lower because a large proportion of the herd is now very young. This is not counterproductive in itself but it makes production planning more difficult and herd output less constant. Information on such changes in culling policies is needed to evaluate a program. A cycle in culling patterns may also occur in newly established or repopulated herds.

The average length of lactation for the herd may also influence the annual removal rate. Herds with shorter lactation periods tend to have higher removal or death rates even though the mean parity at culling is similar (D'Allaire et al. 1989; Paterson et al. 1997a; Koketsu 2000). A reasonable explanation is that the number of litters per sow per year is higher when the lactation period is shorter. Because a sow has a certain probability of being removed during each farrow-to-farrow interval, more farrowings per year result in a higher annual probability of being removed.

Longevity of sows in the herd can also be evaluated by the replacement rate, which is defined as the total number of animals entering the herd divided by the average inventory and multiplied by 100. The removal rate and replacement rate should be similar in a stable herd if the inventory remains constant. However, in a herd undergoing expansion, the replacement rate may be higher than the removal rate. Conversely, when reduction in herd size occurs, the replacement rate may be lower than the removal rate. Therefore, population dynamics should be considered when analyzing these rates.

The mean parity of sows at removal indicates the average length of time that sows stay in the herd; however, because the mean can be influenced by extreme values, a parity distribution of removed sows is usually more in-formative. Breeding-life expectancy is low in most swine breeding herds. Several studies reveal that the average parity at removal is between 2 and 5.6, but it can vary from 2 to 8 for a particular herd (Arganosa et al. 1981b; D'Allaire et al. 1987; Stein et al. 1990; Pedersen 1996; Koketsu et al. 1999; Lucia et al. 2000). Sows are removed from breeding herds at a very young age considering that the "natural" longevity would most likely be 12–15 years (Pond and Mersmann 2001).

A high proportion of females are removed in their early parities. Gilts and first-parity females often represent a large proportion of the cullings, with percentages of up to 40%. Considerable losses are involved with such high removals of young females (see section on "Effects of Sow Longevity on Herd Productivity"). Many authors have reported that from 50–69% of the removals occur before the fourth litter (Dagorn and Aumaitre 1979; Arganosa et al. 1981b; D'Allaire et al. 1987; Kangasniemi 1996; Lucia 1997; Paterson et al. 1997a). The probability of being removed is highest for parity 7 and over, followed by parities 0 and 1 (Tiranti et al. 2004). The risk of being removed for some specific reason is also different among parity groups; for example, there is a higher risk of culling for reproductive and locomotor problems in first-parity females and for inadequate performance and old age in advanced-parity sows (Lucia et al. 1996; Paterson et al. 1997a, b; Boyle et al. 1998).

The parity distribution of the herd is also useful to evaluate the longevity, because it indicates when the sows are more likely to be removed. As stated by Dial et al. (1992), it is difficult to recommend a standard parity distribution. The optimum parity distribution for litter size on one farm may be different from that on another farm, considering the breed, the cost of replacement, the type of facilities, and the husbandry skills. The relationship among parities should, however, be optimized to achieve an ideal parity distribution. To obtain an optimum herd maturity, 90% of the gilts that are started in the herd should reach parity 1, and 90% of the parity 1 animals should reach parity 2 (Leman 1992). Other optimal parity distributions of females in commercial breeding herds have been suggested (Table 63.1). To achieve these targets, it is imperative to limit the culling of younger females from the herd.

REASONS FOR REMOVING SOWS

Sows are culled when they are considered unsuitable for further production. A knowledge of the reasons for removal can be beneficial in identifying underlying diseases or management problems. The list of reasons can be as complete as desired, but for the purpose of data analysis, the reasons should be summarized according to a few categories. Although the classification of reasons has varied between studies, there is reasonable agreement and detailed information to allow regrouping and comparison of reasons. Data from different studies reveal

a general pattern of removal in which reproductive failure is the main reason for culling, followed by old age, inadequate performance, locomotor problems, death, and milking problems (Table 63.2). The culling pattern, however, varies slightly over time and according to the country. The predominant causes of removal may also vary among herds and among parities.

Some authors have used the terms "voluntary" (planned) and "involuntary" (unplanned) removal. A strict definition is difficult; ultimately all removals except death are voluntary. In general voluntary removal refers to culling for old age, inadequate performance, poor progeny, and poor milking, for which the producer makes the decision concerning the cause and the time of removal. Involuntary removal refers to other causes, such as locomotor and reproductive problems, for which the producer does not have as much control. Voluntary culling allows minimization of nonproductive days and better planning of the introduction of replacement animals.

Reasons for removal can be analyzed according to two rates: a proportionate rate, which is the percentage of all removals attributable to a specific reason, and a reason-specific removal rate (D'Allaire 1987). The proportionate rate is useful in indicating the relative importance of a given reason in the total culling picture and helps in determining priorities for improving the herd. The reason-specific removal rate is defined as the number of animals removed for a specific reason divided by the average inventory, multiplied by 100, and measures the annual probability of an animal being removed for that specific reason and indicates the extent of a problem. This latter rate is more informative and is not influenced as much by the number of animals removed for other reasons as the proportionate rate is. As an example, two herds, A and B, both have 15% of their removals due to death (proportionate rate). Herds A and B have an annual removal rate of 20% and 60%, respectively. In herd A, the removal rate for death (reason-specific removal rate) is acceptable, at 3% (20% × 15%); in herd B, this rate is three times higher, at 9% (60% × 15%), although the percentage of all removals for this reason is identical. Unfortunately, in most of the literature, only the proportionate rate is used. In Table 63.3, the average and range of reason-specific removal rates and the mean parity at removal are reported for seven reasons.

Reproductive Failure

Reproductive failure is used to define a variety of conditions: no observed puberty in gilts, no observed postweaning estrus, regular and irregular returns to estrus, negative pregnancy diagnosis, failure to farrow, and abortion. Reproductive failure is the predominant reason for culling, representing between 13% and 49% of all removals. The greatest number of nonproductive days since the last weaning is observed for this category (Paterson et al. 1997a). Thus, good reproductive management with an increased awareness of the reproductive state of each sow at all times should be emphasized.

Table 63.2. Reasons for removing sows and percentage of removals for each reason: Results obtained from 16 studies involving more than one herd

Source	Reproductive Failure	Old Age	Inadequate Performance	Locomotor Problems	Death	Other	No. of Herds or Sows	Country

[a]Study A involved 19 Australian herds with 9096 removed females, including mated gilts. Adapted from Paterson et al. 1996, 1997a.
[b]Study B involved 89 American herds with 7242 females, including selected but unmated gilts. Adapted from D'Allaire et al. 1987.

Young females are more likely than older sows to be culled for reproductive failure (Dagorn and Aumaitre 1979; D'Allaire et al. 1987; Dijkhuizen et al. 1989; Stein et al. 1990; Lucia 1997; Paterson et al. 1997a). The average number of litters produced by these culled sows is between two and four. Inefficient estrous detection, mating at an early age, improper male stimulation, use of young boars that are less mature and can more easily be overused, improper nutrition, infectious or toxic agents, management practices, and environment may be responsible for these high levels of culling for reproductive failure in young females. Older sows that have stayed in the herd also have undergone a selection process and may be less prone to reproductive failure.

Failure to conceive, to maintain pregnancy, or to farrow after a successful mating are the major problems reported. The risk of being removed for failure to farrow was greatest for parity 0 sows (Paterson et al. 1997a). Females that did not conceive are often found only late into their presumed gestation. Sows culled for return to estrus stayed in the herd for an average of 75–79 days, whereas sows removed because they failed to farrow remained for 121–132 days after weaning (Pattison et al. 1980a; Paterson et al. 1997a). It is important to decrease this period of nonproductive days, for it is very costly because of the extra feed and labor required as well as the underutilization of production facilities. To decrease this period, management must differentiate between late loss of pregnancy and late detection of nonpregnant females; these two variables indicate different problems that necessitate different solutions on a farm.

The proportion of females culled because they do not exhibit estrus either at puberty or at weaning is lower than that of sows failing to conceive. However, gilts and first-parity sows are more likely to be removed for anestrus than older sows (Lucia 1997; Paterson et al. 1997a). The acceptable period between introduction or weaning and mating differs among farms and may be partly responsible for the variation in proportion of animals culled. The length of the period allowed is worth investigating; on some farms it might be too short, espe-

cially for younger females, which usually have a longer interval from weaning to breeding, thus unnecessarily increasing the number culled. Comparing farmers' decisions to cull with economic model recommendations, Dijkhuizen et al. (1989) found that females culled for absence of estrus were removed too early from the herd, particularly the younger and high-producing sows. The calculated allowable interval from weaning to removal averages 66 days for first-parity sows, whereas the actual interval was 36 days. Abortions do not seem to be a major reason for removal, generally representing less than 3% of all cullings, except in herds experiencing an outbreak of porcine reproductive and respiratory syndrome (PRRS).

When the proportion of culling for reproductive failure is high, a slaughter check may be useful to compare the reasons given by the producer and the physiologic status of the reproductive tracts. Josse et al. (1980) examined 338 reproductive tracts and compared the findings with the reasons for culling reported by producers. The reason for removal could not be substantiated in 36% of the cases. Einarsson et al. (1974) found similar results in a study of genital organs in gilts: of 54 gilts culled for anestrus, 23 had apparently active corpora lutea and 2 were pregnant. Possible explanations for these discrepancies are inefficient estrous detection or pregnancy testing, silent heat, or physiologic changes occurring between the decision of culling and slaughtering.

Old Age

Old age is often the second most likely reason for removal, accounting for 3 to 33% of all removals; the average parity at culling varies between 7 and 9. As the proportion of sows removed for other reasons decreases, the percentage of sows culled because of old age increases. Overlappings between "old age" and "inadequate performance" are likely to occur, for old sows may experience a decrease in productivity. Old age is relative; some producers routinely cull sows as soon as the fifth or sixth parity, and others only after the tenth litter. Some researchers suggest culling older sows when productiv-

ity in terms of live-born pigs is comparable with that of gilts. This method, however, takes into account only the number of live-born pigs. According to a model developed by Dijkhuizen et al. (1986), the economic optimal herd life for average-producing sows is generally 10 parities. Rarely is it economically beneficial to cull sows before parity 8, considering the economic losses associated with the cost of replacement, the lower litter size and farrowing rate, and the longer interval from weaning to mating in younger sows. Their model took into account the annual replacement rate, the average parity of farrowing and removed sows, the average slaughter price of culled sows, and the cost of replacement gilts.

Inadequate Performance

This category includes a variety of reasons: small litter size at farrowing or weaning, high preweaning mortality, and low piglet birth or weaning weights. Inadequate performance is usually ranked as the second or third most common reason for culling sows, with a range of 4–21% of removals attributable to this category. Pomeroy (1960) reported that inadequate performance was the main reason for removal, accounting for 33% of all cullings. However, management was different in those years; herds were smaller, usually fewer than 10 sows, and were farrowing outside. The preweaning mortality was also high, up to 48% during certain months of the year.

In a herd with a high level of culling for inadequate performance, a parity analysis is useful. If too many young animals are culled for this reason, action should be taken because it is well known that litter size increases with parity until the third litter. In such a herd, the benefit of culling sows for the purpose of improving productivity might be lost because of a decrease in herd productivity associated with a high proportion of young sows. Culled females will have to be replaced by gilts, which are not very predictable. Dijkhuizen et al. (1986) asserted that parity 1 sows with a litter size of even 50% below average should not be culled on economic grounds. Moreover, the repeatability of litter size is low, which means that predicting the next production from the previous one is very inaccurate.

Locomotor Problems

Locomotor problems refer to a variety of conditions, including osteochondrosis, osteoarthrosis, osteomalacia, arthritis, leg weakness, posterior paralysis, foot rot, foot and leg injuries, and fracture. Dewey et al. (1993) examined 51 sows culled for lameness and found that osteochondrosis, followed by infectious arthritis and foot lesions, was the major underlying cause. The proportion of sows removed for locomotor disorders varies between 9% and 20%; some reports, however, have indicated a percentage as high as 45%. It is imperative when investigating culling for locomotion and leg problems to analyze concurrently the death rate (see section on "Death").

In sporadic cases of very high removal for locomotor disorders, housing and flooring types have often been incriminated (Jones 1967; Smith and Robertson 1971). In general, group housing is associated with more injuries, presumably because several animals of different ages are kept together; whereas individual housing is related to a higher incidence of joint, foot, and leg problems, possibly because of a lower frequency of movement. Housing sows individually during gestation limits the amount of exercise and results in decreased muscle weight. Restricting movement may also cause biomechanical stress (Marchant and Broom 1996).

In swine breeding herds, flooring and housing are closely related, and thus it is often difficult to separate the effects of one from the other. Certain types of housing will rarely be found with certain types of flooring; for example, crates will rarely, if ever, be seen on an earthen floor. There may also be an interaction between the flooring type and the housing type. Levels of culling are also influenced by the housing and flooring types used during the rearing period of the replacement gilts; high density of animals and slatted floors during the finishing period are associated with a greater risk of removal in sows (Dewey et al. 1992).

Flooring can vary in many respects, including design, material, quality, the hygienic conditions associated with it, and other characteristics. The adverse effects of slatted floors have often been associated with foot and leg problems, but most of these reports have pertained to faulty slats that were damaged or were poorly designed with rough edges, too wide apart, or with an improper distribution of nonslippery and nonabrasive materials in the concrete (MAFF 1981; Muirhead 1981; Dewey et al. 1992).

The association between housing and flooring types might be further confounded by the type of feeding system used. For group housing during gestation, longevity was shorter for sows individually fed in an electronic feeding system than for sows fed as a group in individual feeding stalls: 3.0 and 3.9 litters, respectively (Olsson 1996). Competition, queue formation, and aggressive incidents were more frequent around the feeding station in the electronic system and resulted in more injuries.

Proper selection for conformation is essential to improve sow longevity, as buck-kneed forelegs, upright pasterns on hindlegs, and swaying hindquarters have been associated with an increased risk of removal for sows (Grindflek and Sehested 1996; Jorgensen 1996). Some of these conformational traits associated with sow longevity have been shown to be moderately heritable (Rothschild and Christian 1988a; Serenius et al. 2001). Low level of backfat has been associated with leg weakness problems (Rothschild and Christian 1988b), suggesting that the selection against backfat used by seedstock producers might have contributed to the increased

locomotor problems recently observed in breeding animals.

The likelihood of a sow being culled for lameness is greater for younger sows, particularly gilts and parity 1 sows (Jovic et al. 1975; Dagorn and Aumaitre 1979; D'Allaire et al. 1987; Dewey et al. 1993; Lucia et al. 1996; Paterson et al. 1997b). Dewey et al. (1992) found that the culling rate due to lameness was higher in start-up than in established herds: 26% and 8%, respectively. Sows culled for locomotor problems produce, on average, only three litters. The reasons that culling for locomotor problems is more frequent in young females are numerous; among the possibilities are marginal nutritional problems, poor selection for conformation and locomotion of gilts, management or environment differing for young females compared with older sows, or a selection process by which sows less prone to problems are kept in the herd. Moreover, clinical signs of osteochondrosis, which is one of the leading causes for removal of lamed sows (Dewey et al. 1993), are mostly observed in animals between 6 and 15 months of age (Grondalen 1974). Some authors have also reported that osteomalacia and osteoporosis are more frequent in first-litter sows (Douglas and Mackinnon 1993). On the other hand, older sows are more likely to have foot problems than younger sows (Dewey et al. 1993).

Sows removed for locomotor problems represent the highest economic losses related to culling (Dijkhuisen et al. 1989). In a study by Paterson et al. (1997b), 25% (range 0–62%) of the sows removed for locomotor problems had to be euthanized for humane reasons; this has an important economic impact due to the loss of the sale value of the animal but also suggests animal welfare problems.

When investigating a problem of high removal rate for locomotor problems, it is important to determine the major causes for lameness and to assess the associated risk factors, for example, housing, flooring, nutrition, genetics, selection process, and management. For more details on risk factors for locomotor disorders, see Chapter 5.

Milking Problems

Milking problems include mastitis, agalactia, low milk production, and poor mothering abilities. This category may overlap with inadequate performance, for milk failure can influence weaning weights and preweaning mortality. The proportion of sows culled for these reasons ranges from less than 1% up to 15%. In some reports, milking problems are included with peripartum problems. In a study from Minnesota (United States), sows culled because of milking problems produced an average of 4.6 litters (D'Allaire et al. 1987). Svendsen et al. (1975) reported that parity 2 sows were more prone to culling for mastitis. Halgaard (1983) observed that the risk of mastitis increased with increasing age up to the third or fourth litter.

Death

Annual death rates of 3–10% are frequently observed; however, they can reach 20% on some farms (Abiven et al. 1998). Recently mortality risks in breeding herds appear to be increasing, especially in the U.S. (Koketsu 2000; Deen and Xue 1999). These high levels of mortality represent significant economic losses and are indicative of compromised welfare. Moreover they are a concern to employees and can affect their morale (Deen and Xue 1999). High levels of death or euthanasia in a herd result in some of the greatest losses per sow (Dijkhuizen et al. 1989, 1990; Paterson et al. 1997a) because of the increased number of nonproductive days, the extra costs (such as veterinary costs before removal and rendering costs), the lack of income associated with unslaughtered sows, or the loss of whole litters, since sow death often occurs around farrowing.

Variation in death rates can be attributed to differences in management, nutrition, environment, and culling policies. Some producers preferably cull their sick sows quickly, hence reducing the death rate. Also, death rate is often negatively correlated with culling rate in order to keep the sow inventory constant within a herd.

In most recording systems, natural death and euthanasia are both included in the mortalities. It is recommended in herds with high mortality that euthanasia rates and reasons be analyzed separately since euthanasia may contribute significantly to the death losses. In a study of 59 herds, the combined death/euthanasia rate was 9%, with 5% for natural deaths and 4% for euthanasia (Paterson et al. 1997a). Similar results were found by Christensen et al. (1995), who reported that among 263 sows submitted to a rendering plant, 36% were euthanized, most of them having locomotor problems. High levels of euthanasia are indicative of a health or welfare problem or a failure to identify and quickly treat sick animals. In that, the work force plays an important role. Employees lacking pig experience and having limited husbandry skills are less likely to recognize sows at risk quickly and institute a prompt and effective treatment before a problem becomes life threatening (Loula 2000). Inappropriate treatments of sows with a product having a long withdrawal period may also preclude the sending of animals to slaughter, hence increasing the euthanasia rate if the health condition of the animals deteriorates. Similarly, a limited availability of transportation as is often observed in large organizations, does not allow timely culling of animals, leading subsequently to euthanasia or death when recovery is not possible.

Christensen et al. (1995) observed that the risk of death for sows was three times higher in herds with more than 100 sows than in herds with fewer than 50 sows. In a study of 130 herds, the death rate was significantly higher in herds with 200 or more sows than in those with fewer than 200 sows: 8% versus 6% (S.

D'Allaire and R. Drolet, 1996 unpublished data). Straw (1984) suggested a target death rate of 3% for herds of 150 sows or less, and 5% for herds of 200 or more sows. Koketsu (2000) observed that as herd size increases by 500 females the mortality risk increases by 0.44%.

Seasonal patterns in sow losses have been observed. In the United Kingdom, Jones (1967, 1968) observed that more than 55% of the dead sows had died during the winter months. These sows were kept inside during winter and outside during summer. A higher incidence of mortality during summer months is reported in studies where herds were kept mainly in total confinement (Chagnon et al. 1991; Drolet et al. 1992; Deen and Xue 1999; Koketsu 2000). A significant percentage of yearly deaths may be associated with thermal stress during periods of warm weather in sows housed indoors (D'Allaire et al. 1996). The annual mortality in Hungarian breeding herds was 5.1% and 12.2% for indoor and outdoor production units, respectively (Karg and Bilkei 2002).

Sows appear to be at risk most during the lactation period (Abiven 1995), and particularly during the peripartum period (Madec 1984; Chagnon et al. 1991; Deen and Xue 1999; Duran 2001). Therefore, particular attention and care should be given to sows during this period of the reproductive cycle to limit sow losses. Older sows are in general at higher risk of dying (Deen and Xue 1999; Koketsu 2000).

The mean parity at death varies between 3.4 and 4.2; the variation among studies and possibly among herds may be a reflection of the relative incidence of certain causes of sow losses, as some of them appear to be age related. Cystitis-pyelonephritis occurs more frequently in older sows (Madec 1984; Paterson et al. 1997a), whereas some locomotor problems seem to be more prevalent in young breeding stock (Spencer 1979; Doige 1982; D'Allaire et al. 1991; Dewey et al. 1993).

Assessing the reasons for death is essential to understand and control the factors influencing sow losses due to mortality. Many conditions responsible for death in sows are often reported by the producers as sudden deaths or rapid deaths associated with some rather non-specific premonitory clinical signs. When trying to ascertain the causes of death in a particular herd, it is imperative to have a significant number of sows necropsied during the year in order to identify the general pattern of causes of death. Standardized protocols and diagnostic approaches have been proposed to help determine the causes of mortality in herds (Chagnon et al. 1991; Pretzer et al. 2000).

The relative proportions of deaths due to different causes vary between studies, and several factors can be responsible for these differences: the system of recording used, and the size and the number of herds. Environment, management practices, and geographical area also influence the occurrence of certain diseases and may explain some of the variation among herds. The material examined may also not be representative of the entire sow population if investigations are based on submissions to diagnostic laboratories; causes of death that can be readily identified by producers (heat stress, uterine prolapse) are obviously underrepresented. Studies based solely on macroscopic postmortem examinations may introduce bias by excluding some causes of death that need laboratory assistance (microbiology, histopathology, toxicology) to reach a diagnosis.

Although sows die from a variety of causes, some of the causes seem to have a greater incidence. Torsion and other accidents involving abdominal organs, heart failure, and cystitis-pyelonephritis are overall the major causes of natural death in sows, whereas locomotion and leg related problems are the most frequent causes for euthanasia.

Torsions and Accidents Involving Abdominal Organs. Torsions and accidents involving abdominal organs probably are among the most significant causes of death in breeding stock. Gastric, splenic, and hepatic lobe torsions are the most common conditions reported within this category (Figure 63.1). Lethal gastric dilation can also occur without concurrent torsion (Ward and Walton 1980; Sanford et al. 1994). Intestinal accidents such as volvulus are also observed in breeding animals but are less frequent than in growing pigs. In studies on sow mortality published before 1980, torsions of abdominal organs are not reported as significant causes of death. The emergence of these problems, recognized in the early 1980s (Ward and Walton 1980; Morin et al. 1984; Sanford et al. 1984), might have been concurrent

63.1. *Gastric torsion and dilation in a sow; right lateral view. The spleen is displaced, congested, and ruptured. The greater omentum is lacerated.*

with the intensification of swine production and the associated changes in management practices. In one study, the proportion of deaths attributable to torsions of abdominal organs was 20.5% for herds kept indoor compared to 4.1% for outdoor units (Karg and Bilkei 2002). In some herds, these conditions may represent a serious problem.

Torsions of abdominal organs are often found in older sows (Morin et al. 1984; Sanford et al. 1984, 1994; Chagnon et al. 1991; Christensen et al. 1995). Although affected sows are usually pregnant, sows may die at any stage of the reproductive cycle. Rough movements and manipulations, noise, and excitement among sows have been incriminated in the pathogenesis of torsion of abdominal organs (Morin et al. 1984). Feeding management and possibly housing type can influence the incidence of these conditions (Abiven et al. 1998). It has been suggested that any factors that provoke a rapid intake of food and water in excited animals predispose to gastric dilation or torsion; such factors include the number of meals per day, omitting a meal, as often occurs during the weekend, and possibly the fineness of the ground feedstuffs. Gastric contents in these cases are generally abundant and fluid.

Torsions and other accidents involving abdominal organs are usually easily recognized grossly on field postmortem examination without the need for further confirmatory laboratory testing, as is the case for some other conditions, such as septicemia.

Heart Failure. Heart failure has been reported as being among the main causes of death in sows (Senk and Sabec 1970; Svendsen et al. 1975; Smith 1984; Chagnon et al. 1991; D'Allaire et al. 1991; Maderbacher et al. 1993; Abiven 1995; Karg and Bilkei 2002), accounting for up to 31% of the mortalities. However, in several other studies, heart failure per se either is not even reported among the causes of death or is considered of negligible incidence in sows (Jones 1967, 1968; Ward and Walton 1980; Madec 1984; Hsu et al. 1985). The diagnosis of heart failure can be difficult to make, particularly in acute cases and has to rely on all current diagnostic procedures available. Diagnosis should be based on the presence of lesions indicative of heart failure such as cutaneous cyanosis; transudate in the pericardial, thoracic, and abdominal cavities; cardiac chamber changes; pulmonary edema; and passive congestion of lungs and liver, along with the absence of other gross, microscopic, and microbiological findings to carefully exclude other diseases (Figure 63.2).

Some of the predisposing factors for this condition have to be regarded in light of the way pigs often overreact to exogenous factors and, probably more important, of their particularly delicate cardiovascular system. The porcine heart has many anatomic and physiologic peculiarities, namely, low volume and small weight, abnormal systolic-to-diastolic ratio, and exceptional myocar-

63.2. *Hydropericardium (arrows) in a sow dead of cardiac failure.*

dial sensitivity to oxygen deficiency. In swine the heart weight to body weight ratio decreases as the size of the animal increases (Stünzi et al. 1959), and in adults, this ratio is considered to be among the smallest of domestic animals (Lee et al. 1975). The swine heart weight to body weight ratio, which is about 0.3% in sows, is much smaller than that of the less sedentary or more athletic species such as the dog, which is about 0.8% (Bienvenu and Drolet 1991). This precarious situation may easily lead to irreversible overload of the circulation and to acute heart failure (Thielscher 1987). The lack of exercise in sows raised in total confinement may also affect cardiovascular fitness. Thus, any factor that requires increased effort from the cardiovascular system in sows may be considered to predispose to heart failure: obesity, parturition, high ambient temperature, and stressful events such as mating, fighting, and transport (Drolet et al. 1992).

Drolet et al. (1992) and Christensen et al. (1995) found that sows that died of heart failure were heavier and fatter than sows dead of other causes. Therefore, in gestation units, sows should be fed properly and not be allowed to put on excessive weight and fat. In a study involving 137 dead sows of which 43 had heart failure, more than 60% of the heart failure deaths occurred during the peripartum period, suggesting that parturition is a demanding event for the cardiovascular system of the sow (Chagnon et al. 1991). Cardiovascular failure associated with high ambient temperatures may be responsible for significant losses in some herds. In a recent study involving 130 breeding herds in which sows were housed indoors, 11% of the yearly deaths occurred during 3 consecutive days of warm weather, which represent only 0.8% of a year (3/365 days) (D'Allaire et al. 1996). Interestingly, only 3 dead sows were submitted for necropsy to the nearby diagnostic laboratory during the week. Causes of death that can be readily identified by producers, such as those occurring on hot days, are underrepresented in submissions to diagnostic laboratories, as was pointed out by Sanford et al. (1994). Sows in total confinement are particularly susceptible to heat

stress; they are not allowed to wallow in mud to decrease their body temperature nor are they exposed to winds that would decrease the ambient humidity and increase heat dissipation. Proper ventilation obviously plays a major role within these confinement systems, especially for periparturient females in the farrowing house. When the ambient temperature and humidity are high, the use of portable fans or other cooling system in the farrowing houses may be beneficial for sows. Other precautions may include removing heat sources (e.g., infrared lamp), less handling of animals to limit stress, and modifying the feeding schedule to avoid the heat of the day.

It is important to distinguish heart failure from malignant hyperthermia (porcine stress syndrome), a genetically transmitted disease. In the latter, prevention through selection of resistant animals will decrease the incidence. Many of the predisposing factors associated with heart failure in sows are also considered triggering factors for the development of malignant hyperthermia in pigs. Both conditions also share many clinical and pathological similarities, which make them difficult to differentiate. Lambert et al. (1996) examined, by molecular biology techniques, tissues from 84 sows previously collected by Chagnon et al. (1991) for the presence of the defective gene responsible for malignant hyperthermia. From these selected sows, 42 were identified as having died from heart failure and 42 as having died from various other causes (control group). The majority of the sows dead from heart failure did not possess the halothane gene mutation on any allele, suggesting that these cases were not related to malignant hyperthermia. Furthermore, the proportion of animals carrying at least one mutant allele (monomutant or dimutant) was not significantly different between sows dead of cardiac failure and the control group.

Cystitis-Pyelonephritis. The proportion of all deaths attributable to cystitis-pyelonephritis generally varies between 3% and 15% (Jones 1968; Senk and Sabec 1970; Svendsen et al. 1975; Hsu et al. 1985; Ward and Walton 1980; Chagnon et al. 1991; D'Allaire et al. 1991; Abiven 1995; Christensen et al. 1995). However, in some studies, urinary tract infection represented the major cause of mortality, accounting for up to 40% of all deaths (Jones 1967; Madec 1984; Smith 1984; Karg and Bilkei 2002).

Bacteria most commonly isolated from cases of cystitis-pyelonephritis (Figure 63.3) are *Escherichia coli* and *Actinobaculum suis* (formerly *Actinomyces suis*) (Madec and David 1983; Smith 1984; D'Allaire et al. 1991; Carr and Walton 1993). Other bacteria commonly associated with urinary tract infection include *Proteus* spp., streptococci, enterococci, micrococci, klebsiellae, and *Arcanobacterium pyogenes*.

Determination of urea concentration in ocular fluids can be a useful aid in diagnosing cystitis-pyelonephritis in dead sows, particularly when a complete necropsy is
63.3. *Cystitis and pyelonephritis due to* Actinobaculum suis *in a sow. The pelvis and ureter are markedly distended with a mucopurulent exudate.*

not possible or when it is difficult to ascertain that the lesions found in the urinary tract are responsible for death (Drolet et al. 1990). A significantly higher aqueous humor urea concentration was found in sows dead of cystitis-pyelonephritis (45–52 mmol/L) than in those dead of other causes (9–10 mmol/L) (Chagnon et al. 1991; Arauz and Perfumo 2000).

The risk of cystitis-pyelonephritis increases with age (Jones 1967; Madec 1984; Pointon et al. 1990; Chagnon et al. 1991; D'Allaire et al. 1991; Paterson et al. 1997a). The underlying reasons for this age-related susceptibility have not yet been fully investigated. Lack of exercise, limb injuries (Madec and David 1983), and obesity (Smith 1983) appear to be more frequent in old sows and predispose to urinary tract infection. These factors are associated with a decreased frequency of micturition, hence leading to a decreased flushing of bacteria and potentiating microbial growth (Smith 1983; Carr et al. 1991). It has also been reported that restricted water intake is one of the major risk factors for cystitis-pyelonephritis (Madec and David 1983; Carr et al. 1991). Urinary problems are also more common when sows are tethered or kept in stalls, possibly due to the lack of exercise and to hygiene conditions (i.e., confined sows often having to lie in their own feces and urine) (Madec and David 1983; Muirhead 1983; Carr et al. 1991). A flooring type that does not allow easy cleaning and good elimination of urine and feces can also lead to urogenital diseases and serious reproductive problems (Madec and David 1983; Muirhead 1983). For detailed information on cystitis-pyelonephritis, see Chapters 9 and 38.

Locomotor Problems. Locomotor problems are a common cause of euthanasia and may significantly increase the mortality in some herds (Senk and Sabec 1970; Svendsen et al. 1975; Christensen et al. 1995; Karg and Bilkei 2002; Perfumo et al. 2003). When investigating the extent of locomotor problems on a farm, it is impor-

tant to assess both the death rate and the culling rate associated with these conditions, since culling policies influence both rates, especially for these problems.

Gastric Ulcers. Lethal gastric ulcers are highly prevalent in some herds. Factors responsible for high mortality due to gastric ulceration are not always easy to pinpoint. Gastric ulceration is a multietiologic condition with several recognized risk factors. Most of these factors are related in some ways to housing management–associated stress, to concurrent diseases, or to some feed processing and dietary factors, including feed particle size, feed intake, grain type, and milling process (see Chapter 54).

Infectious Diseases. Proliferative enteropathy and PRRS, among other infectious diseases, may also increase the death rate. But usually, they will appear as outbreaks or will be of short duration. The mortality can reach up to 10% during these episodes (Yates et al. 1979; Halbur and Bush 1997). The incidence of infectious diseases due to pathogens, such as *Haemophilus parasuis*, is higher in start-up herds and in high-health-status herds.

In most studies, endometritis represents less than 9% of all deaths. This condition can be associated with concurrent urinary tract infection or, less frequently, with mastitis (the latter is an uncommon cause of death in sows).

Pneumonia is not a major cause of mortality; it rarely represents more than 5% of all deaths. Pneumonia is often more severe in young growing pigs than in full-grown pigs (Pijoan 1986). This could partly explain why pneumonia is not a frequent cause of death in adult sows and is more likely to affect younger females (Chagnon et al. 1991).

Sow deaths have also been attributed to *Clostridium novyi* in some countries (Walton and Duran 1992; Abiven 1995). The diagnosis of *C. novyi* sudden death (clostridial hepatopathy) is difficult mainly because this organism is a common and early postmortem invader, especially of adult swine in warm weather (Taylor and Bergeland 1992). Different aspects of this disease have been examined by Duran and Walton (1997). They reported that affected sows had generalized edema, subcutaneous infiltration with bubbles, and foul smelling bloody fluid in body cavities. The liver was enlarged and the parenchyma was infiltrated with gas bubbles, giving a spongy appearance. Several deaths in periparturient sows have been attributed to *Clostridium difficile*; sows had been previously treated with enrofloxacin (Mauch and Bilkei 2003). Septicemia and endocarditis have been observed as sporadic causes of death in some earlier studies.

Uterine Prolapse and Complications at Parturition. Uterine prolapses are generally responsible for fewer than 7% of all deaths (Figure 63.4). This condition is

63.4. Uterine prolapse in a sow.

mostly observed in old sows, and the reasons for this increased frequency are unclear. Among possibilities are large pelvic inlet, long and flaccid uterus, and excessive relaxation of the pelvic and perineal region, which are probably mostly encountered in full-grown females (Roberts 1986).

Although dystocia or complications at parturition are occasionally reported as causes of death, we must be careful not to ascribe every death occurring in the peripartum period to these causes. As mentioned previously, sows are most at risk of dying during the peripartum period, due to a variety of causes. They may be apathic or suffer from exhaustion or downer sow syndrome which may be interpreted as a difficult farrowing by the producer.

EFFECTS OF SOW LONGEVITY ON HERD PRODUCTIVITY

High removal rates can affect herd productivity by causing a shift in the herd age distribution toward younger females, which usually have fewer pigs born alive per litter, a lower conception rate, and a greater number of nonproductive days. They are also more likely to be culled for reproductive failure and locomotor problems. Considerable losses are involved with high removal rates of young females. Kroes and Van Male (1979) reported that the cost per weaner is highest in the first litter and decreases over the next two litters.

The interval between a production event and the removal of a breeding female affects the number of nonproductive days in a herd, which is one of the best biologic predictors of litters per sow per year (Wilson et al. 1986; Duffy and Stein 1988; Dial et al. 1992). A high removal rate is generally associated with an increase in the number of nonproductive sow days. Target values for intervals between different production events and removal have been proposed by Polson et al. (1990). The interval between a production event and culling is determined by two factors: the interval from the produc-

tion event to the decision to cull, and the period between when the decision to cull is made and the actual culling. An excessively long interval may be due to the manager's inefficiency in identifying animals that will eventually have to be culled or to the manager's holding animals to be removed too long after the decision to cull is made. The time lost from cullings, deaths, and abortions was found to add the equivalent of 11 days to the farrowing interval and to result in a decrease of 0.16 in the number of litters per sow per year (Pattison et al. 1980b). Kroes and Van Male (1979) observed an increase of 6–8 days in the farrowing interval for each increase of 12% over an annual removal rate of 31%, which was considered to be the base value.

Lifetime productivity has traditionally been defined as the parity at removal or as the number of pigs weaned at removal. More recently, Lucia (1997) reported that the number of herd days per pig weaned by removed sows is a better estimator of lifetime productivity since it takes into account the number of nonproductive days as well as the number of pigs weaned. This parameter was evaluated at 20–21 days and was lower for older sows, 16–18 days, and higher for younger sows, 25–27 days.

High annual removal rates decrease herd productivity by influencing the herd age distribution and the number of nonproductive sow days. Many authors have documented that high removal rates are associated with a decrease in litters per sow per year and pigs weaned per sow per year (Dagorn and Aumaitre 1979; Kroes and Van Male 1979; Pattison et al. 1980a).

Using a sow replacement model, the loss by premature removal represented the equivalent of 16% of pig farm income, at an annual removal rate of 50% (Dijkhuizen et al. 1989). From different models, it appears rarely economical to cull a sow before her eighth or ninth parity. Improving longevity is highly profitable when the average parity at removal is low (Dijkhuizen et al. 1990; Sehested 1996). For example, increases in average parity at removal from 2.8 to 3.8 and from 3.8 to 4.8 improve the income per sow per year by US$25–35 and US$20–25, respectively (Dijkhuizen et al. 1990). Similarly, improving average longevity by one parity was shown to have the same impact as improving meat lean by 0.5% (Sehested 1996). However, improving longevity above an average value of 5 does not seem as beneficial (Sehested 1996). Several software programs have been developed to determine optimal economic

time to cull sows (Dijkhuizen et al. 1986; Stalder et al. 2003).

LONGEVITY IN BOARS

In herds where artificial insemination (AI) is not used extensively, good boar-culling policies are important, for they facilitate the replacement program. Planning problems associated with boar introduction may be considerable, because boars should be kept in quarantine for a certain period and their full workload is attained only at 1 year of age. High boar removal rates seem to be more frequent than excessively low rates. In a study involving 84 commercial herds, the annual removal rate for boars averaged 59% (D'Allaire and Leman 1990). The lifetime breeding expectancy for boars is estimated at 15–20 months but varies considerably between 0.3 and 38.5 months (Le Denmat et al. 1980; Arganosa et al. 1981a; D'Allaire and Leman 1990).

Overweight and old age, reproductive problems, and locomotor problems are the major reasons for culling boars in commercial herds (Table 63.4). The general pattern of removal may vary according to the breed of the boars: culling for reproductive or leg problems was higher in purebred than in crossbred boars, whereas culling for old age and overweight was more frequent in crossbred than in purebred boars (Le Denmat and Runavot 1980). Accordingly, reasons for culling boars from commercial herds would most likely be different from those in AI centers.

Overweight and Old Age

Since overweight and old age are not always easily distinguishable, they are often grouped into one category to avoid the risk of misclassification. Indeed, some producers use these two reasons interchangeably, because older boars are frequently considered too heavy to appropriately serve younger sows without the risk of injuring them. Both overweight and old age are often in relation to the sow herd. The introduction of many replacement gilts into the herd and the necessary introduction of young boars may require culling older or large boars that are not necessarily aged. This aspect of culling is peculiar to commercial herds; overweight and old age are rarely reported as causes of culling in testing stations or artificial insemination centers (Melrose 1966; Navratil and Forejtek 1978). High rates of removal

Table 63.4.   Reasons for removing boars and percentage of removals for each reason: results obtained from 3 studies involving more than one herd

Source	Reproductive Failure	Old Age and Overweight	Locomotor Problems	Death	Other	No. of Boars	Country

Note: NA = not available.

caused by overweight may also reflect a feeding-management problem, in which case feeding management on the farm should be reviewed and corrected to improve boar longevity.

Reproductive Problems

The proportion of boars culled for reproductive problems is considerably lower in commercial herds than in artificial insemination stations (Melrose 1966; Navratil and Forejtek 1978). These differences may be attributed partly to the fact that semen quality is regularly evaluated for boars from artificial insemination centers. Consequently, boars may be removed more quickly and at a higher rate; the culling rate for poor semen quality can be as high as 23% in these stations (Navratil and Forejtek 1978). In two French studies conducted in commercial breeding herds, reproductive problems represented 20% and 32% of all removals and were considered one of the two major causes of culling (Le Denmat and Runavot 1980; Le Denmat et al. 1980). Breed difference may also be responsible for the variations in the proportion of boars culled for reproductive problems; purebred boars are more likely to be culled for this reason than crossbred boars (Le Denmat and Runavot 1980).

In commercial herds, the reason most frequently reported by producers in this culling category is poor libido or behavioral problems that preclude efficient mating. Culling for low reproductive performance is also reported but to a lesser extent. Low reproductive performance is difficult to confirm for boars in commercial herds. A great amount of information is required to make a valid decision; it takes approximately 50 litters to show a one pig per litter difference from the herd average. Therefore, culling for that reason without sufficient data is rarely justified. On the other hand, by the time this information is available, the boar has often completed his productive life in the herd.

Locomotor Problems

Although locomotor problems are rarely the main cause of culling, the percentage of removal can be very high on certain farms (Einarsson and Larsson 1977; D'Allaire and Leman 1990). In herds with high culling for locomotor disorders, the environment of the boars, such as housing and flooring types, should be evaluated carefully. Attention should be given to selection for locomotion and conformation, particularly in artificial insemination centers, as it has been shown in sows that these traits are associated with longevity (Grindflek and Sehested 1996; Jorgensen 1996). Misclassification between locomotor and reproductive problems may also occur, for locomotor problems often result in poor libido or inability to mate.

Death

Death generally accounts for less than 7% of all removals, giving a herd death rate of lower than 4%

(D'Allaire and Leman 1990). In a study by Senk and Sabec (1970), the causes of death in 30 boars were found to be heart failure (50%), locomotor problems (23%), splenic torsions (10%), gastric ulcer (7%), endocarditis (3%), and unknown (7%).

GENERAL GUIDELINES TO ASSESS REMOVAL POLICIES

Determination of the annual removal rate is the first step in evaluating a culling program. Rates that are too high seem to be more common than excessively low rates. Unusual circumstances, such as a change in inventory or culling policy, may temporarily increase the removal rate. Calculating the mean parity at removal is also useful, but a parity distribution of culled females may be more informative. The removal rate for each category of reasons can indicate the extent of a problem. Analysis of reasons by parity may reveal which group of females is more susceptible or whether some cullings are unjustified, either physiologically or economically. An assessment of the interval between a production event and removal is important because it influences the number of litters per sow per year and pigs weaned per sow per year, and these measures of productivity are important factors in economic loss and gain. Clearly, the failure to identify and remove nonproductive sows at an early stage will increase the number of nonproductive sow days. Factors influencing negatively the longevity of breeding animals should be investigated. They have been reviewed by Stalder et al. (2004). To improve breeding-life expectancy of sows and boars in commercial herds, greater attention to the environment, nutrition, and management should be emphasized.

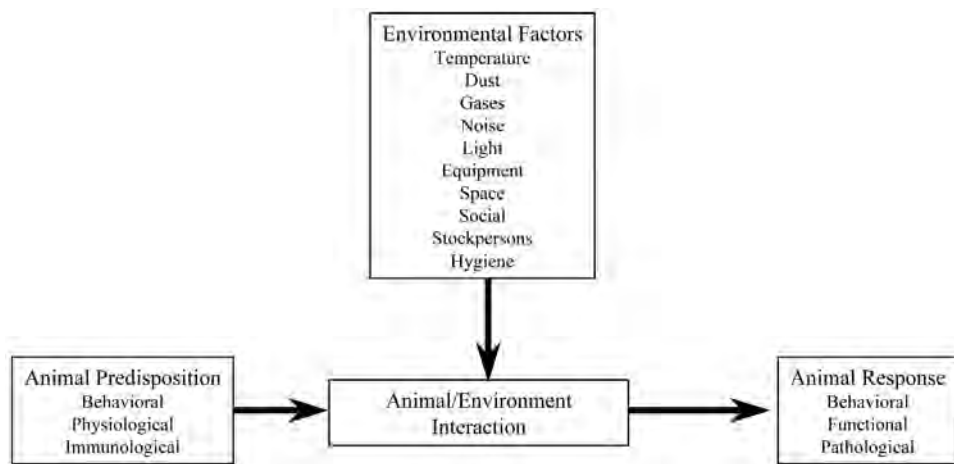
64 Effects of the Environment on Productivity and Disease

Harold W. Gonyou, Stéphane P. Lemay, and Yuanhui Zhang

Environment is a very broad term referring to all factors that impinge upon the animal. It can be divided into two major aspects, the physical and the biological, which in turn can be further subdivided. Not only is the environment complex, but the means by which animals interact with the environment is beyond the simple stimulus-response paradigm. Moberg (1985) outlined the response of animals to environmental stressors as consisting of three general levels of response. The least costly response is behavioral. But if behavioral responses are not capable of alleviating the stress, a change in biological function occurs. Such changes may involve a redirection of energy or substrates from what we view as productive functions, such as growth or reproduction, to defense strategies. One such change in biological function involves the activation of the pituitary-adrenal axis, resulting in release of corticosteroids. A result of this change in function is an altering of the immune response, making the animal more susceptible to some pathogens (Kelley 1982). Moberg (1985) indicates that if the environment is stressful enough, the animal enters a pathological state (Figure 64.1).

Webster (1988) has divided the means by which the environment contributes to pneumonia into three components. First, the environment includes factors that affect the level of pathogens to which the pig is exposed. Second, the environment affects mechanisms by which the pig resists the invasion of pathogens, such as clearance from the lungs. Finally, the environment affects the immune system and how well it can resist the pathogen load. The resulting complexity means that diseases must be viewed as multifactorial in terms of causative factors (Hartung 1994) and in terms of response and susceptibility.

The model presented in Figure 64.1 moves beyond the responses outlined by Moberg (1985) to include the predisposition of the animal (Gonyou 1993). Each animal will respond differently to environmental stressors because of its unique genetic and experiential makeup. Species have different behavioral and physiological characteristics. Some species, such as pigs, react strongly to repel unfamiliar individuals, while others, such as sheep, do not. Some species, such as cattle, react to high environmental temperatures by sweating, while others, such as pigs, do not. But within a species, within a genetic line, or even among genetically identical individuals, predispositions will differ due to experience. Behavior is greatly affected by learning, and physiology may adapt to the environment by relatively permanent changes in pelage, fat cover, and energy partitioning. Changes in the immune system brought about by "experience" with a pathogen are recognized in our immunization programs. Thus the impact of the environment on the animal is a complex combination of environmental features, the predisposition of the animal, and a variety of possible responses.

The multifactorial nature of the relationship of the environment and productivity and disease is illustrated in a series of papers by McFarlane et al. (1989a, b) and McFarlane and Curtis (1989). Using chicks as a model they demonstrated that five different environmental stressors were capable of reducing productivity and affecting physiological and immune responses. When applied in combination, the stressors affected these responses in an additive manner. An extension of this model to swine using high temperatures, crowding, and unstable social conditions confirmed the additive response to multiple stressors (Hyun et al. 1998). In a review of environmental factors recognized to contribute to various pathological conditions in swine, Whittemore (1993; Table 64.1) indicates that several diseases are affected by more than one environmental factor. In assessing the possibility that the environment is contributing to a clinical condition, the practitioner must expect that multiple factors are involved (Curtis and Backstrom 1992) and will likely suggest several changes to the environment in order to remedy the situation. For example, Done (1991) suggests 20 environmental factors to consider when treating for pneumonia. In any one case it is unlikely that only one such factor applies.


64.1. *The animal/environment inter-action. (Adapted from Moberg 1985, and Gonyou 1993.)*

Although each case of reduced productivity or disease may have multiple environmental factors contributing to it, it is necessary to understand each factor adequately to determine the likelihood that it is involved and how it might be corrected.

THERMAL ENVIRONMENT

The pig is a homeothermic animal with a deep body temperature of 39°C (Baxter 1984). Because the pig's environment is generally lower in temperature than its body, the pig loses heat. Heat is lost through various mechanisms: convection with ambient air; conduction to pen floor, walls, and other pigs; radiation to surrounding surfaces; and evaporation into ambient air. By physiological and behavioral means the pig modifies its heat production to balance heat losses.

The thermoneutral zone is defined as the interval of the thermal environment, usually characterized by temperature, within which an animal's total heat production is approximately constant for a given energy intake (CIGR 1984). Total heat production is at a minimum and independent of ambient temperature in the zone of thermoneutrality (Verstegen et al. 1982; Baxter 1984). According to Bruce and Clark (1979), below the thermoneutral zone heat production is increased, and this

can occur in the growing pig only if energy is diverted from productive purposes.

Lower Critical Temperature

The thermoneutral zone is limited by the lower and upper critical temperatures. Swine buildings are not usually provided with a cooling system, and therefore the reduction of inside temperature during the summer is not possible. A properly designed ventilation system will maintain the indoor air temperature less than 3°C above the ambient temperature. In most commercial buildings, no further control of high indoor temperatures can be achieved and the upper critical temperature is thus of lesser concern in the following discussion. With a temperature colder than the lower critical temperature (LCT), the pig uses a larger proportion of its feed intake energy to increase its total heat production. It is therefore important to define the limits of the thermoneutral zone to minimize wastage of energy intake through higher heat losses.

The LCT is calculated with the thermoneutral total heat production and the minimum latent heat production. It depends upon the heat losses of the pig and consequently the pig body weight, feed intake, air velocity, radiative temperature of surrounding surfaces, type of floor, and the number of pigs. Bruce and Clark (1979)

Table 64.1. Environmental factors associated with diseases in swine

Disease	Environmental Factor						
	General	Temperature	Crowding	Hygiene	Social	Gases	Dust
Colibacillosis	+	+	+	+			
Swine dysentery	+		+				
Mycoplasma pneumonia	+	+	+		+	+	+
Atrophic rhinitis	+		+	+		+	+
Actinobacillus pleuropneumonia	+		+	+			
Mastitis				+			
Leptospirosis				+			
Streptococcal meningitis		+	+				

Source: Adapted from Whittemore 1993.

developed an extensive model to predict the LCT of pigs. Recently, Brown-Brandl et al. (1998) demonstrated that current design criteria derived from Bond et al. (1959) underestimate heat production at thermoneutral conditions (18–24°C) by approximately 26%, probably due to the increase of lean tissue deposition for the modern high-lean genetic lines. Even if heat production levels increased over time, the pig still dissipates heat through the same mechanisms, and the Bruce and Clark (1979) model continues to be a relevant tool to describe the impact of the thermal environment on the animal's performance and well being.

With an air velocity of 0.15 m × s⁻¹, a feeding level three times the maintenance energy requirement, and a concrete floor, the LCT of a 20 kg pig in a group of 15 pigs is 16°C. The value for a 100 kg pig in the same conditions is 9°C. A reduction of the feeding level to twice the maintenance requirement increases the LCT of 20 and 100 kg pigs to 21°C and 14°C, respectively.

For a 20 kg pig fed three times the maintenance requirement in a group of 15 pigs housed on concrete slatted floors, the LCT increases from 15°C to 18°C when air velocity increases from 0.15 to 0.55 m × s⁻¹ (Baxter 1984). A higher air velocity increases pig heat losses and consequently the LCT as well. The heavier the pig, the better the pig can tolerate lower temperatures (Nicks and Dechamps 1985). CIGR (1992) indicates that with an air velocity of 0.15 m × s⁻¹ and the same feeding level, the LCT decreases from 21°C to 11°C as the pig grows from 20 kg to 60 kg.

The thermal resistance between the pig body temperature and the floor temperature is influenced by the type of floor. Verstegen and Van Der Hel (1974) mentioned that the effective critical temperature of animals weighing 40 kg is 11–13°C on straw bedding, 14–15°C on asphalt, and 19–20°C on concrete slats. A single 34 kg pig fed 3.3 times the maintenance requirement has an LCT of −5°C when it is 70% embedded in straw (Sällvik and Wejfeldt 1993). A group of 16 pigs has an LCT of −20°C in the same conditions. A group of pigs will huddle in the cold (Bruce and Clark 1979), which explains the lower LCT. In fact, postural behaviors can be used to classify the thermal environment of pigs. Shao et al. (1997) captured pictures of postural behaviors of early weaned pigs submitted to four different air temperature regimes varying from 24.4°C to 31.1°C. As their neural network analysis was capable of properly classifying 78% and 96% of testing and training images, their work demonstrated that a picture of animal behavior can be used as an input variable for an environmental controller instead of the conventional approach of using air temperature.

From a production point of view, the LCT is of prime interest. It is the temperature at which the pig will divert some feed energy to produce more heat. However, air temperature alone is insufficient to characterize pig thermal comfort. To choose the right temperature set-point ensuring the animal's well being and optimal performance, all the parameters previously mentioned should be considered.

