Numerous cell lines or primary cell cultures are permissive to PRV, but porcine cell lines PK-15 or SK-6 are generally used in cultivation (Toma et al. 2004). PRV induces a cytopathic effect (CPE) that usually appears in 24–72 hours, but cell cultures may be incubated for 5–6 days (Figure 25.4). The monolayer develops accumulations of birefringent cells, followed by complete detachment of the cell sheet. Syncytia also develop, the appearance of which is variable. In the absence of obvious CPE, it is advisable to make two blind passages (Granzow et al. 1997).

EPIDEMIOLOGY

PRV is found throughout the world, particularly in regions with dense pig populations, including South America, Europe, and Asia. In Europe, PR has never been reported in Norway, Finland, or Malta. PRV has been eradicated from Germany, Austria, Sweden, Denmark, and the United Kingdom. Canada, New Zealand, and the United States (since 2004) are also free of PR. In these countries, vaccination against PR is prohibited. However, PRV still circulates in wild boar or feral swine populations in the United States, Germany, Poland, France, Italy, and elsewhere (Lipowski and Pejsak 2002).

Pigs are the primary host of the virus, but although a large number of other species can be infected naturally or experimentally. PRV is infectious for cattle, sheep, goats, dogs, cats, foxes in fur farms, rats, and wild mice. PRV in species other than swine causes neurologic disease and death. In cattle, sheep, and goats, clinical pru-

ritus and encephalitis characterize the uniformly fatal infections. Experimentally infected sheep have transmitted PRV to susceptible swine and to other sheep. Live PRV vaccines are lethal to sheep (Beran 1991). It is very difficult to infect horses and birds; large virus doses are necessary and they must be injected either intracerebrally, subcutaneously, or intramuscularly. Higher primates, including humans, are not susceptible to PRV infection (Wittmann 1985). In non-porcine species, the course of infection is lethal at all ages and recovery is an exception (Wittmann 1985).

The pig is the only species able to survive PRV infection and, therefore, serves as a virus reservoir (Babic et al. 1994; Cheung 1995; Granzow et al. 1997; Enquist et al. 1998). This means that eliminating the virus from the porcine population will ultimately lead to eradication of the disease (Mettenleiter 2000; Wittman 1986). Feral swine are as susceptible to PRV infection as domes-

tic pigs (Lipowski 2003). PRV cycles in the feral swine population independently of the cycle in domestic pigs (Lipowski and Pejsak 2002). Therefore, feral swine should be considered a potential PRV reservoir and source of infection for domestic pigs, especially in those countries where PR eradication programs have been implemented (Lipowski and Pejsak 2002). Naturally occurring PRV also has been identified in peccaries in the southwestern U.S. (Corn et al. 1987).

In pigs, PRV morbidity and mortality are dependent upon the age of the animal. Piglets and young pigs are at the greatest risk. Most risk factors for PR, e.g., swine population density, number of breeders, number of fattening pigs, replacement gilt purchasing, are directly or indirectly linked with the number of susceptible pigs in the population.

Virus is transmitted primarily between swine through nose-to-nose contact. Transmission may occur during breeding either from exposure to contaminated vaginal mucosa or semen, transplacentally during gestation (Beran 1991), or by contact with carcasses of rats, raccoons, swine, and other infected animals (Donaldson 1983). Under favorable circumstances virus may be spread by aerosols (Vannier 1988; Christensen et al. 1990).

Susceptibility to infection is dependent on several factors, including the virulence of the virus strain, the exposure dose, the route of exposure, the age of the pigs (piglets are more susceptible than adult pigs), stress, and the condition of the animal. Larger quantities of virus are necessary for oral infection than for nasal infection (Baskerville 1972a; Jakubik 1977).

PRV is not very contagious. This is supported by the fact that, usually, not all the pigs within a building become infected. The percentage of animals infected varies between 10% and 90%. The spread of infection within a herd is dependent on the opportunity of direct contact between animals. Spread of infection is highest within a pen but lower from pen to pen.

The virus can be isolated from nasal swabs of infected pigs for 8–17 days with maximum virus titers of between $10^{5.8}$ and $10^{8.3}$ TCID$_{50}$ per swab. From oropharyngeal swabs, virus can be isolated for 18–25 days with virus titers of up to 10^6 TCID$_{50}$. At the peak of virus excretion one pig may excrete $10^{5.3}$ TCID$_{50}$ into the air during a 24-hr period. Virus is found in vaginal secretions and foreskin secretions (ejaculate) for up to 12 days and for 2–3 days in milk. The virus is occasionally present in urine, but it has not been isolated from the feces, though it has been detected in rectal swabs for up to 10 days. It is important to note that virus excretion starts before the onset of clinical symptoms (Wittmann 1985).

Persistence in the Environment

PRV is stable under various pH and temperature conditions and is considered resistant in the environment. However, it must be realized that the "environment" is complex and includes both factors favorable and factors unfavorable to virus persistence. Therefore, the data given should be considered only a guide (Wittmann 1985).

The virus survives on hay for 30 days in summer and 46 days in winter. It is stable between pH 4 to 12. Stored in 50% glycerol, it survives for 154 days with little loss of virus titer at refrigerator temperatures. At low temperatures, virus in tissue remains viable for many years. Lyophilized virus survives at least 2 years. Ultraviolet light and drying on glass inactivates the virus (Davies and Beran 1981; Wittmann 1985).

The virus is not inactivated in the course of the maturation of pig meat at 4°C (Weyhe and Benndorf 1970). In urine, the virus retains infectivity for 3 weeks in summer and 8–15 weeks in winter (Atanasowa 1972). In slurry, the virus is thought to remain infectious for about 2 months in winter and about 1 month in summer, in biothermically treated slurry, the virus is inactivated in summer within 5 days and in winter within 12 days. In aerated slurry (pH 9.6, temperature up to 44°C), the virus is inactivated within 50 hrs (Böhm et al. 1980). In packed-down manure the virus is inactivated in 8–15 days. In soil, infectious virus was recovered for 5–6 weeks. Virus dried on sacks and wood persisted for about 10 days in summer and 15 days in winter (Kretzschmar 1970). No data are available on untreated edible waste material, but in material fermented by *Lactobacillus acidophilus* PRV was inactivated at 20°C and 30°C within 24 hrs, but persisted for at least 48 hrs at 10°C and at least for 96 hrs at 5°C (Wooley et al. 1981).

PRV is relatively resistant to heat. It is inactivated at 60°C in 30–60 min, at 70°C in 10–15 min, at 80°C in 3 minutes and at 100°C within 1 minutes (Kunev 1978). The virus is very stable at normal temperatures and in the cold. It stays alive at 25°C about 6 weeks, at 15°C about 9 weeks, at 4°C about 20 weeks and at −40°C for years. However, the virus is relatively unstable at −18°C to −25°C, where inactivation occurs within 12 weeks (Davies and Beran 1981).

Between pH values of 4.0 and 12 the virus is stable and even at pH values of 2.0 and 13.5 it takes 2–4 hours before the virus is completely inactivated (Benndorf and Hantschel 1963). By combining low or high pH levels with elevated temperatures, the inactivation time is significantly reduced (Davies and Beran 1981).

Susceptibility to Disinfectants

Effective disinfectants include orthophenolphenate compounds, 5% phenol, 2% Na hydroxide, trisodium phosphate iodine disinfectants, and chlorhexidine solutions (Beran 1991). Quaternary ammonium compounds, hypochlorites, and in fact, all disinfectants are less effective in the presence of organic matter (Brown 1981). When disinfecting on a large scale, cheaper disinfectants are adopted: calcium chloride milk, calcium chloride preparations that dissolve in water, crude chlo-

ramines, and agents containing at least 1% active formaldehyde. For disinfecting slurry, lime (20 kg Ca(OH)2 per cubic meter is recommended (Koch and Euler 1983).

PATHOGENESIS

Following oronasal exposure, primary replication occurs in the epithelia of the upper respiratory tract. Thereafter, infection of tonsils and lungs ensues and the virus is disseminated in the body either in free form or via infected leukocytes. In addition, the virus enters the trigeminal and olfactory nerve endings and invades the central nervous system (Babic et al. 1993; Kritas et al. 1994; Pensaert and Kluge 1989). Replication of PRV in the CNS is characterized by nonsuppurative meningoencephalitis causing severe central nervous disorders (Enquist 1994; Pensaert and Kluge 1989).

The virulence of the infecting strain is, at least in part, determined by viral glycoproteins. According to their relevance for viral replication in cell culture, these have been designated nonessential (gC, gE, gG, gI, gN) and essential (gB, gD, gH, gK, gL). Glycoproteins that mediate attachment of PRV to target cells are of special interest because they may directly determine viral tropism. Primary attachment of PRV to target cells is mediated by binding of the nonessential gC to heparan sulfate proteoglycans (Karger and Mettenleiter 1993; Mettenleiter and Rauh 1990). However, this interaction is not sufficient to trigger fusion between the viral envelope and the cell membrane. The essential glycoprotein gD mediates secondary attachment of PRV (Karger and Mettenleiter 1993) to cellular gD receptors. This gD-gD receptor interaction is thought to be necessary to initiate penetration. Besides gD, gB and the gH-gL complex are required for penetration of free virions into target cells (Mettenleiter 2000). However, in contrast to the situation in herpes simplex virus type 1 (HSV-1) and bovine herpesvirus type 1 (BHV-1), PRV-gD is dispensable for direct viral cell-to-cell spread in vitro (Rauh and Mettenleiter 1991). Thus phenotypically complemented gD-negative PRV (PRV-gD-) is able to infect primary target cells and subsequently spreads via direct cell-to-cell transmission.

Recently, the proteins required for neuroinvasion of PRV were analyzed in detail. Several studies in mice, rats, and pigs have indicated that one of the key proteins in neuroinvasion is glycoprotein E. Deletion of this protein strongly attenuates PRV, but absence of glycoprotein E does not impair primary viral replication in the nasal epithelium after intranasal infection of mice or pigs. It is also not required for the virus to enter primary neurons (Babic et al. 1994, 1996; Enquist 1995). Transsynaptic transfer to second order neurons is, however, severely inhibited, resulting in a dramatic restriction in neuroinvasion. Glycoprotein E, and to a lesser extent glycoprotein I, are the predominant nonessential glycoproteins exhibiting this dramatic phenotype (Enquist et al. 1998).

Latency

Latency is defined as a condition in which viral DNA is present, but infectious virus is not produced. During latency, viral gene expression is restricted to transcription of a distinct part of the viral genome into the so-called latency associated transcripts or LATs (Priola and Stevens 1991).

Latency, with the potential for subsequent reactivation and shedding, is one of the most formidable challenges to the successful control and eradication of PR. A number of studies have suggested that most, if not all, pigs initially exposed to a large quantity of PRV can become latently infected carriers. As a consequence any pig believed to have been previously infected with a field strain of PRV (typically identified by the presence of serum antibody) is assumed to be a latently infected carrier. Despite intensive efforts (Mettenleiter 2000), the molecular basis for alphaherpesvirus latency is still largely unknown. In PRV, latently infected pigs are a constant risk because of the possibility of reactivation, virus shedding (recrudescence), and spread to susceptible individuals.

Major sites of PRV latency are the trigeminal ganglion (TG), the olfactory bulb, and the tonsil. In these organs, viral DNA can be detected in the absence of infectious virus production. LAT transcription can also be demonstrated by highly sensitive methods, such as RT-PCR (Cheung 1995). The most common in vitro method for detecting latency is the examination of the tissue in question via a PCR reaction specific for a portion of the viral genome (Mengeling et al. 1992). The only relatively reliable method for detecting latency in a live pig is to administer large doses of a corticosteroid, with the intent of inducing reactivation followed by virus shedding (Mengeling et al. 1992).

Presumably, after oronasal infection, PRV first replicates in the epithelial tissues and may also directly enter nerve endings of sensory neurons in the nasopharynx. After a first round of replication in the epithelia, progeny virus is abundantly produced, leading to an increased infection of primary neurons. There appears to be a correlation between precolonization of trigeminal ganglia with PRV and failure of a superinfecting strain to become latent itself. This suggests that the number of neurons in which latency can be established is limited and that, probably, a neuron that is already "occupied" resists superinfection. Whether this interference requires a viral function or is dependent on cellular factors is unknown. However, it suggests that attenuated live vaccine strains with a high potential for establishing latency may prevent superinfecting, wild type strains from becoming latent (Schang et al. 1994).

CLINICAL SIGNS

The incubation period for PR ranges from 1–11 days, most frequently 2–6 days. The incubation period in suck-

ling pigs is shorter than in older animals (Wittmann 1986). The clinical severity of PR depends on the age of the pig, the route of infection, and the virulence of the infecting strain, which is at least partially determined by viral glycoproteins (Schmidt et al. 2001), and the immunological status of the animal (Nauwynck 1997). Young piglets are highly susceptible, with mortality rates reaching 100% during the first 2 weeks and decreasing to 50% during the third and fourth week of age. In these animals, severe neurological disorders are observed. The nature of the PRV strain involved determines the degree of the virus invasion within the nervous system of maternally immune neonatal pigs (Kritas et al. 1999).

Differences in the course of the disease are observed between herds. PR may be a rapidly spreading disease affecting swine of all ages, or clinical signs may be absent and infection detected only after serological investigations. The clinical course is more severe in a naive population. In the absence of neonatal pigs, and especially between farrowings, the course of infection is usually inapparent. However, inapparent herd infection does not take place or occurs rarely when PRV is introduced into a herd for the first time and where neonatal pigs are present. This is because these piglets are highly susceptible to PRV infection. In this case, morbidity and mortality may reach 100%.

In breeding herds or separate finishing barns, PRV may cause mild respiratory symptoms, which may be ignored or associated with other etiological agents, e.g., *Streptococcus suis*, *Actinobacillus pleuropneumoniae*, *Pasteurella multocida*, *Mycoplasma hyopneumoniae*, swine influenza virus, or porcine respiratory and reproductive syndrome (PRRS) virus (Zimmerman and Yoon 2003).

According to Kluge et al. (1999), piglets born infected with PRV become listless, anorectic, and within 24 hours, ataxic and convulsive. In such situations, laboratory diagnosis is imperative to establish the role of PRV. The sooner a diagnosis is established, the greater the likelihood of preventing losses by immediate vaccination of the herd against PR.

Piglets that become infected with PRV demonstrate fevers of up to 41°C. Trembling, hypersalivation, incoordination, ataxia, and nystagmus to opistotonos to severe epileptiform-like seizures occur in succession. Pigs may assume the "sitting dog" position because of respiratory distress. Some pigs circle or become recumbent and paddle. Vomiting and diarrhea also occur. In piglets with CNS signs, death occurs within 24–36 hours following the onset of such signs. Mortality of PR in piglets often approaches 100%.

Depending on the dam's level of immunity against PRV, piglets of some litters may not show clinical signs, while piglets in adjacent litters show the clinical signs listed previously. If susceptible sows or gilts are infected with PRV close to parturition, the piglets are born weak, show primarily nervous signs, and die 1–2 days after birth.

In weaned pigs (3–6 weeks), clinical signs are similar to those in neonatal piglets, but less severe, and CNS signs leading to coma and death do not occur as often. Mortality may approach 50%, but it is usually lower. Clinical signs in weaned pigs include listlessness, anorexia, and fever (41–42°C). Respiratory signs are often seen, e.g., sneezing, nasal discharge, dyspnea, and severe cough. Most pigs recover within 5–10 days, with the exception that those demonstrating CNS signs often die. The infection of the respiratory tract with PRV is often complicated by the presence of bacterial infections, e.g., *Pasteurella multocida*, *Actinobacillus pleuropneumoniae*, *Streptococcus suis*, *Haemophilus* spp. or other facultative pathogenic bacteria (Kluge et al. 1999).

In pigs 5–9 weeks of age and in the case of proper veterinary intervention, mortality in pigs 5–9 weeks of age usually does not exceed 10% and is often lower. However, PRV infection in these animals results in a 1- to 8-week delay in reaching market weight compared to uninfected animals.

In grower-finisher pigs, respiratory signs are the most common observation. Morbidity in an infected group often reaches 100%, but in cases uncomplicated by secondary infections, mortality ranges from 1–2%. Complications caused by bacteria, particularly *A. pleuropneumoniae*, increase the losses dramatically. CNS symptoms occur only sporadically. Typically, clinical signs appear in 3–6 days and are characterized by fever (41–42°C), depression, anorexia, and mild-to-severe respiratory signs. Rhinitis with sneezing and nasal discharge may progress to pneumonia. The pigs become gaunt and lose considerable body weight. After 6–10 days, appetite and body temperature return to normal. PRV infection in grower-finisher pigs results in the loss of at least 1 week in the production cycle.

Sows and boars primarily develop respiratory signs. PRV can cross the placenta and infect and kill fetuses in utero. In pregnant females, abortion often occurs and may be the first sign of PR. Sows infected in the first trimester may resorb fetuses and return to estrus. If infection takes place in the second or third trimester of pregnancy, it is usually manifested by abortion or stillborn and/or weak pigs, particularly if the infection occurs close to term. Mortality in adult swine infected with PRV rarely exceeds 2%.

An essential factor affecting the manifestation of clinical signs in a herd is the level of immunization of pregnant sows, weaned pigs, and grower-finisher swine. Likewise, secondary bacterial infections, the age of the animals, and environmental conditions will affect the expression of the disease.

LESIONS

Gross lesions are often absent or minimal, but keratoconjunctivitis, serous-to-fibrinonecrotic rhinitis, laryngitis, tracheitis, and necrotic tonsillitis may be seen.
25.5. *Spleen and liver with multiple small focal areas of necrosis (from Kluge et al. 1999).*

25.6. *Brain with perivascular cuffing (from Kluge et al. 1999).*

Vaccination will reduce both the severity of clinical signs and microscopic lesions (Alva-Valdes et al. 1983). Lesions in the lower respiratory tract range from pulmonary edema to scattered small foci of necrosis, hemorrhage, and/or pneumonia (Becker 1964). Small necrotic white foci (2–3 mm) may be seen on the liver and spleen (Figure 25.5), especially in young pigs that lack passive immunity. In aborted sows, endometritis and a thickened, edematous wall of the uterus are observed (Kluge and Maré 1978). Necrotic placentitis accompanies abortion or parturition. Aborted fetuses may be macerated or, occasionally, mummified. In fetuses or neonatal pigs, necrotic foci in liver and spleen are seen. In addition, hemorrhagic, necrotic foci in lungs and tonsils may be present (Kluge and Maré 1976).

Microscopic lesions most frequently occur in the CNS. These include nonsuppurative meningoencephalitis and ganglioneuritis in the grey and white matter (Baskerville 1972b). Perivascular cuffing (Figure 25.6) consists predominantly of mononuclear cells, with the presence of few granulocytes. Pyknosis and karyorrhexis of the mononuclear cells are often prominent. Neuronal necrosis may be focal, and the neurons surrounded by mononuclear cells or affected neurons may be diffusely scattered. Similar lesions exist in the spinal cord, especially in the cervical and thoracic regions. Meninges over affected areas of brain and cord may be thickened because of infiltrates of mononuclear cells.

Intranuclear inclusion bodies are observed in neurons, astrocytes, and oligodendroglia. According to Kluge et al. (1999) these are much more common in lesions outside the nervous system. They are common in crypt epithelial cells adjacent to necrotic foci. Mucosal epithelial necrosis and submucosal infiltrations of mononuclear cells occur in the upper respiratory tract (Baskerville 1971, 1973). In the lungs, necrotic bronchitis, bronchiolitis, and alveolitis is found. Also, peribronchial mucous gland epithelium may be necrotic.
There is often hemorrhage and fibrin exudation because of the involvement of connective tissue and endothelium. Lesions often are patchy in major airways, and healing by fibrosis is often observed in areas adjacent to acute lesions. Intranuclear inclusion bodies are frequently present in the epithelial lining of the airways, connective tissue cells, and cells sloughed into alveolar spaces.

According to Corner (1965) two types of intranuclear inclusion bodies are observed: a homogenous basophilic body that fills the entire nucleus and an eosinophilic body that has a definite zone between it and the marginated chromatin. In either case, the specificity of the inclusion must be determined by demonstrating PR viral particles or antigen by electron microscopy or immunohistochemistry.

Focal necrotic lesions are similar regardless of the tissue involved. They are most frequently found in spleen, liver, lymph nodes, and adrenal glands. In the uterus, multifocal to diffuse lymphohistiocytic endometritis and vaginitis and necrotic placentitis with coagulative necrosis of chorionic fossae can be found (Bolin et al. 1985; Kluge et al. 1999). Intranuclear inclusion bodies are present in degenerate trophoblasts associated with necrotic lesions (Kluge and Maré 1978; Kluge et al. 1999). In the male reproductive tract there may be degeneration of seminiferous tubules and necrotic foci in the tunica albuginea of the testicles (Hall et al. 1984). Boars with exudative periorchites have necrotic and inflammatory lesions in the serosa covering the genital organs. Spermatozoa abnormalities are found. Focal necrosis of the mucosal epithelium involving the muscularis mucosa and tunica muscularis develops in the intestines (Narita et al. 1984b). Intranuclear inclusion bodies may be present in degenerative crypt epithelial cells. Necrotizing vasculitis of arterioles, venules, and lymphatic vessels around tonsils and submaxillary lymph nodes is observed (Narita et al. 1984a). Endo-

(f) Non-MHC restricted cytotoxic activity.

thelial nuclei are pyknotic and karyorrhectic, and the vessel walls are infiltrated by neutrophils. Intranuclear inclusion bodies often are present in affected endothelial cells (Kluge et al. 1999).

IMMUNITY

PRV infection evokes antibody production and cell-mediated immunity in pigs. However, immunity is not total and upon reinfection the virus can multiply to a limited degree (Wittmann 1985).

According to Eloit et al. (1988) glycoprotein gp50 is a major target of neutralizing antibodies. However, only a few of the numerous potential PRV antigens has been analyzed, and the relative importance of a single protein to the immune response of the host is difficult, if not impossible to assess (Mettenleiter 1996). An improved understanding of the immune response against PRV is necessary in order to develop vaccines capable of boostering specific effector mechanisms.

Antibodies against PRV and specifically against a number of glycosylated and nonglycosylated viral structural and nonstructural proteins have been detected in infected animals. Monoclonal antibodies have been identified that exhibit virus-neutralizing ability in vitro and in vivo. The role of PRV proteins in immunity is summarized in Table 25.2.

The most potent complement-independent virus-neutralizing antibodies are directed against gC and gD (Mettenleiter 1996). These antibodies work by inhibiting virus attachment (anti-gC) or penetration (anti-gD) and thereby block infection at the first stages. Subunit vaccines consisting of gC or gD, as well as anti-idiotypic anti-gD antibodies have been shown to elicit protective immunity, further emphasizing the important role of these proteins in the humoral immune response (Tsuda et al. 1992). In fact, a large part of the neutralizing activity in convalescent sera of swine appears to be directed against gC (Ben-Porat et al. 1986). The role of the other

Table 25.3.   Cell-mediated immunity against PRV (from Mettenleiter 1996)

Cell Type	Antigen Recognized	Negative

CD4+ CD8+ (T-helper)	gB, gC	?

glycoproteins is less clear. However, vaccination with subunit gB vaccines also induces protective immunity in pigs (Nakamura et al. 1993 in Mettenleiter 1996). Glycoproteins are considered the prime targets for the porcine anti-PRV cell mediated immunity (Table 25.3).

A sow immune to PRV transfers specific antibodies to her offspring via the colostrum. Maternal immunity is able to protect neonatal pigs infected with virulent PRV against clinical disease by limiting virus replication in the CNS (Wittmann and Jakubik 1979). Kritas et al. (1997) showed that high SN titers (272–354) were able to protect neonatal pigs almost completely against neural invasion and spread upon challenge with a virulent strain of PRV. Low SN titers (2–3) did not protect pigs against neural invasion and virus spread, particularly via the olfactory pathway, which is readily accessible to the virus due to the pigs' anatomy. Either low or high SN titers protected pigs against clinical disease. However, the protective role of maternally derived antibodies and maternal immunity against spread of PRV in the nasal mucosa depends on the infecting virus strain.

Maternally derived PRV antibody interferes with immunization of the piglets until it declines to a level that often leaves piglets unprotected. However, Brockmeier et al. (1997) found that certain vaccines—for example, recombinant vaccinia vaccines—were able to circumvent maternally derived antibody and stimulate active immunity.

DIAGNOSIS

Clinical diagnosis of PR disease in individual pigs may be difficult or even impossible. Therefore, a diagnosis of PR should be made on a herd basis. Clinical signs suggestive of PR include numerous deaths of suckling pigs showing nervous signs during the first 3 weeks of life. Nasal discharge, coughing, dullness, somnolence, and nervous disorders may be seen in these and older pigs. In pregnant sows, a high frequency of abortions and stillbirth is observed. It is characteristic of PR that morbidity and mortality decrease as the age of the pigs increases. Signs suggestive of PR may be seen in dogs and cats on the farm. Likewise, the discovery of dead animals of these species is suggestive of PR (Wittmann 1986).

When diarrhea is present in newborn pigs, PR may resemble transmissible gastroenteritis or *E. coli* infection. Similar respiratory signs can be caused by bacteria, e.g., *Pasteurella multocida, Actinobacillus pneumoniae,* and *Streptococcus suis*, as well as swine influenza virus. In the latter case, all pigs in all age groups become severely ill without dying. Nervous signs can occasionally occur in classical swine fever (CSF) and, in the absence of gross pathological changes due to CSF, it is difficult to differentiate CSF from PR. Nervous conditions caused by porcine teschovirus infection (previously called Teschen/Talfan disease) are not accompanied by infection of the respiratory tract. NaCl poisoning causes excitement and arsanilic acid and mercurial poisoning causes lethargy of the animals, but these events occur suddenly without fever. Stillbirths and abortion can be induced by parvovirus, *Leptospira*, *Brucella*, and PRRSV infection (Pejsak and Markowska-Daniel 1996; Wittmann 1986; Zimmerman and Yoon 2003).

Classical clinical signs of PR will often lead to a presumptive diagnosis, which is supported if gross lesions—e.g., focal hepatic and splenic necrosis and necrotic tonsillitis—are observed in neonatal pigs. PR is more difficult to diagnose if only grower-finisher pigs or adult swine are involved. A PR outbreak in this age group can easily be misdiagnosed as swine influenza if the disease is manifested only by respiratory signs and lesions. If, however, a few individuals develop CNS signs, it is easier to make a presumptive diagnosis of PR.

In most cases laboratory diagnosis is necessary to confirm the presumptive diagnosis of PR (Toma et al. 2004). The diagnosis of PR can be confirmed by isolation of PRV from the oropharyngeal fluid, nasal fluid (swabs), or tonsil biopsies of living pigs, or from samples from dead pigs. For postmortem isolation of PRV, samples of brain and tonsil are the preferred specimens. In latently infected pigs, the trigeminal ganglion is the most consistent site for virus isolation, although latent virus is usually difficult to culture. Numerous types of cell line or primary cell cultures are sensitive to PRV, but a porcine kidney cell line (PK-15 or SK-6) is generally used. PRV induces a cytopathic effect (CPE, Figure 25.4) that usually appears within 24–72 hours, but cell cultures may be incubated for 5–6 days. The isolation of PRV is confirmation PR, but failure to isolate virus does not guarantee freedom from infection.

In the absence of any obvious CPE, it is advisable to make two blind passages into further cultures. Additional evidence may be obtained by staining infected cover-slip cultures with haematoxylin and eosin to demonstrate the characteristic herpesviral acidophilic intranuclear inclusions with margination of the chromatin. The virus identity should be confirmed by immunofluorescence, immunoperoxidase, or neutralization tests using specific antiserum.

The polymerase chain reaction (PCR) can be used to identify PRV genomes in secretions or organ samples. The primary advantage of PCR over conventional virus isolation techniques is its speed. Preliminary identification can be completed within 1 day, with confirmation of the PCR product on the second day. With the most modern equipment the whole process can be completed in 1 day. Because of the nature of the test, many precautions need to be taken to avoid contamination of samples with extraneous DNA from previous tests or from general environmental contamination in the laboratory. This may limit the value of the test for many laboratories, and therefore this technique cannot be fully recommended for routine diagnosis.

Immunofluorescence (IF) is still of some importance for detection of PRV or its antigen in tissue sections (Wittmann 1986) or in impression smears (Wittmann 1986). IF usually appears in the cytoplasm and only exceptionally in the nucleus.

Virus neutralization (VN) has been recognized as the reference method for serology, but for general diagnostic purposes it has been widely replaced by the enzyme-linked immunosorbent assay (ELISA) because of its suitability for large-scale testing. ELISA can be performed on serum as well as on meat juice (Toma et al. 2004).

The sensitivity of ELISA is generally superior to that of the VN test using 1-hour neutralization without complement. Some weak-positive sera are more readily detected by VN tests using 24-hour neutralization, but others are more readily detectable by ELISA. Commercially available ELISA kits use indirect or competitive techniques for detecting humoral antibody. They differ in their mode of preparation of antigen, conjugate, or substrate, in the period of incubation and in the interpretation of the results. Their general advantage is their capacity for rapid processing of large numbers of samples. Testing can also be automated and the results analyzed by computer. Some of these kits make it possible to differentiate between vaccination and infection with wild-type virus. When using these test systems, it is more appropriate to consider them herd tests rather than individual animal tests.

Interpretation of serological results can be difficult,

especially in young pigs. Maternal antibodies can be present up to 4 months of age. In pigs, the half-life of maternal antibodies is approximately 18 days; for example, it takes 18 days for the antibody titer to decline from 1:16 to 1:8. If pigs from an immune sow are tested too early, they may be identified as infected when the antibody is actually of maternal origin.

Traditional detection methods are complicated by the ability of the PRV to become latent (Gustafson 1986). Several field studies provide circumstantial evidence that pigs can be seronegative to PRV but latently infected (Thawley and Morrison 1988).

PREVENTION AND CONTROL

An essential precondition for effective prevention and control of PR is the obligation for notification. Once a system of notification is in place, the response to the detection of PRV infection in a herd will be largely dictated by local or regional considerations. The primary consideration is whether or not PRV has been, or is in the process of being, eradicated in the area or region and whether vaccination is a control option. Thus, depending on the PRV status of the region, the response may be largely dictated by regional animal health regulations. If permitted, vaccination of the infected herd and neighboring herds should be carried out (Kluge et al. 1999; Wittmann 1985).

Depending on local animal health regulations, control measures imposed on an infected farm could include any of the following: depopulation of the herd; restrictions allowing for movement of pigs to slaughter only; containment and treatment of dead animals, tissues, and offal; decontamination of manure, bedding, waste material, hog lots, and areas of traffic; disinfection of implements, equipment, vehicles, trailers, and buildings; implementation of rat control. Infected herds should refrain from the use of semen for artificial insemination. Unauthorized persons, cats, and dogs should be kept out of the facilities. Persons with access to pigs and facilities should follow strict biosecurity procedures to avoid transporting PRV on their clothing, footwear, or body. Regulations for infected farms may also be adapted to pig markets, pig exhibitions, and to the transport of pigs when a PR outbreak occurs or when animals other than pigs contract PR on a farm.

The most important breakthrough in PR control and eradication has been the development of genetically engineered PR vaccines (Quint et al. 1987) and their accompanying differential ELISA tests (Müller et al. 2003). The use of marker vaccines, i.e., deletion mutants of PRV that do not express glycoprotein gE, has made it possible to identify infected pigs in vaccinated populations. That is, pigs with serum antibodies against gE must necessarily have been infected with wild type virus. Vaccination with marker vaccines increases the virus dose required for infection and reduces, but does not prevent, the shedding of virulent virus and the establishment of latency in pigs infected with virulent PRV. Besides deletion mutant vaccines, there are several conventionally attenuated vaccines containing naturally gE-negative strains (e.g., with Bartha strain).

In general, vaccination prevents or reduces clinical disease and economic losses, but it does not prevent the spread of PRV. Because of the importance of cellular immunity in protection against PRV, live, attenuated vaccines are preferable. In PRV-endemic areas, it is strongly recommended that all animals introduced into the herd be vaccinated. Breeding stock must be vaccinated regularly on breeding or on piglet-producing farms. To reduce circulation of the virus in the herd and to prevent the appearance of subpopulations of susceptible pigs, continuous vaccination of all piglets is recommended. Piglets born to vaccinated sows should be immunized at 10–12 and 14–16 weeks of age. Piglets born to unvaccinated sows should be vaccinated at 6 and 10 weeks of age. Two applications of the vaccine ensure better protection. Unvaccinated animals that stay on the farm should be examined serologically to monitor virus spread. In any case, all such farms remain latently chronically infected and can be sources of virus spread (Kluge et al. 1999; Wittmann 1985). If prophylactic vaccination is practiced, all the fattening herds and all the breeding stock should be vaccinated in the infected geographical area.

As discussed by Mengeling et al. (1992), the most effective method of vaccination is intranasal administration of live, attenuated vaccine. At least part of the advantage of intranasal vaccination can be explained by local replication of virus and by the development of mucosal immunity. Intranasal vaccination is more effective in the presence of passively acquired colostral immunity than intramuscular vaccination (Van Oirschot 1987) and also is most effective at reducing PRV replication and shedding during acute infection. Practical considerations, such as the fact that intranasal vaccination is more labor intensive than intramuscular administration, argues against its wide use. Nevertheless, intranasal vaccination may be recommended for piglets in herds newly infected with PRV.

Eradication

The ultimate objective of PR control is its eradication. Marker vaccines are routinely used for a combined vaccination-eradication program for PR eradication. Such a program generally consists of four elements: a systemic and intensive vaccination campaign; serological screening of pigs for gE-specific antibodies; culling of infected breeding pigs; and in the last stage, abolishment of vaccination (Szweda et al. 2000a, b).

Eradication of PR can be most successfully achieved by the slaughter of all the seropositive animals and by strict control of pig movement. However, such an eradication program is very expensive and time-consuming.

More practical strategies to eliminate PRV include the following:

1. Test-and-removal without vaccination
2. Vaccination followed by test-and-removal
3. Stamping out of infected herds based on serological evidence of PRV in the herd

Test-and-removal is recommended when less than 10% of the breeding herd is PRV-positive and there is no serological evidence of infection in the growing or finishing pens. The entire breeding herd must be tested every 30 days and seropositive swine removed and slaughtered. Following one or two (preferable) negative herd tests, the herd may be considered free of PRV.

Vaccination followed by test-and-removal should be used when a high percentage of the breeding herd is seropositive and/or there is evidence of infection in growing or finishing pigs. The entire herd should be vaccinated with a differential vaccine. Either live or inactivated vaccines can be used in breeding animals, and live vaccines are generally used in weaned pigs. Breeding animals should be vaccinated three times a year (every 4 months). Weaners or/and fattening pigs should be vaccinated twice. Stegeman (1995) showed that the number of finishing pigs showing evidence of infection with wild-type virus (anti-glycoprotein E antibody) at the time of slaughter is higher after a single vaccination than after double vaccination. The first vaccination should be performed at 10–12 weeks of age, followed by revaccination 4 weeks later by either intramuscular, intradermal, or intranasal routes of administration (Visser 1997). If it is only possible to perform a single vaccination, i.e., for economical reasons, immunization should be performed at 14 weeks of age (De Smet et al. 1994). According to Bouma et al. (1997), maternal immunity capable of interfering with vaccine-induced immunity may still be present at 10 weeks of age. On the other hand, a single dose of vaccine at 14 weeks of age may result in transmission of PRV among pigs prior to vaccination.

The vaccination protocol should be followed for at least 3 years. During this period, all sows present on the farm at the start of the program should be rotated out of the herd. Thereafter, a serological survey should be done to determine the level of PRV infection remaining in the herd. If prevalence is sufficiently low, the test-and-removal protocol may be implemented.

Eradication of PR by stamping out should be applied only if the prevalence of PRV-positive farms in a region is very low. Stamping out may be necessary in the last stages of PRV eradication, that is, when only a few PRV-positive farms stand in the way of achieving freedom from PRV.

Inherent to the eradication effort is the control of animal movement and a certification of the health status of herds. All farrowing and farrow-to-finish herds that provide piglets must be free of PR. Likewise, all replace-ment gilts should be tested for the absence of gE antibodies. Monitoring should be done by the purchaser while the pigs are still at the premises of the supplier. Since transportation is a major stress factor and may lead to reactivation and excretion of latent virus, it is strongly recommended that incoming pigs be kept in quarantine for 2–4 weeks, after which they should again be tested for gE antibodies before joining the breeding herd. It is important to recognize that the use of in-herd replacement breeders is responsible in many cases for maintenance of seropositivity in the holdings (Arias and Sanchez-Vizcaino 2002). A regular systematic census of pig herds in the region and at least a yearly serological screening of each pig herd must be performed.

Serological monitoring of expected-negative herds and populations for PRV creates the problem of singleton reactors. In PR surveillance programs in countries free from PRV—e.g., Sweden and Denmark—and in countries infected with PRV, herds are occasionally observed wherein there is a single seropositive pig (Annelli et al. 1991). Singleton reactors create a major problem because the PR status of such farms is uncertain. According to Bascuñana et al. (1997) and Annelli et al. (1991), singleton reactors may represent one of several possibilities. First, the herd may have been infected at some time in the past and the single reactor is the last seropositive pig in the herd. Second, PRV may have been recently introduced into the herd and the single reactor is the first to seroconvert. Third, the singleton reactor may be a false positive and the pig may never have been exposed to the virus. Fourth, for whatever reason, the single reactor may be the only pig in the herd to be infected. And fifth, virulent PRV is circulating in the herd at a low level.

There is currently no uniform regulatory policy for herds with singleton reactors. In the U.S., such herds are quarantined while the reactor is isolated and retested together with a representative sample of other breeding swine. If only the original positive pig retests positive, the herd owner has the option of remaining under quarantine or submitting the reactor for immunosuppressive treatment and diagnostic testing. If the result is positive, the pig should be culled. If PRV is not detected the quarantine is removed (Annelli et al. 1991).

Several PRV prevention, control, and eradication programs, differing to a larger or smaller degree from those previously described, have been implemented in Europe and the U.S. (Andersson et al. 1997; Bech-Nielsen et al. 1995; Müller et al. 2003; Vannier et al. 1997). The approach differs depending on the epidemiological situation and particular opinions of the representatives of the state veterinary services of the country. It should be noted that PR eradication programs are costly (Bech-Nielsen et al. 1995) and efforts to achieve freedom from PRV by the least expensive means possible should be encouraged. In the U.S., the federal government spent $72 million during the first 10 years of the

program. In addition, costs were incurred by the various state governments and private swine producers (Taft 2000). In many areas, the presence of PRV in wild boar and feral pigs poses a challenge to the successful eradication of PRV from domestic swine.

26 Rotavirus and Reovirus

Lijuan Yuan, Gregory W. Stevenson, and Linda J. Saif

Porcine Rotavirus

Rotaviruses (RV) are important causes of diarrheal disease in neonates and the young of many species and a common cause of gastroenteritis in sucking and postweaning pigs. Rotaviruses were first discovered in calves (Mebus et al. 1969) and were later detected in humans (Bishop et al. 1973), pigs (Rodger et al. 1975), and other animals (Estes et al. 1983). Porcine RV have been detected in most swine-producing countries and are associated with economic losses caused by diarrheal disease in pigs (Paul and Stevenson 1999).

Porcine rotaviruses are antigenically diverse with four serogroups (A–C, E) and, within serogroup A, 10 G types (VP7 type for glycoprotein) and 7 P types (VP4 type for protease-sensitive protein). Although information pertaining to all porcine RV groups is included, group A RV are most commonly associated with diarrhea in humans and pigs and, therefore, the most extensively studied. In this chapter, if the RV group is not specified, the information pertains to group A RV.

ETIOLOGY

Virus Morphology

Rotaviruses are 65–75 nm, nonenveloped, icosahedral particles. By electron microscopy (EM), the morphology of complete RV particles resembles a wheel (*Rota* in Latin) with short spikes and a smooth outer rim (~75 nm in diameter). The particles are composed of a three-layered viral protein (VP) capsid: the outer layer (VP7 and VP4), the intermediate layer (VP6), and the inner layer (VP2). The viral genome, composed of 11 segments of double-strained (ds) RNA, is enclosed in VP2 along with the RNA-dependent RNA polymerase (VP1). Only the complete triple-layered particles are infectious (Estes 2001). Double-layered particles lacking the outer layer are smaller (~65 nm) with rough edges (Figure 26.1).

Classification

Rotaviruses are classified in the genus *Rotavirus* in the family *Reoviridae*. Based on VP6 antigens, RV are divided serologically into seven distinct groups (A through G) (Estes 2001; Saif and Jiang 1994). Within a group, RVs share cross-reactive antigens on VP6 detectable by serological tests. Groups A–C infect humans and other animals; group E has only been detected in pigs in the UK (Chasey et al. 1986). Groups D, F and G have been detected only in avian species. When subjected to electrophoresis in polyacrylamide gels (PAGE), the RV genome has a characteristic electrophoretic migration pattern referred to as the electropherotype. Each RV serogroup has a unique electropherotype (Pedley et al. 1986; Saif and Jiang 1994). The RNA segments cluster into regions I, II, III, and IV (Figure 26.2). The cluster patterns include 4:2:3:2 (group A), 4:2:2:3 (group B), 4:3:2:2 (group C), and 5:2:2:2 (group D). The group E pattern is similar to group B, except segments 7–11 migrate equidistant from each other. Genome profile analysis using PAGE is a relatively simple technique to identify RV, differentiate them from reoviruses (10 dsRNA segments), and identify RV groups (Janke et al. 1990). However, serologic and nucleic acid-based assays are needed to confirm RV groups and serotypes.

Rotaviruses within serogroup A are further divided into subgroups. In earlier studies, five subgroups (SG) I, II, I+II, and non-I, non-II were defined according to the presence or absence of two distinct epitopes on VP6 reactive with one, both, or neither of the monoclonal antibodies (MAbs) specific for each of the epitopes (Greenberg et al. 1983). Porcine RV strain OSU belongs to SG I and Gottfried strain belongs to SG II. Recent molecular characterization of the subgroup-defining region of VP6 gene suggested two genogroups: genogroup

435
26.1. *Rotavirus particles in feces viewed by negative-staining electron microscopy (×130,000). (A) Triple-layered virus particles with intact outer capsids have characteristic smooth outlines. (B) Double-layered particles lack outer capsids and have spiked outlines.*
26.2. *Electrophoretic patterns (electropherotypes) of A/OSU, B/IA1146, and C/Cowden strains of groups A, B, and C rotaviruses in polyacrylamide gel stained with silver. Each rotavirus group has a distinct electropherotype. Double-stranded RNA segments cluster in four regions, I–IV. The numbers of bands in the four regions are 4:2:3:2, 4:2:2:3, and 4:3:2:2 for rotavirus groups A, B, and C respectively.*

I (consists of SG I) and genogroup II (includes SG II, I+II, and non-I, non-II) (Iturriza-Gomara et al. 2002).

Within serogroup A, RV are further classified into different G and P serotypes or genotypes (Table 26.1). Serotypes are defined by reactivity of virus in plaque reduction (or fluorescent foci reduction) neutralization assays using polyclonal or MAbs (Estes and Cohen 1989; Hoshino et al. 1984). Genotypes are defined by comparative sequence analysis and/or nucleic acid hybridization data. Strains sharing >89% amino acid sequence identities are considered to belong to the same genotype (Estes 2001; Gorziglia et al. 1990). Serotype is denoted by a number following the letter P or G and genotype is signified by the number in square brackets. For example, porcine RV strain Gottfried is classified as P2B[6]G4 and strain OSU as P9[7]G5. The VP7 serotypes and genotypes are highly consistent; however, a general correlation between P genotypes and P serotypes has not been clearly established due to difficulties in generating type-specific antibodies to VP4 (Estes 2001). Currently, 15 RV G serotypes/genotypes have been identified, whereas, out of 22 different P genotypes reported, only 13 P serotypes have been identified (Hoshino and Kapikian 1996; Hoshino et al. 2002; Liprandi et al. 2003; Martella et al. 2003; Okada et al. 2000). In pigs, at least 10 G types of group A RV (G1–6, 8–10, and 11) and 7 P types (P[5]–[8], [13], [19], and [23]) are associated with diarrhea (Martella et al. 2001). Within serogroup C porcine RV, at least 2 G serotypes have been suggested based on cross-neutralization tests (Tsunemitsu et al. 1992b).

Table 26.1. Serogroup, serotype, and genotype designations of selected porcine rotavirusesa

Serogroup	VP7 Serotype/Genotype	Strain	VP4 (P) Serotype (G) [Genotype]	Strain

*Dual G serotypes were reported.

Other assays used to differentiate RV of different serotypes and/or genotypes include ELISA using serotype-specific MAbs, endonuclease digestion of PCR-amplified VP4 and VP7 gene products (RFLP) (Chang et al. 1996), and reverse transcriptase polymerase chain reaction (RT-PCR) (Barreiros et al. 2003).

Physicochemical and Biological Properties

The RV genome consists of 11 segments of dsRNA that range in size from 0.6–3.3 kilobase pairs (Estes and Cohen 1989). The 11 segments encode six viral structural proteins and six nonstructural proteins (NSP) with segment 12 encoding both NSP5 and 6 (Estes 2001). The six structural proteins are: the core proteins VP1 to 3, the nonglycosylated outer capsid protein VP4 (encoded by gene 4), the major structural component of virions VP6 (encoded by gene 6), and the outer capsid glycoprotein VP7 (encoded by gene 9). Proteolytic cleavage of VP4 into VP5 and VP8 is important for viral infectivity. The VP7 is the second most abundant viral structural protein after VP6. Proteins analogous to VP6 and VP7 have also been described for group C RV (Jiang et al. 1990).

Triple- and double-layered RV particles can be separated by centrifugation in gradients of sucrose or cesium chloride (CsCl). Triple-layered particles have a density of 1.36 g/ml in CsCl and sediment coefficients of 520S to 530S in sucrose, whereas double-layered particles have a density of 1.38 g/cm^3 and sediment at 380S to 400S (Tam et al. 1976). Single-layered core particles have a density of 1.44 g/ml in CsCl and a sedimentation coefficient of 280S (Bican et al. 1982). Treatment of RV particles with calcium-chelating agents (e.g., EDTA) removes the outer capsid and results in loss of infectivity, indicating that calcium plays a critical role in particle stability by stabilizing the outer capsid VP7 (Ahmadian and Shahrabadi 1999; Bridger and Woode 1976; Estes et al. 1979). The concentration of calcium needed to stabilize the outer capsid varies, depending on the virus strain (Ruiz et al. 1996).

Rotavirus is a nonenveloped virus. Therefore, its infectivity and particle integrity are generally resistant to fluorocarbon extraction and exposure to ether, chloroform, or detergents (deoxycholate) (Estes 2001). Chloroform reduces RV infectivity slightly and destroys hemagglutinating activity. Rotavirus infectivity is relatively stable within the pH range of 3.0–9.0. The hemagglutinating VP4 spikes are removed by treatment at high pH. Repeated freezing and thawing will result in loss of infectivity and hemagglutination activity.

Many RV strains, including some strains of porcine RV, agglutinate human type O, guinea pig, and rat erythrocytes (Eiguchi et al. 1987). Hemagglutination is mediated by the interaction of VP4 with sialic acid on the surface of erythrocytes (Fuentes-Panana et al. 1995). The cell surface molecules employed by RV to initiate infection vary, depending on different strains, and have not been fully identified. The initial contact of RV with the cell surface is mediated by either a neuraminidase-sensitive (requiring sialic acid) or a neuraminidase-resistant cell molecule (Ciarlet et al. 2002). The majority of porcine RV strains are sialic acid-dependent with a few exceptions (OSU, A46 and 4F), whereas most human and animal RV strains are sialic acid-independent. Several cell surface proteins have been implicated as attachment or post-attachment receptors for RV, including gangliosides, integrins and the heat shock protein

70 (Graham et al. 2003; Guerrero et al. 2002; Hewish et al. 2000; Isa et al. 2004; Rolsma et al. 1998). Gangliosides play a major role in recognition of host cells by porcine OSU RV strain (Rolsma et al. 1998).

Laboratory Cultivation

Porcine RV were first adapted to grow in primary porcine kidney cell cultures by pretreatment of viral inoculum with trypsin or pancreatin (Theil et al. 1977). Viruses were later successfully propagated in the African green monkey kidney cell line MA-104 (Bohl et al. 1984) by using roller cultures and addition of trypsin or pancreatin. Roller cultures and proteolytic enzymes are essential for isolation of RV. The enzyme concentrations used for virus activation are 10 μg/ml for trypsin or 2.5 μg/ml for pancreatin before infection. Alternatively, trypsin or pancreatin (0.5–1.0 μg/ml) is added to serum-free culture medium after virus adsorption. Cell culture–adapted RV strains produce a cytopathic effect characterized by rounding of cells followed by cell detachment from the monolayer. Viral antigen can be demonstrated in the cytoplasm of virus-infected cells by IF (Figure 26.3) or immunochemical methods. Rotaviruses form plaques under agarose in the presence of proteolytic enzymes (Ramia and Sattar 1980).

Group C and B porcine RV have been propagated in primary porcine kidney cell cultures using roller cultures and high concentrations of pancreatin (Sanekata et al. 1996; Terrett et al. 1987). The porcine group C RV (Cowden) was subsequently adapted to grow in MA-104 cells (Saif et al. 1988) and a porcine intestinal cell line (Proescholdt 1991). Group E RV, most group B RV, and some group A RV still cannot be serially propagated in cell cultures.

EPIDEMIOLOGY

Rotaviruses are ubiquitous in the environment and in swine herds. It is difficult to raise pigs free of porcine RV under normal husbandry conditions (Bridger and Brown 1985). Multiple RV serogroups (A, B, C, and E) and multiple serotypes within serogroups A and C have been detected in pigs (Atii et al. 1990; Barreiros et al. 2003; Bohl et al. 1984; Geyer et al. 1996; Janke et al. 1990; Kim et al. 1999; Markowska-Daniel et al. 1996; Pongsuwanna et al. 1996; Saif 1999; Saif and Jiang 1994; Theil et al. 1985; Wieler et al. 2001; Will et al. 1994; Winiarczyk et al. 2002). The RV serogroup distributions detected in feces of diarrheic pigs are summarized in Table 26.2.

Group A RV is detected most frequently in pigs under 60 days of age from as early as 1 week to the highest prevalence at 3–5 weeks of age (Bohl 1979). The prevalence of infection increases with age during the sucking period due to the decline in maternal antibody titers. When maternally acquired immunity decreases to unprotective levels, pigs become susceptible to RV diar-
26.3. *Immunofluorescent staining of MA-104 cells infected with group A porcine rotavirus showing cytoplasmic accumulation of rotaviral antigens (×400).*

rhea. Infected pigs shed virus for 1–14 days in feces with an average duration of 7.4 days (Fu and Hampson 1987).

In group B RV infections, lower amounts of RV are shed and for a shorter duration (Bridger 1980; Theil et al. 1985). Group C RV caused diarrhea in 8- to 9-week-old weaned pigs with morbidity ranging from 60 to 80%, but with no mortality in Michigan swine farms (Kim et al. 1999). Group E RV has been reported only in one outbreak of pig diarrhea in the UK (Chasey and Davies 1984), but experimental infection of gnotobiotic pigs with group E RV caused mild diarrhea. A serological survey in the UK indicated a widespread distribution of antibodies to this virus in pigs older than 10 weeks (Chasey et al. 1986).

The serologic prevalence of antibodies to RV varies for each serogroup in different regions of the world and is age-related (Table 26.3) (Bridger and Brown 1985; Brown et al. 1987; Chasey et al. 1986; Hung et al. 1987; Nagesha et al. 1988; Terrett et al. 1987; Theil and Saif 1985; Tsunemitsu et al. 1992a).

Molecular genomic methods, e.g., northern-blot and dot-blot hybridization and reverse transcription-polymerase chain reaction (RT-PCR), have led to a better definition of the distribution of group A RV G and P types in pigs. To date, predominant G types identified in pigs are G3 (CRW-like), G4 (Gottfried-like), G5 (OSU-like), and G11 (YM-like); although human types G1, G2, and G9, and bovine types G6, G8, and G10, have also been detected in pigs. The most common P types in pigs are P2B[6] and P9[7], which are Gottfried-like and OSU-like types, respectively. Other porcine P genotypes P[8]

[d]NR = not reported.

and P[6] (M37-like) and bovine P genotypes P[1], P[5] and P[11] have also been detected (Table 26.1) (Barreiros et al. 2003; Gouvea et al. 1994a,b; Martella et al. 2001; Pongsuwanna et al. 1996; Rosen et al. 1994; Santos et al. 1999; Winiarczyk and Gradzki 1999; Winiarczyk et al. 2002; Zaberezhny et al. 1994).

Rotavirus is shed in feces and the major route of transmission is thought to be fecal-oral. However, a recent study of gnotobiotic pigs showed that pigs orally or nasally inoculated with a virulent group A human RV (Wa strain) shed similar titers nasally and in feces for 3–4 days (Saif et al. 2003). Whether porcine RV spreads among pigs via the respiratory route needs to be investigated.

Rotavirus can be detected in dust and dried feces in facilities that have been occupied by young pigs (Fu et al. 1989). Rotavirus maintained infectivity in feces for 7–9 months at room temperature (presumably 18–20°C) (Woode 1978) and was still infectious in feces stored at 10°C for 32 months (Ramos et al. 2000). Persistence of RV in the environment provides a mechanism for constant exposure of pigs.

Rotaviruses are resistant to inactivation by many chemical disinfectants and antiseptics (Abad et al. 1997), but can be inactivated by disinfectants such as phenols, formalin, chlorine, and beta-propiolactone. Ethanol (95%), perhaps the most effective disinfectant, exerts its effect by removing the outer capsid (Estes 2001). Disinfectant spray containing ethanol (0.1% o-phenylphenol and 79% ethanol), bleach (6% sodium hypochlorite diluted to give 800 ppm free chlorine), and phenol-based products (14.7% phenol diluted 1:256 in tap water) effectively reduced the RV titer by 95% to 99% after a 10-minute treatment (Sattar et al. 1994).

Many studies have provided evidence for interspecies RV transmission (pigs and cattle, pigs and horses, pigs and humans) and for reassortment of RV. Martella et al. (2001) reported that RV isolated from diarrheic pigs in Italy displayed typical bovine RV G- and P-type specificities, indicating a pathogenic role for bovine RV in piglets. An experimental study of bovine RV strain PP-1 infection in gnotobiotic pigs illustrated that RV circulating in one animal species can pose a risk to another by the emergence of a pathogenic reassortant RV under appropriate conditions (El-Attar et al. 2001). Antigenic and molecular analyses of a horse RV strain H-1 revealed that this virus is closely related to porcine, but not equine RV, suggesting interspecies transmission from pigs to horses (Ciarlet et al. 2001). Molecular characterization of a human RV strain RMC321 from an outbreak of RV diarrhea in India revealed porcine characteristics in most of the genes including VP4, VP6, and NSP1-5 (95–99% amino acid identity) (Varghese et al. 2004). This study provided strong evidence that porcine RV can cross the species barrier and cause severe gastroenteritis in humans. Many studies have also indicated that reassortment occurs between pig and human RV strains (Alfieri et al. 1996; Das et al. 1993; Dunn et al. 1993; Laird et al. 2003; Nakagomi and Nakagomi 2002) and some of the reassortant viruses caused diarrhea in humans (Esona et al. 2004; Gerna et al. 1992; Santos et al. 1999; Timenetsky Mdo et al. 1997). The zoonotic potential of porcine RV requires further investigation and continued surveillance.

PATHOGENESIS

Rotavirus pathogenesis is complex and diarrhea induction involves several mechanisms (Estes et al. 2001). Maladsorption caused by loss of intestinal absorptive cells resulting from villous atrophy is the widely accepted mechanism of RV-induced diarrhea in pigs and humans (Kapikian et al. 2001). Recent studies have suggested that intestinal inflammatory responses (Zijlstra et al. 1999), activation of the enteric nervous system (Lundgren and Svensson 2001), and the enterotoxin function of RV NSP4 (Ball et al. 1996; Estes et al. 2001) also contribute to a secretory-type diarrhea in RV infection.

Rotavirus replicates predominately in the cytoplasm of differentiated small intestinal villous epithelial cells (Buller and Moxley 1988) and in cecal or colonic epithelia cells (Collins et al. 1989; Theil et al. 1978; Ward et al. 1996b). Virus replicates most extensively longitudinally in the jejunum and ileum of the small intestine. Vertically, RV antigens were observed in nearly all villous epithelial cells in jejunum and ileum and in a few epithelial cells on villous tips in the duodenum at 12 to 48 hours post inoculation (Figure 26.4) (Collins et al.
26.4. *Rotavirus antigen in the cytoplasm of villous epithelial cells as viewed by the indirect fluorescent antibody method (×90). (A) Ileum from 1-day-old gnotobiotic pig 16 hours post inoculation with porcine rotavirus. Nearly all villous epithelial cells contain viral antigen. (B) Midjejunum from a 27-day-old weaned conventional pig 3 days postinoculation. Viral antigen is in epithelial cells on villous tips.*

1989; Saif 1999; Shaw et al. 1989; Stevenson 1990; Theil et al. 1978; Ward et al. 1996b).

Rotavirus replication in the villus enterocytes results in cell lysis and attendant villous blunting and atrophy. The degree of villous atrophy and the distribution of atrophic villi in the small intestine vary relative to the RV strain (Collins et al. 1989), serogroup (Saif 1999) and the age of pigs (Shaw et al. 1989). In general, villous atrophy is more severe and extensive in younger pigs. Porcine group A and C RV tend to induce more severe villous atrophy and diarrhea than group B and E in pigs (Saif 1999). Group B RV produces scattered foci of infection in the villous tips of the distal small intestines and mild diarrhea (Saif and Jiang 1994).

Piglets that developed RV diarrhea following administration of porcine or human RV demonstrated functional alterations in small intestinal villous epithelial cells, including impaired glucose-coupled sodium transport (Davidson et al. 1977; Rhoads et al. 1991), decreased disaccharidase activity (Graham and Estes 1991; Zijlstra et al. 1997), and increased thymidine kinase activity (Davidson et al. 1977). These pathophysiological changes all contribute to the maladsorptive diarrhea (Saif 1999). Of importance for swine management, malnutrition increases the severity and duration of RV diarrhea by delaying the restoration of enzymatic and absorptive capacity and hampering the regeneration of damaged intestinal villi (Zijlstra et al. 1997).

In experimentally infected pigs, RV diarrhea precedes the detection of intestinal histopathologic damage, suggesting that other mechanisms, besides villous atrophy, contribute to the RV-induced disease expression (McAdaragh et al. 1980; Theil et al. 1978; Ward et al. 1996b). Intestinal inflammation activates neural reflex pathways in the enteric nervous system. The latter is a critical component in regulating fluid secretion in the normal gut and a key element in the pathophysiology of several important veterinary pathogens such as *Salmonella* sp., *Cryptosporidium parvum*, and RV (Jones and Blikslager 2002; Lundgren et al. 2000). In mice, at least two-thirds of the fluid and electrolyte secretion caused by RV was ascribed to activation of the enteric nervous system (Lundgren and Svensson 2001). Inflammation can also disrupt mucosal integrity and create leaky membranes, further allowing translocation of bacteria and toxins across the intestinal epithelial barrier and initiation of systemic infection (Blikslager and Roberts 1997). Transient increases in macromolecular permeability were observed in piglets infected with RV (Moon 1997), and in vitro studies showed that RV infection led to enhanced toxin uptake into cells (Liprandi et al. 1997). Such findings suggest that RV infections could predispose pigs to more severe bacterial infections via enhanced uptake of toxins or the bacteria, the latter instance leading to septicemia. Mixed infection by RV and enterotoxigenic *E. coli* resulted in more severe diarrhea than did inoculation of pigs with each agent separately (Benfield et al. 1988).

The RV NSP4 was initially suggested to play a role, along with VP3, VP4, and VP7, in RV pathogenesis in a study using gnotobiotic pigs and reassortant RV (Hoshino et al. 1995). Subsequently, NSP4 was recognized as a viral enterotoxin, contributing to the pathogenesis of RV diarrhea in mice (Ball et al. 1996; Estes et al. 2001). Recombinant baculovirus-expressed NSP4 from simian RV SA11 strain was reported to induce dose- and age-dependent diarrhea in a neonatal mouse model (Ball et al. 1996). It is hypothesized that NSP4 may indirectly participate in the stimulation of the enteric nervous system by causing the release of amines/peptides from villous endocrine cells via its effect on intracellular calcium, which may in turn activate the enteric nervous system in a way similar to that demonstrated for cholera toxin (Lundgren and Svensson 2001). The role of NSP4 in RV diarrhea in pigs and other farm animals has not been confirmed. There are also many other biologically active molecules produced by epithelial cells or immunological cells in RV infection that may participate in activating secretory reflexes in the enteric nervous system and may play a role in RV-induced diarrhea and pathogenesis (Rollo et al. 1999).

Several interrelated factors may be involved in the death of RV-inoculated pigs that could be prevented by effective management strategies. Low environmental temperature (Steel and Torres-Medina 1984), malnutrition (Zijlstra et al. 1997, 1999), and high virus exposure dose (Shaw et al. 1989) are important factors that contribute to more severe diarrhea and higher mortality in RV-infected pigs. Diarrhea causes dehydration and electrolyte imbalances and may lead to exhaustion of extracellular fluid reserves, requiring treatment with oral electrolytes. Malabsorption results in malnutrition and may lead to energy deficiency and hypothermia; which may be countered by providing external heat sources to scouring pigs and rehydration fluids as needed. Observed higher mortality in neonatal pigs is likely related to more severe and extensive villous atrophy, coupled with decreased extracellular fluid and energy reserves, compared to slightly older pigs.

Rotavirus infection was thought to be mostly localized to the intestine. Occasionally, extraintestinal RV infections were reported in humans and animals. Rotavirus was detected in the lung of one of 13 experimentally infected 3-week-old conventional pigs at postinoculation day (PID) two (Shaw et al. 1989). However, recent studies have shown that systemic RV infection (viremia or antigenemia) is not uncommon in animals (calves, mice, rats, and rabbits) and humans (Blutt et al. 2003). A virulent human RV strain (Wa) caused transient viremia in gnotobiotic pigs after oral or intranasal inoculation (Saif et al. 2003). The role of RV viremia in RV pathogenesis and protective immunity to RV is unknown.

CLINICAL SIGNS

Inoculation of naive 1- to 5-day-old gnotobiotic or colostrum-deprived conventional pigs with RV consistently produces severe diarrheal disease (McAdaragh et al. 1980; Pearson and McNulty 1977; Tzipori and Williams 1978; Ward et al. 1996b; Woode et al. 1976). Pigs become listless, anorexic, and occasionally vomit by 12–24 hours after inoculation and then develop profuse watery, yellow-to-white flocculent diarrhea 1–4 hours later. Diarrhea continues for 3–7 days and progressively resolves in 7–14 days. Mortality can reach 50 to 100%. When 7- to 21-day-old pigs are inoculated, diarrhea, and dehydration are less severe and mortality is lower (Crouch and Woode 1978; Shaw et al. 1989; Theil et al. 1978). Conventional pigs inoculated when 28 days old develop mild diarrhea lasting only 1–1.5 days (Lecce et al. 1982; Tzipori et al. 1980c).

Diet influences disease. No clinical disease was observed after RV was inoculated into 21- to 28-day-old pigs that consumed a dry diet for more than 3 days previously (Tzipori et al. 1980c; Paul and Stevenson 1999). In contrast, gnotobiotic pigs fed a liquid diet developed diarrhea when challenged with RV at 7–8 weeks of age (Yuan et al. 1996).

Naturally occurring RV diarrhea is usually less severe than experimental disease due to the impact of maternal lactogenic immunity. Rotavirus infection is endemic in nearly all conventional swine herds. Consequently, a proportion of gilts and sows have immunity to RV, which is passed to their piglets via colostrum and milk (Askaa et al. 1983; Ward et al. 1996a). Levels of RV antibodies in colostrum and milk decline rapidly in the first few days of lactation. Diarrhea occurs in pigs when the oral challenge level of RV exceeds a protective level of lactogenic passive immunity (Saif 1985). Management practices that impact the proportion of dams that are immune (type of housing, sanitation), the level of passive immunity transferred to pigs (factors affecting lactation and suckling), and the level of RV challenge to pigs (crate design, sanitation) differ among swine herds and affect the age of onset and severity of rotaviral diarrhea.

Naturally occurring RV-associated diarrheal disease is reported in 1- to 41-day-old suckling pigs (Askaa et al. 1983; Bohl et al. 1978; Debouck and Pensaert 1983; Roberts et al. 1980; Svensmark et al. 1989; Yaeger et al. 2002) or within 7 days following weaning (Bohl et al. 1978; Lecce and King 1978; Tzipori et al. 1980b; Woode et al. 1976). The age of onset is often consistent in a given herd. Uncomplicated RV diarrhea in suckling pigs usually resolves in 2–3 days. Feces are yellow or white, watery-to-creamy, and variably flocculent. Morbidity is usually less than 20% and mortality due to dehydration is typically less than 15% of diarrheic pigs. Mortality is highest in young pigs. Rotaviral diarrhea in suckling pigs is frequently complicated by infection with *Isospora*

suis (Roberts et al. 1980) or enterotoxigenic *Escherichia coli* (ETEC) (Bohl et al. 1978), which results in more severe disease, higher morbidity, and higher mortality (Lecce et al. 1982; Tzipori et al. 1980a).