Performance

To define the effect of temperature on pig performance, it is necessary to make a distinction between restricted and ad libitum feeding levels. With restricted feeding it appears that the optimum rate of gain is recorded around 20°C, and feed conversion (feed/gain) is minimal from 20–25°C (Verstegen et al. 1978). At similar feed intakes, the rate of gain decreases by 14.3 g × day⁻¹ × °C⁻¹ as the temperature drops from 20°C to 12.5°C (Le Dividich et al. 1985). The growth rate can be maintained constant by an additional supply of food of 38 g × day⁻¹ × °C⁻¹. When pigs are housed at a constant number of degrees below thermoneutrality, the reduction in gain is 14 g × day⁻¹ × °C⁻¹ during the growing period from 25–60 kg (Verstegen et al. 1982). Between 60 kg to 100 kg, the decrease is between 8 and 18 g × day⁻¹ × °C⁻¹ below thermoneutrality. For both growing periods pigs need 25 and 39 g × day⁻¹ of feed to compensate for each degree lower than the thermoneutral zone, respectively.

With pigs fed ad libitum, the maximum growth rate is obtained at an air temperature of 20°C (Nichols et al. 1982; Nienaber et al. 1987a). However, there is no statistical difference in gain observed between 10°C and 20°C or in feed conversion between 15°C and 25°C. As the temperature drops from 10°C to 5°C, the reduction in gain varies from 4 to 21 g × day⁻¹ × °C⁻¹. During summer months, elevated barn temperature reduces animal growth rate by decreasing feed intake (Nienaber et al. 1987a; Lopez et al. 1991; Nienaber et al. 1997). This negative effect on pig performance lengthens the growth period and reduces the productivity level. Experiments showed that when ambient temperature was increased from 20°C to 30°C, the rate of gain was reduced by 17.6–40.0 g × d⁻¹ × °C⁻¹ (Lopez et al. 1991; Nichols et al. 1982; Nienaber et al. 1987a; Massabie et al. 1997). Massabie et al. (1998) measured growth performance of grower-finisher pigs at 17°C and 24°C and at three feed intake levels. For pigs fed ad libitum, the average daily gain of pigs at 17°C (981 g × day⁻¹) was 8% higher than at 24°C (907 g × day⁻¹, reduction of 10.6 g × day⁻¹ × °C⁻¹). However, feed conversion ratio and the percentage of muscle in the carcass were similar at both temperatures.

Diet formulation can have an impact on how pigs will cope with elevated housing temperatures. Bellego et al. (2002) submitted barrows from 27–100 kg body weight and studied the combined effect of reducing the crude protein content of the diet with two housing temperatures (29°C versus 22°C). Overall, increasing the temperature from 22°C to 29°C resulted in a 15% reduction in average daily feed intake and 13% lower average daily gain. The results indicate that a 4-percentage unit reduction of dietary crude protein level does not affect

growth and carcass composition as long as the ratio between essential amino acids and net energy is kept optimal. They also concluded that diets with reduced crude protein limit the effect of high ambient temperature on average daily feed intake.

Previous data suggest that, to maximize growth rate and minimize feed conversion rate, grower-finisher pigs should be housed between 15°C and 20°C. It is apparent that the optimum environmental temperature is a temperature zone in which performance and heat production are not significantly different (Nienaber et al. 1987a).

Health Status

Except in extreme cases, a cold air temperature alone cannot precipitate health problems (Nicks and Dechamps 1985). Outbreaks of respiratory diseases can occur only when the microbial agents are present (Tielen 1987). However, fast air temperature fluctuations can trigger a disease outbreak by changing pathogen supply or animal resistance. For example, the results of Narita et al. (1992) indicate that the stress induced by fluctuating temperatures from 4°C to 30°C enhanced the progress and severity of Aujeszky's disease in pigs.

In an experiment by Hessing and Tielen (1994), weaned pigs exposed to draft and low environmental temperature had more pronounced clinical disease signs (i.e., diarrhea, coughing, sneezing, and cyanosis of the ear) than the control group. Le Dividich and Herpin (1994) recommend a stable ambient temperature for piglets penned on a perforated floor. They conclude that data suggest a complex effect of weaning, level of food intake, and nonoptimal climatic conditions on the health status of the weaned pig.

For grower-finisher pigs, there is evidence that the incidence of respiratory problems can be exacerbated by varying air temperature (Christison 1988). Considering the mortality and the incidence of coughing and tail biting, the air temperature for pigs less than 50 kg should be between 17°C and 25°C, with the allowance of an increasing day-night air temperature variability toward the end of this period (Geers et al. 1988). Above 50 kg liveweight, the air temperature should not be higher than 24–26°C, and day-night air temperature fluctuations should be small. In fact, Nienaber et al. (1987b) submitted growing-finishing pigs to constant temperatures of 5°C and 20°C and to similar average temperatures with ±12°C daily cycles in a sine wave pattern. No effect of cyclic temperature was observed for growing pigs, but the results indicated that cycles of ±12°C were stressful to finishing pigs.

Other research has shown limited adverse effects of lower or fluctuating temperature on either piglets or grower-finisher pigs. Nienaber and Hahn (1989) reported that a reduced nocturnal temperature regimen of 6°C resulted in an increased feed intake for nursery pigs.

No performance difference was measured when young piglets were subjected to ambient temperature as low as 15°C (Jacobson et al. 1984). Nursery piglets from 4–8 weeks of age that had been exposed to a fluctuating diurnal air temperature showed no performance difference on daily gain and feed efficiency (Jacobson et al. 1988). Shelton and Brumm (1986) measured slightly improved performance on pigs that were exposed to a nocturnal temperature that had been lowered by 9°C compared to daytime level.

Brumm et al. (1985) conducted an experiment to expose pigs weaned at 23 ±2 days to either a constant regime (30°C for the first week and then decreased by 1.5°C per week for 5 weeks) or a cycling daily temperature regime (the same day temperature as the control, but temperature lowering to 20°C at night during the first week and further reduced by 1°C per subsequent week). Pigs with a reduced nighttime temperature regime grew 6.1% faster as their daily feed intake increased by 7.8%, and feed efficiency was unaffected.

Lemay et al. (2001) conducted two trials over two summers to evaluate the effect of reduced nocturnal temperature on the performance and carcass quality of growing-finishing pigs. Control rooms had a typical temperature setpoint and the temperature setpoint for treatment rooms was 6°C lower. In Saskatchewan, a reduced temperature setpoint resulted in a lower nocturnal room temperature (1.6°C cooler over 8 weeks), but it had no influence on room daytime temperature. The average daily temperature fluctuation in treatment rooms was increased by 2.1°C. During trial 1, pig average daily gain in the treatment room was increased by 5.2%. For trial 2, feed intake was 3.2% higher in treatment rooms, which increased average daily gain by 2.1% on average over 8 weeks. However, no statistical differences were found for pig performance, feed conversion, and backfat thickness (P >0.05). The results suggest that healthy pigs are not negatively affected by a large daily temperature fluctuation (up to 14.8°C) as long as this fluctuation is progressively achieved.

Sow mortality is affected by high environmental temperatures. D'Allaire et al. (1996) examined data from 130 herds and determined sow mortality during a 7-day period with the highest maximum daily temperatures. During one 3-day period, representing less than 0.8% of the year, more than 10% of the annual death loss occurred.

Pigs' health status is not altered by cold air temperature alone. Moreover, some results show that pigs can develop an important mechanism of acclimation to a cold environment (Derno et al. 1995). However, sudden changes in weather have been cited frequently as important factors in the precipitation of disease, and these may be more important than steady extremes of temperature, to which the animal may adapt (Dennis 1986). To maintain a healthy herd, rapid air temperature fluctuations should be avoided.

Setpoint Temperature

The thermal comfort zone of the pig depends on many environmental factors and changes with pig weight. This fact and the results of previous experiments suggest management should be based on temperature intervals rather than a single setpoint value.

Sows and piglets require different temperatures. The farrowing barn should be maintained between 15°C and 21°C (McFarlane and Cunningham 1993). Sows will have a distinct preference for the floor temperature around farrowing. Phillips et al. (2000) concluded that sows showed a pronounced increase in preference for a warm floor (35°C) during 3 days after the start of farrowing. This change in preference may explain why sows tend to avoid metal flooring at the time of farrowing.

Piglets in the first 2 weeks after birth need a 30°C ±2°C temperature to maintain their body temperature and functions (Zhang 1994). Supplemental heat should be provided for piglets. During the first 2 weeks after weaning, Le Dividich and Herpin (1994) recommend an ambient temperature of 26–28°C for piglets penned on a perforated floor. A study by VIDO (1991) suggests that the nursery temperature at weaning should be 27–32°C. Therefore, a temperature of 26–30°C is acceptable for nursery rooms. To choose the best temperature within this range, the pigs' lying behavior should be observed (VIDO 1991). Comfortable pigs lie stretched out on their sides without huddling or piling. Once regular food intake is established, the ambient temperature may be decreased by 2–3°C/week until the finishing-house temperature is reached (Le Dividich and Herpin 1994). Table 64.2 summarizes literature concerning setpoint temperatures for the pig. Because pig thermal comfort depends upon body weight, floor type, air velocity, and the radiant environment as well as temperature, these values should only be used as guidelines and should be refined by observation of the pigs' behavior.

AIRBORNE DUST IN PIG BARNS

Air is a critical factor to living things. People, on average, consume 15 kg of air per day compared to 1 kg of food and 1.5 kg of water. A market size hog breathes about 40 kg of air per day (compared to 2.7 kg of feed and 4 kg of water). People are now beginning to realize how important high quality air is for health and well-being in humans and animals. Of the air quality in pig facilities, airborne dust and toxic gases are two major concerns.

Dust from pig facilities is primarily responsible for health problems in human workers and animals (Zejda et al. 1993, 1994). Toxic gases, especially odorous gases (e.g., ammonia and hydrogen sulfide), are primarily responsible for nuisance smell and for stresses in public relations. These gases can also become major environmental air pollutants in high-density production areas such as the Netherlands and Denmark. Dust tends to be lived with as part of the job and may be ignored until

Table 64.2. Summary of pig temperature requirements for different stages of production

Stage of Production	Body Mass (kg)	Temperature Range (°C)
Gestation	—	15–24[a,b]
Lactation: sow	—	15–21[b]
Lactation:piglet	—	28–32[a]
Weaning	4–7	25–32[a,c,d]
	7–25	21–27[b]
Growing	25–60	15–24[a,b]
Finishing	60–100	14–21[a,b,e]

permanent damage is done. Toxic gases cause discomfort (or more dramatic symptoms) that attracts immediate attention and requires quick action to solve the problem.

It is the small dust, or respirable dust, that is responsible for the problems of health and well-being in humans and animals. Dust particles smaller than 10 microns (some say smaller than 5 microns) are called *respirable dust,* because they can be inhaled into respiratory systems of human and animals. Grain dust was once considered to be the largest of all dust particles primarily affecting the airways (nose, throat). However, respirable dust, primarily from fecal materials and other organic compounds, permits more particulate material to reach the lung tissue where it can produce serious health hazards. Very fine particles (smaller than 1 micron) can even penetrate into lung tissues and cause permanent lung damage. Dust particles larger than 10 microns likely bypass a human nose and pose less danger to health (Figure 64.2). To put dust particles into perspective, a naked human eye can only see particles larger than 50 microns in a ray of sunlight. Cigarette smoke contains largely particles ranging from 0.1–1 microns. Dust particles of all sizes suspended in the air are called *total dust.* Thus, air may not be as clean as it appears in a

pig barn if it is filled with respirable dust particles because you can not visualize them.

Dusts in pig barns are biologically active and different from ordinary dusts such as field dusts. Swine building dusts are primarily generated from feed grains, fecal materials, animal skin and hair, insects and microorganisms (Donham 1986). They are composed of viable organic compounds, fungi, endotoxins, toxic gases and other hazardous agents (Table 64.3). A dust particle is a very complex mixture with many hazardous agents attached to it. To understand the pathology of health problems caused by dust, it is important to know the dust's microbiological content. Organisms have been isolated and identified as the most important contaminant in swine confinement airspaces (Martin et al. 1996). Some of the organisms such as *Streptococcus suis* and *Alternaria* species are considered particularly hazardous to animals and human beings.

Dust is a carrier of odor. When odor is floated in the air as free molecules, it tends to be diluted quickly into the atmosphere to a less annoying concentration. However, if the odorous molecules are attached to dust particles, they can be carried a long distance and remain present for a long time. For example, a piece of equipment from a pig barn may smell for a couple of months due to the dust adhering to it. Thus, reducing dust con-

centration could have a positive effect on odor reduction. In one study when dust concentration was reduced by 80%, ammonia and hydrogen sulfide were also reduced by 30% and odor was reduced significantly (Zhang et al. 1996).

Threshold values of respirable dust concentration have been recommended to be less than 5 mg/m^3 for workplaces with exposure of 40 hours per week (ACGIH 2003). This threshold limit was established primarily for working environments with inorganic dust, such as the coal-mining industry. A more stringent threshold limit, typically ten times less than that for inorganic dust, has been suggested for pig barn dust concentration because of its biological nature and adverse effects on humans and animals (Donham et al. 1989). High dust concentration is a cause of respiratory problems in pigs, such as bronchitis, coughing, and lung lesions. Dust also has an adverse effect on animal welfare. However, there are few data relating dust concentration to animal performance; one reason is that pigs do not live long enough to develop serious illnesses. Recommendations of threshold limits for dust concentration for animals are not currently available.

The characteristics (e.g., property, behavior and transportation) and pathogenesis of dust in pig barns still remain unclear. However, there is little argument on its adverse effect on the health of people and animals. Therefore, dust in pig barns should be minimized. Improvements to all aspects of swine building design and management practices, such as adding oil to feed have led to a significant reduction in dust (total and respirable) concentration levels in the past decade. The total dust levels in buildings are usually below 3 mg/m^3 compared with the 10 mg/m^3 a decade ago (Barber et al. 1991). However the respirable dust has not been reduced successfully because its origin is primarily the fecal materials and dead microorganisms (Welford et al. 1992). Conventional air cleaning technologies (e.g., fiber and electrostatic filters) for other types of buildings are usually neither efficient nor economical for pig barns due to the high dust concentration. Some new dust control technologies for pig barns have been developed and more research is in process. Dust control strategies involve scrubbing, electrostatic precipitation, ionization, ventilation, filtration and source control technology.

GASES AND HUMIDITY

The primary gases that may affect productivity and the incidence of disease are ammonia, carbon dioxide, hydrogen sulfide (H$_2$S), methane, and carbon monoxide. Hydrogen sulfide and carbon monoxide may be direct causes of death in pig facilities, whereas the other gases are likely to affect production and health indirectly. For example, ammonia at the levels of 50 and 75 ppm has been shown to reduce the ability of young pigs to clear bacteria from their lungs (Drummond et al. 1978). It is

generally recommended, for the comfort of the staff, that ammonia levels be kept at less than 25 ppm. These levels have not been demonstrated to have an effect on the productivity or health status of pigs, but pigs will avoid ammonia levels as low as 10 ppm (Jones et al. 1996).

Under normal barn operation, H_2S concentrations normally stay under 5 ppm. However, manure handling operations within the building, such as pulling plugs to drain pits or power washing rooms, can generate H_2S concentrations many times the levels generally used by occupational health and safety agencies (Chénard et al. 2003). Any manure handling procedure completed in swine facilities should be developed considering the risk associated with H_2S. Readers are referred elsewhere in this volume for more information on these toxic gases (Chapter 60).

Although often ignored as part of the gaseous environment, water vapor is recognized as a contributing environmental factor. Pathogens are best controlled at relative humidity levels between 60% and 80%. Higher or lower levels of humidity result in higher pathogen loads. Respiratory problems are the most commonly observed health problems associated with high levels of humidity. During hot weather high humidity levels may contribute to heat stress because evaporative cooling methods are less effective.

The sources of water vapor include spillage from drinkers, urine, feces, wash water, and water in the feed. Humidity problems are most common during cold weather when ventilation is reduced to conserve heat. Feeding wet feed, particularly on a virtually continuous basis, is a major contributor to humidity problems. The use of water bowls, which waste less water than nipples do, will reduce humidity levels in confinement buildings. The effect of spilled water and of urine will be reduced if the floors are sufficiently sloped for good drainage. Within heated rooms electric heat will result in a drier environment than will gas heaters, which produce water vapor during combustion.

In addition to health concerns, adverse impacts of gases including odor, particulate matter (PM), ammonia (NH_3), hydrogen sulfide (H_2S), carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) emitted from animal production facilities have created significant public concerns. These gases are produced by animals or by decomposing manure (Zhang et al. 1992). Current federal and state air quality regulations typically use emission estimates and air dispersion modeling to assess the impact of specific industries or production process on the environment and human health.

Air emissions typically arise from four main sources: the buildings where the animals are confined, outdoor lots where animals are held, manure storage structures, and land application of manure. One of the most effective methods to reduce gas emissions from confinement animal facilities is to reduce the gas concentration in the rooms because most of the gases are emitted via exhaust fans. Many good management practices (power washing, regular cleaning and flushing, sufficient water in the pit) can substantially reduce the odor and gas production and emission in the building, which in turn reduces emission and complaints.

NOISE

Pigs encounter two types of disturbing noises. The first type consists of sudden, startling noises such as sonic booms. The second type of noise is the persistent background noise from fans or other equipment within barns. Sonic booms or other aircraft noises appear to have little effect on the productivity of pigs (Bond 1971), but the noise of burner ignition on low-flying balloons has been claimed to startle animals, sometimes resulting in injury or death (Penny et al. 1995).

Sows and piglets communicate during the nursing/ suckling sequence via grunts and squeals. Loud fan noise (85 decibels) has been shown to interfere with this communication and result in disrupted nursings (Algers and Jensen 1985). Behavioral problems such as tail biting sometimes occur more often near exhaust or recirculation fans. The noise of these fans may contribute to the general discomfort of the pigs, which leads to tail biting. Fan noise may be reduced by regular servicing.

LIGHT

Pigs have been reported to be both diurnal (day-active) (Stolba and Wood-Gush 1989) and nocturnal (Blasetti et al. 1988). The degree of contact with humans may determine which activity pattern is displayed, as shifts from diurnal to nocturnal have been reported during hunting seasons (Hansen and Karstad 1959). Within barns pigs have been reported to perform well in total darkness (Comberg and Doenen 1968, as cited by Curtis and Backstrom 1992). When given the opportunity to control lighting through operant conditioning, pigs will work to obtain as little as 2 min of light a day (Baldwin and Meese 1977). Lighting patterns affect feeding behavior, but not in terms of total intake. Pigs in continuous light evidence a sinusoidal eating pattern, peaking during midday (Gonyou et al. 1992). Pigs on an alternating light/dark cycle display peaks of eating when the lights turn on or off, little eating during darkness, and intermediate levels during midday (Walker 1991; de Haer and Merks 1992). These results suggest that pigs are remarkably adaptable to lighting patterns.

Lighting has been implicated in three areas of production: reproduction, growth, and injuries. Pigs are reported to be short-day breeders (although only moderately so), because the gradually decreasing day length during the summer stimulates the reproductive performance of both boars and sows (Claus and Weiler 1985). Shortening the photoperiod during lactation

also improves the return to estrus (Prunier et al. 1994). Longer daylight periods have been demonstrated to increase the growth of suckling pigs (Mabry et al. 1982), primarily through increasing the frequency of nursing (Mabry et al. 1983). One of the few situations in which long photoperiods improve feed intake is during the postweaning period (Bruininx et al. 2002). Although the common recommendation is to use low levels of illumination in grower-finisher barns to reduce activity and aggression, Tuovinen et al. (1992) reported that pigs on farms providing only 48 lx of light had more injuries at the time of marketing than did those on farms providing 77 lx. Christison (1996) reported no differences in postweaning aggression or wound scores under diverse light intensity levels.

EQUIPMENT AND PENNING

A common cause of leg injuries in pigs is slippery floors. Pigs are less likely to slip on concrete floors that are dry and broom- or wood-float–finished than on steel-trowel–finished floors (Applegate et al. 1988). Plastic floors are suitable for creep areas and nurseries but are less desirable for finishing pigs or sows. In addition to slippage, the thermal insulation and comfort value of a floor should also be considered, particularly for young animals. Piglets prefer to lie on plastic-coated metal than on expanded-metal, plastic, or fiberglass slats (Pouteaux et al. 1983). Fully slatted floors are becoming a norm of the industry, even though they are generally recognized to result in more leg problems. A compromise would appear to be flooring with normal slatting around the periphery, where dunging occurs, and a lower percentage of slats in the middle or traffic areas of the pen.

Open penning between pens is also becoming the most common type of pen divider. Such penning is particularly important if convective cooling is heavily relied upon. However, solid walls have advantages in terms of controlling dunging patterns (Hacker et al. 1994) and reducing the movement of manure and pathogens between pens. In general, if convective cooling is desirable, open penning should be used and floors should be fully slatted. In cooler climates in which air movement over the pig is undesirable, solid penning and partially slatted floors work well. Penning materials should be easily cleaned and disinfected. Polyvinylchloride is an easily cleaned material suitable for solid penning.

In general, pens for growing finisher pigs should be 1.5–2.5 times as long as they are wide. This shape facilitates good dunging patterns and easy handling of pigs. Pens should be a minimum of 1.5 times the length of a pig wide (approximately 2 m). This width is necessary to maintain free movement within the pen, particularly if the feeder position requires pigs to stand perpendicular to the pen divisions. If it is compatible with feeder design, in narrow pens feeders should be situated so that pigs stand parallel to pen divisions while eating in order to improve freedom of movement. Pigs perform well on floors with slopes as great as 8%, which facilitates drainage and results in dry sleeping areas (Bruce 1990; Arey and Bruce 1993).

Equipment should be properly sized for the pigs using it. Linear dimensions of the pig, such as length and width, are proportional to body weight $(BW)^{0.333}$. To reduce water wastage (a source of humidity) and injuries, nipple drinkers should be mounted slightly above shoulder level of the pig. The appropriate height for downward-pointing nipples, in centimeters, can be calculated as $18 \times BW^{0.333}$, where weight is in kilograms (Gonyou 1996). The number of pigs that can eat simultaneously from a feeder is dependent on the shoulder width of the pigs rather than the number of dividers in the feed trough. The appropriate width of a feeding space is $67 \times BW^{0.333}$, where width is in centimeters and weight is in kilograms (Baxter 1991). Injuries from feeders are caused by rubbing against parts of the feeder while eating and by feeding-related aggression. Aggression can be reduced by protecting feeding spaces with panels extending back to the shoulder of the pig (Baxter 1991). Injury from feeder contact can be reduced by providing easy access to the feed using a spacious feeding trough and by avoiding sharp edges in construction.

The dimensions of farrowing crates are not as well defined as those for feeders. Even small deviations in the height of the bottom bar or the width of the crate can have significant effects on the behavior of sows and piglets (Rohde Parfet et al. 1989). Studies using existing commercial equipment reported lower piglet mortality for farrowing crates in which the sow was closely confined (Svendsen et al. 1986; Vermeer et al. 1993).

SPACE ALLOWANCE

The allometric relationship for space allowance, a two-dimensional factor, is $k \times BW^{0.667}$, where space allowance is in square meters and body weight is in kilograms (Baxter 1985). Use of an allometric equation for determining space allowance has several advantages over standard tables. An equation allows the producer to determine the space allowance for pigs at the weights they have when they are moved or marketed, rather than extrapolating from a table. This is particularly helpful when market weights are increasing beyond those listed in tables. The k for space used by a lying pig is approximately 0.027 (Baxter 1985). Maximum growth is obtained at k values between 0.034 and 0.039 (Gonyou and Stricklin 1998; Edwards et al. 1988). Growth is depressed approximately 5% when a k value of 0.030 is used. Space allowance should be increased during summer months. The space allowance for a pen should be determined using the average weight of the pigs in the pen when the first pig is removed. For grower facilities this is the average of the pen when they move

to the finishing barn. The average weight of the pigs in a pen in the finishing barn is assumed to be approximately 10 kg less than the weight of the largest pig. The weight used for calculating space allowance in finishing facilities should be 10 kg less than market weight.

Overcrowding of pigs results in slower growth and a higher incidence of behavioral problems. Because overcrowding also reduces feed intake, it has been suggested that the performance reduction is due to limited access to the feeding area. If such is the case, increasing the nutrient density of the diet, and thus reducing the time required to consume the feed, should resolve the problem. However, crowding results in similar reductions in intake and growth for pigs that are fed high-density energy (Brumm and Miller 1996), protein (Edmonds et al. 1998), or lysine (Kornegay et al. 1993) diets as well. Chapple (1993) has suggested that stressful conditions may reduce the lean growth potential of pigs, and hence reduce intake. There does not appear to be an effect of crowding on the incidence of stomach ulcers (Eisemann and Argenzio 1999), humoral immune response (Kornegay et al. 1993a), corticosteroid levels, or adrenal weights (Kornegay et al. 1993b). The reduction in growth and feed intake and the increase in behavior problems are indicative of reduced welfare of the animals. However, profitability may be greater under more crowded conditions due to more efficient use of space and capital investment (Edwards et al. 1988; Powell and Brumm 1992). Selection of a space allowance is an ethical decision in which the welfare of the animal must be considered as well as the profitability of the enterprise.

Quality of space refers to how well the space accommodates the behavior of the pig necessary to maintain productivity and comfort. Improving the quality of the space will improve the living conditions of the pigs or at least maintain the quality of life in less space than poor-quality space. Enrichment of the environment is seen as one means of improving the quality of space. Although mechanical toys have not proven to be beneficial (Pedersen 1992), chewable material such as straw or hanging ropes may be useful in reducing behavior problems such as tail biting (Bruce 1990; Feddes and Fraser 1993). Partial partitions in pens for groups of sows allow the formation of subgroups and avoidance of aggressive animals.

SOCIAL

Wild and feral pigs normally live in small groups comprised of closely related individuals (Graves 1984). Even though the animals are related, recognition is based on familiarity rather than genetic similarity (Stookey and Gonyou 1998). When unfamiliar pigs are grouped together, aggression is intense and lasts for several hours. This results in injuries, short-term reduction in growth, and a reduction in immune response. Pigs that are regrouped when young usually recover by the time they

reach market weight. However, when near market weight animals are moved to a new pen and regrouped, they are delayed by 3–5 days in reaching market (Stookey and Gonyou 1994). Regrouping may potentiate susceptibility to other stressors such as crowding (Brumm et al. 2001).

There is some evidence that the composition of a group of pigs can affect their performance. Littermates continue to associate with each other more than with nonlittermates within the same pen throughout the growing-finishing period. However, this association does not confer an advantage on the animals, as small groups of littermates perform just as well as large groups of littermates within the same pen (Gonyou 1997). Pens comprised of very uniform pigs at the time of grouping become more variable as the pigs grow until the within-pen variation is similar to that of highly variable groups (Tindsley and Lean 1984). Within highly variable pens the greatest social stress, as indicated by reduced performance compared to uniform groups, is among the medium-weight pigs (Gonyou et al. 1986). Pens combining pigs of different temperament are more productive than those consisting of pigs with similar personality (Hessing et al. 1994).

Social stress is prevalent in groups of gestating sows that experience the additional stressor of restricted feed intake. Sows added to an established group form a subgroup of their own and are relegated to sleeping in the poorer areas of the pen (Moore et al. 1993). Regrouping during the period of embryonic implantation in bred sows (15–21 days) may result in high return to estrus rates. Social stress in groups of sows can be reduced by providing adequate space (in excess of 2 m^2/sow), straw bedding, and partial partitions to allow subgrouping.

STOCKPERSONS

Stockpersons are part of the biological environment of the pig. The importance of the attitude of stockpersons and their interaction with animals on productivity has been reviewed by Hemsworth et al. (1993) and elsewhere in this volume (Chapter 51). Placing greater emphasis on the training of stockpersons and encouraging them to identify and correct problems early are warranted.

HYGIENE

Control of the pathogen load within the pigs' environment is a critical part of management. Management programs such as sourcing of breeding stock, all-in/all-out pig flow, segregated early weaning, and three-site production are discussed elsewhere in this volume (Chapter 68). Within each of these systems of management there is a need for good hygiene to control pathogens. One of the most common sources of pathogens is the feces of other pigs. Solid divisions between pens or smaller rooms are means of restricting

movement of material from pig to pig. Frequent cleaning and disinfection of surfaces is the most effective means of reducing pathogen loads in the barn. Morgan-Jones (1987) emphasizes four steps in the cleaning process: removal of gross dirt, particularly organic matter; disinfection; a period of rest before refilling; and fumigation, if possible. Disinfectants include cresols, phenols, quaternary ammonium compounds, iodophors, hypochlorite, and sodium hydroxide (Curtis and Backstrom 1992). Facilities disinfected with cresols should be washed with water once surfaces are dry to prevent skin irritation on pigs. The most effective fumigant for pigs barns is formaldehyde gas, but it must be used carefully due to its toxicity. For most operations the use of all-in/all-out pig flow is the best way to facilitate such cleaning.

65 Nursery Pig Management

John R. Pluske, Jean Le Dividich, and David J. Hampson

The young pig is capable of extremely rapid growth after weaning, but unfortunately a number of factors limit the extent to which this inherent genetic potential can be expressed. Whittemore and Green (2001) suggested that growth rates of 100, 200, and 400 g/day in the first, second, and third weeks after weaning, respectively, were commercially acceptable targets under good nutritional, management, disease and environmental conditions. However, it has been recognized for more than 30 years that young, artificially reared pigs (i.e., weaned at 1–2 days of age) given ad libitum access to milk liquid diets can grow in excess of 500 g/day (Hodge 1974; Williams 1976). Excellent growth rates and feed conversion are achievable also in the postweaning period. For example, Pluske et al. (1996) demonstrated that 28-day-old, individually penned weaned pigs fed cow's whole milk every 2 hours for 5 days also grew in excess of 500 g/day and converted milk dry matter to empty body-weight gain at ratios approximating 1.0 (Table 65.1). Williams (2003) commented that if studies such as these were repeated with modern genotypes, young pigs might grow even faster and hence demonstrate a higher potential for lean tissue gain. There is little doubt, therefore, that the commercially reared piglet, both before and after weaning, substantially underperforms relative to what is possible.

Major considerations when discussing overall management and performance of the weanling pig are associations and interactions that occur before and after weaning that can determine future growth. Whittemore and Green (2001) stated that the growth of a pig from birth to maturity is best described by a Gompertz function, which means that the pig has a predetermined growth path and that there are large, fast growing animals and smaller, slower growing animals. The function also means that a larger genotype or a pig with a greater propensity for growth will, at any age, be bigger and grow faster than a smaller genotype, such that pigs heavier at birth and (or) weaning should maintain this advantage as they attain a more mature body size (grow

older) (Williams 2003). The Gompertz function fails, however, to describe the postweaning period where pigs commonly lose weight and then slowly recover. The challenge to people involved in most facets of pig production is to minimize the "growth check" after weaning so that the young pig reestablishes its genetically determined growth path and reaches market weight as quickly as possible.

This chapter commences with a brief description of the variation in piglet weaning age around the world. The chapter then discusses the changes that occur at weaning and is followed by a summary of research concerning the generalized effects of behavior, nutrition and management before weaning on postweaning performance, including the influence of bodyweight at weaning and easing the transition before and after weaning. The chapter concludes with discussion on nutritional and water management and some key nutritional perspectives to promote increased voluntary feed intake and faster gain after weaning.

THE WEANING PROCESS

Weaning generally occurs between 14 and 28 days of age in the major pig producing countries of the world, although key differences exist between and within countries. For example, in the U.S. the majority (60–70%) of pigs are weaned between 16 and 20 days of age, although approximately 15% of the pigs are early-weaned, between 7 and 14 days of age (M. C. Brumm, personal communication) when the passive immunity that the piglet has derived from colostrum and milk is still at a high protective level. In this situation, pigs are moved to off-site facilities or to a nursery physically isolated from older pigs. In contrast, weaning earlier than 21 days of age is banned in the European Union (EU), and legislation might raise this to a minimum of 28 days of age. Moreover, the ban on the use of growth-promoting antibiotics as feed additives in the EU, and legislated reductions in the levels of dietary zinc and copper that can

Table 65.1.   The performance of piglets in the first 5 days after weaning when given either a dry, pelleted starter diet (Starter) offered on an ad libitum basis, or cow's whole milk offered at a calculated maintenance (M) level, a calculated 2.5 times maintenance level (2.5 M), or offered on an ad libitum (Ad Lib) basis.

	Diet Treatment After Weaning				Level of Significance
	Starter	M	2.5 M	Ad Lib	
Bodyweight (BW)					
Weaning	9.0	9.1	9.2	9.2	NS[1]
Slaughter	10.5	9.4	10.5	11.7	NS
Gain, g/day

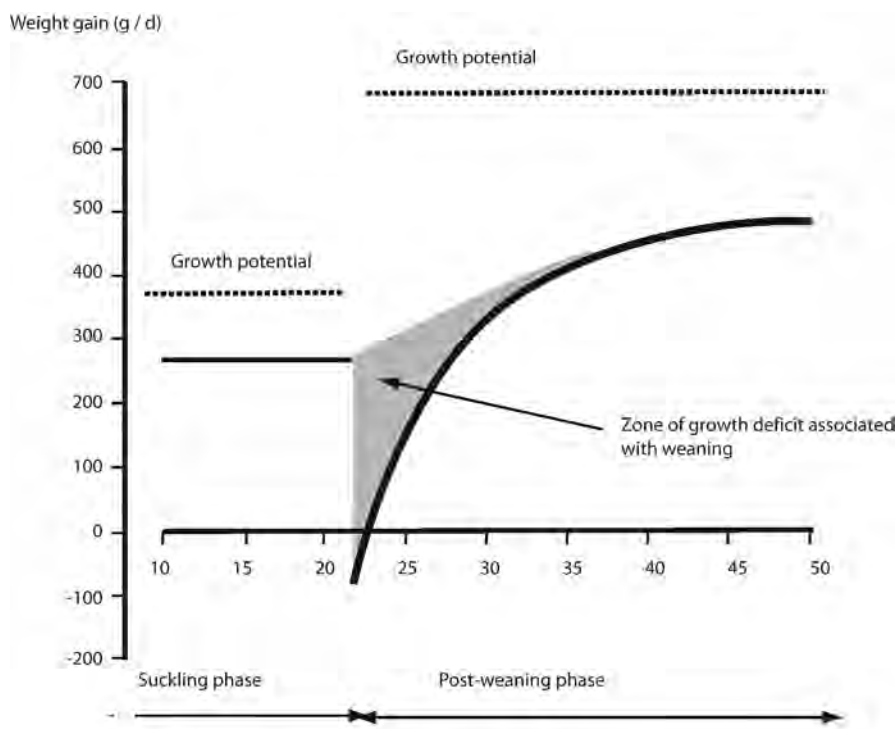
[2]Empty bodyweight is bodyweight of the pig minus contents of the bladder and the gastrointestinal tract.
[3]EBWG: empty bodyweight gain.

help to control postweaning disorders, have caused an increase in weaning age in countries such as Sweden, where piglets are weaned at closer to 35 days of age. Moreover, in France the issue of saving supernumerary piglets from hyperprolific sows is causing a reexamination of weaning age and practices (Le Dividich et al. 2003).

Regardless of weaning age, the process of weaning is a stressful experience because a number of simultaneous and unique problems not experienced elsewhere in other phases of pig growth occurs. These problems can be classified broadly as nutritional (i.e., change from milk liquid diet to a dry, solid diet differing in texture and composition), environmental (e.g., temperature

differences, characteristics of the housing system), social (i.e., separation from the dam, mixing with non littermates) and physical (e.g., transportation, adaptation to new feeding and drinking systems) (Mormède and Hay 2003). Under natural or seminatural conditions, weaning is a progressive process that occurs at 12–17 weeks of age, which is in obvious and stark contrast to commercial pig production. Summaries of the key differences between natural and commercial weaning are described by Brooks and Tsourgiannis (2003).

The collective effect of these actions and events contributes to the postweaning growth check, or lag, which is distinguished by a well-defined period of time in which growth is in deficit (Figure 65.1). The extent of


65.1. The growth potential of piglets and an illustration of the effects of weaning on the growth deficit ("check") that occurs. The least-squares fitted equation of growth rate during the post-weaning phase is as follows:
$y = 650\ (\pm 53) - 784\ (\pm 57)\ e^{-0.103\ (\pm 0.02)x}$, where y = growth rate (g/day), and x = day postweaning (adapted from Le Dividich and Sève 2000).

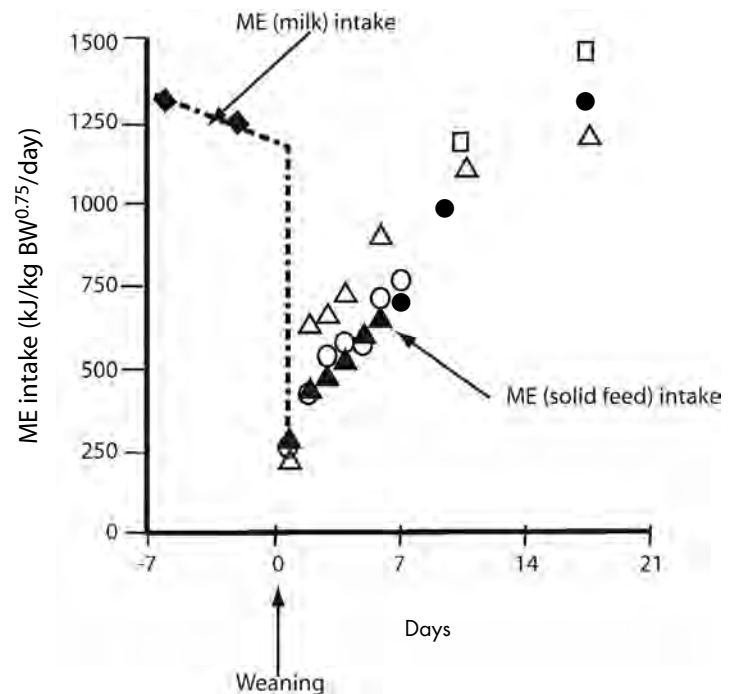
the growth check appears to be greater the younger the pig is weaned (Dunshea et al. 2002a; Main et al. 2004), partially because of incomplete and hence compromised gastrointestinal development and function (Pluske et al. 2003). Given the nature of the changes imposed it is not surprising that the relative rate of growth of the piglet decreases after weaning. The extent and severity of the growth check depends largely on how resilient the piglet is to the changes and how rapidly it can adjust to its new circumstances and regain homeostasis (Williams 2003).

The extent and duration of the growth check is also highly variable, with some piglets seemingly being unaffected while the condition of others can deteriorate very quickly after weaning. Minimizing the growth check at weaning depends to a large extent on the time taken for a pig to commence eating and the subsequent amount of food eaten, although other factors such as water intake, environmental temperature (see Madec et al. 2003), light schedule (Bruininx et al. 2002a), disease burden and so on must also be considered. Behavioral studies by Bruininx et al. (2001, 2004) and data summarized in Brooks and Tsourgiannis (2003) illustrate that although most pigs in a pen have taken their first meal within 24 hours of weaning, in some pigs it is 50–60 hours before they take their first meal. This causes the variability in performance generally seen in the weaner phase of growth, which can persist through to finishing. Fowler and Gill (1989) calculated that if a pig weaned at 21 days of age was to grow at 280 g/day, a growth analogous to that while sucking the sow, it would need to eat 7.8 MJ of digestible energy (DE) per day. To support this growth rate the piglet would therefore need to eat ap-

proximately 500 g of a starter diet containing 15.5 MJ of DE, an intake that is never seen under experimental conditions let alone in commercial practice (Williams 2003).

Commercially, the metabolizable energy (ME) requirement for maintenance is not met until day 3 to 5 after weaning (Le Dividich and Herpin 1994; Bruininx et al. 2002a) (Figure 65.2), and the level of ME intake attained at the end of the first week after weaning accounts for only 60–70% of the preweaning milk ME intake. Usually, 10–14 days are required for pigs to regain their preweaning ME intake. Thereafter, ME intake increases at a rate of 100–120 kJ ME/kg $BW^{0.75}$/day until a plateau is attained at 14–21 days after weaning. Voluntary ME intake attained at the plateau averages 1.5 MJ ME/kg $BW^{0.75}$/day, which is about three times the ME required for maintenance.

Associated with the growth check are changes to the structure and function of the gastrointestinal tract that can predispose to the proliferation of undesirable bacteria (such as enterotoxigenic *Escherichia coli*), leading to general gastrointestinal malaise, diarrhea, morbidity and occasionally mortality. It is not our intention to describe the structural and functional changes occurring in the gastrointestinal tract around weaning because these have been fully and adequately described elsewhere (Hampson 1994; Pluske et al. 1997; Hopwood and Hampson 2003; Miller and Slade 2003; Vente-Spreeuwenberg and Beynen 2003).

The continuous intake of nutrients by the piglet in the immediate postweaning period is generally regarded as being essential to maintain structural and functional integrity of the small intestine (Pluske et al. 1997;


65.2. *The effects of weaning at 21 days of age on the metabolizable energy (ME) intake of pigs fed solid feed. Results were obtained from seven studies. The least-squares fitted equation of ME intake during the postweaning phase is as follows:*
$$y = 1509\ (\pm65) - 1479\ (\pm80)\ e^{-0.127\ (\pm 0.02)x}$$
where y = ME intake (kJ ME/kg^{-1} BW$^{0.75}$/day, and x = day postweaning (adapted from Le Dividich and Herpin 1994; Le Dividich and Sève 2000).

Brooks and Tsourgiannis 2003; Vente-Spreeuwenberg and Beynen 2003) and promote large intestinal function (van Beers-Schreuers et al. 1998). Restrictions on the use of antimicrobial agents in some parts of the world however have led to readvocation of restricted feeding to reduce postweaning diarrhea, although some authors (Madec et al. 1998) have reported that higher levels of feed intake after weaning were associated with a reduced risk of diarrhea. Nevertheless, Geary and Brooks (1998) demonstrated the importance of feed intake *per se* in the postweaning period because they calculated that each 50 g per day increase in dry matter intake in the week following weaning increased bodyweight at day 28 postweaning by 0.87 kg. Dry matter intake in the week after weaning accounted for as much variation in bodyweight at 28 days after weaning as any combination of weaning weight, weaning age, gender and diet (Geary and Brooks 1998). Although pigs in this analysis were fed fermented liquid feed that generally promotes a higher level of feed intake than dry feed, the general principles would also apply to pigs eating solid feed.

BEHAVIOR AFTER WEANING

Pigs are rarely kept in their litter groups after they are weaned, but are mixed with pigs from other litters to form the desired group size. Group size for conventional indoor pens that have fully or partially slatted floors has traditionally ranged from 15–30 pigs per pen. Some production systems however, such as outdoor deep-litter hoops, can contain in excess of 250 weanling pigs per pen. Mixing piglets from different litters causes vigorous fighting for the first few hours after weaning and promotes adverse behaviors such as belly-nosing, but eventually a dominance hierarchy and new social order is formed based on dominance-subordination relationships between the pigs in the group. McGlone (1986) commented that social stability is usually observed within 48 hours of weaning, although sporadic fighting events can continue for up to 120 hours after weaning. These behavioral observations have generally been conducted indoors with small group sizes. Housing newly weaned pigs in larger groups in outdoor hoops most likely changes group behavioral dynamics, as has been observed with growing pigs (Morrison et al. 2003a). Unfortunately little or no research appears to have been conducted in this area with weanling pigs.

Associated with these behavioral events are neuroendocrine changes in response to the stress of weaning (Fitko et al. 1992; Mormède and Hay 2003) or to alterations in energy metabolism, although the latter is thought to be of relatively minor physiological importance (Heetkamp et al. 1995). In this respect, regardless of the age at weaning, a transient increase in plasma cortisol or of urinary excretion of cortisol is usually observed (Carroll et al. 1998; Hohenshell 2000; Hay et al. 2001). Changes in the cortisol level are commonly used

as an index of stress. Cortisol is also a catabolic hormone, with its secretion being enhanced during periods of feed deprivation (Farmer et al. 1992). Therefore, the increased cortisol secretion could reflect both the weaning stress and the catabolism of energy stores occurring at weaning (see review in Le Dividich and Sève 2000). Urinary excretion of catecholamines are also enhanced after weaning and fasting and implicate low feed intake in altered sympathetic nervous system activity (Young and Landsberg 1977; Hay et al. 2001).

A considerable body of research exists examining ways to ameliorate the stress response at weaning and examine subsequent production effects, mostly with equivocal findings. For example, Pluske and Williams (1996b) attempted to minimize some of the social stress at weaning by comingling (familiarizing) piglets from different litters for the last 14 days of a 28-day lactation period and then grouping these piglets together after weaning. Piglets allowed to familiarize with each other in this manner showed significantly reduced aggressive behaviors after weaning compared to piglets that were mixed directly at weaning. However, this practice showed no lasting stimulatory effects on production indexes such as feed disappearance and daily gain. Other researchers have reported similar findings (Friend et al. 1983; McConnell et al. 1987; Pitts et al. 2000; Weary et al. 2002).

Some of these studies have used alterations in pen design/structure as a means of reducing piglet aggression. For example, McGlone and Curtis (1985) and Waran and Broom (1992) reduced aggressive behaviors and increased growth in the first week after weaning when pigs were provided with "hide or escape areas" in the pen, although long-term positive effects on performance were not evident. It appears that the major advantage of reducing aggression at weaning is on pig welfare.

THE IMPORTANCE OF BODYWEIGHT

Piglet weight at weaning and soon thereafter appears to be a major determinant of the subsequent growth performance, although the manner in which pigs reach a heavier weight also appears crucial. Williams (2003) reviewed numerous studies showing that birth weight is correlated to weaning weight, that weight at 1 week of age is correlated to weaning weight, and that weight at weaning is correlated to subsequent performance after weaning. In addition, Tokach et al. (1992) and Azain (1993) reported that pigs growing well (225–340 g/day) in the first week after weaning reached market weight 10–28 days before pigs exhibiting poor gain in that same week (0–110 g/day). The effects of weight gain (and hence feed intake) in the first week after weaning and weaning weight have been shown to be additive and account for 80% of the variation in body weight on day 20 after weaning and 34% at 118 days of age (Miller et al. 1999; Ilsley et al. 2003). Furthermore, Lawlor et al.

(2002a) commented that the type of diet fed after weaning can affect the significance of the relationship between birth weight and postweaning performance. They recommended feeding a high-density diet after weaning to take advantage of this relationship.

Pigs that are heavier at weaning seem to continue their weaning weight advantage to slaughter weight (Mahan and Lepine 1991; Lawlor et al. 2002a; Dunshea et al. 2003). However, the manner by which a piglet attains that weight, such as higher creep feed intake during the lactation period, appears to have a marked influence on subsequent growth performance. Williams (2003) argued that if food intake is genetically determined to drive growth that is also genetically determined, which it must be, then it is most unlikely that a transient period of higher-than-normal nutrition will change a long-term hypothalamic food "setting." Consequently, any increase in weight caused by an increase in growth would, at best, be maintained and, at worst, disappear with time.

Several data sets support this theory and may help to explain the apparent paradox in the literature surrounding this issue. Wolter et al. (2002a) found that increasing weaning weight by means of supplemental milk replacer during a 21-day lactation had no significant effect on performance to 14 kg after weaning or on performance in the period from weaning to slaughter at 110 kg. On the other hand, piglets that were inherently (genetically) heavier at weaning, partially because they were heavier at birth, ate more and grew faster to slaughter (Table 65.2). Nevertheless, piglets fed milk replacer took 3 days fewer to reach slaughter than piglets not offered milk replacer. Lawlor et al. (2002a) reported a 0.6 kg increase in weaning weight at 28 days, attributable to creep feeding. This weight advantage was lost by day 26 after weaning, whereas pigs inherently heavier at weaning (7.1 vs. 5.8 kg) remained heavier 26 days later (17.5 vs. 15.4 kg) because they ate more feed. These data are consistent with those of Fraser et al. (1994) who estimated that creep feed intake in lactation accounted for only 1–4% of the variation in bodyweight gain after weaning. In another study, Wolter and Ellis (2001) reported that weaning weight had a greater effect on age at slaughter than growth rate in the first 2 weeks after weaning, which was manipulated by offering a liquid milk replacer.

In contrast, Dunshea et al. (1997) found that providing skim milk powder (20% dry matter content) from day 10 of a 20-day lactation not only increased weaning weight (0.7 kg), but had a significant positive effect on bodyweight at 42 and 120 days after weaning compared to piglets that did not receive the milk supplement. These contrasting data sets are difficult to reconcile, but Williams (2003) postulated that consumption of skim milk powder during suckling, with its more favorable protein-to-energy ratio compared to sow's milk for lean tissue gain (Campbell and Dunkin 1982; Williams 1995), might have allowed the piglets to compensate for the inferior quality of sow's milk and hence shifted their preprogrammed growth curve.

Management techniques have also been tried to increase weaning weight. Split weaning is a practice whereby half the litter, or some other proportion, usually the heavier piglets, is weaned. The lighter pigs remain to suck the sow, say for an extra 5–7 days, to obtain more milk. Several workers have shown that the light piglets that remain with the sow grow faster than their counterparts that have to compete with their larger littermates (summarized in Le Dividich 1999). For example, Pluske and Williams (1996a) split-weaned the heavier piglets from litters at 22 days of age and showed that the bodyweight of the remaining lighter piglets could be increased by 60% in the following week because of increased milk intake, relative to counterparts not split-weaned. Lighter piglets in the split-weaned litters weighed 15% more (7.7 vs. 6.7 kg) than their counterparts in the full litters at weaning at 29 days of age. However by 9 weeks of age the difference in weight had disappeared (19.3 vs. 19.3 kg).

MANAGEMENT OF THE PIGLET DURING LACTATION

Associations are believed to occur between the preweaning nutrition and behavior of the piglet and subsequent postweaning performance. The piglet relies predominately on the sow for its nutritional requirements before weaning, at least under modern-day pig husbandry and weaning management systems. Piglets consume colostrum in the first 24–36 hours after parturition and then consume milk at regular intervals during the day and night until weaning (Pluske and Dong 1998). Colostrum intake before closure of the small intestine to immunoglobulins is of critical importance to both the subsequent survival and performance of the young pig, even in the postweaning period (Pluske and Dong 1998; King and Pluske 2003). Giving colostrum to weaker piglets, or to litters where the sow is suffering agalactia,

Table 65.2. The effects of birth weight (Heavy vs. Light), weaning weight and supplementary milk replacer during lactation (Milk vs. No Milk) on voluntary feed intake and growth rate to slaughter.

	Birth Weight		Supplementation in Lactation	
	Heavy	Light	Milk	No Milk
Bodyweight, kg				
Birth	1.83	1.38	1.58	1.58
Weaning (21 days)	6.6	5.7	6.6	5.7
Weaning to 110 kg				
Feed intake, kg/day	1.87	1.78	1.84	1.81
Growth rate, g/day	851	796	827	820

Source: Adapted from Wolter et al. (2002a).

is generally used as a management technique to increase survival rates and weaning weight and possibly reduce the variation in weaning weight (King and Pluske 2003). Alternatively, practices such as split weaning/cross suckling immediately after farrowing offer potential to allow a more equitable transfer of colostral immunoglobulins across the spectrum of weights within a litter (Donovan and Dritz 2000). Many studies show the benefits of colostrum for gut development, as an energy source for thermoregulation of the newborn piglet, a substrate for protein synthesis, and a passive supply of protection against enteric pathogens (Le Dividich and Noblet 1981). Collectively, these functions are important in establishing the pig during lactation and, ultimately, after weaning.

Supplementary Feeding during Lactation

Many studies have investigated the effects of "creep" feeding (i.e., offering a solid diet) during lactation on weaning weight and performance thereafter (reviewed by Pluske et al. 1995; King and Pluske 2003). The major argument for offering suckling piglets supplementary food during lactation is to counteract the growing gap between the piglet's energy requirements and sow milk production as lactation advances. For example, Harrell et al. (1993) calculated that the supply of sow's milk probably begins to limit piglet growth at about 10 days of age and that the sow would need to produce an additional 18 kg of milk per day by day 21 of lactation to support equivalent piglet growth rates. This is clearly not possible. A further argument, although one that is less convincing, is that the consumption of creep feed prepares the gastrointestinal tract for the digestion of complex carbohydrates and plant protein that will be supplied after weaning. However, Chapple et al. (1989) reported that the variation in amylolytic activity in the pancreas of piglets was more a function of the sow (litter of origin) than of the intake of solid feed during lactation and immediately after weaning. Lindemann et al. (1986) and de Passille et al. (1989) found that pepsin and maltase activities in the gastrointestinal tract could not be related to weaning weight or to the duration of creep feeding during lactation. More recently, Bruininx et al. (2002b) reported the lack of any association between creep feed intake before weaning and gut structure at 5 days after weaning.

Finally, creep feeding has been said to familiarize piglets to solid feed so that the transition at weaning will be less stressful, but again, there is no robust evidence to support this sentiment. For instance, Kuller et al. (2004) conducted a study in which sows were either (a) intermittently suckled (IS) for 12 hours/day starting from day 11 to encourage their piglets to become familiar with creep feed before weaning and eat more of it during lactation, or (b) continuously suckled (CS), over a 27-day lactation. They found that although IS piglets consumed more creep feed during and after lactation than CS piglets, their bodyweights were the same by the seventh day after weaning.

Creep Feed Intake. In spite of the large body of evidence dealing with supplementary feeding, evidence to support the notion that supplying pigs with dry creep food during lactation will improve preweaning and postweaning growth performance is equivocal. Pluske et al. (1995) and Brooks and Tsourgiannis (2003) reviewed a number of studies presented in the literature and found an enormous variation in the intake of creep-fed piglets. Pluske et al. (1995) calculated that the contribution of creep feed to daily energy intake prior to weaning at 21–35 days of age ranged from 1.2–17.4%. Lawlor et al. (2002a) more recently confirmed this level of contribution to overall energy intake of the piglet. The intake of dry creep food during lactation is generally small and variable and unlikely to significantly influence weaning weight, particularly in piglets weaned at 3 weeks of age or younger (King and Pluske 2003). However, Appleby et al. (1991) reported that creep feed intake during a 27-day lactation was enhanced when piglets were provided a feeder with eight spaces compared to two spaces, and that piglets that ate more solid feed before weaning gained more weight in the 14 days after weaning. In spite of this, pigs with the higher intake were also heavier at birth, thereby confounding the effects. In another study, Appleby et al. (1992) found an inverse relationship between birth weight and creep feeding behavior, but by 42 days of age there was no difference in bodyweight between the groups.

Notwithstanding the positive responses of creep feeding observed in some studies, the literature suggests that growth rate after weaning is often poorly related to the intake of creep food before weaning (Barnett et al. 1989; Pajor et al. 1991; Fraser et al. 1994). Creep feed consumption varies tremendously both within litters and between litters. Fraser et al. (1994) estimated that creep feed intake accounted for only 1–4% of the variation in bodyweight gain in piglets in their first 14 days following 28-day weaning, even though there were significant litter effects on the intake of dry feed during lactation. Pluske et al. (1995) and King and Pluske (2003) commented that there is a highly significant effect, 30–60% of the total variance, of litter on weaning weight and subsequent postweaning performance. This indicates that one or more factors before weaning are having a major influence on both weaning weight and subsequent growth rate, with both prenatal and postnatal components likely having an effect. Rooke et al. (1998) reported that the relative importance of these events was 3:1 in favor of the prenatal effects, begging the question of where one begins to investigate the phenomenon of variation in pig weights. These issues currently remain largely unresolved.

One possible reason for the discrepancy seen between published studies is the methodology used to as-

sess intake of creep feed. The consumption of creep feed has generally been measured on either a litter basis or on an individual piglet basis, where litter consumption of the diet is divided by the number of piglets in the litter to achieve a per piglet consumption. The latter method of expression is erroneous because piglets in the same litter will not all consume the same amount of creep feed. In a unique experimental approach, Bruininx and colleagues (2002b) in The Netherlands used fecal Cr_2O_3 as a marker for classifying piglets as "good," "moderate," or "non" eaters of creep feed during lactation. Using this approach, in conjunction with computerized feeding stations that recorded individual feed intake after weaning, Bruininx et al. (2002b) found that pigs classed as "good eaters" preweaning showed less time between weaning and first feed intake compared to the other groups, and consumed more feed in the first 8 days after weaning. By day 34 after weaning the effect of greater creep feed consumption during the lactation period on feed intake was less pronounced, although daily gain was still higher. The methodology used in this study indicated that some individual pigs eat more than others after weaning because of their higher preweaning consumption of dry feed.

In this regard some pork producers, especially those weaning later than 21 days of age, continue to offer high-quality creep diets to suckling pigs irrespective of the general lack of effects seen at the litter level. In some countries, such as Sweden and Denmark, where weaning age is now 28 days of age or greater and the use of growth-promoting antibiotics and antimicrobial agents such as zinc oxide are banned or strictly regulated, the importance of enhancing the intake of solid feed before weaning is not questioned, and is receiving renewed attention.

Liquid Diets to Enhance Feed Intake Before and After Weaning. In contrast to the generally equivocal results reported with the intake of dry creep feed, providing young pigs with liquid feed, either dry diets in a gruel/slurry form or milk liquid diets, would appear to offer more promise as a management tool to increase both weaning weight and postweaning performance. Brooks and Tsourgiannis (2003) argued that in view of the problems the piglet usually encounters in discriminating between hunger and thirst in the immediate postweaning period, then offering a liquid diet has three potential advantages:

1. It provides a diet with a dry matter content more akin to that of sow's milk.
2. It can provide a diet more closely matched to the piglets' needs for nutrients and water.
3. It overcomes some of the issues piglets face in having to learn to satisfy drives for both hunger and thirst.

The feeding of a solid diet in gruel/slurry form allows piglets to associate feed and water together, which in turn could enhance dry matter intake. Toplis et al. (1999) stimulated piglets to consume an average of 374 g/day of gruel (1:2 meal to water ratio) in the last 10 days of a 24-day lactation; yet they weighed 0.2 kg less than piglets allowed to only suck the sow. This practice, however, stimulated performance after weaning, with gruel-fed pigs growing 150% faster (150 vs. 49 g/day) than piglets that ate no creep feed during lactation, and they grew 30% faster (416 vs. 317 g/day) for 5 weeks after weaning. Lawlor et al. (2002b) found no consistent effects of feeding liquid feed or acidified liquid feed to pigs weaned at 28 days of age, while Le Dividich et al. (unpublished data) showed superior performance of 28-day-old weaned pigs fed liquid diets using a programmable, automated liquid feeder. However, long-term advantages of the system on performance were not seen. From a limited number of studies it would appear that benefits derived from feeding weaner diets in liquid (gruel/slurry) form are equivocal.

Many more studies have investigated feeding milk replacer diets to young pigs. For example, Reale (1987) offered cow's whole milk to piglets from 10.00 h each day, adding fresh milk every 2 hours until 23.00 h, from day 7 to day 28 of lactation. Growth was stimulated by 151 g/day (71%) in the fourth week of lactation and by 87 g/day from day 7 to 28. This practice increased weaning weight by 1.8 kg in comparison to controls that were offered a dry creep feed. King et al. (1998) found that piglets offered liquid skim milk powder from day 5 of lactation were 1.6 kg heavier at weaning at 28 days of age than piglets that received no supplemental nutrients. In addition, piglets appeared to still prefer milk from the sow, because the supply of supplemental milk did not reduce the amount of milk that the piglet obtained directly from the sow.

King and Pluske (2003) reviewed a number of studies and reported a weight advantage of 11–35% at weaning in favor of offering a liquid milk replacer during lactation. Heo et al. (1999) reported that 14-day-old weaned piglets fed a liquid milk replacer achieved a growth rate of 470 g/day in the first 7 days after weaning. Kim et al. (2001) showed that feeding 11-day-old weaned piglets a liquid milk replacer through an automated milk machine for the first 14 days after weaning significantly increased weight at 28 days of age by 1.62 kg. This growth advantage was maintained to market weight with no evidence of compensatory gain in the dry-fed control pigs, with the liquid-fed pigs reaching market weight 3.7 days earlier than the dry-fed pigs. These results demonstrate the potential benefit of additional nutrients on weaning weight and a clear benefit of supplemental milk replacer to increase weaning weight. However, Armstrong and Clawson (1980) failed to stimulate growth in piglets offered liquid milk replacer during a 21-day lactation, perhaps suggesting that the sow was providing sufficient milk.

The use of a liquid milk replacer during the weaning

period has also been shown to reduce the severity and extent of the growth check. Dunshea et al. (1997) attempted to alleviate the postweaning growth check by providing extra milk around the time of weaning. Pigs provided with liquid milk replacer, in addition to access to dry starter feed, gained 1.2 kg during the first week after weaning, whereas pigs that received only dry starter feed gained 0.4 kg in the same period. Supply of a liquid milk replacer to piglets both before weaning and in the first week after weaning had an additive effect; pigs that received liquid milk replacer before and after weaning were 10% heavier at 120 days of age than pigs that suckled the sow only and were weaned onto dry starter feed (Dunshea et al. 1997). Much of this improvement was most likely attributable to the extra nutrient intake from supplemental milk replacer prior to and immediately after weaning.

It would appear that offering newly weaned pigs a liquid milk replacer offers the best potential for overcoming the postweaning decline in dry matter intake that occurs and hence increasing growth rate after weaning. Liquid feeding milk-based diets however can be labor intensive and hygiene must be adhered to for the practice to be successful.

Large-Scale Liquid Feeding and Fermented Liquid Feeding for Weanling Pigs. Large-scale, fully automated liquid feeding systems are used commonly throughout the world to feed growing and finishing pigs, especially to take advantage of cheaper co-products and by-products and modulate the bacterial environment in the fermentation vessel and in the pig. Liquid feeding on a similar scale for weaner pigs has met with less success, largely because of problems in maintaining the feed in a palatable and fresh manner, higher labor costs, poor feed hygiene, and feed wastage, particularly in the first week after weaning. Nevertheless, recent technological advances in liquid feeding, a trend for later weaning ages, a greater understanding of fermentation kinetics and the way fermented feed can modulate the gastrointestinal microbiota (e.g., Jensen and Mikkelsen 1998), and some convincing data showing marked improvements in dry matter intake and daily gain (e.g., Russell et al. 1996) offer exciting opportunities for managing the weanling pig in order to improve production and minimize enteric disturbances.

Use of Flavors in Diets

Research has been conducted in an attempt to increase weaning weight and reduce the growth check after weaning by using various sweeteners and aromatic compounds to increase feed consumption (reviewed by Brooks and Tsourgiannis 2003; King and Pluske 2003). Results have generally been variable. Campbell (1976) added a feed flavor into a creep diet and failed to increase creep food consumption or weaning weight, but unexpectedly the pigs that had been weaned from sows given a flavored diet and then given a flavored diet after weaning consumed more feed, particularly in the first 2 weeks after weaning. King (1979) confirmed this interaction on feed intake after weaning and also demonstrated that when the flavor was added to the sow diet, it was detected in milk samples collected from those sows. Madsen (1977) indicated that feed preferences could be transferred from lactating sows to their litter by incorporating a nonmetabolizable substance into both the lactating sow diet and the diet offered to piglets after weaning. Any positive effects of feed flavors observed in young pigs are more likely to be due to this transference of feed preferences via flavors incorporated in sow's milk, or by masking unacceptable tastes to improve the palatability of the creep feed (King and Pluske 2003).

In some regions of the world it is common practice to include flavors/sweeteners in commercial diets for young pigs, both before and after weaning, and various manufacturers actively promote their inclusion in diets. There is very little, if any, peer-reviewed published information relating to the use of flavors/sweeteners and their effects on production before and after weaning, although their continued use in diets suggests they are perceived to be of some benefit.

NUTRITION, NUTRITIONAL MANAGEMENT, AND THE IMPORTANCE OF WATER IN THE POSTWEANING PERIOD

Many review articles, peer-reviewed papers, popular press articles, and book chapters have been written on different aspects of nutrition and nutritional management of the weanling pig. Some of the more recent and comprehensive articles include those by Nelssen et al. (1999), Mavromichalis and Varley (2003) and Tokach et al. (2003). It is not our intention to reiterate this information; however, the principles of a successful nutritional program for the weanling pig will differ around the world according to a variety of factors, such as weaning age, weaning weight as alluded to previously, ingredient availability and cost, physical environment (e.g., indoor pigs kept on fully slatted floors vs. outdoor pigs kept on deep litter), regulations (e.g., restrictions on the use of antimicrobial agents and animal proteins, if any), the system of weaning (e.g., multisite production vs. farrow to finish), method of feeding (e.g., dry diets vs. liquid diets), nutrition during lactation, sow feeding programs, and adoption or not of phase feeding after weaning. For example, Mavromichalis and Varley (2003) commented that in North America the focus after weaning is predominately on reducing production costs, especially for the large integrated operations, by feeding pigs the cheapest diets as soon as possible after weaning (e.g., a phase feeding program; Tokach et al. 2003), whereas the European approach is based more on achieving maximum growth performance and optimum health status after weaning. Consequently a suc-

cessful transition between lactation and weaning is a multifaceted process that must consider the entire pig production system of any particular enterprise, and not only nutrition.

Campbell (1989) argued that practical nutrition of the young pig at weaning is more of an art than a science and suggested that a dietary regimen that is highly successful and repeatable under research conditions may not apply to commercial practice. This comment presumably reflects the large number of factors that impinge and interact on the piglet at weaning, as outlined previously. Nevertheless, Williams (2003) remarked that high feed intake after weaning, and hence high growth rates, with minimal digestive disturbances can be achieved consistently only with high-density, highly digestible diets. Starter (link) diets are generally required to ease the transition from milk (high-fat, high-lactose) to plant-based diets that are much lower in fat and contain high levels of antinutritional factors, such as nonstarch polysaccharides. Such diets generally need to contain high-quality animal products of milk origin, such as lactose, or products derived from blood. The younger the pig is at weaning the more important this becomes, and this is aptly demonstrated in recent data from Dunshea et al. (2002a). These authors offered piglets a weaner diet containing wheat (550 g/kg), Australian sweet lupins (50 g/kg), soybean meal (50 g/kg), meatmeal (66 g/kg), fishmeal (83 g/kg), skim milk (20 g/kg), blood meal (26 g/kg) and whey powder (100 g/kg), and weaned them at either 14 or 24 days of age. Pigs weaned at the older age gained weight during the first week after weaning; the younger pigs lost weight.

A key factor that has made weaning less problematic in the last 15 years, particularly when weaning at less than 16–18 days of age, is the use of specialized diets containing proteins derived from blood. Products from porcine blood, particularly porcine plasma, are mandatory for diets in parts of the world such as North America because they stimulate voluntary feed intake (Pluske et al. 1995; van Dijk et al. 2001; Tokach et al. 2003). The most favored explanation for this phenomenon is the presence of immunoglobulins, although the exact mechanism(s) of action is/are yet to be elucidated. However, because of the concern about feeding animal proteins to the same species and a ban on the use of plasma/blood proteins in the EU, there is interest in looking at other sources of milk proteins—for example, from cows—to see whether similar effects can be achieved in young pigs.

In New Zealand, Pluske et al. (1999) weaned pigs at 4 weeks of age and found that adding a spray-dried colostrum preparation (containing 150 g/kg IgG) at 50 g/kg diet stimulated food intake by 12% in the first week after weaning. They increased the amount to 10% and stimulated food intake by 25%. This extra food intake boosted growth by 40% and 80%, respectively, so that pigs on the highest level of colostrum grew in excess of

200 g/day in the first week after weaning. King et al. (2001) reported a 25% increase in voluntary food intake in the first 7 days postweaning by adding 60 g/kg of bovine colostrum to a diet after weaning, while Dunshea et al. (2002b) compared porcine and bovine plasma, bovine colostrum and commercially produced skim milk and found relatively little difference between the protein sources in the performance of pigs weaned at 14 days. However, Dunshea et al. (2002b) reported that their studies were conducted in a clean research environment, a factor thought critical in determining whether products such as porcine plasma prove efficacious after weaning (Coffey and Cromwell 1995). Grinstead et al. (2000) indicated that a high protein diet (780 g/kg) with whey protein concentrate provided pig performance comparable to animal plasma in weanling pig diets. More recently, Le Huérou-Luron et al. (2004) found a 22% increase in daily feed intake commensurate with a 33% increase in daily gain in pigs fed a bovine colos-trum preparation in the first week after weaning. It appears, therefore, that high-quality proteins based on colostrum/milk stimulate growth in the immediate postweaning period in a way analogous to porcine plasma, and depending on prevailing price and availability, could be used in regions of the world where blood products are banned or restricted in their use. After the initial phase after weaning, however, plant proteins such as soybean meal, rapeseed meal, peas, beans, and lupins generally form an increasing percentage of diets to minimize the cost per unit gain.

Feeding Management after Weaning

A successful nutritional regimen is one that encourages newly weaned pigs to commence eating as soon as possible after weaning, usually by offering feed on an ad libitum basis, while minimizing feed wastage, simply because diets fed in the immediate postweaning period are expensive. In this chapter, strategies that can be used before and after weaning to promote weight gain have already been discussed, and the intention here is to examine more practical ways to ensure piglets make a good start after weaning. In this regard, Tokach et al. (2003) remarked that the two major keys in management of the feed program are (i) a proper management protocol to encourage feed intake, and (ii) correct adjustment of feeders to reduce wastage.

Mat Feeding after Weaning. Supplying feed on temporary mats and (or) in small trays for several days after weaning has been shown to improve feed intake and growth rate (Mavromichalis and Varley 2003), provided correct management is adhered to. This generally includes adopting a "little but often" feeding policy (100–150 g feed/pig/day in 3–4 feeding episodes) and removing stale and fouled feed regularly. Feed must concurrently be available in self-feeders. Dritz et al. (1996) commented on the importance of trained staff in iden-

tifying "starve out" pigs and then managing them properly, for example, by teaching them how to eat. Mavromichalis and Varley (2003) remarked that pellets and blends of pellets with mash (meal) are best because piglets tend to waste more pellets if they are fed alone. Beattie et al. (1999) attempted to increase feed intake after weaning by providing wet feed in a trough in the pen for 5 days after weaning, and although intake was increased, there were no long-term effects on production. Beattie et al. (1999) remarked that the trough containing wet feed incurred additional labor costs.

Management of the Feeder. Proper adjustment of feeders is a labor- and time-consuming process but is key to good feed efficiency and hence lower feed cost per unit gain. Feed wastage is notoriously difficult to measure or estimate, although Mavromichalis and Varley (2003) estimated wastage of 5–7% in properly managed feeders. Mavromichalis and Varley (2003) and Tokach et al. (2003) recommended that the adjustment gate in the feeder must be closed before filling it with feed, because placing pelleted feed into an empty feeder with the adjustment gate open could increase wastage and cause subsequent problems in proper feeder adjustment.

Tokach et al. (2003) recommended managing the flow of feed into the feeder pan to stimulate the development of feeding behavior by allowing only 50% of the pan to be visible in the first few days after weaning. Mavromichalis and Varley (2003) recommended a 66% coverage with feed. Too much feed in the pan can cause the build-up of fines, leading to blockages. Regardless, as pigs become accustomed to feeding, the amount of feed in the pan can be gradually reduced—for example, to 25–33%, which reduces wastage and reinforces feeding behavior. Care also needs to be taken of feeding pellets or mash (meal) because mash diets, particularly if high in milk products, tend to bridge feeders more than pellets. Mavromichalis and Varley (2003) suggested that observing pigs and looking for wastage underneath the pens and around the feeder were the best ways to assess wastage, and that environmental conditions, such as higher humidity, can cause feed to stick to gate openings. The build-up of fines should also be avoided.

The Importance of Water Intake after Weaning
Voluntary or involuntary deprivation of water in the period after weaning can have dire consequences for piglet physiology, health, and performance. Gill (1989), for example, showed that it could take more than a week after weaning for piglets to restore their daily fluid intake to preweaning levels. There are important behavioral components associated with water intake after weaning that presumably influence the extent and volume of water consumed after weaning. Brooks and Tsourgiannis (2003) explained that sucking pigs have been conditioned to consume milk to satisfy their needs for volumetric "fill," and in the early postweaning period may

fail to distinguish between the separate drives for hunger and thirst. Having been conditioned to a liquid milk diet, newly weaned piglets may mistakenly believe that water is also a source of nutrients.

Part of the reason for low water intake after weaning is most likely related to piglets' having to locate and use the drinker. There is no convincing evidence that familiarization with water and drinkers before weaning enhances water intake and performance after weaning. Even after weaning, using a drip to try and encourage water consumption has proven largely unsuccessful (Ogunbameru et al. 1991). Rather, factors such as drinker design, placement, height, cleanliness, and number of drinkers per pen have been cited as influencing water intake.

Unfortunately, published data relating these factors to water consumption and then to postweaning performance are both scarce and contradictory. Drinkers placed at an incorrect height and angle or in an appropriate part of the pen will discourage intake of water and could promote its wastage. For example, Gill (1989) showed differences in daily gain and water efficiency use after weaning between drinker types. Torrey and Widowski (2004) demonstrated in 15-day-old weaned piglets that providing water via drinker bowls caused higher apparent feed intake in the first 2 days after weaning and that pigs spent less time engaged in drinking behavior, compared to pigs using a nipple drinker. Overall water use was also lower in piglets drinking from bowls. Pigs allowed access to bowl drinkers also spent less time belly-nosing. Horvath et al. (2000) reported that for the subsequent 8 weeks, piglets weaned at 35 days of age drank more water from a trough placed in each pen versus a nipple drinker. In contrast, Phillips and Phillips (1999) offered water to piglets from a number of dispenser options (nipple, float-controlled bowl with contents replaced daily with fresh water, float-controlled bowl that was not cleaned, or a nipple and float-controlled bowl cleaned daily). They found no differences in performance in the first 4 days after weaning, although they did report lower water intake from nipples on the first day following weaning and more wastage. Anecdotally, the use of bell-shaped turkey drinkers that are placed directly onto the floor of the pen after weaning have purportedly shown good results in terms of both water and feed intake (Brooks and Tsourgiannis 2003).

The rate and velocity of water delivered by the drinker have also been shown to influence feed intake and growth after weaning. Barber et al. (1989) reported a positive correlation between water delivery rate (175–700 ml/min) and voluntary feed intake after weaning, although Celis (1996; cited by Brooks and Tsourgiannis 2003) reported no improvement in performance with an increase in flow rate from 70–700 ml/min in piglets weaned at 28 days of age. Such differences between studies are difficult to explain, but they are most

likely related to factors such as drinker design, the number of drinkers and pigs per pen, water quality, drinker cleanliness, and the type of diet(s) fed to pigs. Brooks and Tsourgiannis (2003) remarked, however, that the amount of feed the piglet eats after weaning is determined by the amount of water that it consumes and not the reverse, and so strategies that promote water intake, albeit variable such as the use of sweeteners, can have a positive effect on feed intake after weaning.

FACTORS RELATED TO THE PHYSICAL ENVIRONMENT

Another important consideration regarding management of the weaning pig is the pen structure, which includes flooring materials, feeder and waterer designs, stocking density, and group size. Madec et al. (2003) recently conducted an extensive review of these factors; however, some points require reiteration. Additionally, aspects of the environmental requirements of pigs are covered elsewhere in this book (see Chapter 64).

Feeder Space and Feeder Location

Conventional understanding says that nursery pigs should have sufficient feeder space that allows at least half the pigs in a pen to eat at any one time. In practice this "rule" varies enormously and is not necessarily adhered to. For example, Pluske and Williams (1996c) reported no differences in production indexes in the 28 days after weaning when pigs were offered feed from either a linear trough or a single-space feeder. Laitat et al. (1999) reported similar results comparing a tubetype feeder, allowing piglets to mix feed and water, to a conventional feeder where drinking and water places were separated. Baxter (1989) presented an equation incorporating bodyweight and shoulder width that described the minimum feeding space a pig needs, with a pig weighing 10 kg requiring a minimum feeder space of 13 cm. Commercially, however, this rule is not necessarily followed, particularly in outdoor hoops where feeding behavior patterns can vary dramatically to those for indoor-housed pigs (Morrison et al. 2003b).

In a comprehensive study investigating the interaction between feeder location and group size, Wolter et al. (2000a) used 1,760 17-day-old weaned pigs to examine the effects of three pen designs on pig performance. The designs were (a) large group size (100 pigs/pen) with five two-sided feeders in a single, central location in the pen, (b) large group size (100 pigs/pen) with five two-sided feeders in multiple (five) locations in the pen, and (c) small group size (20 pigs/pen) with a single two-sided feeder in a single central location in the pen. Each feeder provided two 20.3 cm–wide feeding places on each side, and for all treatments, feeder trough space (4 cm/pig) and floor space (0.17 m^2) were the same. A slight yet significant reduction in growth performance (15 g/day) was found due to increased group size, but the approach to providing multiple feeding locations had no effect on production indexes.

Stocking Density

Floor space per pig is usually based on the space required for sternum and fully recumbent resting positions. Using various prediction equations, literature data, and commercial experience on perforated flooring, the current recommendations are 0.25–0.30 m^2 per pig between 5 and 30 kg bodyweight, with pigs on bedded solid floors requiring 20–25% more space (Madec et al. 2003). Extensive housing systems such as hoops on deep litter systems generally provide a more generous space allowance, although there is a dearth of information in this general area relating to the weaning pig.

In a series of studies Wolter et al. (2002b; 2003a, b) investigated the interactive effects of stocking density, feeder trough space, and diet complexity with large numbers of pigs. They reported that although performances to 10–12 weeks after weaning were initially negatively affected by increasing stocking density, reducing feeder space, and feeding a less complex diet, subsequent performances to slaughter at 25 weeks of age were largely unaffected. For example, Wolter et al. (2003b) found that pigs with restricted growth due to low floor space (0.32 m^2 vs. 0.63 m^2) until either 12 or 14 weeks after weaning showed increased growth rate and feed efficiency in the subsequent period to slaughter at 25 weeks postweaning, with only a slight effect on bodyweight and no effect on carcass measures.

Group Size

The optimum group size for maximum performance and efficient feed conversion in the postweaning period is always an area of controversy and interest, particularly in view of the tendency in some countries toward large group sizes (>250 pigs) in outdoor-based, deep-litter housing systems that do not adhere to conventional group size–performance dynamics, as originally proposed by Kornegay and Notter (1984). Moreover, increased group size is sometimes confounded with a decrease in stocking density, so caution needs to be adopted when interpreting data.

In a recent study, Wolter et al. (2000b) used 1,920 weaned piglets weighing 5.3 kg in a 2 x 2 factorially designed study to investigate the effects of group size (20 vs. 100 pigs) and floor-space allowance (calculated requirement vs. calculated requirement minus 50% of free space) on performance after weaning. These authors reported that large groups and reduced floor-space allowance reduced postweaning performance, with pigs in large groups also showing a greater within-pen coefficient of variation in bodyweight at 9 weeks of age. The extent of the difference in bodyweight after 9 weeks of age was less than 5%. In contrast, O'Connell et al. (2001) found no difference in the performance of weaners from 4–10 weeks of age when grouped in pens of 10, 20, 30,

40, or 60 pigs at constant floor space allowances and constant pigs-to-feeder and -drinker ratios. These authors concluded that the group size of pigs could be increased from 10–60 pigs per pen without any adverse effects on performance. From a comprehensive literature review on this subject, Payne et al. (2001) concluded that decreased performance in the weaner phase is not always predictive of decreased or increased performance in the finisher phase or overall performance

In this review, Payne et al. (2001) used statistical regression analysis and surmised that increasing group size from 20–100 pigs per pen appeared to have a small, negative effect on performance of weanling pigs, provided that floor space and the number of feeders and drinkers supplied were adequate. In practice, the economic consequence of increasing group size will depend on relativities between prevailing construction, labor, and feed costs. Housing pigs in large groups decreases construction, maintenance, and cleaning costs, but may increase labor associated with inspection, treatment, and marketing of pigs. Feed efficiency is unlikely to be affected greatly, although slight decreases in growth rate may reduce throughput or sale weight marginally (Payne et al. 2001). These factors must all be considered in any discussion relating group size to postweaning performance.

CONCLUSIONS

The first weeks after weaning are regarded as being crucial in the pork production cycle because they represent a period of adaptation and stress on the young pig. Differences in weaning age, and weaning, housing, and feeding practices worldwide, make it difficult to make *blanket* recommendations for successful feeding management after weaning. However, nutritional and management strategies should be adopted that minimize the stress response and encourage piglets to consume dry matter as soon as possible after the weaning event. A myriad of factors occur that can influence the subsequent performance of pigs and the variability of bodyweight gain. Bodyweight at weaning appears to have a major influence on subsequent production indexes; however, the manner in which a pig becomes heavier at weaning—for example, through having a higher birth weight or consuming supplemental nutrients during lactation—appears also to affect postweaning performance. Consequently, responses to various feeding strategies tend to be variable. Supplementation of piglets before and around weaning with liquid milk diets appears to offer the greatest potential to stimulate preweaning growth rate and to eliminate the postweaning check.

66 Management of Growing-Finishing Pigs

Cornelius F. M. de Lange and Catherine E. Dewey

The main aim in managing growing-finishing pigs is the efficient production of high quality pork meat while considering animal well-being and the potential negative impact of pig production on the environment. With the move toward larger growing-finishing pig units, the impact of relatively minor improvements in production efficiencies will have substantial impact on overall profitability. The main determinant of pork meat production efficiency is lean tissue growth, the accretion rate of dissectible muscle in the pig's body. The pigs' lean tissue growth potential is ultimately under genetic control, and the expression of the pig's lean tissue growth potential is determined by environmental factors such as the presence of disease causing organisms, animal density, the effective environmental temperature, and feeding management. Because feed represents the single biggest cost factor in commercial pork production, close attention should be paid to the development of effective feeding programs and the amount of feed that is consumed by growing-finishing pigs. In this chapter, the importance of accurate production records and monitoring growth and feed intake patterns of growing-finishing pigs is presented briefly. Feeding management and other important aspects of growing-finishing pig management are then addressed.

PRODUCTION RECORDS AND PRODUCTION OBJECTIVES

Both for making meaningful management decisions and to ensure that changes in management result in the anticipated changes in pig performance accurate production data need to be collected. The move towards all-in/all-out production systems has made data collection easier and more accurate. As a minimum the following data is required: cost per feeder pig placed in the barn, number and average body weight of pigs entering the barn and shipped for slaughter, mortality, number of pigs culled or sold as a lightweight pig, total feed usage,

average carcass weight and carcass lean yield, and average carcass value. This will allow for calculation of average daily gain, feed efficiency, feed costs per pig, and a simple estimate of gross margin per pig. The latter can be calculated as carcass value over feed costs and cost of feeder pigs. These production parameters can be adjusted to a common basis such as a constant initial and final body weight and diet nutrient density, which allows for comparison to reasonable production targets (Table 66.1; Tokach and de Lange 2001). Additional useful information relates to seasonal effects on the aforementioned performance parameters, downtime between groups of pigs and variability in final body weight and carcass characteristics. This additional information can serve as a basis for seasonal adjustments to management, to assess space utilization and to relate variation in carcass characteristics to average carcass value and profitability.

An important consideration in managing growing-finishing pig units is the value of average daily gain and barn throughput. When the supply of feeder pigs is unlimited, gross margin per pig may be compromised—for example, by feeding ractopamine to increase preslaughter growth rates or shipping pigs somewhat lighter to optimize gross margin and profit per pig place per year. On the other hand, when the supply of feeder pigs is limited, the production objective in commercial growing-finishing pig units should be to optimize gross margin and profit per pig. In addition, in areas where the potential negative impact of pigs' production on the environment is a concern, reducing nitrogen and phosphorus excretion with manure or controlling the release of odorous compounds from the pig facility should be considered (de Lange 2004). The aforementioned production records allow for benchmarking and some changes to management of growing-finishing pigs. However, to optimize production efficiencies, profits, and nitrogen and phosphorus utilization within individual pig units, more detailed information on lean tissue growth and feed intake patterns is required.

Table 66.1. Feed to gain targets for growing-finishing pigs consuming corn-soybean meal–based diets.[1]

Entry BW, (kg)	Market BW, (kg)	Meal Diets		Pelleted Diets	
		0% fat	5% fat	0% fat	5% fat
18	110	2.92	2.63	2.74	2.47
18	115	2.97	2.67	2.79	2.51
18	120	3.02	2.72	2.84	2.55
23	110	2.97	2.67	2.79	2.51
23	115	3.02	2.72	2.84	2.55
23	120	3.07	2.76	2.89	2.60
28	110	3.02	2.72	2.84	2.55
28	115	3.07	2.76	2.89	2.60
28	120	3.12	2.81	2.93	2.64

[1]Derived from Tokach and de Lange (2001). The values may be adjusted for diets with energy densities that differ from that in a typical corn-soybean meal–based diet (3400 kcal DE/kg), by multiplying the values by 3400 ÷ (actual diet DE content).

BW = body weight.

MONITORING LEAN TISSUE GROWTH AND FEED INTAKE PATTERNS

In growing-finishing pigs, lean tissue growth is closely related to daily gain, feed efficiency, and carcass quality (Schinckel 1994; Table 66.2). Furthermore, lean tissue growth gain is closely related to body protein deposition, the main determinant of dietary amino acid requirements and one of the main determinants of dietary energy requirements (NRC 1998; Schinckel et al. 2002). Across groups of pigs, muscle or lean tissue represents between 28 and 60% of the pigs' body weight (Gu et al. 1992; Quiniou and Noblet 1995). The other main body tissues include visceral organs, fat, integument and bones (de Lange et al. 2001b). The relationships between lean tissue, visceral organs, integument and bones are relatively constant. Therefore, variation in body lean content between groups of pigs is largely influenced by the amount of fat tissue, which can vary between 12 and 30% of the pigs' body weight. Dissectible lean tissue in growing pigs contains about 72% water, 20% protein, and the remainder is made up of lipid, minerals, and some carbohydrates. In contrast, fat tissue contains more than 85% lipid. To minimize feeding costs and optimize carcass value it is thus in the pork producers' interest to optimize carcass lean content in slaughter pigs. Unfortunately, definitions and methods to quantify carcass lean tissue content and lean tissue growth in pigs can vary considerably between countries and individual pig slaughter facilities. For example, the lean tissue content of pigs may be standardized to a fat-free lean tissue content. Alternatively, the trimmed belly that contains fat tissue as well as lean tissue may be considered part of body lean content. Therefore, it is probably more appropriate and objective to characterize groups of pigs in terms of whole body protein deposition rates (Table 66.2). According to NRC (1998) in the

Table 66.2. Impact of fat-free lean tissue growth potential on growth performance of growing-finishing pigs between 25 and 110 kg body weight.[1]

Lean Tissue Growth Potential	High	Medium	Unimproved
Fat-free lean tissue growth potential, g/day	400	350	300
Maximum body protein deposition rate, g/day	157	137	118
Average daily gain, g	842	794	743
Feed : gain, g/g	2.66	2.82	3.03
Dressing percentage, %[2]	79.1	79.4	79.7
Lean yield, %[2]	60.7	59.0	57.6

[1]Derived from de Lange et al. (2001a). Diets contain 3400 kcal DE/kg and optimum levels of amino acids and other nutrients; feed intake is 90% of voluntary intake according to NRC (1998). A feed wastage of 3% is included.
[2]Canadian carcass grading system.

United States fat-free lean tissue can be calculated as body protein deposition × 2.55, but this relationship is likely to vary with pig type and body weight range. The mean average fat-free lean tissue growth rate for groups of growing-finishing pigs may vary between 200 and 450 g/day (NRC 1998; de Lange et al. 2001a).

Estimates of average lean tissue gain for individual groups of growing-finishing pigs may be derived from the average initial and final body weight, the number of days required to grow pigs from initial to final body weight, carcass dressing percentage, and the carcass lean tissue content. Given the relatively low variation in lean tissue content of feeder pigs entering the growing-finishing barn the fat-free lean content of feeder pigs may be estimated from live body weight (NRC 1998).

For the estimation of the pigs' optimum slaughter weight and for the development of the effective multiple phase-feeding programs, the change in lean tissue growth (and feed intake) with increasing body weight needs to be considered as well. In general, there are three segments to a typical lean tissue growth curve. During the early stages of growth, generally up to about 50 kg body weight, the daily lean tissue growth rate increases. Between approximately 50 and 80 kg body weight the daily lean tissue growth rate is relatively constant. Thereafter, the daily lean tissue growth rate starts to gradually decline towards zero when the pigs' mature body weight has been reached. The weight at which pigs are slaughtered generally coincides with the weight at which the daily lean tissue growth rate starts to decline substantially.

Lean tissue growth curves can be established using three different methods: (1) Calculate the average lean tissue growth over the entire growing-finishing periods, as indicated above, and combine this with a standard lean gain curve shape to establish the actual lean gain curves. This is the easiest method and is used in NRC (1998) to estimate nutrient requirements of pigs at the various stages of growth. This is also the least preferred

method because it ignores differences in the shape of lean gain curves between different growing-finishing pig units. (2) Establish a growth curve by relating body weight versus time in the barn based on measurements on at least 40 pigs. To do so, make serial B-mode real-time ultrasound measurements at at least four, preferably five, different body weights that are equally spread out over the entire growing-finishing phase on at least 40 pigs. The main sources of error in this approach are the inaccuracies of the real-time ultrasound measurements and the prediction of lean contents of real-time ultrasound measurements at the various body weights. Relationships between real-time ultrasound measurements and body lean content differ between lines of pigs (Hicks et al. 1998). (3) Establish a growth curve, based on at least four equally spread data points that relate body weight to the number of days in the barn and with observations from at least 40 pigs per data point. Combine this information with an actual feed intake curve and diet nutrient content and use mathematical models that represent nutrient utilization for growth to estimate whole body protein deposition (lean tissue growth) as well as whole body lipid deposition (de Lange et al. 2001a). This approach is sensitive to assumptions about maintenance energy requirements and to the accuracy of the feed intake curve.

Care should be taken with the interpretation of lean tissue growth curves. Various factors, including genotype, gender, environmental stresses (health status, crowding) and nutrient intake affect observed lean tissue growth rates. Lean tissue growth has a medium to high heritability and has received considerable attention in pig breeding strategies over the last years (Schinckel and de Lange 1996). In terms of gender, entire male pigs have a higher lean tissue growth potential than gilts, and barrows have the lowest lean tissue growth potential; the differences between genders varies with pig genotype (Schinckel 1994). The presence of subclinical levels of disease can reduce lean growth rates by more than 30% (Williams et al. 1997). Furthermore, lean tissue growth is generally affected by different factors at the various stages of growth. At lower body weights and when daily lean tissue growth are increasing with increasing body weight, lean tissue growth is generally determined by nutrient intake and most often energy intake. To estimate performance potentials of specific groups of growing-finishing pigs, ideally lean tissue growth curves will be established under conditions where nutrient intake is unlikely to limit lean tissue growth. However, because of environmental stressors pigs may not express their full performance potential under commercial conditions (Black et al. 1995). For practical management purposes, the pigs' operation lean tissue growth potential may be considered, which represents the maximum lean tissue growth rates that pigs can achieve under commercial conditions. This implies that for a specific pig genotype the operation lean

tissue growth potential may vary with environmental conditions, and the difference between the actual and operation lean tissue growth potential provides an indication of the ability of particular pig genotypes to deal with environmental stressors. Mathematical models that represent nutrient utilization for growth, such as the NRC (1998) model, may be used to identify whether nutrient intake affects lean tissue growth and to establish whether an increase in nutrient or energy intake would increase lean tissue growth.

Feed intake can have substantial impacts on animal performance, carcass quality, and profits. In growing pigs, up to approximately 50 kg live body weight, energy intake generally limits lean tissue growth. In these pigs the daily energy and feed intake should be maximized. Finishing pigs, especially those with medium or unimproved lean tissue growth potentials and consuming large quantities of feed, consume more energy than what is required for maximum lean tissue growth. In these pigs excessive body fat is deposited and as a result, carcass value is reduced. In finishing pigs with unimproved or average lean growth potentials, carcass value and feed efficiency can be improved by restricting the daily energy intake. It should be pointed out that as lean growth potentials continue to improve, energy intake is likely to determine lean growth rates up to higher body weights. The body weight at which pigs change from a grower pig, where energy intake limits lean growth, to a finisher pig, where energy intake no longer limits lean growth, remains to be determined for the various modern pig genotypes. At least three recent studies suggest that energy intake limits lean growth up to market weight (Schinckel and de Lange 1996).

Feed intakes can vary considerably between groups of pigs and are affected by a whole range of factors associated with the animal (body weight, gender, genotype, health), feed (diet energy density, nutrient imbalances, freshness, presence of toxins, processing), and environment (effective environmental temperature, pig density, feeder design location and management, quality and availability of water, etc.) (NRC 1987). Indeed the accurate prediction and control of voluntary feed intake in specific groups of pigs is one of the main challenges in commercial pork production. Theoretically the pig's feed intake at a particular body weight may be predicted from the pigs' body protein and body lipid deposition rates. This does require, however, accurate estimates of the lipid deposition in the pigs and assumptions about the pigs' maintenance energy requirements (NRC 1987, 1998; Schinckel et al. 2002).

Increasingly on commercial farms feed intake is monitored in representative groups of growing-finishing pigs and the main factors that are known to influence voluntary feed intake are monitored as well: effective environmental temperature, pig health, feeder design and management, pig genotype, water, and feed quality. Reasonable feed intake curves can be established when

feed intake is measured accurately in representative monitoring pens over at least a 2-week period and at least three different stages of growth that are equally spread over the growing-finishing period (Schinckel and de Lange 1996). Per body weight range, feed intake and body weight data should be obtained from at least two feeders with at least 40 pigs per body weight range. The highest body weight range should be as close to market weight as possible. Relatively simple and inexpensive devises are now available to measure feed disappearance in individual feeders. As an alternative to measuring feed intake in representative monitoring pens, feed intake may be determined for an entire room or barn if these are managed on an all-in/all-out basis. The latter requires that feed deliveries and inventories, as well as the total number of pigs in inventory, be monitored accurately and frequently. Software packages are now becoming available to aid in collection and interpretation of feed intake data. An additional benefit of continuously monitoring feed intake and in particular water usage is that the onset of disease or changes in the pigs' environment can be identified early, allowing a fast response and reducing the long term impact of these stressors on animal productivity. However, closely monitoring feed and water usage is no substitute for daily inspection of pigs for normal growth, comfort and behavior.

Typical levels of feed intake, feed delivered minus feed wastage, of pigs managed under commercial conditions are about 90% of voluntary feed intake according to NRC (1998; Table 66.3) but may vary between 70 and 100% of NRC (1998). If feed intake levels are below average, check feed quality, feeder type and settings, water availability, environmental temperature, animal health, and pig genotype. Poor feeder designs or improper adjustments of feeders can result in substantial feed intake restrictions or substantial feed wastage (Gonyou and Lou 2000). The effect of gender on feed intake differs between pig genotypes; it may be between 3 and 15% higher in barrows than in gilts, and the gender effect increases with body weight (Schinckel 1994).

FEEDING MANAGEMENT

Establishing Optimum Dietary Nutrient and Energy Intake Levels

Energy, lysine, threonine, other amino acids, and phosphorus contribute generally to more than 80% of the dietary nutrient costs and deserve special consideration when formulating pig diets. However, in some situations specific feed additives that provide health or environmental benefits can increase feed costs substantially. The value of additives should be questioned regularly, considering nonnutritional means to deal with health and environmental issues, solid scientific evidence to support efficacy of feed additives, and costs. The impact of some feed additives, such as synthetic lysine and phytase, on nutrient excretion with manure and feed costs has been amply demonstrated (NRC 1998); for other feed additives the cost effectiveness is not established

Table 66.3. Typical marginal and cumulative average daily gain, daily feed intake and cumulative feed usage for pigs between 25 and 120 kg body weight[1]

Body Weight Range, kg	Average Daily Gain, g		Daily Feed Intake, kg	Feed:Gain	Cumulative Feed Usage, kg
	Marginal	Cumulative

[1]Growth follows the Bridges function (Schinckel and de Lange 1996), and feed intake is equivalent to 90% of voluntary daily feed intake according to NRC (1998) and at a diet-digestible energy content of 3400 kcal/kg. Marginal average daily gain represents growth over the specific 5 kg body weight range. Cumulative average daily gain represents average daily gain from 25 kg body weight. Daily feed intakes and feed usage may be adjusted for changes in diet digestible energy content (Table 66.1).

clearly or does not vary considerably between pig units. Moreover, feed additives, and medication in particular, that are used to treat specific disease problems too often continue to be included in the diet after the problem has disappeared.

The optimum energy content of pig diets will vary with the cost of the various energy yielding feed ingredients such as corn, fat, wheat, barley, and wheat shorts. A good starting point in feed formulation is to determine the dietary available energy content at which the cost per unit of available energy ($ per Mcal or KJ digestible energy) is the lowest, whereby the levels of all other essential nutrients are balanced against available energy. This is the dietary energy density that generally results in the lowest feed costs per kg of body weight gain. However, when throughput and average daily gain have economical value, increasing the energy density in the diet will have additional value. The latter applies in particular to growing pigs up to approximately 60 kg of body weight and to growing-finishing pigs that are under mild heat stress. In these two scenarios either the animals' physical feed intake capacity or the animals' capacity to lose body heat will limit pigs from reaching their desired available energy intake.

The optimum dietary levels of lysine, threonine, other amino acids, and phosphorus should be established based on the pigs' body weight, operational lean tissue growth potential, feed intake level, and dietary energy density (Table 66.4). In addition, the body weight range over which subsequent diets are fed in phase-feeding programs and the marginal cost-benefit response may be considered, which requires the use of dynamic models that represent utilization of dietary nutrients for growth in the pig (Black et al. 1986; de Lange et al. 2001a). The importance of accurate estimates of feed intake and matching dietary feed intake and nutrient levels with pig performance potentials is demonstrated with the simulation results presented in Table 66.5.

These results indicate that the cost of suboptimal feeding programs can be very substantial. The data also suggest that pigs with unimproved lean gain potentials perform well when feed is restricted, and feed intake in pigs with improved lean gain potentials should be maximized.

To closely meet the nutrient requirements of specific groups of pigs the genders may be raised separately and different diets may be fed in sequence with increasing pig body weight. When multiple-phase and split-sex feeding concepts are applied, it is critical that the main factors that determine the optimum dietary available nutrient levels are identified at the various stages of growth and that animal productivity is closely monitored. Establishing feed budgets—i.e., determining the amount of each of the diets that need to be fed—provides an effective means to ensure that diets are switched at the proper time (see Table 66.3). Also, the use of an excessive number of diets in a phase-feeding program makes scheduling feed deliveries more difficult and increases the chance of errors. In general terms, separate feeding of barrows and gilts should be applied when three or more diets are used in a phase-feeding program. Moreover, it is important to realize that the incremental financial benefit of including an additional diet in a phase-feeding program diminishes with the number of diets that are used. For example, if the benefit of changing from feeding a single diet to a two-phase feeding program for growing-finishing pigs is $2.00 per pig, the benefit will be approximately $1.00, $0.50, and $0.25 per pig when the third, fourth, and fifth diet are introduced, respectively. The same principle applies to the impact of phase feeding on nitrogen and phosphorus excretion with manure.

Feed Ingredient Sourcing and Feed Preparation

The following aspects should be considered when sourcing pig feed ingredients: available nutrient content, vari-

Table 66.4. Estimated dietary requirements (%) for true ileal digestible lysine (Lys), true ileal digestible threonine (Thr), and available phosphorus (P) for different pigs with different fat-free lean tissue growth potentials at different levels of feed intake (90% and 80% of voluntary digestible energy intake according to NRC 1998) and at two different body weights.[1]

Fat-free Lean Tissue Growth Potential, g/day	Intake 90% of NRC			Intake 80% of NRC		
	Lys	Thr	P	Lys	Thr	P
			30 kg body weight			
400	0.98	0.60	0.35	0.95	0.59	0.34
350	0.87	0.54	0.30	0.88	0.55	0.31
300	0.77	0.49	0.26	0.81	0.51	0.28
			75 kg body weight			
400	0.72	0.46	0.25	0.74	0.47	0.26
350	0.64	0.42	0.22	0.68	0.44	0.23
300	0.56	0.37	0.18	0.62	0.41	0.21

[1]Adjusted from Tokach and de Lange (2001) and de Lange (2004). Based on diet digestible energy content of 3400 kcal/kg. If diet energy density differs, the target diet nutrient levels may be changed proportionally to diet-digestible energy content.

Table 66.5. Interactive effects of feed intake, pig lean tissue growth potentials, and feeding programs on pig performance and profits.[1]

	Unimproved Pig Type			Improved Pig Type

Margin, $/pig	−3.48	−0.07	−2.92	5.62	5.22
Margin, $/pig place /year	−10.42	−0.18	−6.87	19.16	14.23

[1]Derived from de Lange et al. (2001a). Based on: performance between 20 and 105.5 kg body weight; 5% feed wastage; 1% mortality; 14 open days per rotation; standard deviations on carcass lean yield and carcass weight of 2% and 4 kg, respectively; weaner pig price $55.00; variable costs per pig $15.00; price per kg carcass at index 100: $1.30; corn ($130/tonne), soybean meal (47.5% CP;$310/tonne) and premix (3% inclusion; $600/tonne) based diets in a 2-phase feeding program; mixed costs are $15/tonne; diets are switched at 65 kg body weight. For all feeding programs, diet soybean meal levels have been adjusted to maximize profit for each pig type and feeding level.

[2]For the suboptimal feeding program, diet soybean meal levels are the same as the optimum diet soybean meal for this pig type at the high feed allowance. Margin ($/pig) is calculated as: carcass value − feed costs − weaner pig price − variable costs per pig. Margin ($/pig place per year) is calculated as: $/pig × 365 ÷ days per rotation. Calculations are conducted using PPGM—Purina Pork Growth Model (1997).

ability, effect on diet palatability, effects on carcass and meat quality, content of antinutritional factors and mycotoxins, storage and handling, availability, and cost.

Tables are available that provide mean contents of available (true or standardized ileal digestible) amino acids, digestible or metabolizable energy, and available phosphorus in a wide range of pig feed ingredients (NRC 1998). For various reasons, such as variation in growing conditions and/or ingredient processing, available nutrient contents of individual batches of feed ingredients can deviate substantially from published means. Routine sampling of ingredients, especially at harvest time, for analyses of dry matter, protein, and fiber contents is recommended. Dry matter content should be considered as part of any nutrient analyses and provides information about potential spoilage during storage. Protein and fiber contents can be used to estimate amino acid and available energy content, respectively. The need for additional analyses will vary with ingredient type and local conditions. Additional analyses may include fat content (high oil corn, full-fat soybeans, and canola seed), ash, calcium and phosphorus (meat meals, mineral sources), and mycotoxins (corn and wheat samples). In order to reduce costs of nutrient analyses, samples of purchased and variable ingredients may be stored in a dark and cool place and analyzed only if problems with animal productivity are observed.

Based on ingredient specific effects on diet palatability (canola meal, peas) and carcass quality (full-fat soybeans and canola seed) the maximum inclusion level in the diet may be restricted. Alternatively, some ingredients or elevated levels of nutrients in the preslaughter

diet, such as vitamin E, can enhance pork meat quality (Rosenvold and Andersen 2003).

To establish the actual value of pig feed ingredients, least cost—or best cost—feed formulation systems should be used. These systems provide information on the actual financial value versus the actual cost based on the costs of other available ingredients. Clearly, the price of pig feed ingredients has a substantial impact on feed costs and profit in growing-finishing pig units.

Three key aspects of feed preparation are grinding, mixing, and pelleting. The fineness of grinding of feed ingredients is closely associated with nutrient digestibility and thus feed efficiency. Based on a summary of research at Kansas State University (KSU Swine Nutrition Guide 1997) feed efficiency improves by 1.2% for every 100 micron reduction in average feed particle size. This substantial impact of grinding effectiveness on pig productivity warrants a routine monitoring of mean feed particle size, while the benefits of fine grinding should be weighed against the cost of grinding, flow and dustiness of feed, which is less of a concern when diets are pelleted or when fat is included, as well as increased risks of development of stomach ulcers in growing pigs. A reasonable target mean particle size is between 600 and 800 microns. The adequacy of feed mixing can be assessed based on the variability of nutrient content in 10 or more mixed feed samples. These samples may be analyzed for one or more easily analyzed nutrients, such as sodium or chloride, and the coefficient of variation of nutrient content should be targeted at 10% or less. A coefficient of variation larger than 15% can reduce animal productivity, especially of younger pigs (Patience et al. 1995).

Pelleting of pigs diets can improve feed handling and pig performance and allows the use of a wider range of feed ingredients in the diet. Improved feed efficiency due to pelleting can be attributed to reduced feed wastage, improved nutrient digestibility, and increased available nutrient intake. The benefits of pelleting will vary with feed ingredient composition and pig body weight. In growing-finishing pigs fed corn-soybean meal–based diets feed efficiencies may be improved 5–8%; this value is somewhat higher in diets that contain more fibrous feed ingredients, 7–9% for barley-based diets (Patience et al. 1995; KSU Swine Nutrition Guide 1997). Improvements in average daily gains are slightly smaller than improvements in feed efficiency. These improvements in animal performance should be weighed against the cost of pelleting. A concern with using pelleted diets is pellet quality. Poor pellet quality results in increased amounts of fines in feed, which can reduce feed flow, buildup of fines in the feeder, and increased feed wastage. A recent observation has been that feed pelleting, as well as fine grinding of feed, can influence gut microbiota in pigs in a negative manner (Mikkelsen et al. 2004). In particular the fecal shedding of *Salmonella*, which is a food safety concern, can be reduced by changing from a finely ground pelleted feed to a coarsely ground mash feed. Such a change in feed form will coincide with reductions in pig growth performance.