The importance of RV in diarrhea in weaned pigs is less clear. Severe diarrhea in weaned pigs has been associated with RV, but usually in combination with TGE virus (Bohl et al. 1978) or β-hemolytic ETEC (Lecce et al. 1982; Tzipori et al. 1980a). Inoculation studies with RV and β-hemolytic ETEC suggest an important role for RV in postweaning diarrhea (Melin et al. 2004). Inoculation of weaned pigs with RV or β-hemolytic ETEC alone resulted in mild transient or no diarrhea, whereas inoculation with RV followed by hemolytic E. coli resulted in enhanced colonization by β-hemolytic ETEC and severe protracted diarrhea.

LESIONS

Lesions caused by RV are only in the small intestines and are due to RV replication within, and destruction of, villous epithelial cells, as well as subsequent adaptive and regenerative responses. Gross lesions appear slightly before, or with, the onset of diarrhea and are most severe in 1- to 14-day-old pigs (Collins et al. 1989; Janke et al. 1988; Pearson and McNulty 1977; Stevenson 1990; Theil et al. 1978). The stomachs usually contain food, and the distal one-half to two-thirds of the small intestine is thin-walled, flaccid, and dilated with watery, flocculant, yellow or gray fluid. The lacteals in the distal two-thirds of the intestine contain no chyle and the associated mesenteric lymph nodes are small and tan. The cecum and colon are dilated with similar contents. Gross lesions are less severe or are absent in pigs that are 21 days of age or older (Shaw et al. 1989; Stevenson 1990).

Light microscopic lesions (Paul and Stevenson 1999) and scanning electron microscopic lesions (Collins et al. 1989; McAdaragh et al. 1980; Stevenson 1990; Torres-Medina and Underdahl 1980) have been described in numerous RV inoculation studies in suckling pigs. Degeneration begins in epithelial cells on the apical portion of villi by 16–18 hours postinoculation and is evidenced by swollen rarified cytoplasm, nuclear swelling, irregular brush borders, and frequent partial detachment from adjacent cells or the basement membrane. By 16–24 hours postinoculation, sloughing of cells results in significant villous atrophy that is most severe by 24–72 hours postinoculation (Figure 26.5). The tips of atrophic villi are eroded or are covered by swollen or attenuated, nearly squamous epithelial cells (Figure 26.6) and there is cellular debris in the lamina propria. Lateral fusion of villi is seen 24–168 hours postinoculation. Hyperplasia of crypt epithelial cells results in significantly deeper crypts beginning 48–72 hours postinoculation. The time required for complete regeneration of normal villi depends on the age of the pig.

Ultrastructural lesions in RV-infected pigs are typical

of those described for RV in many other mammalian and avian species (Narita et al. 1982; Pearson and McNulty 1979; Saif et al. 1978). The cytoplasm of infected villous epithelial cells contains variably sized, electron-dense granular viroplasms that often have dense subviral cores or double-layered particles on the periphery. Double-layered viral particles obtain the outer capsid by budding through the membranes of the rough endoplasmic reticulum (Figure 26.7). Mature, 75–78 nm triple-layered virus particles accumulate in the cysternae of the endoplasmic reticulum and are released by cell lysis. Other degenerative changes in virus-infected cells include cell swelling, mitochondrial swelling, nuclear swelling, di-

latation of the cytocavity network, and fragmentation of microvilli. Macrophages in the lamina propria contain cellular membrane profiles, virus particles, viroplasm, and other cellular debris in phagosomes.

IMMUNITY

Pigs infected with RV develop intestinal and systemic immune responses. Neonatal gnotobiotic pigs have been used to study immune responses to porcine and human RV infection, correlates of protective immunity, and approaches to improve the immunogenicity and protective efficacy of RV vaccines (Saif et al. 1996, 1997; Yuan and Saif 2002).
26.7. *Ultrastructure of a swollen and degenerate rotavirus-infected villous epithelial cell containing dense granular viroplasm (arrowhead). Virus particles form and obtain outer capsids through budding into the rough endoplasmic reticulum (small arrow). Many double-shelled virus particles are within the cysternae of the endoplasmic reticulum (large arrows) (×23,800).*

Pigs recovered from virulent RV infection are fully protected from reinfection by homotypic (common P or G type), but not heterotypic, RV (Bohl et al. 1982; Hoshino et al. 1988; Saif et al. 1997).

Rotavirus-specific IgM antibody-secreting cells (ASC) in gnotobiotic pigs orally inoculated with porcine RV (SB1A and Gottfried) occurred by PID 3, and numbers peaked in spleen and mesenteric lymphoid tissues by PID 7 and in intestinal lamina propria by PID 7 to 14 (Chen et al. 1995). Numbers of RV-specific IgA and IgG ASC in these tissues peaked at PID 14 to 21. Rotavirus-specific IgA ASC responses were dominant in the intestine. The B and T cell immune responses to virulent and attenuated human RV Wa strain (P1A[8]G1) were compared in the intestinal lamina propria and systemic lymphoid tissues of neonatal gnotobiotic pigs (Ward et al. 1996c; Yuan et al. 1996, 2001a). Pigs inoculated with one oral dose of virulent human RV developed significantly higher numbers of virus-specific IgA and IgG ASC and memory B cells and higher lymphocyte proliferation responses in the intestinal lamina propria compared to pigs given three oral doses of attenuated human RV. The magnitude of the intestinal IgA ASC and lymphocyte proliferation responses, which reflected the degree of viral replication and lesions within the intestine, was positively correlated with the level of protection induced (Ward et al. 1996c; Yuan and Saif 2002).

After RV infection or oral vaccination, protein-specific antibody responses were predominately against RV inner capsid protein VP6, a nonneutralizing antigen, followed by VP4, NSP2, NSP4, and VP7 (Chang et al. 2001; Yuan et al. 2004). Although VP6 is the most immunogenic protein, VP6 antigen administered in the form of VP2/6 virus-like particles (VLPs) did not protect neonatal pigs (Azevedo et al. 2004; Gonzalez et al. 2004;

Iosef et al. 2002; Nguyen et al. 2003; Yuan et al. 2000, 2001b), or neonatal mice born to 2/6VLP vaccinated dams (Coste et al. 2000). These results indicate that antibodies to VP6 are not sufficient to protect against RV disease (Yuan and Saif 2003). Rotavirus VP4 and VP7 outer capsid proteins both induce virus neutralizing antibodies and independently confer protection in pigs (Hoshino et al. 1988).

Protective Immunity

Protective immunity against RV disease in pigs and humans is most closely related to the presence of neutralizing IgA antibodies in the intestine and serum (Azevedo et al. 2004; Coulsen et al. 1992; Coulsen et al. 1998). The roles of T and B cells in protective immunity to RV infection have been extensively studied, but only in adult mice (reviewed by Franco and Greenberg 2000). Limited studies of presumed CD4+ Th cell responses to RV have been performed in pigs (Ward et al. 1996c), lambs (Bruce et al. 1995), calves (Oldham et al. 1993), and humans (Offit et al. 1993) using lymphocyte proliferation assays. Excluding mice, the role of CD8+ T cells in protective immunity to RV was examined only in calves by injection of MAbs to deplete CD4 or CD8 T cells (Oldham et al. 1993). These investigators suggested that although CD8+ T cells contribute to protection against RV, the major role of CD8+ T cells was in restricting and clearing RV primary infection, whereas CD4+ T cells were important in generation of mucosal antibody responses (Oldham et al. 1993).

Although VP4 and VP7 elicit serotype-specific virus neutralizing antibodies independently from each other (homotypic immunity), they also evoke reduced levels and shorter duration of broad, serotype cross-reactive virus neutralizing antibodies (heterotypic immunity)

(reviewed by Hoshino and Kapikian 2000). Among the distinct RV serogroups and serotypes, cross-protection after primary infection or vaccination is minimal or nonexistent, but repeated infection or vaccination (even with the same RV strain) broadens the range of protection against heterotypic RV (Chiba et al. 1993; Gorrell and Bishop 1999). The antigenic divergence among different serotypes/genotypes of RV presents a challenge for design of vaccines capable of inducing heterotypic protection. Reassortant RV containing the VP4 and VP7 genes from different serotypes may be used in multivalent vaccines to induce immunity to each serotype (Hoshino and Kapikian 2000; Hoshino et al. 1988).

Passive Immunity

Pigs are most susceptible to infection with group A RV during the first weeks of life and soon after weaning (Bohl 1979). Outbreaks of diarrhea in animals less than 2 weeks of age are less frequent, presumably because piglets have acquired passive immunity in colostrum/milk from immune dams. Pigs are born agammaglobulinemic and acquire circulating maternal antibodies by consuming colostrum. Piglets are able to uptake antibodies for only a limited time after birth (24–36 hours after birth) before gut closure occurs (Wagstrom et al. 2000). Afterward, maternal antibodies are no longer absorbed from the intestines and only act locally to protect the gut. Piglets born to gilts are more susceptible to RV diarrhea than those born to sows because maternal antibody titers are often lower in gilts (Askaa et al. 1983; Gelberg et al. 1991).

Thus, rotavirus-specific antibodies in the colostrum (mainly IgG) and milk (predominately secretory [S] IgA) provide passive protection against RV to neonatal pigs (Saif 1999). Secretory IgA antibodies are more efficient in mediating protection in the gut of pigs because of their resistance to cleavage by digestive enzymes and higher levels in milk (Saif and Fernandez 1996). High persisting levels of passive IgG RV antibodies transudated from serum back to gut were also protective transiently (Hodgins et al. 1999; Parreno et al. 1999; Parreno et al. 2004; Ward et al. 1996a). Ideally, suckling animals become subclinically infected with RV after receiving adequate passive antibodies to prevent disease and develop active immunity (or are primed) to prevent subsequent diarrhea.

Vaccine Strategies

Current commercially available RV vaccines are used for immunization of sows, as well as nursing pigs. Attenuated RV vaccines are administered orally, orally and intramuscularly (IM), or IM. Inactivated RV vaccines are administered IM in sows and intraperitoneally (IP) in nursing pigs. The efficacy of these vaccines is often uncertain or poor (Saif and Fernandez 1996).

Induction of active immunity in sucking pigs to prevent postweaning diarrhea is problematic because of the presence of maternal antibodies. Improved vaccines and vaccination approaches are needed. Although oral immunization with replicating vaccines is the simplest and most efficient route for priming SIgA responses in the intestines, maternal antibodies have been shown to interfere with the development of active immunity in neonatal pigs (Hodgins et al. 1999; Parreno et al. 1999). Inactivated vaccines given parenterally may be less affected by maternal antibodies. However, IM immunization of RV seronegative piglets with inactivated RV did not induce SIgA antibody responses in the intestine or confer protection (Yuan et al. 1998).

Besides the traditional vaccines, the immunogenicity and protective efficacy of various alternative RV vaccine formulations (recombinant baculovirus-expressed VLP and DNA vaccines), routes of administration, and adjuvants have been evaluated in RV seronegative gnotobiotic pigs (reviewed by Yuan and Saif 2002). The attenuated human RV as an oral priming dose followed by 2/6-VLPs as intranasal (IN) or oral booster doses (Iosef et al. 2002; Yuan and Saif 2002) or VP6 DNA plasmid as IM booster doses (Yuan et al. 2003) were shown to be highly effective in inducing intestinal IgA antibody responses and protection. However, priming with 2 doses of 2/6-VLPs or VP6 DNA followed by attenuated human RV oral boosting was ineffective.

These results suggest new vaccine approaches that could be developed to prevent enteric viral infections in pigs. The combination of multiple vaccine types, vaccination routes, mucosal adjuvants, and new mucosal delivery systems may lead to optimal stimulation of protective immune responses in the presence or absence of maternal antibodies and improved efficacy of RV vaccines.

DIAGNOSIS

The clinical signs of RV infection in pigs are not unique. Diagnosis requires detection of virus, viral antigen, or viral nucleic acid (RNA). Rotavirus should be considered as a cause of diarrhea in neonatal pigs at 1–8 weeks of age. Fecal samples, intestinal contents, or sections should be collected in the acute phase of disease and submitted for diagnosis. RV is shed at highest concentrations in the first 24 hours after the onset of diarrhea. Sampling during this time frame is especially critical for the detection of certain group RV because the onset, amount, and duration of virus shed is less in pigs infected with group B RV (Bridger 1980; Theil et al. 1985).

A number of methods may be used for the detection of RV, including electron microscopy (EM), immune EM (IEM), immunohistochemistry (IHC), immunofluorescence (IF) on frozen sections or impression smears of small intestines, enzyme-linked immunoassay (ELISA), virus isolation (VI), latex agglutination, dot blot hybridization, RNA electropherotyping, and reverse tran-

scription-polymerase chain reaction (RT-PCR) (Kapikian et al. 2001).

Electron microscopy has been extensively used for detection of RV and used frequently to resolve discrepancies in results from other techniques. It is highly specific because RV have a distinctive morphologic appearance. When only a few samples are to be examined for RV, EM is the most rapid diagnostic method because fecal samples can be stained with phosphotungstic acid and examined directly within a few minutes of collection (Brandt et al. 1981). Use of IEM allows differentiation of RV into serogroups (Saif and Jiang 1994).

ELISA is frequently used for the detection of rotaviral antigens in fecal samples or intestinal contents. Commercial diagnostic kits are available for the detection of porcine group A RV (Benfield et al. 1984; Goyal et al. 1987) and MAb capture ELISAs have also been developed for detection of groups B and C RV (Yolken et al. 1988; Ojeh et al. 1992).

Electropherotyping of viral RNA is used for the detection and differentiation of RV groups. Rotaviruses of different serogroups have distinct electropherotypes (Figure 26.2), which provide a tentative serogroup diagnosis. Electropherotyping results should be confirmed by serologic or nucleic acid–based methods. For electropherotyping, viral RNA is isolated from feces and subjected to polyacrylamide gel electrophoresis and silver staining to visualize the RNA bands (Herring et al. 1982).

Serologic tests are of little value in the diagnosis of RV infection because antibodies are common in most swine herds. However, antibody titers and isotypes are indicators of the immune status of animals. High IgM and IgA antibody titers indicate active or recent infection. There are a variety of techniques for measuring a serologic response to RV infection, including IEM, complement fixation (CF), indirect IF, immune adherence hemagglutination assay, ELISA, VN, hemagglutination inhibition (Eiguchi et al. 1987), inhibition of reverse passive hemagglutination, and immunocytochemical staining (Kapikian et al. 2001).

ELISA using isotype-specific MAbs has been used to detect IgM, IgA, and IgG antibody responses to RV (Azevedo et al. 2004; Parreno et al. 1999; Paul et al. 1989; Coulsen et al. 1998). Antibodies to group C RV have also been detected by blocking ELISA using MAbs (Tsunemitsu et al. 1992a). Plaque reduction and fluorescent focus reduction neutralization assays have been used to detect neutralizing antibodies (Hoshino et al. 1984; Coulsen et al. 1998). Neutralization assays yield the most meaningful information about the identity of the infecting RV and the development of a serotype-specific antibody response. An immunocytochemistry assay using recombinant baculoviruses expressing RV proteins has been developed to measure antibody responses to individual RV proteins (Ishida et al. 1997; Yuan et al. 2004). It is highly sensitive to detect antibodies to both conformation-dependent and independent epitopes on VP4 and VP7.

Nucleic acid probe hybridization assays are highly specific and sensitive for detection of RV RNA and for genotyping (Johnson et al. 1990; Koromyslov et al. 1990; Ojeh et al. 1993; Rosen et al. 1990, 1994; Zaberezhny et al. 1994). The limit of detection for purified viral RNA by the dot hybridization procedure was 8 pg in a homologous reaction. It was ten- to hundredfold more sensitive than ELISA for the detection of RV in various dilutions of fecal samples (Flores et al. 1983).

Currently the most widely used methods for RV detection, genogrouping (A–C, E) and genotyping (group A) is RT-PCR (Barreiros et al. 2003; Elschner et al. 2002; Gouvea et al. 1994a,b; Martella et al. 2001; Pongsuwanna et al. 1996; Winiarczyk and Gradzki 1999; Winiarczyk et al. 2002). Multiplex RT-PCR offers the most sensitive and reliable method for G and P genotyping of group A RV. The RT-PCR method is 100,000 times more sensitive than standard electropherotyping and 5,000 times more sensitive than hybridization assays (Wilde et al. 1991; Xu et al. 1990). The RT-PCR has also been applied for detection of group B and C RV (Eiden et al. 1991; Gouvea et al. 1991).

Newly developed oligonucleotide microarray hybridization technology offers another method for the identification of RV genotypes (Chizhikov et al. 2002). This approach combines the high sensitivity of RT-PCR with the selectivity of DNA-DNA hybridization and was capable of unambiguous identification of the G genotypes of all RV strains.

PREVENTION AND CONTROL

Treatments for diarrhea in animals include antibiotics, antisecretory drugs, adsorbents, and fluid electrolyte therapy (Bywater 1983). However, no known therapeutic agents are available for the specific treatment of porcine RV infections. General supportive therapy, management procedures, and antibiotics are recommended to minimize mortality due to RV and secondary bacterial infections (Paul and Stevenson 1999). Electrolyte solutions containing glucose-glycine minimize dehydration and weight loss induced by RV infection (Bywater and Woode 1980). L-glutamine in oral rehydration solution promotes jejunal sodium and chloride absorption in RV-infected pigs (Rhoads et al. 1991). Oral feeding of transforming growth factor-alpha enhanced jejunal mucosal recovery and electrical resistance in piglets with RV enteritis (Rhoads et al. 1995). Chicken egg powder enriched with Ig specific for RV antigen used as additive to sow's milk reduced the prevalence of diarrhea in 2- to 3-day-old pigs; however, the effect of sow's milk was more pronounced than the effect of the egg powder (Hennig-Pauka et al. 2003).

Optimal ambient temperature (35°C) significantly reduces the nursing piglet mortality caused by RV diar-

rhea (Steel and Torres-Medina 1984); low temperatures and temperature fluctuations should be avoided. In herds with a persistent problem of postweaning diarrhea with high mortality, a change in weaner diet and weaning procedures should be considered (Paul and Stevenson 1999). Scheduled feeding of a high-energy weaner diet has been successfully used to reduce RV morbidity and mortality (Tzipori et al. 1980b).

The ubiquity of RV in swine herds and its persistence in the environment make it difficult to eradicate RV from swine herds. Rotaviruses persist as subclinical infections and are shed by adult swine (Benfield et al. 1982). Management of farrowing on swine farms is important in controlling diarrhea caused by RV. Management practices should be designed to reduce the level of RV to which susceptible pigs are exposed and to boost levels of passive immunity (Barreiros et al. 2003; Paul and Stevenson 1999; Saif 1985). Exposure levels may be reduced by sanitation. The floors in farrowing and nurs-

ing houses should be constructed for easy cleaning and minimal fecal buildup. Rooms should be cleaned and disinfected between groups. The farrowing interval should be minimized to prevent RV buildup and infection of the litters farrowed latest. A recent study showed that herds using continuous flow in the nurseries had significantly lower rates of RV infection than the herds using all-in/all-out production, suggesting that nursing pigs exposed to RV in the environment may be able to develop an active immune response under the partial protection of maternal antibodies (Dewey et al. 2003). To enhance passive immunity, replacement gilts should be exposed to the feces of older sows to boost RV antibody titers through repeated exposure to RV. Attention to lactation diet, feed intake, sow comfort, and farrowing crate design are important to ensure adequate milk supply and effective suckling necessary to transfer maternal immunity successfully (Paul and Stevenson 1999).

Porcine Reovirus

Although discovered in 1951 (Tyler 2001), the role of reoviruses in the disease process is unclear (Kasza 1970; Kirkbride and McAdaragh 1978; McFerran and Connor 1970). Natural reovirus infection or antibodies to reovirus have been detected in all animal species (Tyler 2001; Yang et al. 1976). Illnesses associated with reovirus infections in animals have involved primarily the respiratory, gastrointestinal, and nervous system (Hirahara et al. 1988; Fukutomi et al. 1996; Tyler 1998). Reoviruses may be detected in pigs with respiratory, enteric, and reproductive diseases, as well as in healthy pigs.

ETIOLOGY

Reovirus was the first genus named in the family *Reoviridae*. The other two genera of importance to animals are genus *Rotavirus* and genus *Orbivirus*. "Reo" is an acronym for "respiratory and enteric orphan." The name was intended to emphasize the fact that these viruses were not associated with any known disease (hence, orphan) (Tyler 2001). Reovirus virions are non-enveloped, icosahedral particles with a rough outer rim. The particles are 75 nm in diameter with the inner capsid measuring 45–50 nm (Figure 26.8).

Reoviruses have a segmented (10 segments) dsRNA genome. The density of a complete (mature) virion in cesium chloride is 1.36 g/ml. Porcine reoviruses are stable at acidic pH and resistant to ether, chloroform, and trypsin, but susceptible to heat at 50°C for 1 hour. They are sensitive to 0.1% sodium deoxycholate (Hirahara et al. 1988). Porcine reoviruses possess a hemagglutinin that agglutinates human group O and porcine erythro-

cytes at 4°C, 22°C, and 37°C. Mammalian reoviruses share a group antigen that can be detected by complement fixation, IF, and immunodiffusion (Sabin 1959). All mammalian reovirus isolates can be divided serologically into three types: 1, 2, and 3. Reoviruses of different types can be distinguished by serum neutralization and hemagglutination inhibition tests.

Reoviruses can be cultivated in a wide variety of cell cultures from many species (Hirahara et al. 1988; Kasza 1970). The most commonly used cell line is mouse L929 fibroblasts for viral growth, purification, and plaque assay (Tyler 2001). Reovirus replicates slowly and the
26.8. *Electron micrograph of reovirus particles viewed by negative-staining electron microscopy (×115,000).*

majority (80%) of the nascent virus population remains cell associated. The cytopathic effect of reoviruses varies, depending upon the cell line used. In general, cells round up, become granular, and detach from monolayers. Eosinophilic, intracytoplasmic, inclusion bodies can be seen in cultures stained with May-Greenwald-Giemsa stain (Paul and Stevenson 1999).

EPIDEMIOLOGY

Reoviruses are ubiquitous and porcine reovirus infections are widespread in swine herds. Antibodies to all three types have been detected in pigs (Fukumi et al. 1969; Harkness et al. 1971; Yang et al. 1976). Reoviruses are spread via fecal-oral and respiratory routes. Passively acquired antibodies to reoviruses persist in neonatal pigs for about 11 weeks, at which time pigs become susceptible to infection (Watt 1978).

CLINICAL SIGNS

Reoviruses have been isolated from pigs with respiratory or enteric disease, as well as from clinically healthy pigs (Elazhary et al. 1978; Kasza 1970; McFerran et al. 1971; Robl et al. 1971) and from aborted fetuses (Kirkbride and McAdaragh 1978). Experimental inoculations have not consistently reproduced disease. In most of the studies, intranasal (IN), intraperitoneal, or intracerebral inoculation of conventional and gnotobiotic pigs at 1–6 weeks of age with porcine or human reovirus type 1 did not result in clinical disease, except for a transient febrile reaction (Baskerville et al. 1971; Kasza 1970; McFerran and Connor 1970; McFerran et al. 1971; Watt 1978).

Reovirus is excreted in nasal secretions and feces as early as 24 hours postinoculation and may continue for 6–14 days. Mild respiratory disease characterized by pyrexia, sneezing, inappetence, and listlessness was reproduced in colostrum-deprived pigs and conventional pigs inoculated IN or exposed via aerosol to reovirus type 1 (Hirahara et al. 1988). Intravenous or IM inoculation of seronegative sows between 40 and 85 days of gestation with type 3 reovirus resulted in term litters containing a mixture of mummified, stillborn, weak, and normal pigs. The virus can also be isolated from fecal tissues and the placenta of these sows (Paul and Stevenson 1999).

PATHOGENESIS

Reoviruses replicate mainly in the respiratory and intestinal tracts after natural infection. The pathogenesis and pathology of reoviruses have been studied extensively in mice and the findings have greatly improved our understanding of viruses and virus-host interactions (Tyler 2001). In mice, reoviruses are able to spread from the gastrointestinal tract to extraintestinal organs and the central nervous system after oral inoc-ulation. Reovirus-induced myocarditis is associated with virus-induced destruction of cardiac myocytes in the absence of a significant inflammatory response (Tyler 2001). The pathogenesis of reoviruses in pigs is unknown.

LESIONS

Reovirus inoculation studies of pigs revealed few gross lesions and only mild microscopic lesions. Oral inoculation of 1-week-old colostrum-deprived pigs with enteric-origin reovirus resulted in focal villous atrophy in the jejunum and ileum (Elazhary et al. 1978). Aerosol exposure of 4-week-old specific pathogen free (SPF) pigs to porcine type 1 reovirus resulted in no gross lesions, but consistent microscopic lesions in the lungs consisting of multifocal aggregates of lymphocytes and macrophages in alveoli and alveolar septae and mild peribronchiolar nodular lymphocytic hyperplasia (Baskerville et al. 1971). Inoculation of 70 kg SPF pigs IN with a respiratory isolate of porcine type 3 reovirus resulted in lobular atalectasis, vesicular emphysema, and peribronchiolar nodular lymphocytic hyperplasia, which varied in intensity between lobules (Paul and Stevenson 1999). Additional studies are needed to characterize the clinical disease and lesions in swine caused by porcine reoviruses.

DIAGNOSIS

Methods similar to those described for RV may be employed for the detection of reoviruses. Virus isolation has commonly been used for diagnosis. Typing of reovirus is achieved by virus neutralization and hemagglutination inhibition tests with reference antisera to the three reovirus types (Paul and Stevenson 1999).

PREVENTION AND CONTROL

No specific methods are available for treatment or prevention of porcine reovirus infections, and possibly none are warranted until the clinical significance of reovirus infections in swine is documented.

27 Paramyxoviruses: Rubulavirus, Menangle, and Nipah Virus Infections

Peter D. Kirkland and Alberto Stephano

The family *Paramyxoviridae* contains viral pathogens of international significance in most animal species and humans. Until recently, there were no major paramyxovirus pathogens of pigs, the single possible exception being the rubulavirus that causes blue eye (BE) disease (blue eye paramyxovirus, BEP). However, BEP is confined to Mexico, where its economic impact is considered low at present. Then, during a 3-year period commencing in 1997, several new paramyxoviruses were identified, and two (Menangle and Nipah viruses) were found to be serious pathogens of both pigs and humans.

The family *Paramyxoviridae* encompasses a group of large (150–400 nm in diameter) pleomorphic viruses. The genome consists of a long single strand of RNA within a herringbone-like nucleocapsid. The nucleocapsid is surrounded by a lipid envelope that usually contains an outer fringe of surface projections or "spikes."

The paramyxoviruses are currently organized in 2 subfamilies and 7 genera. There are 5 genera in the subfamily *Paramyxovirinae*: *Avulavirus*, *Henipavirus*, *Morbillivirus*, *Respirovirus*, and *Rubulavirus*. There are major pathogens of animals and humans in each of these genera—e.g., Newcastle disease virus of poultry in the genus *Avulavirus*; canine distemper and human measles viruses in the genus *Morbillivirus*; several parainfluenza viruses of animals and humans in the genus *Respirovirus*; and in the genus *Rubulavirus*, human mumps virus, BEP, and Menangle virus. Both of the latter two viruses are infectious for pigs. The genus *Henipavirus* was created for two of the most recently recognized and closely related paramyxoviruses, Hendra and Nipah, reflecting their morphological and genetic differences from other paramyxoviruses.

As a result of their tissue trophisms, there are broad similarities in the diseases caused by paramyxoviruses. Typically, pathogenic paramyxoviruses are associated with diseases of the central nervous system (CNS) (canine distemper and Newcastle disease) and respiratory systems (parainfluenza infections, Hendra, Nipah, and Newcastle disease). Some, especially Menangle virus and BEP, are also important reproductive pathogens.

The only paramyxoviruses that cause significant disease in pigs are BEP, Menangle virus, and Nipah virus. There have been occasional reports of other paramyxoviruses associated with respiratory and CNS disease in pigs in Japan (Sasahara et al. 1954), Canada (Greig et al. 1971), Israel (Lipkind et al. 1986), and the United States (Paul et al. 1994), but none has proven to be of significance. This chapter provides an overview of BEP, Menangle and Nipah viruses, and the diseases they cause.

Rubulavirus (Blue Eye Disease)

As mentioned before, blue eye (BE) is a disease of swine caused by infection with blue eye paramyxovirus (BEP) (Stephano et al. 1988b) or porcine rubulavirus, also known as La Piedad-Michoacan virus (LPMV). The disease was first reported in 1980 in central Mexico, with numerous outbreaks of encephalitis and corneal opacity in piglets (Stephano et al. 1982). A hemagglutinating virus was isolated, characterized, and identified as a serologically distinct member of the family *Paramyxo-* *viridae* (Stephano and Gay 1983, 1984, 1985a; Stephano et al. 1986b).

The first reported outbreak of BE was observed on a commercial farm with 2500 sows located in La Piedad, Michoacán, Mexico (Stephano et al. 1982). Thereafter, BE was recognized as an important pathogen in central Mexico, with serological evidence of BEP in at least 16 states in Mexico (Stephano et al. 1988b). The disease is still recognized in central Mexico, but its economic im-
27.1. *Blue eye paramyxovirus particles showing surface projections by negative-stain electron microscopy (×108,200).*
27.2. *Fraction of a nucleocapsid from a disrupted BEP (negative-stain electron microscopy; ×203,000).*

pact has lessened. BE has not been reported outside of Mexico.

ETIOLOGY

Extensive molecular characterization of BEP (Berg et al. 1991, 1992; Sundqvist et al. 1990, 1992), combined with its morphology and biological properties, supports its placement in the rubulavirus genus.

BEP particles are similar to other paramyxoviruses, measuring 135–148 nm by 257–360 nm (Figure 27.1). The virion is pleomorphic, but usually more or less spherical; no filamentous forms have been observed. Nucleocapsids from disrupted virus particles have a diameter of 20 nm and a length of 1000–1630 nm (Figure 27.2) or more (Stephano and Gay 1985a).

In the laboratory, BEP replicates and produces cytopathology in a wide range of cell cultures from many different animal species, including both continuous cell lines and primary cell cultures. Changes consist of individual rounded cells, cytoplasmic vacuoles, and syncytium formation. Some cells also contain viral inclusion bodies (Moreno-Lopez et al. 1986; Stephano and

Gay 1985a; Stephano et al. 1986a). The chick embryo also supports BEP replication.

BEP agglutinates erythrocytes from a wide range of animal species, as well as humans. Spontaneous elution occurs at 37°C after 30–60 minutes. Hemadsorption of chicken erythrocytes has also been described (Stephano and Gay 1985a; Stephano et al. 1986b).

BEP is not known to share any antigens with other paramyxoviruses (Stephano et al. 1986b) and no antigenic differences have been observed between different strains of BEP (Gay and Stephano 1987).

CLINICAL SIGNS

An outbreak of BE may start in any area of a pig farm, but is usually first observed in the farrowing house, with CNS signs and high piglet mortality. At about the same time, corneal opacity may be observed in some weaned or fattening pigs (Stephano and Gay 1985a, 1986a; Stephano et al. 1988a). The mortality rate increases rapidly and then declines within a short time. Once the initial outbreak is over, no new clinical cases appear, unless susceptible pigs are introduced.

Clinical signs are variable and depend primarily on the age of the pig. However, corneal opacity, the sign that gives the disease its name, frequently occurs in pigs of all ages without other signs and resolves spontaneously.

Piglets 2–15 days old are the most susceptible, and the onset of clinical signs is sudden. Healthy piglets may suddenly become prostrate, generally in lateral recumbency, or show nervous signs. However, the disease usually runs a course that starts with fever, a rough hair coat, and an arched back, sometimes accompanied by constipation or diarrhea. These signs are followed by progressive nervous signs, including ataxia, weakness, rigidity (mainly of the hind legs), muscle tremor, and abnormal posture, such as a sitting position. Anorexia does not occur as long as piglets can still walk. Some piglets are hyperexcitable and may squeal and show paddling movements when handled. Other signs include lethargy with some involuntary movements, dilated pupils, apparent blindness, and, occasionally, nystagmus. Some piglets suffer from conjunctivitis, with swollen eyelids and lacrimation. Often the eyelids are closed and adherent with exudate. In up to 10% of affected piglets, either unilateral or bilateral corneal opacity is present.

Of the litters farrowed during an outbreak, about 20% are affected. In these litters, the piglet morbidity is 20–50%, and mortality in affected piglets is about 90%. In the first cases observed, piglets usually died within 48 hours of the appearance of clinical signs, but in later cases, death occurred after 4–6 days. During an initial outbreak, deaths occur for 2–9 weeks, depending on the management system.

Pigs older than 30 days show moderate and transient clinical signs such as anorexia, fever, sneezing, and coughing. Nervous signs are less common and less obvious but, when present, consist of listlessness, ataxia, circling, and, rarely, swaying of the head. Uni- or bilateral corneal opacity and conjunctivitis continue to appear on the farm for another month without other signs. Fewer than 2% of pigs older than 30 days are affected and the mortality is generally low. Outbreaks with 20% mortality and severe CNS manifestations have been observed in 15–45 kg pigs. Corneal opacity was present in up to 30% of these pigs (Stephano and Gay 1985b).

Most of the sows suckling affected litters are clinically normal. Some show moderate anorexia 1 or 2 days before the appearance of clinical signs in piglets. Corneal opacity has also been observed in the farrowing house during outbreaks.

In pregnant sows, reproductive failure lasting 2–11 months (usually 4 months) is observed. Reproductive signs during outbreaks include an increase in the number of animals returning to estrus, a reduction in farrowing rate, and an increase in the weaning-to-service interval and nonproductive sow days. The rate of stillbirths and mummified fetuses also increases and, conse-

quently, there is a reduction in the number of pigs born alive. Later, there is also a reduction in the total number of pigs born. Abortion is not a cardinal feature, but has sometimes been observed during an acute outbreak. Gilts and other adult pigs occasionally develop corneal opacity.

Boars, like other adult animals, generally do not show clinical signs, but mild anorexia and corneal opacity have been recorded. Semen evaluation demonstrated that, in herds infected by BEP, about 30% of boars show temporary or permanent infertility, with a decrease in concentration, an increase in abnormalities, and a decrease in motility and viability of spermatozoa. In some boars there is azoospermia, the ejaculate becomes clear and resembles coconut water. Some boars develop swollen testicles. The testis and epididymis become turgid with marked edema. Later, some develop a granular texture and most atrophy (generally unilateral) or become soft and flabby with or without granular epididymitis. Boars with severe lesions lose libido (Campos and Carbajal 1989; Stephano et al. 1990).

Differences in clinical signs became evident a few years after the virus was discovered. In 1980, primarily piglets were affected. Mortality and CNS disorders in pigs older than 30 days were uncommon. In 1983, severe outbreaks of encephalitis with high mortality in pigs weighing 15–45 kg were observed on badly managed farms, always with concomitant viral and bacterial diseases (Stephano and Gay 1985b, 1986a). Also in 1983, reproductive failure in sows and transient infertility in boars were identified (Stephano and Gay 1984, 1985a). In 1988, severe problems of orchitis, epididymitis, and testicular atrophy in boars became evident (Campos and Carbajal 1989; Stephano et al. 1990).

EPIDEMIOLOGY

Pigs are the only species known to be affected clinically by BEP following natural exposure. Experimentally, BEP affects mice, rats, and chick embryos. Rabbits, dogs, cats, and peccaries do not show clinical signs, but rabbits, cats, and peccaries produce antibodies (Stephano and Gay 1985a; Stephano et al. 1988a).

Subclinically infected pigs from affected farms are the primary source of BEP. The virus is apparently disseminated by nose-to-nose contact between infected and susceptible pigs. Transmission through semen has not been proven experimentally, but virus can be recovered from semen, testis, epididymis, prostate, seminal vesicles, and bulbo-urethral glands (M. H. Hernandez, personal communication). The virus may be disseminated by people and vehicles, and possibly by birds and wind. Other sources of infection have not been demonstrated.

The disease is self-limiting in closed herds. Sentinel pigs introduced to a farm 6–12 months after an outbreak remain asymptomatic and do not seroconvert. Al-

though there is evidence of persistence of BEP RNA in the brain and lung of experimentally infected pigs, neither infectious virus nor viral antigen was detected after immunosuppression (Wiman et al. 1998). Further, positive animals moved to seronegative herds did not spread the virus (Stephano and Gay 1986b; Stephano et al. 1986a). However, the disease can recur if a susceptible group of pigs is introduced to a farm. Large farms with a continuous system of production may have cases periodically.

PATHOGENESIS

It has been presumed that BEP infection is acquired by inhalation. Experimentally, intratracheal or intranasal exposures are effective routes of infection. The initial site of BEP replication is thought to be the nasal mucosa and tonsils. The virus has also been observed in the axon of neurons. From the initial site of replication, BEP spreads quickly to the brain and lung. CNS manifestations occur early in the disease. Nervous signs have been induced in 1-day-old piglets 20–66 hours after inoculation, some weaned pigs (21–50 days old) developed a nervous syndrome at 11 days postinoculation, and pregnant sows developed reproductive failure when inoculated during pregnancy. Corneal opacity was occasionally observed in these cases. The disease was also reproduced in susceptible pigs placed in contact with experimentally infected pigs as long as 19 days after experimental infection (Stephano and Gay 1983; Stephano et al. 1988b).

The interstitial pneumonia that is observed suggests dissemination by viremia. In experimentally infected piglets, virus could be isolated from the brain, lung, tonsil, liver, turbinate, spleen, kidney, mesenteric lymph node, heart, and blood.

The cause of the corneal opacity is unknown, but anterior uveitis is commonly observed microscopically in the cornea (Stephano and Gay 1986b). The opacity usually occurs late in the course of the disease and is thought to be due to an immunological reaction similar to that observed in dogs after adenovirus-induced hepatitis.

Infection of pregnant sows in the first one-third of gestation results in reproductive failure due to embryonic mortality. Affected sows usually return to estrus. When infection occurs later in gestation, the result is stillbirths and fetal mummification (Stephano and Gay 1984).

Intranasal infection of young boars results in inflammation and edema of the testis and epididymis by 15 days after inoculation. By 30 days, there is necrosis of the seminiferous tubules and rupture of the epithelial wall of the epididymis with leakage of spermatozoa from the lumen, leading to abscess formation. Boars sacrificed 80 days after infection showed fibrosis and granuloma formation in the epididymis as well as testicular atrophy (Ramirez et al. 1995). BEP was recovered from

27.3. *Corneal opacity in a 7-day-old piglet.*

testis, epididymis, prostate, seminal vesicles and bulbourethral glands 10–45 days after inoculation.

PATHOLOGY

There are no specific gross changes in cases of BE. In piglets, a mild pneumonia is frequently observed at the ventral tips of the cranial lung lobes. There is mild distension of the stomach with milk, distension of the urinary bladder, and a slight accumulation of peritoneal fluid with fibrin. The brain is often congested and there is an increase in the quantity of cerebrospinal fluid. Conjunctivitis, chemosis, and varying degrees of corneal opacity (Figure 27.3), usually unilateral, are observed. Vesicle formation, ulcers, and keratoconus have been observed in the cornea as well as exudate in the anterior chamber. Pericardial and renal hemorrhages are occasionally observed (Stephano and Gay 1985a, 1986b).

Boars develop swollen testicles and epididymes. These changes are frequently unilateral. There is orchitis, epididymitis, and, later, atrophy of the testicle, with or without granulomatous formation in the epididymis. Hemorrhages are occasionally observed in the tunica albuginia, epididymis, or testis (Campos and Carbajal 1989; Ramirez et al. 1995; Stephano et al. 1990).

The main histological changes are seen in the brain and spinal cord. These reflect a nonsuppurative encephalomyelitis affecting mainly the gray matter of the thalamus, midbrain, and cerebral cortex and include a multifocal and diffuse gliosis, perivascular cuffing with lymphocytes, plasma cells and reticular cells, neuronal necrosis, neuronophagia, meningitis, and choroiditis (Ramirez and Stephano 1982). Intracytoplasmic inclusion bodies are found in neurons (Stephano and Gay 1986b; Stephano et al. 1988a).

The lungs have localized areas of interstitial pneu-

monia characterized by thickened septa with mononuclear cell infiltration.

Changes in the eye are mainly corneal opacity, characterized by corneal edema and anterior uveitis. Neutrophils, macrophages, or mononuclear cells infiltrate the iridocorneal endothelium, corneo-scleral angle, and cornea (Stephano and Gay 1986b; Stephano et al. 1988a).

In boars, the affected testes show degeneration and necrosis of the germinal epithelium. The interstitial tissue shows Leydig cell hyperplasia, mononuclear cell infiltration, hyalinization of the vascular wall, and fibrosis. The epididymis shows vesicle formation, loss of epithelial cilia, rupture of the epithelial wall, presence of spermatozoa in the intertubular space, and severe infiltration of inflammatory mononuclear cells with macrophage phagocytosis of fragmented sperm. Fibrosis and spermatic granuloma are organized.

DIAGNOSIS

Clinical signs such as encephalitis, corneal opacity, and reproductive failure in the sow and orchitis and epididymitis in the boar are consistent with a diagnosis of BE. Additional diagnostic evidence is provided by histological lesions, such as nonsuppurative encephalitis, anterior uveitis, keratitis, orchitis, and epididymitis. The presence of intracytoplasmic inclusions in neurons and corneal epithelium in conjunction with these clinical signs and histological findings provides strong support for a diagnosis of BE.

Other causes of encephalitis and reproductive disease, especially Aujeszky's disease (pseudorabies) virus and porcine reproductive and respiratory syndrome virus, must be considered. Only BEP produces corneal opacity along with orchitis and epididymitis in boars (Campos and Carbajal 1989; Stephano and Gay 1985b; Stephano et al. 1988a, 1990).

Paired serum samples, 15 days apart, are recommended for serological confirmation. Hemagglutination inhibition (HI), virus neutralization (VN), and enzyme-linked immunosorbent assays (ELISA) have been used for serology. HI is the most frequently used test, but false-positive titers up to 1:16 have been detected when chicken erythrocytes are used or when the antigen is grown in chicken embryos (Ramirez et al. 1996). Therefore, bovine erythrocytes are recommended. Naturally infected pigs develop antibodies that usually persist for life.

Direct immunofluorescence has been performed to detect antigens in tissue sections and monolayers (Stephano and Gay 1985a; Stephano et al. 1988a).

The brain is the best tissue for virus isolation and antigen detection, but lung and tonsil are also suitable (Stephano et al. 1988a). PK-15 cells or primary pig kidney cells are preferred for virus isolation. Virus replication induces syncytium formation, and the virus is identified by neutralization and immunofluorescence.

PREVENTION AND CONTROL

As with most viral diseases of swine, there is no specific treatment. Pigs with corneal opacity frequently recover spontaneously, whereas pigs with central nervous disease generally die. Antimicrobial therapy is commonly used to treat and prevent secondary infections.

Herd health programs are the most reliable method of preventing the introduction of BEP to a farm. New pigs must be derived from a healthy herd and quarantined prior to introduction. Standard biosecurity measures provide insurance against infection, e.g., perimeter fencing; separate load-out areas; changing rooms and showers; control of birds, rats, and mice; prompt waste removal and disposal of dead pigs; and control of the movement of personnel, visitors, and vehicles. Serological screening of replacement animals is recommended.

Elimination of BEP from infected herds has been accomplished by management practices, e.g., herd closure, cleaning and disinfecting, all-in/all-out production, elimination of clinically affected animals, and disposal of dead pigs. The effectiveness of these procedures should be monitored by serological testing and the introduction of sentinel animals (BEP seronegative pigs) to confirm the elimination of BEP (Stephano et al. 1986b).

At present there are two commercial inactivated virus vaccines approved for use in pregnant sows, gilts, boars, and piglets. Development of a recombinant vaccine is in progress.

Menangle Virus

Menangle virus was first identified during a disease outbreak in New South Wales, Australia, in 1997. This virus causes reproductive disease and congenital defects in pigs, occasionally causes moderately severe disease in humans, and has fruit bats (*Pteropus* sp., flying foxes) as a reservoir host.

ETIOLOGY

Like Blue Eye Paramyxovirus, Menangle virus has been placed in the genus Rubulavirus within the family *Paramyxoviridae*, (Bowden et al. 2001). Other well-known viruses in this genus are human parainfluenza viruses types 2 and 4 and human mumps virus.

Menangle virus has typical paramyxoviruses morphology. Virions are pleomorphic with both spherical and elongated forms that range in size from 100–350 nm. Virions possess a single layer of surface spikes approximately 17 nm in length. Ruptured particles reveal long herringbone shaped nucleocapsids with a diameter of approximately 19 nm (Philbey et al. 1998).

Menangle virus induces pronounced cytopathology in cell culture, including prominent vacuolation of cells and the development of large syncytia. The virus replicates and produces cytopathology in a wide range of cell types from many animal species, including birds and fish. There is no evidence of hemadsorption or hemagglutinating activity (Philbey et al. 1998). Menangle virus is not known to be related antigenically to any other paramyxovirus.

CLINICAL SIGNS

To date, there has been only one known disease outbreak due to Menangle virus in pigs (Love et al. 2001; Philbey et al. 1998). In 1997, over a 5-month period (mid-April to early September), sows in a 3000-sow, intensive farrow-to-finish pig farm near Sydney, New South Wales, Australia experienced severe reproductive failure (Love et al. 2001). There was a marked increase in the incidence of mummified fetuses and stillborn piglets. After a period, some of the stillborn piglets were born with severe malformations. Sows in all four breeding units on the farm were affected. There were some weeks when the farrowing rate decreased from an expected 82% to as low as 38%. Many sows showed delayed returns to estrus at around 28 days after mating, and others remained in a state of pseudopregnancy until more than 60 days post-mating. The disease occurred sequentially in all four breeding units at the pig farm, affecting the progeny of sows of all parities. In the weeks of low farrowing rates, up to 45% of sows farrowed litters with reduced numbers of live piglets and an increase in the proportion of mummified and stillborn piglets, some of which had congenital deformities.

Individual litters contained mummified fetuses of varying size, ranging upward in gestational age from 30 days, together with stillborn piglets (some with malformations) and a few normal piglets (Figure 27.4). Teratogenic defects, including arthrogryposis, brachygnathia, and kyphosis, were frequently seen in stillborn piglets, and there were occasional cases of artiodactyla (Love et al. 2001). The cranium of some piglets was slightly domed.

Although the virus was also detected on two associated growing farms, there were no breeding animals held on these farms and no clinical disease was recognized. Virus had apparently spread to these farms (separated from the main farm and each other by several hundred kilometers) when young growing pigs were moved. There were no clinical signs evident in growing

27.4. *Litter of piglets affected by Menangle virus.*

pigs of any age, and the only clinical signs in sows on the main farm were those associated with reproductive failure. It is not known whether Menangle virus can be spread in the semen of acutely infected boars.

Following the isolation of Menangle virus, two seropositive workers were identified (Chant et al. 1998). During subsequent medical investigations, it was found that both had experienced a severe febrile illness with headaches. Extensive testing failed to identify any other possible cause of the illness, and it was concluded that the disease was due to Menangle virus infection (Chant et al. 1998). Both workers recovered fully after a prolonged period of convalescence.

EPIDEMIOLOGY

Studies of archival and newly collected sera suggested that Menangle virus was not highly contagious among the pigs on the affected farm (Kirkland et al. 2001). This was deduced by the relatively slow spread of infection in a building that contained pens of sows, i.e., it took several weeks for all of the sows to become infected. Nevertheless, the virus was widely dispersed through the pig population on the affected farm. About 6 months after the estimated time of entry of the virus to the farm, a high proportion (>90%) of sera collected from pigs of all ages contained high levels of virus-neutralizing (VN) antibody. Positive VN antibody titers ranged from 1:16 to 1:4096 and remained high for at least 2 years after infection. In contrast, all samples collected prior to the estimated time of entry of the virus

into the pig population were negative. All serum samples collected at the two grower-fattening farms were positive (Kirkland et al. 2001). Testing of 1114 swine sera from other pig farms throughout Australia indicated that infection was confined to the affected pig farm and the two associated grow-out facilities.

Following the initial spread of the infection through the herd, the virus was maintained by infection of young pigs at about 10–12 weeks of age as they lost the protection provided by maternally derived antibodies. In a large pig population, the constant availability of susceptible animals was sufficient to ensure persistence of the virus. In smaller pig herds, such persistence would be much less likely. Almost all selected replacement breeding pigs on the farm had been exposed to the virus and were seropositive before mating at around 28–30 weeks of age, preventing further reproductive failure.

It appeared that close contact between pigs was required for spread of infection and that the virus did not survive in the environment for long. Susceptible sentinel pigs moved into an uncleaned area occupied 3 days previously by infected pigs did not become infected.

It is believed that Menangle virus has a reservoir in flying foxes (Kirkland et al. 2001; Philbey et al. 1998). During the summer-autumn period, when the virus was thought to have entered the pig farm, there was a large breeding colony of gray-headed fruit bats (*Pteropus poliocephalus*), as well as little red fruit bats (*P. scapulatus*), roosting within 200 meters of the affected pig farm. Sera collected from gray-headed fruit bats in this colony had VN antibodies to Menangle virus. A more extensive study of sera collected from several species of fruit bats in various locations in Australia found that approximately one-third were seropositive, with VN titers ranging from 1:16–1:256. Positive samples were found in gray-headed fruit bats, black fruit bats (*P. alecto*), and spectacled fruit bats (*P. conspicillatus*), but not in little red fruit bats. These results indicated that Menangle virus was endemic in the fruit bat population and preceded the infection in pigs.

Except for spread to humans, there is no evidence that this virus has spread naturally to other animal species. Samples collected from rodents, birds, cattle, sheep, cats, and a dog in the vicinity of the affected pig farm were all seronegative.

PATHOGENESIS

The route of transmission of Menangle virus and the mechanism of spread have not been established, although fecal-oral or urinary-oral transmission is suspected (Love et al. 2001). Infection in pigs appears to be of short duration (10–14 days) and results in strong immunity. Virus was not detected in surviving piglets born during the outbreak, suggesting that persistent infection is unlikely. There is also strong circumstantial evidence that adult pigs do not become persistently infected.

The principal cause of reproductive loss associated with Menangle virus appears to be in utero infection, often resulting in fetal death. In many sows, there was early death of the whole litter, resulting in a delayed return to estrus or sometimes a state of pseudopregnancy.

At parturition, affected litters sometimes contained piglets of varying size and with a range of abnormalities. Some piglets were mummified and were of different gestational ages, some piglets were stillborn and had congenital malformations, and there were a few normal piglets (refer to Figure 27.4). These findings indicated that, as with parvovirus, transplacental infection of a few fetuses can occur early in gestation followed by progressive spread of the virus from fetus to fetus within the uterus. The teratogenic defects observed are the direct result of virus replication and cell destruction in rapidly developing fetal tissues.

PATHOLOGY

Affected litters usually consist of a mixture of mummified fetuses, autolyzed and fresh stillborn piglets, and a few normal live piglets (Love et al. 2001; Philbey et al. 1998). Congenital defects, including arthrogryposis, brachygnathia, kyphosis, and occasionally, artiodactyla are only seen in dead piglets. Affected stillborn piglets frequently have slight-to-severe degeneration of the brain and spinal cord (Figure 27.5). Gross defects ranging from porencephaly to hydranencephaly are most common in the cerebrum. Occasionally, there may be fibrinous body cavity effusions and pulmonary hypoplasia.

Histological changes are most marked in the central nervous system (Love et al. 2001; Philbey et al. 1998). There is extensive degeneration and necrosis of grey and white matter of the brain and spinal cord associated with infiltrations of macrophages and other inflammatory cells. Intranuclear and intracytoplasmic inclusion bodies may be observed in neurones of the cerebrum and spinal cord. These bodies are eosinophilic to amphophilic and consist of aggregates of nucleocapsids. Nonsuppurative
27.5. *CNS abnormalities due to in utero Menangle virus infection.*

multifocal meningitis, myocarditis, and occasionally, hepatitis may also be present in some cases.

DIAGNOSIS

Because Menangle virus is a recently recognized agent that is pathogenic for pigs and only one outbreak has been recorded, most pig populations should be fully susceptible. The birth of litters with a marked reduction of normal live piglets and a number of stillborn piglets with teratogenic defects is suggestive of Menangle virus infection. The most rapid method of excluding Menangle virus infection is to test affected sows for the presence of specific antibody to the virus.

The birth of litters containing mummified fetuses of varying size together with stillborn piglets is indicative of in utero viral infection. By far the most common cause of similar losses is porcine parvovirus, but a variety of other viral infections, e.g., encephalomyocarditis, classical swine fever (hog cholera), Aujeszky's disease (pseudorabies), Japanese encephalitis, porcine reproductive and respiratory syndrome (PRRS), and porcine rubulavirus (blue eye paramyxovirus, BEP) may cause significant fetal death. A feature that distinguishes Menangle virus infection from all but Japanese encephalitis infection is the presence of congenital malformations in piglets. However, it should be noted that these are evident in only approximately one-third of affected litters. In addition, many of these other viral infections cause disease in both piglets and adults. BEP is the only other paramyxovirus to cause significant fetal loss as a presenting sign, but it differs from Menangle virus in that neurological and other signs are usually observed in young piglets and the virus can be readily distinguished as it agglutinates erythrocytes from mammals and birds (Moreno-Lopez et al. 1986). Reproductive disease is not a major feature of infection with Nipah virus.

For laboratory diagnosis, fetal specimens should be collected for virus isolation, serology, and pathology. Virus can be isolated from a number of organs from stillborn piglets, especially brain, lung, and myocardium. A wide range of cell cultures support replication of Menangle virus, but baby hamster kidney cells (BHK-21) have been used for the isolation of the virus from field specimens. Three to five passages may be necessary before suggestive cytopathology is observed. Because the virus does not hemagglutinate, identification will depend on electron microscopy and neutralization of an isolate with specific antiserum. Specific antibodies may be detected in body cavity fluids of some stillborn piglets.

PREVENTION AND CONTROL

There is no specific treatment for Menangle virus. By the time clinical signs are observed, the virus is likely to be widely disseminated in the affected population, negating measures to limit spread.

Fruit bats (Megachiroptera) are considered the primary source of infection for the pig population. Megachiroptera are not found in North America, but are present in Africa, the Middle East, Southern Asia, Australia, and many Pacific Islands. It is not known whether small bats (Microchiroptera) are susceptible to Menangle virus, but it is important to restrict direct and indirect contact between pigs and bats to prevent introduction of this virus to the pig population. Fruit bats do not normally enter pig farm buildings, but they defecate and urinate during flight over and around buildings, and occasionally inadvertently drop their young in flight. All outside areas, e.g., outside walkways, should be covered to prevent contamination and possible infection. Flowering trees and fruiting trees should not be grown in the immediate vicinity of pig farm buildings because these may attract fruit bat activity.

In an outbreak of reproductive disease, the infection will probably have already spread through the entire population of a pig farm by the time the first affected litters are farrowed. In small piggeries, there would be insufficient numbers of susceptible animals available to maintain a cycle of infection because there is no carrier state and, unlike parvovirus, environmental survival of this virus is poor. In large piggeries, infection may become endemic, with the infection being maintained in groups of pigs as they lose their maternally derived protection. In such a situation, it is important to maximize the opportunity for infection of all selected replacement breeding stock prior to mating.

The eradication of Menangle virus from an endemically infected pig population can be achieved by moving all the age groups in which infection is active, e.g., pigs between 10 and 16 weeks of age, to another site (Love et al. 2001). If affected facilities are cleaned, vacated for a few weeks, and then restocked with unexposed pigs or pigs known to be immune to the virus, the cycle of endemic infection in the herd should be broken and the virus eliminated naturally.

PUBLIC HEALTH

In contrast to Nipah virus, Menangle virus does not appear to be highly infectious for humans. However, care should be taken when working with potentially infected pigs or suspect reproductive specimens. Although only 2 out of more than 30 humans directly exposed to infected pigs became infected with the virus, both experienced a severe febrile illness associated with a macular rash followed by prolonged debility (Chant et al. 1998). There was no evidence of infection in a large number of other people, including veterinarians, abattoir workers, and laboratory workers, who had less direct and less protracted contact with potentially infective material. Transmission to humans may require the contamination of cuts and abrasions with infectious body fluids or tissues or possibly splashing of material onto the conjunctivae (Chant et al. 1998).

Nipah Virus

INTRODUCTION

Nipah virus is an important, recently recognized, zoonotic virus that caused a major epidemic in 1998–1999. Although confined to a relatively small geographic area in Southeast Asia, it was associated with significant human mortality. It is believed that this virus jumped from a wildlife reservoir to domestic pigs. From pigs, the virus spread to humans and to other domestic animals, such as cats, dogs, and horses. The virus was not contagious in cats or dogs, but it was associated with a high case fatality rate. In humans, an epidemic occurred in pig farm workers and in others involved in the handling of pigs.

ETIOLOGY

Nipah virus is a novel negative-stranded RNA virus in the family *Paramyxoviridae*. This virus and the related Hendra virus are the sole members of the new genus *Henipavirus* (Chua et al. 2000).

Nipah is a large pleomorphic virus similar to most paramyxoviruses. Virus particles vary in size, but have an average diameter of 500 nm. Surface spikes on the envelope are approximately 10 nm in length. The typical long "herringbone"-shaped nucleocapsids have a diameter of approximately 21 nm and an average length of 1.67 µm.

Nipah virus replicates readily in several continuous cell lines, especially Vero and BHK-21, and produces suggestive cytopathic effects in 3–4 days. In Vero cells, virus replication induces large syncytia in which the cell nuclei are arranged around the periphery of the multinucleated cell. (Daniels et al. 2002). Antigenically, Nipah virus is closely related to Hendra virus and diagnostic reagents for Hendra virus have been utilized to assist Nipah virus investigations.

CLINICAL SIGNS

Nipah virus differs from most paramyxoviruses in that it causes a severe, often fatal disease in a number of species. The clinical signs observed as a consequence of Nipah virus infection in pigs vary in different age groups (Bunning et al. 2000; Nor et al. 2000).

In weaners and grower pigs, an acute febrile illness has been described with temperatures of 40°C and higher. Respiratory signs ranging from increased or forced respiration to a harsh, paroxysmal nonproductive cough (a loud barking cough) or open mouth breathing are prominent, especially if animals are forced to move. There may also be one or more neurological signs, such as muscle fasciculation, rear leg weakness, and varying degrees of spastic paresis and uncoordinated gait when driven and hurried. Illness may pro-gress to lateral recumbency accompanied by thrashing of the limbs or tetanic spasms. Mortality in this age group is low, probably less than 5%. Animals that die may show blood-tinged discharge from the nose. Infection is frequently asymptomatic.

Sows and boars sometimes died suddenly with no overt illness or after a brief period of illness of less than 24 hours' duration. A bloody nasal discharge was frequently apparent after death. Neurological signs were frequently observed and included head pressing, agitation (displayed as biting at the bars of the pen), tetanic spasms or seizures, an apparent pharyngeal muscle paralysis with an apparent inability to swallow, frothy salivation, and drooping of the tongue. Abortions were also reported.

Suckling pigs showed open mouth breathing, leg weakness with muscle tremors, and neurological twitches. Mortality was high in these young animals, but whether from primary disease or as a result of disease in the sow has not been clearly established.

None of the clinical signs described above is pathognomonic, although the barking cough is considered characteristic and the sudden deaths in sows and boars is unusual.

Nipah virus is a dangerous zoonotic agent. Disease and death in people may be the first indication of an outbreak. A full clinical description of Nipah virus–induced disease in humans has been provided by Chua et al. (1999) and Goh et al. (2000). Human Nipah virus infection presents as an encephalitis. Patients may show fever, headache, dizziness, and vomiting. The condition progresses in over 50% of cases to impaired consciousness accompanied by brain stem dysfunction (Goh et al. 2000).

EPIDEMIOLOGY

The disease outbreak observed in Malaysia is presumed to be a result of virus 'jumping' species into farmed domestic pigs (Chua et al. 2000; Daniels 2000; Field et al. 2001; Yob et al. 2001). There is strong evidence for pteropid bats being a reservoir of this virus. A high prevalence of neutralizing antibodies has been detected in both of the species of wild bat (*P. vampirus* and *P. hyomelanus*) present in Malaysia (Yob et al. 2001). Nipah virus has also been isolated from wild *P. hyomelanus* in Malaysia (Chua et al. 2001).

The movement of infected pigs was the main means of spread of Nipah virus in Malaysia, resulting in the spread of the virus between farms, from state to state, and internationally to Singapore where abattoir workers processing Malaysian pigs became infected (Nor 2001; Nor and Ong 2000; Nor et al. 2000; Paton et al. 1999). The outbreak probably originated from a point source

(Lye et al. 2001), implying that the virus moved from its wildlife reservoir on only one occasion.

Human infection was associated with close human-to-pig contact with infected pigs (Parashar et al. 2000). Feeding or handling pigs and assisting with farrowing, treatment, and/or removal of sick or dead pigs were most likely to result in Nipah virus disease in people on infected farms. Living on an infected pig farm was not a significant risk factor.

The major route of excretion of Nipah virus from pigs is via the airways, although the pattern of human infection suggests spread via sputum or large droplets, rather than by fine aerosol. The coughing reported as a frequent clinical sign in infected pigs would facilitate such a mode of transmission.

Domestic animals other than pigs are susceptible to Nipah virus disease and appear to have become infected when there was potential for close contact with infected pigs. Large numbers of dogs died on infected farms, and clinically affected dogs were identified during investigations of the outbreak (Chua et al. 2000; Daniels et al. 2000). There was, however, no evidence of lateral transmission between dogs (Asiah et al. 2001). Cats were reported by farmers to have been affected. Experimentally, they were shown to be susceptible to infection and to excrete Nipah virus in urine (Muniandy 2001). Because virus was also isolated from the kidney of a clinically affected dog in Malaysia (Chua et al. 2000), urinary excretion by domestic carnivores may also be a possible method of spread. There was no evidence of transmission of Nipah virus among horses and serological studies of rodents on infected farms, and various other wildlife species showed no evidence of Nipah virus infection.

PATHOGENESIS

There have been no structured pathogenesis studies with Nipah virus in susceptible species. Therefore, information is limited mainly to observations of naturally occurring clinical cases.

Nipah virus infection in pigs causes an acute febrile infection that may be self-limiting or fatal. Seroconversion occurs at 10–14 days. There is no evidence that persistent infections occur, although the possibility cannot be excluded. Nipah virus primarily infects vascular endothelium. Respiratory epithelium is susceptible to infection in pigs, but infection has not been observed in the nervous system other than the meninges. Immunohistochemical studies of naturally infected pigs have shown large amounts of Nipah viral antigen in the respiratory epithelium at all levels of the lungs, including the minor and major airways and the trachea (Hooper et al. 2001).

PATHOLOGY

The most common syndrome in pigs is respiratory disease characterized by severe coughing. However, there is no pathognomonic gross pathology and concurrent pulmonary disease from other causes may be present. There is mild-to-severe pulmonary consolidation. On the cut surface, the interlobular septae may be distended, The bronchi and trachea are frequently filled with exudate or frothy fluid that is sometimes tinged with blood (Daniels et al. 2000; Hooper et al. 2001; Shahirudin 2001).

Histologically there is pneumonia at all levels, from the alveoli through to the epithelium of the trachea. Syncytial cells are present throughout the respiratory epithelium and in vascular endothelium. Alveolar macrophages are prominent and there appears to be an infiltration of neutrophils into diseased tissue in the absence of intercurrent infections. Viral antigen is readily detectable by immunohistochemistry in syncytia and in respiratory epithelium at all levels of the respiratory tract. In cases where there is neurological disease, there is a nonsuppurative meningitis rather than encephalitis (Hooper et al. 2001; Middleton et al. 2002).

DIAGNOSIS

Nipah virus may be suspected if a clinical syndrome consistent with Nipah virus disease occurs on a pig farm in an area where there is opportunity for contact with pteropid bats. Nipah virus is classified as a Biosafety Level 4 (BSL4) agent and extreme care must be taken in the diagnosis of cases suspected to involve Nipah virus. Some aspects of laboratory diagnosis should be conducted only in a BSL4 laboratory. Ante- and postmortem sampling should be conducted in a manner that will exclude contact of unprotected personnel with body fluids from affected animals. Respiratory protection is advisable (Daniels et al. 2000).

Clinical diagnosis of Nipah virus is difficult because the infection does not produce pathognomonic clinical signs. Furthermore, clinical signs vary by the age and reproductive status of the animals affected. Thus, the differential diagnosis may vary with the age and class of pigs affected. The list of differential diagnoses should include those that cause sudden death in boars and/or sows; reproductive failure characterized by abortion; respiratory disease in any age group characterized by severe coughing; and neurological disease characterized by tremors, muscle fasciculation, and agonal thrashing of the limbs or tetanic spasms in lateral recumbency.

Nipah virus antigens have been demonstrated in formalin-fixed tissues, especially the lung and upper airways, meninges, spleen, and kidney (Daniels 2001). Demonstration of viral antigen in formalin-fixed postmortem samples is a rapid and safe option for confirmation of a diagnosis.

When isolates of virus are required, either for confirmation of a diagnosis or for additional research, it is preferable that virus isolation be conducted in a laboratory with a high level of biosecurity. Nipah virus has

been isolated from lung, spleen, kidney, tonsil, meninges, and lymph node collected at postmortem and from throat swabs, cerebrospinal fluid, or urine collected from live animals (Daniels 2001). Vero cells are preferred for virus isolation. Cytopathology may be observed within 2–3 days, but several passages of at least 5 days are usually conducted before declaring an isolation attempt unsuccessful. Cytopathology is characterized by the formation of large syncytia. Polymerase chain reaction (PCR) has been developed as a diagnostic tool and it is likely that a retrospective confirmation could be achieved even with formalin-fixed tissues (Chua et al. 1999; Hooper and Williamson 2000).

For antibody detection, ELISA is the preferred method for routine screening because of the availability of inactivated reagents and the ability to test large numbers of samples quickly (Daniels 2001). However, the possibility that serum samples may contain infectious virus should not be overlooked. Testing of suitable numbers of pig sera by ELISA provides a rapid method for the exclusion of Nipah virus from disease episodes where Nipah virus infection may be considered and is also a valuable approach for confirming that populations are free of infection. Any ELISA reactors should be confirmed by the virus neutralization test (Daniels 2001), but because it employs the use of live virus in cell culture, secure laboratory facilities should be used.

PREVENTION AND CONTROL

As Nipah virus is a dangerous zoonotic agent, treatment of affected animals should not be considered.

In countries where Pteropid bats may be a reservoir of Nipah virus, pig farms should be managed to ensure that infection cannot be introduced (Choo 2001; Daniels 2001). That is, farms should be devoid of fruit trees and other vegetation that may attract the bats to the proximity of the animal housing. Strict biosecurity should be in place to preclude the importation of infected animals. If introductions are necessary for breeding or other purposes, a period of quarantine and isolation separate from the main herd should be enforced.

Control measures in cases of confirmed Nipah virus infection will reflect its extreme hazard as a zoonotic agent. It is essential to prevent spread of infection among domestic animals and to preclude the possibility of infection of humans. Rapid eradication is the recommended response. This was achieved in Malaysia by quarantine of infected premises and the culling of all susceptible animals on those premises. It is essential that quarantine and associated movement controls be enforced during this period of culling (Mangat 2001).

PUBLIC HEALTH

Nipah virus presents a serious threat to public health. In the outbreak in Malaysia, there were numerous human infections and deaths of pig farmers and other people who had close contact with pigs, including abattoir workers in a neighboring country. If there is a risk of an outbreak, it is essential to prevent the movement of all animals and minimize human contact with potentially infected animals.

In the last decade, new viral diseases affecting domestic animals and humans have emerged, with various species of fruit bats as the putative source. Such events would suggest a drastic change in the relationship between fruit bats and domestic animals. This may simply be a further reflection of the worldwide destruction of forest habitat, forcing the wild and domestic species into much closer associations. In Australia, the fruit bat population will remain a potential source of Menangle virus infection for pigs and possibly other species, just as Nipah virus poses a continuing threat in Malaysia. The risk that these viruses pose to pigs in other countries and to other animal species has not been determined, but should not be ignored, especially in countries where Pteropid bats are present.

28 Swine Influenza

Christopher W. Olsen, Ian H. Brown, Bernard C. Easterday, and Kristien Van Reeth

Influenza virus infections are a common and important cause of bronchointerstitial pneumonia and respiratory disease in pigs throughout large parts of the world. In any one animal, the disease is typically characterized by an abrupt onset and short course of fever, inappetence, lethargy, coughing, dyspnea, and nasal discharge. However, clinical illness may persist in a herd for several weeks as the virus spreads from pig to pig within the population. Influenza viruses also act synergistically with other viral or bacterial pathogens to cause porcine respiratory disease complex (PRDC). The overall course and severity of an influenza virus infection in a pig may be impacted by these co-infecting agents, the pig's age, overall health and immune status, and, potentially, the strain of influenza virus involved.

Beyond their significance to swine health, influenza virus infections in pigs also pose important human public health concerns, and the histories of influenza in pigs and people are closely linked. In the summer of 1918, an epizootic disease with many clinical and pathologic similarities to influenza in humans appeared among pigs in the north-central U.S., coincident with the 1918 influenza pandemic that killed 20–50 million people around the world. Koen (1919) unapologetically called the disease "flu" because of its similarities to the prevalent clinical disease of flu in human beings. Dorset et al. (1922) also reported on "hog flu" at the annual meeting of the American Veterinary Medical Association in 1922, providing descriptions of the disease that were similar to those given by Koen, and a discussant of the Dorset presentation commented that he believed he had seen a case of "hog flu" in Iowa (U.S.) 5–6 years prior to 1918. Furthermore, McBryde (1927) indicated that it was not uncommon to meet farmers and veterinarians who believed that they had contracted the disease from affected pigs, and he himself suffered an acute febrile disease similar to the hog flu he had been investigating in southeastern Iowa. Finally, Murray (1921) also reported on the nature of influenza in pigs in the U.S. and Beveridge (1977) noted that ". . . in the autumn of 1918

[Aladar Altmann], a Hungarian veterinarian described a disease of pigs which he believed was influenza."

The etiology of swine influenza (SI) was confirmed in 1931 when Shope presented the first reliable experimental evidence that the disease in pigs was caused by a virus (Shope 1931), and 2 years later, Smith et al. (1933) demonstrated that influenza in human beings was also caused by a virus. "When the human pandemic of 1957 . . . first began to spread in Asian countries during the spring of that year, the World Health Organization (WHO) considered it opportune to attempt an animal serum survey in order to throw light on the animal component in the epidemiology of influenza" (Kaplan 1969). That study concluded that the Asian H2N2 strain could infect pigs, and by 1970, there was considerable serologic evidence that people whose occupations brought them into contact with pigs became infected with swine influenza viruses (SIVs). Furthermore, in 1974 and 1975 (Easterday 1986), infections in children were temporally linked to contact with infected pigs, and in 1976, cases of SIV infections occurred among Army recruits at Fort Dix, N.J. (Top and Russell 1977). In the fall of 1976, all speculation about the transmission of SIV from pigs to people came to an end when virus was isolated from pigs and their caretaker on a Wisconsin farm (Easterday et al. unpublished data; Hinshaw et al. 1978).

In more recent times, genetic analyses have confirmed that the early swine viruses and the human viruses of 1918 were closely related to one another, although it remains unclear as to whether a progenitor virus was transmitted from pigs to people or from people to pigs (reviewed in Taubenberger et al. 2001). Currently, more than 85 years since its appearance, SI continues to be an important economic factor in swine production and a public health concern.

ETIOLOGY

Influenza viruses are members of the virus family *Orthomyxoviridae*. They are pleomorphic, enveloped

viruses approximately 80–120 nm in diameter. The lipid envelope makes the viruses highly susceptible to detergents and most commonly used antiviral disinfectants. Influenza viruses encode up to 11 viral proteins on 7 to 8 separate segments of negative-sense RNA. The segmented nature of their genomes is a critical structural feature that allows influenza viruses to undergo genetic reassortment.

Influenza viruses are classified by type, subtype, and more recently, genotype. Of the A, B, and C types of influenza viruses (defined by differences in their matrix [M] and nucleoproteins [NP]), only influenza A viruses are of routine clinical significance as swine pathogens. Influenza A viruses are named using the following convention: A/species of origin/location of isolation/isolate number/year of isolation—e.g., A/Swine/Wisconsin/125/98. (If no species is designated, it is, by default, a human isolate.)

Influenza A virus subtypes are defined by the nature of the hemagglutinin (HA or H) and neuraminidase (NA or N) spike-like glycoproteins that project from the surface of the viral envelope. There are 16 different forms of HA and 9 different forms of NA that can be distinguished antigenically and genetically. The combination of HA and NA forms in a virus defines its subtype, e.g., H1N1, H3N2. Functionally, the HA (organized as trimers) binds to sialic acid (SA)-containing receptors and mediates virus infection of host cells. Sialic acid binding is also responsible for the erythrocyte agglutination that underlies virus detection by hemagglutination and hemagglutination-inhibition (HI) serologic assays. The HA protein also contains the major antigenic sites to which neutralizing antibodies (Abs) are directed. The NA protein (organized as tetramers) catalyzes cleavage of sialic acid from adjacent sugar residues, and, thereby, may function to prevent virion aggregation and to enhance the release of budded virus particles. (See Lamb and Krug 2001 and Wright and Webster 2001 for detailed reviews of influenza virus structure and genetics.)

To understand the epidemiology and evolution of influenza A viruses, it is becoming increasingly important to both subtype and genotype viruses. Genotyping is conducted by determining the genetic sequence of each viral RNA segment and then subjecting the sequences to phylogenetic analyses. These analyses define the evolutionary lineages (based on host species and geographic region of the world) from which each gene originated. Genotyping has been extremely important in recent years for understanding the origins of reassortant SIVs isolated in Europe, Asia, and North America.

EPIDEMIOLOGY

Historically, outbreaks of SI in northern climates of the U.S. and western Europe occurred most frequently during the late fall through early winter months, often in association with the onset of colder temperatures and cold autumn rains (Easterday 1980; Easterday and Van Reeth 1999). However, studies have clearly demonstrated that SIVs circulate year-round (Hinshaw et al. 1978; Olsen et al. 2000), and as swine production has increasingly been conducted in total confinement, the seasonal pattern of clinical disease has become less prominent.

Influenza viruses are most commonly introduced into herds with the movement of animals. The primary route of virus transmission is through pig-to-pig contact via the nasopharyngeal route, with virus being shed in nasal secretions at titers of $\geq 10^7$ infectious particles per ml at the peak of shedding (typically 2–5 days after exposure) (Landolt et al. 2003; Van Reeth et al. 2003a). Once the virus has been introduced into a herd, it may continue to circulate as long as susceptible pigs are available. In all-in/all-out systems, the virus should disappear because of the cycle of depopulation and disinfection of facilities. Nonetheless, virus may be reintroduced with new pigs, thus accounting for what appears to be virus persistence on a farm.

The existence of an SI carrier state has been postulated to account for interepidemic persistence of SIVs and, historically, maintenance of influenza viruses on premises was hypothesized to occur via lungworms and earthworms (Shope 1941). However, there is no clear proof of these mechanisms and it appears more likely that virus is maintained through continual availability of susceptible pigs.

Pandemiology and Evolution

Understanding the pandemiology (global epidemiology) and evolution of influenza viruses in pigs requires an understanding of the ecology and epidemiology of influenza viruses in other species.

In horses, marine mammals, poultry, and human beings—as in pigs—influenza viruses may cause clinically and/or economically important disease. In contrast, influenza viruses in waterfowl and shorebirds are generally highly host-adapted, rarely cause disease, and exhibit low evolutionary rates ("evolutionary stasis") (reviewed in Gorman et al. 1990, Webster and Kawaoka 1994, Webster et al. 1992, and Wright and Webster 2001). All 16 HA and 9 NA subtypes of influenza A viruses have been recovered from aquatic birds. In these species, influenza A viruses replicate primarily in enterocytes and, thus, are shed in feces and can contaminate lake water (Hinshaw et al. 1980; Webster et al. 1978). Consequently, aquatic birds provide an omnipresent, global reservoir of influenza viruses. Phylogenetic data indicate that aquatic birds were also the evolutionary progenitors of the lineages of influenza A viruses in mammals (reviewed in Webster et al. 1992 and Wright and Webster 2001). However, only H1, H3, N1, and N2 subtype viruses have established stable lineages and circulated widely among pigs.

Classical H1N1 Swine Influenza Viruses. Viruses of the classical H1N1 lineage were the dominant cause of influenza among pigs in North America from their first isolation by Shope in 1930 through the 1990s (Arora et al. 1997; Chambers et al. 1991; Hinshaw et al. 1978; Morin et al. 1981; Olsen et al. 2000). Classical H1N1 viruses have also been isolated from pigs in South America, Europe, and Asia (reviewed in Brown 2000 and Olsen et al. 2004). Beyond domestic pigs, there is also evidence for infection of wild pigs with classical H1N1 SIVs (Saliki et al. 1998), as well as transmission to domestic turkeys (Hinshaw et al. 1983; Wright et al. 1992).

The classical H1N1 SIVs in the U.S. remained antigenically and genetically highly conserved from 1965 through the 1980s (Luoh et al. 1992; Noble et al. 1993; Sheerar et al. 1989), but antigenic and genetic variants of classical H1N1 viruses were isolated during the 1990s (Dea et al. 1992; Olsen et al. 1993, 2000; Rekik et al. 1994).

Transmission of Human Influenza Viruses to Pigs. There is only limited evidence for maintenance of human H1N1 influenza viruses after natural introduction into swine populations (reviewed in Brown 2000), but human H3N2 viruses have been recovered frequently from pigs in Asia and Europe (reviewed in Brown 2000 and Olsen et al. 2004). There is also evidence for genetic/antigenic drift among the H3N2 viruses that have persistently circulated among pigs in Europe (de Jong et al. 1999), but the drift is relatively minor when compared to that in the human population. In North America, human H3N2 viruses have been recovered from pigs much less frequently (Bikour et al. 1995; Hinshaw et al. 1978; Karasin et al. 2000c), but introduction of a human H3N2 influenza virus into the pig population was likely a critical factor in the emergence of the reassortant viruses that now dominate the swine population in the U.S.

Transmission of Avian Influenza Viruses to Pigs. Experimental infection studies have shown that pigs can be infected with a wide range of avian influenza viruses (AIVs) (Kida et al. 1994) and naturally acquired infections of pigs with AIVs have also been documented from multiple areas of the world. There have been at least three independent introductions of distinct, wholly avian, H1N1 viruses to pigs (Brown 2000; Guan et al. 1996; Karasin et al. 2004; Pensaert et al. 1981). In particular, an avian H1N1 virus introduced into pigs in Europe in the late 1970s spread throughout much of the European continent and United Kingdom and ultimately became a dominant cause of SI in these areas (Brown et al. 1997b; Donatelli et al. 1991; Scholtissek et al. 1983). These avian-like H1N1 viruses have also undergone genetic/antigenic drift (Brown et al. 1997b; de Jong et al. 2001) and have spread from pigs to domestic turkeys (Ludwig et al. 1994; Wood et al. 1997).

Elsewhere in the world, serum antibodies against avian H4, H5, and H9 viruses have been detected in pigs in China (Ninomiya et al. 2002); avian H1N1, H3N2, and H9N2 viruses have been isolated from Asian pigs (Guan et al. 1996; Kida et al. 1988; Peiris et al. 2001a,b); and avian H4N6, H3N3, and H1N1 viruses have been recovered from pigs in Canada (Karasin et al. 2000b, 2004).

Reassortant Influenza Virus Infections in Pigs. The segmented nature of the influenza genome allows two viruses that co-infect a single host to exchange RNA segments during viral replication. Pigs are susceptible to infection with both human and avian influenza A viruses because the cells of their respiratory tract express both the SAα2,6Gal receptors that are preferentially used by human influenza viruses and the SAα2,3Gal receptors preferred by avian influenza viruses (Ito 2000; Ito et al. 1998a, 2000; Suzuki et al. 1997). Several different forms of reassortant viruses have been isolated from pigs in the U.S. and around the world (Olsen 2002a,b).

Reassortant H3N2 Viruses. Reassortant viruses with mixtures of human and classical swine virus genes have been isolated from pigs in Asia and the U.S. (Nerome et al. 1995; Shu et al. 1994; Zhou et al. 1999). In addition, H3N2 viruses with human HA and NA genes and avian internal protein genes have been isolated from pigs in Asia (Peiris et al. 2001a) and are currently the dominant H3N2 virus among pigs in Europe (Campitelli et al. 1997; Castrucci et al. 1993; Lin et al. 2004). Finally, unique "triple reassortant" H3N2 viruses have been isolated frequently from pigs throughout the U.S. since 1998. These viruses contain HA, NA, and PB1 polymerase genes of human influenza virus origin; NP, M, and NS genes of classical swine H1N1 virus origin; and PB2 and PA polymerase genes of North American avian virus origin (Karasin et al. 2000c; Webby et al. 2000; Zhou et al. 1999). Infection with some of the triple reassortant viruses has been associated not only with respiratory disease, but also spontaneous abortion in sows and death of adult pigs (Karasin et al. 2000c; Zhou et al. 1999). These fatal outcomes are uncommon with classical H1N1 swine viruses, and it remains to be determined whether the reassortant virus-associated abortions are due to direct viral effects or simply to high fevers in the affected animals.

Reassortant H1N2 Viruses. Soon after the initial isolations of the triple reassortant H3N2 viruses, influenza-like illness and abortions were associated with infection of pigs in the U.S. with an H1N2 virus. Phylogenetic analyses demonstrated that this virus retained the overall genotype of the triple reassortant H3N2 viruses but had acquired an H1 HA gene through reassortment with a classical H1N1 swine virus (Karasin et al. 2000a). Similar H1N2 viruses subsequently spread throughout

the swine population of the U.S. (Choi et al. 2002a,b; Karasin et al. 2002), as well as into domestic turkeys in Missouri (Suarez et al. 2002) and into wild waterfowl in North Carolina (Olsen et al. 2003).

Until 1999, H1N2 viruses had not previously been reported among pigs in North America. However, H1N2 viruses had been recovered from pigs in Japan (Ito et al. 1998b; Nerome et al. 1985; Ouchi et al. 1996; Shimada et al. 2003; Sugimura et al. 1980), France (Gourreau et al. 1994), and Taiwan (Tsai and Pan 2003). These H1N2 viruses were reassortants between human (or human-like swine lineage) H3N2, and classical swine H1N1 viruses. Human-avian reassortant H1N2 viruses were first isolated from pigs in the U.K. in 1994 (Brown et al. 1995, 1998) and subsequently spread to the rest of Europe (Marozin et al. 2002; Schrader and Suss 2003; Van Reeth et al. 2000, 2003a,b). These viruses typically contained human-lineage HA and NA genes and internal protein genes derived from the avian-like European H1N1 swine viruses, although some H1N2 viruses from Italian pigs have contained an avian-like swine H1 HA gene (Marozin et al. 2002).

Reassortant H1N1 Viruses. Since 1998, reassortant H1N1 viruses with classical swine H1N1 HA and NA genes and remaining genes from reassortant H3N2 or H1N2 swine viruses have been isolated in the U.S. This virus genotype was first isolated from a human being with influenza-like illness in Wisconsin who had had direct contact with a pig (Cooper et al. 1999). However, viruses of this genotype have been isolated frequently from pigs in the U.S. since 2001 (Olsen et al. unpublished data; Webby et al. 2002), and current surveillance activities suggest that this has become the predominant genotype of H1N1 virus within the North American swine population (Olsen and Webby, unpublished data).

Reassortant H1N7 and H3N1 Swine Influenza Viruses. These subtypes have been identified among pigs on only a very limited basis. Influenza virus of H1N7 subtype was isolated in 1992 from pigs on a single farm in the U.K.. This virus contained A/Equine/Prague/1/56-like NA and M genes, with the remaining genes being of human influenza virus origin, and was of low pathogenicity in pigs infected experimentally (Brown et al. 1994, 1997a). Reassortant H3N1 viruses (human H3N2 X classical swine H1N1 viruses) have been recovered from pigs in the United Kingdom and Taiwan (Brown unpublished data; Tsai and Pan 2003).

Public Health Aspects

The occurrence of influenza virus infections in pigs poses two important public health issues: zoonotic infections of people with swine influenza viruses and the potential for pigs to serve as hosts for the creation of novel viruses of pandemic potential for the human population.

Zoonotic infections (including fatal infections) with SIVs have been reported in the U.S., Asia, and Europe. Most of these were classical H1N1 SIV infections. However, the wholly avian H1N1 viruses from European pigs, reassortant H3N2 viruses with avian internal protein genes from pigs in Europe and Hong Kong, and a reassortant H1N1 virus from pigs in the U.S. have also been recovered from human beings (reviewed in Alexander and Brown 2000, Olsen 2002a, and Olsen et al. 2002, 2004).

The majority of zoonotic SIV infections have involved individuals in direct contact with pigs, and serologic studies in both Europe and the U.S. have documented increased rates of SIV exposure among persons in contact with pigs (Kluska et al. 1961; Nowotny et al. 1997; Schnurrenberger et al. 1970; Woods et al. 1968, 1981). In addition, a study of swine farm personnel and family members in the U.S. (compared to regional urban control subjects) recently found that SIV seropositivity was statistically associated with being a farm owner or farm family member, living on a farm, or entering a swine barn 4 or more days per week (Olsen et al. 2002). Nonetheless, there are examples of zoonotic SIV infections without apparent animal contact. Although such cases suggest the possibility of human-to-human spread of a virus after initial pig-to-person transmission, with the exception of the Fort Dix incident (Top and Russell 1977), there is little evidence for spread of swine viruses from person to person.

It has also been demonstrated that older lineages of human H3N2 viruses may be maintained by circulation in pigs beyond the time of their active circulation among human beings (reviewed in Brown 2000 and Olsen et al. 2004). Subsequent reintroduction of these viruses into the human population would be a particular concern for young children, because they would be immunologically naive to viruses that circulated prior to their birth.

Finally, because of their susceptibility to infection with influenza viruses of both avian and human origins (reviewed in Ito 2000; Ito et al. 1998a), pigs have also been suggested to be "mixing vessel" hosts in which pandemic human influenza viruses emerge through genetic reassortment (Scholtissek and Naylor 1988; Scholtissek et al. 1985; and reviewed in Brown 2000, Webster et al. 1992, Scholtissek et al. 1998, and Wright and Webster 2001).

PATHOGENESIS

Infection with SIV is generally limited to the respiratory tract, with virus replication demonstrated in epithelial cells of the nasal mucosa, tonsils, trachea, lungs, and tracheobronchial lymph nodes (Brown et al. 1993; Heinen et al. 2000; Lanza et al. 1992). Viremia of low titer and short duration has only rarely been detected (Brown et al. 1993). Similarly, attempts to demonstrate

virus replication in extrarespiratory sites have been largely unsuccessful (Choi et al. 2004).

SI is an acute infection and virus clearance is extremely rapid. In most experimental studies, nasal virus shedding begins on day 1 postinoculation (PI) and ceases within 7 days. Likewise, SIV could not be isolated from lungs or other respiratory tract tissues after day 7 (Brown et al. 1993; Choi et al. 2004).

The lungs are clearly the major target organ. Virus titers in the lungs may be $>10^8$ egg infectious dose 50 (EID_{50}) per gram of tissue (Haesebrouck and Pensaert 1986; Van Reeth et al. 1998), and immunofluorescence (IF) and immunohistochemical (IHC) studies demonstrate the virus' highly specific tropism for bronchiolar epithelium (Born et al. 1998; Brown et al. 1993; Haesebrouck and Pensaert 1986; Van Reeth et al. 1998). Up to 100% of the epithelial lining of bronchi/bronchioles and large numbers of alveolar epithelial cells may be positive by IF staining. Typically, bronchi and bronchioli contain exudate with degenerated and detached mucosal cells and neutrophils. However, by 2–3 days after inoculation, lung virus titers and numbers of virus-positive cells begin to decline.

Infection with SIV can be easily reproduced experimentally using intranasal (IN), aerosol, or intratracheal (IT) inoculation routes. However, reproduction of typical SI clinical signs and pathology is most reproducibly accomplished by IT inoculation of high doses of virus ($\geq 10^{7.5}$ EID_{50}) (Maes et al. 1984). Less invasive methods, such as IN inoculation, may result in mild or entirely subclinical infections (Larsen et al. 2000; Van Reeth and Pensaert 1994).

Direct cell damage by influenza viruses has been attributed to apoptosis caused by NA and/or PB1F2 proteins (Gibbs et al. 2003; Morris et al. 1999; Schultz-Cherry and Hinshaw 1996). However, proinflammatory cytokines produced by the host during the very acute stage of an infection probably play a critical role in SI disease development. Support for this comes from studies of the lungs of SIV-infected pigs for interferon-α (IFNα), tumor necrosis factor-α (TNFα), interleukin-1 (IL1) and interleukin-6 (IL6) (Van Reeth et al. 1998, 2002). These cytokines are known to induce lung dysfunction and inflammation, fever, malaise, and loss of appetite, and they can enhance each other's effects. In IT infection experiments, excessive levels of all 4 cytokines were found in lung lavage fluids within 18–24 hours PI, when lung virus titers, neutrophil infiltration in the lungs, and clinical signs peaked. In contrast, IN inoculations of SIV produced lower lung virus titers and failed to induce high cytokine levels, and these infections remained clinically mild or subclinical.

Thus, the amount of virus that reaches the deeper airways and the resulting production of infectious virus likely determine the extent of cytokine production in the lungs, which in turn determines the severity of illness. Many cytokines, however, also have antiviral and immunostimulating effects and thus may contribute to clearance of influenza viruses. Therefore, the specific role of individual cytokines during SIV infection merits further study.

CLINICAL SIGNS

Infection with influenza A viruses is typically a herd disease due to rapid spread of virus. Infections with H1N1, H1N2, and H3N2 subtype viruses are clinically similar, and viruses of all subtypes have been associated with acute respiratory episodes in most European countries (reviewed in Brown 2000) and in the U.S. (Karasin et al. 2000a, c, 2002; Zhou et al. 1999). Disease onset is sudden, after an incubation period of 1–3 days. Disease signs typically appear in a large percentage of animals of all ages within a herd or epidemiological unit.

The signs of SI are essentially as they were described in the 1920s (Dorset et al. 1922; McBryde 1927; Shope 1931). Initial signs include pyrexia, anorexia, inactivity, prostration, huddling, and reluctance to rise. Conjunctivitis, rhinitis, nasal discharge, sneezing, coughing, and weight loss may also be observed. The disease may progress to open-mouthed breathing and dyspnea, especially when animals are forced to move. Morbidity is high (near 100%), but mortality typically is low (usually less than 1%) unless there are concurrent infections and/or the pigs are very young. Generally, recovery begins 5–7 days after onset and is as sudden and remarkable as the onset.

Acute outbreaks of clinically typical SI, as described above, are generally limited to fully susceptible, seronegative pigs, including unprotected nursery pigs or older pigs. For instance, in Europe, the sudden reintroduction of influenza viruses into temporarily seronegative breeding-fattening farms has been associated frequently with acute disease in pigs of 50 kg and greater (Loeffen, personal communication). In contrast, breeding animals that have acquired active immunity as a result of previous infections and their maternally immune offspring mostly remain unaffected. Subclinical infections are evidenced by the high seroprevalence of virus subtypes in finishing pigs in the absence of significant respiratory disease during the fattening period and isolation of virus from pigs with no signs of illness (Hinshaw et al. 1978).

However, multiple factors beyond immune status, e.g., age, infection pressure, concurrent infections, climatic conditions, housing, may interact to affect the clinical outcome of SIV infection. For example, it is widely recognized that secondary infections with any of a number of bacterial pathogens, e.g., *Actinobacillus pleuropneumonia*, *Pasteurella multocida*, *Mycoplamsa hyopneumoniae*, *Haemophilus parasuis*, and *Streptococcus suis* type 2, impact the severity and course of infections with SIVs. More recent observations under natural conditions suggest that respiratory viruses can also act as complicating

factors. The prevalence of dual or triple infections with influenza virus(es) and either porcine respiratory coronavirus (PRCV) or porcine reproductive and respiratory syndrome virus (PRRSV) is extremely high in intensive fattening units in Europe (Houben et al. 1995; Madec et al. 1987; Van Reeth and Pensaert 1994). The hypothesis that influenza viruses may precipitate disease in combination with other respiratory viruses has been supported by experimental dual infection studies (Van Reeth and Pensaert 1994; Van Reeth et al. 1996, 2001c). In these studies, fever, respiratory disease, and growth retardation were significantly more severe and lasting in dual infections as compared to single virus infected pigs. Nevertheless, unknown factors may impact the development of disease following dual virus infections, because in other studies, clinical signs were not enhanced following simultaneous inoculation of pigs with PRCV and either H1N1 or H3N2 viruses (Lanza et al. 1992; Van Reeth et al. 2001c).

Subsequent to an influenza outbreak in a herd, producers and veterinarians occasionally report reduced reproductive performance through increased infertility, abortion, small weak litters, and stillbirths. However, there is insufficient data to conclude that SI viruses have a specific and direct relationship to the occurrence of reproductive problems and, with rare exceptions (Madec et al. 1989; Woods and Mansfield 1974; Young and Underdahl 1949), influenza viruses are not thought to infect the reproductive tract of pigs.

LESIONS

The gross lesions found in uncomplicated SI are mainly those of a viral pneumonia. Abnormalities are most often limited to the apical and cardiac lobes of the lung. The percent of lung tissue with grossly visible consolidation varies greatly within and between experimental infection studies, but more than 50% of the lung may be affected by 4–5 days PI (Born et al. 1998; Richt et al. 2003). Generally, there is a sharp line of demarcation between the affected and normal lung tissue, and the involved areas will be purple and firm. Some interlobular edema may be evident, airways may be filled with blood-tinged fibrinous exudates, and the associated bronchial and mediastinal lymph nodes are usually enlarged. In naturally occurring SI, however, these lesions may be complicated or masked by concurrent infections, especially bacterial.

Microscopically, the hallmark of an SI infection is necrosis of lung epithelia and desquamation of the bronchial epithelial cell layer (Haesebrouck et al. 1985; Haesebrouck and Pensaert 1986). Within 24 hours after experimental IT inoculation, the airways are plugged with inflammatory and necrotic epithelial cells, mainly neutrophils. In lung lavage fluids collected at this stage of infection, neutrophils may account for up to 50% of the cell population, and macrophages are the dominant

cells in uninfected, healthy pigs (Van Reeth et al. 1998). The neutrophils not only cause obstruction of the airways, but they probably also contribute to lung damage by release of their enzymes. After a few days, there is peribronchial and perivascular infiltration of lymphocytes (Richt et al. 2003). Similar pathologic lesions have been observed in clinically typical SIV outbreaks in the field (Done et al. 1996). Like clinical signs, however, lung lesions can also be mild or unremarkable.

Lastly, a proliferative and necrotizing pneumonia (PNP) characterized by a marked proliferation of type II pneumocytes and coagulates of necrotic cells in the alveoli has been associated with strains of H1N1 and H3N2 SIV (Dea et al. 1992; Girard et al. 1992; Morin et al. 1990). However, recent studies have indicated that PRRSV is the key etiologic agent of this condition (Drolet et al. 2003).

IMMUNITY

The adaptive immune response to SIV infection includes both production of antibodies and cell-mediated immunity (CMI). Antibody responses may develop to the HA, NA, M, and NP proteins. However, only antibodies to the globular head region of the HA can block attachment of the virus to host cell receptors and, thus, neutralize viral infectivity. These antibodies can be measured in virus neutralization (VN) or HI assays. Antibodies to the NA, M, and NP proteins cannot prevent the initiation of infection, but they can mediate killing of infected cells by other antibody-dependent mechanisms. Cytotoxic T lymphocytes (CTLs) are mainly directed to the internal NP and M proteins in mouse models of influenza, and to a lesser degree to the HA and NA. Although CTLs are not capable of preventing infection, they may play a key role in clearing virus from the lungs.

The immune response to SIV infection is remarkably rapid and efficient and results in complete elimination of the virus from the respiratory tract within 1 week PI. T cell responses have been detected from 7 days PI onward (Heinen et al. 2001 a, b; Larsen et al. 2000). HI antibodies in serum can be detected by 7–10 days PI and peak at titers of 1:160 to 1:320 by 2–3 weeks PI (Heinen et al. 2000; Larsen et al. 2000). Antibody titers will remain high for several weeks before beginning to decline by 8–10 weeks PI (Van Reeth et al. 2004, and unpublished data). Using highly sensitive ELISA techniques, HA-specific antibodies have been detected in serum as early as day 3 and in nasal secretions on day 4 after inoculation (Lee et al. 1995). Post infection pig sera also contain antibodies to the NA and NP (Heinen et al. 2000, 2001a; Van Reeth et al. 2003a), and anti-NP Abs have also been found in nasal and lung lavage fluids (Heinen et al. 2000). As would be expected, IgM and later IgG, were the dominant isotypes in serum, whereas IgA was the main isotype in nasal washes (Heinen et al. 2000;

Larsen et al. 2000). Larsen et al. (2000) demonstrated antibody-secreting cells in nasal mucosal tissue, which proved that antibodies were locally produced in the respiratory tract of pigs. Antibodies at the lung level are, at least in part, transudated from serum, as suggested by the dominance of virus-specific IgG in bronchoalveolar lavage samples of pigs (Heinen et al. 2000) and other species (White and Fenner 1994). However, substantial IgA levels were also found in lung lavage fluids of SIV-infected pigs (Larsen et al. 2000), and local antibody production in the lung parenchyma cannot be excluded.

After primary infection with SIV, there is solid protection against reinfection with the same or a similar virus strain. Pigs that had been experimentally infected with H1N1 or H3N2 SIV were completely protected against virus replication in the lungs and nose when rechallenged with homologous virus at 6 and 9 weeks after the initial infection, respectively (Heinen et al. 2001b; Larsen et al. 2000). However, the exact duration of protection is not known. HA-specific VN antibodies are likely the main mediators of this "homologous" immunity. Protection studies to prove the role of other immune mechanisms in the pigs are still lacking.

Because of the concurrent circulation of different subtypes of influenza viruses in Europe and in the U.S., pigs may be exposed to multiple, antigenically different, SIVs during their lifetime. Limited cross-protection (reduced virus shedding and clinical illness severity) between the current European H1N1, H3N2, and H1N2 SIVs was demonstrated in experimental infection studies (Heinen et al. 2001a; Van Reeth et al. 2003a), possibly because these viruses have almost identical NP and M proteins despite very different HA and NA proteins (Van Reeth et al. 2004). The true significance of these data for the field situation is still unknown, as are the immune mechanisms that mediate this "broad" protection. Additionally, protection after vaccination is more subtype-specific (Van Reeth et al. 2003b).

The presence of high titers of VN serum antibodies, reaching the lungs by diffusion, is sufficient to reduce SIV replication in the lungs of vaccinated pigs and protect against disease (Haesebrouck and Pensaert 1986). Protection from nasal virus shedding, on the other hand, appears to be minimal in vaccinated pigs (Macklin et al. 1998; Rapp-Gabrielson et al. 2000). This may be due to a lack of virus-specific IgA antibodies in the nasal mucosa.

Maternally derived antibodies can protect young pigs against SIV, but they will also interfere with the development of an active antibody response to vaccination. Maternal SIV antibody levels in newborn pigs are dependent on antibody levels in the dam, they decline over time, and their precise duration can vary from about 4–14 weeks. In experimental studies, none of the pigs with maternal antibodies were completely protected from nasal virus shedding upon challenge, but some pigs showed complete protection of the lungs (Labarque et al. 2004; Loeffen et al. 2003; Renshaw 1975). Pigs with high passive antibody levels did not develop an immune response to the infection and they remained fully susceptible to reinfection with the same virus; a weak and delayed active immune response was seen in pigs with lower levels of maternal antibodies (Loeffen et al. 2003; Renshaw 1975). Recent studies have also confirmed that maternal immunity does not cross-protect between subtypes (Choi et al. 2004; Labarque et al. 2004).

DIAGNOSIS

A clinical diagnosis of SI is presumptive only because there are no pathognomonic signs and SI must be differentiated from a variety of respiratory diseases of swine. A definite diagnosis is possible only in the laboratory, either through isolation of virus, detection of viral proteins or nucleic acid, or demonstration of virus-specific antibodies.

Isolation of SIV from live animals is typically undertaken on samples of mucus obtained by swabbing the nasal passages or, in the case of very small pigs where it is difficult to swab the nasal passages, the pharynx. Virus is most likely to be found in nasal and pharyngeal secretions during the febrile period of illness. Samples should be collected on polyester (e.g., Dacron), not cotton, swabs. Swabs should be suspended in a suitable transport medium (such as glycerol saline) and kept cold (refrigerator temperature, 4°C) during transport to the laboratory. If the samples for virus isolation can be tested within 48 hours after collection, they should be maintained at 4°C. If the samples must be held longer, storage at −70°C is recommended. SIVs are not stable at −20°C. Filtration of the samples should be avoided to conserve small amounts of virus that might be in the transport medium. Adventitious bacterial and fungal agents may be controlled with the addition of appropriate antimicrobial agents to the transport medium.

Virus may also be isolated from trachea or lung tissues of pigs that die or are euthanized during the acute stage of the disease. The tissue material should be held under the same conditions as swab material until ready for culturing. Before testing, the tissue is homogenized in a sterile saline preparation.

Methods for the isolation of virus have been described in detail (Swenson and Foley 2004). Briefly, the virus can be cultivated in embryonated fowl's eggs, generally by allantoic cavity inoculation of 10- to 11-day-old eggs and subsequent incubation at 35°C for 72 hours. SIVs do not typically kill the embryo, but virus can be detected in allantoic fluid using the hemagglutination assay (generally using chicken or turkey erythrocytes), which provides presumptive evidence for the presence of an influenza virus. Up to two blind passages may be required to confirm the absence of virus. Repeated pas-

sages should be done under strictly controlled conditions to avoid cross-contamination in the laboratory.

Increasingly, SIV isolation is being conducted in cell culture. Cell lines of several different origins support the growth of influenza viruses, including bovine, canine, and porcine kidney cells, porcine lung and tracheal epithelial cells, and human diploid cells (Easterday 1975; Ferrari et al. 2003), as well as Vero cells (Govorkova et al. 1995), swine testes cells (Potgeiter et al. 1977), and mink lung cells (Schultz-Cherry et al. 1998). Inoculation of eggs plus cell cultures (Clavijo et al. 2002) or multiple cell lines (Landolt et al. 2005) may enhance recovery of viruses that grow preferentially in different host cells. Furthermore, recent work has demonstrated that Madin-Darby canine kidney and mink lung cells can be co-cultured for SIV isolation (Landolt et al. 2005).

The HA and NA subtypes of influenza viruses have historically been determined in HI and neuraminidase-inhibition (NI) tests (Swenson and Foley 2004). Increasingly, however, molecular-based methods are being used to detect and subtype influenza viruses. The use of reverse transcription-polymerase chain reaction (RT-PCR) assays (both traditional and real-time technologies) offers sensitivity equivalent to virus isolation plus speed and high-volume throughput. These approaches are in their infancy with respect to widespread, commercial diagnostic application for SIV and may have limitations for use in the detection of heterogeneous virus populations. However, such approaches have been used successfully for the detection of the predominant subtypes in pigs and demonstrated good correlation with conventional virus isolation and identification methods (Choi et al. 2002c, 2004; Landolt et al. 2005; Olsen et al. unpublished data; Schorr et al. 1994).

Other methods for detecting virus or viral antigen include direct immunofluorescence techniques applied to lung tissue (Barigazzi et al. 1993), nasal epithelial cells (Onno et al. 1990), or bronchoalveolar lavage contents (Runge et al. 1996); immunohistochemical (IHC) detection in fixed tissues (Haines et al. 1993); ELISA (Lee et al. 1993); rapid cell culture assay using immunoperoxidase staining for typing and subtyping (Ziegler et al. 1995); and a commercially available enzyme immunoassay membrane test (Directigen FLU-A), which rapidly detects influenza A antigen in clinical specimens (Ryan-Poirier et al. 1992).

Serological tests are used to demonstrate the presence of influenza specific antibodies. Diagnosis of acute SIV infection by serology requires the use of paired acute and convalescent (3–4 weeks later) serum samples and appropriate antigens.

Although ELISA assays have become commercially available for SIV, HI remains the most common test for anti-SIV antibody detection. The diagnostician must be aware of the possible presence of nonspecific inhibitors and nonspecific agglutinins in swine serum that may interfere with the HI test. Sera should be treated to reduce or destroy such activity, although some treatments may lower specific antibody levels. The most widely used method is treatment with receptor-destroying enzyme and absorption with chicken erythrocytes (Swenson and Foley 2004). There is considerable antigenic heterogeneity in viruses of the same subtype circulating in pigs because of antigenic drift and lineage variations in different geographical areas of the world. Therefore, the choice of potential viruses for use as antigens in serologic assays should ensure that the strains are well-matched to the current epidemic viruses in a region, country, or continent (Brown et al. 1997b; de Jong et al. 1999; Karasin et al. 2002; Olsen et al. 2000; Richt et al. 2003).

Other assays, such as the VN test (Brown, Olsen, unpublished data) or single radial hemolysis test (Ogawa et al. 1978) have been applied to testing pigs for influenza antibodies. Although these assays do not require pretreatment of sera, they are more appropriate for use in specialized laboratories.

Positive diagnosis of SIV by serological and virological methods among suckling or weanling pigs from dams with antibodies to the virus may be complicated. It has been shown that weanling pigs with maternal antibodies may be infected and may shed virus. The rate of virus recovery and severity of signs of disease are inversely related to levels of maternal antibody (Easterday 1971; Renshaw 1975). In addition, the level of antibody in the convalescent-phase serum will be lower than in the acute-phase serum because of the inhibition of active antibody production by maternal antibody (Easterday 1971; Mensik 1960, 1963, 1966; Renshaw 1975). After maternal antibody is depleted, pigs may be infected again, shed virus, present with signs of disease, and produce a typical primary antibody response.

PREVENTION AND CONTROL

Vaccination and biosecurity remain the primary means of preventing SI in pigs. Commercial inactivated and adjuvanted SIV vaccines for intramuscular administration are available both in Europe and the U.S. Primary vaccination should consist of two injections 2–4 weeks apart. Biannual booster vaccinations are recommended for sows.

SIV vaccine strain composition differs between continents because of the antigenic and genetic differences between SIVs circulating in Europe and the U.S. Vaccines for use in Europe were first licensed during the mid-1980s and contain both subtypes that were prevalent at that time, H1N1 and H3N2. Most of the current vaccines still contain the older human New Jersey/76 (H1N1) and Port Chalmers/73 (H3N2) strains. Whole virus vaccines, as well as "split" vaccines (produced from disrupted highly purified influenza virus) are available. In the U.S., a monovalent H1N1 SIV vaccine was first introduced in 1993. After the emergence of

H3N2 influenza viruses in the U.S. swine population in 1998, monovalent and bivalent (H1N1/H3N2) SIV vaccines became available. The current U.S. vaccines primarily contain a classical H1N1 virus and a triple reassortant H3N2 virus, although a trivalent vaccine also containing reassortant H1N1 virus has recently become available. Autogenous vaccines containing herd-specific strains are also used in the U.S.

Most SIV vaccine efficacy data are from experimental vaccination-challenge studies in which SIV-seronegative pigs are vaccinated twice with commercial vaccine and challenged with virulent SIV 2–6 weeks after the second vaccination. Several studies with European vaccines used a severe IT challenge that results in typical SIV symptoms and high lung virus titers within 24 hours post challenge in unvaccinated controls, but vaccination with New Jersey/76 (H1N1)- and/or Port Chalmers/73 (H3N2)-based commercial vaccines could completely prevent virus replication in the lungs and disease (Haesebrouck and Pensaert 1986; Vandeputte et al. 1986). Based on reports of minor antigenic drift in European H1N1 and H3N2 SIVs during the late 1990s (de Jong et al. 1999, 2001), replacement of the vaccine strains by more recent strains has been considered. In studies in pigs, however, the commercial vaccine still induced high antibody titers to recent H1N1 and H3N2 strains and excellent clinical and virological protection (Heinen et al. 2001b; Van Reeth et al. 2001a,b). Thus, there are no scientific arguments to update H1N1 or H3N2 strains. However, addition of an H1N2 component to these vaccines deserves serious consideration because there is no antigenic cross-reactivity between the European H1N2 virus and the H1N1 and H3N2 strains in the vaccine and because current vaccines failed to protect against H1N2 challenge in experimental infection studies (Van Reeth et al. 2003b).

In studies with U.S. vaccines, challenge has more commonly been by the IN route, and nasal virus shedding was usually the main parameter used to evaluate protection. Complete protection from infection could not be demonstrated, but vaccination could reduce H1N1 challenge virus titers in nasal swabs by 1–2 $\log_{10}$ infectious units. Virus titers in the lungs of vaccinated pigs and macroscopic lung lesion scores were also reduced (Brown and McMillen 1994; Macklin et al. 1998; Rapp-Gabrielson et al. 2000). A bivalent U.S. SIV vaccine was shown to cross-protect against challenge with a 2002 H3N2 isolate that showed genetic drift from the vaccine H3N2 strain (Rapp-Gabrielson et al. 2003).

Though there has to be antigenic overlap between vaccine and challenge strains, antigenic and genetic analyses are not the most accurate predictors of vaccine strain performance. Challenge tests in pigs clearly remain the best measure of vaccine efficacy. Factors other than the nature of the vaccine strains—i.e., the antigenic dose and adjuvant, the health of the pigs at the time of vaccination, proper vaccine administration and

timing—all affect vaccine efficacy. Vaccines with higher antigenic doses will generally be more effective, and highly immunostimulatory oil-based adjuvants are used with most commercial vaccines, although the exact adjuvant formulation may differ among vaccines. New generation adjuvants like Quil A and a combination of Quil A, and alhydrogel also induced high antibody titers when administered with an experimental SIV vaccine (Bikour et al. 1994).

HI antibody titers after administration of two doses of vaccine to seronegative pigs generally range from 1:20 to 1:640, but there may be considerable variation between vaccines and different experiments. Vaccine-induced HI antibodies can be short-lived and significant decreases in serum antibody titer have been reported within 10 weeks after vaccination (Erickson et al. 2002). An inverse correlation between prechallenge serum HI antibody titers and lung virus titers after challenge has been reported by several investigators (Bikour et al. 1996; Haesebrouck and Pensaert 1986; Haesebrouck et al. 1987; Van Reeth et al. 2001 a, b). In the studies by Van Reeth et al. (2001 a, b), all vaccinates with HI titers >160 were completely protected against virus replication in the lungs and disease. However, the antibody titer required for complete protection from infection will also depend on the challenge dose, such that antibody titers ≤160 may be effective against challenge with a lower virus dose or under field conditions (Bikour et al. 1996).

Data regarding SIV vaccine efficacy in the field and cost benefit are quite limited. Most SIV vaccine is used for sow vaccination. In sows routinely receiving pre-farrow booster vaccinations, HI serum antibody titers are frequently 1:160 to 1:640 or greater, and this results in higher and longer lasting maternal SIV antibody levels in their piglets. In a study by Thacker (2000), SIV passive antibody levels dropped below 1:40 by 6 weeks of age in nearly all pigs from unvaccinated sows with low residual HI titers. In contrast, in pigs nursing vaccinated sows, antibody titers did not drop below 1:40 until 16 weeks of age. Sow vaccination, therefore, is important in controlling disease in suckling pigs and often protects pigs through the nursery phase.

Vaccination of feeder pigs is less commonly performed, but this strategy may be beneficial in herds where influenza is a problem in growers/finishers. However, vaccination of feeder pigs may be difficult to combine with vaccination of sows because prolonged passive immunity may interfere with effective vaccination of piglets.

So-called new generation vaccines for SIV have also been tested experimentally, but the results have been rather disappointing. DNA vaccines based on the influenza HA or NP reduced the amount and duration of influenza viral shedding (Macklin et al. 1998), but Olsen and coworkers (2000) found no significant protection from challenge infection following HA DNA vaccination. Still, the DNA vaccination primed pigs for a

stronger antibody response to infection with virulent virus or to vaccination with a conventional killed SIV vaccine (Larsen et al. 2001; Olsen et al. 2000). Heinen et al. (2002) tested a recombinant vaccine expressing the M2 protein and a DNA vaccine containing NP and M genes. Though both vaccines induced the desired immune responses, there was no protection against infection or disease.

29 Swine Pox

Gustavo Delhon, E. R. Tulman, C. L. Afonso, and Dan L. Rock

Swinepox (SWP) is a mild, acute disease of swine characterized by typical poxviral lesions of the skin. SWP is distributed worldwide and is usually associated with poor sanitation. Morbidity may be high in individual herds where young pigs are most severely affected, but mortality is usually negligible. Clinical signs and epidemiology are usually sufficient for SWP diagnosis.

ETIOLOGY

SWP virus (SWPV) is the sole member of the genus *Suipoxvirus* in the family *Poxviridae* (Moyer 2000). The SWPV virion is morphologically similar to vaccinia virus, exhibiting a brick-like structure approximately 320 x 240 nm in horizontal section (Figure 29.1) (Blakemore and Abdussalam 1956; Cheville 1966a; Teppema and de Boer 1975). The virion is composed of a central biconcave core or nucleoid bordered by two ellipsoid lateral bodies and at least two lipid membranes (Blakemore and Abdussalam 1956; Cheville 1966a; Conroy et al. 1971; Kim and Luong 1975; Smid et al. 1973; Teppema and de Boer 1975). SWPV is ether-sensitive.

The SWPV genome is a double-stranded DNA molecule of 146 kilobase pairs predicted to contain 150 genes. It shares features common with other members of the *Poxviridae*, including a conserved central genomic region containing genes necessary for intracytoplasmic replication and virion structure (Afonso et al. 2002). Although genetically related to viruses of other poxviral genera (*capripoxvirus, leporipoxvirus, yatapoxvirus*), SWPV represents a distinct poxvirus genus and contains in terminal genomic regions a unique complement of genes predicted to affect virus/host interaction and aspects of SWPV virulence and host range (Afonso et al. 2002; Massung et al. 1993).

Despite reports of limited antigenic cross-reactivity, SWPV is antigenically distinct, as evidenced by the failure of SWPV antibodies to cross-protect, cross-neutralize, or efficiently immunoprecipitate viral proteins of other poxviruses (de Boer 1975; Massung and Moyer 1991; Meyer and Conroy 1972; Ouchi et al. 1992; Shope 1940).

Although some isolates have been reported to induce first-passage CPE on swine cells (Afonso et al. 2002; Paton et al. 1990), SWPV generally replicates poorly on initial isolation in swine cell cultures. It requires multiple passages before inducing cytopathic effect (CPE), but maintains pathogenicity for swine (Garg and Meyer 1972; Kasza and Griesemer 1962; Kasza et al. 1960; Meyer and Conroy 1972). CPE, characterized by cytoplasmic vacuoles and inclusion bodies, nuclear "vacuoles," and cell rounding and clumping (Borst et al. 1990; de Boer 1975; Kasza et al. 1960; Meyer and Conroy 1972), is seen 3–5 days postinoculation (PI), and isolated plaques remain relatively small in size (≤1.5 mm)(Kasza et al. 1960; Massung and Moyer 1991; Meyer and Conroy 1972). Infection of cell cultures results in expression of early and late SWPV mRNA by 4 and 8 hours PI, respectively, and viral protein synthesis by 4 hours PI (Massung and Moyer 1991).

Most attempts to grow or adapt SWPV for growth in non-swine cell cultures or on chicken chorioallantoic membranes have failed (Garg and Meyer 1972; Kasza et al. 1960; Meyer and Conroy 1972), indicating a host range restriction for replication at the cellular level. Recently, culture-adapted SWPV has been shown to replicate, albeit to lower titers, in non-swine cell lines (Barcena and Blasco 1998; Hahn et al. 2001).

Due to its restricted host range, SWPV has been proposed as a vaccine expression vector (Foley et al. 1991; Tripathy 1999). Genetically engineered SWPV vectors expressing pseudorabies virus (PRV) and classical swine fever virus antigens have been constructed and, in the case of PRV, shown to induce immune responses in pigs (Hahn et al. 2001; van der Leek et al. 1994). In addition, SWPV is able to express antigens in non-swine cells and may represent a safe, host range-restricted, vaccine vector for non-swine species (Barcena and Blasco 1998; Winslow et al. 2003). Availability of the complete
29.1. *Negative stain of swine pox virus particles with characteristic brick-shape and complex woven pattern of external filaments. (Courtesy of D. A. Gregg).*

genome sequence and identification of SWPV virulence and host range genes should enable engineering of live-attenuated, host-range–restricted, SWPV vaccine vectors with enhanced efficacy and greater versatility (Afonso et al. 2002).

EPIDEMIOLOGY

The pig is the only known host of SWPV. Unlike vaccinia virus, SWPV failed to experimentally infect or adapt to several mammalian and avian species (Schwarte and Beiester 1941; Shope 1940), with only a single report of nonproductive SWPV infection following intradermal inoculation of rabbits (Datt 1964). This restricted host range suggests that swine represent the reservoir of SWPV in nature.

SWP is present worldwide. Limited serological survey data from Europe indicated that 8–19% of swine serum samples contained anti-SWPV antibodies (de Boer 1975; Paton et al. 1990). Young swine are most often affected, as adult swine rarely present with clinical disease (McNutt et al. 1929; Kasza et al. 1960). Morbidity rates can be high (up to 100%), but mortality is generally negligible (less than 5%)(de Boer 1975). Overall, SWP is of little economic consequence.

Natural transmission of SWP is not well understood, but is often associated with poor sanitation. SWP has been associated with louse (*Haematopinus suis*) infestation. Lice are able to mechanically transmit SWPV and are thought to affect the extent and distribution of cutaneous lesions, which often occur in less keratinized abdominal and inguinal regions (Kasza et al. 1960; Manninger et al. 1940; Shope 1940). However, SWP without evidence of louse involvement has been described, suggesting a role for other insect vectors or the possibility of horizontal transmission (de Boer 1975; Jubb et al. 1992; Paton et al. 1990; Schwarte and Biester 1941). Vertical SWPV transmission is indicated by sporadic cases of

congenital infection resulting in stillborn fetuses with generalized lesions (Afonso et al. 2002; Borst et al. 1990; Paton et al. 1990).

CLINICAL SIGNS

SWPV causes eruptive dermatitis in pigs. Animals up to 3 months of age are the most susceptible, with adults usually developing a mild, self-limiting form of the disease. Multiple cutaneous lesions are commonly found on the flanks, belly, inner side of the legs, ears, and less frequently, on the face of affected animals (de Boer 1975; Jubb et al. 1992; Kim and Luong 1975; McNutt et al. 1929; Olufemi et al. 1981; Schwarte and Biester 1941). Lesions can also be found in the teats of sows and on the face, lips, and tongue of suckling pigs (Olufemi et al. 1981). In congenital infections, lesions are observed over the entire body and in the oral cavity (Borst et al. 1990; Paton et al. 1990). When virus transmission is associated with mechanical vectors, the distribution of lesions tends to reflect the vector's preferred feeding areas.

The incubation period is thought to be 4–14 days under field conditions (de Boer 1975; McNutt et al. 1929) and 3–5 days after intradermal or intravenous virus inoculation (Kasza and Griesemer 1962; Schwarte and Biester 1941), although longer periods have been described (Shope 1940).

Initial lesions are flat, pale, rounded areas 3–5 mm in diameter (maculae). Over the course of 2 days, these progress to papulae 1–2 mm in height, 1–2 cm in diameter, and occasionally confluent (Figure 29.2). The appearance of papulae may be accompanied by a slight and transient increase in body temperature and loss of appetite (Kasza and Griesemer 1962; Kasza et al. 1960). A true vesicle stage is absent or transient (Borst et al. 1990; Datt 1964; Kasza and Griesemer 1962; Meyer and

29.2. *Swine pox lesions on the skin of a naturally infected pig (Courtesy of B. Brodersen).*

Conroy 1972). The lesions usually become umbilicated and shrink about a week after appearing. They are replaced by crusts, which are eventually shed, leaving discolored spots (Kasza and Griesemer 1962). Complete recovery is observed 15–30 days post exposure, but it may be delayed if secondary bacterial infection occurs (de Boer 1975; McNutt et al. 1929; Miller and Olson 1980; Schwarte and Biester 1941).

PATHOGENESIS

SWPV may enter the host through preexisting skin abrasions and preferentially replicates in epidermal keratinocytes of the stratum spinosum (Meyer and Conroy 1972). Although mature viral particles have been observed in epidermal basal cells (Teppema and de Boer 1975) and viral antigen has been detected in dermal macrophages (Cheville 1966b), there is no indication that these cell types support virus replication. With the exception of moderate changes in superficial lymph nodes, tissues other than the skin are rarely affected. Infectious virus can be readily isolated from the skin of infected animals as early as 3 days postintradermal inoculation (Kasza and Griesemer 1962), and from regional lymph nodes only if skin lesions are severe (Kasza and Griesemer 1962). A viremic stage has been suggested to account for virus spread from the primary to secondary sites of replication in the skin and for congenital infection; however, virus has not been isolated from blood of infected animals (Borst et al. 1990; Kasza and Griesemer 1962; Paton et al. 1990; Shope 1940).

Functional studies on SWPV pathogenesis are lacking. The complement of virus genes with putative roles in virulence and host range suggests that modulation of host immune responses and inhibition of apoptosis may play a role in the course of the disease (Afonso et al. 2002; Kawagishi-Kobayashi et al. 2000; Massung et al. 1993). SWPV contains genes with sequence similarity to cellular and viral genes encoding CD47 and proteins that bind interferon (IFN) alpha/beta, IFN-gamma, tumor necrosis factor alpha, interleukin-18 (IL-18), and CC chemokines. Products of these genes potentially modulate host immune responses, including NK and T cell responses, and may facilitate SWPV replication and dissemination. SWPV encodes proteins similar to inhibitors of host MHC-I, serine proteases, IL-1/Toll-like receptors, and protein kinase PKR, some of which in other poxviruses are known to interfere with or delay inflammatory responses at the site of virus replication.

Convalescent swine are resistant to SWPV challenge, indicating that infection induces protective immunity (de Boer 1975; Garg and Meyer 1972; Kasza et al. 1960; Schwarte and Biester 1941; Shope 1940). However, the immune mechanisms associated with protection are not known. SWPV neutralizing activity is present in swine sera as early as 7 days PI; however, low neutralizing titers, delayed kinetics of antibody response, and lack of neutralizing antibodies at 50 days PI have been reported (Kasza et al. 1960; Meyer and Conroy 1972; Shope 1940; Williams et al. 1989). Suckling pigs may also be protected by maternal antibody (Manninger et al. 1940), although high neonatal mortality rates have been observed (Olufemi et al. 1981). Decreased mitogen and SWPV-induced proliferative responses have been observed in peripheral blood mononuclear cells from experimentally infected swine (Williams et al. 1989).

LESIONS

The most conspicuous histologic change caused by SWPV infection is hydropic degeneration of stratum spinosum keratinocytes (Figure 29.3A, B) (Borst et al. 1990; Cheville 1966a; Kasza and Griesemer 1962; McNutt et al. 1929; Meyer and Conroy 1972; Olufemi et al. 1981; Paton et al. 1990; Schwarte and Biester 1941; Teppema and de Boer 1975). Hyperplasia of epidermal cells is not as marked as in poxviral infections of other mammals, an observation that might be related to the lack of a SWPV-encoded homologue of the poxviral epidermal growth factor-like gene (Afonso et al. 2002; McNutt et al. 1929; Schwarte and Biester 1941). The cytoplasm of affected cells is brightened and enlarged,

contains eosinophilic inclusion bodies resembling poxviral type B inclusion bodies (Teppema and de Boer 1975) (Figure 29.3B), and reacts strongly with antibodies against viral antigens (Cheville 1966b). Hydropic degeneration and inclusion bodies are also observed in the outer root sheaths of the hair follicles (Kasza and Griesemer 1962; Meyer and Conroy 1972). The nucleus of affected cells exhibits margination of chromatin and a large, central "vacuole" resembling the nuclear clearing observed in sheeppox virus-infected keratinocytes (Figure 29.3B) (Cheville 1966a; Kasza and Griesemer 1962; McNutt et al. 1929; Meyer and Conroy 1972; Plowright and Ferris 1958; Teppema and de Boer 1975). No significant fluid accumulation is observed between keratinocytes. Apical keratinocytes undergo necrosis at later stages of infection. Leukocyte infiltration is observed in the underlying dermis and, to a lesser degree, the affected epidermis (Figure 29.3A), with few viral antigen-containing dermal macrophages (Cheville 1966b). When involved, the inguinal lymph nodes present edema, hyperemia, hyperplasia, and few virus antigen-containing cells (Cheville 1966a; Kasza and Griesemer 1962).

Ultrastructurally, infected cells exhibit a marked decrease in keratin precursors (tonofilaments) and loss of intercellular interdigitations characteristic of the stratum spinosum (Cheville 1966a; Teppema and de Boer 1975). Individual inclusion bodies consist of electro-dense central cores surrounded by lamellar bodies and maturing viral particles (viroplasm) (Cheville 1966a; Conroy and Meyer 1971; Kim and Luong 1975; Smid et al 1973; Teppema and de Boer 1975). The large, well-defined nuclear "vacuole" can be more accurately described as a region of low electron density that lacks a surrounding membrane and contains cross-striated fibrils similar to those observed in the cytoplasm.

DIAGNOSIS

Presumptive SWP diagnosis is based on the observation of pox lesions on the skin of affected animals. Differential diagnosis includes vesicular diseases, allergic skin reactions, sunburn, bacterial dermatitis, ringworm, and skin parasitosis (*Tyroglyphus* spp, sarcoptic mange) (Blood and Radostits 1989; Yager and Scott 1985). SWPV involvement can be confirmed by electron microscopy and histopathology and includes pathognomonic epidermal changes: ballooned stratum spinosum keratinocytes containing cytoplasmic eosinophilic inclusion bodies and a "vacuolated" nucleus. SWPV involvement may be definitively confirmed using SWPV-specific antibodies to neutralize virus isolated on swine cell cultures (primary swine kidney cells, PK-15 cell line) (Borst et al. 1990; Meyer and Conroy 1972; Paton et al. 1990) or by performing immunocytochemistry on tissue samples or infected cell cultures (Garg and Meyer 1973; Mohanty et al. 1989; Paton et al. 1990).

Papular/pustular exudate or crusted material are clinical samples of choice for virus isolation. At least seven blind passages should be attempted before considering the sample negative (de Boer 1975).

Serum neutralization and precipitating antibody tests to detect SWPV-specific antibodies in convalescent serum have been described (de Boer 1975; Shope 1940). Since swine do not reliably develop high levels of neutralizing antibodies (Kasza et al. 1960; Shope 1940), negative test results should be interpreted with caution.

The recent availability of the SWPV genome sequence and the identification of unique SWPV gene sequences will permit the development of rapid, sensitive, and specific polymerase chain reaction–based detection and diagnostic assays (Afonso et al. 2002).

Although differential diagnosis of SWP from a vaccinia virus infection in pigs was important when human smallpox vaccination was practiced, this no longer represents a diagnostic concern (Shope 1940).

PREVENTION AND CONTROL

No specific treatment for SWPV exists. Antibiotic regimens are recommended for treatment of secondary bacterial infection. Given that SWP is of relatively low economic impact, no vaccine has been developed. Good animal husbandry, including ectoparasite control, should be practiced.

30 Transmissible Gastroenteritis and Porcine Respiratory Coronavirus

Linda J. Saif and Karol Sestak

Transmissible Gastroenteritis

Transmissible gastroenteritis (TGE) is a highly contagious, enteric viral disease of swine characterized by vomiting, severe diarrhea, and a high mortality (often 100%) in TGEV seronegative piglets under 2 weeks of age. Since the 1980s, the appearance and widespread prevalence of a naturally occurring respiratory deletion mutant of TGE virus (TGEV), the porcine respiratory coronavirus (PRCV), has altered the clinical impact of TGE. Although swine of all ages are susceptible to TGEV or PRCV infection, the mortality in TGEV and/or PRCV seropositive herds and in swine over 5 weeks of age generally is low.

TGE was first reported by Doyle and Hutchings (1946) as occurring in the U.S. in 1945, although it undoubtedly had existed earlier. Since then, it has been reported in most countries worldwide, albeit with its clinical impact altered by the prevalence of PRCV. The disease is most easily diagnosed and causes the highest losses when it occurs in TGEV or PRCV seronegative herds at farrowing. In contrast, it often goes undiagnosed when it occurs in growing, finishing, or adult swine because of the mild clinical signs, which usually consist only of inappetence and mild diarrhea.