An important practical consideration is to prepare feed on the farm versus purchasing a complete feed from a commercial feed mill. In this consideration the cost of feed ingredients, feed preparation, ingredient storage, liability, and quality control should be weighed against the cost of purchased feed. Advantages that commercial feed mills can have over on-farm feed preparation facilities include increased access to a wider range of inexpensive feed ingredients, advanced feed processing, better quality control systems, and the use of multiple feed ingredients to reduce the impact of variation in nutrient content of individual ingredients on nutrient content of the complete feed.

GROUP SIZE, SPACE ALLOWANCE, AND MOVEMENT OF PIGS

In North America, growing-finishing pig facilities have traditionally been designed with pens to house groups of 20–30 pigs. In Western Europe group sizes have generally been smaller and close to the size of a large litter of pigs. Recently there has been a renewed interest in accommodating group sizes of more than 100 pigs. Reasons for this move toward larger group sizes include marginally lower construction costs, the potential to increase stocking density, the ability to mix pigs while minimizing aggressive encounters between pigs, and the use of auto-sort technology to separate pigs destined for slaughter (Brumm 2004). The major limitations of handling large groups of pigs are the difficulty of isolat-

ing individual pigs for medical treatment and additional effort or equipment required to select pigs for slaughter. In the Unites States the movement to larger groups of growing-finishing pigs has coincided with the adoption of wean-to-finish technology, where pigs are maintained in the same pen from weaning until slaughter (Wolter et al. 2001, 2002). The latter is driven largely by labor savings, as a result of reduced pig movement and reduced cleaning of facilities, and to a lesser extent by the negative impact of moving and mixing pigs on growth performance. Weaned pigs are typically placed in wean-to-finish pens at double the pig density expected at the end of the finishing phase. When the pigs reach the grower stage, half of the pigs from the pen are moved to a new pen. This allows the producer to make best use of available space without causing pigs to be crowded as finisher pigs.

In contrast to previous beliefs and observations on starter pigs, recent data suggest no reduction in growth performance of finishing pigs managed in larger groups as compared to conventional group sizes of 20–30 pigs per pen, provided that adequate feeder and drinking space is provided (Wolter et al. 2001; Turner et al. 2003; Table 66.6). Increasing group size and total pen space will result in more space per pen not occupied by pigs. This free space is available for eating, drinking, defecation, urination, and sleeping. It also provides more op-

portunity for submissive pigs to avoid dominant pigs and for individual pigs to seek their optimum thermal microenvironment. Pigs show more tolerant behavior in larger groups. In large pens it is apparently possible to introduce new pigs into an existing group without apparent disturbance of the social order (Brumm 2004). Because of the larger amount of total free space, total floor space area per pig may be reduced to 0.65 m² per finishing pig, which is below the typical value of 0.69 m² per pig in the United States for pens with fully slatted floors and the 0.93 m² per pig required to achieve maximum growth rates in finishing pigs between 54 and 113 kg body weight kept on partly slatted floors and with 7 or more pigs per pen (NCR-89 1993). In this extensive study average daily gains and feed efficiencies improved linearly with space allocation from 0.71 kg/day and 0.265 kg/kg at 0.56 m² per pig to 0.80 kg/day and 0.274 kg/kg at 0.93 m² per pig.

The allometric relationship between body weight (BW) and area of a pen per pig can be expressed by k = A/BW$^{0.667}$, where A is the area in m². The constant k represents a critical value relating to productivity. If growing-finishing pigs are raised on fully slatted or partially slatted floors, the critical values for k are 0.0327 and 0.0337, respectively. When k is below this critical value, average daily gain will decrease. The impact of space restriction on productivity is most evident when pigs are close to market weight. To lessen the impact of space restriction, producers may market the fastest growing animals at 5 kg below target weight. This will add 3% to available space, which essentially removes the overcrowding typically observed just prior to marketing the first group of pigs from a barn (Gonyou and Stricklin 1998).

One of the main determinants of space utilization efficiency is within-group variability in pig body weights. In order to meet the target slaughter weights, pigs are usually removed from the growing-finishing unit in three or more uniform body weight groups. In an all-in/all-out production facility, throughput is thus largely determined by the growth rate of the slowest growing or tail-end pigs in the group. In extreme cases and to clean out the pig unit before the planned arrival of the next group of pigs, the tail-end pigs need to be shipped at below-optimal body weight. The latter can have severe implications for carcass value of the tail-end pigs, as well as mean carcass value for the entire group, space utilization efficiency, and profitability. In a survey of seven commercial operations Dewey et al. (2001) reported coefficients of variation of 20–31% for body weights of pigs at different ages, which are substantially higher than values observed under closely controlled studies (Tables 66.6, 66.7). The main determinants of variation in body weight in growing-finishing pigs appear to be presence of diseases in the herd and the use of all-in/all-out versus continuous flow management (de Grau et al. 2001); variation in body weight of feeder pigs that are

Table 66.7. Effect of sorting pig by body weight at placement in the growing-finishing barn on variability in pig body weight after 91 days in the growing-finishing unit.[1]

	Treatment[2]			
	Heavy	Medium	Light	Unsorted
Pig body weight, kg				
Day 0	37.1	34.0	30.2	33.8
Day 91	123.4	117.8	113.2	119.9[3]

Day 91	6.0	6.5	8.2	7.3
Daily gain, kg	0.94	0.92	0.91	0.94[3]
Daily feed intake, kg	2.67	2.66	2.73	2.70
Feed : Gain	2.85	2.93	3.02	2.88

[1]Derived from O'Quinn et al. (2001).
[2]Treatment represents weight of pigs at sorting on day 0; unsorted represents an equal number of heavy, medium, and light pigs within each pen.
[3]Value for unsorted is different (P <0.05) from the average of the three sorted groups.

placed in the barn and restricted access to good quality feed and water can contribute to this variation as well. Group size and space allocation per pig do not appear to influence within-group variability (Turner et al. 2003).

A common management practice used to be to sort pigs by gender and weight when placing feeder pigs in the growing-finishing unit. Although this practice can be beneficial from a feeding management perspective, it does not result in better overall growth rates and reduced variability in pig body weights at slaughter (O'Quinn et al. 2001; Table 66.7). Apparently, pigs managed in groups have an inherent desire to vary in body weight. The coefficient of variation for within-pen body weight does not change when pigs are placed in pens with a large initial body weight variation, and the coefficient of variation will increase when pigs placed in pens have minimal within-pen initial body weight variation. In units where feeder pigs are placed at a similar age, the practice of sorting pigs for body weight appears to have limited impact on production efficiencies.

EFFECTIVE ENVIRONMENTAL TEMPERATURE AND AIR QUALITY

When pigs are kept dry and in a draft-free environment, the room temperature should be maintained at approximately 18–20°C when feeder pigs first enter the grower barn at approximately 25 kg body weight. Once pigs are adjusted to the new environment and have achieved good levels of feed intake the environmental temperature can be gradually decreased to about 15°C when pigs are approaching market weight (Close 1987; ASAE 1991; Le Dividich et al. 1998). Depending on environmental conditions the actual room air temperature can differ substantially from the effective environmental

temperature—i.e., the environmental temperature that the pig actually "feels" (Close 1987). For example, each 0.30 m/s increase in air movement is equivalent to approximately a 1°C reduction in effective environmental temperature for group-housed growing pigs; a cold and wet floor may have a thermal equivalent of 7–10°C. The temperature of walls will influence the radiant heat loss from pigs; in cold climates and in poorly insulated pig facilities a temperature difference between ambient air and walls of 1–2°C is equivalent to a 1°C change in air temperature. In hot environments and when pigs rely largely on heat loss through evaporation of water the negative impact of high relative humidity of the air on pig well-being can be quite substantial.

When the effective environmental temperature is below the pigs' comfort zone, some of the ingested feed will be used to maintain the pigs' body temperature constant, resulting in reduced feed efficiency and growth rates. For example, Close (1987) estimated that pigs at a body weight of 20, 60, and 110 kg body weight will require 14, 32, and 47 g/day, respectively, of extra feed per 1°C below the thermal comfort zone to maintain a constant body temperature. When the effective environmental temperature is too high, feed intake can be reduced substantially. Per 1°C increase in environmental temperature feed intake will be reduced by approximately 2% in pigs around market weight and by approximately 1% in feeder pigs at approximately 25 kg body weight. These reductions in feed intake will be associated with reductions in growth rate of approximately 3 and 1.5%, respectively. Extreme environmental temperatures can also compromise the pigs' immune response and carcass quality. Clearly compromises need to be made in choosing the environmental temperature when pigs at different stages of growth are all kept in a common airspace.

Both mechanical and natural ventilation systems can be used to control the environmental air temperature and air quality (Baxter 1984). Increasingly these ventilation systems are computer-controlled and driven by actual (real-time) versus targeted air temperatures in the pig room and real-time measures of air quality. Mechanical ventilation systems now include several fixed and variable speed fans to control air exhaust from pig barns in incremental steps and air inlets that are all computer-controlled. In cold climates a minimum amount of air in the pig rooms, about 17.6 m³ per hour per pig (1.47 m³/sec or 3 cfm per pig), needs to be replaced with fresh air in order to remove air contaminates, such as ammonia, carbon dioxide, dust and water vapor. In extremely cold environments and when there is limited opportunity to preheat fresh incoming air, additional heat may be provided to maintain air temperature in the pig rooms above minimum levels. On the other hand, in warm climates or during the summer time, the optimum ventilation rate will be determined by the amount of body heat that is produced by pigs and needs to be removed from the pig room. These maxi-

mum ventilation rates will vary with the temperature and humidity of incoming air and may be as high as 150 m³ per hour per pig (12.5 m³/sec or 70 cfm per pig) (Baxter 1984). In well-designed pig facilities, control of air movement can be used to manipulate manuring patterns within pens and thus the comfort and cleanliness of pigs as well as air quality.

CONCLUSIONS AND IMPLICATIONS

With the move toward larger and highly specialized facilities it is becoming increasingly important to refine management within individual growing-finishing pig units, considering profitability, pig well-being, pork meat quality, and the impact on the environment. In order to make effective management changes, accurate production records need to be collected, and special consideration should be given to monitoring the dynamic changes in lean tissue growth, feed intake, and water usage within pig units. In particular, lean tissue growth is related closely to various aspects of pork production efficiency, such as average daily gains, carcass quality, and feed efficiency. As presented in this chapter, suboptimal feeding programs can have substantial impact on pig productivity, carcass quality, profitability, and nutrient excretion with manure. The recent trend toward all-in/all-out, wean-to-finish management of large pig groups represents a means to reduce production costs, while it may enhance growing-finishing pig productivity. A key challenge in any growing-finishing pig production system remains the control and management of variation in within-group pig body weights. The practice of sorting feeder pigs for body weight when moved into the unit has limited impact on within-group pig body weights at the time of slaughter and production efficiencies in units where feeder pigs are placed at a similar age. Improving the health status of pigs appears to be the most effective means to reduce within-group variability of pig body weights, as well as animal productivity. Computer-controlled and automated ventilation systems are used increasingly to ensure that the animals' thermal environment and air quality requirements are met.

The various aspects of growing-finishing pig management, such as feeding program, pig space allocation, and control of the thermal environment are all interconnected. Current developments toward integrated management systems that involve real-time analyses of pig growth and mathematical models that represent nutrient utilization for growth (Green et al. 2004) provide opportunities to truly optimize management in individual pig production units.

67 Animal Welfare

Sandra A. Edwards, Peter R. English, and David Fraser

At the beginning of the 21st century, many of the industrialized countries saw the emergence of new standards for the welfare of farmed animals. For example:

- In 1999, the United Kingdom enacted a ban on keeping pregnant sows individually in tethers or stalls, and the European Union (EU) passed a directive to phase out the standard battery cage for laying hens within 12 years.
- In 2000, a major fast food chain restaurant in the United States (U.S.) announced animal welfare standards that their suppliers would be required to meet, mainly in the slaughter and egg industries.
- In 2001 another fast food chain restaurant in the U.S. adopted a similar program; the EU passed a directive to ban individual stall housing of pregnant sows effective in 2013; and two Washington-based organizations (the Food Marketing Institute and the National Council of Chain Restaurants) began developing a set of food animal welfare standards on behalf of the U.S. grocery and chain restaurant sectors.
- In 2002 the member countries of the World Organization for Animal Health (OIE), which is recognized by the World Trade Organization as the principal standard-setting body in matters of animal health, unanimously voted to begin developing internationally harmonized animal welfare standards.

In these diverse developments covering a period of only a few years, we see a remarkably rapid movement toward explicit animal welfare standards involving a combination of national legislation, international agreements, and corporate standards. These developments raise a number of questions which this chapter will address briefly. First, what is animal welfare, and how did it become such a prominent area of concern? Second, what is the scientific basis of animal welfare research and standards? And third, what are the current animal welfare concerns that need to be considered in swine production?

BACKGROUND

In one sense, the appropriate treatment of animals is one of the long-standing ethical issues of human civilization, which different cultures and religious traditions have addressed in different ways over the centuries (Preece 1999). In the 1800s many industrialized countries created some form of legal protection for animals, particularly to deal with antisocial acts such as deliberate cruelty and gross neglect. In many countries the mid 20th century saw an expansion of legal protection for food animals—for example, through requirements for humane treatment of animals at slaughter plants and humane animal transportation. Throughout the late 20th century, public attention and sympathy toward animals appeared to show a widespread increase, especially in European and English-speaking countries. Many aspects of animal use—including animal-based research, animals in entertainment, and production of animal-based food—were questioned and debated as never before.

During roughly the same period, swine production in the industrialized world underwent profound changes. Average herd size increased steadily, such that fewer and fewer producers operated increasingly large units. Housing and technology also changed in ways that reduced production costs, generally by keeping animals in indoor environments where labor requirements could be reduced and space could be used efficiently. These changes had complex effects on the health and welfare of the animals, but another significant result was a change in public perception of swine production, away from traditional positive images of the small-scale family-run farm with careful attention to individual animals, and toward more negative images of swine production as a depersonalized, industrial activity. With this change came a greater public scepticism over the humaneness of animal production and a greater will to have animal welfare standards imposed on the industry.

WHAT IS ANIMAL WELFARE?

In debate and discussion of animal welfare, three different but overlapping types of concern have been expressed about the quality of life of animals (Duncan and Fraser 1997; Fraser et al. 1997). A traditional set of concerns centers on the basic health and functioning of animals. This includes freedom from disease, parasites, and injury together with normal growth, development, and functioning of the animal's physiological and behavioral systems. A second major concern centers on the affective states of animals—emotions and feelings, especially unpleasant states such as fear, pain, hunger, and distress. Concern arises, for example, over pain caused by castration, over fear caused by rough handling, and over separation distress caused by abrupt weaning or social isolation. A third concern, arising especially over animals kept in very restrictive or barren environments, is that animals be allowed to live reasonably natural lives, in environments that are well suited to the species. For example, philosopher Bernard Rollin (1995) noted that contemporary concern about animal welfare goes beyond issues of pain and suffering and involves respecting the "nature" of animals.

These different views of animal welfare are by no means mutually exclusive. For example, allowing an overheated sow to wallow should be good for her welfare by all three criteria: it will reduce the negative effects of heat stress (a basic health and functioning criterion), it allows her to carry out her natural thermoregulatory behavior (a natural living criterion), and she will presumably feel more comfortable (an affective state criterion). However, the different views can also lead to different conclusions about some issues. For example, those who emphasize basic health and functioning may conclude that housing sows in narrow stalls throughout most of pregnancy is good for their welfare because it prevents fighting-related injuries and promotes uniform weight gain, whereas those who emphasize natural living criteria might conclude that the stalls are incompatible with good welfare because they prevent most forms of natural behavior. Complicating the resolution of such disagreements, the different views of animal welfare tend to be favored by different sectors of the population. Producers and livestock veterinarians tend to interpret animal welfare in terms of basic health and functioning, whereas consumers, together with some small-scale and organic producers, tend to emphasize natural living criteria (te Velde et al. 2002).

Given this diversity, probably no account of animal welfare will be widely acceptable unless it takes all three of the major concerns into consideration to at least some degree. One general description of animal welfare, which nicely combines the different concerns, is the "Five Freedoms" adapted from Webster (1994):

1. Freedom from malnutrition: the diet should be sufficient in both quantity and quality to promote normal health and vigor.

2. Freedom from thermal and physical discomfort: the animal's environment should be neither excessively hot nor cold and should allow normal rest and activity.
3. Freedom from injury and disease: the husbandry system should minimize the risk of injury and disease and facilitate the immediate recognition and treatment of any cases that do occur.
4. Freedom to express most normal patterns of behavior: the physical and social environment should provide the necessary components to enable the animal to carry out behaviors it has a strong motivation to perform.
5. Freedom from pain, fear, and distress.

SCIENTIFIC APPROACHES TO ANIMAL WELFARE

All three perspectives on animal welfare have given rise to productive research to understand, assess, and improve animal husbandry systems. However, each perspective tends to lead to somewhat different approaches and to emphasize different measures to improve animal welfare.

Functioning of Animals: The Physiology of Stress

When animals experience certain welfare challenges, such as physical injury or fear of a dominant penmate, characteristic physiological responses occur that presumably have evolved as adaptive measures to prepare the animal for "fight or flight" (Stephens 1980). Such "stressors" activate both the sympathetic nervous system and the hypothalamo-pituitary-adrenocortical axis. Sympathetic stimulation results in rapid transmission of signals to key organs in the body and secretion of catecholamines (adrenaline and noradrenaline) into the circulation from the adrenal medulla. Concurrent with this immediate response is a more sustained endocrine cascade whereby corticotropin-releasing factor from the hypothalamus causes release of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which, in turn, stimulates the adrenal cortex to secrete corticosteroid hormones (cortisol and other glucocorticoids) into the circulation. Both neural and endocrine responses mobilize body reserves for activity by releasing glucose into the bloodstream, increasing heart rate and directing blood flow to muscles rather than skin and viscera. A negative feedback of plasma corticosteroid on the hypothalamus restores normal conditions when the stressor is removed.

In assessing welfare from a viewpoint of physiological function, measurements of plasma cortisol or ACTH levels are often made to judge the extent of stress experienced by an animal in a given situation. For example, many studies have shown increased plasma cortisol among sows that are kept tethered during pregnancy, al-

though this may have been due to poorly designed tether stalls, which resulted in unresolved aggression between neighboring animals (Barnett et al. 2001). However, there are a number of problems in using these simple measures. Taking a blood sample to assess hormone levels may, in itself, induce a greater adrenal response than any treatment difference under investigation (Moss 1981), and single blood samples are unreliable because corticosteroid release is pulsatile and shows diurnal patterns that can vary with different circumstances (Johnson and Levine 1973). Some of these problems can be overcome by measurement of corticosteroids and their metabolites in saliva, urine, or feces, which can be obtained noninvasively, but these are still subject to temporal fluctuations. Better measures of chronic stress often rely on detection of changes in morphology or function that result from long-term stimulation of physiological pathways or organs. Such measures include the weight of the adrenal glands, the activity of the enzymes controlling catecholamine synthesis (Stanton and Mueller 1976), and the "adrenal function test" whereby a standard amount of ACTH is injected and the resulting blood level of corticosteroid is measured (Ladewig et al. 1986). Interpretation of such results is still difficult because of genetic differences between animals in adrenal response to ACTH (Hennessy et al. 1988) and because some animals in adverse conditions appear to cease adrenal responsiveness after a period.

For short-term challenges it is sometimes simpler to measure the secondary consequences of the stress response rather than the underlying endocrinology. For example, heart rate, which can be monitored noninvasively using skin surface electrodes, increases when animals encounter a fearful situation such as close proximity to a dominant penmate (Marchant et al. 1995), but heart rate also requires careful interpretation because of possible confounding factors such as activity level.

Functioning of Animals: Production, Health, and Animal Welfare

It is often said by veterinarians and producers that good production performance indicates a high level of animal welfare. In support of this argument, the hormonal stress responses just described influence key metabolic and reproductive processes governing production performance. High corticosteroid levels reduce protein synthesis and lean tissue growth (Spencer 1985), resulting in slower growth and poorer conformation. In breeding animals, physiological stress responses also influence the hypothalamo-pituitary-ovarian axis (Arey and Edwards 1998), resulting in delayed onset of estrus, suppressed estrous activity, and development of cystic ovaries. Furthermore, stress in early pregnancy, at the time of implantation, results in increased embryo mortality and reduced litter size. The effects of stress on performance were well illustrated in experiments by Hemsworth and collaborators (1991) on the adverse ef-

fects of negative handling of pigs by stockpersons. Unpleasant handling, in comparison with sympathetic handling, resulted in pigs with chronically elevated corticosteroid levels, slower growth rate, a lower pregnancy rate in gilts, and delayed reproductive development in young boars.

A key link between welfare and performance is the maintenance of good pig health. Premature death and poor health are unquestionably indicators of impaired welfare, although the converse may not necessarily be true. Thus, health measures such as the incidence of infectious disease, lameness, or lesions of the skin (Backstrom 1973; de Koning 1985) are useful in assessing welfare in many practical circumstances. Moreover, stressful environmental conditions may increase the susceptibility of pigs to disease, partly because stress influences the immune system (Kelley 1980). In particular, sustained high levels of corticosteroid hormones in the blood can reduce proliferation of lymphocytes and decrease antibody production, thus impairing the ability of the pig to resist infection. Because stressors may reduce immune responsiveness, immune challenge techniques provide another potential measure of animal welfare. For example, sows tethered in a barren environment show a poorer immune response when challenged with a novel antigen, and their piglets also have lower antibody levels (Metz and Osterlee 1981). Thus, stressful conditions would be expected to induce higher corticosteroid levels, which are associated with poorer health, higher mortality levels, poorer growth and food conversion efficiency, and depressed reproductive performance.

In addition to these indirect effects on performance, inadequate environments or husbandry can directly affect both performance and welfare. Examples include lesions and lameness that result from faulty floors or inadequate pen design and aggression and vice resulting from poorly managed groups. Similarly, inadequate environmental temperature and nutrition can affect the welfare and performance of the pig. Close (1987) noted that keeping pigs either below their lower critical temperature or above their upper critical temperature can influence comfort, food intake, growth, food conversion efficiency, health, and viability. Nutritional deficiencies, in addition to predisposing to metabolic diseases and reduced growth and reproductive performance, may also contribute to outbreaks of tail biting (Fraser 1987). Inadequate diets have particularly clear effects on animal welfare in the case of early-weaned pigs, where low-cost diets that are not suited to the immature digestive system can cause severe depression in intake and growth and greatly increase the incidence of scouring and death.

In these various cases, welfare and productivity are correlated, and poor productivity can be a useful indicator of a welfare problem. However, the relationship does not always hold. Low growth rate and food conversion efficiency may, for example, be the result of feeding a

low-density diet, which is nevertheless nutritionally adequate and cost-effective in a particular situation. Equally, high productivity does not necessarily indicate a high standard of welfare. For example, the effects of inadequate housing on disease and performance can be masked by the routine use of antibiotics. Similarly, pigs treated with growth hormone or repartitioning agents may deposit lean meat very quickly but at greater risk of metabolic disease, and hyperprolific sow lines carry additional welfare risks for both the lactating sow and her piglets.

Affective States of Animals: Behavioral Measures of Welfare

The behavior of pigs has always been used by stockpersons or veterinarians to identify the onset of problems with health or environment. Simple examples are the apathy of a sick pig or the huddling of a group of pigs that are too cold. Similarly, behavior that results in injury to an animal (such as rooting on inappropriate surfaces) or that inflicts injury on others (such as tail, ear, and flank biting, discussed below) are also generally accepted indicators of impaired welfare.

Behavioral indicators are also used to help understand the "affective states" of animals such as pain, fear, and distress. For example, vocalizations have been used as a metric of separation distress. Piglets that are suddenly separated from the sow call in a pattern so characteristic that experienced pig-keepers immediately recognize the calls as coming from an isolated piglet. The calls begin with quiet grunts made with the mouth closed, progressing to louder grunts made with the mouth open, and then a mixture of loud grunts and squeals. Piglets that are in greater need of being reunited with the sow because they are cold or hungry give more calls, especially more of the high-pitched squeals, and sows respond more vigorously to calls given by such piglets. The calls thus appear to form a communication system which helps reunite sows and isolated piglets, with the number and type of calls reflecting the animals' level of distress at being separated (Weary and Fraser 1995). The calls may be useful for testing ways to reduce separation distress. For example, experiments show that piglets newly separated from the sow vocalize much less if there are several familiar littermates close by. Similar research has used vocalizations to assess pain in piglets when castrated in different ways (Taylor and Weary 2000).

Pig behavior has also been used in experiments designed to assess the needs and preferences of pigs that might contribute to improved welfare (Fraser and Matthews 1997). When given a choice between different circumstances, pigs can express their relative preferences on matters such as diet, floor type, thermal environment, and degree of social contact. However, results of such preference tests must be interpreted with caution, since any preference is relative to the other options available and may be modified by temporary motiva-

tional state and previous experience. A refinement on this approach is the use of instrumental conditioning techniques in which pigs are trained to work for a reward such as food, light, heat, or rooting substrate. The importance of the reward to the pig can then be assessed by measuring the amount of work animals will do to continue receiving that reward. These techniques, when correctly applied, allow the animal to inform us about its relative priorities, and the strength of its motivation to attain them (Ladewig and Matthews 1996). Such knowledge then indicates what we should seek to incorporate in improved husbandry systems.

"Abnormal" behavior has also been interpreted as an indicator of impaired welfare, although the definition of abnormal is not straightforward. Following an international survey of expert opinion, a list of behaviors widely accepted as "abnormal" has been published (Commission of the European Communities 1983). These include vices such as ear, flank, and tail biting, plus stereotypic behaviors as discussed below.

Natural Living: Incorporating Natural Elements into Animal Husbandry

In some cases, the natural behavior of pigs has been used as a guide to improving housing systems for pigs. In a novel approach, Stolba and Wood-Gush (1984) observed pigs that had been turned loose in a hilly, wooded area and identified certain characteristic features of the animals' behavior. In particular, the pigs rooted in the soil, exercised their neck muscles by levering against fallen logs, built nests in secluded areas before giving birth, and used dunging areas well removed from their resting areas. The research also identified certain key stimuli in the environment which were important for these behaviors to be performed. This led to the design of a complex commercial pen which incorporated these key stimuli, with a dunging passage in the front, an area where the pigs could root in soil, a log for levering, separate feeding areas, and secluded areas at the back where sows could be enclosed to farrow. The authors claimed that the animals' welfare was significantly improved by the complex pen. However, because some aspects of basic health and functioning (such as piglet survival) were less good in this system than in more restrictive systems (Edwards 1995), some critics have disagreed with this conclusion.

In contrast to this somewhat radical approach, more conservative approaches have tried to incorporate specific elements of natural behavior into typical commercial production systems in order to solve specific problems. For example, free-living pregnant sows would typically spend much of the day foraging for food. In commercial production they are normally fed a very dense diet which is cheaper to transport and store than a bulky, fiber-rich diet. However, the sow's intake of a dense diet needs to be strictly limited so that the animals do not gain too much weight. The result is that

sows may consume their daily ration in a matter of minutes and remain strongly motivated to find food for much of the day (Lawrence and Terlouw 1993). Under these conditions sows often develop stereotypies— repetitive behaviors that are fixed in form and serve no obvious function for the animal—such as the repetitive head-waving and bar-chewing that some sows perform for several hours per day. Some sows also toy with water dispensers to the point of drinking huge quantities of water. Providing sows with straw or other roughage, or providing a fiber-rich diet, can allow the animals to spend a more natural amount of time in finding and consuming food, and the abnormal behavior and water intake can be greatly reduced (Meunier-Salaun et al. 2001).

Although "natural" behavior provides a useful starting point, the relation between natural behavior and animal welfare is complex. Many behavior patterns are responses to the environment in which the animal is kept. The fact that a pig in intensive housing behaves differently from one in the wild is not in itself an indication of impaired welfare but may provide a useful starting point to explore whether the change reflects an animal welfare problem. For example, the stereotyped behavior of pregnant sows in barren environments does appear to indicate a welfare problem because it seems to reflect a state of chronic hunger in the animals (Appleby and Lawrence 1987), and the development of stereotyped behavior has been linked to neural pathology in at least some species (Garner et al. 2003).

In summary, there are many different approaches for assessing and improving the welfare of pigs. Each approach has its own strengths and associated difficulties, and a sensible combination of some or all of the methods outlined is likely to provide a better understanding of animal welfare than the use of any one approach alone.

CURRENT WELFARE ISSUES IN PIG PRODUCTION

With increased public awareness and concern about pig welfare, there is growing pressure to modify or abolish a number of practices that are currently widespread in the pig industry. Unlike most early welfare concerns and legislation, which were designed to penalize deliberate cruelty toward animals, some more recent concerns (and in some countries legislation) have focused on husbandry systems. The debate has highlighted the many difficulties in generalizing about welfare in a given system and the need to balance different welfare considerations, including cases where benefits to some animals occur at the expense of others.

Gestation Housing

The pregnant sow in a gestation stall has little opportunity for exercise and cannot walk or socialize freely with other animals. From a natural living viewpoint, a preferred system is to house pregnant sows in groups in an environment which provides greater freedom to move, explore, and socialize. However, because pregnant sows are offered very limited amounts of concentrate diets, there can be severe competition for feed when group feeding is practiced, with the dominant sows eating too much and the timid (and younger) sows too little. Although group housing can be improved by providing individual feeders to protect the timid sows during feeding, aggression can still occur at other times (Petherick 1989). In particular, competition for space, chronic hunger, and reestablishment of the dominance hierarchy when sows are regrouped can all result in increased aggression (Edwards 1992). Thus greater behavioral freedom for all sows is sometimes achieved at the expense of increased risk of injury and chronic fear in some individuals.

Farrowing Crates

The farrowing sow and her newborn litter provide another case of conflicting interests. The sow is often confined to a crate during and after farrowing to minimize the risk of crushing her piglets, to facilitate beneficial intervention by the stockperson, and to allow specially warmed creep areas to be arranged adjacent to the udder. These areas provide the temperature required by the newborn piglet to minimize the risk of hypothermia and resulting problems of starvation, crushing, and disease (English 1993). However, this system of housing the sow renders her unable to perform the normal farrowing behaviors seen in the wild, especially preparturient locomotion and nest building. When unable to carry out such behavior, sows show indications of stress in the form of increased corticosteroid levels combined with stereotyped behavior such as floor-nosing and bar chewing (Lawrence et al. 1994). Recent data indicate that confinement per se causes bigger problems in the preparturient period than lack of nesting material (Jarvis et al. 2002); hence, the current EU recommendation for provision of nesting material in farrowing crates is at best only a partial solution. However, no system has yet proven capable, under large-scale indoor commercial conditions, of both permitting full behavioral freedom to the sow and safeguarding the survival and welfare of her piglets (Edwards and Fraser 1997).

Early Weaning

Under natural conditions, pigs are weaned in a gradual process that begins at about 3 weeks after farrowing and is not completed until the young are 3–4 months of age (Jensen 1995). Under commercial conditions, economic pressures to maximize sow output have resulted in abrupt early weaning of pigs at 3–4 weeks of age in the EU (where weaning at less than 28 days is restricted to specific situations, and weaning at less than 21 days is generally forbidden) and sometimes at even younger ages

elsewhere in the world in segregated early weaning. This practice is designed to improve herd health by restricting transfer of pathogens from older animals to the piglet. When weaned at this young age, the piglet has little experience of solid food intake, and an immature digestive and immune system (Curtis and Bourne 1973; de Passillé et al. 1989). These physiological challenges are accompanied by psychological challenges associated with separation from the mother, first experience of a novel environment and, frequently, social regrouping. The piglets often show both behavioral and physiological indications of reduced welfare. Abnormal oral behaviors such as belly-nosing and ear biting can occur at high levels, particularly with earlier weaning ages, and may continue into later life as tail, ear, and flank biting (Gonyou et al. 1998). There is thus conflict between piglet welfare and the commercial need to maximize sow output.

Space Allowance

The cost of high quality housing creates financial pressure on producers to minimize the amount of space per pig. In many countries there are no minimum legal space allowances, and even in Europe, where space allowance is regulated, the adequacy of the allowance is being increasingly questioned (Ekkel et al. 2003). When pigs are overcrowded, they show higher levels of stress hormones, reduced growth and greater probability of health problems and abnormal behaviors such as tail biting (Meunier-Salaun et al. 1987). However, a degree of overcrowding often yields the best financial returns despite some reduction in individual performance. Here again we see some trade-off between animal welfare and commercial goals.

Bedding and Environmental Enrichment

The provision of adequate, good-quality bedding (usually straw) is frequently cited as contributing to the welfare of pigs of all ages because it helps to provide physical comfort, insulation, and recreation (Day et al. 2002). However, straw can also pose a problem for pig health and welfare by increasing the animals' exposure to microbes, dust, fungal spores, and ammonia in the air. An alternative may lie in providing the benefits of bedding in other ways that do not involve the same drawbacks.

One advantage of straw-based systems is the constant availability of a substrate for the exploratory and manipulatory behaviors that comprise a major component of the time budget of pigs under seminatural conditions. In the absence of adequate environmental provision, such behavior can be directed toward penmates and lead to development of injurious behaviors, such as tail biting (van de Weerd et al. 2004). The amount of straw necessary to serve this purpose, and the extent to which alternative bedding materials or toys can replace straw, are still the subject of research. Instrumental conditioning studies indicate that the reward value of full-straw bedding is greater than that of chopped straw or

straw presented in a rack (Ladewig and Matthews 1996). However, a small amount of straw seems effective in providing pigs with recreation (Fraser et al. 1991b; Lyons et al. 1995). Although "toys" (simple enrichment devices such as tires and chains) can provide occupation in the short term, habituation often occurs quite rapidly, and they often provide only 10% of the occupation time provided by full straw bedding, indicating either a lack of the appropriate stimulus properties or inadequate availability to all animals in the group. To attract and maintain interest from pigs, enrichment materials should provide olfactory/gustatory stimulation and respond by changes in form to the chewing behavior of the pigs (Feddes and Fraser 1994; van de Weerd et al. 2003). An ongoing challenge is to develop functional enrichment strategies that meet the needs of pigs but are also practical in large-scale slatted-floor housing.

Invasive Procedures on Piglets: Teeth Clipping, Tail Docking, and Castration

Currently many farms carry out invasive and painful procedures whose long-term benefits are thought to outweigh the transient distress that they cause. Thus, teeth clipping is deemed to be justified because it reduces injury to the faces of littermates during competition for teat position, damage and discomfort to the udder of the sow, and resultant restlessness that might increase the risk of crushing of piglets. Similarly, tail docking is justified on the grounds that it reduces the risk of tail biting in later life, and castration is deemed to be justified because it reduces aggression and harmful sexual behavior in later life while also preventing "boar taint," which renders the meat unpalatable. While such arguments undoubtedly have merit, there is growing public pressure to find alternative methods to achieve the desirable outcomes in less invasive ways. Many farms have found it possible to cease teeth clipping or restrict its use to high-risk litters with temperamental sows, large litter size, or extensive cross-fostering. Castration is more difficult to abolish if pigs are to be slaughtered at heavy weights, but may be superseded in the future by immunological rather than surgical techniques.

Tail biting in growing pigs is a widespread behavioral vice with very significant animal welfare and economic consequences. It is a multifactorial problem, with a variety of identified environmental and nutritional risk factors (Schroder-Petersen and Simonsen 2001). Despite research over many years, the problem has remained intractable in commercial pig production. Where pigs are left with intact tails, serious welfare issues associated with tail biting can be endemic under some environmental conditions (van de Weerd et al. 2004). One reason for the failure to find effective solutions to the vice is that most research into tail biting has involved surveys of only the tail-bitten animals, either on farms or in abattoirs. There is relatively little information on the pigs that actually do the biting and no real understand-

ing of what might initiate the behavior in these individuals, but not others in the same group. Predisposition to tail bite has been shown to have both genetic and metabolic components (Fraser 1987; Fraser et al. 1991a; Breuer et al. 2005), which are exacerbated when pigs are housed in relatively barren environments and subject to other environmental stressors such as overcrowding, extreme temperatures, or drafts. If tail docking is to be rendered unnecessary in the future, a better understanding of the determinants of tail biting is needed to develop effective preventive strategies.

Stockmanship

There is a prevalent and long-held belief that the quality of the stockperson has a more important influence on pig welfare than the choice of production system (Brambell 1965). Increasing scientific evidence suggests that the empathy between stockpersons and the animals in their care is a major factor contributing to animal welfare and performance (English et al. 1992). As highlighted previously, pigs that receive frequent and sympathetic handling are easier to manage and have lower levels of circulating corticosteroid hormones, faster growth rates, and better reproductive performance than those that receive minimal handling or unpleasant handling (Hemsworth et al. 1991). In a comparison of otherwise similar farms, Hemsworth et al. (1981) found that reproductive performance of the unit was higher on those farms where the sows showed little fear of humans. Later work showed that the attitudinal and behavioral profiles of individual stockpersons affected both welfare and performance of their animals (Hemsworth et al. 1989). Legislation in the EU emphasizes the importance of stockmanship, and requires national training programs to be established. However, the quality of stockmanship is still a major limitation on many commercial farms because of the difficulties in attracting and retaining good staff and dealing with the economic pressures to reduce staff time per animal (English et al. 1992).

RESOLVING ANIMAL WELFARE ISSUES

With so many pressures for changes to current practices that are deemed to compromise animal welfare, producers must carefully weigh their future strategy. As detailed previously, a focus on animal welfare should in many cases improve the productivity of farm animals and the quality of their products. In some cases, however, there are likely to be costs associated with conforming to animal welfare standards. For example, requirements to provide straw or to eliminate individual stalls for pregnant sows may create some increase in production costs or at least incur certain expenses during the period of transition. In such cases, producers are understandably concerned about having to compete against lower-priced imports from jurisdictions with less demanding standards.

By the 1990s, debate had arisen about whether countries with high animal welfare standards could block imports from countries lacking equivalent standards. Various mechanisms involving the General Agreement on Tariffs and Trade were proposed, but in each case there are significant difficulties and counter-arguments. The development and acceptance of internationally harmonized standards is an obvious way to avoid conflict among countries over animal welfare standards. As noted above, the World Organization for Animal Health has begun developing international animal welfare standards, initially in the areas of slaughter, killing of animals for disease control, and transport of animals by land and sea. If, and as, standards are adopted, they could help create a level playing field for the industry in different countries. International agreement on contentious production issues, such as minimum weaning age and use of gestation stalls has not yet been attempted outside the European Union.

Resolving animal welfare issues has been made more complicated by the acrimonious and polarized views of modern animal production that are widely presented to the public. On the one hand are thoroughly negative views claiming that confinement systems are inherently bad for animal welfare and for the environment, and that the products of such systems are dangerous for human health. On the other side of the debate are thoroughly positive portrayals of animal agriculture, largely originating from animal producers and their organizations, which claim that modern production is beneficial for animal welfare and the environment, while producing safe and nutritious products (Fraser 2001). With an activity as diverse as swine production, proponents of each of these highly simplified views can cite facts and examples to support their claims.

In this polarized debate, it is sometimes difficult to separate fact from polemic. Some of the modern changes in swine production have had positive effects on animal welfare. The use of indoor housing has eliminated some problems related to predation and cold weather. In some cases confinement has allowed disease prevention through the exclusion of common pathogens. Advances in feeding technology and nutritional knowledge have made it more feasible to meet animals' nutritional needs. Veterinary knowledge and technology allow vaccination, medication, and other disease prevention measures that would not have been possible a half-century ago. However, the changes in production methods have also created a new set of animal welfare problems and dilemmas, as outlined previously. In the midst of the acrimonious debate and the highly charged political environment that has resulted, it will be important for swine producers and veterinarians to retain a constructive focus on animal welfare by building on the positives while solving the problems that current production methods entail.

68 Swine Disease Transmission and Prevention

Sandra F. Amass and Angela Baysinger

Many factors influence whether an animal will become clinically ill after exposure to a pathogen. Factors affecting host susceptibility include age, immunocompetency, vaccination status, genetic predisposition, concurrent illnesses, stress, environment, management, and nutrition. For example, day-old pigs cleared 50% of a lung bacterial load within 3 hours, whereas 26-day-old pigs cleared 95% of the bacterial load in the same period (Curtis et al. 1976). Moreover, ambient temperatures of 6°C inhibited lung clearance of bacteria in 1-day-old pigs as compared to thermoneutral temperatures, but cold temperatures had little effect on pulmonary clearance in 26-day-old pigs (Curtis et al. 1976). Pertinent characteristics of the organism include pathogenicity, infectiousness, contagiousness, viability inside and outside of the host, and the frequency of host exposure to the pathogen. Additionally, factors that can impact the risk of infection include the source of the pathogen (infected animals, environment, zoonotic) and the route of transmission (direct contact, aerosol, arthropod mediated, ingestion, coit) (Thrusfield 1995).

SOURCES OF INFECTION

Pigs are exposed to organisms either through direct contact with an infected animal or other biological vector, or indirect contact with an animal product, fomite, or contaminated environment. The duration of shedding of pathogens by infected animals and information regarding pathogen survival outside of the host are crucial when preparing protocols to minimize sources of infection. The duration of shedding of a pathogen by an infected animal will vary according to host and pathogen factors; however, scientific reports can be used to approximate this time period. Survival of organisms outside of the host animal is also dependent on a variety of factors. Scientific data regarding organism survival are obtained under experimental laboratory conditions and do not necessarily reflect survival times under natural conditions. However, estimations of pathogen survival

time can be derived from these data. Survival time of select swine pathogens in air, water, manure, and on fomites are listed in Tables 68.1 to 68.4.

Data in Tables 68.1 to 68.4 reflect isolation of viable organisms. Results from other methods such as PCR were not included because the viability or infectiousness of the organism cannot be determined with these techniques. For example, *Mycoplasma hyopneumoniae* was detected in air samples of rooms housing acutely infected pigs using a nested PCR assay; however, survival times and transmission distances could not be determined since the viability of the organisms were not evaluated (Stärk et al. 1998).

Semen

Many swine pathogens have been isolated from semen (Table 68.5). Semen can become contaminated naturally from infected boars or postcollection during processing, storage, or transport (Foley et al. 1971; Thacker 1984). Semen collected using an artificial vagina contained 100–1,000,000 cfu per ml (Koppang and Filseth 1958), whereas semen collected using a gloved hand contained 0–3,800 cfu per ml (Waltz et al. 1968). *Alcaligenes xylosoxydans, Burkholderia cepacia, Enterobacter cloacae, Escherichia coli, Serratia marcescens*, and *Stenotrophomonas maltophilia* of both animal and nonanimal origin were isolated from semen. These bacteria are not porcine pathogens but were spermicidal (Althouse et al. 2000). *Pseudomonas aeruginosa, Proteus*, micrococci, streptococci, enterococci, *Candida, Bordetella, Aerobacter, Corynebacterium,* and *Staphylococcus* have also been isolated from boar semen (Koppang and Filseth 1958; Waltz et al. 1968). Staphylococci, streptococci, *Alcaligenes, Pseudomonas,* and *Corynebacterium* were isolated from semen but not the genital tract of respective boars; therefore, contamination likely occurred during collection (Foley et al. 1971). Semen has inherent cytotoxic and antiviral activity (Richmond 1978). Extension of semen could dilute this natural defense.

Clinically normal boars can shed pathogens in their semen. Classical swine fever virus, foot-and-mouth dis-

Table 68.1. Documented survival times for select swine pathogens in air

Organism	Temperature (°C)	Humidity (%)	Survival Time	Source
Actinobacillus pleuropneumoniae	27–32	60–80	Detected	Torremorell et al. 1997

ease (FMD) virus, and swine vesicular disease virus were isolated from semen of clinically normal boars (McVicar et al. 1978; de Smit et al. 1999). Pseudorabies virus was also isolated from semen of clinically normal, vaccinated boars (Medveczky and Szabó 1981). A 5 mm loopful of semen from a clinically normal boar naturally infected with brucellosis yielded 800–1000 colonies of *Brucella suis* (Hutchings and Andrews 1946). Shedding of porcine reproductive and respiratory syndrome (PRRS) virus in semen was variable and was not related to the viremic state or the serostatus of the boar (Christopher-Hennings et al. 1995a).

[1]NR: Not reported.

Dust

Streptococcus suis (Clifton-Hadley and Enright 1984), rotavirus (Fu et al. 1989), *Mycobacterium avium* (Nel 1981; Ichiyama et al. 1988), *Clostridium perfringens* (Sidorenko 1967), *Salmonella* spp. (Eld et al. 1991; Letellier et al. 1999), and pseudorabies virus (Vannier et al. 1989) have been isolated from dust. The length of time that the organisms survived in dust was only reported for *S. suis*: 30–54 days at 0°C, 1–25 days at 9°C, and less than 24 hours at 22–25°C (Clifton-Hadley and Enright 1984).

Soil

Swine raised outdoors can contact pathogens contaminating soil. Laboratory tests found that *E. coli* and *S. typhimurium* added to liquid manure generally penetrated sand and garden soil columns to a depth of 160 cm. Rarely, organisms penetrated soil to depths greater than 160 cm and this was only under conditions of simulated rainfall, and survival was less than 2 weeks at these depths. Organism survival decreased with increasing soil depth regardless of soil type (Tamasi 1981). Survival

Table 68.4. Documented survival times for select swine pathogens on fomites

Organism	Fomite	Temperature (°C)	Survival Time	Source
Classical swine fever virus	Brick	NR	7 days	Slavin 1938
Cytomegalovirus (Human)	Naturally contaminated fomites	NR	Several hours	Pirtle and Beran 1991
Escherichia coli	Painted wallboard, glass, wood, paper towels, metal, insulation, feed bag	15.5–27.2	≤10 days	Marshall et al. 1988
Foot-and-mouth disease virus	Hay	22	20 weeks	Pirtle and Beran 1991; Cottral 1969
	Barns (brick, adobe, wood)	winter	11 weeks	
	Barns (brick, adobe, wood)	summer	2 weeks	
	Cotton clothing, leather shoes, rubber boots	NR	14 weeks	
Influenza A virus	Steel, plastic	27.8–28.3	48 hours	Bean et al. 1982
	Clothing, paper	27.8–28.3	8–12 hours	Bean et al. 1982
Mycobacterium avium	Bedding	22–45	Detected	Nel 1981
Mycoplasma hyopneumoniae	Paper, cloth	15–26	<96 hours	Goodwin 1985
Porcine parvovirus	Uncleaned room	NR	14 weeks	Mengeling and Paul, 1986

	Plastic, metal, cardboard, styrofoam, concrete, rubber	10 and 20	<1–8 hours	Dee et al. 2003
Pseudorabies virus[1]	Steel, plastic, rubber, straw, concrete, wood, denim, sawdust	25	2–18 days	Schoenbaum et al. 1991; Pirtle and Beran 1991
Salmonella spp.	Boots	NR	Detected	Barber et al. 2002
	Pen flooring	NR	Detected	
Streptococcus suis	Plastic flooring, concrete, painted plywood	20	<20 hours	Dee and Corey 1993
Swine vesicular disease virus	Survived on premises after depopulation and disinfection	NR	11 weeks	Pirtle and Beran 1991
Transmissible gastroenteritis virus	Dried and putrefied ground gastrointestinal tract	19.5–21.1	3 days	Bay et al. 1952
	Ground gastrointestinal tract	−28	At least 3.5 years	

NR: Not reported.

[1]Saline-glucose or saline-moistened fomites.

times for select organisms in soil have been documented (Table 68.6).

Insects

Insects have been reported to carry swine pathogens. *Escherichia coli* was recovered from flies for no more than 8 days after contamination of a barn (Marshall et al. 1988) and from flies exposed to experimentally infected pigs (Marshall et al. 1990). *Mycobacterium avium* (Fischer et al. 2001), *Salmonella* sp. (Letellier et al. 1999), transmissible gastroenteritis (TGE) virus (Gough and Jorgenson 1983), and *Yersinia enterocolitica* (Fukushima et al. 1979) have been isolated from flies in swine herds. African swine fever virus was detected in *Ornithodoros moubata* residing in warthog burrows in Tanzania (Plowright et al. 1969b). The survival times of pseudorabies virus in *Musca domestica* varied with the age of the fly and the ambient temperature but the virus did not appear to replicate in living or dead flies (Zimmerman et al. 1989).

Domestic and Feral Animals

Feral swine can be reservoirs of pathogens (Fritzemeier et al. 2000; Artois et al. 2002). Swine pathogens have

also been isolated from domestic and feral animals other than swine. *Salmonella* sp. and *Brachyspira hyodysenteriae* have been isolated from dogs and cats (Schnurrenberger et al. 1968; Songer et al. 1978; Weber and Schramm 1989; Eld et al. 1991; Barber et al. 2002). *Salmonella* spp. was also isolated from opossums (Schnurrenberger et al. 1968). *Leptospira interrogans* serovar *pomona* was isolated from skunks trapped in and near a swine herd during a leptospirosis outbreak (Kingscote 1986). *Streptococcus suis* has been isolated from dogs, cats, horses, a deer, and a zebra from which there was no contact with swine or contact was not reported (Devriese and Haesebrouck 1992; Devriese et al. 1993; Salasia and Lämmler 1994). Pseudorabies virus was isolated from raccoons and cats found dead on or near farms infected with pseudorabies (Kirkpatrick et al. 1980). *Brucella suis* was isolated from hares in Denmark in the same area as a brucellosis epizootic in swine (Bendtsen et al. 1954). *Toxoplasma gondii* was detected in cat feces collected on swine farms (Dubey et al. 1995). *Trichinella spiralis* has been detected in a farm cat (Hanbury et al. 1986), a red fox, coyotes, raccoons, badger, raccoon dogs, mink, wild boar, wolf, and bear (Hirvelä-Koski et al. 1985; Snyder 1987).

Table 68.5. Documented detection of select swine pathogens in semen from infected boars

Organism	Boar Infection Type	Timing of Detection (Test Used)	Source
Adenovirus	Experimental inoculation	65 DPI (virus isolation)	McAdaragh and Anderson 1975
Brucella suis	Natural infection	Detected (bacteriological isolation)	Lord et al. 1997; Hutchings and Andrews 1946
Classical swine fever virus	Experimental inoculation	7 and 11 DPI (virus isolation)	De Smit et al. 1999; Floegel et al. 2000
	Experimental inoculation	7–63 DPI (RT-PCR); 11, 18, 21, and 53 DPI (virus isolation)	Choi and Chae 2003
Foot-and-mouth disease virus	Exposition to experimentally inoculated pen mates	Up to 9 days post exposure (virus isolation)	McVicar et al. 1978
Porcine circovirus	Natural infection	Detected (multiplex nested PCR)	Kim et al. 2001
	Natural infection	Detected (nested PCR)	Hamel et al. 2000
	Experimental inoculation	Intermittently between 5 and 47 DPI (nested PCR)	Larochelle et al. 2000
Porcine enterovirus	Experimental inoculation	45 DPI (virus isolation)	McAdaragh and Anderson 1975
	Natural infection	Detected (virus isolation)	Phillips et al. 1972
Porcine parvovirus	Natural infection	Detected (virus isolation)	McAdaragh and Anderson 1975
	Natural infection	Detected (multiplex seminested PCR)	Kim et al. 2003
Porcine reproductive and respiratory syndrome virus	Experimental inoculation	2–57 DPI (nested PCR)	Shin et al. 1997
		12–21 DPI (nested RT-PCR)	Christopher-Hennings et al. 1998
		Up to 47 DPI (nested RT-PCR)	Christopher-Hennings et al. 1995b
		Up to 92 DPI (nested RT-PCR)	Christopher-Hennings et al. 1995a
		7 and 8 DPI (swine bioassay-seroconversion)	Swenson et al. 1994a
		43 DPI (swine bioassay-seroconversion)	Christopher-Hennings et al. 1995b
		Up to 43 DPI (swine bioassay-seroconversion and virus isolation)	Swenson et al. 1994b
		7 DPI (virus isolation)	Prieto et al. 1994; Shin et al. 1997
		11 DPI (virus isolation)	Christopher-Hennings et al. 1995b
Pseudorabies virus	Natural infection	Detected (virus isolation)	Medveczky and Szabó 1981
Reovirus	Experimental inoculation	65 DPI (virus isolation)	McAdaragh and Anderson 1975
Swine vesicular disease virus	Exposed to experimentally inoculated pen mates	Up to 4 DPI (virus isolation)	McVicar et al. 1978

DPI: Days postinoculation.
PCR: Polymerase chain reaction; RT-PCR: reverse transcriptase—polymerase chain reaction.