Because of these undiagnosed infections, serologic surveys were once a more accurate indication of the prevalence of TGEV. However, since the 1980s the prevalence of cross-reactive PRCV antibodies has confounded the serodiagnosis of TGEV based on conventional assays (Laude et al. 1993; Pensaert and Cox 1989). Surveys through the early 1990s indicated that 19–54% of sampled swine herds in North America were seropositive for TGEV antibodies (Egan 1982; USDA APHIS VS 1992). In 1995, 16 of 22 swine herds examined in Iowa were seropositive for TGEV (Wesley et al. 1997). Recent data indicates a decline in the number of TGEV outbreaks diagnosed in the U.S. compared to historical data, pre-

sumably due to the spread of PRCV (Yaeger et al. 2002). Currently in many European countries, nearly 100% of swine herds are seropositive for TGEV antibodies. This situation is due to PRCV that appeared in 1984 and rapidly spread in Europe (Brown and Cartwright 1986; Laude et al. 1993; Pensaert 1989; Pensaert and Cox 1989; Pensaert et al. 1986, 1993). Economic losses from TGE can be severe (Mousing et al. 1988; Pritchard 1987); however, with the establishment of endemic PRCV, the economic impact of TGE has decreased (Laude et al. 1993; Pensaert and Cox 1989).

In TGEV/PRCV seronegative herds in North America, TGE remains a cause of sickness and death in piglets. Diagnosis of TGE in PRCV-endemic herds has become problematic because the milder disease in all age groups masks the presence of TGEV infections (Kim et al. 2000b). This poses concerns for maintenance or export of TGEV negative breeding stock.

ETIOLOGY

TGEV is a species in the genus *Coronavirus* of the family *Coronaviridae* (Lai and Cavanagh 1997). TGEV is enveloped and pleomorphic, with an overall diameter of 60–160 nm, as viewed by negative-staining electron microscopy (EM) (Figure 30.1) (Granzow et al. 1981; Okaniwa et al. 1968; Phillip et al. 1971). It has a single layer of club-shaped surface projections or spikes 12–25 nm in length.

TGEV antigen can be demonstrated in the cytoplasm by immunofluorescence (IF) as early as 4–5 hours post infection (Pensaert et al. 1970a). Maturation of virus occurs in the cytoplasm by budding through endoplasmic reticulum, and viral particles (65–90 nm in diameter) are often observed within cytoplasmic vacuoles (Figure 30.2A) (Pensaert et al. 1970a; Thake 1968; Wagner et al.
30.1. *Electron micrograph of a TGEV particle showing typical coronavirus morphology. Arrow points to the virus peplomers, or spikes. Bar = 100 nm.*

1973). The virus is frequently seen lining the host cell membranes after exit from infected cells (Figure 30.2B). TGEV glycoproteins have been identified on the surface of infected swine testicular (ST) cells (Laviada et al. 1990).

Biological Properties

TGEV is very stable when stored frozen, but somewhat labile at room temperature or above. No detectable drop in titer occurred when virus of pig intestine origin was stored at −20°C for 6–18 months (Haelterman and Hutchings 1956; Young et al. 1955). In contrast, intestinal virus, when allowed to dry and putrefy at 21°C, was rather labile; after 3 days only two of four inoculated pigs became sick; and after 10 days no viable virus was detected by pig inoculation (Bay et al. 1952). When held at 37°C, there was a log 10 reduction in infectivity titer every 24 hours (Young et al. 1955). Storage of cell culture virus at −20°C, −40°C, or −80°C for 365 days did not result in any significant drop in titer, whereas storage at 37°C for 4 days resulted in total loss of infectivity (Harada et al. 1968). Infectious virus persisted in a liquid manure slurry for more than 8 weeks at 5°C, 2 weeks at 20°C, and 24 hours at 35°C (Haas et al. 1995).

The virus is highly photosensitive. Haelterman (1963) reported that fecal material containing 10^5 pig-infectious doses (PID) was inactivated within 6 hours when exposed to sunlight. Cartwright et al. (1965) reported the photosensitivity of a cytopathic strain when it was exposed to ultraviolet light on a laboratory bench.

In terms of chemical stability, TGEV is inactivated by exposure to 0.03% formalin, 1% Lysovet (phenol and aldehyde), 0.01% beta propiolactone, 1 mM binary ethylenamine, sodium hypochlorite, NaOH, iodines, quaternary ammonium compounds, ether, and chloroform (Brown 1981; Harada et al. 1968; Nakao et al. 1978; VanCott et al. 1993).

As reported for other enteric viruses, TGEV field strains are trypsin resistant, relatively stable in pig bile, and stable at pH 3 (Laude et al. 1981). These properties allow the virus to survive in the stomach and small in-
30.2. *(A) TGEV in vesicles of the endoplasmic reticulum of a pig kidney cell (36 hours post infection). Bar = 100 nm. (B) TGEV lining the cell membrane of a pig kidney cell (36 hours post infection). N = nucleus; bar = 200 nm.*

testine. However, attenuated strains, as well as field strains of TGEV vary in these properties, and most studies have failed to show a correlation between susceptibility to these various treatments and cell culture passage level or degree of virulence (Furuuchi et al. 1975; Laude et al. 1981).

Molecular Properties

TGEV and the deletion mutant, PRCV, are enveloped viruses containing one large, polyadenylated, single-stranded, genomic RNA of positive-sense polarity. The genome organization, replication strategy, and expression of viral proteins are similar to those of other coronaviruses (Enjuanes and Van der Zeist 1995; Laude et al. 1993). The genomic RNA of TGEV is infectious (Brian et al. 1980), and the complete sequence of the Purdue-115 strain of TGEV is 28,579 nucleotides long (Eleouet et al. 1995; Kapke and Brian 1986).

TGEV has a buoyant density in sucrose of 1.18–1.20 g/mL (Brian et al. 1980; Jimenez et al. 1986). The phospholipids and glycolipids incorporated into the virus envelope are derived from the host cell, and thus, the envelope composition is host cell dependent (Enjuanes and Van der Zeist 1995; Pike and Garwes 1977).

Intact TGEV contains four structural proteins: a large surface glycoprotein (spike or S); a small membrane protein (E or sM); an integral membrane glycoprotein (M); and a nucleocapsid protein (N) (Garwes and Pocock 1975; Godet et al. 1992).

The N protein (47 kDa) interacts with viral RNA to form a helical ribonucleoprotein complex. This structure, in association with M protein, forms an internal icosahedral core (Risco et al. 1996). The 29–36 kDa M glycoprotein, embedded in the viral envelope by three or four membrane-spanning regions, is present in two topological forms (Risco et al. 1995). In one conformation, the N terminus of the M protein is external to the virus envelope and the C terminus is internal, whereas, in the second conformation, both ends of the molecule are on the outside of the virion. In both conformations, the hydrophilic N terminus with a single accessible glycosylation site is responsible for interferon induction (Charley and Laude et al. 1988). Epitopes on protruding N-terminal and C-terminal ends of M protein molecules bind complement-dependent neutralizing monoclonal antibodies (MAbs) (Laude et al. 1992; Risco et al. 1995; Woods 1988). S glycoproteins, probably as trimer complexes (Delmas and Laude 1990), are visible in electron micrographs as the virus "corona" (Figure 30.1). Functions attributed to the S glycoprotein (170–220 kDa) include virus neutralization (complement-independent), virus-cell attachment, membrane fusion, as well as hemagglutination. Purified S glycoprotein elicited the production of TGEV-neutralizing antibodies, which neutralize at multiple steps in the virus replication cycle (Nguyen et al. 1986; Sune et al. 1990).

Aminopeptidase N and a second 200 kDa surface protein on ST cells and on porcine intestinal enterocytes have been identified as virus receptors (Delmas et al. 1992; Weingartl and Derbyshire 1994). The receptor binding site for aminopeptidase N and the major neutralizing site (site A) on the S protein are located within the same domain (Godet et al. 1994). Moreover, TGEV binds to sialic acid residues on glycoproteins of target cells. This binding was proposed to initiate infection of intestinal enterocytes (Schwegmann-Wessels et al. 2002). Treatment of TGEV with sialidase enhanced hemagglutinating activity (Noda et al. 1987; Schultze et al. 1996). This hemagglutinating activity is located at the N-terminal region of the TGEV S protein, a region that is missing from the PRCV S protein; thus, determining the presence or absence of hemagglutinating activity (Schultze et al. 1996) could be a method to differentiate PRCV and TGEV strains.

Monoclonal antibodies (MAbs) have been produced against attenuated (Correa et al. 1990; Delmas and Laude 1990; Jimenez et al. 1986) and virulent (Simkins et al. 1992, 1993; Welch and Saif 1988; Zhu et al. 1990) strains of TGEV and used to characterize TGEV proteins and map epitopes that elicit antibodies. The major neutralization determinants on the S protein were highly conserved for TGEV and PRCV strains (Garwes et al. 1987; Jimenez et al. 1986; Sanchez et al. 1990; Simkins et al. 1993; Welch et al. 1988). Use of neutralizing MAbs to map epitopes on the S glycoprotein revealed four distinct antigenic sites (A, B, C, D), with site A-B as the highly conserved immunodominant epitope recognized by strongly neutralizing MAbs (Correa et al. 1990; Delmas and Laude 1990; Garwes et al. 1987; Gebauer et al. 1991; Simkins et al. 1992, 1993), although other sites (D, C) also can induce neutralizing antibodies (Laude et al. 1986; Posthumus et al. 1990). The locations of each of the four major antigenic sites were mapped on the primary structure of the S glycoprotein. Starting from the amino terminal end, these sites were designated C, B, D, and A by the Madrid group (Correa et al. 1990) and D, C, and A-B by the Paris group (Delmas and Laude 1990). Paris sites D, C, and A-B (the designation used in this chapter unless specified otherwise) overlap Madrid sites B, D, and A, respectively. Three subsites (Aa, Ab, Ac) for site A were recognized using TGEV-MAb-resistant mutants (Correa et al. 1990).

Antigenic and Genomic Relationships

Only one serotype of TGEV is known (Kemeny 1976). PRCV strains are not distinguished from enteropathogenic strains of TGEV by the virus neutralization (VN) test (Pensaert 1989; Pensaert and Cox 1989), but can be distinguished by a blocking enzyme-linked immunosorbent assay (ELISA) test (see section on diagnosis) or by a large deletion in the S gene of PRCV resulting in a smaller S protein (170–190 kDa) than the S protein of TGEV (220 kDa).

Seven coronaviruses are related antigenically or by

their genomic sequence (Enjuanes and Van der Zeist 1995). These are TGEV, PRCV, canine coronavirus (CCV), feline infectious peritonitis virus (FIPV), feline enteric coronavirus (FECV), porcine epidemic diarrhea virus (PEDV), and human coronavirus (HCV 229E). Within these group I coronavirus, only TGEV, PRCV, CCV, FIPV, and FECV form an antigenically related subset, based on cross-reactivity in VN and IF tests and with MAbs to the S, N, or M protein (Enjuanes and Van der Zeist 1995; Woods 1982). Moreover, all members of this antigenic subset share the antigenic subsite Ac on the S protein (Enjuanes and Van der Zeist 1995). Additional cross-reactivity between the S, M, and N proteins of TGEV, CCV, and FIPV was shown by radioimmunoprecipitation, immunoblotting, and ELISA, and it was suggested that these viruses may actually represent host range mutants of an ancestral virus strain (Horzinek et al. 1982). Similar cross-reactivity among the S, M, and N structural proteins of TGEV and PRCV was observed using polyclonal antisera in immunoblotting assays (Callebaut et al. 1988).

PEDV is another coronavirus of pigs that causes a disease similar to TGEV; this disease has been documented only in swine in Europe and Asia (DeBouck 1982). Antibodies to PEDV have not been detected in a limited survey of adult swine sera from the U.S. (L. J. Saif and M. B. Pensaert, unpublished data, 1990). Some one-way, immunoblotting cross-reactivity with the N protein has been reported for PEDV, FIPV, CCV, TGEV, and a putative mink coronavirus (Have et al. 1992; Zhou et al. 1988). However, no antigenic cross-reactivity between PEDV and TGEV-related coronaviruses has been detected using polyclonal antisera or MAbs in other serologic assays (Callebaut et al. 1988; Enjuanes and Van der Zeist 1995; Pensaert and Debouck 1978). Another coronavirus of pigs, hemagglutinating encephalomyelitis virus, is antigenically and genetically unrelated to the coronaviruses in group I and is a member of coronavirus group II (Enjuanes and Van der Zeist 1995).

Although TGEV, CCV, and FIPV are antigenically closely related, Reynolds et al. (1980) suggested that TGEV and CCV could be distinguished serologically (with sera from naturally infected animals) by employing two-way cross-neutralization tests. Additional in vitro biological differences also have been detected. Whereas both TGEV and CCV will grow in either canine kidney cells (Welter 1965) or an established feline cell line (Woods 1982), neither CCV nor FIPV will grow in ST or porcine thyroid cells, both of which support the growth of TGEV isolates (Reynolds et al. 1980).

In vivo biological differences also exist among TGEV, CCV, and FIPV in their pathogenicity for neonatal pigs (Woods and Pedersen 1979). Whereas virulent FIPV caused diarrhea and intestinal lesions similar to those of virulent TGEV, CCV caused no clinical signs and only slight villous atrophy. IF, using a porcine anti-TGEV serum conjugate, occurred in villous enterocytes of TGEV- and FIPV-infected pigs but predominated in crypt enterocytes of CCV-infected pigs. CCV shed by acutely infected dogs was shown to infect baby pigs and induced serum neutralizing antibodies for both CCV and TGEV (Woods and Wesley 1992). However, baby pigs and pregnant gilts experimentally infected with FIPV did not produce TGEV-neutralizing antibodies, but did develop some immunity to a TGEV challenge (Woods and Pedersen 1979).

Molecular probes and MAbs are also used to detect and differentiate among these antigenically related coronaviruses. In terms of the S glycoprotein gene that confers host range specificity, the 300 amino acid residues at the N terminus are the most variable. In this domain CCV and FIPV are more similar to each other than to TGEV (Jacobs 1987; Wesseling et al. 1994). Thus, cDNA probes developed from this domain of the TGEV S gene reacted with TGEV RNA but failed to recognize CCV or FIPV RNA under conditions of high stringency. Either cDNA probes or RT-PCR (reverse transcriptase polymerase chain reaction) techniques are used to differentiate U.S. strains of PRCV from prototype strains of TGEV (Bae et al. 1991; Jackwood et al. 1995; Kim et al. 2000a; Vaughn et al. 1994). Similar differentiation of the TGEV-related coronaviruses was possible using certain specific MAbs to the S glycoprotein of TGEV that recognized TGEV strains but failed to react with PRCV, FIPV, or CCV (Callebaut et al. 1988; Laude et al. 1988; Sanchez et al. 1990; Simkins et al. 1992, 1993).

PRCV strains, isolated during the mid-1980s through 2000s, have been characterized and partially sequenced (Britton et al. 1991; Costantini et al. 2004; Kim et al. 2000b; Rasschaert et al. 1990; Vaughn et al. 1995; Wesley et al. 1991b). An overall nucleotide and amino acid sequence homology of 96% between TGEV and PRCV suggests that PRCV evolved from TGEV and that this occurred on a number of independent occasions. Two striking features characterize the PRCV genome: (1) a large deletion (621–681 nucleotides) at a consistent site near the N terminus of the S gene that gives rise to a smaller S protein; and (2) a variable region with deletions that often eliminate the open reading frame (ORF) immediately downstream of the S gene. These genetic changes may account for the altered tissue tropism of PRCV (Ballesteros et al. 1997; Sanchez et al. 1999).

From sequence data, significant homologies occur in the three genes encoding the three main structural proteins within TGEV-related viruses (TGEV, PRCV, CCV, FECV, FIPV) and between TGEV-related viruses and HCV 229E and PEDV (Enjuanes and Van der Zeist 1995). Thus, sequencing data show a genomic relationship between these latter two viruses and TGEV-related viruses that is not demonstrated by serologic analysis (Enjuanes and Van der Zeist 1995).

An altered phenotype was reported for a small plaque (SP) variant of TGEV (Woods 1978; Woods et al. 1981). Although the S gene of the SP variant and the S gene of

wild-type TGEV are similar, a large deletion (462 nucleotides) is present in the SP viral genome just downstream from the S gene (Wesley et al. 1990a). This deletion eliminated the ORF of one potential viral encoded protein and eliminated the N-terminal portion of a second potential viral protein. These two ORFs are also missing from the high cell culture–passaged Nouzilly strain, a second attenuated TGEV with an SP phenotype (Britton et al. 1994). Presumably, the altered pathogenicity of SP virus, the Nouzilly virus, and the PRCVs results from these genetic deletions.

The recently emerged severe acute respiratory syndrome (SARS) is a human pneumoenteric disease caused by a novel coronavirus tentatively assigned to coronavirus group IV. Although SARS is believed to be zoonotic, its genetic relationship to TGEV is relatively distant and its exact animal reservoir remains unknown (Drosten et al. 2003; Ksiazek et al. 2003; Marra et al. 2003; Peiris et al. 2003; Rota et al. 2003). However several investigations have reported that SARS coronavirus cross-reacts with antibodies to group I coronaviruses including TGEV and PRCV, mainly through the N-protein (Nagesha et al. 2004; Ksiazek et al. 2003; Sun and Meng 2004). Attempts to transmit SARS coronavirus to 6-week-old pigs (PRCV seropositive) failed, although pigs seroconverted to SARS and shed virus detected by RT-PCR (Weingartl et al. 2004). It is unknown whether the preexisting PRCV antibodies affected susceptibility of the pigs to SARS.

EPIDEMIOLOGY

On a herd basis, two epidemiologic forms of TGE are recognized: epidemic and endemic. In addition, infections with the TGEV deletion mutant PRCV present a different pattern and greatly complicate seroprevalence studies of the epidemiology of TGEV (Pensaert 1989; Pensaert and Cox 1989).

Epidemic TGE

Epidemic TGE refers to the occurrence of TGE in a herd where most, if not all, of the animals are TGEV/PRCV seronegative and susceptible. When TGEV is introduced into such a herd, the disease usually spreads rapidly to swine of all ages, especially during the winter. Some degree of inappetence, vomition, or diarrhea will occur in most animals. Suckling pigs show marked clinical signs and rapidly dehydrate. Mortality is very high in pigs under 2–3 weeks of age, but gradually decreases in older pigs. Lactating sows often show signs, developing anorexia and agalactia, which further contribute to piglet mortality.

The history and severe clinical signs aid in diagnosis of epidemic TGE in the U.S., since diseases with similar signs have not been reported. However, in Europe, PED had similar clinical signs before it became endemic (Pensaert and DeBouck 1978). Likewise, the presence of

PRCV appears to have greatly reduced the incidence and severity of epidemic TGE (Brown and Patton 1991; Laude et al. 1993; Pensaert et al. 1993; Pensaert and Cox 1989).

Endemic TGE

Endemic TGE refers to the persistence of the virus and disease in a herd. This occurs as a result of the continual or frequent influx of susceptible swine which, when infected, tend to perpetuate the disease. Endemic TGE is limited to seropositive herds that have frequent farrowings (Stepanek 1979) or have frequent additions or commingling of susceptible swine.

Endemic TGE represents a common sequel to a primary outbreak in large breeding herds. In endemically infected herds, TGEV spreads slowly among adult swine, particularly herd replacements (Pritchard 1987). Females saved for breeding are frequently immune and will transfer via their colostrum and milk a variable degree of passive immunity to their suckling pigs. Sows usually do not show clinical signs. In these herds, mild TGEV diarrhea occurs in pigs from about 6 days of age until about 2 weeks after weaning. The pig is clinically affected when viral exposure exceeds the pig's passive immunity. The age at which this occurs is related to the management system used in the herd and the degree of immunity of the sow. Mortality is usually less than 10–20%, being determined by the age when infected and by the variable degree of immunity obtained from immune sows. Endemic TGE in suckling or recently weaned pigs can be difficult to diagnose and must be differentiated from other types of endemic diarrheal problems commonly occurring in young pigs, such as rotaviral diarrhea and colibacillosis. Endemic TGE will persist in the herd as long as susceptible or partially immune swine are exposed to TGEV.

The recrudescence or reintroduction of TGEV may occur in herds that contain immune sows, resulting in discrete episodes of disease (Pritchard 1987). This situation commonly occurs in herds in the concentrated swine-rearing areas of the U.S. or other countries. Herds often become reinfected in the winter, and growing and finishing swine are especially affected. Such animals are susceptible because the herd infection from the previous winter has usually terminated during the intervening summer. If the disease enters the farrowing house, the disease in suckling or weaned pigs will resemble that described above since the sows will usually be immune. It is unclear whether the source of virus in these circumstances comes from reactivation of virus shedding in carrier swine or reintroduction of virus into the herd from an external source.

Porcine Respiratory Coronavirus

Evidence that led to the discovery of PRCV was obtained from serologic surveys of slaughterhouse sows or swine tested for international trade in Europe. In 1984, this led

to the first isolation of PRCV, a nonenteropathogenic coronavirus, in Belgium (Pensaert et al. 1986). In 1989, two herds in the U.S. unexpectedly were seropositive for TGEV antibodies, although these herds had not been vaccinated for TGE nor had they experienced clinical disease (Hill et al. 1990; Wesley et al. 1990b).

PRCV is a TGEV variant that infects epithelial cells of the respiratory tract and alveolar macrophages (Paul et al. 1994; Pensaert 1989; Pensaert and Cox 1989). After experimental challenge, PRCV infects only a few unidentified cells in the small intestine, and thus, virus shedding in feces is limited or not detected (Brim et al. 1994, 1995; Costantini et al. 2004; Cox et al. 1990a, b; O'Toole et al. 1989; VanCott et al. 1993, 1994). Recently, fecal and nasal isolates of PRCV from the same pigs were compared genetically, and small, but consistent, genetic differences (point mutations) were noted in the S protein (Costantini et al. 2004). However, PRCV-infected pigs produce antibodies that neutralize TGEV.

Swine population density, distances between farms, and season influence the epidemiology of PRCV. PRCV infects pigs of all ages by airborne transmission or by contact. In areas with high swine farm density, the virus can spread to pigs on neighboring farms that are several kilometers away (Pensaert and Cox 1989). In addition, the risk of a farm becoming infected increases as the size of a neighboring herd increases (Henningsen et al. 1989).

PRCV infections are often subclinical and the virus has spread rapidly and extensively in pigs in Europe (Brown and Cartwright 1986; Henningsen et al. 1989; Laude et al. 1993; Martin et al. 1994; Pensaert 1989; van Nieuwstadt et al. 1989) and even into countries that were previously free of TGEV (Pensaert 1989). A limited serologic survey in 1995 in the U.S. suggested that many asymptomatic swine herds in Iowa were seropositive for PRCV (Wesley et al. 1997).

PRCV has become endemic in many European swine herds (Lanza et al. 1993; Laude et al. 1993; Pensaert et al. 1993; Pensaert 1989). The virus circulates in the herd, infecting pigs before the age of 20–26 weeks, after passively acquired maternal antibodies have declined (Pensaert et al. 1993). Introduction of pigs into fattening units and commingling of PRCV-negative and PRCV positive pigs from diverse sources resulted in seroconversion to PRCV in pigs shortly after introduction into most units (Van Reeth and Pensaert 1994a).

Susceptible pigs experimentally infected with PRCV shed virus from nasal secretions for a period of less than 2 weeks (Bourgueil et al. 1992; Brim et al. 1994; Onno et al. 1989; VanCott et al. 1993; Wesley et al. 1990b). There is no evidence for the fecal-oral transmission of PRCV. Pensaert et al. (1993) have shown that pigs on closed breeding farms become infected shortly after weaning—even in the presence of maternal antibodies. Thus, PRCV persists in the herd by regularly infecting newly weaned pigs. PRCV can persist in the herd throughout

the entire year or it can disappear temporarily from a herd (mainly in the summer) and reappear in the nursery and fattening units during the colder months of the year (Pensaert et al. 1993). Thus, waves of infection, without clinical disease, coincide with the rainy season in Europe (Laude et al. 1993).

Following the widespread dissemination of PRCV, the seroprevalence of TGEV infections in European swine was examined by blocking ELISA (Brown and Patton 1991; Lanza et al. 1993; Pensaert et al. 1993). The investigators reported low (0.0–7.6%) TGEV seropositives from sows in Spain (Lanza et al. 1993; Pensaert et al. 1993) and from pigs in the U.K. (Brown and Patton 1991). Thus, the seroprevalence of TGEV infections in Europe has decreased coincident with the spread of PRCV.

Transmission and Reservoirs

One of the significant epidemiological features of TGE is its seasonal appearance during the winter months. Haelterman (1962) suggested that this is because the virus is very stable when frozen and more labile when exposed to heat or to sunlight. This would allow virus transmission between herds in winter on fomites or animals. Reduced or fluctuating ambient temperatures also markedly predispose feeder pigs to clinical manifestations of TGE (Shimizu and Shimizu 1979a; Shimizu et al. 1978), thus contributing to transmission in winter.

What is the reservoir of TGEV between seasonal epidemics? Haelterman (1962) proposed at least three possible reservoirs: (1) associated pig farms in which the virus spreads subclinically; (2) hosts other than swine; and (3) carrier pigs.

The most probable explanation for maintenance of the disease is that it exists in an endemic form in feeder-pig operations (Morin et al. 1978) or in herds that are on a continuous farrowing program. These situations could constitute foci for maintenance of the disease during the warmer months and for dissemination during the winter months. This hypothesis is supported by the finding that TGEV infection can spread rather slowly through a group of growing swine under certain conditions, such as during the summer months (Maes and Haelterman 1979).

There is also evidence for the existence of TGEV in non-porcine hosts. Cats, dogs, and foxes have been suggested as possible carriers of TGEV from one herd to another since they can shed virus in their feces for variable periods (Haelterman 1962; McClurkin et al. 1970). Cats and dogs fed TGEV showed no clinical signs, except after repeated passage in dogs and seroconverted to TGEV, but virus excreted by dogs was shown to be infectious for pigs (Haelterman 1962; Reynolds and Garwes 1979).

Massive concentrations of starlings (*Sturnus vulgaris*) in winter in feeding areas of swine may provide a method by which TGEV can be mechanically carried from one farm to another. Pilchard (1965) reported that

TGEV was detected in the droppings of starlings for as long as 32 hours after they were fed TGEV. Houseflies (*Musca domestica*) have also been proposed as possible mechanical vectors for TGEV. TGEV antigen was detected in flies within a swine herd in which TGE was endemic, and experimentally inoculated flies excreted TGEV for 3 days (Gough and Jorgenson 1983).

A third possibility relating to the transmission of TGE is the length of time infected swine shed viable TGEV and the role of the carrier pig. A few reports (Lee et al. 1954; Pensaert 1976; Woods and Wesley 1998) have indicated chronic and/or persistent fecal shedding for periods up to 18 months, rather than the commonly reported 2-week period (Pensaert et al. 1970a). Respiratory shedding of TGEV has been detected in nasal swabs for postexposure periods up to 11 days (Kemeny et al. 1975). However, the virus was detected in lung homogenates for postexposure periods up to 104 days (Underdahl et al. 1975).

TGEV has also been recovered from milk of infected sows during the acute phase of the disease (Kemeny et al. 1975; Kemeny and Woods 1977) and following intramammary infusion or injection of lactating sows with live TGEV (Saif and Bohl 1983). In the latter study, demonstration of TGEV antigen in mammary gland tissue indicated that the virus might replicate in the mammary glands of lactating sows, an event which might contribute to agalactia in sows. Transmission of the virus via milk to suckling piglets, as suggested in the same study, may account, in part, for the rapid spread of the infection among a litter.

Although TGEV has been detected in the intestinal and respiratory tracts for periods of up to 104 days post infection, it is unknown whether such virus is viable and is shed or transmitted in a viable state. Addition of sentinel pigs to a herd at 3, 4, and 5 months after a previous TGE outbreak resulted in no infections in the introduced pigs, as determined by serologic tests (Derbyshire et al. 1969). Nasal shedding of PRCV in experimentally infected pigs occurs through postexposure day 10 (Onno et al. 1989; Wesley et al. 1990b). However, how long pigs recovered from PRCV infection in the field remain infectious is unknown. Thus, a possible role for the long-term carrier hog in transmitting TGEV has been suggested (Woods and Wesley 1998).

CLINICAL SIGNS

Epidemic TGE

The typical clinical signs of TGE in seronegative piglets are transient vomiting and watery, yellowish diarrhea, with rapid loss of weight, dehydration, and high morbidity and mortality in pigs under 2 weeks of age. Diarrhea in young pigs is usually profuse and feces will often contain undigested milk.

The severity of the clinical signs, duration of the disease, and mortality are inversely related to the age of the pig. Most pigs under 7 days of age will die in 2–7 days after first showing clinical signs. Most suckling pigs over 3 weeks of age will survive but are likely to remain stunted. Clinical signs of TGE in growing and finishing swine and in sows are usually limited to inappetence and diarrhea for a few days, with vomiting occasionally observed. The few deaths observed are probably due to complicating factors, such as stress or concurrent infections, which frequently occur after weaning. Some lactating sows become very sick, with an elevated temperature, agalactia, vomiting, inappetence, and diarrhea. These severe signs may be due to a high degree of exposure to the virus from close contact with their affected piglets or to hormonal factors that may influence susceptibility. In contrast, sows in the field having no contact with young infected pigs usually have mild clinical signs or none.

The incubation period is short, usually 18 hours to 3 days. Infection generally spreads rapidly through the entire group of swine so that in 2–3 days most animals are affected, but this is more likely to occur in winter than summer (Maes and Haelterman 1979).

Endemic TGE

Endemic TGE occurs in large herds that have frequent farrowings and in TGEV or PRCV seropositive herds. The clinical signs will usually be less severe than those seen in seronegative pigs of the same age. Death losses are low, especially if pigs are kept warm. The clinical signs in suckling pigs can resemble those caused by rotavirus (Bohl et al. 1978). In some herds, depending on management, endemic TGE is manifested mainly in weaned pigs and may be confused with *Escherichia coli*, coccidia, or rotavirus infections (Pritchard 1987).

Porcine Respiratory Coronavirus

The severity of clinical signs and the degree of pathogenicity appear to be PRCV strain–dependent, and it is speculated that these differences might correlate with slightly different genetic deletions. In addition, infection of swine with PRCV and other respiratory viruses, especially in association with porcine reproductive and respiratory syndrome virus (PRRSV), can alter the severity of disease and clinical signs.

Ultimately, the manifestation of respiratory disease is dependent on a number of variables, including environmental and seasonal factors, management practices, virus load or dose, and presence of other bacterial or viral pathogens in the herd (Van Reeth and Pensaert 1994a, b).

Experimentally infected feeder pigs had only a transient weight loss, whereas 4- and 6-day-old pigs infected with PRCV showed only a reduced rate of weight gain in comparison with control pigs (Lanza et al. 1992; Van Reeth et al. 1996; Vannier 1990; Wesley and Woods 1996).

Many European and American PRCV strains cause subclinical infections, but by histological examination,

interstitial pneumonia affecting 5–60% of the lung may be present (Enjuanes and Van der Zeist 1995; Hayes et al. 2000; Laude et al. 1993; Van Reeth and Pensaert 1992). In one study, when American PRCV strains were compared in pigs under the same conditions, differences were observed in pathogenicity among strains (Halbur et al. 1994). Two PRCV isolates, AR310 and LEPP with the same S gene deletion, induced signs of moderate respiratory disease in pigs, while a third strain (1894) produced only mild respiratory disease. However, at a lower dose, even the AR310 strain was asymptomatic in gnotobiotic pigs (Halbur et al. 1993). Likewise, a Canadian PRCV strain (1Q90) isolated in Quebec caused severe pneumonia and 60% mortality in 1-week-old pigs given $10^{8.5}$ TCID$_{50}$ (median tissue culture infectious doses) of virus, but littermates exposed to PRCV by contact, presumably at a lower dose, exhibited mild signs (Jabrane et al. 1994). Inoculation of pigs with a higher dose of PRCV also resulted in longer shedding of PRCV (VanCott et al. 1993).

Thus, clinical signs seen after experimental PRCV exposure may be highly dose related and influenced by the age of the pigs and inoculation techniques. The results of experimental studies were also influenced by the health status of the pigs and their subsequent treatment (Vannier 1990).

Besides a single-virus infection with PRCV, pigs can be exposed concurrently to other respiratory viruses and agents. Often this occurs when pigs from multiple sources are grouped together in nurseries or grower-finisher units (Van Reeth and Pensaert 1994a). The effects of dual-virus inoculations have been investigated and generally found to be more severe than for a single-virus infection. In particular, respiratory signs were enhanced in PRCV-infected pigs when the pigs were inoculated 2 days later with either swine influenza virus or pseudorabies virus (Van Reeth and Pensaert 1994b; Van Reeth et al. 1996). Combined infections with PRRSV followed by PRCV also resulted in a prolonged fever with respiratory disease, a reduced rate of weight gain or longer shedding of PRCV (Hayes et al. 2000; Van Reeth et al. 1996).

Because many respiratory viruses and bacteria are common in swine populations, these combined infections with PRCV may increase the occurrence and severity of respiratory disease (Hayes et al. 2000; Van Reeth et al. 2000). This subject requires additional research including elucidating the mechanism of disease enhancement and shedding in dual infections.

PATHOGENESIS

The pathogenesis of TGE has been reviewed (Hooper and Haelterman 1966; Moon 1978). The early events have been described as follows: TGEV is ingested, infects the mucosa of the small intestine, and causes villous atrophy because of a rapid and extensive loss of functional epithelial cells.

Intestinal Replication

Whether by the oral or the nasal route, the virus is swallowed and, being resistant to low pH and proteolytic enzymes, remains viable until it comes in contact with the highly susceptible villous epithelial cells of the small intestine. Infection and rapid destruction or alteration in function of these cells result in marked reduction in enzymatic activity in the small intestine, which disrupts digestion and cellular transport of nutrients and electrolytes, causing an acute malabsorption syndrome (Moon 1978). Hooper and Haelterman (1966) suggested that the inability of infected pigs to hydrolyze lactose and other nutrients results in the marked deprivation of nutrients critical to the young pig. Furthermore, they suggested that the presence of undigested lactose exerts an osmotic force that causes a retention of fluid in the lumen of the intestine and, thus, contributes to diarrhea and dehydration. Additional mechanisms contributing to diarrhea in TGEV-infected pigs include altered intestinal sodium transport, with accumulation of electrolytes and water in the intestinal lumen (Butler et al. 1974) and loss of extravascular protein (Prochazka et al. 1975). The ultimate cause of death is probably dehydration and metabolic acidosis coupled with abnormal cardiac function resulting from hyperkalemia.

A marked shortening or atrophy of the villi occurs in the jejunum (Figure 30.3) and to a lesser extent in the ileum, but it is often absent in the proximal portion of the duodenum (Hooper and Haelterman 1966). Both virus production and villous atrophy were greater in newborn pigs than in 3-week-old pigs (Moon et al. 1973; Norman et al. 1973), suggesting higher susceptibility of neonates to TGEV infection. Several mechanisms have been proposed to account for this age-dependent resistance to clinical disease. First, the rapidity with which infected villous epithelial cells can be replaced by migration of epithelial cells from crypts of Lieberkühn in older pigs compared to younger may partially account for the higher fatality rate in newborn pigs (Moon 1978). These newly replaced villous enterocytes are reportedly resistant to TGEV infection (Pensaert et al. 1970b), possibly due to onset of innate immunity and presence of intestinal interferon (La Bonnardiere and Laude 1981) or the inability of these regenerating cells to support virus growth. Second, TGEV accumulates and replicates in the apical tubulovascular system of villous absorptive cells in newborn pigs; this system is lacking in pigs older than 3 weeks (Wagner et al. 1973). Third, virus dose may play a major role in infections. Witte and Walther (1976) demonstrated that the infectious dose of TGEV needed to infect a market hog (about 6 months old) was 10^4 times greater than that needed to infect a 2-day-old piglet. However, the severity of clinical signs due to TGE is also increased when pigs are (1) fed a zinc-deficient ration (Whitenack et al. 1978); (2) anemic (Ackerman et al. 1972); (3) exposed to a low temperature or fluctuation in temperature (Shimizu et al. 1978); or (4) injected with a
30.3. *Villi of the jejunum from a normal pig (A) and from a TGEV-infected pig (B), as viewed through a dissecting microscope (approximately ×10).*

synthetic corticosteroid, dexamethazone (Shimizu and Shimizu 1979a). In regard to the last two factors, the mechanism is thought to be due to an interference with the early initiation of a local cell-mediated immune response (Shimizu and Shimizu 1979a).

The failure of cell culture-attenuated strains of TGEV to infect large numbers of epithelial cells or those located in the cranial portion of the small intestines of pigs probably explains why such strains cause milder diarrhea than that observed with virulent strains (Frederick et al. 1976; Furuuchi et al. 1979; Hess et al. 1977; Pensaert 1979). Furthermore, there was an inverse correlation between the level of cell culture attenuation of TGEV and the extent of intestinal infection (Hess et al. 1977). Cell-cultured strains of TGEV of reduced virulence in combination with a mildly virulent *E. coli* have been shown to cause a more severe disease in germ-free pigs than when either organism was given alone (Underdahl et al. 1972). Concurrent infections with TGEV and *E. coli* or porcine rotavirus have been reported (Hornich et al. 1977; Theil et al. 1979).

Extraintestinal Replication Sites

TGEV. Although ingestion is undoubtedly the most common portal of entry for the virus, the nasal route, or airborne infection, may be important, but the efficiency of this route of transmission for the spread of TGEV appears much less significant than for PRCV. Only in one study were macroscopic lung lesions observed in gnotobiotic pigs inoculated oronasally with TGEV, but no clinical pneumonia occurred (Underdahl et al. 1975). A preliminary report also indicated that TGEV was present in alveolar macrophages of infected neonatal pigs, suggesting a possible role for these cells in lung infection. However, only cell culture–attenuated, but not virulent TGEV, replicated in cultures of alveolar macrophages in vitro (Laude et al. 1984). Highly attenuated strains of TGEV have also been reported that replicate in the upper respiratory tract and lung but not in the intestine of new-

born pigs, thus, resembling PRCV infections (Furuuchi et al. 1979). Interestingly, 2 amino acid changes (nucleotides 219 and 655) occurred in the S gene between virulent (enteric) and attenuated (respiratory/enteric) TGEV strains that may account for this altered respiratory tropism (Ballesteros et al. 1997; Sanchez et al. 1999). Moreover, nasal shedding of TGEV was detected in infected piglets (VanCott et al. 1993) and in lactating sows exposed to infected piglets (Kemeny et al. 1975). In addition, studies have shown that TGEV is capable of replicating in mammary tissue of lactating sows (Saif and Bohl 1983) and that infected sows shed virus in milk (Kemeny and Woods 1977). The significance of possible mammary gland infection with TGEV under field conditions is unclear, as is whether it plays a role in agalactia, often seen in TGEV-infected sows or rapid spread of infection among piglets. Although natural infection of the porcine fetus with TGEV has not been reported, intrafetal inoculation results in the production of villous atrophy and seroconversion to TGEV (Redman et al. 1978).

Porcine Respiratory Coronavirus. PRCV has a tropism for cells of the respiratory tract. It replicates to high titer in porcine lungs (10^7–10^8 TCID$_{50}$) and also infects epithelial cells of the nares, trachea, bronchi, bronchioles, and alveoli and alveolar macrophages (Hayes et al. 2000; O'Toole et al. 1989; Pensaert et al. 1986). Viremia occurs following primary infection, and virus spreads to parenchymal organs and lymph nodes. Only a few scattered cells containing PRCV antigen are found in the small intestine, even when the virus is directly inoculated into the intestinal lumen. These infected cells are located in, or underneath, the epithelial layer of the intestinal villi and crypts, and the virus does not spread to adjacent cells (Cox et al. 1990a, b). This limited intestinal replication of PRCV explains why no or low titers of virus are detected in feces and most fecal PRCV may reflect swallowed virus (Costantini et al. 2004; VanCott et al. 1993, 1994).

Researchers have used MAb neutralization–resistant mutants and recombinant TGEV strains from infectious TGEV clones to explore the molecular basis for the difference in pathogenicity and tissue tropism between TGEV and PRCV strains (Ballesteros et al. 1997; Bernard and Laude 1995; Sanchez et al. 1999).

Bernard and Laude (1995) reported that most TGEV (Purdue-115 strain) MAb-resistant mutants selected with MAbs to S protein site D (absent on PRCV) exhibited a reduced enteropathogenicity in pigs that correlated with a point mutation or small deletion in the S protein gene encoding the N-terminal subregion of the S protein (similar region deleted in PRCV strains). Using recombinants generated between enteric/respiratory (PUR46) and respiratory (PTV) strains of TGEV, Ballesteros et al. (1997) concluded that a substitution in amino acid 219 of the S protein of the PUR46 recombinants was responsible for the loss of enteric tropism observed after inoculation of pigs with the PUR46 recombinants. The authors speculated that two different domains of the S protein (around amino acid 219) are required to infect intestinal epithelial cells: One domain binds to the cellular receptor, aminopeptidase N, and the other domain may be a binding site for an undefined intestinal coreceptor.

LESIONS

Gross Lesions

Gross lesions with TGE are usually confined to the gastrointestinal tract, with the exception of dehydration. The stomach is often distended with curdled milk and may have small areas of hemorrhage on the diaphragmatic side of the stomach (Hooper and Haelterman 1969). The small intestine is distended with yellow, foamy fluid and usually contains flecks of curdled undigested milk. The wall is thin and transparent, probably due to atrophy of the villi. Although lung lesions have been observed in experimentally infected gnotobiotic pigs (Underdahl et al. 1975), they have not been reported in pigs naturally infected with TGEV.

Subgross Lesions

A highly significant lesion of TGE is the markedly shortened villi of the jejunum and ileum, which Hooper and Haelterman (1969) referred to as villous atrophy (Figure 30.3). This is also seen in rotavirus diarrhea, but is not usually as severe or extensive as in TGE (Bohl et al. 1978). Infections with some strains of *E. coli* and coccidia have also been reported to produce this lesion (Hornich et al. 1977). However, the pathologic findings and extent of villous atrophy were highly variable in pigs from endemically infected herds (Pritchard 1987).

Microscopic Lesions

The degree of villous atrophy can be judged in histologic sections by comparing the length of the jejunal villi with the depth of the crypts of Lieberkühn. In normal piglets the villi-crypt ratio is about 7:1; in infected piglets the corresponding ratio is about 1:1 (Hooper and Haelterman 1969). Other lesions reported in experimentally challenged 8-week-old pigs include microulceration of the dome epithelium over Peyer's patches (Chu et al. 1982a). By scanning EM, the intestinal lesions of TGE correlate well with those observed by light microscopy (Moxley and Olson 1989b; Waxler 1972). Using scanning EM, Moxley and Olson (1989b) showed that the level of passive immunity in TGEV-infected pigs influenced not only the degree of villous atrophy but also its segmental distribution. Villous atrophy was minimal in pigs nursing sows previously infected with virulent TGEV, compared to pigs nursing seronegative sows or sows given live attenuated vaccines. In partially protected pigs, villous atrophy was seen primarily in the ileum instead of the jejunum. Similar observations were noted in pigs from herds with endemic TGE. Transmission EM of TGEV-infected epithelial cells of the small intestine has revealed alterations in the microvilli, mitochondria, endoplasmic reticulum, and other cytoplasmic components. Virus particles, primarily in cytoplasmic vacuoles, were observed in villous enterocytes and in M cells, lymphocytes, and macrophages in the dome regions of Peyer's patches (Chu et al. 1982a; Thake 1968; Wagner et al. 1973).

PRCV Lesions

In the case of PRCV, villous atrophy is not observed. However, microscopic examination of lungs from asymptomatic pigs reveals that PRCV causes a diffuse interstitial pneumonia in a high percentage of inoculated animals (Cox et al. 1990a; Hayes et al. 2000; O'Toole et al. 1989; van Nieuwstadt and Pol 1989). Others reported more severe respiratory lesions, dependent upon the strain and dose of PRCV used to experimentally infect pigs (Halbur et al. 1993, 1994; Jabrane et al. 1994; Paul et al. 1994).

IMMUNITY

Active Immunity

The duration of active immunity in swine after oral infection with virulent TGEV has not been well characterized. Intestinal infection of breeding-age swine results in detectable serum antibodies that persist for at least 6 months to possibly several years (Stepanek 1979). However, the serum antibody titer, although providing serologic evidence of TGE, provides little indication of the degree of active immunity. Swine that have recovered from TGE are immune to subsequent short-term challenge, presumably due to local immunity within the intestinal mucosa (Brim et al. 1995; Saif et al. 1994; VanCott et al. 1993, 1994). The age and immune status of the animal at initial infection and the severity of the challenge may greatly influence the completeness and duration of this active immunity.

The mechanism of active immunity in the gut probably relates to stimulation of the secretory IgA (sIgA) immune system with production of intestinal sIgA antibodies by lymphoid cells within the lamina propria (Saif et al. 1994; VanCott et al. 1993, 1994). IgA TGEV antibodies and antibody-secreting cells (ASCs) have been detected in the intestine and serum of pigs after oral, but not parenteral, inoculation with TGEV (Kodama et al. 1980; Saif et al. 1994; VanCott et al. 1993, 1994). Kodama et al. (1980) proposed that detection of IgA antibody in the serum, presumably intestinally derived, might serve as an indicator of active immunity to TGE. In another study, oral inoculation of gnotobiotic pigs with TGEV resulted in development of both serum and intestinal TGEV-neutralizing antibodies detectable from 5 to at least 35 days postexposure (DPE) (Saif 1976). IgM (5–15 DPE) and IgA immunocytes (which remained predominant from 7 to 35 DPE) were detected in the intestinal lamina propria of the TGEV-infected gnotobiotic pigs.

More recently, an enzyme-linked immunospot (ELISPOT) technique was used to investigate the kinetics of IgA and IgG TGEV antibody production by the pig's systemic and local gut-associated lymphoid tissues (GALT). High numbers of IgA ASCs were induced in GALT only by virulent TGEV. In contrast, live attenuated (vaccine) TGEV or PRCV strains induced significantly fewer IgA ASCs (Berthon et al. 1990; Saif et al. 1994; VanCott et al. 1993, 1994).

These and other studies (Stone et al. 1982) indicate that the pig is immunocompetent at birth in regard to humoral and mucosal antibody production, but in the intestine, additional maturational time may be required for antibody responses to reach adult levels.

Besides local antibody-mediated immunity, cell-mediated immune responses may also be important in active immunity against TGEV infections. A number of tests have been used to demonstrate cell-mediated immunity (CMI) to TGEV, including macrophage migration inhibition (Frederick et al. 1976), leukocyte migration inhibition (Woods 1977) direct lymphocyte cytotoxicity (Shimizu and Shimizu 1979b), lymphocyte proliferation (Anton et al. 1995, 1996; Brim et al. 1994, 1995; Shimizu and Shimizu 1979c; Welch and Saif 1988), spontaneous cell-mediated cytotoxicity (SCMC), and antibody-dependent cell-mediated cytotoxicity (ADCMC) (Cepica and Derbyshire 1983).

Only indirect evidence exists concerning the role of CMI in resistance to TGEV infection. CMI was demonstrated with lymphocytes obtained from GALT of swine orally infected with virulent TGEV (Brim et al. 1994, 1995; Frederick et al. 1976; Shimizu and Shimizu 1979c; Welch et al. 1988); swine parenterally or oronasally inoculated with attenuated TGEV or PRCV-developed CMI mainly in systemic sites (spleen or peripheral blood lymphocytes). Lymphoproliferative responses to TGEV persisted within GALT, but not systemic lymphocytes, for at least 110 days after oral infection of 6-month-old

swine (Shimizu and Shimizu 1979c) but for only about 14–21 days after infection of younger (7- to 11-day-old) pigs (Brim et al. 1994; Welch et al. 1988). It was confirmed that CD4 T-helper cells are involved in lymphoproliferative responses to TGEV (Anton et al. 1996).

A correlation between lymphoproliferative responses and lactogenic immunity to TGEV was described in sows vaccinated with attenuated or recombinant TGEV vaccines (Park et al. 1998). Although T-cell epitopes were identified by lymphoproliferation studies for each of the three major proteins of TGEV, a dominant functional T-helper epitope was defined on the N protein (N_{321}) (Anton et al. 1995). The N_{321} peptide-induced T cells collaborated in the in vitro synthesis of TGEV-neutralizing antibodies specific for the S protein. These investigators further reported that production of high levels of TGEV-specific antibodies in vitro (from in vivo TGEV-primed mesenteric lymph node cells) required stimulation by at least two TGEV structural proteins, with maximal responses induced by native S protein rosettes in combination with recombinant N protein. Such findings have important implications for the optimal design of TGEV subunit or other recombinant TGEV vaccines.

Because lymphocyte cytotoxicity was absent in newborn piglets and decreased in parturient sows, it was proposed that a lack of K and NK cell activity against TGEV-infected cells may correlate with the increased susceptibility of newborn piglets and parturient sows to TGEV infection (Cepica and Derbyshire 1984). Thus, CMI may play a role in either recovery from TGEV infection or resistance to reinfection via the rapid elimination of TGEV-infected epithelial cells by any one or all of a combination of SCMC, ADCMC, or sensitized T lymphocyte–mediated cytotoxicity.

PRCV

The observation that epidemic outbreaks of TGE in Europe declined dramatically following the widespread dissemination of PRCV among European swine prompted researchers to examine whether a respiratory PRCV infection could induce active intestinal immunity and protection against TGEV. The consensus from several studies was that prior infection of nursing or weaned pigs with PRCV provided partial immunity against TGEV challenge, evident by a reduced duration and level of virus shedding and diarrhea in most (Brim et al. 1995; Cox et al. 1993; VanCott et al. 1994; Wesley and Woods 1996), but not all (van Nieuwstadt et al. 1989), pigs studied.

The mechanism of this partial immunity presumably is related to the rapid increase in TGEV-neutralizing antibody titers (Cox et al. 1993; Wesley and Woods 1996) and numbers of IgG and IgA ASCs observed in the intestines of PRCV-exposed pigs after TGEV challenge (Saif et al. 1994; VanCott et al. 1994). The latter researchers speculated that the migration of PRCV-specific IgG and IgA ASCs from the bronchus-associated

lymphoid tissues (BALT) to the gut of the PRCV-exposed pigs after TGEV challenge might explain the rapid anamnestic response and the partial protection induced. However, after PRCV exposure of neonatal pigs, at least 6–8 days were required to develop partial immunity to TGEV challenge (Wesley and Woods 1996), suggesting that induction of active immunity might be too late to protect seronegative newborn piglets from epidemic TGE.

Passive Immunity

Passive immunity is of primary importance in providing newborn piglets with immediate protection against TGEV infection. Swine are born devoid of immunoglobulins (Igs), which they acquire after birth via colostrum. Colostral Igs, consisting primarily of IgG, represent a serum transudate that is transferred from the dam across the piglet's intestinal epithelium to its circulation, thus providing the neonate with the same complement of serum antibodies as in the dam (Bourne 1973; Porter and Allen 1972). These passively acquired humoral antibodies function mainly in protection against systemic infection, but do not protect against intestinal infection (Hooper and Haelterman 1966). The concentration of IgG decreases during the first week of lactation, and IgA becomes the predominant Ig in milk (Porter and Allen 1972). Cells seeded from the intestine produce IgA locally in the mammary tissue (Roux et al. 1977). The piglets do not absorb sIgA milk antibodies, but they play an important role in passive intestinal immunity.

Mechanisms of passive immunity to TGEV infections have been reviewed (Pensaert 1979; Saif and Bohl 1979a, 1981a; Saif and Smith 1985; Saif and Jackwood 1990). Swine that have recovered from TGE can transmit passive immunity to their suckling pigs (Bay et al. 1953). Suckling pigs are protected as a result of the frequent ingestion of colostrum or milk that contains TGEV-neutralizing antibodies. Such antibodies in the lumen of the intestine neutralize any ingested TGEV and thus protect the susceptible epithelial cells of the small intestine. Haelterman (1963) referred to this immunogenic mechanism as *lactogenic immunity*. This is accomplished naturally when piglets suckle immune sows about every 2 hours. Passive protection can also be accomplished artificially by continuous feeding of antiserum to piglets (Haelterman 1963; Noble 1964).

TGEV antibodies in colostrum and milk of sows are primarily associated with IgA or IgG (Abou-Youssef and Ristic 1972; Bohl et al. 1972; Saif et al. 1972). TGEV milk antibodies of the IgA class provide the most effective protection, but IgG antibodies were also protective if high titers could be maintained in milk (Bohl and Saif 1975) or by artificial feeding of colostral IgG (Stone et al. 1977). The greater efficacy of IgA TGEV antibodies is probably because (1) they occur in higher levels in milk (Porter and Allen 1972), (2) they are more resistant to

proteolytic enzymes (Underdown and Dorrington 1974), and (3) they selectively bind to gut enterocytes (Nagura et al. 1978). TGEV antibodies in milk of the IgG class are produced as a result of parenteral or systemic immunization. IgA TGEV antibodies occur in the milk following intestinal infection. To explain their occurrence it was proposed that after antigenic sensitization in the gut, IgA immunocytes migrate to the mammary gland, where they localize and secrete IgA antibodies into the colostrum and milk (Saif and Bohl 1979a; Saif and Smith 1985; Saif et al. 1994; Saif and Bohl 1981a; Saif and Jackwood 1990). This "gut-mammary" immunologic axis, first proposed in relation to TGEV infections in swine (Bohl et al. 1972; Saif et al. 1972), is an important concept that provided the initial description of a common mucosal immune system, and was used for designing optimal vaccination procedures to provide effective lactogenic immunity.

DIAGNOSIS

This subject has been reviewed by Bohl (1981). Collection and preservation of appropriate clinical specimens are necessary for reliable diagnosis. Although villous atrophy is a consistent lesion in severely affected seronegative pigs, it frequently occurs in other enteric infections as well (rotavirus, PED, coccidia, and sometimes *E. coli*). Laboratory diagnosis of TGE may be accomplished by one or more of the following procedures: detection of viral antigen, detection of viral nucleic acids, microscopic detection of virus, isolation and identification of virus, or detection of a significant antibody response.

The serologic assays are complicated by the failure of conventional assays to differentiate between PRCV and TGEV antibodies (discussed under differential blocking ELISA). However, evaluation of clinical signs, histologic lesions, and tissue distribution of viral antigen may provide a presumptive diagnosis because PRCV does not cause diarrhea or villous atrophy and replicates almost exclusively in respiratory tissues (Pensaert 1989; Pensaert and Cox 1989). Thus, PRCV is suspected if there is antigen in lung tissues, seroconversion to TGEV/PRCV by VN test, and no signs of enteric disease.

Detection of Viral Antigen

The detection of TGE viral antigen in epithelial cells of the small intestine is probably the most common method for diagnosing TGE in young pigs. Either IF (Pensaert et al. 1970a) or immunocytochemical (Becker et al. 1974; Chu et al. 1982b; Shoup et al. 1996) techniques may be used, but they require pigs in the early stages of diarrhea. Either mucosal scrapings (these yield a greater sample of the intestinal surface area) (Black 1971) or frozen sections from the jejunum and ileum are prepared and stained by either the direct (Figure 30.4) or indirect IF method.
30.4. *Immunofluorescing cells from a TGEV-infected pig. A compression smear was made from a mucosal scraping of the jejunum and stained by the direct fluorescent antibody test (×350).*

Problems that may be encountered in IF tests include (1) lack of sensitivity or specificity of reagents (primary or secondary reagents used must be free of antibodies to other enteric organisms, particularly rotavirus); (2) failure to obtain specimens early after onset of diarrhea before the loss of infected cells (piglets must be euthanized to obtain specimens); and (3) cross-reactions with FIPV, CCV, and PRCV. However, replication of PRCV in villous enterocytes is uncommon, and IF or immunocytochemical staining of villous enterocytes in conjunction with diarrhea almost certainly indicates TGEV.

An immunoperoxidase technique using MAb to the highly conserved N protein of TGEV has been applied to the detection of TGEV (intestinal tissues) or PRCV (lungs) using formalin-fixed paraffin-embedded tissues (Shoup et al. 1996). This permits the diagnosis of TGEV/PRCV on the same tissues as used for histopathology and allows retrospective screening of fixed tissues for TGEV/PRCV. Although polyclonal antibodies will not differentiate between TGEV and PRCV, certain MAbs have been produced that react with TGEV, but not PRCV. These differentiating MAbs have been used in IF and immunocytochemical tests (Garwes et al. 1988; van Nieuwstadt and Pol 1989).

PRCV has been detected in respiratory tissues and nasal epithelial cells by IF and immunocytochemical tests, but use of differentiating MAbs is necessary for confirmation since enteric strains of TGEV may also replicate in these tissues.

A double antibody sandwich ELISA using monoclonal or polyclonal antibodies to TGEV as capture or secondary antibodies is used to detect TGEV antigens in cell culture, feces, and intestinal contents (Bernard et al. 1986; Cornaglia et al. 1994; Lanza et al. 1995; Lu et al. 1991; Sestak et al. 1996, 1999a; van Nieuwstadt et al. 1988) or PRCV antigen in nasal secretions or lung homogenates (Cornaglia et al. 1994; Lanza et al. 1995).

Detection of Viral Nucleic Acids

Nucleic acid hybridization probes have been developed to detect TGEV genome sequences in fecal samples, infected tissues, or infected cell cultures (Benfield et al. 1991; Shockley et al. 1987). Moreover, nucleic acid probes derived from the 5' end of the TGEV spike gene can distinguish between PRCV and TGEV. In a hybridization assay, these probes selectively differentiated enteric TGEV isolates from the U.S., Japan, and England, including live attenuated TGEV vaccine strains from the U.S. and isolates of PRCV, FIPV, and CCV (Bae et al. 1991; Wesley et al. 1990a, 1991a).

RT-PCR and nonradioactive cDNA probes have also been used to detect and differentiate TGEV and PRCV isolates (Costantini et al. 2004; Kim et al. 2000a; Vaughn et al. 1994, 1996). This is accomplished by using PCR primers targeting the region of the S gene spanning the deletion region in PRCV strains.

Electron Microscopy

TGEV has been demonstrated in the intestinal contents and feces of infected pigs by negative-contrast transmission EM (Figure 30.5) (Saif and Bohl 1977). Immune EM (IEM) has advantages over conventional EM in being more sensitive for detecting TGEV and providing serologic identification of the virus from clinical specimens or cell culture harvests. In addition, use of IEM enables one to more readily differentiate TGEV from common enveloped membranous debris and to concurrently detect the presence of other enteric viruses (Saif and Bohl 1977). IEM is at least as sensitive as IF for detection of TGEV. IEM is also ap-
30.5. *Typical virus-antibody aggregates observed by IEM of TGEV and gnotobiotic pig anti-TGEV serum. Bar = 100 nm.*

plicable for detection of PRCV shedding in nasal secretions (L. J. Saif, unpublished). However, this method cannot distinguish between TGEV and PRCV unless MAbs are used, although shedding of large numbers of PRCV in feces would not be expected (VanCott et al. 1993, 1994).

Virus Isolation and Identification

Oral exposure of young, seronegative pigs is probably the most sensitive method for isolating or detecting TGEV (Dulac et al. 1977). However, this procedure is very expensive. Consequently, cell cultures are more frequently used. Primary and secondary pig kidney cells (Bohl and Kumgai 1965) or pig kidney cell lines (Laude et al. 1981), primary porcine salivary gland cells (Stepanek et al. 1971), porcine thyroid cells (Witte 1971), and the McClurkin swine testicle (ST) cell line (McClurkin and Norman 1966) have been successfully used for isolating TGEV from feces or gut contents of infected pigs. However, parvovirus contamination of some cells prepared from porcine thyroid glands may be a disadvantage to the use of these cells (Dulac et al. 1977).

Distinct cytopathogenic effect (CPE) may be negligible upon primary isolation of field strains, and additional passages may be required before CPE is evident. The CPE usually seen in ST and porcine thyroid cells consists of enlarged, rounded, or elongated cells with a balloonlike appearance (Kemeny 1978). The ST cell line has been used for detecting field strains of TGEV by CPE, plaques, or IF (Bohl 1979; Kemeny 1978). For detecting viral CPE or plaques, the sensitivity of ST cells can be further enhanced by adding pancreatin or trypsin to cell culture media (Bohl 1979; Stark et al. 1975; Woods 1982) and using older cells (Stark et al. 1975).

For isolation of PRCV, pig kidney and particularly ST cells have been the cells of choice, but PRCV also grows in a continuous cat fetus cell line (Laude et al. 1993). Nasal swab fluids or lung tissue homogenates from affected swine are used for isolation of PRCV. The CPE resembles that produced by TGEV strains, with syncytia formation frequently observed for PRCV (Pensaert 1989; Pensaert and Cox 1989) similar to that reported for SARS coronavirus grown in Vero cells (Ksiazek et al. 2003; Peiris et al. 2003).

Identification of cell culture virus can be done by VN, IF, or IEM using specific TGEV antiserum. However, MAbs specific for TGEV are required to confirm TGEV and exclude PRCV (Garwes et al. 1988; Laude et al. 1988). Alternatively, isolates can be differentiated using RT-PCR or specific cDNA probes (Enjuanes and Van der Zeist 1995; Kim et al. 2000a; Laude et al. 1993). Confusion with cross-reacting CCV and FIPV should not occur since these viruses do not replicate in ST or pig thyroid cells (Reynolds et al. 1980).

Serology

The detection of TGEV antibodies can assist in diagnosis and control in several different ways. However, the sero-

logic diagnosis of TGEV is complicated by the fact that both TGEV and PRCV induce neutralizing antibodies that are qualitatively and quantitatively similar (Pensaert 1989; Pensaert and Cox 1989). A blocking ELISA test (described later) can differentiate beween these antibodies. Serologic tests can also be used to monitor the TGEV or PRCV infection status of a herd. The entrance of only serologically negative swine will help maintain a herd free of TGEV and PRCV.

A rise in antibody titer between acute and convalescent serum samples provides retrospective evidence for epidemic TGE or infection with PRCV. However, the history of the herd with respect to disease and serologic status is needed to help interpret serologic findings. To determine whether endemic TGE or PRCV is a problem in a herd, serum samples from 2- to 6-month-old swine can be tested for antibodies. At this age, passively acquired antibodies should be absent (Derbyshire et al. 1969); thus, positive results suggest endemic TGEV or PRCV.

TGEV antibodies have been detected by several serologic tests. The VN test has been the most widely used, using cell culture–adapted viruses in cell culture systems by a variety of procedures: inhibition of CPE in microtiter plates (Toma and Benet 1976) and plaque reduction assays (Bohl and Kumgai 1965; Thomas and Dulac 1976) are the most common. Neutralizing antibodies to TGEV can be detected in serum as early as 7–8 days after infection and may persist for at least 18 months. Little is known about the persistence of neutralizing antibodies to PRCV within a herd (Cartwright 1968; Vannier et al. 1982).

Sensitive ELISA tests (Bernard et al. 1989; Berthon et al. 1990; Callebaut et al. 1989; Garwes et al. 1988; Hohdatsu et al. 1987; Nelson and Kelling 1984; Paul et al. 1986; Sestak et al. 1999a, b; van Nieuwstadt et al. 1989) have been described, but require concentrated purified virus or S protein for coating ELISA plates.

Complement-fixing antibodies have not been demonstrated in convalescent swine (Dulac et al. 1977).

Blocking ELISA for Serologic Differentiation of PRCV and TGEV

Studies using MAbs to TGEV have shown that certain antigenic sites on TGEV are not present on the S protein of PRCV because of the deletion from the S protein (Callebaut et al. 1989; Laude et al. 1988; Sanchez et al. 1990; Sestak et al. 1999b; Simkins et al. 1992, 1993). This difference between TGEV and PRCV serves as the basis of serologic tests to determine whether a swine herd is infected with TGEV or PRCV (Bernard et al. 1989; Callebaut et al. 1989; Garwes et al. 1988; Simkins et al. 1993; van Nieuwstadt and Boonstra 1992).

In the blocking ELISA, TGEV antigen or recombinant S protein (Sestak et al. 1999b) coated onto ELISA plates is reacted with either TGEV or PRCV antiserum followed by the distinguishing MAb. TGEV antiserum contains competing antibody that blocks the binding of the

MAb, whereas the PRCV antiserum does not block and allows the MAb to bind. Thus, a negative (no blocking) reaction in ELISA and a positive result in the VN test are evidence of a PRCV infection. The test should be evaluated only on a herd basis because some pigs with low TGEV or PRCV antibody titers, as occurs early in the infection process (7–14 days) or after infection with some TGEV strains, may go undiagnosed (Callebaut et al. 1989; Sestak et al. 1999b; Simkins et al. 1993; van Nieuwstadt and Boonstra 1992). Presently, to export TGE-free swine from countries where PRCV infections occur, only this test provides the differential information required to confirm TGEV seropositive animals. The accuracy of commercial ELISAs for differentiating U.S. strains of PRCV and TGEV is low and therefore appears to be applicable on a herd, but not individual pig, basis (Sestak et al. 1999b).

PREVENTION AND CONTROL

Treatment

Antiviral agents have not yet been developed for the specific treatment of TGE. Some inhibition of TGEV replication in cell culture has been reported for the antiviral compounds amantadine (Dimitrov 1982) and isathiazone (Potopal'skii et al. 1983).

Although high levels of type 1 interferon were detected in the intestine of pigs in the early phase of TGEV infection, the role of this interferon in the recovery or pathogenesis of TGE was undetermined (La Bonnardiere and Laude 1981). Studies suggest that interferon may activate natural killer cells in newborn pigs, thereby contributing a degree of resistance to challenge with TGEV (Lesnick and Derbyshire 1988; Loewen and Derbyshire 1988). In addition, during a field outbreak of TGE, 1- to 12-day-old piglets treated orally for 4 days with 1–20 IU of human interferon-alpha had significantly greater survival rates than placebo-treated piglets (Cummins et al. 1995). However, no increased survival was seen in piglets given human interferon-alpha shortly after birth. Whether such therapy could be cost-effective for treatment of TGEV-infected piglets was not assessed.

The only treatment for TGE presently available is to alleviate starvation, dehydration, and acidosis. Parenteral treatment with fluids, electrolytes, and nutrients would be effective in treating young pigs, but not practical under farm conditions. Oral therapy with balanced electrolyte and glucose solutions is contraindicated in young pigs (Moon 1978). The following measures are suggested: provide a warm (preferably above 32°C), draft-free, dry environment and make water or nutrient solution freely accessible to the thirsty TGEV-infected pigs. Such measures will tend to reduce mortality in pigs that are infected at more than 3–4 days of age. Antibacterial therapy might be beneficial in 2- to 5-week-old pigs, especially if there is concurrent infection with pathogenic strains of *E. coli*. Cross-fostering or put-

ting infected or susceptible litters onto TGE-immune sows was found useful in various field outbreaks (Pritchard 1982; Stepanek 1979).

Management

Preventing Entrance of TGEV into a Herd. Swine in the incubative stage of the disease or those in the viral shedding or carrier state can carry TGEV into a herd. Some precautions to help prevent this possibility are to introduce swine that originate from herds known to be free of TGE, are serologically negative, and/or have been placed in isolation on the farm for 2–4 weeks before being added to the herd proper. A frequent question is, "How soon after a TGE outbreak can pigs be moved to another herd without spreading the disease?" A practical answer to this question is that a period of 4 weeks should elapse from the last sign of disease before introducing such animals into a "clean" herd.

Animal vectors, such as starlings, have been incriminated as a means of spread between herds in winter months because of their tendency to gather in large flocks and feed around swine. Cats, dogs, or foxes might play a role in spreading TGE between herds under certain situations (see section on epidemiology). Feces from TGEV-infected swine can be carried on boots, shoes, clothing, truck beds, feeds, etc., and can be a source of infection to other herds. Especially in winter, this is probably an important means by which TGEV is transmitted during the transport of livestock and feed. Consequently, precautions should be taken to minimize such occurrences.

After Onset of TGE. When TGE has occurred on a farm and pregnant animals have not yet been exposed, two procedures may minimize losses of newborn pigs.

1. If the animals are due to farrow in more than 2 weeks, purposely expose them to virulent virus, such as the minced intestines of infected pigs, so that they will be immune at farrowing.
2. If the animals will farrow in less than 2 weeks, attempt to provide facilities and management procedures that will avoid exposure to TGEV until at least 3 weeks postfarrowing.

To minimize deaths, provide young pigs with a warm, dry, draft-free environment and access to water, nutrient solution, or milk replacer (see section on treatment).

Some success has been achieved in elimination of TGEV from epidemically infected closed breeder herds without depopulation by the following procedures (Harris et al. 1987):

1. Bring in all breeding stock replacements for the next 4–6 months.
2. In the face of an outbreak, feed TGEV-infected minced intestines simultaneously to all pigs in the

herd (including replacement stock) to eliminate susceptible hosts, thereby shortening the time the disease progresses through the herd and ensuring more uniform exposure levels in all pigs.

3. Maintain strict all-in/all-out production in farrowing and nursery units.
4. Add sentinel seronegative pigs about 2 months after clinical signs of TGE disappear and monitor these pigs for seroconversion to TGEV.

Potential hazards associated with feedback control of TGE include possible spread of other pathogens to pregnant sows and throughout the herd.

Endemic TGE. Two approaches can be considered in attempting to control or terminate an endemic TGE herd problem.

First, pregnant seropositive sows can be vaccinated intramuscularly (IM) late in gestation or shortly after farrowing with live attenuated TGEV to boost immunity. Although only limited information is available, this procedure should boost milk antibody levels (Saif and Bohl 1983) and provide longer passive immunity to suckling pigs (Leopoldt and Meyer 1978; Stepanek 1979). Although this procedure may only delay the onset of TGE in exposed pigs, it can be beneficial in reducing mortality.

Second, alterations in management can be made to break the cycle of infection by eliminating reservoirs of susceptible pigs in a unit: prevent the continual influx of susceptible animals into the herd (e.g., by temporarily altering the farrowing schedule), temporarily utilize other facilities, and create smaller farrowing and nursing units to more nearly achieve an all-in/all-out management system.

Immunoprophylaxis

TGE Vaccination of Neonatal or Weaned Pigs.
Neonatal pigs have been orally vaccinated with attenuated TGEV in an attempt to induce rapid protection via either interference or local immunity. No early interference has been demonstrated and generally more than 5 days were required before protection due to active immunity could be induced (Pensaert 1979). One study reported a slightly earlier onset of protection, by 3–4 DPI, after maintaining vaccinated pigs at a lowered temperature (18–20°C) to enhance replication of the attenuated virus (Furuuchi et al. 1976). Failure to induce an early interference phenomenon and the delay required for development of active immunity make neonatal vaccination an unlikely method of providing immediate protection against TGEV within the critical first few days of life.

Active immunization of suckling or feeder pigs could be important for control of endemic infections, especially in newly weaned pigs, in which TGEV infections may result in increased mortality. Live attenuated and inactivated TGEV vaccines have been federally licensed for oral or intraperitoneal administration, respectively, shortly after birth. One limited preliminary study reported greater protection in vaccinated, seropositive suckling pigs compared to controls, even though serum antibody levels were not enhanced but were comparable in the two groups (Graham 1980). However, challenge in older piglets usually is much more difficult to standardize, due to age resistance to infection.

Further studies reported that the presence of maternal antibodies in vaccinated pigs decreased (Hess et al. 1982; Lanza et al. 1995; Sestak et al. 1996) or completely suppressed (Furuuchi et al. 1978) active antibody production following oral administration of live TGEV. In the latter study, conducted in suckling piglets nursing naturally infected sows (Furuuchi et al. 1978), high levels of both passive circulating and intestinal antibodies in the suckling piglets probably accounted for the complete interference with active immunization by an attenuated strain of TGEV.

Other approaches have been used in attempts to actively immunize young pigs against TGEV. Woods and Pedersen (1979) noted 33% mortality in challenged pigs vaccinated orally/intraperitoneally with two doses of the antigenically related live virulent FIPV. In comparison, 100% of the challenged pigs died that were orally vaccinated once with an attenuated SP variant of TGEV. Gough and Jorgenson (1983) reported that young weaned pigs inoculated IM with two or three doses of an adjuvanted, soluble, undefined TGEV subunit (23 kDa) vaccine were protected against virus challenge. However, parenteral administration of three doses of a baculovirus-expressed recombinant S protein (containing the four major antigenic sites, A–D) in adjuvant to suckling piglets elicited neutralizing antibodies to TGEV in serum but failed to protect pigs against TGEV challenge (Shoup et al. 1997). When the three major TGEV baculovirus-exressed structural proteins were coadministered intraperitoneally with *E. coli* thermolabile adjuvant to 3-week-old piglets, immune responses associated with virus-specific IgA resulted in markedly reduced rectal virus shedding upon challenge with TGEV (Sestak et al. 1999a). The later study suggests that TGEV-derived baculovirus constructs can be exploited for stimulation of protective mucosal and systemic immune responses.

TGEV Vaccination of the Seronegative Pregnant Dam.
A variety of viral vaccines (virulent, attenuated, inactivated, and subunit) and routes of administration (oral, intranasal, intramuscular, subcutaneous, and intramammary) (Bohl and Saif 1975; Kaji and Shimizu 1978; Moxley and Olson 1989a; Pensaert 1979; Saif and Bohl 1979a; Saif et al. 1994; Saif and Jackwood 1990; Voets et al. 1980) have been tested for induction of lactogenic immunity. Oral administration of live virulent virus to pregnant sows generally gave the highest level of immu-

nity, resulting in protective immunity for the sow and consistently producing high titers of persisting IgA TGEV antibodies in milk associated with protective lactogenic immunity for suckling pigs.

Vaccines and Vaccination. There are presently several federally licensed TGEV vaccines. All contain inactivated or live attenuated TGEV and are approved for use in pregnant or neonatal swine. These vaccines and their efficacy will be considered in the following sections according to their respective routes of administration. Many variables complicate the evaluation of both experimental and commercial TGEV vaccines, often resulting in conflicting data. These include the challenge dose and strain of TGEV; the age of the pig at challenge; environmental conditions, especially temperature; the milking efficiency of the vaccinated sow; and the immune status of the dam at vaccination.

Oral and/or Intranasal Vaccination. Based on the observation that sows infected with TGEV during gestation could transmit immunity to their piglets, "planned" infection of pregnant swine with virulent TGEV has been used to mimic this natural immunity. This procedure is accomplished by feeding virulent autogenous virus to pregnant swine at least 2 weeks before farrowing. The virus may consist of minced guts from young pigs acutely infected with TGEV and is administered to sows with food.

Oral vaccination of pregnant swine with attenuated TGEV is a logical route of vaccination for stimulating milk IgA TGEV antibodies aimed at duplicating the natural route of infection and induction of immunity. The intranasal (IN) route alone or with the oral route is used because attenuated strains of TGEV replicate in the respiratory tract (Furuuchi et al. 1979) and upon being swallowed might seed additional virus to the gut. However, results using attenuated strains orally and/or IN have generally been disappointing (Henning and Thomas 1981; Moxley and Olson 1989a; Saif and Bohl 1979a, 1981a; Voets et al. 1980). In previous studies using the high-passaged Purdue strain of TGEV orally, or orally and IM, few IgA TGEV antibodies were evident, and mortality among challenged pigs from vaccinated dams ranged from 25% to 100% (Moxley and Olson 1989a; Saif and Bohl 1979a, b; Saif and Jackwood 1990; Voets et al. 1980).

Concerns that attenuated strains of TGEV might not survive passage through the acidic environment of the stomach prompted studies using lyophilized attenuated virus in enteric-coated gelatin capsules (Hess et al. 1978; Voets et al. 1980). Hess et al. (1978), using the high titered B1 strain of TGEV (300 cell culture passages), reported high levels of IgA TGEV antibodies in milk and only 10% piglet mortality. Voets et al. (1980) used the high-passaged Purdue strain and found that most sows failed to seroconvert after oral vaccination, and even the

sows that seroconverted had a 44% piglet mortality rate. Fichtner et al. (1982) reported 30% mortality in challenged piglets after feeding attenuated Riems TGEV to the dams for 10 days during gestation.

In further efforts to ensure that vaccine virus reached the small intestine, two studies used direct inoculation of attenuated viruses into the intestinal lumen. Again, protection was poor (62% mortality) (Voets et al. 1980) in challenged piglets from dams given a single intralumenal inoculation of attenuated Purdue TGEV during gestation, but greater protection (10% mortality) was achieved when dams received repeated intralumenal inoculations (Fichtner et al. 1982).

Other researchers selected variants of high- and low-passaged TGEV strains resistant to low pH and proteolytic enzymes in vitro and used these strains as vaccines for passive protection studies (Aynaud et al. 1985; Bernard et al. 1989; Chen 1985; Shirai et al. 1988). They reported inconsistent results, with mortality varying from 0–73% among litters challenged with virulent TGEV. In the latter two studies, data interpretation was confounded somewhat by variations in the ages of the pigs at challenge, a factor shown in other studies to dramatically influence piglet survivability (Moxley and Olson 1989a).

A live attenuated SP variant TGEV grown in a persistently infected porcine leukocyte cell line has been used to vaccinate pregnant swine by the oral/IN and/or intramammary routes (Woods 1978, 1984). Challenge of the suckling pigs resulted in mortality of 14–34%. In the latter study the author reported generally high TGEV IgA and IgG antibody titers in 3–4 days postfarrowing (DPF) milk. However, three of eight sows vaccinated with SP TGEV became mildly sick after challenge exposure of their nursing pigs. Although diarrhea was observed in pigs nursing SP-TGEV vaccinates (48% morbidity), it was reportedly mild and delayed in onset (3 DPF). The SP TGEV has been reported to be avirulent for newborn pigs, replicating within the intestinal lamina propria but not epithelial cells (Woods et al. 1981).

Molecular analysis of several attenuated TGEV strains revealed changes in mRNA 2 and 3 affecting the S protein and nonstructural protein 3 (Register and Wesley 1994). Inconsistent results were noted in vaccination studies using a commercial vaccine administered twice orally (in feed) and once IM. Whereas Welter (1980) reported 8% mortality among challenged pigs, others reported higher mortality, similar to that in piglets suckling unvaccinated sows (Bohl et al. 1982; Moxley and Olson 1989a; Saif and Bohl 1981b). The generally poor results obtained with oral or IN vaccination of sows using attenuated TGEV strains may be attributed to the superficial or limited replication of most attenuated strains in the sow's intestine (Frederick et al. 1976; Hess et al. 1977). Consequently, this results in little antigenic stimulation of underlying intestinal IgA plasma cells and correspondingly little IgA antibody secretion in milk.

Attempts to use a low cell culture–passaged TGEV to induce passive immunity led to erratic results in terms of both seroconversion in orally/IN exposed sows and protection in piglets (Saif and Bohl 1979b). The dilemma remains of how to commercially develop a vaccine to prevent epidemic TGEV capable of stimulating IgA in the gut of sows but being sufficiently attenuated or noninfectious so as not to produce disease in newborn pigs.

Parenteral Vaccination. Various experimental and two commercial vaccines composed of live attenuated virus were administered IM about 6 and 2 weeks prefarrowing. Experimental evaluations of this vaccination regime have generally indicated reduced piglet mortality (38–56% in vaccinates compared with 71–92% in controls), but not morbidity (Bohl and Saif 1975; Moxley and Olson 1989a; Voets et al. 1980). However, vaccination results were poor when compared with almost complete protection (0–9% mortality) in litters of naturally infected sows.

Henning and Thomas (1981) and Matisheck et al. (1982) reported more favorable vaccination results, i.e., mortality of 10% and 18%, using two commercial vaccines. The IM vaccination procedure has two major disadvantages. (1) Vaccinated swine develop little or no gut immunity; they usually get sick when exposed to TGEV. If this occurs during lactation, their suckling pigs will be deprived of adequate milk. (2) The TGEV antibodies found in the milk of these vaccinated sows are of the IgG class and of low titer and fail to provide optimal passive protection to suckling pigs.

Intramammary injection of seronegative pregnant swine with TGEV resulted in high titers of primarily IgG TGEV antibodies in milk, whereas similar injections in lactating sows resulted in IgA and IgM TGEV antibodies. Specific antibody activity was found not only in milk from injected glands but also in milk from noninjected glands (Bohl and Saif 1975; Saif and Bohl 1983). Protection was good (14–26% mortality) in litters of intramammarily vaccinated pregnant swine, presumably because exceptionally high levels of IgG antibodies persisted in the milk at the time of challenge, 3 days postfarrowing (Bohl and Saif 1975; Shibley et al. 1973).

A similar, greatly enhanced, predominantly IgG milk antibody titer was noted in two sows vaccinated IM/IN with the high-titered (10^8–$10^{9.3}$ $TCID_{50}$) attenuated TO163 strain of TGEV. No mortality occurred in either of these litters, confirming the protective ability of IgG TGEV antibodies when present in high titers in milk (Kaji and Shimizu 1978).

Heterologous Vaccines. The antigenic relationship between TGEV and FIPV was the basis for studies of the possible efficacy of FIPV as a heterologous coronavirus vaccine in swine. Preliminary studies indicated that some immunity (25% mortality) against TGE was con-

ferred in pigs nursing two sows vaccinated during gestation orally/IN and intramammarily with live virulent FIPV. However, this FIPV was pathogenic in newborn pigs (Woods and Pedersen 1979). Subsequent studies using cell culture–adapted attenuated FIPV in sows by the same routes of inoculation resulted in higher litter mortality (52%) and low TGEV antibody titers of the IgG class in milk (Woods 1984).

Vaccination of TGEV-Infected Swine. Vaccines have been used on two populations of pregnant swine: those that have, and those that have not, previously been naturally infected with TGEV or PRCV. There are significant differences in the immune responses and, consequently, piglet protection in these two groups of animals following vaccination. These differences may account for some of the discrepant results seen in vaccine challenge studies, if previously infected swine were unknowingly used. This possibility can be eliminated only by using a very sensitive test (such as plaque reduction VN) to measure TGEV/PRCV antibodies and by knowing the herd history of test animals in terms of previous TGE outbreaks. Occurrence of PRCV in herds further complicate TGEV vaccine studies.

Limited laboratory research has indicated that parenteral inoculation of previously infected swine during gestation using attenuated TGEV resulted in a boost in TGEV milk antibodies in both the IgA and IgG classes (Saif and Bohl 1981a, b, 1983; Saif and Smith 1985). Others have also reported increased milk TGEV antibody titers (4–7-fold) after intramammary inoculation of previously infected swine with inactivated TGEV (Thorsen and Djurickovic 1971). Currently available parenterally administered TGEV vaccines may be more effective in boosting immunity in previously TGEV or PRCV infected pregnant swine than in initiating immunity in previously uninfected seronegative pregnant swine. These vaccines may be especially useful in herds in which endemic TGE is a problem (Leopoldt and Meyer 1978; Stepanek 1979).

PRCV Maternal Vaccines to Prevent TGE. Since PRCV became widespread in the European swine herds, the incidence and severity of TGE in countries with PRCV have declined (Laude et al. 1993; Pensaert and Cox 1989). This suggests that previous exposure of swine to PRCV imparts partial immunity to TGEV (Pensaert 1989; Pensaert and Cox 1989).

A number of researchers have examined the relationship between PRCV infection of sows and passive immunity to TGEV in piglets. Prior natural exposure of sows to PRCV induced a variable degree (44–53% mortality) of passive protection against experimental TGEV challenge of suckling pigs (Bernard et al. 1989; Paton and Brown 1990). Variable protection in the field during TGE outbreaks was also noted among litters of PRCV-exposed sows (Callebaut et al. 1990; Pensaert and Cox

1989). Similar variable levels of protection (30–67% mortality) were reported after TGEV challenge of piglets suckling sows that had been experimentally infected or reinfected with PRCV during pregnancy (Callebaut et al. 1990; De Diego et al. 1992; Lanza et al. 1995; Sestak et al. 1996; Wesley and Woods 1993). Noteworthy in the latter two studies, litter mortality was lowest (range = 0–27%) and IgA and IgG milk antibody titers were highest, in sows multiply exposed to PRCV during two subsequent pregnancies. These experimental findings agree with other reports (Callebaut et al. 1990) that naturally PRCV-exposed sows that are reinfected with PRCV during pregnancy secreted IgA TGEV antibodies in milk and provided a high degree of protection (0–12.5% mortality) to TGEV challenge.

Besides levels of IgA antibodies in milk, a hallmark of protection in these and another study (Wesley and Woods 1993) of passive immunity to TGEV induced by PRCV appeared to be induction of active immunity to TGEV in the sow, preventing illness and/or agalactia. Diarrhea mortality was consistently lower in litters of PRCV-exposed sows that did not become ill or develop agalactia after TGEV challenge of their litters.

The mechanism for the induction of IgA antibodies observed inconsistently in the milk of PRCV-exposed sows is unclear, as is the correlation of such antibodies with passive protection to TGEV challenge (Callebaut et al. 1990; Pensaert and Cox 1989). After a primary exposure to PRCV, IgA antibodies occurred in the milk of only 30% of sows; this percentage increased to 84% in sows reinfected with PRCV. These results concur with a report by Sestak et al. (1996) that the titers of IgA (and IgG) antibodies to TGEV were significantly increased in the milk of sows multiply exposed to PRCV during two sequential pregnancies. The variable IgA antibody responses observed in the milk of sows after primary exposure to PRCV could relate to the low numbers of virus-specific IgA ASCs observed in BALT, GALT, and mesenteric lymph nodes of seronegative pigs exposed to PRCV (VanCott et al. 1993, 1994). Repeated PRCV infections may be necessary to boost numbers of IgA ASCs in BALT and to increase the efficiency of a possible sIgA immunologic link between BALT and the mammary gland. Because IgG antibodies are also prevalent in the milk of sows exposed to other viruses that replicate in the respiratory tract, e.g., attenuated TGEV strains and pseudorabies virus (Saif and Bohl 1977), it is conceivable that an IgG immunologic link may also exist between BALT and the mammary gland in sows, or alternatively, BALT stimulation contributes serum IgG antibodies that are subsequently transudated into the milk.

Besides quantitative differences in the levels of IgA antibodies induced in milk after exposure to TGEV or PRCV, researchers have investigated potential differences in virus epitopes recognized by the IgA milk antibodies induced after TGEV versus PRCV infection of sows (De Diego et al. 1992, 1994). In TGEV-infected sows, antigenic subsite A (Aa, Ab, Ac), followed by antigenic subsite D (Madrid), was the best inducer of IgA antibodies, whereas after PRCV infection, antigenic site D and subsite Ab were immunodominant. These authors concluded that only IgA recognizing at least antigenic sites A and D conferred good protection in vivo, whereas any Ig class recognizing only one antigenic site neutralized virus in cell culture.

Clearly, additional studies are necessary to clarify the levels and mechanisms of active and passive immunity to TGEV established in swine by previous exposure to PRCV. In particular, it is important to elucidate the mechanism by which IgA antibodies are induced after infection with PRCV, whether a BALT-mammary gland immunologic link exists but is less efficient than the gut-mammary link for induction of IgA in milk, why IgA antibodies occur only in some PRCV-exposed sows, and the effectiveness of these IgA antibodies in protecting suckling pigs against intestinal TGEV infections.

New Vaccine Approaches. With existing vaccines being either too attenuated or applied at a dose that is too low, protection is inconsistent (Saif 1996; Saif and Jackwood 1990; Shoup et al. 1997; VanCott et al. 1993) and the search for more reliable vaccines continues. For protection of suckling piglets, research continues to focus on the principle of colostral and lacteal intake of IgA antibodies after immunization of sows with live attenuated vaccines (Park et al. 1998; Saif 1996; Sestak et al. 1999a).

During the last decade, emphasis has been on the construction of TGEV protein subunit vaccines. Among the three major structural proteins of TGEV, the S protein contains immunodominant epitopes that are recognized by virus-neutralizing antibodies (Delmas et al. 1986; Jimenez et al. 1986). Some of these epitopes were shown to be continuous domains (Delmas and Laude 1990; Gebauer et al. 1991; Posthumus et al. 1990), prompting the design of antigenic synthetic peptides derived from the S protein (Posthumus et al. 1991). It was found that the N protein contains the major T helper cell epitopes (Anton et al. 1995). A synthetic 15-mer peptide epitope derived from the N protein was shown to cooperate with the S protein for in vitro induction of TGEV-specific antibody (Anton et al. 1996).

To express the TGEV S, M, or N proteins, several prokaryotic and eukaryotic systems such as *E. coli*, salmonella, adenovirus, vaccinia virus, baculovirus, and plants were used (Britton et al. 1987; Enjuanes et al. 1992; Godet et al. 1991; Gomez et al. 2000; Park et al. 1998; Pulford and Britton 1991; Shoup et al. 1997; Smerdou et al. 1996a; Smerdou et al. 1996b; Torres et al. 1996; Tuboly et al. 1994, 2000). In some studies, protective antibodies were induced in inoculated animals, correlating with partial protection (Torres et al. 1995). In other studies, no induction of protective antibodies was reported (Gomez et al. 1998, 2000; Smerdou et al.

1996a, b; Tuboly et al. 2000) or only serum IgG virus-neutralizing antibodies were induced (Park et al. 1998; Shoup et al. 1997)

When prokaryotic vectors (*E. coli*) including live vectors (attenuated salmonella) were used to express the TGEV S gene or S gene fragments, low or no neutralizing antibodies were induced in mice (Hu et al. 1985), rabbits (Smerdou et al. 1996a), or pigs (Sestak and Schifferli, unpublished, 2004). These failures were attributed to loss or lack of the glycosylation-dependent conformational immunodominant site A in the bacterial expressed S proteins.

Various levels of neutralizing antibodies and protection were induced using eukaryotic vectors to express the TGEV S glycoprotein encoding the glycosylation-dependent antigenic determinants (sites A, B) with or without sites C and D.

The S glycoprotein of TGEV expressed in vaccinia virus induced low titers of neutralizing antibodies, but no protection (Hu et al. 1985). The baculovirus-expressed S protein induced virus neutralizing antibodies to TGEV, detected in the serum of rats and pigs (Shoup et al. 1997; Tuboly et al. 1995). However, the protective ability of these systemic antibodies was low(Godet et al. 1991; Shoup et al. 1997; Tuboly et al. 1995). Only S glycoprotein constructs containing antigenic site A induced high neutralizing antibody titers. S fragments containing sites C and D induced only low titer neutralizing antibodies, but interestingly, they primed pigs for secondary serum antibody responses after challenge (Shoup et al. 1997). When the baculovirus-expressed S glycoprotein with incomplete Freund's adjuvant was administered intramammarily and IM to TGEV seronegative pregnant sows, only low titer IgG antibodies to TGEV were detected in sows' colostrum and milk (Shoup et al. 1997). There was no significant decrease in morbidity or mortality after TGEV challenge exposure of litters from these sows (Shoup et al. 1997).

Similar findings were evident in studies using the same baculovirus-expressed S constructs administered IM to boost antibody responses in sows orally vaccinated with attenuated TGEV vaccines: the S glycoprotein vaccine generated antibody titers in colostrum/milk and partial protection rates (43% mortality) comparable to IM boosting with attenuated TGEV vaccine (57% mortality) (Park et al. 1998). In studies using baculovirus-expressed TGEV structural proteins (S, N, and M) coadministered IP with *E. coli* mutant LT-adjuvant, immune responses associated with IgA antibodies to TGEV were associated with reduced TGEV shedding in the feces of challenged pigs (Sestak et al. 1999a).

Live vectored vaccines expressing TGEV S protein fragments have also been evaluated. A human adenovirus 5 engineered to express the TGEV S protein sites A–D and a smaller fragment expressing sites B+C induced serum neutralizing antibodies in pigs inoculated oronasally and IP (Torres et al. 1996). When newborn

piglets passively fed the immune serum were orally challenged with the immune serum-TGEV mixture, only pigs fed immune serum from swine vaccinated with the S constructs with sites A–D were passively protected against TGE mortality and partially protected against infection.

Other researchers developed a recombinant human adenovirus vector expressing the full length S protein of PRCV (Callebaut et al. 1996). Pigs inoculated oronasally with the recombinant adenovirus S vaccine were not protected against PRCV nasal shedding after PRCV challenge, but they had shorter shedding and a rapid anamnestic neutralizing antibody response to PRCV. In other studies, a porcine adenovirus 5 expressing the TGEV S glycoprotein was used for oral immunization of pigs (Tuboly and Nagy 2001). Although IgA antibodies to TGEV were induced in the intestines of the inoculated pigs, the pigs shed TGEV in feces after challenge (Callebaut et al. 1996).

Recent studies with TGEV infectious cDNA minigenomes indicate that this approach can also be exploited for targeted delivery of immunogens derived from other pathogens to the intestine or respiratory tract (Alonso et al. 2002; Gonzalez et al. 2002; Sola et al. 2003). When nonessential TGEV open reading frames 3a or 3b were replaced by a heterologous green fluorescence gene it was shown that the virus retained immunogenic and also enteropathogenic properties (Sola et al. 2003).

Since the pathology of TGEV remains localized in the intestine, an effective vaccine should primarily elicit an intestinal immune response that can be targeted by oronasal immunizations with adequate doses and forms of attenuated vaccines (Saif and Jackwood 1990; VanCott et al. 1993). Further improvements of TGEV vaccines might be achieved by the use of supplementary mucosal delivery systems such as immunostimulating complexes (ISCOMs), biodegradable microspheres, or infectious recombinant TGEV clones engineered to enhance TGEV immunogenicity and reduce pathogenicity.

31 Vesicular Diseases

Juan Lubroth, Luis Rodríguez, and Aldo Dekker

The principal vesicular diseases that affect swine are foot-and-mouth disease (FMD), vesicular stomatitis (VS), and swine vesicular disease (SVD). There are other infectious diseases and conditions that can produce signs and pathologies in pigs similar to those seen in these three viral diseases, but they cannot be covered adequately in the scope of this chapter. Salient among the diseases not covered are two caliciviruses (vesicular exanthema of swine virus and San Miguel sea lion virus) and conditions such as caustic agents. It is imperative that practitioners attending a case of a vesicular disease immediately notify and collaborate with the veterinary authorities. The figures included in this chapter are purposely not identified as to which vesicular disease is the causative agent with the objective of emphasizing their identical clinical appearance.

GENERAL CONSIDERATIONS FOR THE OUTBREAK OF A VESICULAR DISEASE (DIFFERENTIAL DIAGNOSIS)

A farm with signs of a vesicular disease should be considered infected with FMD until proven otherwise. This is because of the highly infectious nature of the foot-and-mouth disease virus (FMDV), the fact that lesions caused by agents causing vesicular lesions cannot be differentiated on the basis of gross lesions, and because of the severe consequences for international trade.

When the investigation ensues, it is essential that samples are collected properly and submitted to a laboratory qualified to conduct the appropriate testing. FMDV can be grown on several tissue cell types, but samples for virus isolation recovered from a ruminant species should be assayed on permissive ruminant cells—i.e., bovine thyroid, lamb kidney—and those from swine on permissive swine cells—i.e., swine kidney/IBRS-2. Virus isolation for SVD on IBRS-2 cells is considered one of the most sensitive methods for laboratory diagnosis. In addition to IBRS-2 cells, SK6, PK-15, and primary or secondary porcine kidney cells are also sus-

ceptible to SVDV. Among the cells most commonly used to grow VSV in the laboratory are monkey kidney cells (Vero), hamster cells (BHK, CHO), chick embryo cells, and mouse cells.

As with FMD and VS, RT-PCR techniques have also been developed to detect SVD viral genome (Callahan et al. 2002; Callens and De Clercq 1999; Lin et al. 1997; Niedbalski et al. 2000; Reid et al. 2000). Virus isolation and RT-PCR are the tests of first choice for detection of SVDV in feces or from the principal tissues described earlier. In fresh vesicular material, the amount of virus (FMD, VSV, or SVD) is very high and an ELISA can be used for antigen detection and identification (Hamblin and Crowther 1995).

Other causes of vesicular or erosive lesions, including infectious (swine pox, parvovirus, or mycotic dermatitis), toxic (parsnip or celery contact dermatitis), and chemical burns (Kresse et al. 1985; Montgomery et al. 1987), should also be considered in the diagnostic workup.

THE VETERINARY PRACTITIONER'S RESPONSE

The veterinary practitioner who suspects a vesicular disease, having notified the relevant veterinary authorities, should immediately disinfect their equipment, boots, and vehicle, and should not visit any other premises on which other susceptible animals are kept. Rapid detection and immediate notification of outbreaks are imperative for control of the disease (Geering and Lubroth 2002). The practitioner could provide assistance to the veterinary authorities by beginning a line of epidemiological questioning regarding movements on and off the farm, identification of contacts, e.g., livestock market deliveries, purchases of feed, bedding, or exchanges with other farms. The practitioner's knowledge of the area with regard to producers, auctions and markets, feed distributors, and the activities of other clinicians, can be a valuable asset to the authorities in their attempts to contain and ascertain disease transmission paths.

Foot-and-Mouth Disease

Foot-and-mouth disease virus (FMDV) was recognized over 100 years ago, making it the first animal virus to be discovered. In 1897, Loeffler and Frosch presented their seminal experiments showing that a filterable agent (virus), not a toxin, was responsible for the disease. The disease itself was described in several ancient literary and historical accounts, the first attributed to Aristotle in the third century before the Common Era. Later, a more accurate description appeared in the writings of the Italian poet and physician Girolamo Fracastoro in *De Contagione et Contagiosis Morbis et Curatione* in 1546 (reprinted in part in Casas Olascoaga et al. 1999).

Of all the diseases known to human and animal medicine, foot-and-mouth disease (FMD) is probably the most contagious. Infected animals can shed high titers of virus in excretions, secretions, and from superficial lesions. The virus is found in semen, feces, oropharyngeal fluids, and contaminated food products and waste, and can be carried by aerosols across considerable distances. Importantly, the plethora of virus types makes it difficult to make generalizations based on the characteristics of one virus subtype that apply to all virus types and subtypes. Furthermore, since FMD viruses affect numerous hosts, including both domestic and wild animals, observations based on a certain virus in a specific host may not necessarily be true for another virus in the same or different host species.

All continents have historically been affected by FMD, with the exception of Antarctica. Trade barriers imposed on countries with FMD infection limit their access to international markets. Thus, several regions have either eradicated FMD (i.e., North America and Western Europe) or have undertaken extraordinary regional efforts to control its incidence and eliminate its occurrence altogether (i.e., South America and Oceania). Continued surveillance for vesicular diseases is of the utmost importance to FMDV-free countries and to those that have established control campaigns. Early detection of FMD and early response to its presence are critical to the mission of veterinary services around the world.

Because of its highly infectious nature, FMD has been the leading force behind much of the national and international veterinary service legislation and regulations regarding markets, exports and imports, quarantine, inspection, diagnostic competencies, and the need to establish contingency and emergency response plans.

ETIOLOGY

The viruses of FMD belong to the Genus *Aphthovirus* (*aphtho*—vesicle, blister) in the family *Picornaviridae*. Included in the family are poliovirus, hepatitis A virus, the rhinoviruses, and enteroviruses (such as SVD virus, which is discussed later in this chapter).

Aphthoviruses are small (~25 nm) and composed of ~8.5 kilobases of single-stranded, positive-sense RNA wrapped in a nonenveloped capsid structure comprised of 60 copies each of four viral proteins. The viral RNA encodes for a single polyprotein of some 3000 amino acids. During translation the nascent polyprotein is cleaved into 13 proteins. Proteins, 1A, 1B, 1C, and 1D (historical nomenclature defines these as VP2, VP4, VP3, and VP1, respectively, as reviewed in Grubman and Baxt 2004) form the viral capsid with 3B viral protein linked to the RNA. The nonstructural proteins (2A, 2B, 2C, 3A, 3B [of which there are three copies], 3C, and 3D), are involved in virus replication and host-cell shut off.

Within the FMD viruses, seven distinct serotypes are recognized: serotype A (French for Germany—*Allemagne*); serotype O (for the Oise Region in France, but once referred to as type B); serotype C (the third virus to be recognized as antigenically distinct); serotype Southern African Territories (SAT) 1, SAT 2, and SAT 3; and serotype Asia 1 (Bachrach 1968). Multiple variants or subtypes exist within each serotype (Bachrach 1968; Carrillo et al. 1990; Domingo et al. 1995).

EPIDEMIOLOGY

Geographic Distribution

In Asia, FMDV is endemic in all countries in the region except Brunei, East Timor, Indonesia, Japan, Singapore, and South Korea. The eastern states of Malaysia are also free and the Philippines is well on the way to eradication, with the exception of peri-urban occurrence of FMD around Manila. The most prevalent serotypes are O, A, and Asia 1. The disease causes considerable loss of buffalo draft power for rice cropping and production losses in pigs and cattle, and is a major constraint to trade in cattle, pigs, or their products within the region. The spread of FMD in Asia is closely related to the unofficial movement patterns of cattle and pigs (or their products) for trade purposes. Wildlife reservoirs for FMD in the region are not known, although the possibility exists in wild bovine and porcine species in several countries.

In recent years, the highly contagious Pan-Asian Type O virus has spread through several countries in Asia, including Bangladesh (1996) and Bhutan (1998), Taiwan (1997, 1999), Japan (2000, which had been FMD-free since 1908), the Republic of Korea (2000, which had been FMD-free since 1929), Mongolia (2000, which had been FMD-free for 27 years prior), and the far east of Russia (2000, which had been FMD-free for 36 years prior).

In East Asia, an O virus with a unique tropism for swine emerged in several countries, including Viet Nam, Hong Kong, the Philippines, and Taiwan, producing high mortality in pig populations (Dunn and Donaldson 1997; Knowles et al. 2001). This FMDV has often been erroneously referred to as a "pig-adapted" FMDV. Adaptation, in the ecological sense, connotes cohabitation and symbiosis, which is far from the case for this virulent, porcinophillic virus (Beard and Mason 2000; Mason et al. 2003).

FMDV was introduced to South America in 1870 through the importation of cattle to southern regions (Argentina) from Europe, but only reached northern countries (Colombia and Venezuela, for instance) in the 1950s. Through the *Comisión Sur Americana para la Lucha Contra la Fiebre Aftosa*, the incidence of FMD has declined from several thousand cases in 1980 to a few by early in the 21st century by maintaining effective surveillance, animal control, and vaccination programs in most countries. Critical areas of virus persistence remain in parts of Bolivia, Ecuador, and Venezuela. The only serotypes recorded in South America are A, O, and C. Type C has not been isolated from the field in nearly 10 years and may have disappeared, but its eradication requires confirmation. (Addendum: at the time of publication, Type C has been reported in northern Brazil.)

The situation in Africa is poorly described. This reflects the difficulties for veterinary services of mounting effective disease control initiatives, implementing timely reporting, and garnering sufficient resources to engage villages or incipient private ventures in sustainable healthy livestock development. Six of the seven serotypes of FMDV occur in different African ecosystems. Only Asia 1 has never been reported. South Africa, Namibia, Botswana, and Zimbabwe have been able to control FMD through the production of suitable vaccines, well-designed vaccination campaigns, and the formation of wildlife sanctuaries that separate persistently infected buffalo from domestic operations. Regrettably, land resettlement and civil unrest in Zimbabwe eroded veterinary systems in the early 2000s. Widespread FMD outbreaks have led to the closure of lucrative markets outside Africa and pose a threat to neighboring countries. Although the predominant serotype in the region is SAT-2, others still present a risk. As in South America, type C appears to have disappeared from Africa, but adequate active surveillance is required for confirmation. In southern Africa, the Cape buffalo herds harbor SAT viruses and represent potential sources of infection to domestic livestock.

In the Middle East and Arabian Peninsula, virus types A, O, Asia 1, and occasionally SAT-2 have been identified. Swine are not an important species in these regions and control efforts are focused almost entirely in dairy cattle and small ruminants. However, the needs of the region, in terms of animal protein, necessitate extensive importation from the Horn of Africa or elsewhere. This situation increases the risk for the entry of FMDV or other transboundary animal diseases. Exclusion of FMDV is, therefore, dependent upon careful pre-embarkation, regulated quarantine, and official laboratory testing undertaken for this purpose. In northern Africa, FMD usually moves in a westerly direction, or as seen in the outbreak in Algeria in the mid-1990s, from western Africa to the north, paralleling the movement of livestock; but again, swine are not part of the disease dynamics in this region either.

Susceptible Species

Natural hosts of FMDV include all artiodactyls (ungulates with a cloven hoof). As such, domestic cattle, buffalo, sheep, goats, camels, South American camelids, deer, antelope, wildebeest, as well as those of the suborder *Suiformes* (domestic swine, feral swine, and wild boar) are susceptible to FMDV infection. FMDV infection has also been reported in other species, including elephants, hedgehogs, and capybara (reviewed in Casas Olascoaga et al. 1999). Of notable epidemiological importance in Africa is the Cape buffalo (*Syncerus caffer*), which serves as a FMDV reservoir host in the region and a potential source of viruses to adjacent livestock production areas (Condy et al. 1985; Dawe et al. 1994). Laboratory models for FMDV include guinea pigs and suckling mice, which historically have been used for virus isolation and studies of vaccine protection determinants (Casas Olascoaga et al. 1999).

Nonhuman primates have also been studied as to their susceptibility to FMD (Schudel et al. 1981). Although there are confirmed cases of FMDV infections in humans, these have been incidental and FMD viruses should not be considered zoonotic (Casas Olascoaga et al. 1999). FMDV is widespread around the world, and the exposure of farmers, veterinarians, and other animal health workers, abattoir personnel, butchers, or researchers is commonplace. However, humans exposed to FMD-infected animals or carcasses have rarely, if ever, developed disease or seroconverted to the virus.

Although equine rhinitis A virus belongs to the aphthovirus genus (King et al. 1999), the FMD viruses do not affect solipeds.

Transmission

FMD viruses can be isolated from exhalations, secretions, urine, feces, milk, and semen during prodromal phases of the infection and during early clinical disease (Casas Olascoaga et al. 1999; Lubroth 2002). Once lesions develop, the virus is easily found in and around the exudations of ruptured vesicles of lesions.

The most common form of transmission is through contact between an infected animal and susceptible cohorts. At the height of clinical manifestation, swine generate more viruses in their exhalations than other species, and thus are often referred to as amplifiers of the virus (Alexandersen and Donaldson 2002). It is esti-

mated that an infected pig can exhale up to 3000 times that of an affected cow. The 1981 FMD outbreak on the Isle of Wight was reported to have come from an infected piggery on France's northern coast, and carried by the prevailing winds and proper humidity from France to England (Donaldson 1986; Gloster and Alexandersen 2004). However, certain FMD viruses isolated from swine actually show the opposite characteristic and are poorly aerosolized, even when pigs are housed in the same room and separated by a double fence meters apart.

As omnivores, pigs ingesting poorly cooked, virus-infected swill or other foodstuffs can acquire FMD. Retrospective epidemiological investigations have shown that ingestion of infected products by swine has been responsible for some important outbreaks of the disease in recent times, such as that in the United Kingdom in 2001 (Gibbens et al. 2001).

Embryo transfer studies in FMD-infected cattle have shown that even at the time of greatest risk—that of peak viremia—proper washing of the collected embryos following protocols established by the International Embryo Transfer Society, will reduce the risk of transmitting the virus to zero, provided that the *zona pellucida* remains intact (Mebus and Singh 1991). FMDV can be recovered from semen from FMD-infected boars, but artificial insemination with contaminated semen failed to transmit the diseases to serviced sows (McVicar et al. 1978).

The persistently infected animal is defined as an animal that harbors the virus in the esophageal-pharyngeal region beyond 28 days post infection (Hedger 1971; Salt 1993). The persistent carrier state has been well described in cattle and buffalo, but less so in sheep and goats, with swine expected not to sustain the virus long term (Salt 1993; Lubroth and Brown 1995). It is likely that persistence is related not only to host factors, but also to those of the specific virus under study.

Salted and processed pork meats can contain viable FMDV under different conditions (Cottral 1969). Studies conducted using Italian and Spanish traditional processes found that by 200 days after post product preparation, no FMDV could be isolated from processed meats (Mebus et al. 1993). During carcass maturation, the lactic acid build up in the skeletal musculature is sufficient to inactivate FMDV, with infectious virus remaining principally in lymph nodes, glands, and bone marrow. It is for this specific reason that export of fresh beef exported from once-endemic areas (South America and southern Africa, primarily) require that it be deboned and deglanded.

FMD viruses are generally subject to rapid inactivation under many physical and chemical environments, but it can survive pasteurization at 72°C for 15 seconds; in cattle stalls after 14 days from urine after 39 days, 28, and 3 days in autumn and summer, respectively; and from contaminated hay after 5 months at 22°C (Cottral

1969; Pirtle and Beran 1991). Thus, under temperate climates characterized by overcast skies and cool temperatures, the virus may survive for a considerable period of time with direct sunlight, dry ambient temperatures destroying the virus. FMD viruses are highly labile to low pH (below 6.7) and high pH (above 10.5). As picornaviruses are nonenveloped, detergents, lipid solvents, and ether-based compounds do not have a primary inactivation effect.

PATHOGENESIS

Great variation exists in susceptibility and clinical presentation of FMD among species and between indigenous and exotic breeds. In addition, variation exists in the virulence of one virus versus another in the same host (Lubroth 2002).

The FMD viruses usually gain entry via the respiratory route, with as few as 10 infectious particles causing infection in cattle (Donaldson et al. 1987). Even if virus-contaminated swill is the source of infection, inhalation of aerosolized virus or entry through breaks in the buccal mucosa leads to viral replication, drainage to local lymph nodes, and subsequent viremia. The lungs, perhaps surprisingly, do not contain as high titers of virus as the upper respiratory tract, particularly the pharyngeal area (Alexandersen et al. 2001). The dissemination of the virus throughout virtually all tissues of the body occurs with remarkable speed, but the classical lesions develop only in the nasal, mucosal, and podal epithelia.

CLINICAL SIGNS

FMD in swine is a crippling disease in adult pigs and often fatal in piglets. The incubation period for FMD may range from 2–10 days following exposure to the virus. In a vaccinated animal, where immunity may vary, the incubation period is often prolonged as the homologous virus replicates (or a closely related one) and eventually overcomes waning immunity.

Infected pigs develop a fever within 24–48 hours and by the third day the fever may surpass 41°C (106°F). Affected pigs are likely prostrate and shivering (Figure 31.1). Blanched areas may be seen at the level of the coronary bands, fringed by congested areas. The feet are warm to the touch. By the fourth to sixth day vesicular lesions, which quickly rupture leaving a raw denuded area and epithelial tags, will have developed along the coronary band; interdigital spaces and bulbs of the heel; and rostral areas of the snout, nares, and chin—all common signs exhibited by affected animals throughout the piggery. Heavy adults often remain prostrate for long periods leading to pressure sores that develop overnight with the epithelia eroding off from carpi and tarsi and much squealing when coaxed to move. Unlike cattle affected by FMD, vesicles rarely develop on the dorsal surface of the tongue in affected pigs. If not humanely

31.1. *Prostration and huddling in swine affected by a vesicular disease. Circle and arrow, foot lesions; arrow, rostral aspect of the snout with ruptured vesicle.*

culled, some pigs will slough off their hooves exposing the raw, underlying, sensitive laminae.

In uncomplicated cases, recovery can be quick and is often complete within 2 weeks, when all mucosal lesions have healed. However, deformation of the claws may be a sequel to the foot lesions. Animals that have lost their claws should be euthanized on humanitarian grounds.

In disease-free areas, the infection can spread quickly and the clinical presentation may become widespread, with a morbidity approaching 100%. In regions where the disease is endemic, or where some degree of vaccination is undertaken, extensive clinical signs may be less pronounced.

The high fevers in sows can lead to abortion storms in the farrowing pens. Piglet mortality can exceed 50% due to virus-induced myocarditis, even before vesicles have developed in these or the adult animals.

By the time the veterinary practitioners or inspectors arrive at the farm, the disease in pigs is characterized by erosions and thick epithelial flaps from ruptured vesicles on the snout, around the nares, under the chin, coronary bands, pads of the heels, bulbs, and interdigital spaces (Figures 31.2–31.5). Some pigs may have sloughed their hooves. Animals in the earliest stages of disease are likely to show turgid or flocculent vesicles on the snout ranging from 4 mm to 2.5 cm and occurring circumferentially around the coronary band. The severity of clinical signs is greatest in heavier pigs. Teat vesicles ranging from a few millimeters to one centimeter may also be apparent (Figure 31.6). The heart muscle from piglets that died due to FMDV should be examined for blanched striations along the epicardium, endocardium, and septum, indicative of myocardial infarction and necrosis.

LESIONS

Histopathologically, early changes can be seen as ballooning degeneration of cells in the midsection of the *stratum spinosum* within the stratified epithelium, with the *stratum germinativum* remaining intact and without neutrophilic infiltrates, unless there are opportunistic pathogens that contaminate the wound. As the cellular pathology progresses, pyknotic nuclei become more salient, and some of the degenerating cells begin to coalesce forming fluid-filled pockets containing large amounts of virus. Subsequently, the multiloculated epithelial changes lead to the formation of a larger blister. This pattern of lesion development is similar in various parts of the body, varying only in the extent of keratinization of the epithelium examined. Histopathological examination of affected myocardial tissues shows wide clusters of cells with eosinophilic shrunken cytoplasms and pyknotic nuclei and wide extracellular spaces.

IMMUNITY

Rapid humoral immunity is elicited by the virus, with neutralizing antibodies directed at the three surface capsid proteins: VP1, VP2, and VP3 (Salt 1993). VP1, the immunodominant protein, is also responsible for the serotype classification of the different viruses as well as differentiation between subtypes. As such, vaccine design and certain diagnostic tests, utilize information on the amino acid composition and genomic sequence of VP1 to assess vaccine-virus suitability, molecular epidemiological analysis, and immune response (Doel 1999; Domingo et al. 1995; Knowles and Samuel 1999). However, immune responses to the other viral structural proteins (VP2, VP3, and VP4) and the nonstructural proteins (2C, 3AB, 3ABC, 3D) can also be detected. Reactivity to the nonstructural FMDV proteins is an indication that viral replication has occurred in the host and is the basis for the development of assays that can differentiate between vaccinated, but not infected, animals and those that were infected regardless of their FMD vaccination history (Lubroth 1998; Meyer et al. 1997; Mezencio et al. 1998; Sorensen et al. 1998).

Studies on the duration of protective immunity after recovery from natural infection has been inadequately studied, but in endemic situations where there are at least two viruses in circulation and an ever-changing (replacement) dynamic population, as occurs in flocks of small ruminants, it would appear that protective immunity at the herd level is approximately 2 years in duration (Lubroth, unpublished observations).

No cross-protection is seen across serotypes of FMD viruses (type A to Asia 1, for instance), and only a limited level of protection across virus subtypes (i.e., A5 and A24). There is no cross-protective immunity conferred by infection with other picornaviruses, such as the enteroviruses of domestic animals.

DIAGNOSIS

The veterinary practitioner should take epidemiological considerations into account when trying to determine the causative agent, but must rely on laboratory specialists to confirm the diagnosis using discriminating tests that can quickly differentiate one infectious agent from another (see the section on differential diagnosis).

Laboratory confirmation of FMD depends heavily on the quality of the samples submitted to the diagnostic laboratory. Vesicular fluid or epithelium from oral, nasal, or foot lesions should be fresh, representative of the herd, and collected from several animals. Under field settings, once the veterinary practitioner is called to the farm, intact vesicles may no longer be evident, and the tissues collected for laboratory diagnosis should be from the area of the lesion most apt to contain viral antigens—i.e., at the junction between affected and healthy tissue. If vesicles are seen, fine needle aspirates are an ideal sample for submission, but collection is not easy. Lesions that are 2–3 days old will often have cream-colored coagulated exudate covering the lesion, but these, though easy to sample, are not appropriate diagnostic specimens.

It must be stressed that, when a vesicular disease in swine (or other species) is suspected, the practitioner should immediately contact the official veterinary authorities to conduct a thorough epidemiological evaluation of the incident and collect the appropriate samples for proper laboratory submission.

Antigen-capture enzyme-linked immunoassays (ELISA) using vesicular fluid or well-preserved epithelial tissue samples are used in most countries with endemic FMD or those that have surveillance systems in place as part of their contingency and emergency preparation plans. ELISA has largely replaced the complement fixation test for antigen detection due to its ease in standardization, speed, and high throughput capabilities (Casas Olascoaga et al. 1999).

Penside tests are currently becoming available, but these are limited to subjective interpretation and should be seen as screening tools with a competent laboratory performing the more objective and analytical confirmatory assays.

The inclusion of molecular techniques, such as PCR, into laboratory confirmation can allow rapid identification of group-specific (aphthovirus) or virus-specific (type A24, A96, A22, for instance) gene sequences (Alexandersen et al. 2001; House and Meyer 1993; Reid et al. 2000). Results from ELISA or PCR can be obtained within 3–5 hours after receipt of the samples. Applied research into real-time PCR, in which gene sequences are amplified and visualized on portable computer screens within the hour, has been established for FMD as an ancillary method for diagnosis and is being applied in the field in some countries (Callahan et al. 2002). If the results are negative using these methods, however, samples should still be processed for virus isolation using sensitive cell culture systems. Most capable laboratories actually begin attempts at virus isolation at the same time as the quicker assays, since virus isolation may take several days to complete and the initial preparation of the specimen is often the same. One of the drawbacks to virus isolation is that it can only be conducted in specially equipped laboratories with trained staff. Once there is evidence that a viral agent has been isolated, the cell culture is tested by ELISA or PCR much the same way as a tissue or vesicular sample.

The more common antibody detection methods for the diagnosis of FMD viruses are ELISA and virus neutralization (VN) assays, both of which have been internationally standardized and included in the *Manual of Standards for Diagnostic Tests and Vaccines,* published by the Office International des Epizooties. ELISA tests can be conducted within a few hours. VN requires 3 days and the use of live virus and cell culture systems, which limit its use to specialized laboratories. VN also requires that the laboratory have antisera and epidemiological knowledge of the circulating viruses to use in the assay system.

The detection of FMDV nonstructural proteins can be accomplished using specific ELISA formats and some rapid penside tests to demonstrate virus persistence or circulation within a herd (Meyer et al. 1997; Shin et al. 2002; Sorensen et al. 1998). The specific detection of the 3D nonstructural FMDV protein (once termed "virus-infection associated antigen" or VIAA) was extensively used as an agar-gel immunodiffusion test. Although still in use today in some laboratories, it has been largely replaced by ELISA methods. ELISA testing has also been developed to detect antibody responses to several other nonstructural proteins and can be used to identify animals in which virus replication has occurred, thereby serving as an indirect method to identify potentially persistently infected animals. Antibodies to VIAA were long used to detect for evidence of virus infection in a population, particularly cattle, but studies have shown that animals receiving multiple doses of vaccine will also develop antibodies to 3D or VIAA, thus limiting its value as an indication of previous infection (Casas Olascoaga et al. 1999; Salt 1993). Countries that do not vaccinate, however, could use a 3D-based assay (or other nonstructural protein), because this protein is highly immunogenic and highly conserved among all FMD viruses, making one test applicable for all serotypes and subtypes. In countries where vaccination is practiced, the use of nonstructural proteins other than 3D could be of great value for determining whether virus circulation and transmission is ongoing in a herd without clinical disease.

PREVENTION AND CONTROL

The only treatment available for pigs infected with FMDV is palliative. The use of antibiotics to prevent sec-

ondary bacterial infection could be warranted under endemic situations. FMD is considered a foreign animal disease by many countries and there are ongoing regional and national programs for its progressive control, so treatment is not an option.

The most common method of FMD introduction the world over has been through the movement of clinically ill animals, or those incubating the disease, into a susceptible population (Casas Olascoaga et al. 1999; Geering and Lubroth 2002; Grubman and Baxt 2004; Salt 1993). Contaminated products or by-products of animal origin have also been repeatedly shown as a likely method of spread. Product control restrictions, safety testing of biologicals entering disease-free areas, requirements for health certificates, pre- and post-quarantine testing by government authorities are all attempts to preclude FMD and other diseases from entering into a country or zone.

At the farm level, the application of biosecurity principles has the same basic value as those implemented at an international level. The origin of newly acquired animals should be known and authoritatively certified as healthy. On the farm, recently purchased animals should be quarantined at a distance from the remainder of the herd for a period of 20–40 days to provide added security. Changing outer clothes and footwear when moving between different pens and age groups, with the frequent use of disinfection baths and separate equipment, minimizes the spread of infectious diseases.

The farmer or producer should know the reliability of on-farm contracted services and the origin of all supplies, including feed, veterinary care, equipment, and transport or waste management vehicles. The use of discarded foodstuff as animal feed, even if cooked sufficiently to destroy the virus, should not be allowed. The use of swill for feeding pigs is a high-risk practice and responsible for virus persistence and outbreak occurrence in many parts of the world.

Vaccination

FMD vaccines should contain inactivated antigens representative of the circulating viruses within the region (Doel 2003). Since mutations, antigenic drift, or newly occurring viruses may limit vaccine efficacy, it is critical that laboratory and epidemiological studies be carried out regularly to ensure that vaccine antigens used for the protection of livestock are protective against prevailing viruses.

Two types of vaccines are currently available: aqueous formulations and those emulsified as single or double oil formulations (Black et al. 1984; Casas Olascoaga et al. 1999; Doel 2003). Although ruminants can be vaccinated with either formulation, swine respond to only those prepared with oil adjuvants (Black et al. 1984). Colostral immunity interferes with the induction of protection (Francis and Black 1986a, b).

To obtain herd level protection, all susceptible animals on the premises should be vaccinated in order to ensure that over 80% of the population be adequately immunized. The most successful use of vaccination in FMD-endemic situations has been when quality controlled vaccines are administered twice a year under the supervision of government authorities, with follow-up serological surveys.

The concentration of antigen (referred to as the payload of a vaccine), is one indicator of quality, and those vaccines that have a high payload have been shown to induce some degree of protection 4–5 days after administration (Doel et al. 1994; Doel 2003). Such vaccines can also be used under emergency management of an outbreak if the decision to use vaccine is taken by government authorities.

Some countries, or even continents such as South America, have relied on vaccine coverage in cattle in lieu of swine, sheep and goats, or even wildlife, with much success. In parts of Asia, endemicity differs from the Latin American context in that pig production and marketing are likely to contribute more to the circulation of FMDV. However, vaccination of pigs is haphazard, and progressive control has rarely been achieved.

International and commercial pressure has been placed on vaccine companies to ensure that vaccines are highly purified and do not induce antibodies to FMDV nonstructural proteins. This permits vaccinating countries to demonstrate by serological testing of vaccinates that virus circulation has been halted, thus ensuring access to international markets for their animals and livestock products.

Research into improving vaccines has been undertaken by several government agencies. These include attempts to induce more rapid immunity, vectored vaccines (where FMDV components are incorporated into carrier viruses), and/or the inclusion of antiviral agents or inducers of antiviral properties within vaccine formulations (Moraes et al. 2003). These vaccines have not yet been tested in an endemic or outbreak setting (Grubman and Baxt 2004). In addition, vaccines capable of providing longer duration of protection, able to protect against a wider range of virus subtypes, and without the need for specialized preservation (i.e., refrigeration) are needed.

From the standpoint of an exotic animal disease, the quick and humane elimination of all clinically ill animals and their cohorts to halt further environmental contamination and spread can be warranted (Geering and Lubroth 2002). Burial of the culled animals should be on the affected premises themselves, if an environmentally sound area is available (i.e., away from the water table). When performed correctly, burial is preferable than incineration. Although incineration is suitable for destroying the virus, it falters in that the smoke, smell, and imagery often leads to a strong public outcry regarding animal welfare and it raises environmental

concerns that hinder regulatory performance of control operations. In the event that culled animals are to be moved off the farm to burial sites elsewhere or for rendering, it should be done in sealed container trucks and under the escort of regulatory officials, police, or military personnel assisting in the operations.

Biosecurity onto and off farms should be of paramount importance in every instance of FMD occurrence (Geering and Lubroth 2002). Salient in the management of a FMD outbreak are strict standstill orders on animal movement from the outbreak area and restrictions on the movement of people, equipment, and products off affected premises or infected zones, regardless of what other control measures are employed (i.e., emergency vaccination, culling, or allowing the disease to pass its course with the required palliative treatment).

Vesicular Stomatitis

Vesicular stomatitis (VS) is a viral disease affecting swine, cattle, and horses caused by vesicular stomatitis virus (VSV). In cattle and swine, its clinical appearance resembles that of foot-and-mouth disease (FMD) (see the section on differential diagnosis). Economic losses are incurred due to quarantine and trade restrictions and also to decreased production and weight loss. Mortality is rare (Rodriguez and Nichol 1999).

Historical reports dating as far back as 1862 describe vesicular disease in cattle, horses, and swine. The causal agent was first isolated in the United States in 1925 in New Jersey and a year later in Indiana (Cotton 1927). These isolates were determined to be serologically distinguishable and were later classified as serotypes New Jersey (VSNJV) and Indiana (VSIV) (Cartwright and Brown 1972).

VSV is the most common cause of vesicular disease in the Americas, causing thousands of outbreaks every year from southern Mexico to northern South America. VS is considered an exotic animal disease in Europe, Asia, and Australia and is listed by the OIE as a reportable disease. Its report is obligatory within 24 hours of a confirmed diagnosis. In addition to farm animals, VSV can infect humans, resulting in flu-like symptoms and, occasionally, nonfatal encephalitis (Fields and Hawkins 1967; Quiroz et al. 1988). Unlike the other viral agents causing vesicular disease in swine covered in this chapter, which are transmissible by direct contact and fomites, VSV is also transmitted by insects (Stallknecht et al. 1999).

ETIOLOGY

VSV belongs to the Order *Mononegavirales* (nonsegmented, negative-sense RNA viruses), family *Rhabdoviridae*, and genus V*esiculovirus*. VSV have been classified into two serotypes: New Jersey (VSNJV) and Indiana (VSIV). Two subtypes of VSIV have been found causing livestock disease in South America: Cocal virus or VSIV-2 and Alagoas virus (VSIV-3). A number of vesiculoviruses have been found in nature infecting insects and wild animals. However, only vesicular stomatitis viruses cause outbreaks of vesicular disease in domestic animals (Rodriguez 2002).

VSV has the typical rhabdovirus morphology, with enveloped bullet-shaped virions approximately 70×180 nm in length (Bradish and Kirkham 1966). The core of the virion consists of a helical ribonucleoprotein containing the nucleocapsid (N), polymerase (L), and phosphoprotein (P). The outer shell is made of the matrix protein (M) covered with a lipid membrane containing the glycoprotein (G). Viral entry and exit to and from the infected cell are mediated by the glycoprotein, which also contains the main neutralizing antigenic sites.

The genome consists of a single strand of RNA of negative polarity approximately 1100–1300 nucleotides in length, depending on the virus (Rodriguez et al. 2002). Gene expression is regulated by a simple, yet elegant, mechanism in which level of expression is determined by the distance of each gene from a single promoter near the 3' end of the genome. Gene order is N, P, M, G, L. Therefore, the most frequently expressed gene is N and the least expressed gene is L (Ball et al. 1999). All genes code for a single protein except P, which contains a second open reading frame coding for two additional small basic proteins (C and C') of undetermined function (Kretzschmar et al. 1996; Spiropoulou and Nichol 1993).

In addition to protein and RNA, VS virions contain lipid and carbohydrates associated with the envelope. VSV can persist in the environment for short periods of time. The infectivity of VSV is unstable at pH 3, but stable between pH 5–10. It is rapidly inactivated at 56°C and by UV and x-ray irradiation. Virus infectivity is also sensitive to lipid solvents, detergents, formalin, and various common disinfectants such as sodium hypochlorite (bleach) (Rodriguez and Nichol 1999).

VS viruses are capable of infecting a wide variety of mammalian cell types, as well as insect, amphibian, and fish cells (Seganti et al. 1986). Some studies have implicated phosphatidyl serine, a component of the cell membrane of a wide variety of cells, as a receptor for VSV (Coll 1997; Schlegel et al. 1983). This might explain the wide range of cells that VSV can infect.

Peripheral blood mononuclear cells seem to be resistant to viral infection.

EPIDEMIOLOGY

Outbreaks of vesicular stomatitis are reported every year from southern Mexico to northern South America (Colombia, Venezuela, Ecuador, and Peru). In the United States, VS outbreaks occur in sporadic cycles at approximately 10-year intervals (Rodriguez 2002). The great majority of outbreaks are caused by VSNJV (>80%) and to a lesser extent VSIV-1. In Brazil, two subtypes of VSIV, Cocal (VSIV-2) and Alagoas (VSIV-3), commonly cause outbreaks, and sporadic outbreaks of VSIV-2 have been reported in Argentina (Rodriguez et al. 2000).

VS is not reported to occur outside the Americas, although there was one report of VS in France and other parts of Europe during World War I that was associated with the importation of horses from the United States (Letchworth et al. 1999). There are also reports of "erosive stomatitis" and "acute stomatitis" in cattle in South Africa; however, the causative agent was not identified (Hanson 1950).

Vesicular stomatitis commonly affects cattle, horses, and to a lesser extent swine. However, swine are very susceptible, particularly to VSNJV, and a large number of animals can be affected during outbreaks in swine farms. Sheep and goats seem to be relatively resistant to VSV infection, with clinical cases rarely reported (Hanson 1981). Despite the fact that antibodies to VSV are found in a large number of wild animals, such as peccaries, whitetail deer, several species of rodents, monkeys, and even birds, naturally occurring disease has not been reported in these species.

VSV infects humans causing flu-like symptoms, such as fever, myalgia, and severe headaches. Infections in veterinary and farm personnel during outbreaks of disease in livestock are usually associated with unprotected direct contact with sick animals, particularly when vesicular fluid or contaminated saliva are unintentionally sprayed onto the face. Gloves, goggles, and face masks are recommended to prevent exposure during examination of sick animals (Hanson et al. 1950). Laboratory infections are usually associated with procedures that generate infectious aerosols, such as centrifugation. All laboratory procedures with field viruses should be performed under biological safety level 3. At least one case of encephalitis in a child caused by VSIV-1 has been documented (Quiroz et al. 1988). Symptoms usually resolve within a week and fatalities have never been reported.