Table 68.6. Documented survival times for select swine pathogens in soil

Organism	Soil Type	Temperature (°C)	Survival Time	Source
Brachyspira hyodysenteriae	Sandy clay soil	10	10 days	Boye et al. 2001
Brachyspira pilosicoli	Sandy clay soil	10	119 days	Boye et al. 2001
Clostridium perfringens	NR	NR	Detected	Hang'ombe et al. 2000
Erysipelothrix rhusiopathiae	Sand, silt, clay	3	35 days	Wood 1973
		12	18 days	
		20	10 days	
		30	2 days	
	Swine pen soils	12	11–16 days	
Escherichia coli	Sand	8	90–131 days	Tamási 1981
	Garden soil	8	37–108 days	
	Sand	20	31–102 days	
	Garden soil	20	8–54 days	
Leptospires	Humus boggy-peaty	NR	Detected	Karaseva et al. 1977
	Lake shore soil	0.5–18.5	Detected	Henry and Johnson 1978
Mycobacterium avium	Soil and ditch mud	NR	Detected	Ichiyama et al. 1988
	NR	NR	Detected	Nel 1981
Pasteurella multocida	Siltic clay loam	−1.5–13.3	<20 days	Backstrand and Botzler 1986
Salmonella spp.	Sand	8	16–131 days	Tamási 1981
	Sand	20	74–131 days	
	Garden soil	8 and 20	76–96 days	
	Agricultural soil	NR	76–96 days	Baloda et al. 2001
Trichuris suis ova	Chalky, flinty	3–22	>2 years	Burden and Hammet 1979

NR: Not reported.

Antibodies to *Toxoplasma gondii* were detected in cats, opossums, raccoons, and skunks that were live-trapped on 19 Iowa swine farms. The authors hypothesized that *Toxoplasma* oocysts from cat feces may be a source of contamination for swine (Smith et al. 1992). *Lawsonia intracellularis* was detected in fecal samples of dogs, calves, hedgehogs, hamster, horse, deer, ostrich, and one giraffe by polymerase chain reaction (Cooper et al. 1997; Herbst et al. 2003). Finally, foot-and-mouth disease virus has been isolated from naturally and experimentally infected deer (Forman and Gibbs 1974).

Rodents

Swine pathogens that have been isolated from rodents or rodent feces include *Bordetella bronchiseptica* (Le Moine et al. 1987; Bemis et al. 2003)*, Salmonella* sp. (Davis 1948; Schnurrenberger et al. 1968; Le Moine et al. 1987; Letellier et al. 1999; Barber et al. 2002), *E. coli* (Le Moine et al. 1987; Marshall et al. 1990), rotavirus (Le Moine et al. 1987), *Brachyspira hyodysenteriae* (Joens and Kinyon 1982; Blaha 1983), *Leptospira* spp. (Songer et al. 1983), *Toxoplasma gondii* (Dubey et al. 1995), and *Trichinella spiralis* (Martin et al. 1968; Hirvelä-Koski et al. 1985; Hanbury et al. 1986). Rats and mice have also been shown to seroconvert to TGE virus (Le Moine et al. 1987). Rodents do not appear to be field reservoirs of PRRS virus (Hooper et al. 1994) or pseudorabies virus, even though rats were susceptible to experimental inoculation with pseudorabies virus (Maes et al. 1979).

Birds

Swine pathogens that have been isolated from birds include *Bordetella bronchiseptica* (Farrington and Jorgenson 1976), *Mycobacterium avium* (Bickford et al. 1966), *Streptococcus suis* (Devriese et al. 1994), and *Salmonella* sp. (Schnurrenberger et al. 1968; Eld et al. 1991; Barber et al. 2002; Kirk et al. 2002). Virus isolation from Muscovy ducks, Mallard ducks, guinea fowl, and chickens orally inoculated with PRRSV was attempted on several days from day 0 to 24 postinoculation. The virus was recovered from the feces of guinea fowl on days 5 and 12 postinoculation, from chickens on day 5 postinoculation, and from Mallard ducks on nearly all sample days from day 5 to 24 postinoculation (Zimmerman et al. 1997)

People

Multiple swine pathogens have been detected on people and outerwear including *E. coli*, FMD virus, PRRS virus, *Salmonella* sp.*, Mycobacterium avium,* and swine vesicular disease. Two people that entered a barn in which *E. coli* was experimentally aerosolized were sampled. *Escherichia coli* was recovered from their hair for up to 5 hours, clothing for at least 2 hours, and skin for up to 70 minutes after aerosol release (Marshall et al. 1988). Foot-and-mouth disease virus was isolated from the nasal passages of one of eight people at 28 hours, but not at 48

hours, after exposure to infected animals (Sellers et al. 1970). In another study, human nasal carriage of FMD virus was detected in one of four people upon exit of a containment facility after having been exposed to infected animals for the previous 10 hours. Nasal carriage of FMD virus was not detected in any of the four people at time points up to 4 days after exit of the containment facility (Amass et al. 2003b). Porcine reproductive and respiratory syndrome virus has been isolated from contaminated boots and coveralls (Otake et al. 2002b). *Salmonella* sp. have been isolated from boots on a swine farm (Letellier et al. 1999). *Mycobacterium avium* was detected in the sputa of healthy people (Nel 1981). Swine vesicular disease virus was detected in the nasal passages of people that had contacted infected pigs for at least 5 minutes (Sellers and Herniman 1974). The duration of nasal carriage was not reported. Conversely, *Mycoplasma hyopneumoniae* was not detected from the hair of a swine caretaker (Goodwin 1985).

Vehicles

Contaminated vehicles are a potential source of pathogen introduction to farms. Salmonellae were isolated from swab samples of the grain box of 3 of 22 feed delivery trucks (Fedorka-Cray et al. 1997). *Salmonella* and *E. coli* have been isolated from flooring of trailers used to haul pigs. *Salmonella* was isolated from the flooring of 25 of 32 trailers sampled and *E. coli* was isolated from the flooring of all 32 trailers sampled immediately after pigs were unloaded. Trailer contamination with *Salmonella* and *E. coli* was not found to be related to distance traveled hauling pigs or season (Rajkowski et al. 1998). Similarly, *Salmonella* was isolated from the floors of transport trucks before loading pigs. *Salmonella* serovars isolated from transported pigs matched the serovar detected in the truck, but not serovars from the farm of origin. Thus, infection during transport to slaughter is of concern (Gebreyes et al. 2004).

Carcasses

The process of composting swine carcasses in piles was sufficient to kill *Erysipelothrix rhusiopathiae* and pseudorabies virus under experimental conditions. Survival of *Salmonella* varied but most cultures were killed. *Salmonella* cultures placed at the top and bottom of the pile survived (Morrow et al. 1995).

Salmonella sp. have also been isolated from dead swine and manure from dead swine (Letellier et al. 1999).

Animal Feed

Salmonella sp. (Schnurrenberger et al. 1968; Mårtensson et al. 1984; Eld et al. 1991; Fedorka-Cray et al. 1997; Harris et al. 1997; Letellier et al. 1999), *Mycobacterium avium* (Nel 1981) and *Toxoplasma gondii* oocysts (Dubey et al. 1995) have been isolated from samples of feed or feed ingredients. Researchers have not examined whether the number of organisms detected in feed samples were sufficient

to or had adversely affected the health of pigs consuming the feed. In contrast, a field survey of six swine farms in Illinois did not detect *Salmonella* in any of 221 feed samples collected. These farms produced most of their own feed and samples were collected from closed feed bags or the top layer of feed in bins (Barber et al. 2002).

Contaminated Foods

Contaminated foods pose a potential risk of introduction of exotic diseases to countries free of those diseases. For example, the 2000 outbreak of classical swine fever (CSF) in the U.K. was thought to have originated from a tourist throwing a CSF-contaminated ham sandwich to a pig (Dudley and Woodford 2002). Some porcine pathogens survive for extended periods in contaminated foods. Swine vesicular disease virus survived for at least 200 days in dry salami, pepperoni sausage, and intestinal casings but not in hams heated to internal temperatures of 68.8°C (McKercher et al. 1974). In one case, swine vesicular disease virus survived in a Serrano ham for 539 days, exceeding the curing time of 365 days (Mebus et al. 1997). Swine vesicular disease virus survived for 90–300 days in Parma hams; however, Parma hams are not considered a risk for introduction of swine vesicular disease because Parma hams are cured for at least 365 days (McKercher et al. 1985). Foot and mouth disease virus survived in salt-cured ham for 89 days, salt-cured bacon for 10 days, and salt-cured sausages for 4 days at 1–7°C (Savi et al. 1962; Cottral 1969). Foot-and-mouth disease virus, African swine fever virus, and CSF fever virus appear to be inactivated by commercial curing processes (Mebus et al. 1993). Classical swine fever virus was detected in Italian salami for up to 75 days of curing (Panina et al. 1992); however, heating ham to 65°C for 30 minutes eliminated all virus (Terpstra and Krol 1976).

ROUTES OF TRANSMISSION

Pathogens are spread by biological, mechanical, and aerosol transmission. Biological transmission can occur from sow to pig or pig to pig or through exposure to infected semen or embryos. Biological transmission of swine pathogens among swine and people is also possible. Mechanical spread of pathogens can occur via contaminated fomites, people, other animals, and pests. The route of transmission traditionally thought to offer the greatest risk of infection is direct contact with an infected animal. However, instances of area spread in which no movement of infected animals was reported have occurred. Alternative methods of area spread such as transmission by aerosol, insects, other animals, vehicles, or people have been hypothesized in these cases.

Sow to Pig

Pathogens can be transmitted from sow to pig in utero (Mengeling et al. 1996), during passage of pig through the vagina or by direct or indirect contact after parturition. Technologies such as cesarean-derived pigs and various modifications of early weaning can assist in minimizing transmission from dam to pig (Young et al. 1955; Meyer at al. 1964; Alexander et al. 1980; Mészáros et al. 1985; Harris et al. 1992). Dam-to-pig transfer of *Actinobacillus pleuropneumoniae*, *Pasteurella multocida*, and in all but one case, *Mycoplasma hyopneumoniae* was prevented by weaning pigs at 14 days of age and rearing pigs with age-matched cohorts. *Streptococcus suis* and *Haemophilus parasuis* were not eliminated from these pigs. Transfer of pseudorabies virus but not PRRS virus was prevented (Clark et al. 1994). Mycoplasmal pneumonia and *A. pleuropneumonia* were eliminated from pigs weaned at 7–10 days of age (Dritz et al. 1996). Many factors will determine the feasibility of using early weaning to prevent sow to pig transmission of pathogens on a commercial farm, including facilities, pig husbandry skills, immune status of herd, pathogen characteristics, and timing of infection. Early weaning can exacerbate some diseases (Pyburn and Schwartz 1995; Fangman and Tubbs 1997; Amass 1998a).

Pig to Pig

Pathogens can be spread when susceptible pigs either contact infected pigs directly or contact the secretions or excretions of infected pigs.

Semen and Embryo Transfer

Some organisms have been reported to be transmissible by semen or embryo transfer. Only three swine pathogens have been proven to be transmissible by semen under experimental conditions: CSF after experimental inoculation of boars (de Smit et al. 1999) and porcine parvovirus (Lucas et al. 1974) and PRRS virus (Prieto et al. 1997b) were transmitted by artificial insemination after experimental inoculation of semen.

Literature regarding interactions between porcine pathogens and embryos is limited; thus, pathogens of interest should be individually tested to determine transmissibility by embryo transfer (Shelton 1987). Porcine reproductive and respiratory syndrome virus was isolated from embryos of experimentally infected gilts at 20 days of gestation but not at 10 days of gestation (Prieto et al. 1997a). However, PRRS virus was not transmitted to embryos, recipient gilts, or resultant piglets when embryos from experimentally infected gilts were transferred to susceptible recipient gilts (Randall et al. 1999). Porcine reproductive and respiratory syndrome virus did not infect the 4- to 16-cell-stage embryos cultured in vitro with PRRSV (Prieto et al. 1996). Porcine parvovirus was not isolated from 4-day-old, 15-day-old, and 32-day-old embryos of experimentally infected gilts (Gradil et al. 1994), but was isolated from the 4- to 8-cell-stage embryos after in vitro incubation with virus (Bane et al. 1990). Pseudorabies virus was not detected in intact or zona pellucida–free 2- to 16-

cell-stage porcine embryos that were exposed to virus in vitro for at least 1 hour (Bolin et al. 1981). However, pseudorabies-neutralizing antibodies were detected at 21 days after embryo transfer in recipients of embryos exposed to pseudorabies virus in vitro or embryos collected from experimentally infected donors (Bolin et al. 1982). African swine fever virus, FMD virus, vesicular stomatitis virus, and CSF virus have been detected on zona pellucida–intact, 4-day-old embryos after exposure to respective viruses in vitro for 2–18 hours followed by washing (Singh et al. 1984; Singh et al. 1986; Singh and Thomas 1987; Dulac et al. 1988).

Aerosol

Evidence points to aerosol transmission in the field under specific conditions of large numbers of pathogens being shed by a large population of animals, low temperatures, high humidity, low wind speeds, smooth topography, and low sunlight (Gloster et al. 1981; Christensen et al 1990; Grant et al. 1994; Stärk 1999). However, the ideal temperatures and relative humidity required for aerosol transmission vary for individual pathogens (Stärk 1999). A Gaussian diffusion model was used to explain an epizootic of pseudorabies virus that affected 10 farms across a 150 km^2 area (Scheidt et al. 1991; Grant et al. 1994). Evidence of aerosol transmission of pseudorabies virus over distances of 15–80 km has been reported (Christensen et al. 1990). Experimental transmission of CSF virus was reported after air was forced by positive pressure from handmade large rectangular metal cans containing pigs inoculated with the virus to cans containing susceptible pigs (Hughes and Gustafson 1960) and under experimental conditions without forced air flow (Laevens et al. 1999). Multiple instances of long distance spread of FMD virus by aerosol have been reported (Sellers and Gloster 1980; Donaldson et al. 1982; Gloster et al. 1982). However, aerosol transmission of FMD virus as a consequence of

burning infected animal carcasses has not been established (Gloster at al. 2001; Champion et al. 2002; Jones et al. 2004). Aerosol transmission of pathogens outside of experimental laboratories cannot be definitively proven due to the variety of confounding factors. Moreover, replicating field conditions for laboratory studies of aerosol transmission is difficult due to the limitation of animal numbers. Porcine reproductive and respiratory syndrome virus did not spread between two buildings located 1 meter apart that housed infected and sentinel pigs, respectively, under controlled field conditions; moreover, PRRS virus was not detected in the air exhausted from the barn containing infected pigs (Otake et al. 2002a). Consequently, pathogens generally travel for short distances by aerosol under experimental conditions (Table 68.7). With the exception of virus, swine pathogens rarely have been reported to travel greater than 3.2 km by air.

People

Biological transmission of swine pathogens by people is possible when zoonotic organisms are considered. Pig-to-person transmission has been documented for zoonotic agents such as *S. suis* and swine influenza virus. *Streptococcus suis* is considered an occupational health hazard for those working in the pork industry in some areas of the world. Over 150 cases of human infection with *S. suis* have been documented (Amass 1998b). However, a pilot study of personnel on five Indiana swine farms did not detect human carriage of *S. suis* (Amass et al. 1998). Similarly, H1N1 swine influenza virus was transmitted to humans after exposure to experimentally infected pigs (Wentworth et al. 1997). Transmission of these pathogens from people back to pigs has little documentation aside from anecdotal evidence. Finally, xenotransplantation of pig organs into human beings offers the potential risk of xenozoonoses (Borie et al. 1998); however, the risk of pig contamina-

tion by humans with porcine xenotransplants has not been determined.

People can mechanically transmit a pig-infectious dose of certain swine pathogens from infected to susceptible pigs. Contact with contaminated people has been implicated in the spread of CSF virus (Fritzemeier et al. 2000). Transfer of the FMD virus from people to one of four susceptible steers was reported when people exhaled directly into the nasal passages of susceptible steers after showering, but within 30 minutes of contacting FMD virus-infected pigs (Sellers et al. 1971). Similarly, personnel in contact with FMD virus-infected pigs mechanically transmitted an infectious dose to susceptible pigs and sheep (Amass et al. 2003b). Mechanical transmission of *E. coli* (Amass et al. 2003a) and TGE virus of swine (Alvarez et al. 2001) by people from infected to susceptible pigs has been reported under conditions simulating natural field exposure levels. Mechanical transmission by people of PRRS virus from infected to susceptible pigs has been reported when personnel took extraordinary measures to contaminate hands and outerwear with blood, nasal secretions, saliva, and manure, and then allowed pigs direct contact with contaminated outerwear for 24 hours after the exit of personnel from the room (Otake et al. 2002b). Mechanical transmission by people of PRRS virus from infected to susceptible pigs was not demonstrated when contamination of personnel reflected levels found on a typical pork production unit (Amass et al. 2000a). Contact with contaminated boots and clothing did not significantly contribute to the spread of CSF virus (Laevens et al. 1998).

Rodents

Rodents are potential mechanical and biological vectors of disease. Transmission of swine disease by rodents in the field has not been definitively proven; although rodents are considered a risk factor in the spread of swine dysentery and leptospirosis. Pigs exposed to feces from mice that had been experimentally infected with *B. hyodysenteriae* developed clinical swine dysentery after 11–13 days (Joens 1980).

Insects

Insects can act as biological and/or mechanical vectors of swine pathogens (Table 68.8). *Musca domestica* reportedly traveled 1.5 km to adjacent farms (Denholm et al. 1985). Marked mosquitoes (*Anopheles vestitipennis*) were 80.48% faithful in returning to the original animal host for a second blood meal (Ulloa et al. 2002). Most reports of transmission of pathogens by insects are the result of experimental data and may not reflect the actual risk of insects as vectors of these pathogens.

Domestic and Feral Non-Swine Animals

Susceptible non-porcine hosts can act as biological vectors, in which case, the animals would become infected with the pathogen and then shed the pathogen in secretions and excretions to susceptible pigs by direct or indirect contact. Nonsusceptible species can act as mechanical vectors by tracking the pathogen-laden excretions (manure) to areas containing susceptible pigs, which can then become exposed. There is little definitive evidence that non-swine animals are vectors of swine path-

[1]Note: *Musca domestica* are not biting flies. Experimental transmission occurred when flies fed on blood from experimentally scarified areas of skin on the backs of pigs.

ogens. Under experimental conditions, pseudorabies virus was isolated from nasal discharges of pigs 8 days after pigs were fed the viscera of raccoons that were experimentally inoculated with pseudorabies virus (Kirkpatrick et al. 1980). In the field, a watchdog was implicated in the reintroduction of *B. suis* to a swine herd 2 years after the infected herd was depopulated and repopulated with brucellosis-free stock. *Brucella suis* was isolated from the asymptomatic watchdog used to guard the original infected herd, and subsequently the newly populated herd (Körmendy and Nagy 1982). Transmissible gastroenteritis virus was transmitted to pigs that had been fed jejunal material from experimentally infected dogs (Larson et al. 1979). A risk association study in the United States reported that pigs on farms were 6.33 and 6.95 times more likely to be seropositive to *Trichinella* when pigs had access to wildlife and wildlife carcasses (Gamble et al. 1999).

Birds

Introduction of swine pathogens to farms by birds has been hypothesized but not definitively documented. Pigs fed droppings from starlings that were experimentally fed a suspension of transmissible gastroenteritis virus developed clinical signs of transmissible gastroenteritis but virus isolation was not performed (Pilchard 1965). English sparrows mechanically transmitted CSF under experimental conditions (Hughes and Gustafson 1960). An influenza A strain originating in wild ducks was thought to be responsible for an outbreak of influenza in pigs in Belgium. The strains of influenza isolated from the pigs were related to influenza viruses isolated from wild ducks in North America and Germany (Pensaert et al. 1981).

Fomites

Iatrogenic mechanical transmission by use of contaminated needles has been reported for PRRSV (Otake et al. 2002c).

Carcasses

Cannibalism of infected pig carcasses was determined to be the mode of transmission of *Trichinella spiralis* on an Illinois swine farm (Hanbury et al. 1986).

Vehicles

Contact with contaminated vehicles was implicated in the spread of CSF virus (Fritzemeier et al. 2000). Farms with more than two animal transport vehicles per month, greater than 30 rendering trucks per year, and greater than one veterinarian or technician vehicle entering every 2 months had an increased risk of occurrence of two or more respiratory disease outbreaks per year by 5.1, 3.2, and 5.5 times, respectively, than farms with less vehicle entries (Rose and Madec 2002). Under experimental conditions, carriers composed of non-chlorinated well water and snow were injected with $10^{4.4}$ TCID$_{50}$ of PRRSV and attached to the rear wheel wells of a truck to simulate potential transport of PRRSV by a contaminated vehicle in winter. The truck was driven 50 km at temperatures of <0°C to a truck wash. The truck was manually cleaned to ensure that the carriers fell to the cement floor of the truck wash. The carriers were then stepped on. Porcine reproductive and respiratory syndrome virus was recovered by virus isolation from the floor of the truck wash facility in 5 of 10 replicates (Dee et al. 2002). This experiment was repeated in warm weather (10–16°C) using a carrier composed of a ball of soil inoculated with PRRS virus, and the virus was recovered by virus isolation from the floor of the truck wash facility in 6 of 10 replicates (Dee et al. 2003). These experimental conditions might not reflect the level of vehicle contamination that naturally occurs in the field.

ASSESSING RISK OF INFECTION

Assessing the exact risk of infection is difficult because of the numerous factors involved in disease transmission. However, risk can be estimated by using mathematical models. One can estimate the average number of new cases of an infection that would result from the introduction of a single infected animal to the population, given information regarding the pathogen and the specific population of swine. This number is called the basic reproduction number, basic reproduction ratio or basic reproductive rate, and is symbolized by R_0. The basic reproduction number (R_0) is calculated by multiplying the probability of infection after contact with the infectious animal (p), the number of contacts per unit time with the infectious animal (c), and the duration of infectiousness of that animal (D). Thus, $R_0 = pcD$ (Anderson and Nokes 1991). The probability of an epizootic through direct contact is calculated as $P_{epizootic} = 1 - 1/R_0 I_0$, where I_0 is the initial number of infectious animals. The basic reproductive number can also be used to calculate the proportion of susceptible animals that should be vaccinated to prevent an epizootic: $P_{vaccinated} = 1 - (1 \div R_0)$ (Anderson and May 1982; Anderson and Nokes 1991). A major limitation of these equations is that the calculations do not account for indirect contact with the pathogen. However, swine veterinarians can use these formulas as a starting point to estimate risk of infection and subsequent costs. The R_0 of the CSF virus during the 1997–1998 epidemic in The Netherlands was estimated to be 2.9 (Stegeman et al. 1999), whereas the R_0 for CSF under experimental conditions has ranged from 13.7 (Laevens et al. 1999) to 81.3 (Laevens et al. 1998). The R_0 for pseudorabies virus in unvaccinated and vaccinated pigs was 10 and 0.36–0.5, respectively (de Jong and Kimman 1994; Bouma et al. 1995). The R_0 for transmissible gastroenteritis virus was estimated at 2 for the breeding animals and 4 for growing pigs (Hone 1994).

BIOSECURITY: CONTROL OF ENZOOTIC, EPIZOOTIC, AND EXOTIC DISEASES

Location

Increased distance between animal facilities reduced the risk of aerosol infection (Müller et al. 1978). Farms located within 2 km of five or more farms were 2.9 times more likely to experience two or more respiratory disease outbreaks per year than farms located within 2 km of less than five farms (Rose and Madec 2002). Risk factor indices for infection with *M. hyopneumoniae* were developed using characteristics of 55 infected herds and 57 uninfected herds. The most important risk factor for infection was the reciprocal of the square of the distance to the nearest farm. Distances within 3.2 km had the highest risk (Goodwin 1985). Further modeling has suggested that the risk of a noninfected herd becoming infected with *Mycoplasma hyopneumoniae* increased as the distance between that herd and the nearest infected farm decreased (Jorsal and Thomsen 1988; Stärk et al. 1992; Thomsen et al. 1992).

Factors that can be used to prevent aerosol transmission among farms include vaccination of animals to prevent infection and decrease shedding of organisms and selection of a low pig density area. Increasing the distance between the nearest swine farm and manure spreading area is preferable but cannot absolutely prevent airborne infections (Stärk 1999). Within barns, PRRS virus was transmitted among pigs, without direct contact, over short distances in two of five trials. Transmission by aerosol could not be confirmed because experimental design did not prevent the transfer of feed, feces, and urine among pens; however, the authors hypothesized that separation of pens by short distances (46–102 cm) could result in subpopulations of noninfected pigs (Wills et al. 1997). Factors that can be used in general to prevent aerosol transmission within buildings include dust reduction through adding fat to feed, minimizing animal movement, maintaining relative humidity <60%, and optimizing ventilation (Stärk 1999). There was no difference in the concentration of organisms isolated from the air of mechanically ventilated and naturally ventilated swine barns (Predicala et al. 2002).

Introduction of Genetics

Limiting the number of genetic sources can minimize the risk of pathogen introduction to a herd. Danish SPF herds purchasing stock from more than one source per year were 2.7 times more likely to become reinfected with *M. hyopneumoniae* than herds purchasing from a single source (Jorsal and Thomsen 1988). Additionally, introduction of live boars to a herd poses a greater risk of pathogen introduction than bringing in semen (Bouma 2000). However, similar questions should be asked of your semen supplier as of your live animal supplier to determine the health risk posed by the semen source.

Moreover, a boar stud could unintentionally distribute infected semen to large numbers of animals in a wide geographic range; therefore, semen distribution should cease during a disease outbreak in the stud (Bouma 2000). The American Association of Swine Veterinarians has published guidelines for boar studs distributing semen within United States (Althouse et al. 2003). Additionally, procedures to minimize contamination of semen during collection and processing have been published (Althouse et al. 2000). Removal of the preputial diverticulum is a surgical method to decrease contamination of semen (Aamdal et al. 1958).

Veterinarians of the source and the recipient herds should work together to determine the health status and testing procedures to minimize risk of disease introduction. Animals can be tested prior to purchase to determine whether they meet the herd health standards. Animals can then be tested on arrival to establish baseline exposure to disease and any change in health status. Incoming stock can be isolated, monitored for signs of disease, and tested before introduction to the herd. Finally, animals can be retested before exiting isolation facilities. All animals should appear healthy and test negative to diseases of concern, prior to entering the existing herd facilities.

Isolation of incoming animals is one method to lessen the risk of disease introduction to a herd. Isolation provides the opportunity to recognize clinical signs of disease in incoming animals before carrier animals can infect the entire herd. Models have estimated that 6–30 days would elapse before clinical signs of transmissible gastroenteritis virus were detected in a herd after the introduction of a carrier pig (Hone 1994). Isolation also provides an opportunity to test incoming animals for pathogens and acclimatize incoming animals by direct exposure or vaccination before entry to the main herd. The duration of isolation will vary with the pathogen of concern, but it generally lasts at least 30 days.

People

A study of swine herds consisting of greater than 2000 pigs in three California counties reported that swine herds were contacted by people (and vehicles) that had contacted other livestock facilities between 374.9–1239.5 times per month with an average indirect contact rate of 807 times per month (Bates et al. 2001). The ease of transportation in the modern world has resulted in increased frequency of contacts, which could increase the risk of disease transfer.

African swine fever virus was not detected in nasal swabs of people immediately after 30 minutes of exposure to infected pigs (Wilkinson et al. 1977). Moreover, downtimes were not needed to prevent mechanical transmission of *E. coli*, FMD virus (O/UK/35/2001), TGE virus, or PRRS virus by people in experimental trials, provided that the appropriate decontamination methods for each pathogen were implemented (Amass et al.

1998, 2003ab; Alvarez et al. 2001; Otake et al. 2002b). In contrast, nose blowing or washing was not effective in eliminating FMD virus, and cloth or industrial masks were not effective in preventing inhalation of the FMD virus (Sellers et al. 1970). Similarly, use of goggles, gloves, and dust masks were not effective in preventing human infection with swine influenza virus (Wentworth et al. 1997).

Showering and donning clean coveralls, boots, and gloves was sufficient to prevent mechanical transmission of FMD virus (O/UK/35/2001) from infected pigs to susceptible pigs and sheep (Amass et al. 2003b). Hand washing and donning clean outerwear was sufficient to prevent mechanical transmission of FMD virus (O/UK/35/2001) from infected pigs to susceptible pigs, but sheep remained susceptible (Amass et al. 2003b). Pigs are more resistant to FMD virus (O/UK/35/2001) compared to sheep (Donaldson and Alexandersen 2001). Presumably, hand washing and changing outerwear reduced the dose mechanically transmitted by people to that below the infectious dose for swine, but a sheep-infectious dose was still transmitted (Amass et al. 2003b). Similarly, showering and donning clean outerwear was effective in preventing the mechanical transmission of *E. coli* by people from infected to susceptible pigs, while hand washing and donning clean outerwear did not prevent such transmission (Amass et al. 2003a). Hand washing or showering and donning clean outerwear were both effective in preventing a person from mechanically transmitting TGE virus of swine from infected to susceptible pigs (Alvarez et al. 2001). Finally, hand washing or showering and donning clean outerwear were both sufficient to prevent the mechanical transmission of PRRS virus under conditions of extraordinary contamination of people (Otake et al. 2002b).

Scientific studies regarding effective showering procedures are absent, with the exception of those studies cited above wherein showering was used as an intervention for disease transmission. Presumably, showering procedures should ensure that sufficient time is spent to remove all organic material from body surfaces. Similarly, most hand washing studies were performed under experimental or hospital conditions that do not reflect the extent of hand contamination following procedures performed in a swine unit. Both resident and transient bacteria colonize hands. The goal of hand washing is to remove the transient bacteria. The effectiveness of hand washing as a hygiene tool will vary with the contaminant organisms. For example, the percentage reduction in *E. coli* on hands after 10 seconds of hand washing was significantly greater than the percentage reduction of human rotavirus, regardless of the washing media (antimicrobial soap, unmedicated soap, or tap water) used (Ansari et al. 1991). The efficacy of medicated soap in reducing transient bacterial flora after 30 seconds of hand washing varied according to bacterial type, with some medicated soaps more efficacious than others for certain classes of bacteria (Puthucheary et al. 1981).

Current hand washing recommendations for visibly contaminated hands consist of wetting the hands, then using plain or antimicrobial soaps to wash the hands by vigorously rubbing together all hand surfaces for at least 15 seconds. The hands should then be thoroughly rinsed and dried (Centers for Disease Control and Prevention 2002). Fifteen seconds of washing might not be sufficient for grossly contaminated hands; therefore, washing presumably should continue for 15 seconds after the time that hands are visibly free of organic material.

Generally, in cases where hands were not visibly contaminated, use of at least 1–3 ml of an alcohol-based hand antiseptic reduced bacterial counts more than washing with medicated or unmedicated soap and water. Applying less than 0.5 ml of alcohol-based antiseptic to hands was not more effective than washing hands with plain soap and water. The exact volume of alcohol-based solution that is most effective likely varies among products, but generally, hands should still feel wet from the alcohol after rubbing them together for 15 seconds to ensure that a sufficient volume of product was used. Swine care workers should be cautioned that alcohols are not effective on visibly contaminated hands (Centers for Disease Control and Prevention 2002).

Drying hands following washing is an important part of hand hygiene. Drying hands for either 10 seconds with a cloth towel or 20 seconds with an air dryer reduced bacterial transfer from hands to pieces of plastic by 99% when compared to bacterial transfer from wet hands (Patrick et al. 1997). Electric air-drying of hands for 10 seconds was more effective in reducing numbers of both *E. coli* and rotavirus compared to drying hands with a paper or cloth towel for 10 seconds (Ansari et al. 1991).

Wearing gloves can decrease the gross contamination of hands but does not prevent the need for hand washing. Hands can become contaminated through holes in the gloves and/or during glove donning and doffing (Centers for Disease Control and Prevention 2002). Thus, hand washing is recommended following the removal of gloves.

There is little evidence to require restrictions regarding off-farm contact among personnel working at different swine farms to prevent indirect transmission of swine pathogens from farm to farm. Person-to-person transfer of swine pathogens is possible but the frequency of occurrence under field conditions is unknown. Transfer of FMD virus between people was documented after persons in contact with infected animals spoke to unexposed colleagues in a box for 4 minutes (Sellers et al. 1970). Circumstantial evidence of transmission of swine influenza virus among people has been documented but not definitively proven. The 1976 outbreak of swine influenza A at Fort Dix affected at least

230 military personnel and was probably introduced by a new trainee (Top and Russell 1977). However, the initial human source of the virus was never proven and there was no evidence, aside from the viral strain, linking the outbreak to contact with swine (Kendal et al. 1977). Circumstantial evidence exists that a woman attending a county fair in which there was a flulike illness became infected with swine influenza virus from the pigs and subsequently spread the virus to health care workers (Wells et al. 1991). In contrast, an 8-year-old boy that was infected with swine influenza virus and lived on a swine farm did not transmit the virus to his parents or to his five siblings, despite close contact (O'Brien et al. 1977). Notably, definitive evidence of people infected with swine influenza virus transmitting the virus to swine has not been documented, despite some evidence of person-to-person transmission.

Non-Porcine Vectors

Farm management plans should include procedures for the control of wildlife and feral animals that can act as disease vectors.

Insects

Sanitation is the key measure for controlling insects (Williams 1992). From observations of *Musca domestica* in England, it was reported that fly numbers were fairly constant in closed buildings with fly numbers dropping when rooms were cleaned between groups of pigs, but increasing when rooms were restocked (Denholm et al. 1985). Manure, spoiled feed, and wet areas should be removed at least twice a week (Williams 1992). Flies and mosquitoes can be controlled by spraying pigs with insecticides or treating the environments with sprays, fogs, baits, and larvicides (Williams 1992). Persistent use

of the same insecticide, especially in houseflies overwintering in indoor buildings was thought to contribute to maintenance of insecticide-resistant fly populations (Denholm et al. 1985). Traps and screens can be used to mechanically rid an area of insects (Williams 1992). Nematodes can be used to control housefly populations. Fewer flies were counted on a farm when baits of the nematode *Steinernema feltiae* were used compared to methomyl baits (Renn 1998).

Cleaning and Disinfection

One route of infection for pigs is through contact with a contaminated environment. Therefore, thorough cleaning and disinfection of all surfaces is crucial to a successful biosecurity program. Swine exposed to a *Salmonella* Typhimurium-contaminated environment for as little as 2 hours became infected (Hurd et al. 2001). Cleaning prior to disinfection is the most important step. All visible organic material (feed, urine, manure, secretions) should be removed from the surface(s) to be disinfected. A general target for the number of aerobic bacteria present following cleaning of surfaces and prior to disinfection is 10^6 cfu/cm^2 (Böhm 1998).

Disinfectants should be applied according to label directions. Extralabel use of most disinfectants is a violation of United States federal law. Disinfectant classes have general properties (Table 68.9) but an individual formulation could have a broader or more limited spectrum of activity (Jeffrey 1995; McDonnell and Russell 1999). Human health risks have been associated with some classes of disinfectants (Table 68.9) (Bruins and Dyer 1995).

The field efficacy of a disinfectant is dependent on a variety of factors, including but not limited to the surfaces to be disinfected, pathogens present, water quality,

Table 68.9.   General properties and human health risks of disinfectants

Disinfectant	Acitivity against					Human Health Effects
	Bacteria	Virus	Fungi	Spores	Mycobacterium	
Alcohols	bactericidal	virucidal	fungicidal	inhibit sporulation and spore formation	mycobactericidal	
Formaldehyde	bactericidal	virucidal		sporicidal		100 ppm formaldehyde can be life threatening, formaldehyde gas is unstable and can explode, allergenic, potentially carcinogenic
Biguanides	bacteriostatic	virucidal	fungicidal			irritating to skin
Glutaraldehyde	bactericidal	virucidal	fungicidal	sporicidal		allergenic
Halogen releasing compounds	bactericidal	virucidal	fungicidal	sporicidal		irritating to skin and eyes
Phenols	bactericidal	virucidal	fungicidal		mycobactericidal	toxic, irritating to skin
Quaternary ammonium compounds	bactericidal	lipophilic virucidal		sporostatic		
Peroxygen compounds	bactericidal	virucidal	fungicidal	sporicidal		

and organic material. Thus, label claims do not always translate into effectiveness in field situations (Kennedy et al. 1995).

An initial disinfectant choice should be based on disinfectant class properties, label claims, and independent data if available. Disinfectants should be prepared and applied according to label directions. Ideally, the disinfectant should be allowed to dry, or, at minimum, the contact time recommended on the label should elapse. Cleaning and disinfection protocol effectiveness can be determined by sampling the environment for specific pathogens or by using aerobic bacterial counts as a marker for contamination. The target for number of aerobic bacteria present after disinfection is 1 cfu/cm^2 (Tamasi 1995). However, a target of 10^3 cfu/cm^2 has been suggested for disinfection of livestock facilities and transport vehicles (Böhm 1998). Sentinel animals can also be used to monitor for specific pathogens following depopulation of a facility.

Processing Equipment. Dipping processing instruments in disinfectant is a common method of decontaminating instruments between litters of pigs. However, dipping tail clippers in chlorhexidine diacetate solution after a single use did not significantly reduce the mean aerobic bacterial counts on the blade when compared to untreated clippers (Alvarez et al. 2002). Wiping the blade with a clean cloth did significantly reduce the mean aerobic bacterial counts on the clippers (Alvarez et al. 2002). Wiping the blade physically removes organic contamination that dipping does not eliminate. Moreover, dipping instruments in disinfectant does not allow the minimum contact time needed for the disinfectant to work.

Boots. Farms maintain boot baths with the goal of preventing mechanical transmission of pathogens among groups of pigs. Frequently boot baths are grossly contaminated with organic matter as their maintenance is often lacking. They are also inconvenient and people commonly avoid the bath or step through the bath without stopping to clean their boots.

One suggestion for effective utilization of boot baths consisted of cleaning boots in a preliminary bath filled with dilute detergent, followed by immersion of clean boots to a depth of 15 cm, for at least 1 minute, in a second bath filled with detergent (Quinn 1991). Additionally recommendations included that large units prepare new boot baths daily or when visibly contaminated, and small units prepare new boot baths every 3 days (Quinn 1991).

Glutaraldehyde, chlorhexidine, sodium hypochlorite, iodine, phenolic, quaternary ammonium, and peroxygen disinfectants were evaluated utilizing various boot bath protocols. Bacterial counts on boots were not effectively lowered when the boots were contaminated with manure and then dipped in disinfectant (Amass et al. 2001) or soaked in disinfectant for 2 minutes (Amass et al. 2000b, 2001). Bacterial counts were effectively reduced when manure was removed from the boots by either scrubbing off manure in a clean disinfectant boot bath (Amass et al. 2000b, 2001) or scrubbing off manure in water and then dipping boots in a clean disinfectant boot bath (Amass et al. 2001). Contaminated boot baths, even those used only once previously, increased bacterial contamination of the boot (Amass et al. 2000b).

Dipping disposable plastic boots that were experimentally contaminated with PRRS virus into a fresh bath of undiluted 6% sodium hypochlorite for 5 seconds reduced the number of boots that were PCR-positive for PRRS virus as compared to boots that were experimentally contaminated and then dipped in a water bath without disinfectant (Dee et al. 2004). Similar results were reported when this experiment was repeated using fecal contamination in addition to virus contamination of boots (Dee et al. 2004). The disinfectant was not neutralized after sampling in these trials; therefore, the effective contact time likely exceeded 5 seconds. Moreover, virus isolation was not used to determine PRRSV viability.

Laundry. Contaminated clothing is a potential fomite in disease transmission. Poliovirus and vaccinia virus were experimentally transferred from contaminated to sterile fabrics when dry pieces of fabric were randomly tumbled in a jar. Maximum virus transfer occurred between 1 and 30 minutes (Sidwell et al. 1970). Microorganisms were also transferred from contaminated to sterile fabrics during laundering in a washing machine (Wiksell et al. 1973).

The effect of water temperature during laundering varies and is likely dependent on the contaminating pathogens, detergents and laundry chemicals used, and water characteristics such as hardness and pH. Early research recommended that hospital laundry be washed for 13 minutes at 60°C for optimal bacterial reduction (Walter and Schillinger 1975). Later, bacterial counts from hospital towels and sheets laundered at 71°C (160°F) and 22°C (72°F) were reported as not significantly different (Blaser et al. 1984). Washing at 47.8°C (118°F) to 60°C (140°F) with detergent and bleach was just as effective at removing bacteria as washing using similar procedures at 73.9°C (165°F) to 77.2°C (171°F) (Christian et al. 1983). Increased concentrations of bleach could compensate for lower washing temperatures (Christian et al. 1983). In contrast, water temperatures of 54°C to 60°C were more effective at removing poliovirus from contaminated fabrics than laundering at water temperatures of 21°C to 27°C or 38°C to 43°C (Sidwell et al. 1971). Laundering cloth contaminated with enterococci at temperatures of 71°C to 80°C for 3.5–10 minutes was effective even though the enterococci strains used survived for 30 minutes at 85°C under laboratory conditions (Orr et al. 2002). Thus, a correla-

tion cannot always be found between the thermotolerance of an organism and survival during laundering (Orr et al. 2002).

Rinse water discharged from washing machines can contain viable bacteria and viruses. Concentrations of viable bacteria in rinse water were detected at levels from 100–5,000 cfu per ml at wash temperature of 38°C, 12–398 cfu/ml at wash temperature of 49°C, and 3–302 cfu/ml at wash temperature of 60°C. The final rinse had less than or equal to 20 cfu per ml regardless of wash water temperature used (Walter and Schillinger 1975). Viable poliovirus was not recovered from rinse water when laundering at water temperatures of 54°C to 60°C, but it was recovered when water temperatures of 21°C to 27°C or 38°C to 43°C were used (Sidwell et al. 1971).

The target for the number of bacteria adhered to fabric after laundering is 0.2 cfu/cm^2 (Walter and Schillinger 1975). However, quantification of bacteria on fabrics is difficult. Results from impression cultures using RODAC plates (replicate organism detection and counting) do not correlate well with more accurate destructive techniques such as cultures of macerated fabric samples (Nicholes 1970; Wetzler et al. 1971). Thus, the effectiveness of laundry procedures is more accurately determined by culturing fabrics for specific pathogens of concern instead of general quantification of total microorganisms (Wetzler et al. 1971).

Vehicles

Restricting entry of vehicles to farm premises, especially livestock trailers, to those that have been cleaned and disinfected should minimize the chance of pathogen introduction. Farms with parking for pig transport vehicles located within 300 meters of the farm site were 9.28 times more likely to become reinfected with *M. hyopneumoniae* or *A. pleuropneumoniae* than farms with no parking site near the farm (Hege et al. 2002). Cleaning and sanitizing trailers was effective in significantly reducing the numbers of *Salmonella* and *E. coli* on trailer flooring, but it did not eliminate bacterial contamination in all cases (Rajkowski et al. 1998). The principles of vehicle sanitation follow those outlined for facilities and equipment (Poumian 1995). However, cleaning and disinfecting vehicles can be difficult because surfaces are irregular and multiple materials are involved (Böhm 1998). Moreover, low outdoor temperatures prevent adequate decontamination if an indoor washing facility is not available (Böhm 1998). Ideally, vehicles should be decontaminated in an indoor facility at temperatures above 10°C (Böhm 1998). Selection of disinfectants for vehicles should ensure that the disinfectant used is not corrosive.

Water

On-farm water supplies range from freshwater to rural water. They also include sources such as rainwater, including runoff, ground water, rivers, and streams. Reducing the risk of pathogens in water depends on several possible approaches that take into account the source of water, physical treatment (filtration, sedimentation), and chemical treatment (disinfection). Water safety and quality can be determined by bacterial analysis of water samples. Depending on previous history of the water source, a water analysis may need to be done annually at a minimum.

Carcass Disposal

Carcasses of previously ill pigs have the potential to be a source of pathogens. Prompt carcass disposal is recommended for aesthetic as well as biosecurity reasons. Farms storing carcasses inside the perimeter of the farm premises were 3.4 times more likely to experience two or more respiratory disease outbreaks per year than farms that did not maintain carcasses on site (Rose and Madec 2002). Approved carcass disposal options vary according to local regulations. Options for carcass disposal include burial, landfills, composting, rendering, tissue digestion, and incineration (Sander et al. 2002).

Manure

Inactivation of viruses in liquid manure is not practical but could be necessary prior to repopulation after a disease outbreak. Long-term storage of manure for at least 6 months at 4°C without addition of new manure should be effective assuming a virus titer reduction of 1–2 log$_{10}$ units per month. A directive of the Federal Ministry of Agriculture in Germany recommends the following methods for disinfection of manure: 40% solution of lime hydrate at a concentration of 40–60 liters per cubic meter of liquid manure can be used at temperatures between 0 and −10°C; or a 50% solution of sodium hydroxide at a concentration of 16–30 liters per cubic meter of liquid manure can be used at temperatures between 0 and 10°C. Manure should be stirred prior to, during, and for 6 hours after chemical disinfection. The duration of exposure of manure to chemicals should be at least 4 days and preferably 1 week. Peracetic acid at a concentration of 25–40 liters per cubic meter of liquid manure can be used at temperatures between 0 and 10°C. The exposure time in this case is at least 1 hour and often is not practical due to excessive foaming (Haas et al. 1995).

Feed

Outbreaks of exotic diseases such as classical swine fever have been traced back to swill feeding (Fritzemeier et al. 2000). United States federal law states "No person shall feed or permit the feeding of garbage to swine unless the garbage is treated to kill disease organisms . . ." (9 CFR Ch. 1, Part 166—Swine Health Protection, Section 166.2, 1-1-98 Edition). However, some individual states forbid feeding both treated and untreated garbage. Feed and feed ingredients can be proactively monitored for pathogens and toxins.

Control of Movement

Modifications of pig flow can be used to control disease transmission. Sow-to-pig transmission of certain pathogens can be prevented or minimized by weaning pigs while they still have colostral immunity to their dam's pathogens to a pathogen-free environment with other pigs of similar health status (Clark et al. 1994; Dritz et al. 1996). Strategic medication and vaccination can be used as adjunct procedures for early weaning programs (Alexander et al. 1980; Mészáros et al. 1985; Harris et al. 1992).

Similarly, segregating pigs in groups by age minimizes transfer of pathogens from older to younger pigs. Age-segregated growing pigs can then be moved in cohorts in all-in/all-out fashion by filling and emptying rooms, buildings or sites over a short time frame, and cleaning and disinfecting pig areas between groups of pigs. These procedures are thought to minimize transmission of pathogens from older infected pigs or contaminated environments to susceptible pigs. In contrast, continuous flow systems that continuously commingle pigs of various ages without periodic cleaning of the environment offer increased possibilities of disease transmission from infected to susceptible pigs or through contact with a contaminated environment. The process of age segregation has recently been applied to the breeding herd and designated parity segregation. Parity segregation houses the gilts separately from the existing breeding herd. The gilts are exposed to the sow herd pathogens in the same way as gilts in acclimation. The gilts will farrow at this separate site. They will enter the existing breeding herd after weaning the first litter. This allows a longer "cool down" period for infectious organisms.

Pig Movement

In several countries, a national animal identification plan is used or is being developed to assist tracking pig movement intrastate, interstate, and internationally. In 1924, the Office International des Epizooties (OIE) was formed to encourage and coordinate research for the worldwide monitoring and control of animal diseases. The OIE provides information on the animal disease status of member countries and publishes international animal health standards for import and export of animals and animal products.

People Movement

Limiting visitors to essential personnel is one method of minimizing the risk of pathogen introduction by people. People who have been on farms with disease outbreaks should, at minimum, shower and change clothing before entering a population of susceptible swine. Generally, people movement should flow from healthy pigs to sick or carrier pigs. People flow from young to old pigs is also recommended.

Vaccination and Medication

Strategic vaccination and medication are an essential part of any herd health program. An effective vaccination program should reduce transmission of pathogens within a herd. An experiment to quantify pseudorabies virus transmission among vaccinated and unvaccinated pigs found that the number of secondary cases of pseudorabies per infected pig was 10 in unvaccinated pigs, but only 0.5 in vaccinated pigs (de Jong and Kimman 1994).

Surveillance Testing Programs

Periodic testing can be used to assess herd health status. Tests used will be determined by the pathogens of interest. Sample size will be dependent on expected disease prevalence in the population. Sampling can be simple and random or systematic (Thrusfield 1995). Cross-sectional and longitudinal sampling methods are often used in a complementary fashion. For more detailed information on surveillance programs, see Chapter 69 on disease surveillance in swine populations.

Record Keeping for Surveillance and Regulated Diseases

Morbidity, mortality, reproductive, and growth performance records can be used proactively to identify indicators of pathogen introduction.

Records also become important when regulated diseases are suspected. Information regarding the origin of all animals, animal products (including modified live vaccines, biologicals, and semen), feedstuffs (grain, supplements), equipment, vehicles (for livestock, feed, swine specialists), and people (sales and feed representatives, visitors, veterinarians, technicians, mail delivery personnel, service personnel) that have visited the farm prior to the outbreak is used in "traceback" procedures to identify the source of the pathogen and determine how the pathogen was introduced. Procedures can be implemented to minimize future risk of disease introduction once the source of the pathogen has been identified. Similar information regarding animal and equipment movements off the farm are used in "trace-forward" procedures to determine other premises that possibly received infected animals, animal products, or contaminated equipment.

Maintaining herd records and updated back-up copies of records routinely can assist in both traceforward and traceback procedures when needed. Attempting to acquire information during an outbreak situation is difficult due to the chaotic nature of a disease outbreak. Regular herd records allow the producer to rapidly and accurately produce movement records facilitating the tracking procedures. Moreover, individual animal identification (within sow herds) will enhance the efficiency of tracking procedures. A single individual on each premise should be responsible for maintaining accurate records although every employee should know how to access the records in case of an emergency.

The following are recommendations for records to be kept on a regular basis:

1. Inventory of animals in the herd: number of animals, animal identification, breed, age, species, origin. Animals that die or are culled from the herd should be identified.
2. Animal movement to and from the farm: date, animal identification, origin, destination, reason, driver, vehicle used, previous owners' name and phone number.
3. Visitor: names, phone numbers, reason for visit, time since last contact with livestock, facilities entered. Visitors include all nonemployees: veterinarians, feed salesman, livestock dealers, repairmen, neighbors, etc.
4. Vehicles: driver, dates, origins, destinations. All vehicles other than those recorded in the visitor log should be included, e.g., those used for package delivery, propane trucks, trash pick-up, electric company, etc.
5. Equipment, feed, semen movement: dates, origins, destinations, delivery person, salesman.
6. Manure application/movement: dates, origin, application site, volume, and application method.
7. Vaccination and treatment records: animal identification, date, reason for treatment/vaccination, medication used.
8. Employee records: name, address, phone number, whether the employee has contact with other livestock.
9. Pets and other animals located on the premises.
10. Cull animals sold: number, date, location.

Additional information will be requested in the event of an outbreak of a regulated disease (United States Department of Agriculture 1992). Immediately after a presumptive and/or confirmed diagnosis of a regulated disease, investigators require information regarding all movements of animals (livestock and pets), products (meat), manure, equipment, vehicles, people, and feed to the farm premises for the 21 days preceding the outbreak. Information designated above will be used.

CERTIFICATION PROGRAMS

Certification programs can be used to establish that a herd is free of a specific pathogen. Certification programs can be used on a local level as a transition step for large eradication projects. The Trichinae Certification Program is one example of a program recently initiated to control a pathogen (Pybrun 2003).

ERADICATION PROGRAMS

Eradication programs can be designed on the herd, local, regional, national, or international level. Eradica-

tion can sometimes be achieved through normal replacement of breeding stock. In other cases, programs such as test and removal with or without vaccination, partial depopulation or total depopulation are required.

Emergency vaccination as a tool for eradication of List A diseases has been reviewed (Laddomada 2003). Attempts have been made to eliminate porcine reproductive and respiratory disease virus from swine herds by using test and removal, and nursery depopulation with or without vaccination of the breeding herd (Dee and Joo 1994; Dee et al. 1998, 2001). Transmissible gastroenteritis virus has been eliminated from swine herds by depopulation and test and removal (Gunn 1996). Partial depopulation by removing all animals under 10 months of age from the farm, cleaning and disinfecting facilities, and medicating adult animals was successful in 81% of the attempts to eradicate *M. hyopneumoniae* (Heinonen et al. 1999).

Herd factors will determine the best strategy for eradication. Pseudorabies eradication was used in one decision-making model. Vaccination was preferred in large herds with low seroprevalence in sows and high farm density, partial depopulation was preferred with high seroprevalence in sows, and test and removal was preferred with low seroprevalence in sows. Finally, outdoor operations tended toward depopulation and repopulation (Siegel and Weigel 1999).

Depopulation and repopulation protocols are expensive to implement and require much planning. Briefly, the herd should first be assessed to determine current and desired performance, cost of the enzootic diseases, cost of medications and veterinary care, value of current genetics, labor requirements, antibiotic usage, feed costs, and psychological costs of the disease on personnel. Next, protocols for the timing of depopulation, downtime, cleanup procedures, and methods of repopulation should be investigated to determine whether the plan is feasible (McNaughton 1988). Available data is insufficient to be dogmatic about downtimes needed before repopulation. For example, a review of research on FMD virus survival led to estimates of downtimes of at least 3 months for hot climates (>20°C) and greater than 6 months for cold climates (Bartley et al. 2002).