Transmission of VSV can occur by direct contact or by insect bites. Strains of VSNJV seem to be more readily transmissible by direct contact than those of VSIV-1 (Stallknecht et al. 1999; Martinez et al. 2003). Swine infected with VSNJV either clinically or subclinically can readily transmit to other swine by direct contact (Stallknecht 1999). Transmission by fomites is not well documented, but there are anecdotal accounts of transmission by contaminated milking equipment, feed, and rough forage (Hanson 1950; Hansen et al. 1985). Aerosol transmission from animal to animal has never been documented.

At least two groups of biting insects, sand flies (*Lutzomyia* spp.) and black flies (*Simulium* spp.), have been demonstrated to transmit VSV to susceptible hosts (Cupp et al. 1992; Tesh et al. 1972). In addition, virus has been isolated from several groups of wild-caught insects, including gnats and mosquitoes, during VS outbreaks or in the absence of outbreaks in endemic areas (Francy et al. 1988; Sudia et al. 1967). Insect transmission resulting in clinical disease in pigs has been recently demonstrated (Mead et al. 2004).

In infected animals, vesicular stomatitis virus is primarily localized to epithelial surfaces on the snout, mouth, tongue, coronary bands, teats, and lymph nodes draining the affected areas. Virus is not found in blood or urine and only rarely in feces, but saliva, vesicular fluid, and sloughing epithelium can contain large amounts of virus. Virus has been found in epithelial samples and oropharyngeal fluids for up to 10 days after initiation of clinical signs (Martinez et al. 2003).

PATHOGENESIS

Most information on the pathogenesis of VSV is from laboratory inoculation of swine or cattle. VSV pathogenesis is dependent on viral strain, host characteristics, route of inoculation, and virus dose. In swine, clinical disease consistently results when virus is inoculated intradermally by epidermal scarification of the snout or the coronary band with at least 10^6 virus infectious doses. Intradermal inoculation at other sites or intranasal instillation does not result in clinical disease, but virus can be isolated from tonsil swabs, indicating subclinical infection (Howerth et al. 1997).

VSV is a localized infection, with no viremia detected in cattle, horses, or swine. Primary replication seems to occur locally in keratinocytes (Rodriguez, unpublished results). Virus is readily found at the site of lesions or in the tonsil from which virus is shed in saliva or from local draining lymph nodes. Virus is not found in other tissues, including muscle, brain, liver, spleen, mesenteric lymph nodes, kidneys, and spinal cord (Rodriguez, unpublished results). Subclinically infected pigs can shed virus for several days via the saliva and transmit infection to other swine by direct contact (Stallknecht et al. 1999).

Vesicular stomatitis serotype New Jersey seems to cause more severe disease in swine than serotype Indiana. Pigs inoculated with VSNJV by scarification of the snout develop large vesicles at the inoculation site in 2–3 days, followed by coronary band lesions by 5–7 days postinoculation. In contrast, VSINV inoculated swine

develop only small lesions at the inoculated site and rarely generalize to the feet or transmit the infection to contact pigs. This difference in virulence between serotypes in swine is likely associated with the glycoprotein gene (Martinez et al. 2003). Host factors also seem to affect outcome of infection; lactating adult animals seem more susceptible to clinical disease than younger animals (Vanleeuwen et al. 1995).

CLINICAL SIGNS

Field studies following animal populations over time in endemic areas or during active outbreaks in areas of sporadic occurrence have demonstrated that the great majority of infections are subclinical (Mumford et al. 1998; Rodriguez et al. 1990; Stallknecht et al. 1985; Webb et al. 1987). The incubation period varies from 2–5 days, depending on the virus, route, and dose of inoculation. Initial signs in swine may include fever of 40–41°C, lethargy, loss of appetite, and increased salivation. Lesions appear 3–4 days after infection. Pigs tend to remain prostrate, because foot lesions can be severe and painful. Snout lesions can be severe and lead to loss of epithelium, leaving a raw reddish surface (refer to Figure 31.3). After vesicles rupture, there is usually crusting of the lesions before healing is complete 2–3 weeks later (Martinez et al. 2003). Morbidity can be high, and in some cases approach 90–100% of individuals in swine herds. But individual cases are also reported, particularly in endemic areas. Mortality is rare.

Factors affecting clinical signs are not clearly defined. Laboratory inoculation models can only partially duplicate the severity of disease. It is hypothesized that environmental factors, such as insect bites, influence the development and severity of disease by modulating the immune response or other host-protective mechanisms (Tabachnick 2000). There is evidence that insect saliva can potentiate virus infection in vitro by decreasing cellular interferon response (Limesand et al. 2000).

LESIONS

Typically, vesicles appear on the snout, tongue, lips, mouth, coronary bands, interdigital space, or foot pads. Multiple lesions at different sites can occur in the same animal. Lesions begin as blanched areas with raised borders that evolve into vesicles or directly into crusted lesions. There may be loss of epithelium, leaving a reddish area covered by clear exudates or dry vesicular fluid. Profuse bleeding is not common. However, in severe cases bleeding may be associated with the loss of claws or epithelium. There are no characteristics unique to VSV gross lesions that differentiate them from other causes of vesicular disease in swine (SVD, FMD, and VES) (Jubb et al. 1985).

Histopathologically, VSV vesicular lesions start at the stratum spinosum with intercellular edema and mi-

crovesicles, followed by acantholysis. In early vesicles, epithelial cells remain attached by intercellular desmosomes, giving the tissue a reticular pattern sometimes compared to a stretched Japanese lantern (D. Gregg, personal communication). Later, there are infected and dead keratinocytes and a severe infiltrate of inflammatory cells, mostly neutrophils. Lesions rarely invade the stratum basale. Upper layers above the stratum basale separate, microvesicles coalesce, and vesicular fluid accumulates filling the vesicles (Seibold and Sharp 1960).

IMMUNITY

Immune responses to VSV in livestock species are poorly understood. Neutralizing antibodies are readily detectable as early as 4 days after clinical infection, with antibody titers increasing over time. Interestingly, subclinical infections also result in increasing titers of neutralizing antibodies, but higher titers (2–4 $\log_{10}$) are observed in clinical than in subclinical infections (1–1.5 $\log_{10}$). In endemic regions, neutralizing antibody titers fluctuate among animals without clinical disease, but fourfold increases or greater are usually associated with clinical infections (Rodriguez et al. 1990).

Isotype analyses show a typical IgM response at 4 days post infection, followed by IgG1 and IgG2 responses after 14–21 days, indicating both T-helper-1 and T-helper-2 responses in both clinical and subclinical cases (Rodriguez, unpublished results).

Antibody titers after subclinical infection in livestock do not correlate well with protection. Field evidence suggests that neutralizing antibodies are not protective, even against the homologous serotype, and animals can become clinically ill despite the presence of significant titers of neutralizing antibodies (Rodriguez et al. 1990). Furthermore, viral strains causing disease are fully neutralized by sera obtained from the same animals prior to clinical disease, and there is no evidence of neutralizing escape mutants (Vernon et al. 1990). There is no cross protection between serotypes.

Young animals are less susceptible to clinical disease than adults, but the basis of this resistance is unknown. Maternal neutralizing antibodies are detectable in calves born to seropositive dams, with titers decreasing over time. In most cases, maternal antibodies become undetectable by 6 months of age, but can persist for up to 10 months (Remmers et al. 2000).

DIAGNOSIS

VS lesions are localized in the mouth, tongue, coronary bands, and interdigital space, with occasional lesions in teats of lactating sows. Internal organs are not affected, but virus can also be found in local lymph nodes draining lesion sites (Mebus 1977).

Complement fixation is the traditional laboratory test for detection of viral antigens (Stone and DeLay

1963). The complement fixation test, though still practiced in many countries, has largely been replaced by the antigen-capture ELISA (Ferris and Donaldson 1988). However, the gold standard assay remains virus isolation in green monkey kidney cells (Vero), with subsequent agent characterization. Molecular detection of viral RNA has also been used, including detection by reverse transcription polymerase chain reaction (RT-PCR) individually or in multiplex assays with other vesicular disease (Nuñez et al. 1998; Rodriguez et al. 1993).

The gold standard test for antibody detection is VN using Vero cells as indicators. Nonspecific neutralizing activity of certain sera to VSV can result in false positives, particularly at lower serum dilutions. Paired sera and confirmatory tests, such as complement fixation and ELISA, are recommended (Katz et al. 1997). A competitive ELISA capable of detecting antibodies in various species has also been described (Katz et al. 1995).

PREVENTION AND CONTROL

Treatment of affected animals is not widely recommended, except for palliative measures such as feeding soft feeds and avoiding hard surfaced floors. Topical treatment of lesions with local antiseptics is advised for faster healing and decreasing the risk of secondary opportunistic pathogens. Disinfection of the facilities and separation of affected animals to minimize contact transmission is also recommended. Antibiotic therapy may be implemented to avoid secondary bacterial infections in severe foot or mouth lesions.

Since VSV is transmitted by insects, preventive measures should incorporate insect control with approved insecticides for farm use. Recent studies suggest that permethrin and similar compounds can reduce insect attacks for extended periods (Schmidtmann et al. 2001). In addition, housing animals during times of high insect activity (dawn and dusk) may reduce the attack rate (Hurd et al. 1999). Precautions should be taken to avoid transferring equipment and personnel from affected farms.

Vaccination is available in some endemic countries, where vaccines containing inactivated virus of each serotype are used prior to periods of high vector activity (Arbelaez and Cardona 1982). Vaccination is not recommended or cost-effective in countries with sporadic occurrence of VS. Once an outbreak has occurred, animals should be kept on the premises for at least 30 days after the last clinical case has resolved to avoid spread.

Swine Vesicular Disease

In 1966 a new disease emerged in Italy. The disease was clinically recognized as FMD, but was caused by another enterovirus distinct from FMD (Nardelli et al. 1968). This newly described disease was later called swine vesicular disease (SVD). The virus (SVDV) was subsequently isolated in an FMD vaccine trial in Hong Kong in 1971 (Mowat et al. 1972). In 1972, SVD was diagnosed in Great Britain, Austria, Italy, and Poland. The first case of SVD in the Netherlands occurred in 1975 (Franssen 1975). Recently Portugal (2004) and Italy (2004) have reported outbreaks of SVD (Table 31.1). The last outbreak in Taiwan was reported in 1999, but the virus is probably still present in Asian countries. North and South America are considered free of SVDV, and reports from cases of swine with vesicular conditions in Bolivia and Nicaragua (Table 31.1) are likely considered misdiagnoses.

SVD is currently classified as a list A disease by the Office International des Epizooties (OIE) because the lesions caused by SVD resemble those caused by foot-and-mouth disease. Because of the frequency of subclinical infection, most of the recent outbreaks in Italy were not discovered by clinical inspection, but by serological screening. In the absence of serological screening, the disease would probably be under-reported in Italy. Therefore, it is likely that the virus is present in more countries than those that officially report absence of the disease.

Human infection has been strongly suggested (Brown et al. 1976; Graves 1973), with subsequent need for hospitalization of the infected persons. Sequence homologies to Coxsackie-B5 virus (structural part of the virus) and Echo-virus 9 (nonstructural part of the virus; Zhang et al. 1999) suggest a common ancestor for these viruses. Therefore, SVDV infection in cell lines of human origin would not be surprising. Severe illness in humans, however, has not been reported recently, not even from laboratories working with large quantities of live virus during large-scale screening, so it remains questionable whether the illness leading to hospitalization in earlier reports was actually caused by SVDV.

ETIOLOGY

SVDV is classified as an enterovirus within family *Picornaviridae*. SVD virus is small (30–32 nm), nonenveloped, and contains a single strand of RNA with a positive polarity. Studies with polyclonal antibodies reveal only small antigenic differences among different isolates, and thus SVDV is considered to be a single serotype. Isolates, however, can be divided into four distinct phylogenetic groups by comparing them against panels of monoclonal antibody reaction patterns or nucleotide sequences of the 1D (VP1) gene (Borrego et al. 2002a, b; Brocchi et al. 1997).

The SVDV genome consists of approximately 7400

Table 31.1.   Year of last appearance of swine vesicular disease outbreaks in the world. Based on the *FAO-OIE-WHO Animal Health Yearbook (1971–1995)* and information obtained from the European reference laboratory for vesicular diseases in Pirbright (U.K.)

nucleotides and encodes for a single polyprotein of 2815 amino acids (Inoue et al. 1989). This polyprotein is post-translationally cleaved into 11 proteins. Four of these proteins, 1A, 1B, 1C, and 1D, form the virus capsid (Fry et al. 2003; Jimenez Clavero et al. 2003) and one of these proteins, 3B, is linked to the viral RNA. The nonstructural proteins are involved in virus replication and host-cell shut-off.

SVDV is extremely resistant to adverse environmental conditions and many commonly used disinfectants (Terpstra 1992). The virus remains infectious for months in carcasses and processed meat, e.g., salami or pepperoni sausages (Hedger and Mann 1989; Mebus et al. 1997).

The virus can be grown on primary or secondary porcine kidney cells and a wide range of pig kidney-derived cell lines and secondary lamb kidney cells (Dekker, unpublished data). SVDV can be differentiated from FMDV on the basis of its inability to grow on primary bovine thyroid cells.

SVDV infections in humans have been documented (Brown et al. 1976), and the virus is lethal to newborn mice (Nardelli et al. 1968). It shares with Coxsackie viruses its ability to infect mice, unlike other enteroviruses (Graves 1973). Because of these characteristics (host tropism and antigenic similarity) SVDV is thought to be closely related to Coxsackie B5 virus and likely represents a porcinophillic Coxsackie B5 isolate (Graves 1973). Nucleic acid sequence data show that SVDV has ~75–85% homology with Coxsackie B5 virus (Knowles and McCauley 1997), and phylogenetic analysis indicate that SVDV and recent Coxsackie B5 isolates probably shared a common ancestor in the period between 1945 and 1965 (Zhang et al. 1999).

EPIDEMIOLOGY

Outbreaks of SVD have been limited to a small number of countries (Table 31.1). However, since subclinical infections are common, the disease might have been present or is likely present in other countries and documentation is poor.

Clinical disease is restricted to pigs; not only Euro-Asian pigs, but also American one-toed pigs are susceptible (Wilder et al. 1974). Relatively high titers of SVDV have been detected in the pharynx of sheep kept in close contact with SVD-infected pigs (Burrows et al. 1974). Even neutralizing antibodies were detected in some of these contact sheep, which might indicate that the virus had replicated in this species.

An epidemiological field study in Great Britain revealed that the main source of infection was movement of pigs (48%), either because infected pigs were transported (16%), contaminated transport vehicles were used (21%), or because of contacts at markets (11%). A second source of infection (15%) was feeding of contaminated waste food (Hedger and Mann 1989). The exceptionally high stability of the virus outside the host is the reason why indirect contacts like transporting vehicles or waste food play an essential role in the epidemiology of SVD. Dekker et al. (1995a) showed that contact with a contaminated environment can lead to viremia in 1 day and clinical signs within 2 days. Studies on SVDV transmission within an outbreak farm showed that spread between pens most likely occurs when there is a shared open drainage system or frequent movement of pigs between pens. SVD, therefore, is considered a "pen disease" rather than a farm disease (Hedger and Mann 1989; Dekker et al. 2002).

Because infected herds are culled immediately in countries that maintain heightened surveillance and operational contingency plans, it is not easy to study the transmission of SVD in the field. IgM and IgG ELISAs have been developed to study the time the virus was introduced (Brocchi et al. 1995; Dekker et al. 2002). With these ELISAs, however, the exact time of introduction cannot be fully assessed, and after approximately 50 days the antibody isotype profiles of most infected animals are similar. Therefore, an estimation of the time of

introduction beyond 50 days is not possible (Dekker et al. 2002). In contrast to FMDV infections in ruminants, persistence of SVD in infected pigs is not common. There is one report where SVD virus was recovered up to 126 days after infection (Lin et al. 1998), but it has been difficult to reproduce these findings (Lin et al. 2001).

PATHOGENESIS

It has been suggested that SVDV enters the pig through the skin or the mucous membrane of the digestive tract (Chu et al. 1979; Lai et al. 1979; Mann and Hutchings 1980). Experimental SVDV infection can lead to clinical signs within 2 days and SVDV has been isolated from a wide range of tissues (Burrows et al. 1974; Chu et al. 1979; Dekker et al. 1995a; Lai et al. 1979). When pigs are exposed to an SVDV-contaminated environment, viremia can develop within 1 day. This is identical to the time frame when pigs are directly inoculated (Dekker et al. 1995a), which further suggests a mucous or abrasion point of entry.

SVDV has a strong tropism for epithelial tissues, but virus titers in myocardial and brain samples significantly exceed those found in plasma. As such, epithelial tissues, myocardium, and brain are probably the sites of virus replication (Chu et al. 1979; Lai et al. 1979) and excellent samples for analysis. Nevertheless, lymph nodes have also been shown to contain high titers of SVDV after experimental infection, either because of lymphatic drainage or true virus replication (Dekker et al. 1995a).

In vitro studies showed that immunological staining of cells is more efficient than in situ hybridization, with infected cells showing a positive reaction by immunohistochemistry after only 3.5 hours post infection of porcine kidney tissue culture. In situ hybridization, however, seems to be superior when used for staining of SVDV-infected tissue samples (Mulder et al. 1997).

Additional research is required to identify the cells that support SVDV replication, which may help identify the mechanism behind the host tropism of the virus.

CLINICAL SIGNS

Clinical disease is restricted to pigs. In pigs infected with SVDV, vesicles appear principally around the coronary bands (refer to Figures 31.4, 31.5); on the skin of the metacarpus and metatarsus; and to a lesser extent on the snout, tongue, and lips. Lesions are indistinguishable from those induced by an FMD infection. The clinical signs caused by SVD are, however, much milder than those caused by FMD. In the experimental studies performed by the author, fever was always absent and lameness was almost never observed. Sudden death, due to myocardial infarction and necrosis, often observed in young piglets affected with FMD, is not seen in SVD.

Strains of SVDV vary in virulence, and the disease may run a subclinical, mild, or severe course. The latter

is usually only seen when pigs are housed on concrete floor structures in humid conditions (Hedger and Mann 1989; Kanno et al. 1996; Kodama et al. 1980).

LESIONS

In typical cases of SVD, lesions are first noticed at the junction of the heel and the coronary band (as can be seen in Figures 31.4 and 31.5). The entire coronary band may eventually be affected with lesions spreading to the metatarsal and metacarpal regions. The horn and sole may be damaged so extensively that the claw(s) slough off. In lactating sows, lesions on the udder and teats can be seen (refer to Figure 31.6). Occasionally, the skin of the thorax and abdomen is also involved, which is not a finding with FMD or VSV infections. Lesions in the mouth, lips, and snout are not too common, but can be seen in approximately 10% of cases. Vesicular snout lesions are usually on the dorsal face of the rostrum and may be hemorrhagic in appearance. Tongue lesions are transient and heal rapidly (Hedger and Mann 1989). In experimentally infected animals, nonsuppurative meningoencephalitis may occur, but this does not result in signs of impaired central nervous system function (Chu et al. 1979).

DIAGNOSIS

The antibody response to SVDV infection is rapid. An IgM-based ELISA can detect a nascent immune response by day 4 post infection in 50% of experimental cases, by day 5 using the VN test, and by day 12 with an IgG-based ELISA (Dekker et al. 2002).

In the aftermath of an outbreak, absence of specific antibodies is essential to prove that no infected farms have been missed, since high titers of neutralizing antibodies are found (Nardelli et al. 1968) and subclinical infection may occur. VN tests, however, are laborious and ELISAs have been developed (Armstrong and Barnett 1989; Brocchi et al. 1995; Chenard et al. 1998; Dekker et al. 1995b; Hamblin and Crowther 1995). Although the ELISA is easier to perform than VN, it produces more false positive results. The specificity of the ELISA can be increased by using specific monoclonal antibodies (Brocchi et al. 1995; Chenard et al. 1998). This protocol has been adopted as the standard assay by the OIE and has been shown to be highly efficient in large-scale serosurveillance (Dekker 2000).

PREVENTION AND CONTROL

When SVD was first recognized, it was not easy to differentiate from FMD, VS, or vesicular exanthema. Therefore, it was generally accepted that SVD would not be tolerated in countries free from the other vesicular diseases. For this reason, SVD was placed on the list A diseases of the OIE and is, therefore, a notifiable disease in

most countries. In the case of an outbreak, SVD is strictly controlled by "stamping out" and the imposition of stringent restrictions on livestock movement. Stamping out involves the slaughter and destruction of the infected herds followed by thorough epidemiological tracing and surveillance of pigs on other premises that may have been exposed to infection. After the slaughter and disposal of pigs, the premises are cleaned and disinfected. Adequate disinfection is often difficult, especially in farms with damaged floors and walls. Several cases of recurring infection have been reported after stamping out measures, with infection recurring in the pens where the infected pigs had been previously housed (Hedger and Mann 1989). The costs of control measures and trade restrictions can be very high.

Because clinical signs are not always observed, serosurveillance is required, especially in the aftermath of an outbreak. Serological screening can detect subclinical or previously undetected clinical infections (Hendrie et al. 1978; Larenaudie et al. 1982; Pappous et al. 1980; Tokui et al. 1975). The Netherlands, Italy, and Spain are the only countries in the European Union to have large-scale serosurveillance programs. All other countries in the region rely on detection of SVD on the basis of clinical signs. Because of the large number of sera examined (approximately 500,000 a year in each country), considerable numbers of false-positive reactions are detected, each of which requires an exhaustive and extensive epidemiological study to determine the true status of the result. False-positive reactions, referred to as "singleton reactors," often show cross-reactive antibodies of the IgM isotype (De Clercq 1998). Studies to determine the cause of singleton reactors have identified a sole factor. Moonen et al. (2000) studied the possible role of human Coxsackie B5 as a confounding factor, but all singleton reactor sera reacted more strongly with SVDV than Coxsackie B5 virus. Kadoi et al. (2001), however, reported natural infection of pigs with Coxsackie B5 virus.

Experimental vaccines have been developed to control SVD infection (Delagneau et al. 1974; Gourreau et al. 1975; McKercher and Graves 1976; Mowat et al. 1974). In addition to SVD monovalent vaccines, combinations with FMD (McKercher and Graves 1976; Mitev et al. 1978) and, recently, an SVD subunit vaccine have been described. The latter vaccine was shown not to be efficacious (Jimenez Clavero et al. 1998). Although inactivated virus preparations are efficacious in protecting against clinical signs, these have not been evaluated relative to their ability to reduce wild-type virus transmission. Currently, no SVD vaccine is commercially available and vaccination has not been undertaken in the field.

32 Miscellaneous Viral Infections

X. J. Meng, C. A. Baldwin, François Elvinger, Patrick G. Halbur, and Carolyn A. Wilson

This chapter focuses on viruses that are currently important to veterinary and human public health from a zoonotic and xenozoonotic perspective. The clinical significance and economic impact of these viruses on pig health are still uncertain. Swine hepatitis E virus (swine HEV), porcine endogenous retroviruses (PERV), and porcine lymphotropic herpesviruses (PLHV) are all of concern in human xenotransplantation with pig organs, tissues, and cells. Eastern equine encephalomyelitis virus (EEEV), Rabies virus, and swine HEV all pose zoonotic risks.

Swine Hepatitis E Virus
X.J. Meng and P.G. Halbur

Hepatitis E virus (HEV), the causative agent of human hepatitis E, is an important public health problem in many developing countries in Asia and Africa (Emerson and Purcell 2003; Purcell and Emerson 2001). The mortality rate associated with HEV infection is generally low (<1%) but can reach up to 25% during pregnancy (Kumar et al. 2004; Purcell and Emerson 2001). Although only sporadic cases of acute hepatitis E have been diagnosed in patients from industrialized countries, including the United States, a surprisingly high HEV antibody (anti-HEV) prevalence rate has been reported (Drobeniuc et al. 2001; Meng et al. 1999, 2002). The existence of a population of individuals in industrialized countries who are positive for anti-HEV has led to a hypothesis that an animal reservoir for HEV exists and that hepatitis E is a zoonosis (Meng 2003, 2004).

The first experimental evidence of HEV infection of pigs was reported by Balayan et al. (1990) who experimentally infected domestic pigs with a Central Asian strain of human HEV. Clayson et al. (1995) subsequently reported the detection of anti-HEV IgG in 18 of 55 pigs and of HEV RNA from sera and feces in 3 of 47 swine in Nepal. Unfortunately, the identity of the virus infecting swine in those studies was not determined. Meng et al. (1997) isolated and characterized the first animal strain of HEV, swine hepatitis E virus (swine HEV), from pigs in the United States. To isolate swine HEV, a prospective study was conducted in a commercial swine farm in Illinois. Twenty piglets, born to both anti-HEV negative and positive sows, were closely monitored for more than 5 months for evidence of HEV infection. A virus antigenically and genetically related to human HEV, designated swine HEV, was identified from the acute phase sera of the naturally infected piglets. Koch's postulates were subsequently fulfilled, as swine HEV infection was experimentally reproduced in specific-pathogen-free (SPF) pigs, and swine HEV was recovered from experimentally infected SPF pigs (Halbur et al. 2001; Meng et al. 1998a, 1998b).

The discovery of swine HEV and the demonstrated ability of swine HEV to infect across species raised potential concerns relative to food safety, public health, and xenotransplantation with pig organs and cells. However, the clinical implication of this virus in swine health is uncertain.

ETIOLOGY

HEV was initially classified in the family *Caliciviridae* based on the superficial similarity of its genomic organization to the caliciviruses. However, further comparative sequence analyses revealed that the codon usage and genomic organization of HEV are more related to that of rubella virus (a togavirus) than to that of the cali-
32.1. *Genomic organization of swine HEV. ORF1 encodes for nonstructural proteins, ORF2 for capsid protein and ORF3 for a small protein of unknown function. NCR, nocoding region; MT, methyltransferase; Y, "Y" domain; PLP, a papain-like cysteine protease; Pro, a proline-rich domain that may provide flexibility; HVR, a hypervariable region; Hel, helicase; RdRp, RNA-dependent RNA polymerase.*

civiruses (Koonin et al. 1992). Additionally, HEV possesses a cap structure at its 5′ end of the genome that is absent in calicivirus and does not share significant sequence homology with caliciviruses. Therefore, HEV has recently been reclassified in the new family *Hepeviridae* (Emerson and Purcell 2003). All strains of HEV identified thus far, including swine HEV, belong to the prototype genus *hepevirus* within the family.

HEV is a spherical, nonenveloped, symmetrical virus particle approximately 32–34 nm in diameter, with cup-shaped depressions on the surface similar to caliciviruses (Purcell and Emerson 2001). The morphology of swine HEV is not known, but is expected to be similar to that of human HEV. Like human HEV, swine HEV cannot be efficiently cultivated in cell culture.

The complete genome of swine HEV has been sequenced and shown to be a polyadenylated, single-stranded positive sense RNA molecule of approximately 7.2 kb in size (Meng et al. 1998a). Sequence analyses revealed that the genome of swine HEV contains three open reading frames (ORFs), a short 5′ noncoding region (NCR), and a short 3′ NCR (Figure 32.1).

ORF1, located at the 5′ end of the genome, is predicted to encode the nonstructural proteins. Several putative functional domains and motifs have been identified in the swine HEV ORF1, including the methyltransferase domain, a papain-like cysteine protease (PLP), a proline-rich domain that may provide flexibility, a hypervariable region (HVR), a helicase, and an RNA-dependent RNA polymerase (RdRp) (refer to Figure 32.1).

ORF2 encodes the immunogenic capsid protein. ORF3, encoding a small protein with unknown function, partially overlaps both ORF1 and ORF2. The ORF3 of human HEV is a cytoskeleton-associated phosphoprotein that may be involved in virus replication (Zafrullah et al. 1997).

EPIDEMIOLOGY

Seroepidemiological studies have shown that swine HEV infection is ubiquitous in pigs worldwide, both developing and industrialized countries, regardless of whether HEV is endemic in the respective human population (refer to Table 32.1). Seroprevalence rates vary from herd to herd and from region to region (Table 32.1).

Infected pigs generally have a transit viremia lasting for 1–2 weeks and shed viruses in feces for 3–7 weeks (Huang et al. 2002; Meng et al. 1998b; Takahashi et al. 2003). HEV infection generally occurs at 2–3 months of age (Figure 32.2), shortly after maternal antibodies have waned. This coincides with the time frame when pigs are moved to pens, an environment with increased opportunity for fecal cross-contamination (Huang et al. 2002; Meng et al. 1997). Adult pigs, sows, and boars, although commonly positive for anti-HEV IgG, are generally free of virus shedding.

Sequence analyses of swine HEV isolates identified thus far revealed the existence of at least two genotypes of swine HEV worldwide, i.e., genotypes 3 and 4 (Figure 32.3). In humans, both genotypes 3 and 4 HEV strains are known to cause sporadic cases of hepatitis E, whereas HEV strains of genotypes 1 and 2 are often associated with hepatitis E epidemics in Asia and Mexico (Meng 2004).

Besides domestic pigs, swine HEV also infects wild boars (Chandler et al. 1999). Under experimental conditions, rhesus monkeys and chimpanzees were susceptible to infection by swine HEV (Meng et al. 1998a). Rhesus monkeys experimentally inoculated with swine HEV seroconverted to anti-HEV IgG 4 weeks postinoculation. Viremia and fecal excretion of swine HEV were detected in inoculated rhesus monkeys. Serum liver enzymes, alanine aminotransferase (ALT), and isocitrate dehydrogenase (ICD) were both slightly elevated in the inoculated primates (Figure 32.4). Mild acute viral hepatitis characterized by focal necroinflammatory changes was observed in liver biopsies near the time of serum liver enzyme elevations. A chimpanzee inoculated with swine HEV also became infected, as the chimpanzee seroconverted to anti-HEV and swine HEV RNA was detected in feces.

Infection of nonhuman primates with swine HEV demonstrated the ability of swine HEV to infect across species barriers. Importantly, a genotype 3 human strain of HEV (strain US-2) has been shown to infect SPF pigs (Halbur et al. 2001; Meng et al. 1998a). The inoculated pigs rapidly became viremic and seroconverted to

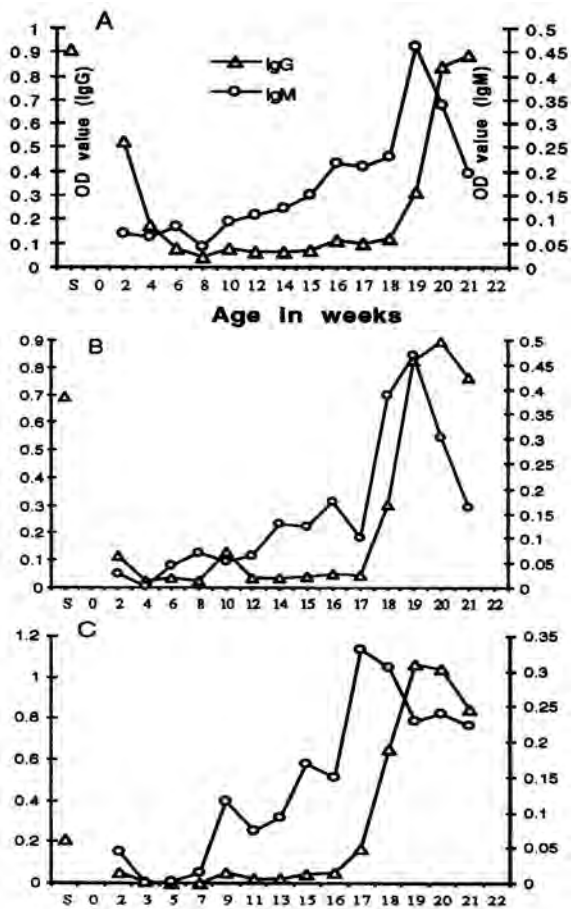
HEV, suggesting that the US-2 strain of human HEV is already competent to replicate in pigs and may be of swine origin.

Cross-species infection of HEV has also been reported in other animal species. Lambs were reportedly infected with human HEV isolates (Usmanov et al. 1994). Similarly, Wistar rats were reportedly infected with a human stool suspension containing infectious HEV (Maneerat et al. 1996). However, attempts to infect laboratory rats and mice experimentally with swine HEV were unsuccessful (Sun and Meng, unpublished data).

Increasing evidence indicates that swine HEV also infects humans. Hsieh et al. (1999) found that about 27% of the Taiwanese pig handlers were positive for anti-HEV compared to only about 8% of control subjects. Recently, Meng et al. (2002) tested a total of 465 swine veterinarians for anti-HEV IgG using recombi-

nant capsid antigens from swine HEV and a Pakistani Sar-55 strain of human HEV. Among the 295 swine veterinarians from 8 U.S. States from which 400 normal U.S. blood donors were available, about 23% (swine HEV antigen) or 27% (Sar-55 antigen) of swine veterinarians were positive for anti-HEV compared to 17% (swine HEV antigen) or 18% (Sar-55 antigen) in normal blood donors. Swine veterinarians in the U.S. were 1.51 times (swine HEV antigen, $p = 0.03$) and 1.46 times (Sar-55 antigen, $p = 0.06$) more likely to be anti-HEV positive than normal U.S. blood donors. Veterinarians who reported having needle sticks while performing procedures on pigs were about 1.9 times more likely to be seropositive than those who did not. Also, subjects from traditional major swine states appeared to be more likely seropositive than those from traditionally non-swine States. For example, subjects from Minnesota, a major swine state, were about 5–6 times more likely to be


32.2. *Anti-HEV responses of three representative piglets from a prospective study in a commercial swine farm. (A) Piglet born to a seropositive sow with a high titer of IgG anti-HEV. (Reproduced with permission by the National Academy of Science from Meng et al. 1997.)*

seropositive than those from Alabama, which is traditionally not a major swine state.

Drobeniuc et al. (2001) also assessed the anti-HEV prevalence and risk factors to HEV infection in 264 swine farmers and 255 control subjects in Moldova. About 51% of swine farmers were anti-HEV positive whereas only 25% of control subjects with no occupational exposure to swine were seropositive. Withers et al. (2002) reported that swine workers (n = 165) in North Carolina had a 4.5-fold higher anti-HEV prevalence (10.9%) than the control subjects (2.4%, n = 127).

These data provide compelling evidence that hepatitis E is a zoonotic disease and that pigs are reservoirs (Meng 2003, 2004).

The transmission route for swine HEV is presumably fecal-oral. Feces from infected pigs are likely the main source of virus for transmission. It has been shown that an uninoculated sentinel SPF pig housed in the same room with a swine HEV-inoculated pig became infected about 2 weeks after the experimentally inoculated pig had become infected (Meng et al. 1998a).

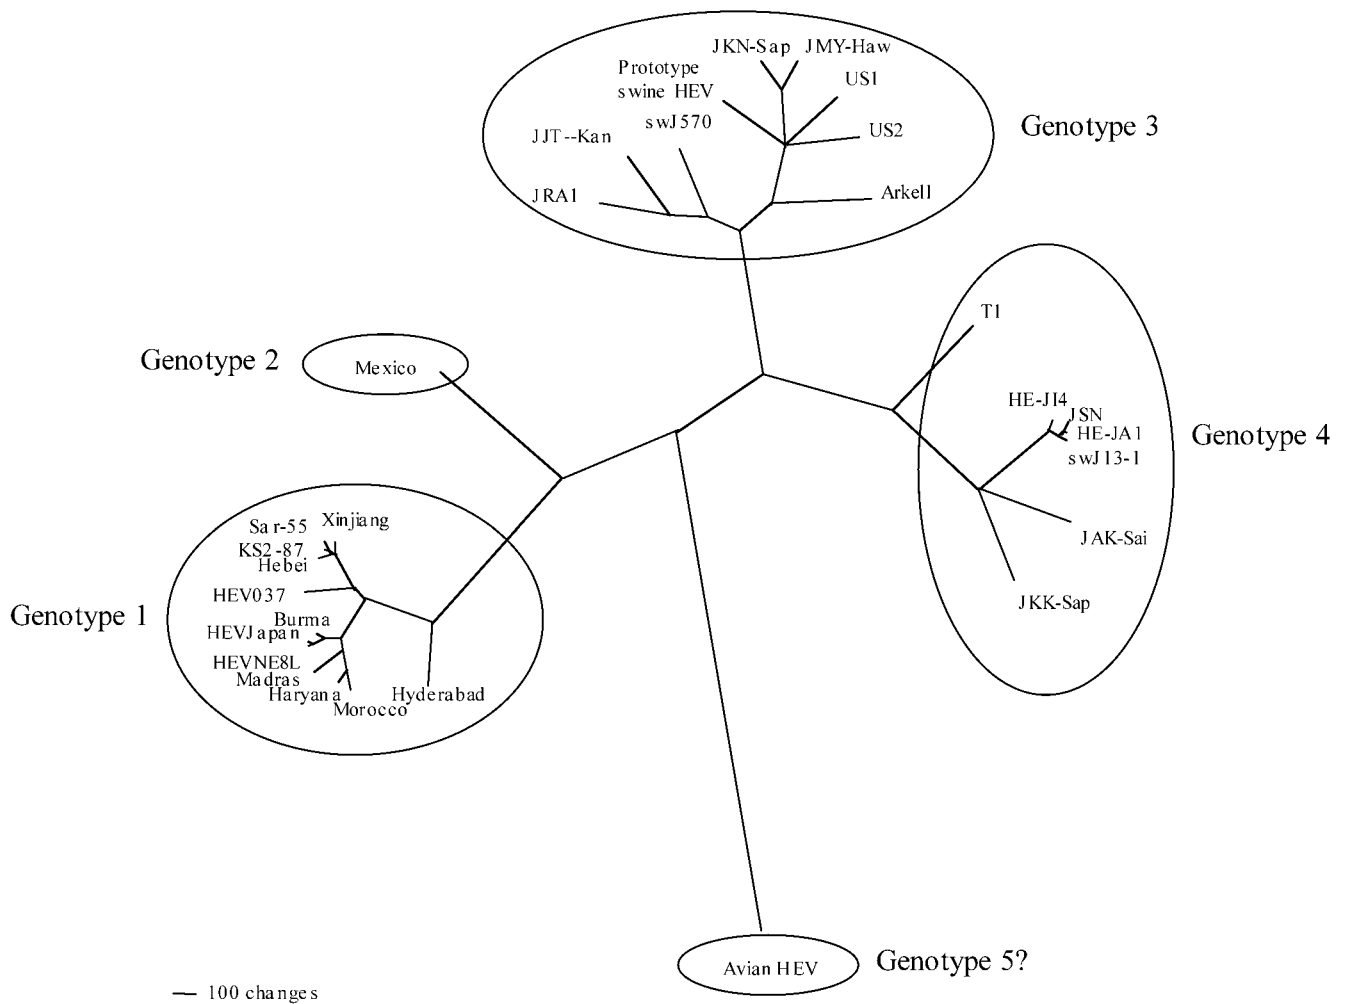
It is believed that pigs acquire infection through direct contact with infected pigs or through ingestion of feces-contaminated feed or water. However, experimental reproduction of swine HEV infection in pigs via the oral route of inoculation proved to be difficult (Kasorndorkbua et al. 2002), even though pigs can be readily infected with swine HEV via the intravenous route of inoculation (Halbur et al. 2001; Meng et al. 1998a, b). Other route(s) of transmission cannot be ruled out.

As a fecal-orally transmitted disease, waterborne epidemics are characteristic of hepatitis E outbreaks in humans (Purcell and Emerson 2001). Feces from infected pigs contain large amounts of virus, and thus swine manure and feces could contaminate irrigation water or coastal waters, thereby leading to possible contamination of produce or shellfish (Meng 2004). HEV strains of swine origins have been detected in sewage water (Clemente-Casares et al. 2003; Pina et al. 2000).

Yazaki et al. (2003) recently reported that sporadic cases of acute hepatitis E in Hokkaido, Japan were epidemiologically linked to consumption of grilled or undercooked pig livers about 2–8 weeks prior to the onset of disease. The partial sequences of seven swine HEV isolates recovered from packaged pig livers in local grocery stores are very closely related, or identical in a few cases, to the viruses recovered from human hepatitis E patients, and thus provide more direct evidence of zoonotic transmission between pigs and humans.

PATHOGENESIS

The pathogenesis of swine HEV is largely unknown. It is believed that swine HEV enters the host through the fecal-oral route (Purcell and Emerson 2001; Williams et al. 2001). The primary site of swine HEV replication in pigs is not known. In primates and pigs experimentally infected with swine HEV, virus replication in the liver has been demonstrated (Meng et al. 1998a, b).

It is believed that, after replication in liver, swine HEV is released to the gallbladder from hepatocytes and is then excreted in feces. Williams et al. (2001) showed the existence of extrahepatic sites of HEV replication in pigs experimentally infected with swine HEV and the US-2 strain of human HEV. By using a negative strand-specific RT-PCR, replicative negative-strand HEV RNA, indicative of virus replication, was detected in the liver, as well as in several extrahepatic tissues and organs, including small intestines, colon, and hepatic and mesenteric lymph nodes of infected pigs. Using in situ hybridization, Choi and Chae (2003) also detected swine HEV RNA in hepatocytes and bile duct epithelium as well as in small and large intestines, lymph nodes, tonsil, spleen, and kidney. Although the clinical and pathological significance of these extrahepatic sites of virus


32.3. *A phylogenetic tree based on the complete genomic sequences of 30 human, swine, and avian HEV strains. Swine HEV strains identified thus far belong to either genotype 3 or 4. replication is not known, it is believed that swine HEV may first replicate in the gastrointestinal tract and subsequently spread to its target organ, the liver, via primary viremia.

In humans, it has been reported that pregnancy increased the severity and mortality of the disease. The overall mortality rate caused by HEV in infected pregnant women can reach 25% (Kumar et al. 2004; Purcell and Emerson 2001). However, under experimental conditions, fulminant hepatitis E could not be reproduced in infected pregnant rhesus monkeys, nor was there increased severity of hepatitis in pregnant monkeys when compared to nonpregnant monkeys (Tsarev et al. 1995). Similarly, pregnant gilts experimentally infected with swine HEV did not exhibit any more severe disease than the nonpregnant controls (Kasorndorkbua et al. 2003). Reproductive failure or clinical hepatitis was not observed in HEV-infected gilts. Therefore, the mechanism of fulminant hepatitis E in infected pregnant women is still not known.

CLINICAL SIGNS

Pigs naturally and experimentally infected with swine HEV are asymptomatic. The incubation period, from the time of infection to virus shedding in feces, ranged from 1–4 weeks (Halbur et al. 2001; Meng et al. 1998a, b). The percentage of HEV-infected pigs within a herd is very high (refer to Table 32.1); however, the morbidity and mortality attributable to swine HEV infection is not known.

LESIONS

Four piglets naturally infected with swine HEV in a prospective study were necropsied during the acute stage of infection (Meng et al. 1997). Gross lesions were not detected in the liver or 18 other tissues and organs examined during necropsy. However, all four piglets had microscopic evidence of hepatitis, characterized by mild-to-moderate multifocal and periportal lympho-

32.4. *Experimental infection of rhesus monkeys with swine HEV. Levels of serum liver enzymes (ALT and ICD) are plotted. Presence (filled circle) or absence (open circle) of anti-HEV and swine HEV RNA in serum and feces is indicated. Half-filled circles indicated detection of swine HEV RNA only by a nested PCR. The degree of liver lesions in liver biopsies is indicated (scale of 0 to 4+). (Modified with permission from Meng et al. 1998.)*

32.5. *Histological liver lesions in pigs experimentally infected with swine HEV or human HEV. (A) Liver of a pig experimentally infected with the swine HEV, showing mild focal infiltration of lymphocytes, plasma cells, and macrophages and mild diffuse inflammation in hepatic sinusoids at 14 days postinoculation (DPI). Hepatocytes are mildly swollen and vacuolated. (B) Liver of a pig experimentally infected with the US-2 strain of human HEV, showing moderate lymphoplasmacytic and histiocytic hepatitis and severe vacuolar degeneration and swelling of hepatocytes at 14 DPI. Hematoxylin and Eosin stain. (Reproduced with permission by the American Society for Microbiology from Halbur et al. 2001.)*

plasmacytic hepatitis with mild focal hepatocellular necrosis. All four piglets also had mild lymphoplasmacytic enteritis and three piglets had mild multifocal lymphoplasmacytic interstitial nephritis.

Under experimental conditions, SPF pigs inoculated with swine HEV and the US2 human HEV remained clinically normal. However, the infected pigs did have mildly to moderately enlarged hepatic and mesenteric lymph nodes from 7–55 days postinoculation (DPI). Microscopic lesions characterized by mild-to-moderate multifocal lymphoplasmacytic hepatitis and focal hepatocellular necrosis were observed in experimentally infected pigs (Figure 32.5). Hepatic inflammation and hepatocellular necrosis peaked in severity at 20 DPI. HEV RNA was detected in feces, liver tissue, and bile of infected pigs from 3–27 DPI (Halbur et al. 2001).

All 12 pregnant gilts experimentally inoculated intravenously with swine HEV at various stages of gestation became infected and shed the virus in feces (Kasorn-

dorkbua et al. 2003). These gilts had no clinical signs of hepatitis or elevation of liver enzymes throughout the 55 days of the study. There was no significant effect of swine HEV on fetal size, fetal viability, or offspring birth weight or weight gain. There were no remarkable gross lesions in the gilts, fetuses, or piglets from gilts that were allowed to farrow. Mild multifocal lymphohistiocytic hepatitis and individual hepatocelluar necrosis was observed in 4 of the gilts. There were no remarkable lesions in the fetuses from HEV-infected dams. Evidence that HEV is a reproductive pathogen in pigs is currently lacking.

IMMUNITY

The immune response in pigs to swine HEV infection, characterized by a transient appearance of anti-HEV

IgM followed by long-lasting anti-HEV IgG, appears late during the period of viremia and fecal virus shedding (Meng et al. 1998a, b). Like human HEV, the capsid protein of swine HEV is immunogenic and induces protective immunity. It has been demonstrated that the ORF2 capsid protein of swine HEV shares common antigenic epitopes with that of human HEV and the newly identified avian hepatitis E virus (Haqshenas et al. 2002). All HEV strains identified thus far, including the genotypes 3 and 4 swine HEV, appear to belong to a single serotype. Cross-challenge experiments in primates have demonstrated cross-protection following infection with different genotypes of human HEV strains (Purcell et al. 2003).

Sows with high anti-HEV titers can passively transfer anti-HEV to their offspring, and thus some piglets are seropositive shortly after birth. Piglets born to seropositive sows had maternal antibodies lasting about 7–9 weeks (Meng et al. 1997). It is believed that maternal antibodies confer protective immunity to the piglets against swine HEV infection.

DIAGNOSIS

Swine HEV is a difficult virus to work with because it does not grow in cell culture or cause any clinical disease in pigs. Currently, the diagnosis of swine HEV infection is primarily based on PCR and ELISA (Engle et al. 2002; Huang et al. 2002). However, the sensitivity and specificity of these assays are largely not known. The recombinant human HEV capsid antigen cross-reacted well with antibodies to swine HEV in an ELISA assay and has been used to detect anti-HEV antibody in swine (Engle et al. 2002; Meng et al. 1999, 2002). The capsid protein of a genotype 3 swine HEV has also been expressed and used in an ELISA to detect anti-HEV (Meng et al. 2002). ELISA results based on the recombinant swine HEV antigen correlated well with those obtained with a recombinant antigen from the Sar-55 strain of human HEV. Therefore, both swine HEV and human HEV capsid antigens are suitable for diagnosis of swine HEV infection by ELISA. There is no specific test for differentiating between infections with swine HEV and human HEV.

Serological assays alone are inadequate in screening for acute swine HEV infection since anti-HEV IgG generally occurs in pigs at least 2 weeks after infection. Viremia and fecal virus shedding occur in infected pigs much earlier than the appearance of anti-HEV, and thus seronegative pigs could still be infected with swine HEV (Meng et al. 1998a, b). A sensitive and specific RT-PCR assay has been successfully developed for the detection of swine HEV from infected pigs (Huang et al. 2002). However, the specificity of the current RT-PCR assays in detecting swine HEV in pigs from different geographic regions is not known. Swine HEV strains identified from pigs in different geographic regions vary considerably in their genomic sequences and belong to at least two different genotypes (Meng 2004). Therefore, genetic identification and characterization of additional field strains of swine HEV from different geographic regions will be critical for developing a universal RT-PCR assay that can detect all strains of swine HEV in pigs. Since genotypes 3 and 4 swine and human HEVs are genetically indistinguishable, a differential diagnostic assay for swine HEV is not possible or necessary.

PREVENTION AND CONTROL

Swine HEV is ubiquitous in pigs worldwide and has the ability to infect humans. Therefore, the major concerns for swine HEV are (1) infection in high risk groups, such as swine veterinarians, swine producers, and other pig handlers, and (2) transmission of swine HEV from pig xenografts to human transplant recipients in xenotransplantation and the potential subsequent transmission of the virus to others.

Although swine HEV caused only subclinical infection in pigs, the outcome of exposure of immunosuppressed xenograft recipients is uncertain (Meng 2003). Unlike some other porcine viruses, such as the porcine endogenous retrovirus, xenograft donor pigs free of swine HEV can be derived from infected breeding herds. A recent study showed that piglets negative for swine HEV can be successfully generated through segregated early weaning from pregnant sows experimentally infected with swine HEV (Kasorndorkbua et al. 2003; Brad Thacker, personal communication). Therefore, the potential xenozoonotic risk of infection by swine HEV in xenotransplantation is preventable through adequate screening and strict rearing procedures for donor pigs.

As a zoonotic virus, swine HEV poses a potential public health concern. A vaccine against HEV is not yet available, but experimental recombinant HEV vaccines appear to be effective (Purcell et al. 2003), although their efficacy must be thoroughly evaluated for protection against emerging strains of HEV including genotypes 3 and 4 swine HEV. Vaccination of pig handlers in industrialized countries against HEV, when a vaccine becomes available, appears unnecessary since a high proportion of swine handlers were seropositive for HEV but had no clinical symptoms. However, the occurrence of acute hepatitis E in industrialized countries may be underestimated because sporadic cases of acute hepatitis E may go undiagnosed. Adequate personal and public hygiene can minimize the transmission of the virus. A simple preventive measure for pig handlers is to wash hands thoroughly with soap and water after handling pigs.

Although swine HEV is nonpathogenic in pigs, it is not known whether concurrent infections of swine HEV with other swine pathogens could have any synergistic effects. Therefore, it will be advantageous for the swine industry to produce HEV-free pigs for purposes such as seed stock production, biomedical research, and xeno-

transplantation. If sporadic cases of hepatitis E continue to occur in people as a result of consumption of under-cooked pork, it may also become important to eliminate swine HEV from commercial production.

Porcine Retroviruses

C. A. Wilson

Retroviruses are defined by the requirement for reverse transcription of their RNA genome into a double-stranded DNA intermediate as a key element to their replication strategy. While there are no known exogenous retrovirus infections of pigs, pigs do carry porcine endogenous retroviruses (PERVs). PERVs comprise a group of heritable viruses that, unlike exogenous viruses, cannot be excluded from pig herds because they are present as genetic elements in the genomes of all pigs.

Although no swine disease has been definitively attributed to PERV, type C retrovirus particles have been detected in porcine cell lines derived from leukemias or lymphomas (Frazier et al. 1969; Moennig et al. 1974) fueling speculation that the endogenous retrovirus of pigs may be tumorigenic. In addition, PERV is related morphologically and genetically to murine retroviruses shown to be the cause of leukemias in mice (Czauderna et al. 2000). However, the association of PERV with leukemic cell lines was not sufficient to assign PERV as the causative agent, since it was impossible to distinguish cause from effect in these studies. As a result, the investigations into whether PERVs may be tumorigenic were ultimately abandoned.

Scientific interest in PERVs was renewed when it was found that co-culture of primary pig cells (Martin et al. 1998; Wilson et al. 1998) or established pig cell lines (Patience et al. 1997) with human cell lines resulted in a productive infection of the human cells. These findings took on particular importance as they coincided with increased interest in developing clinical xenotransplantation, i.e., the transplantation of nonhuman cells or organs into humans. The development of transgenic pigs carrying two human genes that were thought to prevent hyperacute rejection was hoped to spearhead the clinical application of xenotransplantation (Byrne et al. 1997). However, the finding that pig cells harbored endogenous retroviruses capable of infecting human cells underscored the potential public health concerns of xenotransplantation. Many scientists predicted that it would be unlikely that PERV could be removed from the pig genome, given an estimated presence of 50–200 copies of PERV sequences per cell (Akiyoshi et al. 1998; Patience et al. 1997).

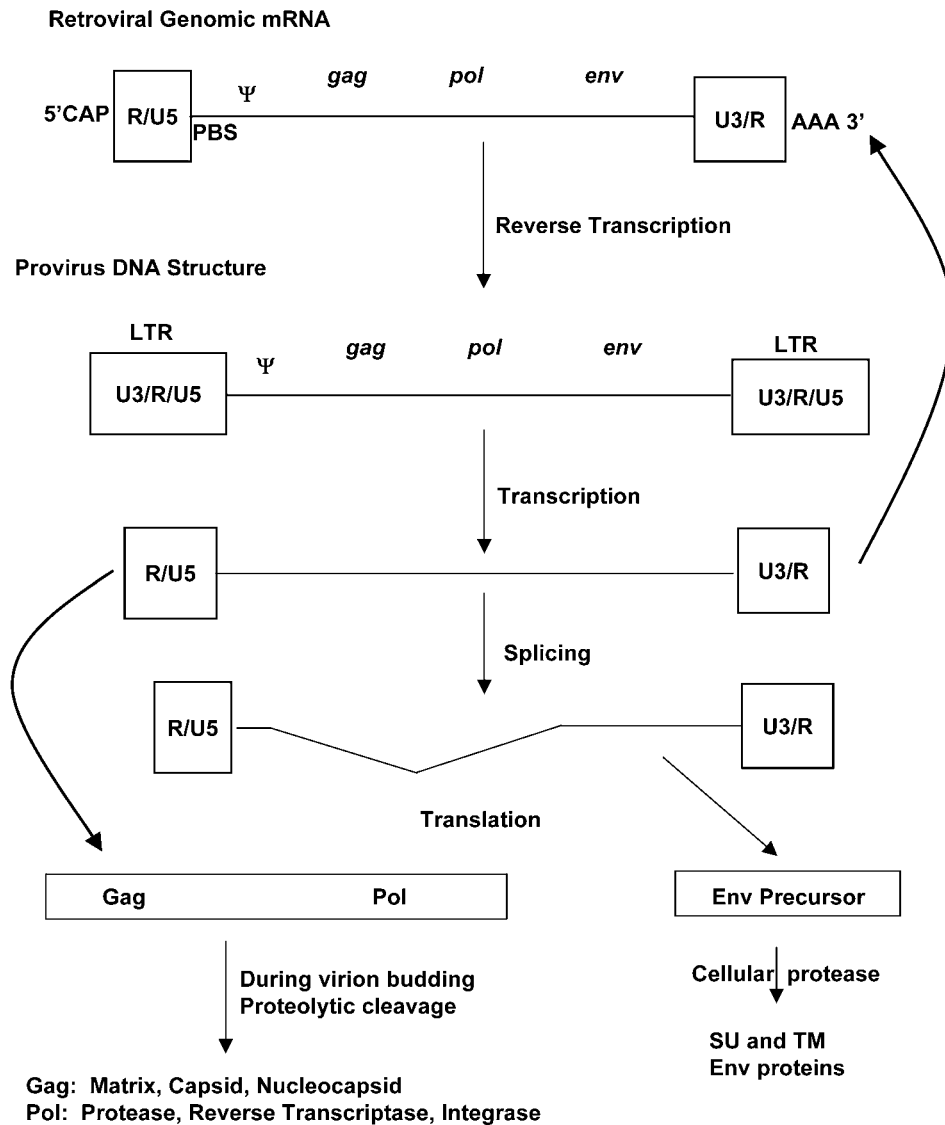
While some scientists argued that the pathogenic potential of PERV in humans is low, based on past human exposure to pigs as domesticated animals, others argued that xenotransplantation procedures differed significantly:

1. Xenotransplantation by its nature breaks down the usual boundaries of cross-species transmission of infectious agents, such as skin and mucosal membranes, resulting in essentially a chronic coculture of animal and human cells in vivo.
2. The likelihood that xenotransplant recipients will be immune-suppressed circumvents another natural barrier to transmission of infectious agents.
3. The possibility that transgenic modifications of human complement regulatory proteins could reduce the ability of natural antibodies to protect against PERV transmission.

These considerations were supported by historical examples of naturally occurring cross-species transmission of viruses where the recipient species developed a disease not seen in the host species. For example, HIV is thought to be an outcome of transmission of a nonpathogenic animal virus into humans, resulting in a fatal disease (Hahn et al. 2000). Therefore, efforts to prevent PERV transmission or eliminate PERVs from pig herds are under study because success would enhance the safety profile of xenotransplantation procedures in humans and reduce the potential impact on the public health.

ETIOLOGY

PERVs belong to the family *Retroviridae*, genus *Gamma-retrovirus*. Retrovirus particles are characteristically 100 nm in diameter and carry a plasma membrane-derived lipid bilayer envelope and a single-stranded RNA genome in diploid form. The characteristic enzymatic activity of retroviruses is the ability to catalyze the conversion of the retroviral single-stranded RNA genome into a double-stranded DNA intermediate using the virally derived enzyme RNA-dependent DNA polymerase (or reverse transcriptase). A second virally encoded enzyme, integrase, mediates integration into the host genome of the double-stranded viral DNA.

The genomic organization of PERVs is analogous to other gammaretroviruses and has been shown to consist of three open reading frames, gag, pol, and env (Akiyoshi et al. 1998; Czauderna et al. 2000) (Figure 32.6). The genomic RNA also includes elements found at the 5' and 3' ends that are required for poly-adenylation (U5), packaging (Ψ), reverse transcription (primer binding site, PBS), and RNA transcription (U3/R). As an outcome of reverse transcription, the U3/R/U5 elements are repeated at each end of the double-stranded DNA intermediate, and these are termed the Long Terminal Repeats (LTRs). After integration, the promoter and enhancer elements present in the U3 of the 5' LTR mediate RNA transcription of two mRNAs: 1) a full-length genomic RNA that is used for encapsidation into the viral particle as well as for translation of the gag-pol polyprotein, and 2) a spliced mRNA that encodes the envelope precursor. Cellular proteases cleave the envelope precursor into the mature surface envelope glycoproteins (SU) and transmembrane protein (TM). The gag-pol polyprotein is auto-proteolytically cleaved by the virally encoded enzyme, protease, during budding of the viral particle (refer to Figure 32.6). In fact, it is this proteolytic cleavage that results in the change in morphology from an immature particle with an electron dense C-shape into a mature particle bearing the characteristic electron-dense spherical core (Figure 32.7).


32.6. *Genomic organization and gene expression of porcine endogenous retrovirus. (See text for detailed description.)*
32.7. *Electron micrograph of porcine endogenous retrovirus. Human cells (HeLa) were infected with PERV and then fixed and negatively stained for electron microscopic observation. The micrograph shown is 25,000×. The particle labeled (1) is an immature viral particle demonstrating the hallmark C-shaped electron dense structure within the budding particle. The particle labeled (2) is a particle that has undergone proteolytic cleavage and has the electron-dense spherical structure within the mature virion.*

PERV is somewhat more labile than other gammaretroviruses. It has been shown that PERV infectivity is reduced over hundredfold by storage at −70°C (Wilson, unpublished data), a condition that would typically reduce virus infectivity by only five- to tenfold. Likewise, pelleting virions by ultracentrifugation, a method used to concentrate other gammaretroviruses with moderate impacts on infectivity, will completely abolish PERV infectivity (Wilson, unpublished data).

PERVs have been classified into three receptor classes on the basis of superinfection interference and in vitro cell tropism studies (Takeuchi et al. 1998). PERV-A and PERV-B use distinct receptors, but are both able to infect human cells, while PERV-C essentially only infects porcine cells in vitro. All three receptor classes can be cultured on established cell lines using classic retroviral techniques. PERV-A and PERV-B replicate most efficiently in the human embryonic kidney cell line, HEK293 cells, while viruses representing any of the three receptor classes will also replicate efficiently in the swine testis cell line, ST-IOWA (Takeuchi et al. 1998; Wilson et al. 2000).

EPIDEMIOLOGY

Pigs of all breeds carry in their genome endogenous retrovirus elements. Not all genomic elements will necessarily encode replication competent retrovirus, nor will all replicating retroviruses derived from the pig genome be able to infect human cells (Oldmixon et al. 2002). In fact, molecular analyses of DNA from representative species of the family *Suidae* and *Tayassuidae* have revealed the presence of PERV-like elements in the genomes of these wild relatives to the domesticated pig (Patience et al. 2001; Tonjes and Niebert 2003), indicating that the retroviral sequences were introduced into the germline of the pig long before domestication. Consistent with that observation are reports that PERV

sequences can be identified in all breeds of domesticated pigs examined to date (Edamura et al. 2004; Jin et al. 2000).

Some of the most detailed genetic and phenotypic studies of PERV have been performed in an inbred herd of miniature swine. The results of these studies indicate that genetic heterogeneity of the endogenous retroviral elements in the pig genome give rise to variable results within a herd with respect to whether infectious virus is present and whether that virus may be infectious for human cells in vitro (Oldmixon et al. 2002). In other words, one cannot predict whether a particular herd would express a form of PERV that replicates in human cells, since each individual animal may vary with respect to this characteristic. This finding is promising since it suggests a means to identify and selectively breed those animals that do not express human-tropic PERV.

Although comprehensive examination of PERV expression in different pig tissues and cells has not been reported, there are some data available for certain pig breeds and tissues. While most endogenous retroviruses (for example, those of mice) are maintained in a transcriptionally silent state, where activation of expression may only occur under rare conditions, such as immune activation, PERV may be different. For example, infectious PERV has been directly cultured from pig plasma, indicating that at least some tissue compartments of the pig may constitutively express infectious PERV (Takefman et al. 2001). Likewise, primary cultures of unstimulated pig endothelial cells as well as unstimulated or stimulated porcine bone marrow mononuclear cultures have also been shown to express infectious PERV (Martin et al. 1998; McIntyre et al. 2003). PERV has also been readily isolated from primary cultures of mitogenically activated peripheral blood mononuclear cells (Wilson et al. 1998), as well as cultured porcine islets (van der Laan et al. 2000). Expression of PERV RNA has been shown in a wide variety of other pig tissues (Clemenceau et al. 1999), indicating that perhaps under the right conditions, virus could be isolated from almost any type of pig cell. In general, reports have indicated that tissue-specific expression does not necessarily correspond across different breeds, nor would one animal within a breed necessarily represent all members of the breed with respect to PERV expression (Wilson 2001).

DIAGNOSIS

PERV is not known to cause disease in pigs. Likewise, no disease has been observed in any animals (mice, guinea pigs, nonhuman primates) exposed to PERV to date, although it should be noted that limited or no viral replication has been observed in these studies (Argaw et al. 2004; Martin et al. 1999; van der Laan et al. 2000).

Since PERV is an endogenous retrovirus, all pigs will be positive in laboratory assays used to detect PERV DNA

by PCR or Southern blot analysis (Table 32.2). Likewise, detection of PERV RNA expression by RT-PCR, Northern blot analysis, or detection of reverse transcriptase (RT) activity would indicate only that a PERV genetic locus, or loci, is transcriptionally active. However, RNA expression or RT activity may not always correlate with presence of infectious virus because many of the loci encoding PERV are defective due to deletions or point mutations. Therefore, the method recommended by the U.S. Food and Drug Administration (FDA) to qualify a particular porcine tissue or cell type for use in xenotransplantation clinical protocols is to use a culture assay (See *FDA Guidance for Industry: Source Animal, Product, Preclinical, and Clinical Issues Concerning the Use of Xenotransplantation Products in Humans—4/3/2003*). Co-culture of the cells of interest with target cells is used most reliably to detect infectious PERV. FDA has recommended that culture assays include the target cell lines ST-IOWA (to detect PERV-C) and HEK 293 (to detect PERV-A and B). In most cases reported to date, primary pig cells tend to express low levels of PERV, so a culture period of at least 30 days is recommended. At the end of the culture period (or at set time points during the culture), the cells can be examined for evidence of infection by either of these methods: a) detection of the retroviral enzyme, reverse transcriptase by conventional or PCR-enhanced assays (Phan-Thanh et al. 1990; Takefman et al. 2001); or b) detection of PERV DNA or RNA by conventional or quantitative PCR or RT-PCR (Argaw et al. 2002). FDA has recommended that a positive signal be confirmed by serial passage of the virus onto naive indicator cells to show that the signal is indeed due to presence of infectious virus that can replicate in the test system.

In addition to culture methods (refer to Table 32.2), several laboratories have also developed serologic methods for detection of PERV-specific antibody (Galbraith et al. 2000; Matthews et al. 1999; Tacke et al. 2001). These methods would not be of use for screening pigs, since pigs would likely be tolerant to PERV. However, serologic methods have been used to analyze the anti-PERV response in animal models (Argaw et al. 2004;

Specke et al. 2002) or in human subjects of xenotransplantation clinical trials (Heneine et al. 1998; Paradis et al. 1999; Patience et al. 1998; Xu et al. 2003).

PREVENTION AND CONTROL

PERV infection cannot be prevented within a pig, since it is embedded in the genome. However, recent reports indicate that the human-tropic form of PERV may, in some pig breeds, be an exogenous infection (Wood et al. 2004) and that the pig germline may not contain a replication-competent human-tropic PERV (Scobie et al. 2004). These findings suggest that a selective breeding program of individual pigs within a herd that do not contain human-tropic PERV sequences in the germline may allow one to develop a herd of animals that are less likely to express the human-tropic PERV. Use of transgenic knockout technology to eliminate genetic loci that encode infectious PERV has been suggested, but not attempted. Recent reports that the gene encoding the alpha-1,3-galactosyl transferase gene in pigs has been eliminated using this technology (Phelps et al. 2003) demonstrates that a genetic knockout approach is feasible. In addition, newer technologies are being explored. For example, intracellular expression of a heavy-chain variable fragment specific to the PERV matrix protein (part of gag) prevents production of infectious PERV from porcine cells (Dekker et al. 2003). This result could be further developed in the form of transgenic pigs engineered to express this antibody fragment, with the intention that the resulting pigs would not express PERV. Alternatively, transgenic pigs containing PERV-specific siRNAs may prevent expression of infectious PERV, based on studies of siRNA inhibition of replication for a number of other viruses (Joost Haasnoot et al. 2003).

In addition to trying to modulate expression of PERV in the pig, a number of strategies are being explored to determine whether existing antiviral drugs would be useful to treat PERV infection (Qari et al. 2001; Wilhelm et al. 2002). For example, some, but not all inhibitors of RT have been shown to reduce PERV infectivity in vitro, although typically at higher IC50 concentrations than

Table 32.2.   Diagnostic methods for PERV detection

Method	Purpose	Specimen	Comments
DNA PCR or Southern blot	Detection of PERV DNA	Pig cells	Will be positive for all tissues
RT-PCR or Northern blot	Detection of PERV RNA	Pig cells	Will likely be positive; may not correlate with presence of infectious virus
Reverse transcriptase assay	Detection of viral enzymatic activity (RT)	Pig cells	Will likely be positive; may not correlate with presence of infectious virus
Culture assay	Detection of infectious virus	Pig cells or fluids cultured with ST-IOWA or HEK-293	Best method to identify infectious virus; detection should include RT assay or RT-PCR or DNA-PCR assays to increase sensitivity
ELISA or Western blot	Detection of immune response to PERV	Human serum	Indicates immune response to PERV in human recipients of xenotransplantation products; possibly indicating transmission of virus.

required for HIV inhibition. In contrast, HIV protease inhibitors have no effect on PERV infectivity.

   Naturally preexisting xenoreactive antibody present in human serum against the carbohydrate alpha-1,3-galactosyl epitope present on the PERV envelope (when derived from porcine cells) has been shown to prevent PERV infection of cells both *in vitro* and in vivo (Fujita et al. 2003; McKane et al. 2003). While these data suggest that humans may be naturally protected against PERV infection, recent genetic modifications of pigs (i.e., the functional deletion of alpha-1,3-galactosyl transferase) may circumvent this mechanism of immune protection to PERV infection in humans (Chapman and Wilson 2003).

Porcine Lymphotropic Herpesviruses

X.J. Meng, P.G. Halbur

Until recently, only two species of herpesviruses have been recognized in swine: pseudorabies virus (PRV) and porcine cytomegalovirus (PCMV) (Chmielewicz et al. 2003a; Murphy et al. 1999). PRV is an alpha-herpesvirus that causes respiratory, reproductive, and central nervous system diseases in pigs. PCMV is a beta-herpesvirus that causes inclusion body rhinitis in swine. Prior to 1999, gamma-herpesvirus was not known to infect pigs. By using a pan-herpesvirus consensus PCR assay, Ehlers et al. (1999a) discovered two closely related gamma-herpesviruses in pigs, designated porcine lymphotropic herpesviruses 1 and 2 (PLHV-1 and PLHV-2). More recently, a third porcine gamma-herpesvirus with considerable sequence differences with PLHV-1 and PLHV-2 was identified and designated PLHV-3 (Chmielewicz et al. 2003b). All three viruses were frequently detected in the blood and lymphoid organs of domestic pigs in different geographic regions. The discoveries of these novel porcine gamma-herpesviruses have raised concerns for the inadvertent transmission of animal pathogens to humans during xenotransplantation with pig cells, tissues, and organs (Chmielewicz et al. 2003b; Tucker et al. 2002, 2003). However, the clinical significance on pig health and the pathogenic potential of these novel viruses alone or in combination with other pathogens in pigs are unknown.

ETIOLOGY

The PLHV group belongs to the subfamily *Gammaherpesvirinae* of the family *Herpesviridae* (Ehlers et al. 1999a). Amino acid sequence analyses based on the partial DNA polymerase gene revealed that PHLV-1 and PHLV-2 displayed the highest (68%) sequence identity to the ruminant gamma-herpesviruses, alcelaphine herpesvirus type 1 (AlHV-1) and ovine herpesvirus type 2 (OvHV-2), about 67% sequence identity to bovine lymphotropic herpesvirus (BLHV), but shared only about 41% sequence identity to porcine alphaherpesvirus PRV and less than 45% identity to porcine betaherpesvirus PCMV (Ehlers et al. 1999a).

The complete DNA polymerase genes of PLHV-1 and PLHV-2 differed by about 7% from each other at the nucleotide sequence level, and 5% from each other at the amino acid sequence level. Since there are 50 amino acid differences between PLHV-1 and PLHV-2 in the DNA polymerase genes, the two viruses belong to two different species rather than strains of the same species (Ulrich et al. 1999).

PLHV-3 was initially detected from the blood sample of a German domestic pig, and was found to share only about 66% amino acid sequence identity in the DNA polymerase gene region with PLHV-1 and PLHV-2 (Chmielewicz et al. 2003b). Phylogenetic analyses showed that all three PLHV viruses clustered together with ruminant gammaherpesviruses BLHV, AlHV-1, OvHV-2, and caprine herpesvirus (CprHV-2) (Figure 32.8); however, PHLV-3 is more distantly related to PLHV-1 and PLHV-2 than the two viruses to each other (Chmielewicz et al. 2003b).

For gammaherpesviruses, the conserved genes are
32.8. *A phylogenetic tree based on the concatenated multiple amino acid sequence alignments of conserved regions of gB and DPOL of PLHV-1, -2, and –3 and other related herpesviruses. The bootstrap values derived from 100 replicons are indicated at the branching points of the tree. The upper values were obtained with neighbor/joining analysis, the lower values with parsimonial analysis. Viruses classified to the genus Rhadinovirus and to the genus Lymphocryptovirus are indicated. The PLHVs and several ruminant gammaherpesviruses forming a separate clade are highlighted by gray background. (Reproduced with permission by Academic Press from Chmielewicz et al. 2003b.)*

organized in a common block. Approximately 73 kb genomic sequence of PLHV-1 has been determined and found to encode ORFs 3 to 52 spanning the entire first and second conserved gene blocks and the beginning of the third block (Goltz et al. 2002). In addition, two ORFs not conserved among gammaherpesviruses—E4/BALF1h and A5/BILF1h—three nonconserved ORFs between the second and third conserved gene blocks, and eight unique ORFs outside the conserved gene blocks were also identified in PLHV-1 genome (Goltz et al. 2002). The available 60 kb genomic sequence of PLHV-3 included the first and the majority of the second conserved gene blocks consisting of ORFs 3–46 as well as a putative chemokine receptor and a v-bcl-2 gene (Chmielewicz et al. 2003b). The gene organization of PLHV-3 is identical to that of PLHV-1 and PLHV-2 in the region where sequences are available for all three viruses, including the conserved herpesvirus ORFs; the gammaherpesvirus-specific ORFs 3, 10, 11, 23, and 27; and the nonconserved ORFs E4/BALF1h and A5/BILF1h (Chmielewicz et al. 2003b; Goltz et al. 2002).

Currently, there are no reports of the propagation and isolation of PLHV in cell cultures, and consequently the physicochemical and biological properties of PLHV

are not yet known. However, PLHV-3 has been detected in a persistently infected porcine B cell line L23, which harbors approximately 400 genome copies of PLHV per cell (Chmielewicz et al. 2003b).

EPIDEMIOLOGY

Little is known regarding the epidemiology of PLHV.

Ehlers et al. (1999a) tested peripheral blood mononuclear cells (PBMC) from 42 pigs and spleen samples from 19 pigs in Germany for evidence of PLHV infection, and found that 88% of PBMC and 95% of the spleen samples were positive for PLHV DNA. Three of 8 Spanish pigs tested were also positive. Chmielewicz et al. (2003b) reported that 47 of 92 (51%) peripheral blood leukocyte samples of pigs from 16 different herds in Germany were positive for PLHV-3 DNA. Approximately 88% (14/16) of the swine herds were also positive. Using real-time PCR, PLHV-1 and PLHV-2 DNA were detected in 54% and 16%, respectively, in the same set of samples (Table 32.3). PLHV-1, -2, and –3 DNA were detected in 78%, 41%, and 59% of lung tissue samples and in 59%, 26%, and 62% of the spleen samples, respectively. Of the 20 Italian pigs tested, PLHV-1, -2, and –3 DNA were

found in 80%, 20%, and 65% of the samples, respectively (Table 32.3). All three PLHV species were also detected from pigs in France, Spain, and the United States (Chmielewicz et al., 2003b).

Analyses of PLHV sequences from pigs in different countries revealed very little variation, indicating that the PLHVs are genetically stable, regardless of their geographic origin. Approximately 21% (9/44) of the miniature swine PBMC were also positive (Tucker et al. 2003). Feral pigs are also found to have a high prevalence of both PLHV-1 and PLHV-2 (Ulrich et al. 1999). Using a pan-herpes consensus PCR assay, Chmielewicz et al. (2003a) analyzed 495 blood and tissue samples collected from 294 pigs, and PLHV sequence was detected in 128 (26%). These molecular epidemiological data suggested that PLHV infection is ubiquitous in commercial swine herds.

The transmission route of PLHV is unknown. Tucker et al. (2003) found that about 80% of the conventional swine spleen samples (15/15) but only 13% (6/47) of cesarean-derived qualified pathogen free (QPF) swine spleen samples were positive for PLHV DNA. The reduced incidence of PLHV infection in cesarean-derived QPF pigs raised in strict biosecurity environment suggested that PLHV transmission may be a combination of both prepartum vertical (transplacental) transfer and postpartum horizontal (piglet-to-piglet, sow-to-piglet). However, the results from a small, transplacental infection study showed that 4 of the 5 sows were positive for PLHV sequences, whereas only one of 33 cesarean-

derived offspring were positive, suggesting that transplacental transfer of PLHV is rare (Tucker et al. 2003).

PATHOGENESIS, CLINICAL SIGNS, AND LESIONS

PLHV infection is not associated with any known disease in pigs under natural conditions. However, due to the close genetic relationship with several pathogenic gammaherpesviruses such as AIHV-1, the cause of malignant catarrhal fever in cattle, it is possible that PLHV might also be pathogenic in pigs. The short lifespan of commercial pigs, generally about 6 months, could make such a disease unrecognizable, especially if it causes a chronic disease. Nevertheless, it has been recently reported that PLHV-1 is associated with posttransplant lymphoproliferative disease (PTLD) in miniature pigs following allogeneic hematopoietic stem cell transplantation (Goltz et al. 2002; Huang et al. 2001). PLHV-1 DNA was abundantly detected in PBMC and lymph node tissues of PTLD pigs (Huang et al. 2001). Most importantly, many PLHV-1 genes such as the immediate-early and late genes, the G-protein coupled receptor (GCR) gene, and the viral homolog of bcl-2 oncogene (v-bcl-2), are actively transcribed in PTLD pigs, but not in healthy pigs (Goltz et al. 2002), supporting the hypothesis that PLHV-1 may be involved in the etiology of porcine PTLD. Since PLHV-2 and PLHV-3 are genetically closely related to PLHV-1, it is reasonable to assume that PLHV-2 and PLHV-3 might also be associated with lym-
32.9. *Histopathological section from a pig with posttransplantation lymphoproliferative disorder (PTLD) associated with porcine lymphotropic gammaherpesvirus infection. Hematoxylin and eosin staining of mesenteric lymph node tissue taken from a pig during PTLD on day 48 (A) and following complete resolution of PTLD at day 69 (B). Typical polymorphous PTLD with a mixture of immunoblasts, plasmacytoid cells, and plasma cells can be seen in the day 48 but not the day 69 tissue sample (original magnification X 500). (Reproduced with permission from Huang et al. 2001.*

phoproliferative disease in pigs. The clinical symptoms of experimental porcine PTLD, such as fever, lethargy, anorexia, high WBC count, and palpable lymph nodes, are similar to those of human PTLD, which was linked to a human gammaherpesvirus, Epstein-Barr virus (EBV) (Loren et al. 2003; Paya et al. 1999). Characteristic gross pathological lesions in PTLD pigs include enlargement of tonsils and lymph nodes throughout the body with involvement of the gastrointestinal tract and spleen. The enlarged pulmonary lymph nodes and tonsils caused airway obstruction and respiratory failure in these pigs (Huang et al. 2001; Talpe et al. 2001). Microscopically, typical polymorphous PTLD cells with a mixture of immunoblasts, plasmacytoid cells, and plasma cells were seen in the lymph nodes (Figure 32.9).

Several animal gammaherpesviruses, including AlHV-1 and OvHV-2, are genetically closely related to PLHV; however, these viruses are nonpathogenic in their natural hosts, wildebeest and sheep, but cause serious lymphoproliferative and inflammatory diseases in other species such as cattle and deer (Goltz et al. 2002). Therefore, even if PLHV is not associated with any disease in pigs, it could become pathogenic in other animal species, especially in the case of pig-to-human xeno-

transplantation. During xenotransplantation, PLHV could bypass the natural defense barriers such as the mucosal surfaces and be directly introduced into the body of the human recipient via infected organs or cells, thus favoring cross-species infection between pigs and humans. Under immunosuppressive conditions, PLHV could become pathogenic in xenotransplant recipients and cause similar lymphoproliferative diseases in humans (Chmielewicz et al. 2003a; Goltz et al. 2002; Paul et al. 2003; Tucker et al. 2003). The possibility also exists that PLHV from infected xenografts might recombine with known human gammaherpesviruses, which are usually reactivated in the posttransplantation stage. Therefore, donor pigs intended for xenotransplantation should be adequately screened for the presence of PLHV infection.

IMMUNITY

Little is known regarding the immunity of PLHVs or the type of immune response they induce. Several lines of evidence indicated that PLHVs have B cell tropism. PLHV-3 was identified in a continuous porcine B-cell line L23 (Chmielewicz et al. 2003b). In immunosuppressed pigs with PTLD, oligoclonal proliferation of B lineage cells increased by a factor of approximately 10^2, and the amount of PLHV-1 genome copies increased concomitantly by a factor of 10^5 (Huang et al. 2001). In the tissues of PTLD pigs, the transcriptional activity of two ORFs (A7/BZLF2h and A8/BLLF1h) encoding proteins responsible for B cell entry was detected (Goltz et al. 2002). Under field conditions, PLHVs were predominately detected in PBMC in the blood and spleen tissues (Chmielewicz et al. 2003a, b; Ehlers et al. 1999a; Ulrich et al. 1999). Taken together, these data strongly suggested that PLHV infects B-cells. However, it is unclear whether the function of B cells becomes compromised in PLHV-infected pigs.

DIAGNOSIS

PCR is the only diagnostic assay currently available for PLHVs. A pan-herpes consensus PCR assay targeting the conserved regions of herpesvirus DNA polymerase genes has been developed and can detect more than 20 different herpesviruses (Chmielewicz et al. 2003a, b; Ehlers et al. 1999a, b). This pan-herpes consensus PCR assay, when performed in a nested format with degenerate and deoxyinosine-containing primers, can easily detect all three species of PLHV in porcine blood PBMC and spleen tissues. A quantitative real-time PCR assay has also been developed to quantify PLHV-1, -2, and –3 genomic DNA copy numbers in swine samples (Goltz et al. 2003). Ehlers et al. (1999a) developed a differential PCR assay that can differentiate between infections caused by PLHV-1 and PLHV-2. As a group of lymphotropic viruses, PLHV sequences are frequently detected

in blood PBMC, spleen, tonsils, and lymph nodes. However, for diagnosis purpose, only blood PBMC is readily available from live pigs. An efficient cell culture for PLHV has not been established, and serological assays are not available.

PREVENTION AND CONTROL

A major concern regarding PLHV is the potential risk of human infection associated with xenotransplantation of pig cells, tissues, and organs (Chmielewicz et al. 2003a; Tucker et al. 2002). PLHV-1 has been shown to be associated with porcine PTLD; thus PLHV–1 is not only potentially pathogenic for pigs, but for human xenograft recipients, as well. Therefore, recipients of xenotransplants from pigs should be carefully monitored for potential PLHV transmission. Adequate screening of donor pigs by PCR assay for PLHV is important to prevent potential infection in xenograft recipients.

Appropriate breeding procedures could eliminate or minimize the risk of PLHV infection. A recent study showed that piglets free of PLHV could be generated through cesarian-derived and barrier-reared breeding procedure (Tucker et al. 2003). Therefore, xenograft donor pigs free of PLHV infection can be produced through a strict breeding and production process.

Eastern Equine Encephalomyelitis Virus

F. Elvinger, C.A. Baldwin

Eastern equine encephalomyelitis (EEE) is endemic in the eastern United States (Atlantic and Gulf coasts), several Central and South American countries, and Caribbean islands. Naturally occurring EEE in swine was first reported in 1972 (Pursell et al.) when 160 of 200 pigs in one herd died in an outbreak in Georgia, USA. Exposure of domestic and feral swine to the agent had been described earlier in serologic surveys in the states of Georgia, Massachusetts, and Wisconsin (Feemster et al. 1958; Karstad and Hanson 1958, 1959). The disease is diagnosed sporadically in porcine case material at veterinary diagnostic laboratories, but it is likely underrecognized in the field.

The causative agent of EEE, eastern equine encephalomyelitis virus (EEEV), is classified in the United States as a Category B bioterrorism agent because of its moderate ease to disseminate, moderate morbidity, and high case-fatality rates in humans, and its potential impact on the Center for Disease Control and Prevention (CDC)'s diagnostic, surveillance and response capabilities.

ETIOLOGY

EEEV is a single-strand RNA virus in the genus *Alphavirus*, family *Togaviridae*. There are 26 confirmed members in the genus *Alphavirus*, including western equine encephalomyelitis virus (WEEV) and Venezuelan equine encephalomyelitis virus (Hahn et al. 1988). EEEV was described and serologically differentiated from WEEV in 1933 (TenBroeck and Merrill).

Nucleic acid analysis has demonstrated that EEEV has evolved independently into North and South American antigenic varieties (Casals 1964; Weaver et al. 1991), each with distinct virulence characteristics (Walder et al. 1980). Isolates appear to be genetically stable over a discrete time period within a geographic region of transmission (Brault et al. 1999; Roehrig et al. 1990).

EPIDEMIOLOGY

EEEV circulates endemically among many bird species considered to be reservoirs and amplifiers of the virus. EEEV is transmitted from bird-to-bird, mainly by the ornithophilic mosquito vector *Culiseta melanuris*. Other mosquito species from genera such as *Aedes* and *Anopheles* also transmit EEEV. Mosquito species with opportunistic feeding habits on both birds and mammals are responsible for the epidemic virus transmission to mammals. The appearance of EEE in mammals is associated with climatic conditions that influence vector population dynamics and enhance their density (Francy and Wagner 1992; Letson et al. 1993).

Clinical outbreaks have been reported from Georgia and Florida (Elvinger et al. 1994, 1996b; Pursell et al. 1972). Swine on 9 of 45 (20%) farms tested in recent serologic surveys in Georgia had antibodies to EEEV, and 16% of 376 feral swine on a Georgia barrier island had serum virus neutralization antibody titers that ranged from 4 to 128 (Elvinger et al. 1996b).

In general, mammals are considered dead-end hosts due to low virus titers that are insufficient to infect vectors. However, nursing pigs that were experimentally infected developed high titer viremia that lasted up to 168 hours. Virus could be recovered from oropharyngeal and rectal swabs up to 96 hours after virus administration, and virus could be isolated from tonsils of pigs up to 20 days after experimental infection. Contact control pigs, in addition, have seroconverted in experimental infection studies (Baldwin et al. 1993; Karstad and Hanson 1958). Thus, it is conceivable that infected nursing pigs are a source of virus for both vectors and, by direct transmission, for mammals in their close proximity.

CLINICAL SIGNS

EEEV predominantly affects nursing pigs. Clinical signs include depression, anorexia, ataxia, prostration, lateral recumbence, convulsions, and ultimately death. However, clinical disease is not commonly observed following experimental or natural exposure to EEEV. Most nursing pigs exhibit only a transient temperature increase, even when high doses of EEEV are experimentally given by oral, intradermal, or intravenous routes (Baldwin et al. 1993; Elvinger et al. 1996a). Predisposing factors, including adverse environmental conditions or concurrent disease, may contribute to the high mortality observed in natural outbreaks of EEE in swine (Elvinger et al. 1994; Pursell et al. 1972). Experimental infection of older animals did not lead to clinical disease (Karstad and Hanson 1959) and EEE has not been described in adult swine. The oldest pig recorded with clinical EEE was a 2-month-old female (Pursell et al. 1983), however, seroconversion was detected in adult animals following disease outbreaks in piglets (Elvinger et al. 1994).

PATHOGENESIS

Natural infection of pigs likely occurs through transmission of virus by hematophagous vectors, while experimental infection has been achieved by intracranial, intradermal, intravenous, and oral routes of virus administration (Baldwin et al. 1993; Karstad and Hanson 1959; Pursell et al. 1972). Rectal temperature increases within 24 hours of virus administration and is elevated for less than 12 hours in all experimentally infected pigs; however, clinical signs of central nervous system disease are observed in only a few pigs between 18 and 72 hours after virus administration (Baldwin et al. 1993). Circulating virus was isolated 6 hours after experimental infection, regardless of route of infection, and was present in blood for up to 168 hours. Neutralizing antibodies are detectable approximately 120 hours after experimental infection. After the acute viremic phase, EEEV was isolated only from tonsils and central nervous tissues. Virus was isolated or demonstrated by oligonucleotide probe in tonsils up to 20 days after experimental infection. Consequently, tonsil tissues of infected pigs could be a significant source of virus dispersion, especially since contact pigs become infected (Baldwin et al. 1993; Karstad and Hanson 1958). Oligonucleotide probing revealed EEEV in transient liver lesions that appeared early during the viremic phase of the infection, prior to the appearance of lesions in myocardium and central nervous system (Baldwin et al. 1993, 1994a, b). Presence of virus in liver lesions may indicate virus tropism for hepatic tissue and viral replication in the liver.

LESIONS

No gross lesions indicative of EEE have been observed in naturally or experimentally infected pigs (Baldwin et al. 1993; Elvinger et al. 1994, 1996a; Karstad and Hanson 1959; Pursell et al. 1972). Microscopically, necrotizing

hepatitis appeared within 12 hours of experimental infection, increasing in size over the next 24 hours, resolving partially by 48 hours, and resolving completely by 72 hours after infection (Baldwin et al. 1993). Central nervous system lesions may not be present in pigs that die in the acute phase of disease. The earliest lesions appeared in brain approximately 48 hours after infection. The appearance of these lesions was concurrent with the appearance of mild lesions in heart and resolution of lesions in liver. Encephalitis was characterized by infiltration of inflammatory cells, disseminated perivascular cuffing, neuronal necrosis and neuronophagia, nodules of glial proliferation, and malacia (Baldwin et al. 1993; Elvinger et al. 1994, 1996a; Pursell et al. 1972). Viral inclusion bodies were not observed. Initially, neutrophils predominated in infiltrates and perivascular cuffs, while lymphocytes were more common at later stages. In addition, histiocytes, adventitial cells, eosinophils, and cellular debris were observed. Hyaline or granular thrombi were found in blood vessels. Lesions occurred primarily in gray matter of brain and spinal cord, but white matter was also affected. Patches of inflammatory cells were noted in the meninges. Multifocal myocardial necrosis had been reported in naturally infected pigs and reproduced in experimental infection (Baldwin et al. 1993; Elvinger et al. 1994, 1996a). Pigs that survived experimental infection with no apparent clinical signs occasionally had lesions of mild encephalitis with lymphocytic perivascular cuffs, focal areas of gliosis and foci of myocardial necrosis that were partially mineralized and surrounded by macrophages (Baldwin et al. 1993).

DIAGNOSIS

Death losses in nursing pigs following clinical signs of central nervous system disease in EEE endemic areas are indicative of virus activity, particularly when climatic conditions are conducive to the development of vector populations. Histopathologic lesions may first appear in liver and myocardium. Lesions in brain consistent with EEE may not have had time to develop in pigs that die during the early viremic phase.

A definitive diagnosis can be supported by virus isolation or detection of virus RNA or antigen. Serologic evidence of exposure in surviving pigs is a good indicator of EEE virus activity, although antibody titers may be due to earlier exposure of sows and transmission of antibodies through colostrum.

A wide spectrum of tests to isolate virus, demonstrate and identify EEEV RNA or antigen, or detect antibodies to EEEV are used to diagnose natural and experimental infections with EEEV (Tsai and Chandler 2003). Fresh and formalin-fixed specimens of brain, spinal cord, liver, heart, and tonsil should be submitted for histopathological examination and virus isolation when EEE is suspected in a swine herd. Virus isolation can be at-tempted on oropharyngeal swabs from herdmates, since EEEV can persist in tonsil tissue. Precautions should be taken to avoid accidental human infection when collecting the specimens. Serum from affected and nonaffected pigs should be submitted for serologic examination, although disease and death likely will precede the onset of a detectable immune response.

PREVENTION AND CONTROL

Treatment of swine clinically affected with EEE has not been attempted. No treatment of affected horses has been described, and therapeutic efforts in human cases are directed toward management of symptoms (Craven 1991).

Two routes for prevention of EEE can be taken: 1) vaccination of animals at risk, and 2) vector control. Vaccination of sows is an option for protecting swine producers from catastrophic losses due to EEEV infection in pigs. Sows vaccinated experimentally with commercial equine vaccines transferred antibodies to piglets via colostrum that were protective for experimentally infected, early-weaned pigs (Elvinger et al. 1996a). Maternally derived antibodies were measured in pigs for up to 11 weeks after colostrum intake and should be protective until natural susceptibility to clinical disease is outgrown in piglets from vaccinated and naturally infected sows.

The second approach to prevention of EEE is control of exposure to EEEV vectors. Incident cases of EEE in any mammalian or avian species can serve as sentinel cases signaling the need to initiate application of insecticides by local and state governments. Aerial application of insecticides for public health protection benefits swine producers in endemic areas directly by preventing outbreaks and economic losses and, indirectly, by preventing amplification of EEEV in pigs that would put the producers and farm laborers at risk of contracting infection.

Rabies
F. Elvinger

Rabies is an acute, nearly always lethal, viral, zoonotic disease of the central nervous system (CNS). All mammalian species are believed to be susceptible to rabies virus, although some appear to require higher infectious doses to develop clinical disease, and only a few carnivores/omnivores and bats are important as disease reservoirs.

The geographic distribution of rabies is almost global, with the exception of island nations in the South Pacific (New Zealand and others), where rabies has never been recorded. In Japan, the United Kingdom, Norway, and a few other countries, rabies has been eradicated. The World Health Organization classifies a country as rabies-free if no indigenous cases of rabies have been confirmed in any animal species and humans during the previous 2 years. In some countries, like Australia, rabies-related bat-associated lyssaviruses recently have been described that can cause rabies-like disease and death in humans and terrestrial mammals.

Incidence of rabies is not uniform across regions. The public health and economic impact of the disease varies greatly from highly to less developed regions of the world, from urban to rural environments, and across social strata within countries. Meltzer and Rupprecht (1998a, b) produced a two-part economic assessment in which they estimated costs of a case of human or animal rabies and contrasted those costs to various modalities of control of rabies in dogs and wildlife, and of treatment of exposed human and animal subjects. Costs of rabies are not limited to the economic loss of affected livestock, but also include the costs of regulatory intervention, medical treatment of exposed persons, and the nonfinancial costs of anguish of people who themselves or whose animals have been exposed to the disease.

ETIOLOGY

The bullet-shaped rabies virus of about 180 nm in length and 75 nm in width is a single-stranded, nonsegmented, negative-sense RNA-virus in the *Lyssavirus* genus, family *Rhabdoviridae*, in the order *Mononegavirales*. Another genus in family *Rhabdoviridae* is the genus *Vesiculovirus*, which includes the vesicular stomatitis viruses. Molecular biological analysis and cross-protection assays distinguished 7 genetic lineages in the Lyssavirus genus: rabies virus (classic rabies virus, serotype/genotype 1) and rabies-related viruses including the African viruses Lagos, Mokola, and Duvenhage (serotype/genotypes 2, 3, and 4, respectively); the European bat viruses I and II (genotypes 5 and 6, respectively); and the

Australian bat virus (genotype 7), which, with the exception of Lagos, have all caused disease and death in humans. Additional lyssaviruses that belong to the rabies serogroup, including the Kotonkan and Obodhiang strains from African flies and mosquitoes and the Rochembeau strain from French Guyana mosquitoes currently have been isolated only in invertebrate hosts.

The rabies virion consists of 5 viral proteins of which two are of special interest. The phosphorylated nucleoprotein (N) includes the antibody-binding epitopes that contribute to the differentiation of the various virus groups. Glycoprotein (G) covers the virion, except at the planar end. It is the only one of the 5 proteins that binds virus-neutralizing antibodies, and variation in its amino acid sequence appears to contribute to the variation in pathogenicity of the different strains. Antigenic variation within the sero-type 1 rabies viruses does not appear to affect the efficacy of commonly used vaccines.

EPIDEMIOLOGY

Rabies virus propagates in two epidemiologic cycles. In the *urban cycle,* the street virus circulates in feral and domestic dogs and still puts humans at great risk of exposure and infection in many developing countries. In the developed world there has been a shift from the urban to the *sylvatic cycle,* in which distinctive rabies virus variants circulate in specific wildlife reservoirs within discrete geographic clusters. Reservoirs include different fox species, jackals and coyotes, raccoons, skunks and mongooses, and bats. Wolves and cats can efficiently transmit rabies, but do not serve as reservoirs. Other susceptible animal species in general do not transmit the disease further and are epidemiologically dead-ends. Rabies in humans, companion animals, and livestock in Europe and North America results from spillover from the sylvatic cycle.

The incidence of rabies in swine in North America is low. Two of 2601 rabies cases reported from 1998 through 2003 in Canada (Canadian Food Inspection Agency 2004) and 14 out of 89,011 cases reported from 1991 through 2000 in the United States were in swine (Krebs et al. 2001). Porcine cases, however, are reported to the Office International des Epizooties every year and from all continents (OIE 2003).

PATHOGENESIS

The bite by a rabid animal effectively constitutes a subcutaneous and intramuscular inoculation of large amounts of virus in saliva. Following an eclipse phase, in which virus replication occurs, possibly in myocytes at the bite site, the virus migrates through the axoplasm of the peripheral or cranial nerves to reach the CNS. The lag time between inoculation and neural invasion may be the grace time during which post-exposure prophy-

lactic treatment is most likely to be effective (Acha and Szyfres 2003). Following replication in the CNS, the virus moves centrifugally into non-nervous tissues, including the salivary glands and eyes. Virus may be shed in saliva of infected animals prior to, at, or after onset of clinical disease (Rupprecht et al. 2002).

The incubation period of the disease varies between as little as a few days to several months. The duration of the incubation period depends in part on the virus strain, the site of the bite and the amount of virus transmitted, and the age and immune status of the bitten animal. In a single event in which two of five sows and one boar bitten by a rabid fox developed rabies and died, incubation periods were 39, 56 (boar), and 123 days (Reichel and Möckelmann 1963). Baer and Olson (1972) recorded 32- to 47-day incubation periods in nonlethal infections in feeder pigs. Younger pigs bitten by rabid rats developed rabies 23–42 days after being bitten (Mamatov et al. 1974).

CLINICAL SIGNS

Clinical signs in most species may progress through three phases: the prodromal phase, in which nonspecific respiratory, gastrointestinal or CNS disease signs, including initial behavioral changes may appear; the furious, excitative phase, in which the animal is agitated and aggressive, and which progresses through seizures to coma and death; and the dumb phase, characterized by paralysis, coma, and death.

In swine, as in other species, clinical presentation may be very diverse. Lack of overt clinical signs has been recorded in feeder pigs (Hazlett and Koller 1986). Reported clinical signs include uneasiness, dullness and incoordination, excitement with a tendency to root or attack, drooling/salivation, marked thirst, anorexia, hoarse grunts and vocalizations or lack of squealing, front leg paralysis, twitching of nose and rapid chewing movements with excessive salivation in affected sows, clonic convulsions, fever, and general paralysis proceeding into coma and death (Dhillon and Dhingra 1973; Hazlett and Koller 1986; Merriman 1966; Morehouse et al. 1968; Yates et al. 1983). Duration of the clinical phase in pigs has been reported to be short, lasting from 12 hours to 5 days. Frequently litter- and penmates are affected as well, due to common exposure when attacked by rabid animals. Baer and Olson (1972) described clinical signs of CNS disorder in 4 of 6 pigs bitten by a rabid skunk, including progressive paralysis starting at the forelimbs, and sexual excitement. These signs subsided within 1–2 weeks, and all pigs survived with elevated serum-neutralizing antibody titers to rabies until slaughter 2 months later. Recovery from clinical rabies and survival, including a virus carrier state, have been described in various animal species (Doege and Northrop 1974; Fekadu 1991), and may have occurred in these pigs as well.

LESIONS

Gross lesions due to rabies are not likely to be detected in swine. Swine with rabies may be in good condition, with stomachs full of fresh, normal feed, given the usually short duration of clinical signs (Merriman 1966). Negri bodies, which are eosinophilic inclusions in the cytoplasm of nerve cells and dendrites of infected animals, are frequently absent in rabid swine (Merriman 1966; Morehouse et al. 1968; Reichel and Möckelmann 1963). The most detailed presentation of histopathological changes is given by Morehouse et al. (1968) who examined 5 pigs of 16 that died over a period of 2 months in an outbreak at a Missouri swine farm. Microscopic changes in the CNS varied widely, ranging from mild vasculitis and focal gliosis in the brain to extensive meningoencephalitis and marked neuronal degeneration in brain and spinal cord.

LABORATORY DIAGNOSIS

The direct fluorescent antibody test (FAT) for rabies virus has been, and still is, the most commonly used diagnostic test for rabies in all species. This test, introduced in 1958, is recommended by both the Office International des Epizooties and by the World Health Organization (Aubert et al. 2000). Antigen may be detected in all parts of the CNS of infected animals, in corneal impressions, and in skin biopsies (Fekadu and Smith 1984; Smith 2003). However, the test is the most sensitive (approaches 100%) when examining impression smears from fresh tissues from the medulla oblongata, cerebellum, and hippocampus (Ammon's horn), in which the greatest antigen quantities can be expected. Virus isolation techniques may be slightly more sensitive than the FAT in some tissues; however, the FAT is more likely to detect antigen in specimens in which replication of rabies virus is impaired because of tissue decay or presence of antibodies. The FAT is most sensitive on fresh brain tissue and loses some of its sensitivity when using formalin-fixed specimens following enzymatic treatment of the fixed sample (90–100% relative sensitivity compared to fresh tissue). False-negative FAT have been reported in swine in which rabies was confirmed by mouse inoculation tests (Dhillon and Dhingra 1973; Morehouse et al. 1968; Yates et al. 1983). Mouse inoculation or cell culture tests should be used when the FAT gives an uncertain result or when the FAT is negative, and when there has been human exposure to an animal in which clinical signs strongly suggest rabies. Negri bodies, i.e., intracytoplasmatic acidophilic antigen aggregates, are detected in only 75–80% of specimens found positive by more sensitive diagnostic methods (Fekadu and Smith 1984), and sensitivity of rabies diagnosis by detection of Negri bodies may be even lower in rabid pigs (Merriman 1966; Morehouse et al. 1968; Reichel and Möckelman 1963).

PREVENTION AND CONTROL

Protection of humans and animals from rabies relies on prevention. Control of stray dogs and, later, vaccination of owned dogs had the greatest impact in the reduction of rabies incidence in humans, companion animals, and livestock.

In general, vaccination of swine is not recommended, given the very low number of porcine cases annually in the United States, western Europe, and other countries, which may be due to lower susceptibility of swine to rabies. In the United States there is currently no rabies vaccine licensed for use in swine. Prophylactic vaccination requires the extralabel use of a vaccine product approved for other species.

In case of exposure, unvaccinated livestock should be slaughtered immediately: "If the animal is slaughtered within 7 days of being bitten, its tissues may be eaten without risk of infection, provided that liberal portions of exposed area are discarded" (National Association of State Public Health Veterinarians 2004). Such an animal can be slaughtered for personal consumption in the United States; however, "federal guidelines for meat inspectors require that any animal known to have been exposed to rabies within 8 months be rejected for slaughter."

Prophylactic post-exposure treatment may be indicated to save valuable animals or in countries where culling may impose excessive hardship on the owners of exposed animals. Mitmoonpitak et al. (2002) reported that, following severe rabies exposure involving deep bite wounds on nose, shoulder, vulva, and tail from a rabid dog, 11 pigs received either vaccine alone (inactivated, Rabisin manufactured by Rhone Merieux, France) or vaccine with equine rabies immunoglobulin (ERIG, 40 IU/kg bodyweight; Pasteur Merieux Connaught, France). All treated pigs had detectable antibodies to rabies by 14 days post treatment, and all pigs survived for 1 year following the exposure. Thus, post-exposure rabies treatment of valuable farm animals may be a safe and effective alternative to immediate slaughter. It needs to be pointed out, however, that the lack of licensed rabies vaccine for swine and the potential for the existence of rabies carrier states dictates caution in rabies endemic areas and requires that access of the public to swine in petting zoos or other facilities be restricted (Massachusetts Department of Public Health 2004).

III Bacterial Diseases

33 *Actinobacillus pleuropneumoniae*

Marcelo Gottschalk and David J. Taylor

Actinobacillus pleuropneumoniae is the etiologic agent of pleuropneumonia in pigs. The first observations of this disease were made by Pattison et al. (1957), Matthews and Pattison (1961), and Olander (1963). Shope (1964) later described an acute outbreak of a similar infection on a farm in Argentina. The name *Haemophilus pleuropneumoniae* was given to the causal organism by Shope et al. (1964) and White et al. (1964). The name was confirmed by Kilian et al. (1978). The designation *Haemophilus parahaemolyticus* given to the California strains (Olander 1963) and the Swiss isolates (Nicolet 1968) is considered a synonym.

H. pleuropneumoniae was later transferred to the genus *Actinobacillus* and designated *Actinobacillus pleuropneumoniae* after DNA homology studies had demonstrated the close relationship of *H. pleuropneumoniae* to *A. lignieresii* (Pohl et al. 1983). The *Pasteurella* haemolytica–like organism described by Bertschinger and Seifert (1978) as a causative agent of necrotizing pleuropneumonia is considered to be a nicotinamide adenine dinucleotide (NAD)–independent biotype of *A. pleuropneumoniae* (Pohl et al. 1983) and is known as *A. pleuropneumoniae* biotype II.

Pleuropneumonia is one of the important bacterial diseases of the respiratory tract of the pig and occurs in most pig-keeping countries. The clinical disease is relatively well controlled in the United States and Canada, but it is still a major problem in Latin American and European countries (Gottschalk et al. 2003). Its importance derives from the fact that it can cause pneumonia that results in death, clinical disease that may become chronic, or subclinical disease in successive batches of pigs and causes losses from death, reduced production, and increased costs of medication or vaccination. One of the problems of this disease for the clinician is that animals may be treated with antimicrobials effective against the organism, but they may not respond because of the severity of the initial lesions and their nature. Some herds may be subclinically infected without previous evident episodes of the disease and with the absence of suggestive lesions at the abattoir. This happens often in conventional herds which may be simultaneously infected not only with several serotypes of low pathogenicity (see below) but also with serotypes highly likely to cause disease. In these cases, outbreaks may suddenly appear in the presence of concomitant diseases or as a consequence of changes in management. Hence, early identification of subclinically infected herds is important for the control of the disease because carrier animals are the main source of transmission between herds.

Both the organism and the disease have been studied extensively and in considerable detail, and the knowledge has been used to design new vaccines and diagnostic methods and to propose relatively highly effective eradication programs. However, the best and most economical methods for control of the disease are still a matter for discussion.

ETIOLOGY

The etiologic agent *A. pleuropneumoniae* (formerly *Haemophilus pleuropneumoniae*, *H. parahaemolyticus*) is a small, gram-negative, encapsulated rod with typical coccobacillary morphology. The organism does not grow on blood agar unless it is supplemented with NAD and shows satellitism around colonies of staphylococci (biotype I strains). Staphylococcal streaks are normally required for primary isolation on this medium. The biotype I organism forms colonies 0.5–1 mm after 24h of incubation on blood agar in the presence of staphylococcal colonies and is beta-hemolytic, particularly when sheep red blood cells are used. Biotype I is NAD-dependent, and *A. pleuropneumoniae* produces an increased zone of hemolysis within the zone of partial lysis surrounding a beta-toxinogenic *Staphylococcus aureus* (the CAMP phenomenon) (Nicolet 1970; Kilian 1976), and this CAMP phenomenon has been shown to be related to the possession of the three cytolysins ApxI, ApxII, and ApxIII (Frey et al. 1994; Jansen et al.

1995). Additional detailed morphologic and biochemical characteristics may be found in the original reports (Shope 1964; Nicolet 1968; Kilian et al. 1978). Biotype I strains should differentiate from other actinobacilli normally present in the upper respiratory tract of swine (Kielstein et al. 2001; Gottschalk et al. 2003). Biotype II strains grow easily on blood agar plates without the presence of *Staphylococcus aureus*, and colonies might be similar to those of *Actinobacillus suis*. It is important for diagnostic laboratories to carry out a complete biochemical identification in order to differentiate both species.

A. pleuropneumoniae biotype I has been divided into 13 serotypes and biotype II into 2 serotypes, for a total of 15 serotypes. Serotypes 1–5 were recognized by Kilian et al. (1978), with serotype 5 subdivided into subtypes 5a and 5b (Nielsen 1986a); however, this subdivision has neither epidemiological nor pathological significance, and most laboratories do not perform the subtyping. Subsequently, serotypes 6, 7 (Rosendal and Boyd 1982), 8 (Nielsen and O'Connor 1984), 9 (Nielsen 1985b), 10 (Nielsen 1985c), 11 (Kamp et al. 1987), and 12 (Nielsen 1986b) have been proposed. Serotype 10 was erroneously proposed by Kamp et al. (1987) and was later referred to as serotype 12 (Nielsen 1986b). Nielsen et al. (1997) proposed an integration of the serotyping schemes for biotypes 1 and 2, with two new serotypes, serotypes 13 and 14, belonging to biotype II being added. More recently, Blackall et al. (2002) reported that a new NAD-dependent biotype I serotype (serotype 15) is the predominant serotype in Australia. The association of serotypes and biotypes are not necessarily exclusive, since biotype II strains belonging to serotypes 2, 4, 7, and 9 (normally found among biotype I strains) have been reported (Beck et al. 1994). Two biotype I strains belonging to serotype 13 (a "biotype II serotype") have recently been isolated in Canada and the United States (M. Gottschalk, unpublished observations).

The serologic specificity is given by the capsular polysaccharides (CPS) and the cell wall lipopolysaccharides (LPS). However, some serotypes show structural similarities or have identical LPS O chains, thus explaining the cross-reactions observed between serotypes 1, 9, and 11; serotypes 3, 6, and 8; and serotypes 4 and 7 (Perry et al. 1990; Dubreuil et al. 2000).

Combinations of a given serotype at the capsule and a different serotype at the LPS level have been reported. For example, strains of CPS/LPS of serotype 1/7 and 2/7 have been reported in North America and Europe, respectively (Gottschalk et al. 2000; Nielsen et al. 1996). These strains could complicate the diagnosis, due to the presence of atypical cross-reactions. It has been suggested that serotypes of *A. pleuropneumoniae* would be more rigorously defined by specifying both capsular (K) and LPS (O) antigens (Perry et al. 1990), but this nomenclature has not been widely adopted (Dubreuil et al. 2000).

EPIDEMIOLOGY

Pleuropneumonia of the pig is widely distributed. It has become more important as pig production has become more intensive. Outbreaks have been reported from practically all European countries and from different parts of the United States and Canada, Mexico, South America, Japan, Korea, Taiwan, and Australia. Although some serotypes are prevalent in certain countries (e.g., serotype 2 in Switzerland, Denmark, France and Sweden and serotypes 1 and 5 in the United States, Canada and Mexico), several serotypes often occur in the same country (Dubreuil et al. 2000). Some serotypes (e.g., serotype 3), considered to be of low virulence and of no epidemiologic importance in certain countries, may be epidemic in others (Desrosiers et al. 1984; Brandreth and Smith 1985; Gottschalk et al. 2003). A series of papers provided information on the distribution of serotypes within countries (e.g., Austria, where serotypes 4, 6, and 10 are most common; see Hofer et al. 1996) or within regions of countries (e.g., Catalonia, Spain, where 11 serotypes, principally 1, 2, 4, 7, 9, and 11, have been identified; see Clota et al. 1996; and Quebec, Canada, where serotypes 1, 5, and 7 are predominant; see Mittal et al. 1992). McDowell and Ball (1994) showed that serotypes 1 and 4 were absent from the British Isles, which may reflect the restrictions on imports of live pigs to the U.K. from neighboring countries of the European Union where these serotypes exist. Serotype 4, considered absent from North America in the past, has been isolated from carrier animals in Canada (Lebrun et al. 1999). Different serotypes may also occur within farms. In fact, most conventional herds are infected with more than one serotype of *A. pleuropneumoniae* (Gottschalk et al. 2003). The international relationship of the different serotypes is of special interest, because it points to a transmission through international exchange of animals. For example, serotype 2 is a highly virulent serotype in European countries, but it is infrequently isolated from clinical cases in North America. Recent data showed that European strains produce two toxins, whereas North American strains produce only one (see pathogenesis), which may explain the differences in virulence (M. Kobisch, M. Jacques, and M. Gottschalk, unpublished observations). Biotype II strains are more commonly isolated in Europe than in the United States, where only one report is available (Frank et al. 1992). More recently, an untypable strain of a biotype II *A. pleruopneumoniae* has been reported in the U.S. as an important cause of disease in a commercial herd (Gottschalk et al. 2003). Biotype II strains, considered as low virulence for a long time, seem to be able to cause cases of fatal pleuropneumonia (Gambade and Morvan 2001; Maldonado et al. 2004).

Strains belonging to the same serotype have been genotypically compared. Moeller et al. (1992) analyzed

the multilocus enzyme electrophoresis (MEE) types of organisms in one restricted area and found that the electrophoretic type (ET) was unrelated to the severity of the disease. In addition, they concluded that serotype 5 strains possessed a clonal structure. This was confirmed by Chatellier et al. (1999), who used random amplified polymorphic DNA analysis or RAPD to compare Canadian field strains isolated from lungs of diseased animals and from nasal cavities or tonsils of clinically healthy pigs, indicating that these strains have the same potential for virulence. Fussing (1998) reported that serotype 2 field strains were clonally related, using ribotyping, sequence analysis of ribosomal intergenic regions, and pulsed-field gel electrophoresis. On the other hand, Chatellier et al. (1999) showed a relatively high heterogeneity among strains of *A. pleuropneumoniae* serotype 1, especially those recovered from healthy animals, using the RAPD technique.

The economic importance of the disease is principally due to the mortality, production and medical costs in acute outbreaks. In chronically infected herds, results from studies investigating the effect of pneumonia on the average daily gain have been controversial. Hunneman (1986) found that the rate of daily weight gain was not affected, although a study by Hartley et al. (1988) showed that pleurisy at slaughter was associated with an increase of 1 day to slaughter, and clinical disease with an increase of 8 days to slaughter. More recently, Andreasen et al. (2001) explained the lack of significant reduction in the average daily weight gain in *A. pleuropneumoniae* and *Mycoplasma hyopneumoniae* chronically infected herds by either the fact that most pigs included in the study were subclinically infected or because a temporary negative influence of the infection is hidden due to an increased growth in the period following infection.

A. pleuropneumoniae is a parasite of the respiratory tract with high host specificity for pigs. In peracute and acute infections, it can be found not only in pneumonic lesions but also in large numbers in nasal discharges. The incubation period can be quite variable. Experimental infections show that an exposure to large numbers of organisms leads to death within a few hours to a few days. Either exposure to low levels of infection or survival following acute infections may result in subclinical disease, and these animals become carriers. In these cases, the infectious agent is located mainly in necrotic lung lesions and/or in the tonsils, less frequently in the nasal cavity (Kume et al. 1984). Animals that have recovered from acute episodes may remain carriers for several months (Desrosiers 2004).

The main route of spread is by direct contact from pig to pig or by droplets within short distances. In acute outbreaks the infection may not occur in every pen, suggesting the possible role of aerosols and air movement in the transmission of the disease over longer distances within buildings or the indirect transmission of contaminated exudates from acutely infected pigs by farm personnel. Transmission between herds occurs through the introduction of carrier animals to naive populations. Different studies showed that *A. pleuropneumoniae* may be transmitted by aerosol over short distances (see Desrosiers 2004), and Kristensen et al. (2004) reported that airborne transmission between closely located pig units is possible but rare. Moving and mixing pigs increases the risk of pleuropneumonia. Introduction of the disease by artificial insemination or embryo transfer is improbable, since the genital tract is not a common site of infection, and antimicrobials in the diluent would prevent survival of the contaminating organism. Transmission by small rodents or birds is doubtful and it is not considered as significant. Survival of the organism in the environment is considered to be of short duration. However, when protected with mucus or other organic matter, it can survive for several days (even weeks) and it can survive in clean water for periods of up to 30 days at 4°C.

Infected sows will transmit the infection to the offspring. It has been suggested that only few piglets get infected by *A. pleuropneumoniae* from their respective sow during the nursing period (when the level of maternal antibodies is usually high), and that these infected pigs spread the bacteria to other pigs after weaning, the age period that corresponds to the age at which the proportion of pigs with detectable levels of colostral antibodies against *A. pleuropneumoniae* is declining (Vigre et al. 2002). These two events (colonization and level of colostral antibodies) are most probably associated. The persistence of colostral antibody in piglets may range from 2 weeks to 2 months postpartum, mainly depending on the initial level of acquired colostral antibodies, and to the serological technique used to measure them (Vigre et al. 2003; M. Gottschalk, unpublished observations).

In the acute phase of the disease, morbidity is generally high. Mortality depends on the virulence of the strain and on the particular environment. Factors such as crowding and adverse climatic conditions, such as rapid changes in temperature and high relative humidity, coupled with insufficient ventilation encourage the development and spread of the disease and, consequently, also affect morbidity and mortality. It is, therefore, not surprising that the highest incidence of outbreaks is observed in growing and finishing pigs, mainly in seasons with adverse weather conditions. As a rule, large herds that mix pigs frequently are more at risk than small herds or herds with separate units. Data from the field seem to indicate that both morbidity and mortality may be exacerbated by the presence of diseases such as Aujeszky's disease and porcine reproductive and respiratory syndrome (PRRS), although experimental studies showed that combined infection with *A. pleuropneumoniae* and PRRS virus may not necessarily result in more severe disease (Pol et al. 1997).

VIRULENCE FACTORS AND PATHOGENESIS OF THE INFECTION

The pathogenesis of swine pleuropneumonia has been studied extensively, both in terms of the development of the lesions and in terms of the relationship of the organism to the tissues at a more molecular level. For a recent complete review, please refer to Bosse et al. (2002). Infection is usually by aerosol or by contact, and experimental studies have shown that the organism can colonize the tonsil and adhere to the alveolar epithelium. In fact, colonization is usually the first step of the infectious process. Chiers et al. (1999) demonstrated that after experimental infection with *A. pleuropneumoniae*, bacteria were mainly associated with the stratified squamous epithelium and detached epithelial cells. Vacuolization and desquamation of the epithelium was observed and many transmigrating neutrophils were present. At later times after inoculation, bacteria were found closely associated with the crypt-walls and with detached cells present in the crypts. A strong neutrophil migration was observed mainly in the deeper parts of the crypts. It was concluded that attachment of *A. pleuropneumoniae* to tonsillar epithelial cells probably constitutes a first step in establishing bacteria at this body site. It seems that this pathogen does not bind well to the cilia or epithelium of the trachea or bronchi (Bosse et al. 2002). However, it seems to significantly adhere to cells of the lower respiratory tract (Bosse et al. 2002; van Overbeke et al. 2002). The presence of fimbriae and fimbrial subunits has been well confirmed (Zhang et al. 2000). It seems that their expression is regulated by growth conditions, which may explain their presence after growth in some media but not in others (Bosse et al. 2002). However, their role in the colonization or any other aspect of the pathogenesis of the infection remains to be elucidated.

Cell adhesion seems to be mediated either by proteins or polysaccharides (van Overbeke et al. 2002). It has been clearly demonstrated that the LPS play an important role in adherence of *A. pleuropneumoniae* to swine cells (Paradis et al. 1999). Recently, glycosphingolipids (gangliotriaosylceramide or GgO_3 and gangliotetraosylceramide or GgO_4) present in respiratory epithelial cells have been identified as possible receptors for *A. pleuropneumoniae* (Abul-Milh et al. 1999). Originally, high-molecular-mass polysaccharide from the LPS was thought to be involved as adhesin. However, GgO_3 and GgO_4 were shown to interact with the core oligosaccharide rather than the long chain O polysaccharide (Abul-Milh et al. 1999). Evidence from other pathogen-host cell interactons suggests that adherence to host cells is a complex and multifactorial process (Bosse and Matyunas 1999).

Once in the respiratory tract environment, certain bacterial nutrients are scarce. One of the most important is iron. Mechanisms for overcoming iron-restriction are complex. *A. pleuropneumoniae* expresses a number of factors that are involved in the acquisition and uptake of iron (for a recent review, see Jacques 2004). Among other mechanisms, *A. pleuropneumoniae* is capable of utilizing porcine transferrin and haem compounds including free haem, haemin, haematin, and haemoglobin (Bosse and Matyunas 1999). It also possesses a siderophore (Jacques 2004).

After being able to adhere, resist the clearing function of the normal mucociliary system, and survive in the lower respiratory tract, *A. pleuropneumoniae* may be eliminated by phagocytic cells. Both macrophages and neutrophils phagocytose *A. pleuropneumoniae* in the presence of convalescent pig serum (Cruijsen et al. 1992; Bosse and Matyunas 1999). Production of immunoglobulin proteases, which might interfere with opsonophagocytosis is controversial (Bosse and Matyunas 1999; Negrete-Abascal et al. 1994). Following phagocytosis, *A. pleuropneumoniae* can survive for a certain period of time inside macrophages, but not neutrophils. Different factors produced by this microorganism may contribute to its ability to survive within some phagocytic cells (Bosse and Matyunas 1999). In addition, it appears to be resistant to the action of complement, mainly due to the capsular polysaccharide (CPS) (in the case of serotype 5) and the LPS (in the case of serotype 1) (Ward and Inzana 1994; Rioux et al. 1999, 2000). The presence of the capsule as a protective factor for *A. pleuropneumoniae* serotypes 1 and 5 has been demonstrated by the characterization of nonvirulent isogenic mutants lacking this factor (Bosse and Matyunas 1999; Rioux et al. 2000).

The most important factors involved in impairment of phagocytic function of both macrophages and neutrophils are the RTX-toxins, ApxI, ApxII, and ApxIII, produced by different serotypes of *A. pleuropneumoniae* (Haesebrouck et al. 1997; Frey 2003). In general, strains of serotypes 1, 5, 9, and 11 produce ApxI and ApxII; strains of serotypes 2, 3, 4, 6, 8, and 15 produce ApxII and ApxIII; strains of serotypes 7, 12, and 13 produce only ApxII, and strains of serotypes 10 and 14 produce only ApxI (Gottschalk et al. 2003). It seems that strains of serotype 3 secrete low levels of ApxII. The possible role of the more recently described toxin (ApxIV, produced only in vivo) on macrophages and neutrophils remains to be elucidated (Frey 2003). ApxI and ApxIII are highly toxic for leukocytes, whereas ApxII is moderately toxic for these cells. In fact, most of the pathological consequences of porcine pleuropneumonia can be attributed to these toxins which exert cytotoxic effects on different type of cells (Haesebrouck et al. 1997; Frey et al. 1993; Frey 2003). The production of two toxins by virulent serotypes seems to be important. For example, it has recently been demonstrated that both ApxI and ApxII toxins are necessary for full virulence in serotype 1 strains (Boekema et al. 2004). In addition, highly virulent serotype 2 strains from Europe produce two toxins

as expected, but low virulent North American strains produce only ApxII (M. Gottschalk, M. Jacques, and M. Kobisch, unpublished observations). LPS is also considered a cause of toxic effects, due probably to an exacerbation of the inflammatory response (Fenwick 1990). Although several reports indicate an important release of pro-inflammatory mediators (Baarsch et al. 1995), a recent study indicates that pneumonia caused by *A. pleuropneumoniae* infection is not due to the release of systemic inflammatory cytokines (Myers et al. 2004). Other factors include secreted proteases and flagella, but their role in the pathogenesis of the infection remains to be elucidated (Negrete-Abascal et al. 1994, 2000; Negrete-Abascal 2003).

Differences in the virulence between the serotypes or even within the same serotype have often been observed. It is suggested that such differences are due to capsular structure (Jacques et al. 1988), LPS composition (Jensen and Bertram 1986), or type of hemolysin (Frey 2003). In general, strains of serotypes 2, 9, and 11 (in Europe) and 1 and 5 (North America) are found to be more virulent than those of other serotypes. Although it has been previously reported that serotype 10 may be highly virulent (Komal and Mittal 1990), very few clinical cases are reported worldwide. Pigs experimentally infected with this serotype generally present a low level of clinical signs and mortality, but relatively high level of chronic pleuropneumonia and chronic pleuritis (Sorensen 1997; M. Gottschalk, unpublished observations). Interestingly, animals may be carriers of fully virulent strains of serotype 1 or 5 in a herd without the presence of clinical signs. Finally, strains of serotype 1, with no atypical CPS, LPS, or toxin profile have also been shown to be of low virulence after experimental infections (Gottschalk et al. 2003). It is important to note that results obtained after experimental infection may depend on the route of inoculation (intranasal, intratracheal, aerosol, etc.), the dose used, and the immune status of the animals. Conventional animals that might have been in contact with low virulent serotypes of *A. pleuropneumoniae* or with *A. suis* may be more resistant to the infection with a specific strain than specific pathogen-free animals that are negative to all serotypes of *A. pleuropneumoniae* (M. Gottschalk, unpublished observations). Serotypes considered as low pathogenic (such as serotype 3 and 12) can sometimes induce clinical problems, especially in the presence of other pathogens. Concomitant infections with other pathogens of the respiratory tract that aid the development of pleuropneumonia have been described by Caruso and Ross (1990).

Lung lesions resulting from the toxic changes may be seen as early as 3 hours after experimental infection and become progressively more obvious. The alveolar wall becomes edematous and capillary congestion develops. The lymphatics become dilated with edema fluid, fibrin, and inflammatory cells. Platelet aggregation and neu-trophil accumulation may also be seen in the damaged alveolar wall, and both arteriolar thrombosis and wall necrosis may develop to produce infarction. Microcolonies of the organism may be seen in infected alveoli, and bacteremia may occur. The edges of the lesions become filled with dead and damaged macrophages or debris and can easily be demarcated from the surrounding lung by 4 days post infection. Purulent exudate containing organisms is present in the bronchi. As the lesions age, their centers become necrotic and healing occurs by fibrosis.

Experimental or natural infections stimulate an immune response, and circulating antibodies can be detected approximately 10–14 days post infection. These antibodies reach a maximum level within 4–6 weeks post infection and may persist for many months (Desrosiers 2004). However, more studies are needed to confirm this fact. Immune sows confer passive immunity on their offspring. Such colostral antibodies may persist for about 5–12 weeks (Vigre et al. 2003), but this may depend on the sensitivity of the test used to detect the antibodies and on the initial level of acquired colostral antibodies. Protection may last for only as little as 3 weeks in some cases (Nielsen 1975), but these data may be due to the use of a very insensitive test such as the complement fixation test. The antibodies are directed against a wide range of bacterial structures and products, including capsule, LPS antigens, toxins (which can be neutralized), outer-membrane proteins, superoxide dismutase, and iron-binding proteins. Both local IgA antibodies and serum IgG antibodies are produced.

CLINICAL SIGNS

Clinical signs vary with the age of the animals, their state of immunity, the environmental conditions, and the degree of exposure to the infectious agent. The clinical course can be peracute, acute, or chronic (Nicolet et al. 1969; Shope 1964; Shope et al. 1964).

In the peracute form, one or more weaned pigs in the same or different pens suddenly becomes very ill with fever to 106.7°F (41.5°C), apathy, and anorexia. There is a short period of slight diarrhea and vomiting. The affected animals lie on the floor without distinct respiratory signs, the pulse rate increases very early, and cardiac and circulatory failure develop. The skin on the nose, ears, legs, and later the whole body becomes cyanotic. In the terminal phase, there is a severe dyspnea with mouth breathing, animals remain in a sitting posture, and rectal temperatures decrease markedly. Shortly before death, there is usually a copious, foamy, blood-tinged discharge through the mouth and nostrils. Death occurs within 24–36 hours of the development of clinical signs. Occasionally an animal may die suddenly without premonitory clinical signs or be found dead in a pen; experimental studies have shown that the course of the disease may be as little as 3 hours from infection

to death. In neonatal pigs the disease occurs as a septicemia with fatal results.

In the acute form, many pigs in the same or different pens are affected. Body temperature rises to 105–106°F (40.5–41°C), the skin may be reddened, and the animals are depressed, are reluctant to rise, refuse food, and are reluctant to drink (Pijpers et al. 1990). Severe respiratory symptoms with dyspnea, cough, and sometimes mouth breathing are evident. Cardiac and circulatory failure are usually present, with congestion of the extremities. There is a marked loss of condition, which is apparent within 24 hours of the onset of the disease. The course of the disease differs from animal to animal, depending on the extent of the lung lesions and the time of initiation of therapy. All stages of disease, from intermediate to fatal, subacute, or chronic, may develop within an affected group.

The chronic form develops after the disappearance of acute signs. There is little or no fever, and a spontaneous or intermittent cough of varying intensity develops. Appetite may be reduced, and this may contribute to the decreased rate of gain in body weight. Affected animals can be identified by their intolerance of exercise. When moved, they lag behind the group and struggle only feebly when restrained. In chronically infected herds there are often many subclinically diseased animals. The clinical signs may be exacerbated by other respiratory infections (mycoplasmal, bacterial, or viral). Although a certain synergy between PRRSV and *A. pleuropneumoniae* is often suspected in the field, experimental studies have not shown that previous PRRSV infection of SPF pigs enhanced the severity of a A. pleuropneumoniae infection (Pol et al. 1997). In primary outbreaks abortions may be observed (Wilson and Kierstead 1976), especially in SPF herds. Middle-ear disease has also been associated with *A. pleuropneumoniae* infection (Duff et al. 1996).

It is important to add that some herds are in fact infected by *A. pleuropneumoniae* without the presence of visible clinical signs and with absence of significant lesions at slaughter. These are considered as subclinically infected herds.

LESIONS

The gross pathological lesions are located mainly in the respiratory tract (Nicolet and Köning 1966). The pneumonia is mostly bilateral, with involvement of the cardiac and apical lobes, as well as at least part of the diaphragmatic lobes, where pneumonic lesions are often focal and well demarcated (Figure 33.1). In rapidly fatal cases the trachea and bronchi are filled with a foamy, blood-tinged, mucous exudate and few gross changes may be obvious. In slightly later peracute cases, the pneumonic areas appear dark and solid with little or no fibrinous pleurisy; and the cut surface is friable. Fibrinous pleurisy is very obvious in animals that die in

the acute stage of the disease, at least 24 hours after infection, and the thoracic cavity contains a blood-tinged fluid. As the lesions age, the fibrinous pleurisy over the affected areas of lung becomes fibrous and may adhere so strongly to the parietal pleura that lung parenchyma may remain attached to the parietal pleura when the lungs are removed at postmortem examination. The uniform dark red or black of the early lung lesion becomes lighter in color and remains firm only in the worst-affected areas. The lesions shrink in size as resolution progresses, until in more chronic cases nodules of different sizes remain, mostly in the diaphragmatic lobes. These abscess-like nodules are delimited by a thick capsule of connective tissue (Figure 33.2) and may be associated with areas of adhesive fibrous pleurisy. In many cases the lung lesion resolves, and only a residual focus of adhesive fibrous pleurisy remains. A high prevalence of chronic pleuritis at slaughter is very suggestive of pleuropneumonia.