Depopulation is mandatory for many exotic disease eradication programs. Euthanasia of infected animals and preemptive culling of surrounding susceptible livestock are thought to be the most effective means of controlling a FMD outbreak (Ferguson et al. 2001). In some cases, clinically healthy animals must be euthanized because animal and feed movement restrictions impair their well-being. Animal welfare should be considered when designing and implementing depopulation protocols with a euthanasia component (Whiting 2003). The American Association of Swine Veterinarians and the National Pork Board have published acceptable swine euthanasia options. Additionally, options for euthana-

sia of large numbers of swine have been published (Lambooy and van Voorst 1986).

69 Disease Surveillance in Swine Populations

Peter R. Davies and Katharina D. C. Stärk

Animal disease surveillance is in a phase of rapid evolution and innovation. The impetus for this change arises from several factors including greater recognition of the frequency and impact of emerging diseases, increasing volumes of international trade in animal products, requirements of trading countries and obligations specified under agreements of the World Trade Organization (WTO), ongoing consolidation of animal production worldwide into fewer and larger populations, and the threat of agriterrorism in the wake of September 11. Collectively these factors translate into greater demand among government agencies and other entities for more powerful tools for detecting changing patterns of disease in animal populations. In the contemporary global business environment, efficient disease surveillance provides the foundation for trust in international trade in animals and animal products (Salman et al. 2003). Ongoing advances in communications technology and information management, and technological advances in diagnostics (Risatti et al. 2003), are creating new opportunities for animal disease surveillance.

A recent text edited by Salman (2003) provides a comprehensive overview of the fundamentals of animal disease surveillance and survey systems, principally from the perspective of government agencies responsible for regulated disease control and eradication programs. However, disease surveillance has a growing role in other arenas, particularly at an industry level and in large corporate production systems that make up much of the swine industry of many developed countries (Table 69.1).

Wildlife populations can be important reservoirs for animal diseases (Elbers et al. 2000; Morner et al. 2002), and increased wildlife surveillance has been prompted by increased recognition of the role of wildlife in emerging diseases. At the level of individual commercial herds, disease surveillance has historically involved recording of gross lesions in slaughtered pigs. Readers seeking specific information on slaughter surveillance in swine are referred to the previous edition of *Diseases*

of Swine (Pointon et al. 1999). In contrast, due to cost considerations, routine surveillance using laboratory testing has been traditionally less frequent at the herd level. However, demographic changes in the industry (increased herd sizes, consolidation, multiple-site production), improved diagnostic tests, and persistent problems with porcine reproductive and respiratory syndrome (PRRS) in many countries including the U.S., have altered both the need for and feasibility of herd-level surveillance systems (Torrison 1998). In this chapter we attempt to provide an update on current developments in animal health surveillance, and identify opportunities for enhancing surveillance efforts in the context of modern swine production in developed countries.

THE SCOPE OF SURVEILLANCE IN SWINE PRODUCTION

Disease surveillance is a management information tool. In essence, surveillance encompasses activities undertaken to measure disease events in defined populations in order to obtain information of value to decision makers (e.g., producers, veterinarians, industry, government agencies). Surveillance information is applicable to support decisions about health status certification; compliance with customer requirements; compliance with regulatory requirements; and health management decisions, including treatment and preventive measures and altering pig flow. Fundamental objectives of surveillance are to establish the qualitative status of animal populations (groups, sites, pods, companies, regions, or countries) with respect to the presence or absence of a specific disease or agent, or to quantify frequency of disease in affected populations and its distribution in space and time (determining disease trends). Salman et al. (2003) addressed the distinction between monitoring and surveillance that pervades the veterinary literature, and adopted the acronym "MOSS" (designating "monitoring or surveillance system") as an umbrella term to

Table 69.1. Overview of overall objectives and purposes of surveillance activities in different arenas

Arena	Objective	Purpose
National (State)	Demonstrate freedom from disease	Maintain trade access
	Outbreak detection	Facilitate response capability to exotic and novel diseases
	Disease control and eradication	Optimize operational efficiency of regulatory programs
	Monitor notifiable diseases	Gather epidemiologic intelligence to support regulatory decisions
	Monitor zoonotic and foodborne pathogens	Protect public health; maintain trade access
	Monitor emerging diseases	Early detection of novel pathogens
Industry/Corporate	Assure freedom from disease	Breeding stock suppliers; boar studs—protect production pyramids
	Outbreak detection	Protect production pyramids
	Define herd disease status	Inform pig flow decisions
	Monitor endemic production diseases	Epidemiologic intelligence to support health management decisions
	Monitor zoonotic and foodborne pathogens	Public health and trade access; quality assurance and product differentiation
	Indexes of animal welfare	Address consumer concerns; quality assurance
Commercial production	Monitor endemic production diseases	Support health management decisions
	Outbreak detection	Early response to minimize disease impact
Wildlife	Establish disease status	Support regulatory decisions and control programs

discuss the relevant concepts. Similarly, for simplicity we will use the term *surveillance* in a generic sense to include the spectrum of activities that encompass either surveillance or monitoring.

The cornerstone of any epidemiologic endeavor is case definition. Historically the primary focus of animal disease surveillance has been agent-defined infectious diseases, such as diseases listed by the Office International des Épizooties (OIE), or zoonotic or other diseases targeted in national control programs (tuberculosis, brucellosis, hog cholera, pseudorabies). As such, case definition is typically founded on use of agent-specific diagnostic tests (see Chapter 10 on interpretation of laboratory results). Growing concerns about the emergence of apparently novel diseases and of bioterrorism targeting human or animal populations, have led to development of systems for "syndromic" surveillance in both the human and animal arenas (de Groot et al. 2003; Pavlin 2003). Case definition in syndromic surveillance is based on clinical symptoms rather than agent-specific diagnostic testing. For both agent-defined and syndromic surveillance, the precision and accuracy of data are influenced by case definition and other factors and can be enhanced by implementation of standard approaches for quality control (Stärk et al. 2002; Salman et al. 2003).

Although the term *syndromic surveillance* is now very much in mode, both the concept and practice are established pillars of population medicine in food animals. Most of the standard indexes that veterinarians and producers use to assess herd population health and performance are syndromic. Obvious examples are mortality incidence in different age groups of stock, prevalence of stillbirths and mummification in neonatal pigs, and lameness or abortion rates. Typically, fail-ure to meet predetermined targets triggers further investigation or corrective actions, and these concepts have been widely addressed in the production medicine literature (Deen at al. 2001). For this reason, we will focus our discussion on surveillance opportunities in relation to known and emerging diseases of swine. Because government and regulatory perspectives on surveillance issues have been well covered elsewhere (Salman 2003), our emphasis will be in the arena of modern commercial production, where veterinarians are confronted with rapid change and increasingly complex decisions about disease surveillance in large systems.

COMPONENTS OF A SURVEILLANCE SYSTEM

Surveillance comprises collection, analysis, and interpretation of disease data, coupled with dissemination of the information to decision-makers responsible for implementing appropriate actions (Buehler 1998). At the herd level in traditional farrow-to-finish production, surveillance of pig health has included monitoring of clinical signs, production indexes, and lesions in slaughtered pigs as predominantly syndromic indicators, triggering more specific diagnostic efforts when aberrations were detected. Structural (e.g., multiple-site production in large systems) and operational (e.g., artificial insemination based around boar studs) changes in the industry have ushered in new challenges in surveillance as a tool for managing health risks in swine populations. Veterinarians serving these systems are now confronted with more complex problems of designing sampling and testing programs to obtain the information they require at acceptable cost.

There are many potential sources of surveillance

data, ranging from surveys of producers about animal health to results of diagnostic tests performed in national or international reference laboratories (Doherr and Audige 2001). Inevitably there are trade-offs between the reliability and scope of data, and at a regulatory level diagnostic laboratories have provided the bulk of surveillance data. However, different sources of data provide different (and probably complementary) perspectives on the frequency of health events in herds (McIntyre et al. 2002). Because the utility of disease surveillance is in part determined by timeliness, ideally the processes of data collection and analysis should approach real time, and the value of diagnostic data decays over time (Schlosser and Ebel 2001).

DESIGN ASPECTS OF POPULATION SURVEILLANCE

The principles underlying the use and interpretation of diagnostic testing are reviewed elsewhere in this text (see Chapter 10). It is imperative for veterinarians who confront complex surveillance decisions to have a strong theoretical understanding of the relationships between diagnostic test performance, sampling theory, and disease prevalence that underpin the interpretation of aggregate (herd-level) testing. In evaluating testing strategies for classical swine fever in Denmark, Stärk et al. (2000) list the following factors for consideration in designing testing protocols: diseases to be selected and their epidemiology, unit of analysis (e.g., animal, herd, or region), target population (age group or farm type), test characteristics, and sample size. In recent years, there have been important theoretical advances in diagnostic test interpretation in veterinary medicine, particularly at the aggregate level (Cameron and Baldock 1998; Christensen and Gardner 2000; Greiner and Gardner 2000; Cannon 2001; Johnson et al. 2004). These have led to the development of some practical tools to facilitate quantitative approaches to the design and interpretation of population testing protocols. For example, Survey Toolbox is a suite of software programs designed to support planning and analysis of animal health surveys.[1] One component of this suite is an epidemiological probability calculator (FreeCalc) to support testing to evaluate freedom from disease. FreeCalc has two modules that enable calculation of sample sizes and analysis of test results for freedom from disease. It accounts for imperfections in diagnostic tests and population size and requires inputs for test sensitivity and specificity, population size, minimum expected prevalence of disease (if present). FreeCalc also allows the user to define acceptable error levels. More sophisticated tools are becoming available that extend this approach to incorporate uncertainty in test performance characteristics and expected prevalence (Audige et al. 2001; Johnson et al. 2004). The latter publication explains freely available software (BayesFreeCalc)[2] for

evaluating the probability of freedom from disease allowing for uncertainty in input parameters. A further extension that is required is the incorporation of testing costs as well as the respective costs of misclassification errors (false positive, false negative) that need to be considered when designing surveillance strategies (Greiner 1996; Hilden and Glasziou 1996; Smith and Slenning 2000).

RISK-BASED SURVEILLANCE

The term *risk-based surveillance* is becoming more prevalent in government documents in various countries, and has been applied in relation to residue monitoring, disease surveillance and foodborne hazards. This term conveys the economic axiom that limited surveillance resources need to be applied where risk is greatest and so that the greatest economic return will be realized (Stärk et al., submitted). At any level (farm, company, region, nation), establishing a disease surveillance system is an investment decision for allocating limited financial resources. Logically this requires designing sampling and testing protocols weighted to yield the most valuable mix of disease information. The most topical and controversial example of risk-based approaches to disease is the surveillance options for bovine spongiform encephalopathy (BSE) (Doherr et al. 2001). The strategy of focusing on high-risk population subgroups (older cattle, emergency slaughter, and fallen stock in the case of BSE) to improve the sensitivity of surveillance programs is intuitively obvious. Similarly, swine veterinarians increasingly are sampling nursery pigs for evidence of PRRS virus infection acquired in breeding herds and will usually focus on poor-doing pigs that are assumed more likely to be infected. In the absence of unlimited resources for diagnostic testing, a level of residual risk of disease must be tolerated, and at some point further investment in surveillance becomes unwise because resources would be more effectively allocated to other areas (e.g., improving biosecurity or response capability). The effective implementation of risk-based (or targeted) surveillance strategies is reliant on valid epidemiologic intelligence that accurately reflects the risk profile of the population involved.

In the context of food safety, risk-based approaches are also being developed. The Codex Alimentarius Commission is proposing risk-based systems for meat inspection.[3] In such a system, inspection of carcasses at slaughter may be conducted in alternative ways depending on the health and/or hygiene status of the farm of origin. Surveillance data from farms will be needed at slaughter in order to decide whether a simplified inspection is acceptable or whether intensified inspection with or without laboratory testing is required. This concept has already been included in the new meat hygiene legislation of the European Union.

DEMONSTRATING FREEDOM FROM DISEASE—THE BOAR STUD DILEMMA

Demonstrating freedom of a population from disease is problematic for a number of reasons, recently expounded by Cameron et al. (2003):

- Freedom from disease implies complete absence of disease in the population. This means that a large population may not contain a single infected animal.
- Detection of disease at very low prevalences (e.g., the detection of a single infected animal) is not possible using sampling techniques. To guarantee that a population is free from disease, all animals in the population must be examined.
- The test that is used to detect disease in individual animals must have perfect sensitivity (i.e., always correctly identify diseased animals). Hardly any tests currently available are able to achieve this.
- Because disease may enter a population at any time, it is conceivable that the population has become infected by the time the last animal is tested.

As concluded by those authors, freedom from disease can be guaranteed only if all animals in a population are evaluated simultaneously with a perfectly sensitive test; yet usually herds (and countries) are perpetually exposed to the possibility of disease introduction. The report by Cameron et al. (2003) provides a thorough discussion of issues involved in assuring disease freedom in the context of assessing the status of Denmark with respect to classical swine fever (hog cholera).

Thurmond (2003) provides an insightful discussion of problems derived from temporal delays between the introduction of a disease and its ability to be detected using conventional sampling and testing protocols. This is most relevant to the challenge of surveillance of boar studs to prevent shipment of semen contaminated with PRRS virus. In hog-dense areas in the U.S., introductions of PRRS virus continue to occur despite extensive biosecurity efforts. Given the likely financial consequences of shipping infective semen to multiple breeding farms, considerable investment is warranted to prevent it, both in surveillance and in improving biosecurity of boar studs. From a surveillance perspective, key decisions include the samples to be collected (blood vs. semen), the tests to be applied (e.g., ELISA or PCR), and the frequency and intensity (sample size or census) of sampling. In this scenario, where rapid detection of disease at very low prevalence is desired, serological surveillance is of limited value due to the delay in antibody production following infection. Although PCR testing of semen for PRRS virus is routinely performed in many studs (because sample collection is convenient), the sensitivity of PCR testing of semen for detecting infected animals during the early stages of infection appears to be much lower (approximately tenfold) than PCR test-

ing of serum (Reicks et al. 2004). Ongoing studies point to the future availability of practical approaches for routine blood sampling of boars during semen collection (Darwin Reicks, personal communication).

VETERINARY CLINICAL SURVEILLANCE

While historically focused on diseases under regulatory control, improved surveillance systems can also contribute to improved control of endemic diseases (McIntyre et al. 2002). Concerns about emerging human diseases have led to the development of surveillance systems such as the Rapid Syndrome Validation Project (RSVP) for detecting changing patterns of disease at a broad population level or similar programs involving health care providers (Lombardo et al. 2003). Although veterinarians are the frontline of response to disease problems in food animals, the collective efforts of veterinarians are a virtually untapped resource for epidemiologic intelligence (McIntyre et al. 2003; de Groot et al. 2003).

Consolidation of food animal production (and its veterinary services) together with advances in information technology have increased the potential for harnessing the efforts of veterinary clinicians for purposes of disease surveillance. Pioneering efforts to capture "coal face" food animal disease data from practicing veterinarians have been initiated with dairy cattle veterinarians in New Zealand (McIntyre et al. 2003) and beef veterinarians in Kansas (de Groot et al. 2003). The latter project (RSVP-Animal) is based conceptually on the human RSVP project. Both these veterinary initiatives use palm-held computers for field data capture, integrate data into centralized databases, analyze disease trends, and enable practicing veterinarians to access summary data by location. The Multi-Hazard Threat Database (MHTD) project of the North Carolina Department of Agriculture and Consumer Services represents a significant step forward in integrating veterinary clinical and government regulatory activities. The system, designed to minimize the impact from any disaster or disease on agriculture, integrates information systems of numerous federal, state, and local agencies to offer extensive, real-time information in the event of an emergency, natural disaster, or bioterrorism attack. While primarily designed to support emergency responses, it also provides decision support for veterinarians by enabling web access to real-time maps of endemic disease status (currently PRRS and TGE).

We believe that these initiatives using modern communications technology to capture veterinary activities offer great potential for enhanced surveillance and regional approaches to disease control in the U.S. swine industry. However, there remain numerous issues to address with respect of ownership and confidentiality of data, the sensitivity, specificity of clinical diagnoses, and value (vs. cost) of the information obtained.

SYNDROMIC SURVEILLANCE

Syndromic surveillance is arguably the most novel dimension of contemporary disease surveillance. The key distinction of syndromic surveillance is that, unlike conventional disease reporting, the data collected are not diagnoses of defined diseases, but data on clinical symptoms or other events (e.g., emergency room visits). The Center for Disease Control estimates that syndromic surveillance systems have been implemented by more than 100 public health entities in the U.S., with the goal of achieving earlier detection and public health responses to epidemics (Buehler et al. 2004). The principal motive for syndromic surveillance has been elevated concern about emerging diseases and bioterrorism, and the concept has been enabled through rapid advances in the field of biomedical informatics. The RSVP system exploits Internet connectivity for low-cost capture of data from a network of sentinel physicians who report signs and symptoms, and who are able to view map displays depicting regional disease patterns. Syndromic surveillance systems for public health use statistical tools for cluster detection, such as time series analysis and statistical process control, and may incorporate integrated alarms when threshold levels are exceeded (Reis and Mandl 2003). In common with other diagnostic systems, syndromic systems are evaluated in terms of sensitivity, specificity, and timeliness, and the cost effectiveness of syndromic surveillance as a tool for improving outbreak detection remains to be determined. In order to evaluate the operational performance of syndromic surveillance systems, Duchin (2003) pointed out that it will be necessary to conduct ongoing investigations of clusters identified through syndromic systems. Identifying appropriate epidemiological responses to surveillance signals will depend on effective standardization of methods for the collection, analysis, and interpretation of data (Duchin 2003).

We are aware of two initiatives to apply syndromic surveillance in veterinary medicine. The RSVP-Animal project in Kansas has been developed to enhance detection of emerging diseases in feedlot cattle based on veterinary clinical observations (de Groot et al. 2003). A large companion animal electronic database linking 360 hospitals in 47 U.S. states is being used to detect changes in patterns of clinical signs in dogs and cats (Moore et al. 2004). Syndromic definitions have been defined using CDC descriptions of likely bioterrorism agents, based on the concept that changes in animal health may have sentinel value for the human population.

SURVEILLANCE RELATED TO PUBLIC ISSUES—FOOD SAFETY, ANTIMICROBIAL RESISTANCE, AND ANIMAL WELFARE

Surveillance activities in swine populations already extend beyond the domain of animal health. Over the last 10 years, general advocacy of the concept of preharvest food safety has stimulated efforts to develop suitable surveillance systems for foodborne hazards in animal populations. Although the objective has been to determine the status of animals on farms, for logistic reasons diagnostic testing has been generally confined to samples collected at harvest. The effectiveness of preharvest strategies for reducing foodborne disease risk depends on the efficacy of preharvest interventions for reducing the prevalence of infection in conjunction with post-farm procedures that ensure a low probability of recontamination of animals or food products (Davies et al. 2004). For several decades the Swedish government has maintained *Salmonella* control programs in its swine and poultry industries based on bacteriologic surveillance and regulatory controls (Boqvist et al. 2003). More recently, industrywide serological surveillance of herds for *Salmonella enterica* was implemented in Denmark, and it was subsequently implemented by other European countries (Mousing et al. 1997; Sorensen et al. 2004). Although the use of serological testing has greatly reduced the cost of testing compared with bacteriology, testing costs remain substantial, and considerable research continues to be directed at establishing the validity and reducing the costs of serological testing for *Salmonella* (Alban et al. 2002; Ekeroth et al. 2003; Sorensen et al. 2004). In the U.S., bacteriologic culture of *Salmonella* on swine carcasses is mandated under the Hazard Analysis Critical Control Point/Pathogen Reduction Act of 1995. However, this testing is conducted as part of the evaluation of hygienic measures in slaughter plants rather than for evaluating *Salmonella* in farm animal populations. Serological methods have also been developed for monitoring other foodborne pathogens occurring in swine, including *Trichinella spiralis* (Gamble 1998), *Toxoplasma gondii* (Dubey et al. 1995), and *Yersinia enterocolitica* (Thibodeau et al. 2001). However, routine surveillance for these agents as part of a coordinated control programs is still limited. National surveys conducted by the USDA-National Animal Health Monitoring System in 1990 and 1995 demonstrated a very low and declining prevalence (0.16% and 0.013%, respectively) of antibodies to *T. spiralis* in commercial pigs (Gamble and Bush 1999). Similarly, surveys of domestic and wild pigs in Canada indicate that the parasite is essentially absent from those populations (Gajadhar et al. 1997). Clearly, there is questionable rationale to implementing routine surveillance when infection occurs at low prevalence, and intermittent surveys are to be preferred. In Europe, the Zoonosis Directive (2003/99/EC) is expanding the demands for systematic surveillance of zoonoses and zoonotic agents along the food production chain in member countries.[4] In addition to *Salmonella* spp., the directive now includes—apart from others—also *Campylobacter* spp., verotoxigenic *E. coli,* and antimicrobial resistance surveillance. Results of these surveillance efforts are published as annual reports.

The persistent controversy over the significance of the contribution of antimicrobial use in food animals to the problem of antimicrobial resistance in human pathogens has prompted calls for improved monitoring of patterns of antimicrobial use and of resistance profiles of animal pathogens and commensal organisms (Anderson et al. 2003). Systematic surveillance of antimicrobial use, and of antimicrobial resistance, has yet to be widely implemented in many countries. Again, Danish national surveillance programs set the standard, documenting patterns of antimicrobial use under veterinary prescription (Stege et al. 2003) and trends in antimicrobial resistance in selected animal and human pathogens and commensal organisms (Bager 2000). The Danish swine industry has also implemented a program of surveillance of skin lesions in slaughtered sows assumed to reflect poor welfare conditions on farms, which may provide a basis for classifying farms by welfare status (Cleveland-Nielsen et al. 2004). International recommendations on the surveillance of antimicrobial resistance and antimicrobial usage are available (Anonymous 2003).

FUTURE POSSIBILITIES

Doherr and Audige (2001) state that "the health and safety of the animal and human generations depend on our continuous ability to detect, monitor and control newly emerging or reemerging livestock diseases and zoonoses rapidly." To do so will require scientific approaches that incorporate technological and conceptual advances as well as effective cooperation between stakeholders (government, researchers, industry, clinicians). Over the last 15 years, apparently novel diseases have afflicted the world's swine populations with surprising frequency. However, with few exceptions, our systems for recognizing and responding to these events have not advanced greatly. On a regional scale, disease surveillance efforts in the swine industry are not yet capturing the available technological opportunities. Integration of near real-time clinical disease surveillance with geographical information systems and advanced tools for temporospatial analysis of disease is becoming increasingly feasible, and this has the potential to deliver epidemiologic intelligence that far exceeds existing capability. There is a great opportunity to build upon initiatives such as the MHTD program in North Carolina and the RSVP, a syndromic surveillance system in Kansas, to increase the level of sophistication with which the swine veterinary profession addresses both endemic and emerging diseases.

70 Anesthesia and Surgical Procedures in Swine

Guy St. Jean and David E. Anderson

ROLE OF THE SURGEON

Veterinarian's roles in the swine industry have changed markedly over the past 20 years. Surgical procedures increasingly conflict with economic goals. The veterinarian must critically evaluate economic benefit versus cost and prognosis of surgery. In most scenarios, services offered by the veterinarian are directed to the need of the enterprise. Surgery on an individual pig is not always cost efficient. However, pigs selected for genetic improvement, show pigs, and pet pigs have individual value, and surgery may be performed with little regard to costs. Some conditions like hernia, prolapse, dystocia, and atresia that can occur in large numbers of animals can be very costly and need to be investigated so that a solution and treatment can be applied. In a commercial swine operation, the veterinarian is often a teacher, showing the manager and experienced personnel how to perform some minor surgical procedures during baby pig processing (castration, ear notching, canine teeth clipping, tail amputation) in a cost-effective fashion. It is the veterinarian's role to make sure that these procedures are done properly.

Among purebred and pet pigs, or pigs used as animal models in biomedical research (because of their anatomic and physiologic similarities to human beings), the individual animal often is of high perceived value, and surgery often is requested. A veterinarian who is able to offer excellent surgical service to swine producers often will have greater credibility as a herd consultant. The purpose of this chapter is to describe clinical swine anesthesia and review baby pig processing, hernia repair, and some common surgical procedures of the digestive, urogenital, and musculoskeletal systems in swine.

ANESTHESIA

Minor surgical procedures (ear notching, teeth clipping, tail amputation, castration) in young swine often are performed without anesthetizing the animal. Performed skillfully, these surgical procedures are tolerated well by young pigs without an anesthetic. Sometimes economics has an influence in the use of an anesthetic. However, public scrutiny of management practices increasingly demands attention to pain and prevention of unnecessary distress. Management of swine anesthesia presents some difficulties. Swine resist mechanical restraint more and are usually more difficult to hold than other species. Strong assistance often is needed. When possible, adult swine should be held off feed for 24 hours before general anesthesia, whereas piglets, which are prone to hypoglycemia, should be held from suckling for only 1–2 hours before anesthetic induction.

Malignant hyperthermia or porcine stress syndrome is a heritable condition in swine that can be triggered in a susceptible pig by any stress and many injectable (acepromazine, ketamine, succinyl choline) and inhalant anesthetics. Susceptible pigs are extremely muscular and usually have reduced subcutaneous fat. Halothane traditionally has been incriminated, but delayed onset of malignant hyperthermia can occur with exposure to isoflurane (Wedel et al. 1993). The clinical signs of malignant hyperthermia can be any of the following: a severe increase in body temperature, muscle rigidity, tachycardia, tachypnea, hypoxemia, cardiac arrhythmias, unstable blood pressure, and myoglobinuria. Death of an affected animal appears to be the result of peripheral circulatory changes that are produced by severe acidosis, vasoconstriction, hyperkalemia, decreased cardiac output, and hypotension. This susceptibility to malignant hyperthermia is due to an autosomal recessive defect in the gene that codes for the ryanodine receptor calcium channel in skeletal muscle (Rosenberg and Fletcher 1994). In response to a trigger, intracellular calcium rises abruptly, which causes muscle contracture and release of heat. Treatment of malignant hyperthermia is largely symptomatic. Early recognition is the key to successful treatment. Whenever malignant hyperthermia is suspected, volatile anesthetics should be dis-

continued. Aggressive cooling should be instituted using iced packs and alcohol baths. Dantrolene sodium is effective in the treatment of a malignant hyperthermia or as a prophylaxis when given before the anticipated trigger. Suggested doses for swine are 1 to 3 mg/kg IV for treatment and 5 mg/kg orally given prophylactically. (For more information on porcine stress syndrome, please refer to Chapter 58).

Anticholinergics (atropine and glycopyrollate) are recommended before sedation and anesthetic techniques in pigs. Atropine sulfate (0.04 mg/kg IM) or glycopyrollate (0.02 mg/kg IM) will decrease the risk of bradycardia, excessive salivation, bronchoconstriction, and excessive airway secretion. In healthy swine receiving light surgical anesthesia, administration of supportive fluids is not considered necessary, unless the animal was off feed and water for more than 24 hours. However, long general anesthesia is best managed with intravenous fluid support. In swine that are hypovolemic or showing other signs of shock, fluid therapy is essential preferably before or during anesthesia. Fluid therapy is best administered in the ear vein. In the authors' experience, fluid therapy using balanced electrolyte solution before and during anesthesia is essential during cesarean section with dead piglets in utero.

Anesthetic considerations for swine cesarean are important. One needs to remember that sow-fetal drug distribution is quite complete. Therefore, it must be assumed that any drug in the maternal circulation reaches the fetus rapidly in relatively high concentration. Because the fetal blood-brain barrier is extremely permeable, these drugs exert a profound anesthetic effect on the fetus. Also, anesthesia tends to persist after delivery because of the neonate's poorly developed liver enzymes and renal function. Anesthetic agents should be chosen that will minimize fetal depression. General anesthesia will induce greater neonatal depression than regional anesthesia.

Injectable Anesthetics

Injectable agents are most appropriate for field use. With injectable agents, a minimum of equipment is needed, requiring only a small investment. The drugs can be transported easily to the animal, compared to inhalation anesthetics, which are more expensive and can be difficult to transport to a field situation. Pigs have few superficial veins and arteries suitable for catheter placement and intravenous drug administration (Sakaguchi et al. 1996). Also, variation in accessibility of these vessels exists among swine breeds. The auricular (ear) vein is the safest and most accessible vein. It usually is located along the caudal margin of the ear. To inject or place a catheter in the ear vein, the pig can be restrained. The vein is held at the base of the ear by the fingers, forceps, or a rubber band to distend it. Rubbing the ear with alcohol and vigorous massage seem to create better visualization for needle insertion. Inserting a small catheter

70.1. *Catheterization of medial saphenous vein in a pig.*

(20-gauge) will allow the administration of fluid or injection of additional anesthetic solution intravenously. The medial saphenous vein can be catheterized easily in the anesthetized or well restrained pig (Figure 70.1). Anesthesia can be induced using IM drug protocols or gas anesthetics via face mask followed by catheterization for IV fluids therapy or drug administration. Intramedullary cannulation should be considered when vascular access is vital but an IV catheter has not been established. An 18 gauge cannula can easily be inserted into the greater tubercle of the humerus or via the trochanteric fossa of the femur for intramedullary infusions. Fluid and drug administration is easily done in immature pigs. Older pigs may have sufficient fat and fibrosis of the medullary canal so as to limit administration rate.

Intramuscular injections should be given with a 2 inch needle in the cervical muscles to assure that the drug goes into the muscle and not in the fat. To obtain the maximal effect with the drug the pig should be in a quiet environment if possible. Combinations of anesthetic agents administered in appropriate doses are often superior to any one agent (Table 70.1).

Few drugs currently are approved for use in swine. Practically all anesthetics used are unapproved drugs for swine, and their use is considered extra label (Papich 1996). However, veterinarians often recognize the necessity of relieving pain, anesthetizing a swine for a procedure, or administering a drug as an anesthetic adjunct. Often, no alternative exists to using the drug in an extra label manner. For public protection, steps must be taken to ensure that no harmful residues occur from treated animals by assigning an appropriate withdrawal time before the marketing of meat.

The reader is encouraged to consult the Food Animal Residue Avoidance Data Bank for appropriate withdrawal times in swine (www.farad.org; phone 1-888-873-2723; e-mail farad@ncsu.edu).

Table 70.1.   Injectable anesthetic agents for swine

Drug	Dose	Route	Onset (min)	Duration (min)
Pentobarbital	10–30 mg/kg	IV	1–10	15–45
	45 mg/kg	each testicle	10	10
Thiopental	10–20 mg/kg	IV	Immediate	2–10
Acepromazine	0.1–0.5 mg/kg	IM	20–30	30–60
Acepromazine	0.4 mg/kg	IM	5	15–30
and Ketamine	15 mg/kg	IM		
Acepromazine	0.03 mg/kg	IM	2–4	40–50
and Ketamine	2.2 mg/kg			
and Telazol	4.4 mg/kg			
Diazepam	1–2 mg/kg	IM	10	20–40
and Ketamine	10–15 mg/kg	IM		
Midazolam	0.1–0.5 mg/kg	IM	5–10	20–40
and Ketamine	10–15 mg/kg	IM		
Azaperone	2–8 mg/kg	IM	5–15	60–120
Xylazine	0.5–3 mg/kg	IM	5	10
Xylazine	2 mg/kg	IM	7–10	20–40
and Ketamine	20 mg/kg			
Xylazine	2.2 mg/kg/hour	IV	Immediate	As needed
and Ketamine	(see text)			
and Guaifenesin				
Xylazine	4.4 mg/kg	IM	1–2	60
and Ketamine	2.2 mg/kg			
and Telazol	4.4 mg/kg			
Ketamine	20 mg/kg	IM	Immediate	5–30
and Thiopental	6–11 mg/kg	IV		
Medetomidine	80 µg/kg	IM	1–5	60–120
and Butorphanol	200 µg/kg			
and Ketamine	2 mg/kg			
Metedomidine	80 µg/kg	IM	1–5	75–120
and Butorphenol	200 µg/kg			
and Ketamine	10 mg/kg			
Xylazine	2 mg/kg	IM	1–5	60 – 120
and Butorphenol	200 µg/kg			
and Ketamine	10 mg/kg			
Propofol	11 mg/kg/hour	IV	Immediate	Continuous infusion
and Fentanyl	2.5 mg/kg q30 min	IV		

Barbiturates. Barbiturates as a group are poor analgesics. Pentobarbital and thiopental are the most commonly used barbiturates. Pentobarbital is a potent central nervous system depressant and can be administered intravenously, intraperitoneally, and intratesticularly. We do not recommend intraperitoneal injection because of the risk of peritonitis. Because young pigs do not have the hepatic enzymatic capacity of adults, pentobarbital should not be used as a general anesthetic in young piglets.

In adults, an intravenous dose of 10–30 mg per kg will provide 20–30 minutes of relatively safe anesthesia, provided a patent airway is established and maintained until swallowing and other airway protective reflexes have returned. Preanesthetic medication (e.g., diazepam, acepromazine, xylazine) will decrease the amount of pentobarbital required for surgical anesthesia (Table 70.1). Recovery from pentobarbital administration often is prolonged and requires close patient surveillance.

For intratesticular injections, 45 mg per kg of body weight of a 30% solution is injected below the tail of the epididymis in the upper one-third of each testicle. The maximum volume is 20 ml per testicle, the onset of anesthesia is in 10 minutes, and recovery takes 20–40 minutes. Castration must be performed as quickly as possible to prevent continued absorption of the drug and a potentially lethal overdose (Henry 1968). The testes must be disposed of in a safe place. There are reports of fatal poisoning of dogs as a result of eating testes containing the residual drug. Blood on the floor is also dangerous (Henry 1968).

The shorter-acting barbiturate thiopental (10–20 mg/kg) is used sometimes for induction before inhalation anesthesia or for very short procedures. A 2.5–5% solution should be used and one-half of the calculated dose quickly injected. When the pig lies down, incremental amounts are injected until the desired plane of anesthesia is achieved. Apnea often is observed, and means of assisting ventilation should be readily available.

Acepromazine. Acepromazine decreases spontaneous motor activity. Used alone, it usually provides only

slight inconsistent sedation in swine. Acepromazine also will predispose to hypotension and hypothermia and should not be used in debilitated pigs. The maximum dose recommended is a total of 10 mg. Acepromazine has been reported to decrease the incidence of malignant hyperthermia (Moon and Smith 1996). It is useful when combined with ketamine or tiletamine-zolazepam (Table 70.1).

Benzodiozepines (Diazepam and Midazolam). Diazepam (1–2 mg/kg IM) can be used in combination with ketamine or xylazine (Table 70.1). Midazolam can be absorbed more rapidly and completely than diazepam because it is water soluble. They both ensure a smooth recovery and have a longer effect then xylazine. The expense associated with these drugs may make them impractical in some swine commercial operations.

Azaperone. Azaperone is a neuroleptic agent and can be given to tranquilize or immobilize swine (Table 70.1). The degree of sedation is dose dependent and should not exceed 1 mg/kg in large boars, because priapism has been reported (Moon and Smith 1996). Azaperone must be given intramuscularly, because intravenous injection often results in excitation. Excessive salivation, hypothermia, sensitivity to noise, and hypotension has been seen in pigs receiving azaperone (Greene 1979). Azaperone is not an analgesic and often is used in combination with other drugs for surgical procedure. Deep tranquilization from azaperone should be obtained before ketamine is given. If azaperone is used alone for surgical procedures, local or regional anesthesia should be administered.

Alpha-2 Receptor Agonists (Xylazine, Medetomidine). Swine are fairly resistant to xylazine compared to other meat-producing animals (Table 70.1). Sedation will result, but animals are aroused easily. Xylazine usually is used in combination with other drugs to produce good muscle relaxation and a smooth recovery. Vomiting has been seen following the use of xylazine in pigs with digestive disturbances.

Medetomidine is a more potent alpha-2 agonist than is xylazine (Sakaguchi et al. 1992). Medetomidine in combination with atropine induces deeper sedation than does xylazine and its effects are enhanced by butorphanol. The anesthetic state is characterized by profound somatic analgesia, but visceral analgesia is poor. Medetomidine, butorphanol, and ketamine induce excellent surgical anesthesia in pigs (Table 70.1). This anesthetic regimen can be reversed by atipamezole (240 µg/kg), a selective and potent alpha-2 antagonist.

Ketamine. Ketamine induces rapid onset of unconsciousness (Thurmon 1986). The anesthetic state is characterized by somatic analgesia, but visceral analgesia is poor. Ketamine has been used as a major component of

many regimens to induce chemical restraint or anesthesia in pigs. Ketamine can be given IM, IV, or intratesticularly. Intratesticularly, a combination of ketamine (6 mg/kg) and xylazine (2 mg/kg) has been used successfully for castration (Thurmon 1986). When ketamine is used alone, it exerts some undesirable effects, such as poor muscle relaxation and analgesia-emergence delirium, tachycardia, and hypertension. Ketamine commonly is combined with a muscle relaxant or sedative such as acepromazine, diazepam, xylazine, or droperidol (Table 70.1).

Tiletamine—Zolazepam (Telazol). Telazol provides some muscle relaxation and sedation and also immobilizes swine (Moon and Smith 1996). Telazol requires a smaller volume of injectable compared to ketamine. Telazol frequently is combined with xylazine or acepromazine to provide better muscle relaxation and an easier recovery (Table 70.1).

Propofol. Propofol has recently been used for IV anesthesia in pigs (Martin-Cancho et al. 2004). One dosage regimen reported was 11 mg/kg body weight per hour for abdominal surgery. This was done in combination with fentanyl (2.5 mg/kg IV every 30 min). Compared with pigs anesthetized with isoflurane, propofol-anesthetized pigs required significantly longer to recover consciousness.

Guaifenesin. Guaifenesin is a centrally acting muscle relaxant. Because it produces little analgesia, it should not be used alone. Intravenous infusion of guaifenesin combined with thiobarbiturates and with ketamine and xylazine has been used for induction and maintenance of anesthesia (Thurmon 1986). The authors recommend adding 500 mg of ketamine and 500 mg of xylazine to each 500 ml of 5% guaifenesin in 5% dextrose in water. The mixture is given rapidly in a catheter in the ear vein at a dose of 0.5–1 ml per kg for induction. Anesthesia is maintained by continuous infusion at a rate of 2.2 mg per kg per hour. At the end of the surgery, recovery time may be hastened by administration of yohimbine (0.125 mg/kg) or tolazoline (2.5–5 mg/kg) to reverse the effect xylazine (Thurmon 1986).

Combination Injectable Anesthesia. Combinations of injectable drugs have been used to increase quality, duration, and analgesia of anesthesia when they can be administered safely. A recent study compared three regimes for maintaining anesthesia in pigs induced using azaperone (1 mg/kg, IM) and ketamine (2.5 mg/kg IM). These pigs were divided into three groups: (I) etomidate (200 µg/kg IV) and midazolam (100 µg/kg IV); (II) ketamine (2 mg/kg IV) and midazolam (100 µg/kg IV); (III) pentobarbitone (15 to 20 mg/kg IV) (Clutton et al. 1997). Pentobarbitone provided the least satisfactory anesthesia because of profound respiratory depression,

difficulty completing orotracheal intubation, and prolonged time to standing. Another study compared metedomidine-butorphenol-ketamine (MBK: 80 µg/kg–200 µg/kg–10mg/kg, respectively, all IM) with xylazine-butorphenol-ketamine (XBK: 2 mg/kg–200 µg/kg–10 mg/kg, respectively, all IM) (Sakaguchi et al. 1996). MBK was found to provide longer and more satisfactory anesthesia as compared with XBK.

Inhalation Anesthetics

For debilitated swine, for surgical procedures lasting more than 30 minutes, for difficult procedures, or for valuable swine, an inhalation anesthetic provides a more controlled plane of anesthesia. For economic reasons, halothane is the most commonly used inhalation anesthetic in swine. Halothane possesses physical properties and potency consistent with rapid induction, alteration of anesthetic depth, and recovery from anesthesia. Inhalation anesthetics can be administered to small pigs by an open or semiopen method; in larger swine, the semiclosed or closed system is preferred. Swine weighing up to 140 kg can be anesthetized with an anesthetic machine designed for small animals (Tranquilli 1986).

Selection of induction technique and anesthetic protocol depends on the size and special needs of the swine, preference of the veterinarians, and availability of drugs and equipment. Sedation is desirable to reduce the stress of physical restraint before induction of anesthesia (Table 70.1). Swine up to 100 kg can be restrained in a webbed stanchion. Large swine can be restrained in a crate with a head catch or by a snare. Induction of anesthesia can be accomplished with a rapid bolus of injectable agent (barbiturate), by rapid infusions of a combination of drugs (Table 70.1), or by using a face mask delivering a high concentration of anesthetic agent (5% halothane). Tracheal intubation assures a patent airway for delivery of anesthetic and protects the airway from aspiration pneumonia. In the authors' experience, facial, pharyngeal, and laryngeal anatomy of the pig makes endotracheal intubation more challenging than in other meat-producing species. It is often difficult to open the jaws wide enough for good laryngeal exposure, and the pig has a small narrow larynx that deviates ventrally, creating a sharp angle from the pharynx to the tracheal opening. Also laryngeal spasms occur frequently and are induced easily. Occurrence of spasms can be reduced by achieving a sufficient depth of anesthesia prior to intubation or by spraying the larynx with lidocaine.

Following induction, the pig should be placed in sternal recumbency, and the jaws should be held open with small rope. The tongue is pulled forward by an assistant. A laryngoscope and blades of different lengths are needed. For adult swine, the blade length must be at least 25 cm. The blade of the laryngoscope is placed at the base of the tongue and downward pressure is applied until an unobstructed view of the larynx is provided. Endotracheal tubes should be available in sizes from 3 to 20 mm outside diameter and lengths of 25–50 cm. A malleable metal rod with the first 5 cm bent at a 30° angle is placed inside the endotracheal tube to act as a guide. With the laryngeal opening visualized, the endotracheal tube with the stylet extending slightly beyond the tip is placed into the laryngeal opening. The endotracheal tube is pushed over the tip of the stylet and with a twisting motion is passed through the larynx into the trachea. The tracheal diameter is surprisingly small in the pig. A 50 kg pig often requires only a 7–9 mm tube, and a 10–14 mm tube often is adequate for adult sows (Tranquilli 1986).

Safe maintenance of inhalation anesthesia requires knowledge of the signs associated with anesthetic depth and continual monitoring of the patient and anesthetic equipment. Routinely monitored signs should include pulse quality and rate, respiratory rate, color of mucous membranes, capillary refill time, blood pressure, and electrocardiogram. The body temperature should be evaluated regularly, and appropriate padding should be placed. The pulse can be palpated over the median auricular artery. Direct auscultation of the heart also should be done. The normal heart rate in swine ranges from 60–90 beats per minute and may vary greatly during inhalation anesthesia.

During recovery from inhalation anesthesia, frequent and careful monitoring is necessary, because life-threatening complications can occur (Moon and Smith 1996). Recovery should be in a quiet place, and the pig should be placed in sternal recumbency as soon as possible. The endotracheal tube should be maintained until the pig is spontaneously moving its head or will not tolerate the tube. The pig should not be returned to the herd until it is fully awake.

Local Anesthesia

The use of local anesthesia without additional chemical restraint is limited in swine. Pigs, even in the absence of pain, will resist physical restraint by continuing to struggle. In addition to chemical restraint, infiltration of 2% lidocaine around the surgical site will facilitate surgery involving the skin and superficial underlying tissues. Local infiltration of lidocaine is used commonly for surgical repair of umbilical and inguinal hernias and scirrhous cord removal.

Epidural Regional Anesthesia

Lumbosacral epidural anesthesia is the most commonly used form of regional analgesia in swine (Figure 70.2) (Skarda 1996). Minimal equipment and expense are necessary to perform the procedure during epidural anesthesia. Compared to general anesthesia, the swine is in an awake state so the risk of aspiration pneumonia is minimal. Local infiltration of lidocaine compared to epidural anesthesia has several disadvantages. Infiltra-
70.2. *The injection site (needle placement) for a lumbosacral anesthesia in swine. L6 is the sixth lumbar vertebra; S1 is the first sacral vertebra.*

tion requires a larger amount of lidocaine and can retard wound healing and muscle relaxation, and analgesia is not as profound. Lumbosacral epidural anesthesia is relatively easy to perform and greatly facilitates cesarean section; repair of rectal, uterine, or vaginal prolapses; repair of hernia; and surgery of the prepuce and penis or rear limbs (Skarda 1996). Lumbosacral epidural anesthesia should be avoided in patients that are in shock or toxemic because of sympathetic blockade and consequent depression of blood pressure (Skarda 1996). Also, general anesthesia may be more appropriate then regional anesthesia when the sow is very aggressive.

Complications that may result from faulty techniques during lumbosacral epidural injection include cardiovascular and respiratory collapse after overdose or subarachnoid injection, meningitis associated with septic technique and tremor, and vomiting and convulsions after injection of the analgesic into the vertebral venous sinus.

The block can best be administered while the animal is standing and restrained with a hog snare, lariat, or head catch. Large hogs can be restrained by placing their heads in the head catch of a cattle chute. The site for injection for epidural anesthesia in the pig is the lumbosacral space. The conus medullaris of the cauda equina of the pig terminates in the region of the first or second sacral vertebra. The filum terminale terminates at the sixth or seventh coxygeal vertebra. Although the meninges extend beyond the lumbosacral articulation, there is only a very slight probability of entering the subarachnoid space. The lumbosacral space is on the midline and identified by drawing a line across the animal's back from tuber coxa to tuber coxa. This line will be just cranial to the point of the stifle joint (Skarda 1996). The

line passes usually through the spinous process of the last lumbar vertebra. The injection site is usually 2.5–5 cm caudal to this transverse line (Figure 70.2).

The site of injection is prepared by clipping or shaving the hair, thoroughly scrubbing the site with a surgical soap, and applying a skin antiseptic. The location is infiltrated with a local anesthetic agent prior to needle insertion. A 6–8 cm 20-gauge needle is used for pigs up to 30 kg. A 10 cm 18-gauge needle is used for pigs between 35 and 90 kg, and a 12–16 cm needle for pigs over 90 kg. The needle is inserted with the level directed cranially and at an angle 10° caudal to perpendicular between the last lumbar and first sacral vertebrae. The needle penetrates the skin, back fat, muscle, and then the fibrous interarticular spinous ligament. The needle passes through a definite area of resistance as it encounters the ligament and a slight pop is felt as the needle passes into the epidural space and drops to the floor of the spinal canal. The lumbosacral space is large in the pig (1.5 × 2.5 cm) and allows for a relatively large margin of error (Skarda 1996). Aspiration should be attempted before injection of the anesthetic to ensure that the subarachnoid space or a blood vessel has not been entered. Little resistance to injection will be encountered if the needle is located properly in the epidural space.

The anesthetic agent most commonly used is 2% lidocaine. The dose is calculated by either weight or length of the pig (Skarda 1996). Generally, a dose of 1 ml/9 kg of body weight is adequate. Analgesia should be present within 10 minutes and last approximately 2 hours. A total dose of 20 ml must not be exceeded regardless of the weight. Four ml per 100 kg and 6 ml per 200 kg of body weight are sufficient for standing castrations (Skarda 1996). Ten ml per 100 kg, 15 ml per 200 kg, and 20 ml per 300 kg have given satisfactory results for cesarean section (Skarda 1996). If the pig is restrained in lateral recumbency, it is important that the head not be placed in extension. In swine with the head extended, the soft palate can occlude the airway, and the patient can suffocate (Benson 1986).

In 28–35 kg pigs, epidural injections of xylazine (2 mg/kg diluted in 5 ml of 0.9% NaCl solution) at the lumbosacral intervertebral space induce immobilization, mild sedation, and regional anesthesia that extends from the anus to the umbilicus within 10 minutes and lasts at least 2 hours (Ko et al. 1992). The injection of a xylazine (1 mg/kg 10% solution) and lidocaine (10 ml, 2% solution) combination into the lumbosacral epidural space has produced excellent anesthesia for cesarean in large sows (Ko et al. 1993). The forequarters in these sows were immobilized by IV injection of 0.003 ml of telazol, mixture containing 50 mg of telazol per ml, 50 mg of ketamine per ml, and 50 mg of xylazine per ml per kg of body weight (Ko et al. 1993). In preparing the telazol, ketamine, and xylazine combination, 2.5 ml of 10% ketamine (250 mg) and 2.5 ml of 10% xylazine (250

mg xylazine) were used as the diluent instead of sterile water. A mean of 3 ml of this combination was given per sow; the sows were quiet and immobilized for an average of 105 minutes (Ko et al. 1993). The sows were able to walk 12 hours after surgery, and the piglets were without signs of sedation or tranquilization. Intravenous tolazoline (2.2 mg/kg) partially reversed the telazol, ketamine, xylazine-induced sedation after surgery but did not antagonize the xylazine-lidocaine epidural effect (Ko et al. 1993).

Epidural analgesia used in combination with general anesthesia allows a light plane of anesthesia with good muscle relaxation distal to the midthoracic region. Medetomidine (0.5 mg/kg diluted in 5 ml of 0.9% NaCl solution) injected epidurally in the lumbosacral space of swine produced sedation and decubitus but minimal analgesia caudal to the umbilicus. The onset of these effects occurred in 10 minutes, and they lasted for less than 30 minutes. Intravenous administration of atipamezole (0.2 mg/kg of body weight) reversed epidurally administered detomidine-induced sedation and immobilization (Ko et al. 1992). Atipamezole had no effect on epidurally administered xylazine-induced sedation and immobilization (Ko et al. 1992).

PAIN MANAGEMENT

Pain management through drug therapy has received relatively little attention in pigs, possibly because of the massive scale of pig operations, because of economics, and because many procedures are done in young pigs at ages where distress can be minimized. One study evaluated postoperative pain and compared transdermal fentanyl patches (25 µg/hour and 50 µg/hour) with buprenorphine (0.1 mg/kg, as needed) (Harvey-Clark et al. 2000). Assessment of analgesia was variable, but 50 µg/hour transdermal patches placed on 26 kg pigs achieved blood concentrations similar to that considered to be in the analgesic range for humans. Another study evaluated the use of isoflurane anesthestic gas for piglet castration at 14 days old (Walker et al. 2004). In that study, piglets castrated under isoflurane gas had significantly fewer reactions to the surgical procedure but stress hormone concentrations after castration were similar among groups. Application of local anesthesia immediately prior to castration of pigs 10–14 days old was associated with less resistance to the procedure (Horn et al. 1999).

GENITOURINARY SURGERY

Castration

Castration of male pigs is routinely performed with the intention to improve performance, feed conversion, and carcass traits (Kiley 1976). Also, management of castrated pigs through finishing may be easier than for intact male pigs. With the onset of puberty, boar meat be-

comes tainted with an unpleasant odor and taste. However, recommendations for pig age at the time of castration are variable. Stress of castration was evaluated for pigs castrated at 1, 2, 4, 8, 16, and 24 days of age (White et al. 1995). This study indicated that pigs castrated after administration of lidocaine anesthetic subcutaneously and around the spermatic cords had lower heart rate and less vocalization than pigs castrated without local anesthesia. This effect was greatest for pigs castrated after 8 days old. Castration associated behavioral changes were evaluated for pigs castrated at 1, 5, 10, 15, and 20 days old (McGlone et al. 1993). Castration caused reduced suckling, reduced standing, and increased lying time compared with intact male pigs at all ages. Pigs castrated at 14 days old were heavier at weaning and had a higher rate of gain compared with pigs castrated at 1 day old. Administration of aspirin or butorphenol failed to improve castration associated reduction in feeding time and weight gain. Administration of lidocaine anesthesia prior to castration prevented castration-induced nursing behavior suppression (McGlone and Hellman 1988) in 2-week-old pigs. This effect was not observed for pigs castrated at 7 weeks old. Pigs castrated at 2 weeks old had less pronounced behavioral changes than pigs castrated at 7 weeks old. Castrating baby pigs at 2 weeks old minimizes the stress of castration and maximizes performance to weaning.

Castration of 14-day-old pigs is done by suspending the pig by the hind limbs while lying the pig across a smooth rail. The surgical site is wiped clean with alcohol or 2% tincture of iodine. If used, lidocaine anesthetic is injected subcutaneously (0.5 ml per site), overlying each testicle, and over each spermatic cord (0.5 ml per site) in the inguinal canal. A 1 cm long incision is made over each testicle and the testicles pulled from the scrotum. Hemorrhage is minimal at this age. Transfixation ligation of the spermatic cord is recommended for older pigs (see the section on castration of older pigs). Topical antiseptic ointment or spray may be applied at this time. Systemic antibiotics are usually not required, except when castrating older pigs. Castrated baby pigs are placed under a heat lamp in the farrowing crate for convalescence.

Castration of Older Pigs. Pigs are routinely castrated prior to or at 2 weeks old. However, veterinarians may be asked to castrate older pigs that are intended for show or mature boars that are no longer to be used for breeding. Castration of older pigs are best performed with the pig sedated or under general anesthesia (see the section on anesthesia), but manual restraint and local anesthesia may be adequate for pigs weighing 50 kg or less (Becker 1986). The boar is restrained in lateral recumbency and the surgical site aseptically prepared. A 4–6 cm incision is made overlying the testicle at the ventral aspect of the scrotum. The testicle should be removed with the vaginal tunic intact. Inguinal fat and soft tissue are stripped

70.3. *Surgical repair of an inguinal hernia showing the tunic and testicle being twisted to force intestines into the peritoneal cavity.*
70.4. *Illustration of vaginal tunic twisted to the level of the external inguinal ring for transfixation suture fixation.*

from the spermatic cord and evaluated for the presence of an inguinal hernia. The vaginal tunic and the spermatic cord are twisted until the cord is tightly compressed to the level of the external inguinal ring (Figures 70.3 and 70.4). Two transfixation ligatures (no. 1 chromic gut) are placed securing the vaginal tunic and spermatic cord to the medial aspect of the external inguinal ring. These sutures are intended to close the vaginal tunic and prevent the development of postoperative inguinal hernia. An emasculator may be used, but this method for orchiectomy does not result in closure of the vaginal tunic nor prevent inguinal hernia. Closure of the surgical wound should only be performed if asepsis has been maintained. Subcutaneous tissues may be sutured with no. 0 chromic gut in simple continuous pattern to reduce dead space and minimize postoperative swelling. Skin sutures are placed in a Mayo (Ford) interlocking pattern. We prefer to administer antibiotics for 3 days, beginning the day of surgery, to reduce the incidence of postoperative infection. Also, the barrow should be kept in a clean, dry stall during this period.

Complications of Castration. The most common complications following castration of pigs are hemorrhage, abscess, scirrhus cord, inguinal hernia, and seroma or hematoma formation. Fatal hemorrhagic shock has been reported after castration of 7-week-old pigs by a lay person (Libke 1967). The testicles had been pulled through a 10 cm incision and cut using a knife. Fatal hemorrhage occurred into the pelvic canal and abdomen; thus, the cause of death was not recognized until necropsy. This report emphasizes the need for routine necropsy examination of all deaths for which the cause is not apparent.

Meat inspection of 131 pigs with postcastration abscesses revealed that *Arcanobacterium pyogenes,* ß-hemolytic streptococci, *Streptococcus viridans, Staphylococcus aureus,* and *Pasteurella multocida* were the most common bacteria isolated (Százados 1985). Approximately 65% of the abscesses were monomicrobial and 35% were polymicrobial infections. Evidence for bacteremia and septicemia was found in 28% and 11%, respectively. Of the 131 pigs inspected, 11% were judged to be unfit for human consumption. Bilateral hydronephrosis also has been reported as a complication of castration in a Hampshire pig castrated at 8 weeks old (McGavin and Schoneweis 1972). A ventral midline incision was used to remove both testicles and tincture of iodine applied after castration. Infection of the soft tissues occurred and the ensuing infection resulted in progressive occlusion of urethra at the level of the sigmoid flexure. Chronic resistance to urine outflow caused hydronephrosis and the pig died 4 weeks after castration. This case illustrates the importance of adequate ventral drainage after castration.

Unilateral Castration. Indications for removal of only one testicle include testicular trauma, hematoma, seroma, and orchitis or periorchitis (Becker 1986). The damaged testicle may cause enough swelling, heat, and pressure to reduce fertility. The boar is placed under general anesthesia, a 6 cm incision is made over the testicle starting at the most ventral aspect of the scrotum, and the testicle is removed by transfixation ligation and excision. The wound may be left open or closed. Strict asepsis and clean housing are required for closure of the wound to prevent abscess formation. We prefer to leave the wound open for second intention healing. Antiseptic ointment is placed in the defect, antibiotics are administered for 5–7 days, and daily hydrotherapy is used to minimize postoperative swelling. Affected boars may return to productive service 30–60 days after surgery.

Testicular Abnormality (Cryptorchidism, Testicular Atrophy, Ectopic Testicle)

Veterinarians may be presented with barrows demonstrating "boar-like" traits for removal of retained testicular tissues. The testicles of swine descend in the last 30 days of gestation and should be palpable at birth (Van

Straaten et al. 1979). True cryptorchidism (testicle not descended at birth) is a common congenital defect in swine. A homozygous recessive trait involving two gene loci has been postulated based on a breeding trial of cryptorchid Duroc swine (Rothschild et al. 1988). A progeny study of Lacombe and Yorkshire true cryptorchid boars resulted in 10.9% and 31.4% of male progeny being cryptorchid (Fredeen and Newman 1968). Of boars with "late-onset" cryptorchidism (normal at birth but having only one testicle at 42 days old), 3.8% of male progeny were cryptorchid. Cryptorchid testicles are usually intraabdominal and are usually found midway between the ipsilateral kidney and the inguinal ring (Thornton 1972). However, the affected testicle may be located within the inguinal canal and not readily palpable from either the inguinal region or from the peritoneal cavity (Lachmayr 1966). Previous removal of the descended testis makes surgical removal of the retained testis more difficult because the incision is best made over the affected inguinal ring. Often, determination of which testicle has been removed is difficult.

Manual restraint and local anesthesia may be adequate for pigs less than 50 kg, but we prefer to perform cryptorchid surgery with the pig under general anesthesia. A 6 cm incision is made over the appropriate inguinal ring. Laparotomy may be performed by making a 4 cm incision 1–2 cm medial to the inguinal canal (parainguinal incision), or the inguinal ring may be enlarged by starting the incision at the cranial commissure of the external inguinal ring. The fingers of one hand are used to perform an exploration of the abdominal cavity starting at the pelvic brim and searching along the dorsal and lateral abdominal wall until the kidneys are encountered. For show pigs, we prefer to perform laparoscopic exploration and removal of abdominal testes because better cosmesis, fewer incisional complications, and more rapid incisional healing is achieved.

True cryptorchidism should be differentiated from testicular atrophy or degeneration (late-onset cryptorchidism) and ectopic testicular tissue. Pigs affected by testicular atrophy are reported to have palpably normal testicles at birth and weaning but having only one testicle present at 42 days old (Fredeen and Newman 1968). Of 122 cryptorchid studied, 21 had "late onset" cryptorchidism. At slaughter, only one testicle can be found and, occasionally, a small mass of lymphoid tissue or epididymis is identified. Ectopic testicular tissue has been observed in numerous pigs at the time of slaughter (Todd et al. 1968). These tissues occur as smooth, pink or tan nodules on the surface of the liver, spleen, mesentery, and other abdominal viscera. Initially, these masses may be interpreted as metastatic neoplasia, but histology reveals the presence of convoluted seminiferous tubules and interstitial cells. No evidence for neoplasia is seen. Ectopic testicular tissues may be found in castrated or intact male pigs.

Prolapsed Penis

Penile and preputial prolapse have been seen after administration of neuroleptic drugs, but also may occur as a result of trauma to the penis or congenital defect (Figure 70.5). While prolapsed, the penis is at great risk of further injury. The penis and prepuce must be returned to their normal position as soon as possible after prolapse. Treatment of penile prolapse usually required that the boar be placed under general anesthesia. The penis is thoroughly cleaned with cold water and a topical antiseptic ointment applied to the surface of the penis. If a penile wound is present, debridement may be done. Penile wounds typically are not sutured closed unless they have occurred recently (within 2–4 hours) because of the likelihood of formation of an abscess. The penis and prepuce are gently massaged until reduction into the sheath is completed. Use of hydroscopic agents (e.g., anhydrous glycerin) may help reduce the swelling by resolving edema. After the penis and prepuce have been repositioned, a purse-string suture may be used to prevent reoccurrence of the prolapse. The purse string should be removed in 5–7 days. If wounds or abrasions are present, daily preputial lavage or administration of systemic antibiotics and antiinflammatory drugs is indicated. If wounds are not present, sexual rest should be enforced for at least 14 days. If wounds requiring treatment are present, sexual rest should be enforced for 30–60 days (depending on the severity of the wound). Reevaluation of the penile injury is advisable prior to use for mating.

70.5. *Congenital penile and preputial prolapse in a miniature breed pig.*

Preputial Diverticulum

Abnormalities of the preputial diverticulum may cause reproductive unsoundness. Preputial diverticulitis, diverticular ulcers, diverticular stones, urine retention, and penile deviation into the diverticulum may be found (Figure 70.6) (Wieringa and Mouwen 1983; Dutton 1997; Tyler et al. 2000). Preputial diverticulectomy may restore breeding soundness to affected boars. The boar is placed under general anesthesia and prepared for surgery. Any of three procedures for diverticulectomy may be performed:

1. Preputial diverticulectomy via the preputial orifice is done by passing forceps through the preputial orifice, into one lobe of the bilobate diverticulum, gently everting the lobe out through the orifice, and repeating this procedure for the remaining lobe (Figures 70.7 and 70.8). After both lobes of the preputial diverticulum are everted, the diverticulum is excised. Suturing is not required for young boars, but the opening to the diverticulum may be sutured closed in adults.
2. A 6 cm incision is made overlying the lateral aspect of one lobe of the preputial diverticulum. The diverticulum is everted through the preputial orifice, excised, and sutured closed.
3. A 6 cm incision is made as above, but the diverticulum is dissected free from the surrounding soft tissues, excised, and sutured closed (Figure 70.9).

For methods 2 and 3, extreme care must be taken not to perforate the diverticulum prior to removal because contamination will result in incisional infection. Flushing of the preputial diverticulum with antiseptic solutions before surgery is recommended to reduce this possibility. Also, filling the diverticulum with antiseptic solution or gauze pads before surgery makes identification of the diverticulum easier at the time of surgery.

70.6. *Excised preputial diverticulum. Note extensive ulceration of diverticulum.*

70.9. *Surgical dissection and isolation of the preputial diverticulum in a mature boar.*

Preputial Prolapse

Prolapse of the prepuce may occur with penile prolapse or may result from preputial injury and swelling. If wounds to the prepuce are not present, the prepuce may be repositioned within the sheath, as described for penile prolapse, and a purse-string suture used to maintain the reduction (Schoneweis 1971). Careful evaluation of the preputial swelling should be done to ensure that urination is possible. Preputial edema may be reduced by application of hydroscopic agents (anhydrous glycerin, saturated magnesium sulfate solution). A preputial retaining tube, constructed from rubber or polyurethane tubing, may be placed into the preputial space to prevent prolapse but allow exit of urine. Stay sutures are placed through the tubing and attached to the skin at the preputial orifice. Four sutures are placed 90° from each other suture to maintain the proper position of the tube. Alternatively, a 1.25 cm diameter Penrose drain may be sutured to the tip of the penis (no. 2-0 chromic gut suture) to ensure urine outflow. Often, the prolapsed prepuce has been traumatized and surgical removal of the affected tissues is indicated. Preputial amputation may be performed, but the opening to the urethral diverticulum must be maintained. Alternatively, the preputial diverticulum may be removed at the time of surgery.

The boar is placed under general anesthesia, the prepuce is pulled cranially until normal preputial epithelium is exposed, and stay sutures or crossed pins (7.6 cm, 18-gauge needles) are placed through the exposed prepuce to prevent premature retraction into the sheath. The damaged tissues are amputated and the two layers of the prepuce are sutured closed using an interrupted suture pattern (no. 2-0 chromic gut, PDS, or polyglycolic acid suture). After anastomosis, antiseptic ointment is placed on the prepuce and it is replaced into the sheath. A purse-string suture is placed at the preputial orifice for 7–10 days and sexual rest is enforced for 30–60 days. Systemic antibiotics should be administered perioperatively.

Vasectomy or Epididymectomy

Vasectomy or epididymectomy is done to produce teaser boars used for heat detection in sows for artificial insemination or breeding to valuable boars, or to promote onset of cyclicity in confined gilts (Becker 1986). For vasectomy, the boar is placed in dorsal recumbency under general anesthesia and a 4 cm incision is made over each spermatic cord approximately 6 cm cranial to the ventral aspect of the scrotum. Each spermatic cord is elevated, incised, and the vas deferens isolated. The vas deferens lies next to the spermatic artery, is firm and pale, and an arterial pulse is not present. A 3–4 cm segment of the vas deferens is excised and each end ligated. The incision through the tunic is sutured with no. 2-0 PDS or polyglycolic acid, and the skin is sutured with no. 0 polymerized caprolactam in a Mayo (Ford) interlocking suture pattern. An alternative technique for vasectomizing boars enables the surgery to be done with the boar in lateral recumbency (Althouse and Evans 1997).

Epididymectomy is done by making a 2 cm incision in the scrotum overlying the tail of the epididymis. The tail and 1 cm of the body of the epididymis is isolated. Ligatures are placed between the testicle and the tail of the epididymis and around the exposed portion of the body of the epididymis. The epididymis is excised between these two ligatures. The skin is closed with no. 0 polymerized caprolactam in an interrupted pattern.

Persistent Frenulum

The epithelial attachment of the penis and prepuce atrophies and these tissues separate between 4 and 6 months old in boars. Sexual maturity is achieved by 7–8 months old. Persistence of the frenulum attachment between the penis and prepuce beyond sexual maturity causes failure of breeding soundness and has been observed in boars (Roberts 1986). Surgical removal of the persistent frenulum is performed with the boar under general anesthesia or during a hand mating exercise. Resection of the tissue may be performed with scissors. Ligation is not required in most cases and minimal bleeding is observed after excision. Sexual rest should be enforced for 7–10 days after surgery.

Vaginal Prolapse

Vaginal prolapse occurs as a prepartum event. The cause of vaginal prolapse is unknown, but straining to urinate or defecate may be involved. Sows with lateral deviation of the bladder and difficulty urinating or with inflammation associated with cystitis and urethritis may develop vaginal prolapse because of straining. When the cause can be found, treatment should be aimed at resolving the initial lesion. The vagina is cleaned with cold water, hydroscopic agents (anhydrous glycerin, sugar, etc.) are applied, a towel is wrapped around the prolapsed portion, and constant gentle pressure used to reduce the edema and swelling. The prolapse can usually be reduced in 15–20 minutes. The vagina should be cleansed and topical antibiotic or antiseptic ointments used to reduce the secondary bacterial vaginitis that invariably occurs. Administration of antiinflammatory drugs may reduce straining and shorten convalescence. The bladder should be evaluated to ensure that it is in a normal position (see the section on urinary bladder displacement). Often, partial rectal prolapse accompanies vaginal prolapse. The rectal prolapse should be treated appropriately (see the section on rectal prolapse). A Bühner suture is placed around the vagina to prevent reoccurrence of the prolapse. The sow should be closely monitored and the Bühner suture removed at the first indication of farrowing. If excessive swelling of the soft tissues in the pelvic canal has occurred, a cesarean section is indicated and should be performed early in the process of farrowing.

Bladder Displacement (Lateroflexed)

Displacement of the bladder occurs in multiparous sows in the latter stages of gestation. The bladder is displaced laterally and, occasionally, may become displaced caudally. When this occurs, urination is difficult. The displaced bladder may give the appearance of a vaginal prolapse when the sow is lying down. Affected sows may be seen straining because of the difficulty urinating, and this may lead to true vaginal prolapse. Decompression of the urinary bladder by cystocentesis or catheterization may allow permanent replacement of the bladder. When displacement recurs, an indwelling urinary catheter may be used to allow urination until after parturition. Ascending bacterial cystitis is a complication of the indwelling urinary catheter.

Urethral Obstruction

Urethral obstruction has been observed in miniature pigs most commonly. Clinical signs include signs of abdominal pain, tail flagging, straining to urinate, blood in urine, decreased activity or restlessness, decreased appetite, and teeth grinding. Potential causes of urethral obstruction to be considered include urolithiasis, urethral polyps, and urethral stricture or trauma. Retrograde catheterization of the pelvic urethra and bladder is difficult because of the urethral recess and mucosal flap, which prevent passage of the catheter. Tube cystostomy with positive contrast urethrography was reported to be useful for diagnosis of obstruction of the distal urethra (Palmer et al. 1998). Urethral polyps were reported as a cause of urethral outflow obstruction in Vietnamese potbellied pigs (Helman et al. 1996). Surgical management of urethral outflow obstruction include urethrotomy, cystostomy with normograde flushing, tube cystostomy, perineal urethrostomy, prepubic urethrostomy, and prepubic cystostomy. Prepubic cystostomy was successful in two Vietnamese pigs with urethral injury from castration or urethral stricture (Leon et al. 1997). In these two pigs, the pelvic urethral was exteriorized cranial to the brim of the pelvis and the urethral spatulated and the mucosa sutured to the skin. Both pigs maintained urinary continence. Urethroscopy with laser lithotripsy was used successfully in two potbellied pigs to allieviate urethral obstruction caused by uroliths (Halland et al. 2002).

Tube Cystostomy Procedure. Patients are placed in dorsal recumbency under general anesthesia. An 8–10 cm paramedian approach is made 4 cm lateral to the prepuce and extending from immediately caudal to the preputial orifice to 4 cm cranial to the brim of the pelvis. The bladder is exteriorized and two stay sutures placed near the apex. A cystotomy is performed near the apex, and suction and lavage with saline used to evacuate urine and debris from the bladder. A gallstone scoop may be used to facilitate removal of stones if present. Particular attention is paid to suctioning the region of the trigone and urethral origin to remove debris that may have migrated into the urethra during positioning for surgery. Normograde flushing is attempted to clear the urethra of debris. The cystotomy incision is then closed in two inverting layers using no. 0 or 2-0 absorbable monofilament suture material. A purse-string suture is then preplaced in the ventrolateral aspect of the bladder, near the apex on the same side as the celiotomy incision. A Foley catheter of size appropriate to the animal (range 12–18 F) is placed through a stab incision lateral to the paramedian body wall incision to enter the abdominal cavity. The end of the Foley catheter is then placed through a stab incision in the bladder within the purse-string suture. The purse-string suture is then tied tightly and the catheter balloon inflated with saline. The bladder is pulled close to the body wall using tension on the Foley catheter, which was secured to the skin with a trapping suture pattern. The celiotomy incision is closed routinely using various suture materials, depending on surgeon preference.

Oophorectomy

Removal of the ovaries is rarely indicated in swine. However, oophorectomy may be requested to facilitate research or for pet pigs. For pet pigs, removal of the ovaries is easier, faster, and has less risk of fatal hemorrhage than ovariohysterectomy (OVX). The blood vessels of the broad ligaments of the uterus are extensive and require ligation when OVX is chosen. Both ovaries may be removed from a paralumbar (flank), ventrolateral, paramedian, or ventral midline incision. We prefer to perform ovariectomy via a flank or ventral midline incision. Access to the abdomen is excellent with these incisions, and, in our experience, the risk of postoperative complications (incisional infection, hernia) is less. In either case, we prefer to use general anesthesia while performing the surgery.

For ventral midline approach, the incision may be started immediately caudal to the umbilicus and extended caudally. For a paralumbar approach, the incision is started ventral to the transverse processes of the lumbar vertebrae, midway between the tuber coxae and the last rib. Each ovary is elevated through the incision, two hemostatic forceps are placed on the ovarian pedicle, two ligatures (no. 2-0 polygalactin 910) are placed proximal to the first hemostat, the pedicle is cut between the two hemostats and the ovary removed. Each ovarian artery must be observed for hemorrhage prior to closure. Closure of the ventral midline is done using no. 1 PDS or polyglactin 910 in an interrupted suture pattern. Chromic gut suture should not be used in the linea alba because of the increased risk of postoperative incisional hernia. The skin is closed with no. 2 polymerized caprolactam in a Mayo (Ford) interlocking suture pattern. Paralumbar incisions are closed in three layers (transversus abdominis muscle and peritoneum, internal and external abdominal oblique muscles, and skin).

Ovariectomy, alone, may be performed in pet pigs that have not begun normal estrous cycles. Uterine atrophy is expected to occur after ovariectomy. We recommend OVX in sexually mature pigs because of the potential risk for pyometra in a uterus where the cervix has been open.

Uterus

Hysterectomy. Hysterectomy may be performed as part of cesarean section, and is discussed below. Elective hysterectomy is rarely done in swine. However, hysterectomy may be requested for research purposes or for pet pigs (Figure 70.10). When hysterectomy is performed for pet pigs, the ovaries also are removed. General anesthesia should be used during hysterectomy. The uterus may be removed via a flank, ventrolateral, paramedian, or ventral midline incision. We prefer to perform hysterectomy via either flank or ventral midline incision. The uterus is elevated through the incision, the ovaries are removed as described above, the broad ligament of the uterus is ligated using two to four overlapping simple interrupted sutures for mass ligation of the blood vessels, and transfixation ligatures are placed in the uterine body immediately cranial to the internal os of the cervix. The uterus and ovaries are removed and the incision closed as described above. All sutured pedicles should be checked for adequate hemostasis prior to closure.

70.10. *Uterus and ovaries exteriorized for ovariohysterectomy in a 4-month-old pet pig.*

Cesarean Section: Indication and Decision Analysis. Cesarean section is required when transcervical extraction of pigs from the uterus is not possible (complicated dystocia) and to obtain gnotobiotic or specific pathogen free (SPF) pigs. Cesarean section for gnotobiotic pigs is usually performed with the sow under general anesthesia and is discussed below. The most common reported causes of dystocia in swine are uterine inertia, small pelvic size, inadequate dilation of the birth canal, fetal-to-maternal disproportion, fetal malpresentation, and abnormalities of the birth canal (Titze 1977).

Cesarean section for dystocia is usually chosen as a "last-resort" procedure for fetal extraction because of economic pressures. Therefore, the mortality rate among sows and gilts having cesarean section is expected to be higher than for other species. This is not surprising because affected swine suffer extreme physical exhaustion, stress, and shock by the time the decision for cesarean section is made. Interestingly, multiparous sows had a higher frequency of collapse (25.8%) prior to cesarean section compared with primiparous pigs (16.4%) (Dimigen 1972). Owners and veterinarians may become reluctant to perform cesarean section because of expense, previous experiences with fatalities, and the high rate of dead pigs delivered. It is our opinion that unnecessary delays in the decision for surgery is the principle cause of sow and baby pig mortality associated with cesarean section. When the veterinarian is presented with a sow in dystocia, the decision as to whether the owner is willing to incur the costs of cesarean section should be ascertained as early as possible during the initial examination. Other factors influencing the decision for cesarean section includes the cause of dystocia, how long the sow has been in labor, how long the owner has tried to extract the pigs manually, and how swollen or traumatized the sow's pelvic canal has become. Many owners are adept at extracting pigs, and their failure to remove pigs successfully may justify immediate cesarean if the cause of dystocia is not apparent. The most common indications for cesarean section in pigs are undersized pelvic canal, inadequate cervical and soft tissue dilation, prolonged labor (including uterine inertia), fetal-to-maternal disproportion, and trauma to the birth canal (Titze 1977). In our experience, cesarean section performed at the earliest indication has a high success rate for survival of the sow and a higher rate of live pigs obtained (Table 70.2).

Table 70.2.   Outcome of cesarean section in sows with respect to duration of labor

Duration of Labor	Number of Sows	% Sows Having >50% Live Pigs	% Sows Having <50% Live Pigs	% Sows Having All Dead Pigs	% Sows Died or Culled
<18 hours	125	66.7	7.9	25.4	13.4
18–48 hours	81	19.7	13.5	66.7	32.1
>48 hours	21	0	4.7	95.3	28.5
Overall	227	43.7	9.7	46.6	21.5

Source: Adapted from Dimigen 1972.

Swine that are physically exhausted, stressed, or in shock must be stabilized prior to cesarean section. Thirteen percent of sows in labor for less than 18 hours died or were salvaged, compared with 60% of sows in labor for more than 18 hours (Dimigen 1972). Among sows necropsied after sudden death, retained fetuses and toxemia were found in approximately 10% (Sanford et al. 1994). Stabilization of the sow often is simple and readily achieved. We routinely place a 16 or 18 gauge, 2-inch intravenous catheter in an ear vein. This catheter is sutured or glued in place and intravenous fluids (0.9% saline or lactated Ringer's solution) administered rapidly (initially 20–40 ml/kg of body weight/hour; then, 4 ml/kg/hour once stabilized) and continued for the duration of the surgery. We prefer to add dextrose (1.25% final solution) and calcium (1 ml/kg) to intravenous fluids after the patient has been stabilized. Further, the shock status of the sow may be improved by administration of dexamethasone (0.5 to 1.0 mg/kg, IV) or flunixin meglumine (1 mg/kg, IV). Because extensive manipulation of the intrauterine environment prior to cesarean section increases the risk for postoperative septic peritonitis, we prefer to administer preoperative antibiotics (procaine penicillin G, ceftiofur HCl, or oxytetracycline).

In severely compromised sows, sedation (see the section on anesthesia section) and local or regional anesthesia may be adequate for surgery. Intravenous fluids should be administered continuously. Epidural anesthesia (lumbosacral level) also may be useful. Overall, we prefer to perform general anesthesia rather than attempt cesarean using physical restraint and epidural anesthesia. In our experience, this causes the least stress on the patient, surgeon, and assistants. The respiratory rate and heart rate should be monitored and supportive therapy adjusted appropriately.

Surgical Approach for Cesarean Section. Multiple surgical approaches have been described for cesarean section. Selection of the surgical approach depends upon the preference of the surgeon, the condition of the patient, and means of restraint and anesthesia used for surgery. The most common approaches are paralumbar fossa, ventrolateral (horizontal low flank), ventral midline, paramedian, or paramammary (Mather 1966; Turner and McIlwraith 1989). With a ventral or paramedian approach, movement by the sow must be prevented because of the risk for contamination of the incision. Also, the mammary veins must be carefully avoided or ligated to prevent excessive loss of blood during the procedure. In our experience, ventral and paramedian incisions have the highest risk for development of postoperative incisional infection (contamination on the floor and trauma from pigs searching for nipples).

The ventrolateral incision is made parallel and ventral to the flank, and lateral to the mammary chain (Mather 1966). The sow is placed in lateral recumbency with the uppermost hind limb tied in adduction and ex-

tension. The incision is started approximately 10 cm cranial to the inguinal region and extended cranially for 15 cm.

For paralumbar fossa incision, the sow is placed in lateral recumbency and the incision is started cranial and ventral to the tuber coxae. The incision is extended ventrally to a point approximately 5 cm dorsal to the cranial skin fold of the flank.

Ventrolateral and paralumbar incisions are relatively easy to perform, have little blood loss during surgery, and are less likely to become infected after surgery. Fewer fat deposits are encountered with ventrolateral incisions, and the meat portion of the flank is left undisturbed. After exteriorizing the closest uterine horn, a 6–8 cm long incision is made parallel with the uterine horn and as close to the bifurcation of the uterine horns as possible. All pigs may not be able to be removed from a single incision in the uterus (Figure 70.11).

Closure of cesarean section incision is based upon the conditions under which the surgery was performed. For a healthy uterus containing live or recently dead pigs, we use no. 1 chromic gut or no. 0 PDS or polyglycolic acid placed in a cushing or Utrecht (modified cushing) pattern for closure of the uterus. Some veterinarians have advocated hysterectomy when performing cesarean section (Schoneweis 1971). This practice allows rapid removal of all pigs soon after entering the abdomen, ensures culling of the sow after the pigs have been weaned, and minimizes surgery time because removal of individual pigs is done by an assistant after removal of the uterus. The uterine arteries are ligated with no. 0 chromic gut, the broad ligaments are divided along the axis of the uterine horns, and the uterine body is ligated using rubber tubing. The rubber tubing may be secured to the uterine body using no. 1 chromic gut suture. Alternatively, sterile 1 cm cotton tape (umbilical tape) suture may be used to perform transfixation

70.11. *Suturing uterus closed after removal of pigs. Sow was positioned in lateral recumbency for a cesarean section via paramammary approach.*

ligation of the uterine body. Then, the gravid uterus is removed. We urge caution with hysterectomy that precise hemostasis must be achieved prior to removal of the uterus. Ligation of abdominal bleeders after removal of the uterus is difficult, and life-threatening hemorrhage may occur if the uterine arteries are inadequately ligated. We close the transversus abdominis muscle and peritoneum, together, and the external abdominal oblique and internal abdominal oblique muscles, together, using no. 2 chromic gut or no. 1 PDS or polyglycolic acid placed in simple continuous pattern. For closure of ventral midline or paramedian incisions, we do not recommend the use of chromic gut because of the higher rate of postoperative hernia formation. We use no. 1 PDS or polyglycolic acid suture placed in simple interrupted or interrupted cruciate pattern. Skin is closed using no. 0 polymerized caprolactam in a Mayo (Ford) interlocking pattern. The sow should remain confined for a minimum of 14 days after surgery.

Gnotobiotic Pigs. The production of gnotobiotic or SPF pigs is an accepted model for scientific research. The selected sow should be placed under general anesthesia and the surgery site aseptically prepared. Several methods have been described for obtaining gnotobiotic pigs including hysterectomy, closed hysterotomy (using a sterile chamber attached to the side of the sow through which surgery is performed), and open hysterotomy with germicidal trap. All methods are expected to have a baby pig mortality rate of less than 15%, except open hysterotomy performed with local anesthesia which may have a 35% baby pig mortality rate (Tavernor et al. 1971; Miniats and Jol 1978). When a hysterectomy technique is selected, baby pig survival is better when the surgery is performed with the sow under general anesthesia rather than euthanized prior to hysterectomy.

Uterine Prolapse. Prolapse of the uterus is occasionally seen in sows during or up to several days after parturition. Excessive straining because of fetal malpositioning, fetal-to-maternal disproportion, or trauma with swelling and inflammation in the birth canal is thought to cause uterine prolapse. Prolapse of the entire uterus has the greatest potential for a life-threatening crisis because of profuse hemorrhage, but partial prolapse also may occur. The sow must be stabilized prior to attempts to replace the uterus into its normal position. If hemorrhage, hypovolemia, or shock (tachycardia, peripheral cyanosis) are present, the sow should be placed into a warm environment, an IV catheter placed into an auricular vein, and intravenous fluids administered. Hypertonic saline may be administered rapidly (5–7 ml/kg body weight, IV over 5–10 minutes) followed by isotonic crystalline fluids (5–10 ml/kg/hour).

For replacement of the prolapse, the sow may be placed on an inclined floor or platform in sternal recumbency with the hindquarters elevated. Epidural anesthe-sia (administered at the lumbosacral space), sedation, or general anesthesia may be required to eliminate struggling, straining, and agitation of the sow. The uterus is thoroughly cleaned with cold water and assessed for the presence of lacerations and necrosis. Small lacerations may be cleaned, superficially debrided, and sutured closed (no. 0 chromic gut, simple continuous pattern). Hemorrhage may be stopped by ligating affected vessels or by performing en bloc tissue imbrication. Sutures may be placed over stents to increase the region of pressure to control hemorrhage. Then, hydroscopic agents (e.g., anhydrous glycerin, sugar, etc.) may be applied to the uterus to assist in reducing edema. The uterus is wrapped into a towel and gentle pressure applied, starting from the tip of the uterine horn and working toward the body of the uterus. After approximately 15 minutes, the edema should be sufficiently reduced to allow manipulation of the uterine horns. Each horn should be inverted starting with the tip and gradually reduced until the uterine body has been reached.

Often, progress is impeded because of the extensive edema and swelling of the soft tissues of the pelvic canal. When this occurs, left paralumbar fossa laparotomy is indicated (Raleigh 1977). After appropriate preparation of the surgical site and surgeon, a 10 cm long, vertically oriented incision is made in the middle of the left paralumbar fossae. The left arm is passed into the peritoneal cavity and into the everted uterus. One of the uterine horns is grasped and pulled back into the peritoneal cavity. The right arm or an assistant helps by applying gentle pressure on the everted horn from the exterior. After the uterus has been repositioned, all remaining fetuses should be removed. The laparotomy incision should be closed in three layers (transversus abdominis muscle and peritoneum, internal and external abdominal oblique muscles, and skin). Chromic gut (no. 3) or a synthetic absorbable suture (polydioxinone, polyglactin 910, polyglycolic acid) is placed in simple continuous suture patterns in the muscle layers. Polymerized caprolactam (no. 2 braunamide) is placed in a Mayo (Ford) interlocking pattern in the skin. Antimicrobial and antiinflammatory medications are desirable, but strict attention should be paid to drug residues in the meat prior to slaughter. Finally, a Bühner suture should be placed around the vulva to prevent reoccurrence of the prolapse. The Bühner suture (6.4 mm wide sterile cotton tape) should be deeply placed at the junction of the labia and the skin of the perineum to recreate the function of the vestibular sphincter muscle. The Bühner suture may be removed in 7–10 days with minimal risk of prolapse. Oxytocin (20 units) is routinely administered to facilitate contraction and involution of the uterus and cervix. If prolapse reduction using laparotomy is not used as a "last resort" treatment, sows should survive partial prolapse of the uterus (>75% survival), but complete prolapse carries a guarded prognosis (<50% survival).

Amputation of the Uterus. Amputation of the uterus is indicated when excessive bleeding, extensive laceration, trauma, or necrosis of a uterine prolapse is found. The prognosis with uterine prolapse is guarded to poor for survival and affected sows must be provided with supportive care as soon as possible (shelter, IV fluids via ear vein catheter, etc.). Focal lacerations and bleeders can be repaired and the uterus replaced into the abdomen. When severe injury has occurred, amputation of the uterus provides the best option for salvage of the sow. Prior to amputation, the uterus should be closely inspected to ensure that the bladder or small intestine are not entrapped. Hypovolemic or hemorrhagic shock may be present and should be addressed during the course of treatment. If the uterus is swollen, it should be elevated above the pig to encourage drainage of venous congestion. We recommend placing towels around the uterus so that pressure may be applied without further trauma to the wall of the uterus. Hydroscopic agents (e.g., anhydrous glycerin, granular sugar) may be used to help resolve edema of the uterine tissues.

After venous congestion has been reduced, amputation is more easily performed. Transfixation ligatures are placed around the circumference of the uterus. Heavy suture material (0.5 cm sterile cotton tape, no. 3 polymerized caprolactam) is used because the thickness of the uterus requires extreme tension to completely occlude the uterine arteries. Stay sutures or cross pins (using 15 cm long 18 gauge needles) are placed in the vital uterus and the prolapsed portion amputated. Then, any bleeders are ligated with no. 1 chromic gut before the remaining tissues are released and placed back into the pelvic canal. A Bühner suture or purse-string suture should be placed into the labia at the level of the vestibular sphincter to prevent prolapse of the remaining tissues. Affected sows are salvaged as soon as possible or after weaning of the litter.

Mastectomy

Chronic infection of the mammae may result in the formation of abscesses, granulomas, and mammary fistulas (Figure 70.12). The swellings may become large and problematic for the sow. Surgical removal of the mammae is indicated for return of the sow to production soundness. Sows with at least 12 intact mammary glands and that are not in the first week or last 4 weeks of gestation are suitable candidates for surgery (Bollwahn 1992).

The sow is placed under general anesthesia and the affected mammary gland prepared for surgery. An elliptical incision is made approximately 1 cm from the base of the swelling so that enough tissue remains to allow closure of the tissues with minimal tension. A combination of sharp and blunt dissection is used to extirpate the gland, granuloma, and abscesses. The cranial superficial epigastric vein (subcutaneous abdominal vein) should not be compromised, but hemostasis is essential. Hemostasis is ensured by using 2-0 chromic gut ligature

70.12. *Chronic mastitis.*

of transected blood vessels. The wound is closed in three layers: deep subcutaneous, superficial subcutaneous, and skin. Each subcutaneous tissue layer is sutured with a simple continuous suture pattern (no. 0 chromic gut, no. 2-0 PDS or polyglycolic acid). Each suture is anchored to the deeper tissue layer in an attempt to close all dead space, thus minimizing the formation of postoperative seroma, hematoma, and abscess. Administration of perioperative antibiotics is indicated.

ABDOMINAL SURGERY

Umbilical Hernia

Umbilical hernia is a developmental defect of pigs. An umbilical hernia is a discontinuity of the abdominal wall at the umbilicus with protrusion of abdominal content into a hernia sac formed by the skin and surrounding connective tissue (Figure 70.13). In swine herds, the frequency of umbilical hernias ranges from 0.4 to 1.2% and varies with breed and sex (Searcy-Bernal et al. 1994). In addition to heredity, the etiology of umbilical hernia may be navel infection and umbilical abscess. After the umbilical cord is cut at birth, iodine should be applied to decrease the likelihood of infection. Pigs with umbilical hernias may suffer from growth retardation and may die from intestinal strangulation. In one study, pigs sired by American Spotted and Duroc boars were more likely to develop hernia than those sired by Yorkshire, and umbilical hernias often were detected in pigs between 9 and 14 weeks of age (Searcy-Bernal et al. 1994). One possible reason for the recognition of the condition at that age may be the rapid growth of pigs, combined with increased weight of the abdominal contents, leading to a hernia of significant size. Females were at an increased risk of developing umbilical hernia.

As with many other swine surgical conditions, the cost of treatment may preclude surgical correction. In that case, pigs should be consigned to an early slaughter soon (within 1 month) after detection of the hernia, before evisceration or intestinal strangulation or fistula oc-

70.13. *Surgical repair of an umbilical hernia in a female. An elliptical incision is made around the hernia sac and the excess skin is discarded.*

curs. A case of intestinal umbilical fistula has been described in a 30 kg castrated male pig (Lewis 1973). The risk of intestinal incarceration and strangulation is more frequent with an umbilical hernia of small dimension, i.e., hernia ring smaller than 8 cm. However, a pig with an umbilical hernia often will be discounted when it goes to slaughter.

Reduced growth rate in untreated pigs with umbilical hernias may encourage surgical correction of the defect. However, whether surgical correction of umbilical hernia will restore the growth potential is unknown. In purebred, show animals and pigs kept as pets, surgical correction often is indicated.

Herniorrhaphy should be performed early in life. Following anesthesia, the pig is restrained in dorsal recumbency in a V-shaped trough. The surgical area then is cleaned and prepared for surgery. If surgical correction is performed on a male, the prepuce, preputial diverticulum, and penis should be reflected posteriorly or to one side. The hernia sac then is isolated, and dissection is performed to the hernia ring. The hernia sac with an abscess, if present, should be removed, and the edges of the ring freshened. If intestinal contents are adhered to the hernia sac, the adhesions are separated and bowel viability is assessed; if judged acceptable, the bowel is replaced in the abdomen. If intestinal viability is compromised, resection and anastomosis of viable intestine should be performed. If no infection is present, the hernia sac also can be inverted into the abdomen. The abdominal defect then is closed using an overlapping or simple continuous pattern. The prepuce, preputial diverticulum, and penis then are repositioned and sutured to the abdominal muscle with absorbable suture material. The skin then is sutured using a simple interrupted pattern of nonabsorbable suture material.

For surgical correction of umbilical hernia in the female, an elliptical incision is made around the hernia sac, and the excess skin is discarded. With a combination of sharp and blunt dissection, the hernia sac then is cut and removed and the abdominal muscle closed, as

in the male. The subcutaneous tissue and skin then are closed. Systemic antibiotic should be administered for 5 days, and the skin suture removed in 10 days.

Inguinal or Scrotal Hernia
Inguinal hernia and scrotal hernia are variants of a defect in which intestines or other abdominal organs pass into the inguinal canal. The hernia develops when there is an abnormally large and patent vaginal orifice through which the vaginal process and peritoneal cavity communicate. Scrotal hernia is the more exaggerated form of the defect in that the organs protrude into the scrotum (Vogt and Ellersieck 1990). These hernias are common in swine and have been the most common defect observed in swine (Vogt and Ellersieck 1990). The frequency of scrotal hernia among the porcine population varied between 0 and 15.7% with a realistic number of about 1% (Vogt and Ellersieck 1990). The development of these hernias seems to be genetically influenced. One study indicated that the variation associated with anatomic structures relevant to scrotal hernia is influenced polygenically. In that study, the heritabilities of susceptibility to scrotal hernia development were estimated to be 0.29, 0.34, and 0.34 in Duroc-, Landrace-, and Yorkshire-sired pig groups, respectively (Vogt and Ellersieck 1990). Inguinal and scrotal hernias need to be differentiated from hydrocele, scirrhous cord, and hematoma of the testicle. Taking a good history (e.g., a pig that has been castrated before is more likely to have a scirrhous cord) and direct manipulation often will give the diagnosis. If necessary, ultrasonography and needle aspiration can be used. Inguinal hernias often are encountered at the time of castration. Some of these hernias will reduce spontaneously but recur later. With chronic inguinal hernia, intestinal incarceration and strangulation may be observed.

Surgical repair of an inguinal or scrotal hernia is easier if done before the pig is castrated. With the pig restrained in dorsal recumbency and its rear quarters elevated, the inguinal and scrotal area is thoroughly cleaned and prepared for surgery. An oblique incision is made over the affected external inguinal ring. Once through the skin, the subcutaneous tissue is dissected bluntly. Also by blunt dissection, the tunica vaginalis is isolated. The tunica vaginalis should be kept intact, because this will keep the intestine contained. While external pressure is put on the scrotum, the tunics are gently pulled free from their scrotal attachment. The entire hernia sac is removed through the inguinal incision. The tunic and testicle then are twisted to force the intestines into the peritoneal cavity. The tunics and spermatic cord are transfixed as close to the inguinal ring as possible. The tunic and cord then are cut, and the inguinal ring is closed with interrupted or horizontal mattress suture. The herniorrhaphy then is checked by applying external pressure on the abdomen. The skin then is closed using absorbable sutures. The authors always

recommend checking the other side for possible bilateral herniation before performing a castration.

If the surgery was done to repair a large hernia in which marked serum accumulation in the scrotum is expected, an incision in the most ventral aspect of the scrotum should be performed via the inguinal incision before suturing to provide ventral drainage. If intestinal adhesion and incarceration are observed during surgical correction of a scrotal hernia, the vaginal tunic should be opened and the intestine dissected free or an intestinal resection and end-to-end anastomosis performed. If an inguinal hernia occurs after castration, one needs to clean and lavage the herniated bowel, enlarge the inguinal ring and replace the prolapsed intestine (if it is judged to still be viable), and then suture the inguinal ring.

Visceral Torsion or Volvulus

In one series of cases, acute abdominal accidents were characterized clinically by sudden death and were observed more commonly in dry sows (Morin et al. 1984). It was proposed that feeding dry sows in large breeding units once a day or every other day might be an important provoking factor. This feeding method often will make sows ingest large quantity of feed and water rapidly. In swine with gastric torsion, death was preceded sometimes by a short period of anorexia, abdominal distension, shortness of breath, cyanosis, and salivation. At necropsy, clockwise torsions were more common than counterclockwise. The torsions were about the longitudinal axis of the organ and the stomach was distended severely with fluid, gas, and food (Morin et al. 1984). The spleen had rotated with the stomach in some sows; affected spleens were congested severely and some had ruptured, causing hemoperitoneum. Torsion of the liver also was seen occasionally (Morin et al. 1984). In eight sows, intestinal volvulus was observed and it was more common in younger sows. In four sows the entire small intestine was included in the volvulus, the posterior half of the small intestine in one, the small intestine and colon in one, and the cecum and colon in the last one (Morin et al. 1984).

Intestinal Obstruction

In swine with intestinal obstructions from intussusceptions or foreign bodies, clinical signs observed may include depression, vomiting, abdominal distension, and decrease in the amount of feces, sometimes with blood and mucus in it. These two conditions are diagnosed rarely in live animals. If the condition is diagnosed early, a ventral midline celiotomy and an enterotomy are performed for the foreign body obstruction, and an intestinal resection and anastomosis are done for the intussusception. Spiral colon obstruction was diagnosed in an 8-year-old potbellied pig with depression, inappetance, and abdominal distension (Gallardo et al. 2003). Exploratory laparotomy found a stricture at the

proximal centripetal loop of the spiral colon and megacolon proximal to the stricture. A side-to-side colonic anastomosis was performed and the pig returned to normal after surgery. A 7-month-old female potbellied pig was diagnosed with idiopathic megacolon based on abdominal palpation, abdominal radiographs, and exploratory surgery (Bassett et al. 1999). A subtotal colectomy was performed and an ileocolonic anastomosis performed. The pig survived and, after a period of diarrhea, stool returned to normal.

Gastric Ulcers

Gastric ulcers are common conditions of the gastrointestinal tract of the pig. Clinical signs are pale mucous membrane (anemia) and dark, tarry feces. In valuable pigs, sometimes gastrotomy can be the best treatment option. With the animal in dorsal recumbency, an incision is made on the ventral midline starting at the xiphoid cartilages. The stomach is isolated from the rest of the abdomen, and the serosal surface is evaluated for changes in color and appearance that would indicate an ulcer. A gastrotomy then is done, and the stomach contents are removed. If an ulcer is found, it can be surgically dissected and the edges electrocoagulated or ligated with some suture material. The wall of the stomach then is closed with a double row of suture material using an inverting pattern. If multiple bleeding ulcers are present, the prognosis is poor even with surgery (see Chapter 54 on gastric ulcers).

Atresia Ani and Rectal Stricture

Atresia ani occurs more frequently in the pig than any other species and is possibly the most important cause of intestinal obstruction. This congenital defect is transmitted genetically. The diagnosis is made by an absence of anal opening, abdominal distension, slower growth rate, and vomiting (Figure 70.14). Because the pigs are able to vomit, the diagnosis of atresia ani may not be made until 3–4 weeks of age. In the female piglet, a fistula may occur between the rectum and vagina, so that the feces may be voided through the vulva. Surgical treatment of atresia ani is necessary for survival. Following anesthesia, a circular piece of skin is excised below the tail over the bulging rectum. Feces usually are discharged immediately. If the rectum is not present at the skin opening, pelvic dissection may be necessary. Depending on the location of the rectum, or if atresia of the rectum is also present, surgical correction may not be possible. In these extreme cases, a celiotomy and colostomy may be necessary but rarely justifiable economically.

Pigs with rectal stricture often show similar clinical signs as pigs with atresia ani, except that they have an anus and are generally older. In one series of cases, pigs with rectal stricture were 16–18 weeks of age (Saunders 1974). After being affected for 2 weeks, these pigs suffered from weight loss compared to their herdmates, no

70.14. *Female pig with atresia ani.*

feces were passed, and the abdomen continued to distend. These pigs were slaughtered or killed by other pigs (Saunders 1974). Most cases of rectal stricture are the results of a rectal prolapse that has constricted after repair causing an obstruction. At necropsy, these pigs show a distended cecum and colon. The rectum usually is occluded for 3–5 cm by a band of fibrous tissue. It is speculated that inflammation of the rectal mucosa leads to rectal scar formation with subsequent stenosis and eventually possible complete obstruction (Saunders 1974). Pigs with rectal stricture may respond to celiotomy with colostomy or ileocutaneous anastomosis. Ileocutaneous anastomosis has been successfully performed in pigs as young as 10 days old (Anderson et al. 2000).

Rectal Prolapse and Rectal Amputation

Rectal prolapse is a common occurrence in swine. Prolapse of the rectal mucosa occurs following straining to defecate. The mucosa rapidly becomes edematous and often shows bleeding lesions. Many factors have been associated with the development of rectal prolapse, including genetics, a birth weight of less than 1 kg, being male, diarrhea, coughing, short tails, autumn and winter piling as a consequence of chilling, chronic water shortage, certain antibiotics, zearalenone toxicosis, and a diet containing excess lysine (20% more than required) (Amass et al. 1995). Diagnosis of rectal prolapse is not difficult, but care should be taken that the prolapse does not contain other organs.

The simplest procedure for correction of rectal prolapse is reduction by gentle massage and retention by application of a purse-string suture pattern using umbilical tape. The suture is passed in and out through the skin around the anal opening at a distance of 1 cm from the anus. A one-finger opening should be left when tying the purse string. The suture usually is left in place for 5 days. This should be done only if the rectal mucosa is viable and no laceration is present on close inspection.

If the mucosa is too necrotic to replace, correction of the prolapse can be approached in different ways (Vonderfecht 1978). One technique is a surgical amputation. For this surgery, required instruments are hemostats, blade, scissors, thumb forceps, two 18-gauge needles 8–10 cm long, suture material, and a small-diameter rubber tube. Following anesthesia, the tube is inserted in the rectum until 5 or 8 cm protrude. The tube is fixed in the rectum by inserting the two needles through the rectum at right angles to each other so that they pass through the rectum and tube and emerge from the opposite side. The dissection is started about one centimeter from the mucocutaneous border where the mucosa is still healthy, and the entire circumference of the exposed mucosa of the rectum is cut down to the serosa of the inner wall. Hemorrhaging is usually minor and controlled with gauge until all the layers have been dissected and the dorsal artery of the rectum is cut. Once the dissection is completed around the prolapse, the rectum is held in place because it is attached to the rubber tube with needles. Instead of using tubing and needles, one could use forceps applied at two or three places as the prolapsed rectum is amputated to prevent telescoping into the animal's body (Kjar 1976). To suture the ends of the rectum together, the authors suggest using size 0 absorbable suture material in an inside-out continuous pattern. After the simple continuous pattern has been placed around the rectum, the needles are pulled from the tube, and the tube is removed from the rectum. The rectum then automatically retracts into place.

An alternative method of rectal amputation is to use a prolapse ring, PVC tubing, syringe case, or corrugated tube (Douglas 1985). The ring or tubing is placed in the rectum, and the halfway point on the tube needs to be inserted as far as the anal sphincter. A ligature or rubber band then is applied over the prolapse as near as possible to the anus. The ligature or rubber band must be tight enough to disrupt blood supply to the prolapse. Feces may go through the tube or may block the tube. Usually, the necrotic prolapse falls in 5–7 days with the implant in place, and then fecal production returns to normal.

Three possible complications seen with rectal prolapse are bladder retroversion, eventration of the small intestine, and rectal stricture (Peyton et al. 1980). In a 1-month-old castrated pig, eventration of the small bowel was seen concurrently with a rectal prolapse. The rectal prolapse was 5 cm long, edematous, and purple-black. A small tear was found in the rectum in the pelvic area, and eventration of small intestine was observed. It was speculated that the prolapse was of long duration, al-

lowing necrosis to occur. This provided a friable area, and during straining to defecate, the small intestine perforated this necrotic area (Peyton et al. 1980).

Surgical correction of small intestine eventration in the pig is usually not economically feasible. If treatment is requested, preoperative medical management is often necessary, because these pigs are often in shock. Under general anesthesia, the intestine then is examined and most likely will have to be resected. A ventral midline incision then is made to occlude the lumen of the intestine that remained within the abdominal cavity, and the portion of the intestine that is going to the rectal laceration is resected close to the rectum. The viable end of intestine then is exteriorized through the ventral midline incision, and an end-to-end anastomosis performed (Peyton et al. 1980).

Bladder retroversion with rectal prolapse has been observed in a sow 2 days after normal farrowing (Greenwood 1989). The sow had a grapefruit-sized rectal prolapse with protrusion and tension of the perineal area. The bladder was drained by passage of a polypropylene catheter. One week postpartum, the prolapsed rectum was amputated. The sow reared nine piglets to 6 weeks of age and was sent for slaughter 1 week after weaning the piglets (Greenwood 1989).

MUSCULOSKELETAL SURGERY

Septic Arthritis
Septic arthritis may be caused by bacteremia, direct inoculation of bacteria into the joint, or extension of a local infection into the joint. Bacteremia and polyarthritis are discussed in Chapter 5. Septic arthritis caused by direct inoculation or local extension are treated by wound management, joint lavage, and systemic antibiotic therapy. Infected joints may require daily, or every other day, lavage for 7–10 days or until granulation tissue has covered the wound. Sterile isotonic electrolyte solutions (0.9% saline, lactated Ringer's solution) are lavaged through the joint by inserting an 18- or 14-gauge needle into the joint, injecting the solution under pressure into the joint, and inserting a second needle into the joint with as much separation as possible between the two needles. Approximately 500 ml of the solution are flushed through the joint. After lavage, antibiotics may be instilled directly into the joint to achieve maximal local antibiotic concentration. Success of treatment is assessed by improvement in lameness and wound appearance.

Digit Amputation
Digit amputation is indicated when severe foot abscesses or septic arthritis of the interphalangeal joints have caused unmanageable damage to a single digit. These injuries are most commonly caused by wounds from trauma on concrete flooring or metal side panels. The decision for amputation should not be delayed. If the infection has extended to the fetlock or more proxi-

mally on the limb, digit amputation will not be curative. Also, the soundness of the opposite digit should be assessed to determine if the pig will be able to ambulate on the remaining digit after amputation.

After induction of general anesthesia, the affected digit is cleaned and prepared for surgery. A tourniquet is placed proximal to the surgery site to prevent extensive hemorrhage during surgery. A circumferential incision is made through the skin and soft tissues at a 45° angle to the coronary band, starting at the axial aspect of the digit and continuing proximally to the abaxial surface. The skin is reflected proximal to the site for amputation, and a sterile obstetrical wire is used to amputate the digit. The third phalanx and a portion of the second phalanx is removed by this procedure. The remainder of the second phalanx also should be removed. The remaining tissues are debrided, cleaned thoroughly, and the skin is opposed over the wound. A sufficient opening is left to allow drainage or a Penrose drain is placed into the wound. The foot is placed in a padded bandage for 7–10 days. Then, the foot is cleaned daily with water until the wound is healed. Perioperative antibiotics and antiinflammatory drugs are indicated.

Ankylosis of the Proximal or Distal Interphalangeal Joint
Septic arthritis of the proximal or distal interphalangeal joint is an indication for digit amputation. However, the lateral claw of the hind limb is important to normal ambulation and breeding activity. Salvage of the digit by facilitated ankylosis is an option to preserve normal ambulation. The affected pig is placed under general anesthesia and the digit prepared for surgery. A 1 cm incision is made into the affected joint. The distal interphalangeal joint is approached by placing a 3.75 cm long needle into the joint by inserting the needle immediately proximal to the coronary band and inserting the needle distally. The proximal interphalangeal joint may be located by palpation or insertion of the needle in the midpastern region.

After the arthrotomy has been made, a 4 or 6 mm diameter drill bit is used to destroy the articular surfaces of the joint. Curettes are used to debride the joint and remove all infected subchondral bone. A distinct difference in texture and hardness will be noted between the necrotic (gritty and irregular) and healthy (smooth and hard) bone. Thorough curettage of all infected bone is critical to establishing effective joint ankylosis. The tissues are extensively lavaged with normal saline and antibiotics are administered for 10–14 days. Strict confinement for 6–8 weeks is needed for ankylosis to occur. A cast extending from the ground to the carpus or hock will hasten convalescence.

Fracture Repair
Swine with fracture of long bones are often salvaged because economic considerations preclude treatment.

However, veterinarians may be asked to treat fractures in swine of potential value for genetic improvement. Treatment of fractures can be rewarding and Vaughan (1966) reported clinical experiences with fracture fixation in commercial swine. Fractures were associated with breeding injury (2 pigs), injury on concrete flooring (3 pigs), fighting injury (1 pig), and were of unknown cause in 5 pigs. The most common fractures treated were tibia and fibula (5 pigs), femur (3 pigs), humerus (2 pigs), and tibiotarsal joint luxation with fracture of the fibula (2 pigs). Affected pigs weighed between 64 and 168 kg and were 6 months to 2 years old. Fractures of the tibia and fibula were treated by open reduction and internal fixation using a bone plate and a full limb cast (3 pigs) or by using a full limb cast alone (2 pigs). Fracture of the femur was treated by application of a bone plate (3 pigs). Humerus fractures were treated by confinement (1 pig) or by application of a bone plate (1 pig). Tibiotarsal joint luxation with fracture of the fibula was treated by application of a bone plate and use of a full limb cast (2 pigs). Of these 12 pigs, 10 returned to normal production use and 2 were salvaged; 1 pig with tibiotarsal joint luxation developed *Escherichia coli* osteomyelitis, and 1 pig with humeral fracture repaired by internal fixation suffered permanent radial nerve damage.

Surgical repair of articular fracture of the humeral condyles have been reported for miniature pigs (Figures 70.15 and 70.16) (Payne et al. 1995). The medial humeral condyle was most commonly fractured, but Y-type fractures and supracondylar fractures of the humerus have been found in some miniature pigs. Fractures were repaired using lag screw and Kirschner wire fixation. Five

70.15. *Medial condylar fracture of humerus in a Vietnamese pot-bellied pig.*

pigs were reexamined 2 months after surgery and all were walking sound at that time.

Femoral fractures were diagnosed in 20 pigs over a 6-month period (Rousseaux et al. 1981). Nutritional analysis revealed inadequate calcium and phosphorus (both in absolute concentration and calcium to phosphorus ratio) in the feed. Affected pigs were approximately 20 weeks old and weighed between 80 and 90 kg. Pigs walked with a stilted gait and arched back. Necropsy found separation of the proximal femoral epiphysis from the femoral neck. After correction of dietary calcium and phosphorus, clinical evidence of femoral fracture was not observed in any additional pigs. Femoral, pelvic, and vertebral fractures have been found in pigs after accidental electrical shock (Bildfell et al. 1991). Multiple trauma injuries and fractures associated with nutritional deficiency are poor candidates for surgical repair. Fracture of the greater trochanter of the femur also has been identified as causes of lameness in pigs (Blowey 1992, 1994). A simple, oblique fracture of the mid-diaphysis of the femur was successfully repaired in a 10-month-old 150 kg Berkshire boar using a bone plate (Grisel and Huber 1996). The boar returned to normal breeding 190 days after surgery.

CANINE TOOTH (TUSK) REMOVAL AND RESECTION

Removal of the canine teeth of adult boars is challenging because of the long dental root embedded in the mandible. Canine tooth extraction is done with the boar under general anesthesia. The gingiva and perios-

teum of the mandible are reflected laterally and ventrally using a periosteal elevator. Then the lateral alveolar plate of the tooth alveolus is resected following the course of the tooth root. After the periapical region of the alveolus has been reached, a periodontal elevator is used to disrupt the periodontal membrane around the circumference of the tooth and the tooth is removed. The alveolus is debrided, rinsed, and sutured closed. Alternatively, the alveolus can be left open to heal by second-intention healing.

Resection of the mandibular canine teeth is an easy and rapid method of preventing tusk injuries to personnel and other pigs. The boar is placed under general anesthesia and obstetrical wire is placed around the tooth. The wire is used to saw through the tooth approximately 3 mm above the gingival margin to prevent exposure of the pulp cavity. This procedure is repeated every 6–12 months as needed to restrict growth of the tusks.

Drug Therapy and Prophylaxis

Robert M. Friendship and John F. Prescott

This chapter gives an overview of some of the major drugs and biological agents used in swine, with a particular focus on antimicrobial drugs and the basic principles on which effective drug use are based.

USE OF DRUGS: MAJOR CONSIDERATIONS

Managing the effective use of drugs or biological agents for prevention and treatment of disease is an important responsibility of swine veterinarians, which involves detailed knowledge of these agents, including the risks involved in their use and the national and sometimes international regulations governing their use. The major regulatory and industry consideration is the production of safe, uncontaminated meat, followed by considerations of the welfare of the animals, cost, efficacy, and ease of application. However, many other factors need to be considered (Table 71.1) before implementing drug treatment or prophylactic use, with the underlying recognition that all such use involves a calculation that benefits of use exceed the risks involved in using most drugs or biological agents. The underlying goal is to make the minimum use of drugs in swine consistent with the production of healthy animals in a humane, cost-effective, and consumer and environmentally safe manner. Changes in swine production practices have reduced reliance on antimicrobial drugs, but there is still considerable room for further reduction in their untargeted use in many countries.

Routes of Drug Treatment

In general, individual animal treatment through injection is reserved for serious, rapidly developing infections such as acute systemic infections (septicemia, acute pneumonia, or streptococcal meningitis), but mass medication is preferred because of ease, efficacy, and lack of necessity to handle and disturb animals. Intramuscular (IM) injection is preferred for serious infections since it usually results in more complete absorption of drug and higher tissue concentrations than oral

administration. Parenteral therapy of individual animals by IM injection is administered just behind the ear on the lateral side of the neck. This site is chosen in case the drug preparation causes local tissue damage as well as to prevent the possible additional effect of sciatic nerve damage if the ham muscles were used.

Oral medication is easier to apply to groups of pigs and reduces injection-related problems of broken needles, abscesses, and tissue damage. Water medication is a more rapid method of treating a group of sick pigs than feed medication, with the advantages of immediate implementation and that sick pigs will drink when they will not eat. However, the disadvantages are that not all drugs are water soluble, that water may be spilled, and that some drug carriers may block nipple watering systems. Administration of drugs by water is through an in-line proportioner containing a concentrated drug solution or by a water tank containing the appropriately dosed drug. Pigs drink about 8–10% of their body weight daily (Table 71.2), depending on environmental temperature and palatability of the drug. An approximate rule is that pigs should be dosed through water at 5–6 liters (1.32 U.S. gallons) per 60 kg weight (145 lbs).

In-feed medication is the most common route of administration of anthelmintic and antimicrobial drugs. The disadvantage for treatment of acute infections is not only that sick pigs may not eat but also that existing nonmedicated feed needs to be either removed or eaten. For this reason, in-feed medication is often reserved for long term use in the prevention or treatment of chronic infections.

Principles of Treatment

The general principle of treatment is to maximize therapeutic efficacy while minimizing adverse effects such as toxicity, antimicrobial resistance, harmful tissue residues, or adverse environmental impact. This implies a confirmed or reasonable clinical diagnosis with the actual drug chosen according to the required purpose and administered to give optimal effect, consistent usually

Table 71.1. Considerations in drug use in swine

Major Consideration	Further Considerations
Human safety	Direct drug toxicity to user; toxicity to consumer through tissue residues.
Animal welfare	Prevention or reduction of disease; ease of administration for animal.
Host damage and adverse effects	Direct toxicity to pig; tissue damage; adverse drug interactions. Indirect adverse effects: resistance in microorganisms; disruption of microflora.
Regulations	Availability of products; national regulations on use; international regulations for export; extra-label drug use (AMDUCA in U.S.); veterinary-client relationship; withdrawal period.
Efficacy and cost	Assessment of efficacy; cost: benefit of treatment.
Drug dosage and application	Route, ease of administration; physicochemical properties; pharmacokinetic properties; pharmacodynamic properties.
Principles of treatment	Dosage; dosage modification; duration; clinical evidence; drug trial data.
Principles of prophylaxis	Dosage; duration; clinical evidence; drug trial data.
Record keeping	Drug use records.
Stability of drug	Storage conditions.

Table 71.2. Average daily water consumption

Weight or Type of Pig	Liters/Head/Day
7–20 kg body weight	2–4
20–50 body weight	4–6
50–100 body weight	6–8
Pregnant sow	8–12
Lactating sow	16–20

with labeled dosage and always within regulations concerning the use of the drugs. For antimicrobial drugs, discussed below, many of the principles of optimal treatment are well established. Duration of treatment depends on the drug and disease process but should be based on scientific data and/or on clinical experience.

Evaluation of Clinical Trials

The best method for evaluating animal health interventions and to guide clinical decision-making is to conduct on-farm clinical trials (Dohoo et al. 2003). In a clinical trial, exposure to disease occurs naturally and the pigs are housed and managed under normal farm conditions but the treatment is randomly assigned with a second group used as a control population. Clinical trials are difficult to conduct and there is considerable potential for errors in design and misinterpretation of findings. The consequences of these failings may be inappropriate therapeutic recommendations and overall lack of success in treatment programs. Practitioners need to be aware of proper methodology as it relates to design and interpretation in order to evaluate therapeutics either by conducting a trial on a client's farm, or in interpreting claims for a new drug as presented by a pharmaceutical company.

First, a study should have a limited number of objectives, generally one primary and possibly two or three secondary objectives, and these must be clearly stated (Dewey 1999). For example, a trial examining the use of a drug to control pneumonia in a finishing unit might have decreased mortality as its primary objective, and as

secondary objectives the researchers may be interested in improved growth rate and reduced weight variation. The design of the trial would likely be different if the primary objective was reduced weight variation.

Other important elements of a clinical trial include a defined study population, random allocation of subjects, masking or blinding of the observer, thorough follow-up, and appropriate analysis (Dewey 1999). A common error in the design of a trial is to base the statistical analysis on individual pigs but to assign treatments on the basis of pen or even barn. Statistical analysis should be conducted at the smallest level at which the treatment can be applied. Therefore, in a feed trial where all the pigs in a pen are assigned one feed and all the pigs in the next pen are given a second feed, the pen is the unit of concern. The number of animals or pens or barns required to assess whether a drug is beneficial or not can be calculated using formulas that can be found in standard statistics text books. The number of units will depend on the variation you expect and the magnitude of the difference you consider important. For example, if one assumes a coefficient of variation (mean ÷ standard deviation) of 7% for growth rate, one would need approximately 43 pens per treatment to detect a difference in average daily gain of 5%. Whereas it would require only 12 pens per treatment to detect an average daily gain of 10%.

Typically, the confidence interval is chosen to be 95%, implying that the probability that the results were real and not due to chance alone is 95%. The P-value or level of significance is the opposite (i.e., P = 0.05 means there is a 5% chance that the results are due to chance alone). Statistical power is typically set at 80%, implying that there is an 80% probability that we will find a difference when a difference truly exists. Therefore, 20% of the time such a trial will not distinguish a difference between treatment and control when there really is a difference. Statistical power can be increased by increasing sample size.

It is important that bias is minimized wherever possible. Therefore, subjects need to be assigned to a treat-

ment group in a truly random manner, and if this is not possible, an alternatively systematic assignment may be used. The intervention given to the control group needs to be similar to the treatment group. For example, if the treatment group needs to be restrained and injected with a product, the controls need to be handled in a similar manner and given a placebo. Ideally, the animal care givers and whoever records the clinical observations should be kept blind to which animals are in the treatment group and which are in the control group.

Even when animals are assigned in a random manner and trials are carefully designed, confounding factors and other sources of error can be introduced so that a great deal of care is needed in assessing the information gained from a clinical trial, but this is still the best basis to judge efficacy of therapeutic measures, and no amount of in vitro studies can match the value of this type of on-farm assessment.

ANTIMICROBIAL DRUGS

Major Classes of Antimicrobial Drugs

A brief overview of some key aspects of the major classes of antimicrobial drugs, their antimicrobial activities, pharmacokinetic properties, toxic or other adverse effects, and major clinical applications is given in Table 71.3. Further details are available through manufacturer's package inserts or through pharmacology and related textbooks (Prescott et al. 2000).

Antimicrobial Therapy

Rational use of antimicrobial therapy first requires a diagnosis. This may be made clinically and preferably confirmed by laboratory diagnosis, which would include antimicrobial susceptibility testing. Antimicrobial treatment will, however, usually start before laboratory results are available. The selection of a particular drug depends on knowledge of the likely or actual susceptibility of the microorganism, knowledge of factors affecting drug concentration (dosage, pharmacokinetic properties) and activity (pharmacodynamic properties) at the site of infection, knowledge of drug toxicity and factors that enhance it, cost of treatment, and consideration of regulations about drug use, including withdrawal times. The ideal drug is one to which the organism is most susceptible and that achieves effective concentration at the site of infection without damaging the host. Bactericidal drugs are required in serious life-threatening infections, when host defenses are impaired, and in infections of vital tissues such as meninges, endocardium, and bones where host defenses are also not fully functional. In other cases bacteriostatic agents may be equally useful. Where feasible, a narrow spectrum drug may be more appropriate than a broad spectrum antibacterial because the narrow spectrum drug interferes less with the normal microbial flora and is less likely to select for widespread resistance.

To some extent, drug dosage can be tailored to the susceptibility of the organism, the site of infection, and the pharmacokinetic and pharmacodynamic properties of the selected antimicrobial agent. However, in vitro susceptibility data are laboratory-derived and the standardized conditions under which the susceptibility data are generated do not exist at the site of infection. Factors involved in tailoring a dosing regimen include, among other things, the susceptibility of the pathogen in terms of minimum inhibitory concentration (MIC), the concentration of the antimicrobial agent at the site of infection in active form (pharmacokinetic properties of the drug), and the pharmacodynamic properties of the antimicrobial agent. Some antimicrobials (aminoglycosides, fluoroquinolones) are concentration-dependent (optimum action of the drug depends on concentration of the drug above MIC), whereas others (beta-lactams, lincosamides, macrolides, trimethoprim-sulfamethazine) are time-dependent (optimum activity depends on time above MIC). The complex issues involved in optimal antimicrobial therapy are beyond the scope of this chapter although it can be concluded that some dosage recommendations for drugs licensed in the past have not taken modern understanding into account and are suboptimal or inappropriate. Labeled recommendations can therefore be expected to change in the future. In the United States, the Food and Drug Administration's professional flexible labeling approach allows veterinarians to adjust the dose based on the MIC of the pathogen. Although a number of factors determine optimal dosage, the factor that most frequently limits dosage is toxicity. The upper level of the recommended dosage should not be exceeded, because this is often determined by toxicity. Sometimes, however, a drug's antibacterial effects may be limiting and may determine the upper level of dosage. For example, the killing rate of beta-lactam drugs has an optimal concentration, whereas that of the aminoglycosides or fluoroquinolones is proportional to drug concentration. Penicillin G is virtually nontoxic in nonallergenic patients, but its dosage is limited by its antibacterial action. By contrast the dosage of aminoglycoside is limited not by antibacterial effects but by its toxicity.

In terms of duration of treatment, the variables affecting length of treatment have not been defined. Responses of different types of infections to antimicrobial drugs vary, and clinical experience with many infections is important in assessing response to treatment. For acute infections, it will usually be clear within 2 days whether or not therapy is clinically effective. If no response is seen by that time, both the diagnosis and treatment should be reconsidered. Treatment of acute infections should be continued for at least 2 days after clinical and microbiologic resolution of infection. For serious acute infections, treatment should probably last 7–10 days. For chronic infections, treatment will be considerably longer.

Table 71.3. Overview of major classes and identities of antimicrobial drugs used in swine, their antimicrobial activities, pharmacokinetic properties, toxic or other adverse effects, and major clinical applications

Drug Class	Specific Agent or Example of Agents	Antibacterial Activity, Resistance	Pharmacokinetic Properties	Toxic or Adverse Effects	Major Applications
Sulfonamides	Sulfamethazine intermediate acting; others also used	Bacteriostatic; broad-spectrum, gram+, gram− aerobes; anaerobes; acquired resistance very widespread. Active intracellular bacteria, protozoa	Rapidly absorbed from intestine, well distributed in tissues	Violative kidney residues from feed use through recycling, feed contamination if feed not withdrawn 15 days before slaughter	Minor value; largely growth promotional, possible disease prevention
Sulfonamide-diaminopyrimidine combinations	Sulfamethazine-trimethoprim	Bactericidal; gram+, gram− aerobes; anaerobes. *Mycoplasma*, *Leptospira* resistant	Rapidly absorbed from intestine, well distributed in tissues; crosses uninflamed blood-brain barrier	Wide safety margin	Largely IM use for acute infections (pneumonia, streptococcal meningitis). In feed for atrophic rhinitis
Beta-lactam	Penam penicillins, Group 1: Penicillin G	Bactericidal; highly active many gram+, some fastidious gram− aerobe, e.g., *H. parasuis*, *P. multocida*; anaerobes; *Leptospira*. Enteric bacteria and *Mycoplasma* resistant	Poorly absorbed from intestine, relatively poorly distributed in tissues; crosses only inflamed blood-brain barrier. Procaine penicillin is long-acting form for IM use since unconjugated drug rapidly excreted	Safe drug; possible anaphylaxis or procaine-induced excitement	Excellent for IM use in erysipelas, streptococcal infections including meningitis, clostridial infections. Some bacterial pneumonias
Beta-lactam	Penam penicillins, Group 4: ampicillin, amoxycillin	As penicillin G, broader activity against gram− aerobes, but resistance widespread	As penicillin G, but better absorbed orally and distributed through tissues	Safe drug	Similar to penicillin G. Addition of beta-lactamase inhibitors (e.g., clavulanic acid) has resurrected penam penicillins use in other species
Beta-lactam	Group 4, "third generation" cephalosporins; ceftiofur	Bactericidal; gram− aerobes especially, including *E. coli*, *Salmonella*, gram+ aerobes, anaerobes. *Mycoplasma* resistant	Poorly absorbed from intestine, relatively poorly distributed in tissues; crosses only inflamed blood-brain barrier	May predispose to *Clostridium difficile* colitis if used in neonatal pigs. Resistance emerging in *Salmonella* may represent human health hazard	Excellent for IM use in gram− aerobic infections, including colibacillosis, salmonellosis, gram− bacterial pneumonias
Aminoglycoside	Gentamicin, neomycin	Bactericidal; gram− aerobes, including enterics	Poorly absorbed from intestine, relatively poorly distributed in tissues	Nephrotoxic with prolonged parenteral use; persistent kidney residues	Gentamicin IM for neonatal *E. coli* infections; neomycin orally for *E. coli* infection
Aminocyclitol	Apramycin, spectinomycin	Bactericidal; gram− aerobes, including enterics	Poorly absorbed from intestine, relatively poorly distributed in tissues	Nephrotoxic with prolonged parenteral use; persistent kidney residues	Orally for *E. coli* infection
Lincosamide	Lincomycin	Bacteriostatic; gram+ aerobes, anaerobes including *B. hyodysenteriae*; *Mycoplasma*	Well absorbed from intestine and well distributed in tissues	Safe drug in swine	Oral use for control of *Brachyspira*; oral or IM use for control of *Mycoplasma*
Macrolide	Tylosin	Bacteriostatic; gram+ aerobes, anaerobes, some gram− aerobes; *Mycoplasma*	Well absorbed from intestine and well distributed in tissues	Safe drug in swine; IM irritant, may cause edema, pruritis, anal protrusion	Oral use for control of proliferative enteropathy, atrophic rhinitis, possibly leptospirosis

Table 71.3. *(continued)*

Drug Class	Specific Agent or Example of Agents	Antibacterial Activity, Resistance	Pharmacokinetic Properties	Toxic or Adverse Effects	Major Applications
Pleuromutilin	Tiamulin	Bacteriostatic; gram+ aerobes, anaerobes, some gram− aerobes; *Mycoplasma*. More active than tylosin	Well absorbed from intestine and well distributed in tissues	Safe drug in swine	Oral use for control of *Brachyspira, Mycoplasma*, chronic pneumonias, proliferative enteropathy, leptospirosis
Tetracyclines	Oxy-, Chlor-, tetracycline	Bacteriostatic; classically broad-spectrum, gram+, gram− but acquired resistance extremely widespread. *Erysipelothrix, Haemophilus, Leptospira, Pasteurella* are exceptions	Well absorbed from intestine and well distributed in tissues	Safe drugs in swine	Oral use as "feed" drugs for growth promotion and nonspecific disease prophylaxis in countries where allowed. Used in feed, occasionally IM, for treatment of infections caused by bacteria listed as being susceptible

Treatment failure has many causes. The antimicrobial selected may be inappropriate because of misdiagnosis, inactivity at the site of infection, failure to culture infections, inaccurate or inapplicable laboratory results, resistance of pathogens, chronic nature of the infection (which may affect metabolic state of the pathogen), or errors in sampling. These factors are more likely to cause failure than inadequate dosage although this may also be important. It is important that producers comply with dosing instructions. When failure occurs, diagnosis must be reassessed and samples collected for laboratory analysis.

Principles of Prophylaxis

Antimicrobial drugs are administered to swine for the prevention of particular diseases. The generally accepted principles of antimicrobial prophylaxis are:

- Medication should be directed against specific pathogens or diseases.
- Prophylaxis should be used only where efficacy is established. Prophylaxis should be of a duration that is as short as possible consistent with efficacy.
- Dosage should be the same as that used therapeutically.
- Adverse effects itemized earlier should be minimized.

In general, as discussed below, antimicrobial drugs of therapeutic importance in both humans and animals have been markedly overused for both growth promotional and disease prophylactic purposes in swine, in a manner inconsistent with generally accepted principles of prophylaxis. Alternatives to these antimicrobial use practices need to be found, as discussed below.

One reasonable prophylactic practice is that of "pulse medication," whereby a therapeutic level of a specific drug is included in the feed at therapeutic concentrations for a short period for the prevention of endemic diseases, such as proliferative enteropathy or enzootic pneumonia before the predictable onset of these diseases in a particular setting.

Regulations

The use of antimicrobial drugs in animals is regulated by law in many countries, so that veterinarians need to know and abide by the regulations. The regulations involve an approval process of drugs produced by a particular manufacturer only if they meet human and animal safety standards as well as being shown to be efficacious at specified dosages for particular purposes (the labeled dose/purpose). An example of regulated use of antimicrobial drugs, that of the United States, is outlined in Table 71.4. In the United States, failure to comply with the regulations may result in fines or imprisonment.

Antimicrobial Drug Withdrawal

Most antimicrobial drugs must not be used near slaughter, to avoid any significant residues in meat products. The precise period varies with the drug and the dosage. For drugs used at the labeled dosage, this will be specified on the package insert. For extra-label drug use, withdrawal information may be obtained from the manufacturer or in some cases from national or international databases such as, in the United States, the Food Animal Residue Avoidance Databank (toll-free number in the United States, 1-800-USFARAD). Examples of preslaughter medication withdrawal time in the United States are shown in Table 71.5.

Table 71.4. Regulation of antimicrobial drug use for food animals in the United States.

Drug Category or Regulation	Description
Production feed drugs	Growth promotion and feed efficiency including subtherapeutic or therapeutic use for specified purposes in feed. Strict dose, duration, withdrawal period specified. Nonprescription.
Over-the-counter drugs	Drugs for oral or parenteral use available without prescription. Strict dose, duration, withdrawal period specified.
Prescription drugs	Veterinary prescription parenteral use only. Strict dose, duration, withdrawal period specified.
Professional flexible labeling	Approved products have expanded dosage ranges for veterinarian use.
Veterinary Feed Directive	Used in feed only under direction of a veterinarian. Strict recording requirements.
Extra-label use	Regulation under Animal Medicinal Drug Clarification Act (AMDUCA) when actual or intended use of a drug is not in accordance with approved labeling. Only when available labeled products ineffective. Strict recording and other requirements, including prohibited uses.

Table 71.5. Examples of preslaughter withdrawal times from last medication for swine in the United States

Dosage Form	Drug for Labeled Use	Days
Parenteral drug	Ceftiofur	0
	Gentamicin (neonatal pigs only)	40
	Procaine penicillin	7
Oral, water-soluble drugs	Bacitracin	1
	Chlortetracycline	5
	Neomycin	20
	Tylosin	2
Oral, feed forms (maximum time may vary with dose)	Apramycin	28
	Chlortetracycline, procaine penicillin, sulfamethazole	15
	Tiamulin	0–2

The Antimicrobial Resistance Crisis and Its Impact on Antimicrobial Drug Use in Swine

There is both need and considerable scope to reduce the use of antimicrobial drugs in swine. Human medicine is experiencing an antimicrobial resistance crisis because of the surge of resistance in important human pathogens in the last decade. The emergence of this crisis has resulted from many causes, including widespread use and overuse of some drugs for many years, changing social practices including daycare centers and group homes for the elderly, the increasing number of immunosuppressed people, and possibly changes in the drugs being used. As medical science tries to reduce resistance, it again focuses on the widespread use of antimicrobial drugs in farm animals. Agriculture uses about half of all antimicrobials produced, with use in swine being a major component. Why antimicrobials can be administered to animals on a wide scale over long periods to promote growth and prevent endemic disease cannot be understood by physicians desperate to preserve effective antimicrobials. The extent of the contribution of farm animal use to resistance in human pathogens has been the subject of vigorous debate for many years. Although it is easy to document that bacteria, including resistant bacteria, move from farm animals including swine to people, the scale and to some extent the importance of the movement is unclear. The extent and type of resistance in commensal *E. coli* isolated from swine has been shown to be directly propor-

tional to the extent and type of antimicrobial use in pigs (Dunlop et al. 1998). On a broader scale, the use of antimicrobial drugs over many years may not only have selected for resistant bacterial pathogens and an enormous reservoir of resistance genes in commensal bacteria, but it may also have promoted or enhanced the ability of bacteria to move resistance and other genes through enhancement of mobile genetic elements such as transposons, plasmids, and integrons, and thus perhaps to change more rapidly. There is a high frequency of resistance to multiple antimicrobial drugs in porcine enterotoxigenic *E. coli*, with some evidence that the emergence of resistant new serotypes with apparently enhanced virulence may have virulence genes linked to those of resistance (Noamani et al. 2003), so that use of antimicrobial drugs may not only maintain resistant but also virulent bacteria.

In 1999, the European Union banned the use of growth-promoting antimicrobial drugs in food animals. The impetus for the ban on avoparcin, bacitracin, spiramycin, tylosin, and virginiamycin was because of the entry of Sweden into the Union. Sweden had banned these growth promoters in 1986 but, because it needed to harmonize its regulations with those of the EU, it persuaded the EU to change the Union's regulations. This ban was supported by Denmark and Danish pork producers, who had agreed on a voluntary ban shortly before 1999. The impetus for the Danish ban was the convincing evidence that avoparcin use in poultry, swine, and calves

was selecting for vancomycin-resistant enterococci (VREs), which were reaching the European population through the food chain (Bager et al. 1997). Vancomycin-resistant enterococci have become major nosocomial pathogens in human hospitals, particularly in the United States. *Enterococcus faecium* are innately highly resistant bacteria for which vancomycin is often the only drug to which they are susceptible; VREs are essentially untreatable infections. The ban on these growth promoters in Denmark led to an over 50% reduction in antimicrobial drug use, a dramatic reduction in enterococci resistant to the growth promoters and a minor increase in the cost of production of swine estimated at about one Euro (World Health Organization 2002).

Numerous reports have recommended that all stakeholders concerned with the use of antimicrobials in both food animals and humans must be involved in an overarching global strategy to contain resistance (e.g., World Health Organization 2000a) and have recommended steps to enhance the prudent use of antimicrobials in animals, including the removal of growth promoters if these drugs are important in human medicine (e.g., World Health Organization 2000b). At the international level, the World Organization for Animal Health (Office International des Epizooties) (2003, 2004) continues to formulate recommendations and options for risk management relating to antimicrobial use in animals. Outside the EU, other countries are in the process of assessing or starting to reassess the use of antimicrobial drugs in food animals based on the importance of the drug in human medicine and the likelihood of exposure of humans to resistant bacteria or resistance genes arising from animals (e.g., Health Canada 2002; Center for Veterinary Medicine, U.S. Food and Drug Administration 2004).

In recent years many countries have started to monitor resistance in both important pathogens (e.g., *Campylobacter jejuni*, *Salmonella*) as well as "indicator" commensal bacteria (e.g., *Enterococcus* species) isolated from animals, foodstuffs, and humans. For example, in the United States the National Antimicrobial Resistance Monitoring System (NARMS) established in 1996 is designed to document emerging resistance problems, as well as to provide data on which public health policy decisions can be made for the use of antimicrobial drugs in food-producing animals. In Canada, the Canadian Integrated Program for Antimicrobial Resistance Surveillance has taken a similar approach to NARMS.

One emerging resistance problem that will likely become of even greater concern in the future is expanded-spectrum cephalosporin resistance in multidrug-resistant *E. coli* and *Salmonella* serovars (Winokur et al. 2001; Zhao et al. 2003), in which the *cmy-2* gene encoding expanded-spectrum cephalosporin resistance may be found on several different plasmids that can readily be transferred through bacterial conjugation (Caratolli et al. 2002).

Prudent Use Guidelines

The widespread concern about antimicrobial resistance and the animal-human resistance link has led most major national veterinary organizations to improve antimicrobial drug use by development of prudent use guidelines. Such guidelines represent first steps in the more judicious use of antimicrobial drugs that may become considerably more complex over time if they address antimicrobial drug choice for particular diseases. An example of such guidelines, that of the American Association of Swine Veterinarians, is shown in Table 71.6.

Drug Selection for Specific Diseases

Table 71.7 contains recommendations for treatment of specific bacterial disease conditions commonly encountered in North America. It is beyond the scope of this

Table 71.6. American Association of Swine Veterinarians Basic Guidelines of Judicious Therapeutic Use of Antimicrobials in Pork Production

(1) Preventive strategies, such as appropriate husbandry and hygiene, routine health monitoring, and immunization, should be emphasized.
(2) Other therapeutic options should be considered prior to or in conjunction with antimicrobial therapy.
(3) Judicious use of antimicrobials, when under the direction of a veterinarian, should meet all requirements of a veterinarian-client-patient relationship.
(4) Prescription, Veterinary Feed Directive, and extra-label use of antimicrobials must meet all the requirements of a valid veterinarian-client-patient relationship.
(5) Extra-label antimicrobial therapy must be prescribed only in accordance with the Animal Medicinal Drug Use Clarification Act amendments to the Food, Drug, and Cosmetic Act and its regulations.
(6) Veterinarians should work with those responsible for the care of animals to use antimicrobials judiciously regardless of the distribution system through which the antimicrobial was obtained.
(7) Regimens for therapeutic antimicrobial use should be optimized using current pharmacological information and principles.
(8) Antimicrobials considered important in treating refractory infections in human or veterinary medicine should be used in animals only after careful review and reasonable justification. Consider using other antimicrobials for initial therapy.
(9) Utilize culture and susceptibility results to aid in the selection of antimicrobials when clinically relevant.
(10) Therapeutic antimicrobial use should be confined to appropriate clinical indications.
(11) Therapeutic exposure to antimicrobials should be minimized by treating only for as long as needed for the desired clinical response.
(12) Limit therapeutic antimicrobial treatment to ill or at risk animals, treating the fewest animals indicated.
(13) Minimize environmental contamination with antimicrobials whenever possible.
(14) Accurate records of treatment and outcome should be used to evaluate therapeutic regimens.

Note: The AASV website elaborates on these basic guidelines listed above (http://www.aasp.org/aasv/jug.html).

Table 71.7. Antimicrobial drug selection for specific bacterial diseases (Warning—These dosages may not conform to government regulations or label instructions.)

Diagnosis	Causative Agent	Comments	Suggested Drug(s)
ENTERIC DISEASES			
Clostridial enteritis	*Clostridium perfringens* type A and C	Treatment of sick piglets affected with type C is not effective. Medicate sows to reduce shedding.	Bacitracin in sow diet (100 gm per ton of feed) Ampicillin (6 mg/kg, oral)
Coccidiosis	*Isospora suis*	Treatment must begin before diarrhea occurs (3- to 6-day-old piglets).	Toltrazuril (20–30 mg/kg, oral) Amprolium 9.6%, (2 ml per piglet/day for days 3–5)
Colibacillosis	*Escherichia coli*	Neonatal piglets must be treated promptly and provision of electrolytes helps minimize effects of dehydration. Post-weaned pigs best treated with antibiotics in water.	*Neonates:* Gentamicin (5 mg per kg, oral) Neomycin (7 mg per kg, oral) Spectinomycin (50 mg twice a day) *Weanlings:* Apramycin (12.5 mg/kg per day, in water)
Colitis	*Brachyspira pilosicoli*	Disease is often mild and responds to change in feed, but if more severe, treat in similar fashion to swine dysentery	
Proliferative enteropathy	*Lawsonia intracellularis*	All-in/all-out management and good hygiene may minimize the need for antibiotics. Feed medication can prevent clinical signs.	Tylosin (100 g per ton of feed) Lincomycin (100 g per ton of feed) Tiamulin (35 g per ton of feed)
Salmonellosis	*Salmonella typhimurium* and other serovars	Antimicrobials may be contraindicated in that they prolong shedding and promote resistance.	
Swine dysentery	*Brachyspira hyodysenteriae*	Resistance against older drugs is common. Treatment for extended period after clinical signs disappear is necessary. Water medicate in acute outbreak.	Tiamulin (200 g/ton of feed to treat) (35 g/ton to prevent) Carbadox (50 g/ton of feed)
MULTISYSTEMIC DISEASES			
Actinobacillus Septicemia	*Actinobacillus suis*	*A. suis* is sensitive to most antibiotics but disease occurs acutely so treatment may not be in time.	Procaine penicillin G 20,000 IU/kg IM
Erysipelas	*Erysipelothrix rhusiopathiae*	Resistance to penicillin does not appear to be a problem.	Procaine penicillin G 20,000 IU/kg IM but also tylosin, tetracyclines, or lincomycin
Glasser's disease	*Haemophilus parasuis*	High dosages, administered parenterally to all members of the affected group. Some resistance to penicillin.	Procaine penicillin G 20,000 IU/kg IM or higher Ceftiofur, 3 mg/kg IM Trimethoprim-sulfadoxine 16 mg/kg IM
Mycoplasma polyserositis	*Mycoplasma hyorhinis*	High dosages, administered parenterally, but results tend to be poor.	Lincomycin 10 mg/kg IM Tylosin 9 mg/kg IM Tiamulin 11 mg/kg IM
Salmonellosis	*Salmonella choleraesuis*	Vigorous treatment early can reduce duration and severity.	Ceftiofur 3 mg/kg IM Trimethoprim-sulfadoxine 16 mg/kg IM
MUSCULOSKELETAL DISEASES			
Foot rot	*Arcanobacterium pyogenes* *Fusobacterium necrophorum*	Improved flooring and sanitation. Topical disinfectants may help. Generally poor response to treatment.	Procaine penicillin G 20,000 IU/kg IM Oxytetracycline 6.6 mg/kg IM
Mycoplasma arthritis	*Mycoplasma hyosynoviae*	Injectable antibiotics and possibly corticosteroids.	Lincomycin 10 mg/kg IM Tiamulin 11 mg/kg IM Tylosin 9 mg/kg IM
Neonatal polyarthritis	*Staphylococcus* spp. *Streptococcus* spp. and others	Treatment is ineffective unless started early.	Procaine pencillin G 20,000 IU/kg IM
Suppurative arthritis	*Arcanobacterium pyogenes*	Treatment is generally ineffective.	Procaine penicillin G 20,000 IU/kg IM Oxytetracycline 6.6 mg/kg IM
NEUROLOGICAL DISEASES			
Edema disease	*Escherichia coli*	Sick pigs eat and drink very little and must be treated parenterally.	Trimethoprim-sulfadoxine 16 mg/kg IM Ceftiofur 3mg/kg IM
Otitis media (Middle ear infection)	*Staphylococci* spp. *Streptococci* spp. *Arcanobacterium pyogenes*	Abscesses can occur and relapses are common.	Trimethoprim-sulfadoxine 16 mg/kg IM Ceftiofur 3 mg/kg
Tetanus	*Clostridium tetani*	Poor prognosis.	

1138

Table 71.7.   (*continued*)

Diagnosis	Causative Agent	Comments	Suggested Drug(s)
REPRODUCTIVE DISEASES			
Leptospirosis	*Leptospira* spp.	Antibiotics may not eliminate carrier state.	Streptomycin 25 mg/kg IM Chlor or oxytetracycline at 600–800 g/ton of feed

Mastitis and/
  or metritis
	Generally gram-
	  negative bacteria
		Attention needs to be paid to cross-fostering
		  piglets. Treatment varies depending on
		  microorganism and sensitivity.
			Ampicillin 6 mg/kg IM

RESPIRATORY DISEASES			

Enzootic pneumonia	*Mycoplasma hyopneu-
	  moniae* and secon-
	  daries
		Preferably sick animals are treated parenter-
		  ally to achieve high tissue levels.
			Oxytetracycline 6.6 mg/kg
			  Trimethoprimsulfadoxine 3 mg/kg IM
			Ceftiofur 3 mg/kg IM
			Tulathromycin 2.5 mg/kg IM

Pleuropneumonia	*Actinobacillus pleuro-
	  pneumoniae*
		Parenteral treatment because acutely sick
		  pigs eat and drink very little.
			Same as above
			Tilmicocin (181–363 g/ton of feed)

Progressive Atrophic
  Rhinitis
	Bordetella bronchiseptica
	  and toxigenic strains
	  of *Pasteurella multocida*
		Responsive to housing/management and
		  vaccination programs.
			Oxytetracycline 20 mg/kg IM
			Sulfamethazine 400–2000 g/ton of feed
			  in nursery ration

SKIN DISEASE			

Exudative epidermitis
  (Greasy pig disease)
	Staphylococcus hyicus	May see resistance to penicillin, need to
		  treat fresh wounds topically.
			Procaine penicillin G 20,000 IU/kg IM

URINARY TRACT DISEASE			

Cystitis	*Actinobaculum suis* and
	  possibly others
		Relapses are common.	Procaine penicillin G 20,000 IU/kg IM
			Ampicillin 6 mg/kg IM
			Chlor or oxytetracycline 600–800
			  gm/ton of feed

text to discuss all product indications and cautions, but the user should always review the information provided by the package insert and the product label. Nor is it within the scope of this text to include all possible treatment options; instead, this table should be considered a general guideline.

ALTERNATIVES TO ANTIMICROBIAL DRUGS

Management and Biosecurity

Modern housing and husbandry methods that tend to segregate age groups, allow for cleaning of the environment between production groups, and minimize the risk of disease introduction through strict biosecurity measures, are the most important methods of reducing the use of antimicrobials and other therapeutic products. Immune system stimulation results in decreased feed efficiency and growth rate whether or not clinical disease occurs. The value of in-feed antibiotics is questionable when high-health status grower-finisher pigs are raised in a clean, biosecure environment (Van Lunen 2003). However, even under ideal management there are circumstances when treatment is required and success of therapy very much depends on the diligence of stockpeople to identify clinical signs of illness early, to treat appropriately, and to provide an environment for the sick pig that promotes healing.

Vaccines

Vaccines are extensively used in swine production, and in fact there are few diseases for which a vaccine is not available. Unfortunately, the fact that a vaccine is licensed and available does not mean it works (Ribble 1990). The usefulness of vaccination varies from disease to disease and even from herd to herd. Despite rapid advances in the fields of immunology and molecular biology there are still diseases for which vaccines have only moderate to poor efficacy (Haesebrouck et al. 2004). Details of the mechanisms of pathogenesis and immune response are covered elsewhere in this text.

There are a number of important considerations that a veterinarian needs to evaluate in order to decide upon a vaccination program for a particular herd. The cost-benefit of vaccination needs to be considered, and this includes estimating the cost of the program, including labor to administer the vaccine; estimating the improvement one would expect from the vaccination program, which requires a knowledge of the vaccines efficacy and an understanding of the disease costs present in the herd; and evaluating the value of alternative control measures. In addition, the veterinarian needs to be aware of possible negative side effects, such as a potential tissue reaction that might lead to trimming losses or a transient loss of appetite that could cause a reduction in growth.

The decision to institute a vaccination program is complex, and unfortunately there is a scarcity of unbiased data regarding the efficacy of vaccines used under practical farm conditions (Moon and Bunn 1993). There are good examples of vaccines that have worked well in controlled experimental infection models but are of no value in the field. Many of the important diseases of swine are a complex of one or more infectious agents and of host, environmental, and management factors.

Swine practitioners are sometimes faced with an unexpected vaccination failure in a situation when using a product that has worked well under similar circumstances in the past. Possible causes of a failure include improper storage and handling of the vaccine, such as failure to refrigerate or protect from light; incorrect administration, such as subcutaneous injection when an intramuscular injection is required; or possibly omitting to vaccinate whole groups of animals. In the case of vaccines administered via the drinking water, there are a number of concerns but possibly the most important is chlorine present in the water, which may kill live attenuated bacteria in vaccines (Kolb 1996).

Timing of a vaccination program is often a problem. In order to maximize compliance and minimize labor, the swine industry prefers to use combination vaccines that require a single injection to be given at a time when animals are ordinarily handled (such as at weaning). Among the problems associated with this approach is the concern that for newly weaned pigs there may still be high levels of passive immunity present to interfere with the stimulation of immunity from vaccination. Therefore, one has to weigh the consequences of vaccinating at a time of greatest convenience versus the extra labor costs and stress to the animals of vaccinating at the most appropriate time to ensure vaccine efficacy.

Passive Immunity

Spray-dried animal plasma has been widely used in diets for newly weaned pigs and is associated with increased growth rates in the order of 27% (van Dijk et al. 2001). The mode of action of spray-dried animal plasma is not fully understood but is assumed to be at least partly due to the presence of immunoglobulins, which may provide a certain level of protection to the newly weaned piglet at a time when the supply of immunoglobulins from sow's milk has ceased. The ability of plasma proteins to neutralize the effect of specific organisms is dependent on the immunizations and disease history of the pigs from which the blood is collected.

Specific antibodies from chicken egg-yolk have been examined as a source of passive immunity for newly weaned pigs as well. Laying hens are vaccinated against specific pig pathogens such as *E. coli*. Antibodies are secreted into the yolk of the egg (IgY) in large quantities (up to 200 mg/egg) (Marquardt and Li 2001), and dried yolk is incorporated in nursery pig rations. Trials using

specific egg-yolk products to prevent postweaning *E. coli* diarrhea have produced inconsistent results (Chernysheva et al. 2004). Stability of the product during feed processing and passage through the pig's gastrointestinal system are major concerns.

Other Biological Products

Direct-Fed Microbials (Probiotic). Probiotics are defined as live microbials provided in the feed in an attempt to encourage proliferation in the intestine of the specific microorganism fed with the objective of providing health benefits to the host animals (Fuller 1989). The most commonly used probiotics include species of *Lactobacillus*, *Enterococcus*, *Bifidobacterium*, and *Saccharomyces* (Alverez-Olmos and Oberhelman 2001; Holzapfel et al. 2001; Rolfe 2000). Most studies involving probiotics have concentrated on improving intestinal health, particularly during the weaning period when the pig gut microflora undergoes dramatic change.

It is generally accepted that with careful attention to the criteria used to select the particular probiotic strain, there may be a place for probiotics in prevention of enteric disease, but results to date are inconsistent. There are a number of criteria that potential probiotic strains must meet in order to be considered for use as a probiotic, including the ability to demonstrate predictable and measurable health benefits. The screening and selection of a probiotic includes testing in vitro or in vivo of the following criteria:

- It must be nonpathogenic and proven safe.
- It must have stability in an acid environment, in the presence of bile, and resistant to degradation by digestive enzymes.
- It must adhere to gut epithelial tissue and be able to persist in the gastrointestinal tract of the host.

In addition, the microbials used as probiotics must retain viability and stability during commercial production, feed processing, storage, and delivery, and must be cost-effective.

The main mechanisms whereby probiotics exert protective or therapeutic effects are not fully understood, but several ways have been postulated. Probiotics produce antimicrobial substances such as organic acids, fatty free acids, ammonia, hydrogen peroxide, and bacteriocins (Alverez-Olmos and Oberhelman 2001). In addition, probiotics may enhance specific and nonspecific host immunity (Kailasapathy and Chin 2000), and probiotics may prevent colonization of pathogenic microorganisms by competitive inhibition for microbial adhesion sites.

Inconsistent findings have been observed when probiotics have been used in trials to control pig disease or improve growth performance (Conway 1999). It is unlikely they will be capable of replacing antibiotics in the control of disease but they may have a place alongside

other techniques for improving the health of the gut microflora and reducing the shedding of pathogens such as *Salmonella*.

There is considerable interest in the use of fermented liquid feed and there appears to be an association between its use and a reduction in *Salmonella* prevalence (van der Wolf et al. 2001). A possible explanation for the beneficial effect of fermented liquid feed is that the reduced pH of the diet and the presence of large numbers of organic acid producing bacteria in the feed have a positive effect on the gut microflora and create an environment unsuitable for *Salmonella* and other coliform bacteria.

Bacteriophages. Bacteriophages or phages are bacterial viruses that invade bacterial cells and in the case of lytic phages, disrupt bacterial metabolism and cause the bacterium to lyse (Sulakvelideze et al. 2001). From a clinical standpoint, phages appear to be innocuous, do not attack normal gut flora, and are extremely common in the environment. In spite of all the positive properties of lytic phages, they are not commonly used prophylactically or therapeutically and their efficacy is still a matter of controversy almost 100 years after their initial discovery.

Nutrients

There are a plentiful supply of physiologically active feed ingredients that can improve pig performance and health by modifying the environment of the digestive tract (Pettigrew 2003). Zinc oxide added to nursery rations at a level of 2500 ppm for 2 weeks will result in increased growth rate and reduced prevalence of diarrhea (Jensen-Waern et al. 1998). In vitro studies have shown that zinc has antimicrobial effects, but in vivo studies show no reduction in *E. coli* numbers and no change in function of circulating neutrophils. There are concerns that high levels of zinc oxide will cause liver toxicity if fed longer than 3–4 weeks.

Likewise, copper sulfate at levels of up to 250 ppm has been added to pig feed to promote growth. However, the combination of zinc and copper does not result in an additive growth response (Hill et al. 2000). In the case of both copper and zinc, there are environmental concerns regarding their use because of the build up of these minerals in manure.

The quest for alternatives to antibiotics in pig feed has caused interest in natural remedies, including herbs, spices, botanicals, and essential oils. These products may improve performance by improving feed palatability and by exerting antibacterial effects, but there needs to be further evidence of their effectiveness (Pettigrew 2003).

Organic acids (fumaric, formic, and lactic) are commonly added to feed or water in order to improve growth and reduce diarrhea during the postweaning period (Tsiloyiannis et al. 2001). Modes of action claimed

for the growth-promoting effect of organic acids include decreased gastric pH, reduced coliform population, stimulated pancreatic exocrine secretion, increased pepsin activation, altered gut morphology, and improved intake and digestibility (Partanen 2001).

Response to acidification has been variable and may be attributed to feed and animal factors as well as differences in the properties of the various organic acids. Two problems that are associated with the use of high levels of organic acids are the acids may have a negative effect on palatability and the feed is corrosive to cement and steel in swine housing (Canibe et al. 2001).

An alternative approach to altering the gut microflora is to feed nondigestible material that provide a substrate for beneficial bacteria such as lactic acid-producing bacteria. These products are often referred to as prebiotics. In order for a feed to be classified as a prebiotic it must be neither hydrolyzed nor absorbed in the upper part of the gastrointestinal tract, be a selective substrate for one or a limited number of potentially beneficial commensal bacteria, and induce luminal or systemic effects that are beneficial to the host's health (Roberfroid 2001). Nondigestible oligosaccharides are the most common type of prebiotics, including fructo-oligosaccharides and mannan-oligosaccharides. In general, prebiotics are considered to provide small but positive improvements in growth rate, and are widely used in the swine industry. However, their role in providing health benefits, such as reducing *Salmonella* shedding, needs to be clarified.

Enzymes added to feed to encourage improved feed efficiency and in some cases potential health benefits are used widely. For example, feed can be supplemented with phytase to allow swine to digest plant phosphorus that is in the form of phytate. It has been hypothesized that the use of enzymes may allow the industry to utilize coarse feed particle size as a means of reducing gastric ulcers and the prevalence of *Salmonella* but still maintaining acceptable feed conversion.

There is a possibility that in-feed antimcriobials for growth promotion could be reduced through a combination of feeding manipulations, such as the use of various combinations of liquid feeds or coarse particle size, enzymes, probiotics, prebiotics, and acidifiers.

OTHER THERAPEUTICS

Anesthetics, Tranquilizers

There are few products licensed for use in swine. Most commonly a combination of drugs used in an off-label manner are employed in order to provide satisfactory anesthesia in the field. This has become a controversial area because the swine industry has come under pressure to reduce the potential suffering of pigs during and following routine surgical procedures, such as castration or after a traumatic injury, and yet minimize the use of drugs without proper licensing approval.

Table 71.8. Common swine anthelminitics and dosages

Product	Dosage
Dichlorvos	11.2–21.6 mg/kg body weight in feed with 1/3 of regular ration
Doramectin	300 µg/kg body weight IM
Fenbendazole	9 mg/kg body weight over 3–12 days via feed
Ivermectin	300 µg/kg SQ or 100 µg/kg body weight for 7 days via feed
Piperazine	275–440 mg/kg body weight in feed or water
Pyrantel tartrate	22 mg/kg of body weight as 1 day treatment or 96 g/ton of feed as prophylactic dose

Antiparasitics

In modern confinement operations, there are few parasitic problems (Roepstorff and Jorsal 1989). Under conditions of good hygiene and management, the regular application of anthelminitics may be of little or no benefit (Roepstorff 1997). Ascariasis is generally the main concern, and strategic medication with a wide range of effective products can easily control this parasite.

External parasitism caused by mange mites and lice is no longer a significant problem because of good husbandry practices and effective drugs, particularly the avermectins. Failure to control sarcoptic mange or lice infestation is generally due to a poor understanding of the epidemiology of the organisms and apathy on the part of the herdsman (Cargill et al. 1997). Antiparasitic products and their application are presented in Table 71.8.

Hormones

Oxytocin is widely used as an aid in stimulating parturition and milk letdown. Prostaglandin $F_{2\alpha}$ or a synthetic analog can be used to induce parturition. Puberty can be induced in gilts by treatment with a single injection of 200 IU of human chorionic gonadotropin and 400 IU of equine chorionic gonadotropin. The injection of follicular stimulating hormone at weaning and an injection of luteinizing hormone approximately 72–80 hours later has been shown to induce a predictable ovulation (Barnabe 2002) and can be used in artificial insemination programs where these hormones are licensed for this purpose. Estrus can be synchronized by administering a progestin for 14–18 days. The progestin inhibits follicular maturation until the progestin is withdrawn.

Hormones are also used in certain countries for growth manipulation. Daily injection of porcine somatotropin (PST) strongly influences feed efficiency, growth, and carcass composition. Ractopamine, a phenethanolamine or ß-agonist is used as a feed additive in several countries. Its function is as a repartitioning agent causing improved feed efficiency and a lean carcass at slaughter.