In the early stages of the disease, the histopathologic changes are characterized by necrosis, hemorrhage, neutrophil infiltration, macrophage and platelet activation, vascular thrombosis, widespread edema, and fibrinous exudate (Bertram 1985, 1986, 1990; Liggett and Harrison 1987). Following the acute response, macrophage infiltration, marked fibrosis around areas of

necrosis, and fibrous pleuritis are characteristic (Häni et al. 1973).

DIAGNOSIS

Pleuropneumonia may be suspected clinically in acute outbreaks. In such cases the presence of characteristic lung lesions with pleurisy at postmortem examination enhances suspicion, which is enforced by the histological appearance of the lesions. The presence of an acute exudative pneumonia with areas of necrosis surrounded by palisades and whorls of neutrophil debris provides further evidence for pleuropneumonia. In chronic infections the necropsy findings of firm, well-demarcated abscesses associated with pleurisy and pericarditis are very suggestive. In view of the importance of this disease to herd health control programs and the potential for economic loss, bacteriologic confirmation of the diagnosis should be carried out. Hog cholera, erysipelas, and streptococcal infections must be considered in the possible differential diagnosis of peracute and acute cases. Lung lesions caused by other porcine actinobacilli may be indistinguishable from those of pleuropneumonia, and acute pasteurellosis may sometimes resemble pleuropneumonia.

It is relatively easy to demonstrate the etiologic agent in pneumonic lesions from freshly dead animals. Gram-stained smears of lung lesions contain numerous gram-negative coccobacilli. Primary isolation of *A. pleuropneumoniae* from tissues and secretions may be carried out on 5% sheep blood agar with a cross-streak of *Staphylococcus epidermidis* or *S. aureus*. After aerobic incubation overnight, small colonies appear in the neighborhood of the streak (NAD requirement) surrounded by a clear zone of complete hemolysis. This allows a rapid presumptive bacteriologic diagnosis. For some serotypes (such as serotypes 7 and 12), the zone of hemolysis is usually less intense. Altered blood agars ("chocolate agar") allow the

growth of the organism, but it is less distinctive on these media. Presumptive biochemical identification can be carried out by demonstrating the CAMP phenomenon and urease activity. Usually, serotyping will confirm the identity of *A. pleuropneumoniae*. When biochemically atypical isolates are recovered (for example, urease negative isolates) or when the isolates are untypable, it is recommended to carry out a PCR test (see below). Biotype II isolates (NAD-independent) have been recovered more frequently in the last years (Gambade and Morvan 2001; Gottschalk et al. 2003; Maldonado et al. 2004). These isolates might be misidentified as *A. suis*; in these cases, a complete biochemical identification must be done before sending the isolate for serotyping. In fact, *A. suis* isolates present strong cross-reactions with sera against serotypes 3, 6, and 8 of *A. pleuropneumoniae* (unpublished observations). It is strongly recommended to perform a PCR test to confirm the identity of biotype II isolates of *A. pleuropneumoniae*.

The serotyping of isolates is recommended for rapid confirmation of the bacteriologic diagnosis of typical *A. pleuropneumoniae* isolates and is essential when vaccination policy is being considered. It demonstrates the local distribution of serotypes and allows the epidemiologic situation to be evaluated and the performance of specific serologic tests to be monitored. Serotyping can be routinely achieved by slide agglutination from a subculture on a medium enriched with serum (Mittal et al. 1987), unless nonspecific cross-reactions are usually observed (unpublished observations). The coagglutination test (Mittal et al. 1987) is routinely used, but many isolates react with different sera (due to common epitopes) and a confirmatory test, such as agar gel diffusion and indirect hemagglutination (Mittal et al. 1987) is needed. A critical evaluation of the earlier serotyping methods is given by Lida et al. (1990). The use of monoclonal antibodies for serotyping has also been reported (Rodriguez-Barbosa et al. 1995; Lacouture et al. 1997; Lebrun et al.

1999). Finally, toxin typing using a well-described PCR (Frey et al. 1995) could be done in order to anticipate the virulence of the isolated strain.

Bacteriological diagnosis of chronic disease is more complex. It is difficult to culture *A. pleuropneumoniae* from chronic lesions in lungs. Tests for direct detection of *A. pleuropneumoniae* in lung tissues are immunofluorescence, ring precipitation, coagglutination, latex agglutination, ELISA, and counter-immunoelectrophoresis (Dubreuil et al. 2000). Their presence can be confirmed as *A. pleuropneumoniae* either by using a fluorescent or immunoperoxidase antibody test (Gutierrez et al. 1993), or by detection of serotype-specific antigens in lung extracts with a coagglutination test (Mittal et al. 1983). Nucleic acid from bacteria may be detected by a number of methods, including labeled DNA probes in tissue and polymerase chain reaction (PCR). Direct confirmation by PCR of the presence of *A. pleuropneumoniae* in lung tissue is not yet routine.

The detection of *A. pleuropneumoniae* from clinically healthy carrier animals (in subclinically infected herds) is even more complex. Bacteria are usually localized in tonsils and, less frequently, in the nasal cavities. Selective media have been described (Sidibe et al. 1993; Jacobsen and Nielsen 1995), although their sensitivity is very low. In fact, the swine nasal cavities and tonsils are heavily colonized with several NAD-dependent bacterial species, many of them being members of the commensal flora, such as *Actinobacillus minor*, *Actinobacillus porcinus,* and *Actinobacillus indolicus* (Moeller et al. 1996; Kielstein et al. 2001). Their identity as well as their role as pathogens is controversial (Kielstein et al. 2001; Gottschalk et al. 2003). Although most of these bacterial species probably do not play any significant role as swine pathogens, they may interfere with the culture and identification of *A. pleuropneumoniae*. A bacterial species which is biochemically and antigenically very similar to *A. pleuropneumoniae* has recently been described (Gottschalk et al. 2003). To overcome the presence of a highly contaminating flora, an immunomagnetic separation technique for the selective isolation of a given serotype of *A. pleuropneumoniae* from tonsils has been developed (Gagné et al. 1998). The sensitivity of this technique is a thousandfold higher than direct culture. Molecular techniques can also be used for the detection of *A. pleuropneumoniae* from tonsils. In fact, within the last years, several PCR techniques that amplify well-defined sequences of the *A. pleuropneumoniae* genome have been described as valuable tools for the rapid and affordable detection of the pathogen, and a ready-to-use PCR kit has even been commercialized. Recently, Fittipaldi et al. (2003) have evaluated eight PCR tests for their abilities to detect *A. pleuropneumoniae* from swine tonsils. At first they were compared regarding their specificities by using *A. pleuropneumoniae* and related bacterial species and their analytical sensitivities by using tonsils experimentally infected in vitro. PCRs

were carried out both directly with tonsil homogenates (direct PCR) and after culture of the sample (post-culture PCR). Most tests demonstrated good specificities; however, some tests gave false-positive results with some non–*A. pleuropneumoniae* species. High degrees of variation in the analytical sensitivities among the tests were observed for the direct PCRs (10^9 to 10^2 CFU/g of tonsil), whereas those of most of the post-culture PCRs were similar (10^2 CFU/g of tonsil) (Fittipaldi et al. 2003). When some of these techniques were validated in the field, it was shown that the PCR was more sensitive than the standard isolation method with whole tonsils from three infected herds. Post-culture PCR offered the highest degree of sensitivity and the detection rate was higher with whole tonsils than with tonsil biopsy specimens. Most of these tests are specific for the species *A. pleuropneumoniae* and they cannot differentiate among serotypes; since most conventional herds are infected with several low pathogenic serotypes, a positive result is difficult to interpret. To overcome this problem, serotype-specific PCR tests have more recently been described (Jessing et al. 2003; Angen and Jessing 2004; Hussy et al. 2004).

Serological testing has been used widely for the control of swine pleuropneumonia, to replace the fastidious task of detecting individual carrier animals. In fact, serology is the most powerful tool to diagnose subclinical infections due to *A. pleuropneumoniae*. Some countries, such as Canada and Denmark, use serology for the epidemiological surveillance of different herds on a routine basis. Different assays directed to the detection of antibodies against either the toxins or somatic and/or capsular antigens have been developed (for more details, see Dubreuil et al. 2000). Most tests detecting antibodies against ApxI, ApxII, and ApxIII toxins have low specificity, since other microorganisms such as *A. suis* can also produce similar toxins (Dubreuil et al. 2000; Nielsen et al. 2000). An ELISA test detecting antibodies against the ApxIV toxin has recently been reported (Dreyfus et al. 2004). This test would be highly specific for *A. pleuropneumoniae*, but it cannot differentiate among serotypes. Indeed, most conventional herds would probably present high levels of antibodies and its use as a diagnostic tool would be questionable. Although some ELISA tests based on CPS have been reported, some cross-reactions (probably due to antigen contamination during the purification process) were observed (Dubreuil et al. 2000). The tests most commonly used are ELISA tests using O-chain LPS as antigens (Gottschalk et al. 1994; Dubreuil et al. 2000; Klausen et al. 2002; Grondahl-Hansen et al. 2003). These ELISA tests can identify groups of serotypes as follows: 1, 9, and 11; 2; 3, 6, and 8; 4 and 7; 10; and 12. LPS antigens are also used in blocking ELISA tests using polyclonal antibodies (Andresen et al. 2002). Serological tests such as the complement fixation test and the 2-mercaptoethanol test are no longer used due to prob-

lems of sensitivity and specificity, respectively (Dubreuil et al. 2000).

TREATMENT

In general, *A. pleuropneumoniae* is susceptible in vitro to penicillin, ampicillin, cephalosporin, chloramphenicol, colistin, sulfonamide, cotrimoxazole (trimethoprim + sulfamethoxazole), and gentamicin, to which it has low minimum inhibitory concentrations (MIC). High MIC values are found for streptomycin, kanamycin, spectinomycin, spiramycin, and lincomycin (Gilbride and Rosendal 1984; Nadeau et al. 1988; Aarestrup and Jensen 1999; Yoshimura et al. 2002). Although antibiotics belonging to the betalactam family (penicillin, ampicillin, amoxycillin) normally show good activity against *A. pleuropneumoniae*, sporadic data from the U.S. and other countries reported a relatively high number of resistant isolates (Nadeau et al. 1988). Resistance seems to be frequent especially in serotypes 1, 3, 5, and 7 (Gilbride and Rosendal 1984; Vaillancourt et al. 1988). The antimicrobial of first choice should be the one with the lowest MIC and with the most satisfactory pharmacokinetic properties. Consequently, the betalactams (principally penicillin and cephalosporin), chloramphenicol, and cotrimoxazole are considered to be most active. Quinolone derivatives (enrofloxacin) (Kobisch et al. 1990) or the semisynthetic cephalosporin ceftiofur sodium (Stephano et al. 1990) have been shown to be particularly effective after experimental challenge. Satisfactory results in the field have been reported with tiamulin (Anderson and Williams 1990) and a combination of lincomycin and spectinomycin (Hsu 1990). Tilmicosin has also been reported as effective (Paradis et al. 2004). The determination of an antibiogram is recommended where problems are being experienced with treatment.

Antibiotic therapy is effective in clinically affected animals only in the initial phase of the disease, when it can reduce mortality. The nature of the lesions means that delay in treatment can result in a degree of infarction and chronic damage which will leave the animal as a respiratory cripple even if it recovers. Antibiotics should be given parenterally (subcutaneously or intramuscularly) and in high dosage, because affected animals may not eat or drink (Pijpers et al. 1990). To ensure effective and durable blood concentrations, repeated injections may be required, depending on the pharmacokinetic properties of the antibiotic used. The success of therapy depends mainly on early detection of clinical signs and on rapid therapeutic intervention. Water treatment may be used to treat members of the affected group that are still able to drink. Feed medicated with any of the above antimicrobials may be used successfully if all pigs have a normal food and water intake. Feed and water medication can be used for the strategic treatment of infected groups on entry to an airspace. A combination of parenteral and peroral medication in a recent outbreak often yields the best results. In spite of apparent clinical success, it must be remembered that antibiotic therapy does not eliminate infection in a herd. Chronic infections in lung abscesses or on the tonsils of carriers persist to form an important source of infection for other animals. Severely affected animals may not recover even after treatment and nursing and should be killed.

PREVENTION

Prevention and control of pleuropneumonia may be accomplished in a number of different ways. Farms free from the disease and infection should maintain a policy of isolation coupled with the use of semen or embryos to introduce new genes. As mentioned, there are good serological tools to monitor herds from where replacement animals are introduced. There are many SPF herds that are free of all serotypes of *A. pleuropneumoniae*. It may be appropriate to hold replacements in quarantine prior to introduction to the herd.

After the infection has been established on a farm, it is difficult to eliminate the infectious agent, although the herd may become clinically normal. Control programs must take account of the epidemiologic features of pleuropneumonia. The first priority must be to control economic loss (mortality, clinical and subclinical disease) and then to consider the control or elimination of infection. Mortality can be controlled by the treatment of cases and of infected groups using the methods and antimicrobials outlined above. Disease may be treated at an early stage by treating groups of animals into clean airspaces and then maintaining them as a group in isolation until slaughter. Where this may not be possible, control of environmental factors such as temperature and ventilation and use of solid partitions between pens may minimize the development and severity of disease. Continuous medication or pulse dosing may be practiced, but neither should be used for long, and the antimicrobial sensitivity of the organism should be monitored continuously. Strategic medication should be targeted at periods of risk, which can be identified by routine postmortem examinations, clinical examinations, and herd antibody profiles. The generalized methods used to control respiratory disease, such as the all-in/all-out system in fattening units, segregated early weaning, and large airspaces with separation, will all considerably reduce the risk of infection. Animals should be brought in only from herds free from infection to avoid introducing new serotypes or new antimicrobial resistances. In chronically infected herds, purchased seronegative animals should be vaccinated before introduction to the herd.

A wide range of vaccines has been developed for this disease. They fall into two main groups: the killed organisms and the subunit vaccines. Vaccination with killed organisms is serotype specific (Nielsen 1984), with

possible cross-immunity with cross-reacting serotypes (Nielsen 1984, 1985a). The protection afforded has been extended by including all the serotypes present in an area (e.g., 3, 6, and 8 in the United Kingdom). The type of adjuvant used may affect efficacy, and care may also be necessary before using certain adjuvants in pigs intended for human consumption, because some vaccines can produce undesirable granulomatous lesions at the site of injection (Straw et al. 1985). Recently, a new generation subunit vaccine, composed of the three major RTX exotoxins (ApxI, ApxII, and ApxIII) and a 42 kDa outer membrane protein of *A. pleuropneumoniae*, has been developed and shown to give high protection against all 12 major serotypes (serotypes 1–12) under experimental conditions as well as in field trials (van den Bosch and Frey 2003). Keeping in mind the very complex pathogenesis of porcine pleuropneumonia, inclusion of other bacterial virulence factors in vaccines might also be of value (Haesebrouck et al. 2004). A vaccine containing both Apx toxins and transferrin binding proteins induced better protection against severe challenge than a vaccine solely based on Apx toxins (van Overbeke et al. 2001). A wide range of antigens administered either by parenteral, aerosol, or oral routes have been found to be experimentally protective, but none of them have been used in the field. A live vaccine, based on the use of a nonencapsulated mutant (Inzana et al. 1993), has been commercialized in the United States in the last years.

Vaccines may provide high levels of protection against morbidity in experiments, reduce mortality, reduce the number of treatments required, increase daily liveweight gain, and improve feed conversion efficiency. The quality of the carcass is also improved, with fewer condemnations for pneumonia and lower slaughtering costs through reductions in pleurisy and pericarditis. The decision to vaccinate should be carefully evaluated; the costs of mortality alone should not be the sole consideration, because the other effects on productivity listed above contribute to the benefits of vaccination.

Control of pleuropneumonia on a farm can be accomplished by combining treatment, vaccination, and husbandry practices such as those outlined above. Disinfection should be included in any control program; the organism is sensitive to a wide range of commonly used disinfectants (Gutierrez et al. 1995).

Control of pleuropneumonia in a region or breeding pyramid involves health schemes aimed at pleuropneumonia-free breeding and multiplying herds, serologic monitoring, monitoring at slaughter and postmortem examination of casualties, control of management, and controlled pig traffic (serologic testing, quarantine). For herds infected with *A. pleuropneumoniae* intending to join such a scheme, an eradication program is the method of choice but requires careful evaluation of the economic consequences. Depopulation and restocking with pigs originating from certified pleuropneumonia-free herds can be used; however, this method is expensive and may lead to the loss of important bloodlines. Other methods that have succeeded in the past include an eradication program in the existing herd area but weaning at another farm, at the same time supported by a program of vaccination, medication, and culling and repopulation with disease-free gilts (Larsen et al. 1990). Age of weaning and level of maternal antibodies may have an important influence on the colonization of piglets by *A. pleuropneumoniae* (Vigre et al. 2002). There are several herds that successfully eradicated *A. pleuropneumoniae* using a good medicated early weaning program (M. Gottschalk, unpublished observations). Breeding herds with a relatively low percentage of seropositive animals (up to 30%) have used the "test-and-removal" of seropositive animals under medication (Nielsen et al. 1976). There are different methodologies, but basically the principle is based on the serologic testing of sows shortly before farrowing and by weaning the piglets at 2 weeks of age under strict separation from the potentially infected stock. These piglets, which are seronegative up to the age of 12 weeks, serve to restock the herd. Seropositive sows are systematically eliminated until the entire breeding stock is seronegative. This program can take 6–12 months. During the elimination procedure, the whole herd is protected from reinfection by medicated feed—for example, cotrimoxazole (trimethoprim + sulfamethoxazole 1:20, 250 mg/kg feed). Certain reports suggest that only partial success (Lariviere et al. 1990) or even failure (Hunnemann 1986) has resulted from the application of such eradication programs. In addition, the successful outcome of this method is principally based on the serological test used: a test with low sensitivity will not eliminate all carrier sows, and a test with low specificity will eliminate healthy noncarrier animals, which considerably increases the cost of the program. A successful elimination of certain serotypes *A. pleuropneumoniae* with partial depopulation and tilmicosin has been suggested (Andersen and Gram 2004). However, it has also been demonstrated that tilmicosin treatment cannot completely eliminate the pathogen from carrier animals (Klopfenstein et al. 2004).

34 Progressive and Nonprogressive Atrophic Rhinitis

M. F. de Jong

A disease condition in pigs referred to as "atrophic rhinitis" (or "infectious atrophic rhinitis") and "chronic atrophic rhinitis" has been recognized for nearly two centuries. A disease of the pig characterized by stunted development or total disappearance of the nasal turbinates (called "turbinate atrophy") has been recognized for over 160 years and was first described as "*Schnüffelkrankheit*" in Germany (Franque 1830), where it became prevalent in several areas.

These conditions are now classified as either nonprogressive atrophic rhinitis (NPAR), caused by toxigenic *Bordetella bronchiseptica,* or progressive atrophic rhinitis (PAR), caused by toxigenic *Pasteurella multocida,* alone or in combination with other agents (e.g., *B. bronchiseptica*). The characteristic lesion caused by both agents is a hypoplasia of the nasal turbinate bones (conchal atrophy); in moderate to severe outbreaks this is accompanied by degrees of facial distortion (including brachygnathia superior, lateral deviation of the snout, and septum deviation) and nasal hemorrhage as a result of frequent sneezing. Nasal hemorrhage is rare in NPAR but characteristic in PAR.

In contrast to NPAR, PAR is of global economic significance to swine production, since in PAR, these signs are accompanied by poor growth of fattening pigs (Pedersen and Barfod 1981). Toxigenic *P. multocida* is still spreading in the pig population, especially where disease control measurements are carried out ineffectively (Glattleider et al. 1996; Frymus et al. 1996). The PAR toxigenic *P. multocida* is also able to cause disease in other species, such as rabbits, goats, sheep, cattle, poultry, and turkeys. Even humans can become infected, and lesions somewhat comparable to those in swine can result. Poultry, sheep, and cattle, along with rats, cats, and dogs, are described as carriers (Avril et al. 1990; Donnio et al. 1991; Nielsen and Frederiksen 1990). Toxigenic *P. multocida* should therefore be considered a zoonosis and should be of concern to governmental and human and veterinary health organizations.

Toxigenic *B. bronchiseptica* is widespread in swine production and considered to cause a minor or insignificant growth depression in diseased pigs and is therefore called nonprogressive atrophic rhinitis.

The individual and combined importance of both agents will be discussed in this chapter.

The precise etiology of the "condition" atrophic rhinitis (AR) has been actively debated, with intermittent attempts at definition, for well over a century. Since the 1930s, observations by Ratke (1938), Thunberg and Carlstrom (1940), and Philips (1946) have implied that the disease was contagious. Shortly thereafter it was demonstrated experimentally that turbinate atrophy was transmissible between pigs; when young pigs were inoculated intranasally with crude material from atrophic turbinates, they frequently developed turbinate atrophy (Jones 1947; MacNabb 1948; Philips et al. 1948; Gwatkin et al. 1949, 1951; Terpstra and Akkermans 1960). Much research has since been directed toward defining the precise microbiological agent(s) responsible. While several management and husbandry factors can influence the severity and clinical expression of PAR, this disease is now established primarily as an infectious disease despite attempts at one time to redefine it as a disorder fundamentally of nutritional origin (Brown et al. 1966).

In 1956 Switzer suggested that turbinate atrophy may be caused by several agents, including trichomonads (Switzer 1951), filter-passing agents (Switzer 1953), viruses (Switzer and L'Ecuyer 1960; Edington et al. 1976), and mycoplasmas (Switzer 1955; Edington et al. 1976; Gois et al. 1977). Only special AR-toxigenic strains of *B. bronchiseptica* and AR-toxigenic strains of *P. multocida* have consistently produced "turbinate atrophy" when sufficient quantities of pure (broth) cultures have been inoculated intranasally into young susceptible (e.g., colostrum-deprived specific pathogen free [SPF]) pigs. Despite these observations, however, clinical (and pathological) disease cannot be attributed solely to infection with either one or both agents, since these infections can occur in the field in the (temporary) absence of clinical disease (the so-called subclinical stage of PAR). Interruptions between

periods of clinical disease that can vary in duration from approximately 2 months to about 2 years can occur in infected herds. Herd monitoring based on clinical (and/or pathological) features, therefore, cannot guarantee the absence of infectious PAR in a pig herd. Complementary monitoring of a herd or connected (breeding) herds for over 1 year, based on bacteriologic and/or serologic detection of the PAR-toxigenic *P. multocida*, may be necessary to obtain sufficient information concerning the PAR-infected or PAR-free status of the herd.

DEFINITION

At this point it is important to define carefully the conditions described in this chapter. All diseases that cause turbinate atrophy in swine are called infectious atrophic rhinitis by farmers. The term "infectious progressive atrophic rhinitis" should be reserved for the disease produced by one etiologic agent, *P. multocida*. Pedersen and Nielsen (1983) first recommended the use of this term as a result of the deliberations of a European Economic Community commission of specialists on PAR. To obtain a consensus in a worldwide forum, the proposal was repeated by Pedersen and coworkers in 1988. The first agreement among specialists in swine diseases from Europe, North and South America, and Asia was achieved in 1988 (de Jong and Nielsen 1990). It was agreed to define PAR as a disease caused by infection with toxigenic *P. multocida*. In herds where suspicious manifestations such as sneezing, nose bleeding, snout deformation, growth retardation, turbinate atrophy, and septum deviation are observed and where toxigenic *P. multocida* is detected (bacteriologically or serologically), the diagnosis of PAR can be confirmed. However, the disease may also develop in or be transmitted by pigs from herds harboring toxigenic *P. multocida* even though only slight or subclinical disease is present. The advantage of an etiologic definition of PAR rests on the possibility of identifying, independently of actual clinical status, those herds that are able to transmit or develop the severe clinical disease (Bollwahn 1988).

Estimates of the economic impact of PAR in swine have varied, but in moderate to severe outbreaks it can be of considerable economic importance (Pedersen and Nielsen 1983; Glattleider et al. 1996). From the clinical and pathological points of view, it is probably no longer useful to employ the term "atrophic rhinitis" as denoting a single disease complex. Rather, bordetellosis and toxigenic pasteurellosis should be distinguished as NPAR and PAR. The infectious agents have completely different economic impacts in swine production and require different methods and strategies for prevention and treatment.

ETIOLOGY

Research suggests that toxigenic strains of both *B. bronchiseptica* and *P. multocida* are the primary infectious eti-

ologic factors in NPAR and PAR, respectively. The severity of the disease that develops in a pig is related to the amount of one or of both toxins absorbed by the animal (Van Diemen et al. 1994a). The susceptibility of pigs to a certain amount of toxin that causes turbinate bone reduction has been shown to be age related. Toxigenic strains of *P. multocida* have been shown to produce severe PAR, including extreme growth retardation, even in pigs older than 3 months of age; toxigenic strains of *B. bronchiseptica* produce turbinate hypoplasia only in pigs until about the age of 6 weeks.

The conditions for the growth and/or colonization of *P. multocida* or *B. bronchiseptica* necessary to produce sufficient amounts of toxin are influenced by bacteriologic and/or virologic damage to the mucosa and by certain environmental, management, and husbandry factors that create the (multifactorial) disease complex. When these factors are all present, very severe clinical PAR can result. Since growth retardation and clinical PAR also occur after parenteral dosing with the toxin of *P. multocida*, colonization of toxigenic *P. multocida* in the nose may not be necessary for the development of the disease. Tonsils and lungs also have to be considered as locations for toxin production (Ackermann et al. 1994).

Infectious Agents
Bordetella Bronchiseptica. *B. bronchiseptica* is a small, motile, gram-negative rod or coccobacillus measuring approximately 1.0×0.3 μm in size. The bacterium is aerobic, does not ferment carbohydrates, utilizes citrate, and splits urea.

B. bronchiseptica has been isolated widely from young pigs with rhinitis and from pigs with pneumonia and also from animals in herds showing no clinical signs of respiratory disease. It is also a pathogen or potential pathogen of many other mammals, including dogs, cats, and rats.

In the United States during the 1960s, *B. bronchiseptica* was said to be the principal cause of atrophic rhinitis (Switzer and Farrington 1975). After intranasal instillation of pure cultures of *B. bronchiseptica* in colostrum-deprived pigs a few days old, Cross and Claflin (1962) were able to produce typical experimental turbinate atrophy. This work was repeated by Ross et al. (1967), who were able to reproduce turbinate atrophy with pure cultures of AR-toxigenic *B. bronchiseptica* in 95% of pigs inoculated at 1–3 days of age but in only 66% of 4-week-old pigs. Brassinne et al. (1976) reported that only high numbers of AR-toxigenic *B. bronchiseptica* caused turbinate lesions. A toxigenic strain that caused 100% turbinate atrophy in 3-week-old colostrum-deprived SPF pigs did not cause typical atrophy when intranasally instilled during 4 successive days in 6-week-old pigs (de Jong and Akkermans 1986). This indicated that between 3 and 6 weeks of age, the sensitivity to a heavy infection with an AR-toxigenic *B. bronchiseptica* strain dropped

drastically. Duncan et al. (1966a) had already stated that experimental infections with *B. bronchiseptica* did not cause severe progressive lesions. Pearce and Roe (1966) were unsuccessful in producing turbinate atrophy with cultures of *B. bronchiseptica* in naturally farrowed pigs but were able to produce the lesions when the culture was inoculated into colostrum-deprived pigs. This indicated protection against AR lesions by colostral immunity.

Bacteriologic data from nasal swabs taken from pigs at different ages suggested that *B. bronchiseptica* infection starts to build up in conventional herds with and without clinical signs of PAR in the third week of age, when the nasal sensitivity for toxigenic *B. bronchiseptica* has already started to decrease (Pedersen and Nielsen 1983; de Jong 1985). This meant that, under natural (conventional) conditions, the influence of *B. bronchiseptica* as a primary cause of PAR has been overestimated. Turbinate atrophy can occur in 2- to 3-month-old piglets in exceptional circumstances, such as after a primary *B. bronchiseptica* infection in SPF herds (Schöss 1982) and after experimental infections in piglets free from antibodies. Partial or total regeneration of such atrophy has been described and such infections seem to result in only a limited and low percentage of transient clinical snout deviations; animals with lesions caused by *B. bronchiseptica* did not develop significant growth depression (Pedersen and Barfod 1982).

Nearly all *B. bronchiseptica* strains from pigs produced the thermolabile AR toxin. *B. bronchiseptica* can also affect the lower respiratory system, and toxin production from such regions may have some influence on clinical symptoms of NPAR.

Variations in virulence among porcine *B. bronchiseptica* strains are known to exist. Collings and Rutter (1985) determined that only those strains in phase 1 and isolated from pigs caused turbinate atrophy, and they established that the ability to both colonize the nasal cavity in large numbers and produce a cytotoxin were important virulence determinants. The role of the cytotoxin was clearly established by Magyar et al. (1988), who also examined the role of several other putative virulence determinants, including a hemolysin, adenylate cyclase, and an adhesin. By comparing the pathogenic effects of a porcine cytotoxic phase 1 strain with a noncytotoxic phase 1 strain also of porcine origin, they established that it is the cytotoxin (which is probably the same as the mouse lethal factor and dermonecrotic toxin) that is the key virulence determinant in the production of turbinate hypoplasia.

In a comparison of three biological assays for the detection of toxigenic properties of *B. bronchiseptica*, discrepancies were found between the guinea pig skin test, the mouse spleen atrophy assay, and the suckling mice mortality assay (Mendoza 1993), suggesting that differences exist between these toxigenic properties.

Discrepancies in the results of studies obtained in different countries could arise from variation in virulence or the amount of toxin produced by the organism concerned. This has been reported for isolates of *B. bronchiseptica* in the United States (Ross et al. 1967; Skelly et al. 1980), Canada (Miniats and Johnson 1980), the United Kingdom (Collings 1983), and Hungary (Elias et al. 1982). However, even the most virulent of 10 U.K. isolates did not cause progressive turbinate atrophy or significant snout deformation in experimental infections (Rutter and Rojas 1982). More important, strains isolated from herds with or without progressive disease in the United Kingdom all caused nonprogressive lesions of similar severity (Rutter and Rojas 1982; Giles and Smith 1983). From observations in this laboratory, it appeared that strains isolated in PAR-diseased herds and in herds not suspected of PAR produced roughly the same amount of toxin. Only a few strains differed from this pattern (de Jong and Akkermans 1986). Thus, there is strong evidence, contrary to the opinions of Kielstein (1983) and Nakai et al. (1986), that although there are differences in the virulence of isolates of *B. bronchiseptica*, the severe lesions of clinical PAR cannot be attributed only to this organism. Pigs infected with *B. bronchiseptica* in the deeper respiratory system may be more sensitive to other pulmonary infections. This means that *B. bronchiseptica* infections should not be neglected as a respiratory pathogen.

Pasteurella Multocida. *P. multocida* is a nonmotile, gram-negative rod or coccobacillus approximately 0.3×0.6 μm in size. The bacterium is aerobic, ferments glucose without gas, and produces indole. In fresh smears the organism shows distinct bipolar staining. The colonies of *P. multocida* type A are larger and more mucoid than those of type D. On blood agar plates a characteristic odor is generally produced.

P. multocida and its subspecies have been isolated widely from pigs with and without clinical symptoms of rhinitis or pneumonia. Early studies (reviewed by Gwatkin 1959) established that *P. multocida* could experimentally produce turbinate atrophy in pigs and rabbits and that it was frequently but not always isolated from field outbreaks.

Several workers subsequently examined the ability of this organism to produce turbinate atrophy under controlled experimental conditions. Some strains studied produced a mild rhinitis but were unable to induce marked turbinate hypoplasia (Harris and Switzer 1968; Smith 1971; Koshimizu et al. 1973; Nakagawa et al. 1974; Edington et al. 1976), whereas in other studies, particularly from Europe, cultures of *P. multocida* produced nasal deformity and turbinate atrophy (Dirks et al. 1973) and even severe PAR (Nielsen et al. 1976). In Germany and in the Netherlands particularly, *P. multocida* was considered to be an important primary pathogen in PAR (Dirks et al. 1973). Medication and vaccination with bordetella vaccines in PAR herds reduced *B. bronchiseptica*

successfully but failed to affect PAR. In these herds *P. multocida* was found to be the major pathogen. Reducing *P. multocida* in these herds decreased PAR (de Jong 1976–1979, 1980).

A major step in resolving these conflicting opinions began in the Netherlands when de Jong (1976–1979) and de Jong et al. (1980) began to test different *P. multocida* strains isolated from herds with and without PAR in colostrum-deprived SPF piglets, as described earlier by Ross et al. (1967) for *B. bronchiseptica*.

P. multocida grows in a semifluid mucus on the mucosal membrane of the nose rather than on the nasal epithelium itself, so studies were redirected from cultures washed off solid medium and resuspended to broth cultures. These broth cultures contained substances excreted by the bacteria. After this change it was easy to reproduce AR lesions with the same strain in 3-week-old pigs (or older) instead of in 3-day-old pigs.

Martineau et al. (1982) showed the importance of using broth cultures instead of cultures washed from solid media, and explained that this could be a possible reason for the different findings of investigators (Nakai et al. 1986). Pure cultures of both dermonecrotic and nondermonecrotic type D and type A isolates of *P. multocida* establish themselves poorly in the nasal cavity of healthy conventional (Voets 1990), SPF (de Jong 1985), and gnotobiotic piglets (Rutter and Rojas 1982; Rutter 1983). Nasal instillations of pure broth cultures of toxigenic *P. multocida* needed to be repeated for approximately 4 days to produce a severe *P. multocida* nasal infection that resulted in PAR. Uninoculated pigs kept in contact with inoculated pigs became infected, but only mild lesions were noticed 4 weeks later. Sneezing was sporadic in these experiments with gnotobiotic and SPF pigs. In contrast, experimental infection with toxigenic *P. multocida* in conventional pigs pretreated with chemical irritants or with *B. bronchiseptica* resulted in sneezing, and PAR lesions also occurred in pigs in contact. The strains that caused PAR lesions were called AR pathogenic. This characteristic correlated with the ability to produce a thermolabile toxin. PAR could be reproduced completely with bacteria-free filtrates of these unheated toxins.

Nasal infection by aerosol with 0.5 mL 5 and 13 µg toxin/mL per nostril in 4-week-old piglets induced subclinical ventral turbinate hypoplasia (atrophy). Amounts of 40 µg/mL induced severe lesions. During the 5-week period after challenge, depression of weight gain started in week 3 after challenge. In the 5, 13, 20, and 40 µg/mL groups, the growth depressions during this period were 32, 54, 52, and 96 grams/day/pig, respectively (Van Diemen et al. 1994a). The severity of atrophy depended on the amount of toxin administered into the nose of the pig.

The first publication explaining the role of toxigenic *P. multocida* in AR was by Ilina and Zasukhin (1975) in Russia and it encouraged the development of tests for se-

lecting toxigenic *P. multocida* isolates. Instead of using a rabbit test, the guinea pig skin test was chosen because it also selected AR-pathogenic *B. bronchiseptica* strains (de Jong 1980; Blobel and Schliesser 1981; de Jong and Akkermans 1986). Differences between infections with toxigenic *B. bronchiseptica* and toxigenic *P. multocida* strains were revealed when pure broth cultures were instilled intranasally in groups of colostrum-deprived SPF pigs aged 3, 6, 9, 12, and 16 weeks. In pigs infected with *B. bronchiseptica*, macroscopic turbinate lesions were noticed only in 3- and 6-week-old pigs, not in pigs of 9 weeks and older. Toxigenic *P. multocida* still induced typical snout and turbinate alterations, including septal deviation, in pigs infected at 12 and at 16 weeks of age. The severity of nose lesions decreased with increasing age with the same dose of toxigenic *P. multocida*.

Other Factors

Despite the major role of infectious agents, other factors contribute to the cause or at least the clinical expression of AR, but they have proved difficult to evaluate and have been inadequately defined quantitatively. Most experienced clinicians have concluded that the severity of the disease is markedly influenced by extrinsic factors (Penny 1977; Goodwin 1980). Smith (1983) provided a useful review of these noninfectious determinants.

Nutrition. Although the role of the dietary calcium: phosphorus imbalance is now discounted as a primary cause (Brown et al. 1966), nutritional deficiency of any kind may enhance the severity of infectious disease. Feed consumption may be influenced by AR, since piglets with an acute rhinitis may accept feed less readily and become stunted and weak. Growing pigs with conchal damage may also have reduced feed intake, thus contributing to the reduced daily gain associated with the condition.

Genetic Influences. In the past it has been suggested that heredity played a major role, but heritability estimates have varied greatly, and attempts to control the disease solely by genetic selection have failed. There is probably a measure of genetically linked predisposition to AR, since breeds and strains that vary in susceptibility to the disease and are susceptible to genetic pressure do occur. In the United Kingdom, for example, Large White pigs are now generally considered more vulnerable than Landrace pigs, although 30 years ago the reverse could have been the case. The subject has been reviewed by Smith (1983), Voets et al. (1986a), and Martineau et al. (1988).

Management, Housing, and Environment. Severe growth-retarding AR is closely associated with intensive methods of production; it is undoubtedly most severe when successive batches of pigs are housed in densely stocked, continuously occupied, poorly ventilated

Table 34.1. Management factors influencing the severity of atrophic rhinitis

Increase	Decrease
Large herds, open herds	Small herds, closed herds
Expanding herds	Static herd size
High proportion of gilts	Mainly old sows
Large farrowing unit	Small or single farrowing unit (all-in/all-out)
Multiple suckling—piglets fostered between litters	Single suckling
Large weaner pools	More isolation, modular systems (all-in/all-out)
Large number in one airspace	Small number in one airspace
Frequent moving and mixing	Little movement and mixing
Intensive systems indoors	Outdoor rearing
High stocking density	Low stocking density
Poor ventilation and no temperature control	Good ventilation and temperature control
Poor hygiene, little disinfection	Good hygiene and disinfection
Continual pig throughput	Buildings rested
Dry-feeding, dusty atmosphere	Wet-feeding, clean atmosphere
Mechanical food handling	Hand delivery

Source: After Penny 1977.

buildings (Smith and Giles 1980). Penny (1977) has identified several management factors that tend to predispose to an increased severity of AR (Table 34.1).

Instances have been observed where the disease was controlled, or at least reduced to economically acceptable levels, solely by the manipulation of housing and environment and improved management. It is also a common belief that the disease may be more severe in a dusty atmosphere, particularly where dry and dusty feed is delivered by automatic equipment. The influences of housing and feed, including the feed delivery system, on respiratory diseases of the pig have been reviewed by Owen (1982) and Strang (1982), respectively.

EPIDEMIOLOGY

Bordetella bronchiseptica

B. bronchiseptica is widely prevalent in the pig population in countries with major swine-producing industries. The prevalence of *B. bronchiseptica* infection greatly exceeds that of clinical AR or marked turbinate atrophy at slaughter (Cameron et al. 1980), and although *B. bronchiseptica* is frequently isolated from young pigs in outbreaks of AR, the infection also occurs widely in herds without the condition (Tornoe et al. 1976; Giles et al. 1980; Rutter 1981; Whittlestone 1982).

The dam has been considered a possible source of the important nasal infections for her suckling piglets, and she has been reliably incriminated as a source of *B. bronchiseptica* and *P. multocida*. Transmission also occurs between sows and boars. Although traditionally viewed as important, some observers have concluded that the sow's role might be minor, since clinically NPAR-free progeny resulted when sows from an affected herd were reared under improved conditions (Bercovich 1978).

The degree of resistance to natural *B. bronchiseptica* infection among sows does not appear to be marked, but younger sows are more likely to be active shedders of the organism. Although infection from the dam is probably the chief method of initiating the infection among populations of suckling piglets, infection in weaner houses may often be endemic because of infection passing laterally between different batches, particularly in systems where an all-in/all-out approach is not practiced.

B. bronchiseptica is primarily introduced by the introduction of carrier pigs (in SPF herds); recently purchased breeding stock are often held responsible.

Whether or not the sow is important in transmission, the recognized infectious agents pass readily between populations of young weaned pigs. Infection of pigs at an early age may be vital, even when the clinical signs appear late in the fattening period.

The chief mode of transmission of *B. bronchiseptica* from pig to pig is by aerosol droplet infection. The high prevalence of infection among growing pigs suggests that transmission may occur at any age, but it is probably more common and more readily accomplished in susceptible young pigs, in which an active rhinitis with sneezing develops. The infection can certainly spread rapidly among populations of susceptible (nonimmune) piglets (Smith et al. 1982).

B. bronchiseptica colonizes the ciliated mucosa of the porcine respiratory tract very effectively; it is frequently isolated from the tonsils, and large numbers have been found in the intestinal contents of infected gnotobiotic pigs (Rutter 1985). Thus, direct-contact droplet infection, and perhaps ingestion of fecal material, are likely to be the main routes of transmission. The cycle of infection appears to be maintained by a small proportion of breeding females. Litters within the farrowing house become infected at an early age, but in the United Kingdom as well as in the Netherlands, the major spread seems to occur after 2–3 weeks of age or after weaning, especially in large groups on flat decks, when 70–80% of

a group can become infected. The infection persists for several months, with a gradual reduction in the intensity and rate of infection. The age at which animals first become infected with *B. bronchiseptica* has an important effect on the development of lesions. The most severe lesions occur in nonimmune animals infected during the first week of life (Duncan et al. 1966a). Animals infected at 4 weeks show less-severe lesions, while those infected at 9 weeks show virtually no lesions (de Jong and Akkermans 1986).

The amount and type of immunity also influence the epidemiology of bordetella infection. The presence of passive antibody in the sera of piglets born to naturally infected dams (with toxigenic bordetellae) appeared to provide protection against the development of turbinate lesions (Rutter 1981) but not against infection (Kobisch and Pennings 1989; Voets 1990). However, vaccination of sows appeared to delay infection in their piglets until 12–16 weeks of age compared to nonvaccinated herds, in which litters became infected by 2 weeks of age (Rutter et al. 1984).

B. bronchiseptica shedding from vaccinated sows seems to be reduced in herds in which the sow population has been vaccinated for some years.

B. bronchiseptica has been isolated from most domestic and wild animal species (Goodnow 1980), and because it is a ubiquitous pathogen, there is always the risk that infection could be introduced by nonporcine vectors. Most isolates from other species appear to be of low virulence in pigs, but it is possible that rodents might become infected with pig strains and transmit them. Virtually every pig herd is infected with *B. bronchiseptica*, and variable amounts of brachygnathia superior (BS), moderately severe turbinate atrophy, and moderate signs of septum deviation can be expected in all herds. For this to occur, pigs from nonimmune dams must become infected within the first 4 weeks of life and develop lesions that persist to slaughter, but in most, regeneration of turbinates begins approximately 4 weeks after the start of infection, when the scrolls are not totally damaged. Lesions such as septal deviation, turbinate bone hyperplasia, and BS may be apparent at slaughter. The percentage of pigs with a twisted snout generally does not reach 1%.

In the field, however, the picture is likely to be more complicated. For example, there are reports that *Haemophilus parasuis* in combined infections with type A strains of *P. multocida* can produce mild turbinate lesions (Gois et al. 1983a). Others could not repeat these results.

B. bronchiseptica is killed in 30 minutes at 56°C. It survives outside the body in dried droplets for up to 5 days on glass, 3 days on cloth, and a few hours on paper. The survival time of *B. bronchiseptica* in soil is about 6 weeks. Low humidity and raised temperatures rapidly reduce numbers of live bacteria. In liquid media *B. bronchiseptica* survived for more than 8 weeks at 21°C. In lake water and in phosphate buffered saline solution (PBS), *B. bronchiseptica* remained viable for at least 3 weeks (Porter et al. 1991). In a rotating aerosol chamber, the mean half-life at 21°C and 76% relative humidity was 118.8 minutes (Stehmann et al. 1992), and at 23°C and 75% relative humidity, it was 56.7 minutes (Müller et al. 1992). The organism is sensitive to common disinfectants (Stehmann et al. 1990).

Pasteurella multocida

The introduction of a disease and its subsequent spread within a population depend on numerous factors, including the nature of the etiologic agent, the host, and the structure of the population. In intensive pig rearing, many animals are in close contact and there is often widespread movement of breeding and replacement stock between herds. The main risks of introducing infection are associated with purchased pigs, and disease may then spread rapidly within a seronegative herd. Early reports that did not distinguish between PAR and NPAR clearly recognized that (P)AR was introduced by carrier pigs. The disease appeared in many Norwegian herds that had imported pigs, several of which eventually developed severe clinical signs. This led Braend and Flatla (1954) to conclude that "atrophic rhinitis was practically unknown in Norway prior to [World War II,] after which it has been rather common, most certainly because of importation of pigs from Sweden where the disease is common." It was, therefore, assumed that a new infectious organism had been imported. The disease was declared notifiable, and a slaughter policy was carried out. This strategy was also followed in other European countries, such as in the United Kingdom until 1959 and in the Netherlands until 1980. Similarly, the introduction of AR into the United Kingdom was attributed to the importation of Swedish stock (Anon. 1954). There are at least two possible explanations for these observations: either *B. bronchiseptica* was introduced in uninfected animals and exacerbated existing infections with toxigenic *P. multocida* or, more likely, toxigenic *P. multocida* was introduced with the imported stock.

Estimates of the prevalence of PAR, whether from an individual farm or larger population, are usually conducted by an examination of the heads of pigs after slaughter. Such surveys have indicated that macroscopic nasal turbinate atrophy is widespread in pig populations. It occurred in about 40% of Danish and British herds (Nielsen 1983) in the late 1970s, although a later estimate from England showed a decline to 25% (Cameron et al. 1980). Such a high level of turbinate atrophy, however, does not reflect an equivalent level of clinical disease, since mild lesions are common in commercial fattening pigs, and mild or even moderate atrophy in individuals may occur in herds without obvious clinical disease or adverse economic effects. Today it is believed that these lesions are caused by *B. bronchiseptica*

(NPAR); growth retardation associated with more severe outbreaks has proved difficult to quantify, and some observers (Straw et al. 1983) have found no correlation between the degree of turbinate atrophy and production parameters and, in these herds, now consider atrophy to result from infection with *B. bronchiseptica* (NPAR). Nevertheless, where clinically apparent disease occurs, there is frequently a reduction in average daily gain; this has been conservatively estimated as 5–8% for pigs with severe atrophy (Nielsen 1983). In combination with pleurisy and pneumonia this reduction can double.

The epidemiology of *P. multocida* infection in pigs is less well understood than that of *B. bronchiseptica*. The organism colonizes the tonsils, but some factor or factors, the mechanisms of which are not understood, are needed to assist colonization of the nasal mucosa. Nontoxigenic and toxigenic type A strains can be isolated from the lungs of pigs with pneumonia (Baekbo 1988), but *P. multocida* is much less effective than *B. bronchiseptica* in colonizing the trachea. In contrast to type A strains, toxigenic and nontoxigenic type D strains are isolated less frequently in the lungs but more frequently in the nose. *P. multocida* has also been isolated from most animal species and is well recognized as an important pathogen in cattle, rabbits, poultry, and turkeys (Carter 1967). In some studies its distribution in pig herds was limited; only 9% were infected in one report (Harris and Switzer 1969), but such results may be attributable to the presence of the commensal flora in the nasal cavity (Chanter and Rutter 1989). Today in most laboratories, selective media and the technique of mouse passage can be used for primary isolation of the organism. Material from herds examined in this way (Rutter 1985) has yielded toxigenic and nontoxigenic isolates of type A or D, and mixed infections with these two types in the same pig can occur.

In contrast, the distribution of toxigenic isolates of *P. multocida* appears to be limited to those herds with PAR or a history of the disease (Rutter 1985). In Germany, the Netherlands, and Denmark (Pedersen 1983), the picture is similar, indicating that the majority of herds infected with toxigenic *P. multocida* exhibit clinical signs of progressive disease. In the Netherlands, however, toxigenic *P. multocida* has been isolated from 15% of breeding herds with no history or clinical signs of progressive disease at the moment of the first detection of the toxigenic *P. multocida*. Most of these breeding herds were monitored and became clinically diseased within 2 years after this detection. Only 5% of pigs 4–12 weeks of age were infected in these herds. A few herds remain clinically unaffected for some years (de Jong 1983a; Goodwin et al. 1990), which indicates that toxigenic strains may be present in some clinically unaffected herds, and these could transmit progressive disease if infected stock were purchased from them.

The main source of *P. multocida* infection for young pigs appears to be pharyngeal transport of the organism among breeding stock; 10–15% of sows in farrowing houses were infected with toxigenic isolates (de Jong 1983b), and some piglets were already infected with these strains within a week after birth. Toxigenic *P. multocida* was also isolated from the vaginas of a few sows. The age at which piglets first become infected with *P. multocida* affects the severity of the lesions produced, but unlike *B. bronchiseptica* infection, older pigs may still develop lesions. Significant turbinate atrophy occurred in pigs infected with toxigenic *P. multocida* up to 16 weeks of age; Rutter et al. (1984) found that pigs that became naturally infected between 12 and 16 weeks of age had turbinate lesions. It has been shown that apparently healthy 3-month-old pigs can develop PAR when introduced into a commercial production unit where severe disease is occurring (Nielsen et al. 1976). Injection of *P. multocida* toxin (125 µg/kg) produced significant atrophy in conventional pigs of 10 weeks of age (Rutter 1985). With 13 µg/mL instilled nasally, a subclinical PAR could be achieved in 4-week-old piglets necropsied 5 weeks later. With 40 µg/mL, severe lesions were obtained in the trials (Van Diemen et al. 1994a).

The prevalence of toxigenic *P. multocida* may be related to the extent of clinical disease. The organism was isolated from 50% to 60% of young pigs sampled in a herd in which almost 30% of fattening pigs had twisted snouts. In less severely affected herds, larger numbers of young pigs had to be sampled before toxigenic strains were isolated (Rutter 1985; de Jong et al. 1988).

The distribution of toxigenic *P. multocida* in other species has still to be determined. Pedersen (1983), de Jong (1985), Rutter (1985), Baalsrud (1987), Ohkubo et al. (1987), Kamp et al. (1990), and Frymus et al. (1996) reported that dermonecrotic strains occurred in cattle, rabbits, dogs, cats, rats, poultry, goats, and sheep. A toxigenic strain from pasteurellosis in turkeys produced severe turbinate atrophy in gnotobiotic pigs, but a toxigenic strain thought to have been isolated from ovine pneumonia colonized the nasal cavity of pigs poorly and did not produce significant lesions in combined infection with *B. bronchiseptica* (Rutter 1983, 1985). Toxigenic strains were isolated from humans suffering from tonsilitis, rhinitis, sinusitis, pleuritis, appendicitis, and septicemia and were pathogenic for pigs (Nielsen and Frederiksen 1990; Donnio et al. 1991). This implies special risks for all persons who have contact with herds or animals infected with toxigenic *P. multocida*: farmers and their families, farmhands, drivers, merchants, vets, consultants, butchers, and employees of slaughterhouses. Wearing face masks will reduce the risk of becoming infected and spreading the infection.

The infectious agents are usually introduced into a previously unaffected herd by carrier pigs. Recently purchased breeding stock, gilts or boars, are commonly held responsible, although the evidence for their involvement is often circumstantial. The introduction of toxigenic strains of *P. multocida* is the principal event

preceding an outbreak. Poorly colonizing strains with a low toxin production may represent an exception (Kavanagh 1994). Infection from other sources is rare but seems to become more important if the spread of toxigenic *P. multocida* in pigs is not stopped.

P. multocida is easily destroyed by 60°C in 10 minutes, by 0.5% phenol in 15 minutes, and by a 3.5% solution of cresol in a few minutes. In manure *P. multocida* remains infective for a month and in decomposing or frozen carcasses for 3 months. In a rotating aerosol chamber, the mean half-life was 20.85 minutes at 23°C and 75% relative humidity.

The organism is susceptible to commonly used disinfectants, including those of the following general categories: quaternary ammonium compounds, phenolics, sodium hypochlorite, iodophores, glutaraldehyde, and chlorhexidine.

Formalin at a concentration of 0.2% or greater and phenol at 0.5% will kill in less than 18 hours at 3°C. On stock culture agar *P. multocida* often survives for months or even years if kept at room temperature, but if stored in the refrigerator, the bacteria may die in several days. Their viability can be maintained for many years in blood or tissues in the frozen state at −20°C or lower (Blobel and Schliesser 1981).

PATHOGENESIS

Bordetella bronchiseptica

It is believed that *B. bronchiseptica* colonizes the nasal cavity by adhering to the nasal mucosa, where it probably preferentially attaches to the ciliated epithelial cells (Yokomizo and Shimizu 1979). This is followed by multiplication at the mucosal surface and toxin production, leading to inflammatory, proliferative, and degenerative changes in the nasal epithelium, including the loss of cilia (Duncan et al. 1966a; Edington et al. 1976). The organism is not believed to invade the deeper tissues.

It is assumed that the organism at the mucosal surface elaborates a toxin that diffuses into the osseous core of the nasal turbinate and is responsible for the osteopathy. The nature of this toxic factor has received much attention. Cell-free sonicated extracts from phase 1 *B. bronchiseptica* were originally shown to contain a heat-labile and dermonecrotic toxin, and it was assumed that this was probably an important factor in the pathogenesis. Since then, such bacteria-free extracts containing high levels of this toxin have been repeatedly inoculated intranasally into piglets, where they produce nasal lesions similar to those seen in naturally occurring AR (Hanada et al. 1979; Nakase et al. 1980; Magyar et al. 1988).

The degree of severity of the hypoplastic lesions seen in young pigs varies, and only rarely does severe hypoplasia result (Figs. 34.1–34.3). The ventral scroll of the ventral turbinate is the area most commonly and consistently affected; grossly it varies in appearance from a slightly shrunken and distorted scroll to virtually complete absence. In the more severe cases the dorsal scrolls of the ventral turbinate and the dorsal turbinate are also usually affected. The important factors that affect the severity of the hypoplasia are the degree of resistance of the pig to the infection (Smith et al. 1982) and the age when it was first acquired, since susceptibility to the damage the infection can produce declines as the pig gets older.

The histologic changes in bordetella-induced hypoplastic rhinitis have been reported by Duncan et al. (1966a) and are detailed in Switzer and Farrington (1975). Briefly, there is a hyperplasia of the epithelium and, in places, a metaplasia, the epithelium becoming more stratified in structure with polyhedral cells devoid of cilia. There is a degree of cellular infiltration (principally with neutrophils and mononuclear cells), a fibroblastic proliferation in the lamina propria, and a reduction in size and replacement fibrosis of the osseous core. In more chronic stages there are increased numbers of osteoblasts around the trabeculae, but osteoclasts are rarely found.

34.2. *Turbinate hypoplasia in three pigs experimentally infected at 5 and 10 days old with* B. bronchiseptica *and necropsied 40 days postinfection (Va 6-7-8). (Courtesy P. Schöss.)*

34.3. *Cross section of the snouts of four pigs infected at 5 and 10 days old with + and slaughtered at 6 months of age. Presumed turbinate regeneration and deformations of the ventral turbinates and nasal bones (os vomer) (Va 9-10-11-12). (Courtesy P. Schöss.)*

There is some variation in the toxigenicity of different strains of *B. bronchiseptica*; porcine phase 1 strains are more toxigenic than phase 3 or nonporcine isolates (Collings and Rutter 1985).

Turbinate Regeneration. There is considerable field and experimental evidence that the hypoplasia of the turbinates produced by the uncomplicated infection of young pigs (up to about 8 weeks old) is capable of regeneration, which may sometimes be almost complete (Duncan et al. 1966a; Tornoe and Nielsen 1976; Rutter 1981; Smith et al. 1982).

A degree of turbinate hypoplasia in young pigs (Fig. 34.2), with a variable amount of subsequent regeneration as the pig grows to slaughter weight (Fig. 34.3), may thus occur in most herds infected with *B. bronchiseptica*. This probably accounts for the high prevalence of mild lesions of turbinate atrophy seen at slaughter in the many bordetella-infected herds free from obvious clinical AR, especially in cases where the nasal cavity remains

infected with other species, particularly with nontoxigenic *P. multocida* or *Haemophilus spp.*

A reaction in the regeneration of the scrolls is the irregular increased ("hyperplastic") bone structures in the turbinate bones and other nose bones as well. Once induced, the BS does not seem to regenerate and is difficult to separate from breed-associated BS. Only after elimination of *B. bronchiseptica* in such pig populations can the breed-associated BS be studied properly.

Pasteurella multocida

The mechanisms of colonization by *P. multocida* and the subsequent processes affecting the turbinate bone cells and leading to progressive atrophy and clinical PAR have been partially clarified. Furthermore, the mechanisms by which these chronic nasal changes and their associated malfunctions cause growth retardation have been clarified to a large extent (Becker et al. 1986; Williams et al. 1986; Doster et al. 1990; Dugal and Jacques 1990).

P. multocida apparently colonizes the nasal cavity

poorly unless there is preexisting mucosal damage (Elling and Pedersen 1983). Chemical irritants (e.g., acetic acid and *B. bronchiseptica*) induce different modifications of the nasal epithelium, but both actions cause the production of nasal mucus, which results in a nasal environment favorable to colonization by *P. multocida* (Gagne and Martineau-Doize 1993). The different types of mucins produced by the piglets' nasal mucosa at different ages may contribute to an understanding of *P. multocida* and *B. bronchiseptica* colonization (Martineau-Doize et al. 1991a, b).

Given this preconditioning, the organism will set up a nasal infection and, if toxigenic, the toxin will be elaborated. The nasal cavity, however, is not necessarily the only possible site of toxin production. The toxin appears to be of crucial significance in the pathogenesis of PAR, since only toxigenic strains of *P. multocida* produce PAR lesions; furthermore, the toxin will produce progressive snout shortening and turbinate atrophy when given to pigs intranasally (Ilina and Zasukhin 1975) and by a variety of parenteral routes (Rutter and Mackenzie 1984).

The precise mechanism of action of the *P. multocida* toxin has not been clearly defined; but it will produce a variety of changes in the ventral turbinates, consisting of epithelial hyperplasia, atrophy of mucosal glands, increasing volume of blood vessels, osteolysis, and a proliferation of mesenchymal cells. These eventually will replace the bone trabeculae and osteogenic and osteoclastic tissues (Rutter and Mackenzie 1984). PAR therefore seems to result from a combination of early osteoblastic damage followed by a series of toxin-induced chronic changes that result in osteolysis and subsequent replacement fibrosis. The toxins of *B. bronchiseptica* and *P. multocida* are different. Also, the ways in which the turbinates are destroyed differ. The combination of both toxins has detrimental effects on the turbinates and skull bones (Martineau-Doize et al. 1990).

CLINICAL SIGNS

Bordetella bronchiseptica

Rhinitis. The principal signs seen in bordetellosis are sneezing and snuffling in young pigs. This can occur in piglets as young as 1 week but is frequently seen at 3–4 weeks of age or about the time of weaning, which may be related to both maternal colostral protection and the mixing of pigs at this stage.

Affected piglets sneeze, snuffle, and snort with a variable degree of catarrhal rhinitis producing a variable amount of serous or frequently mucopurulent nasal discharge, which may be observed by swabbing the nasal cavity. Generally, the younger the piglet when initially affected, the more severe the clinical signs. The appetite is usually only moderately to slightly impaired. The clinical signs increase in severity for a time, then tend to abate after a few weeks, except in herds with clinical PAR, where continued progressive turbinate damage

causes frequent sneezing to continue. Uncomplicated *B. bronchiseptica* infections in older pigs produce only mild signs or remain clinically inapparent.

Not all sneezing in young pigs is attributable solely to *B. bronchiseptica*, since infection with porcine cytomegalovirus or other agents may also produce or exacerbate these signs.

Bronchopneumonia. A more severe manifestation of infection is bronchopneumonia, which is usually seen as a primary condition in very young piglets (3–4 days). Although this type of disease is relatively uncommon compared with the wide prevalence of nasal infection, *B. bronchiseptica* is an important pathogen in those cases of pneumonia with bronchitis that occur in young pigs. The condition only affects young pigs and is most common in winter (Whittlestone 1982). The major clinical sign is coughing, perhaps with whooping and dyspnea. Pyrexia is not usually marked (Switzer and Farrington 1975). Morbidity is high within litters, and mortality may be so in untreated cases.

B. bronchiseptica is not infrequently isolated from pneumonic lesions in older fattening pigs, but it is considered to be a secondary opportunist pathogen, and the clinical significance of its presence remains largely unknown.

Pasteurella multocida

Clinical signs of PAR are not usually seen in pigs until about 4–12 weeks of age or later, depending on the severity of the outbreak, but sneezing and snuffling in baby pigs are commonly recorded as the first signs. They are not, however, specific to or diagnostic of the condition, since they frequently occur in the absence of subsequent clinical PAR. Sneezing and snuffling in baby pigs is merely a reflection of an acute catarrhal rhinitis, which may be due to bordetellosis and/or infection with porcine cytomegalovirus; other agents may possibly be involved, for example, *Mycoplasma* sp., *Actinobacillus* sp., and Aujeszky's disease, influenza, and porcine reproductive and respiratory syndrome (PRRS) viruses. In herds where subsequent infectious and other factors combine to cause progression to clinical AR, affected pigs will continue to sneeze, snuffle, and snort throughout the growing period; this is accompanied by a variable amount of serous to mucopurulent nasal discharge. In severely affected animals, sneezing may be pronounced and occasionally nasal bleeding may occur. Hemorrhage is usually unilateral and varies in severity. Blood may be seen on the walls of the pen or on the backs of the pigs; mucopurulent material and even pieces of turbinate debris may be expelled from the nose following episodes of forceful, violent sneezing. In gilts and sows the hemorrhage in late gestation and farrowing can be life threatening to the dam and her piglets.

The most characteristic clinical signs of PAR are due to disturbances of normal bone development of the

34.4. *A 17-week-old pig with clinical PAR showing marked brachygnathia superior, wrinkling of the skin on the dorsum of the nose, and tear staining.*

nose; conspicuous deformities of the face may occur. The most common is BS, in which the upper jaw is shortened in relation to the lower, as a result of growth depression of the ossa nasales and maxillares, giving the face a "pushed-up" appearance. The skin and subcutis over the dorsum of the shortened snout are thrown into folds; when the disturbance of bone growth affects one side of the face more than the other, lateral deviation of the snout occurs (Figs. 34.4 and 34.5). This may vary in severity from a barely perceptible misalignment to severe twisting (possibly by as much as 50°). These facial deformities reflect an underlying turbinate atrophy; in the case of lateral deviation the atrophy is more pronounced on the side of the deviation. The prevalence of facial distortion varies among outbreaks, and not all pigs with significant turbinate atrophy develop marked facial distortion.

Dirty streaks on the face radiating from the medial canthus of the eye, caused by tear staining and the entrapment of dust following occlusion of the nasolachrymal duct, are common in PAR outbreaks (Fig. 34.4). However, they are not diagnostic and may occur in the absence of PAR.

In moderate to severe herd outbreaks of PAR, the clinical signs are frequently accompanied by growth retardation and reduction in the efficiency of feed utilization. Feed utilization is particularly reduced in severely diseased pigs. The amount of *P. multocida* toxin may influence growth performance (Doster et al. 1990; Van Diemen et al. 1994a).

Some clinical parameters have been used in an attempt to monitor and quantify disease levels. The prevalence of gross distortion among growing pigs is a crude measure of disease level but is not a sensitive index of turbinate atrophy. The prevalence and degree of BS in weaned pigs can provide useful information (Bercovich and de Jong 1976) but is not always diagnostic (Schöss 1983), and confusion can arise with breeds that are nat-

urally brachygnathic (e.g., Large White) (Van Groenland 1984). Sneeze counts have been used successfully in an attempt to assess the effects of treatment (Douglas and Ripley 1984; Kobisch and Pennings 1989).

LESIONS OF NPAR AND PAR

Gross Lesions

The gross lesions of PAR are restricted to the nasal cavity and adjacent structures of the skull, although in severe cases the pig may also be stunted. At necropsy both BS and facial distortion are observed in the intact head. The dominant lesion is an atrophy of the ventral and dorsal turbinates, and this can vary greatly in severity. The atrophy is assessed by a cross section of the snout at the level of the first/second upper premolar, at which point the conchae, dorsal and ventral, are symmetrically and maximally developed in the normal pig (Fig. 34.6). In mild to moderate cases the ventral scrolls of the turbinates are by far the most consistently and severely affected area; they vary from slightly shrunken to complete atrophy (Figs. 34.7 and 34.8).

In more severe cases, atrophy of the dorsal scrolls of the ventral turbinate and the dorsal and ethmoidal turbinates may occur (Figs. 34.9 and 34.10); in the most severe form there is a complete absence of all turbinate structures (Fig. 34.11). In between these mild and severe

34.6. *Cross section of the snout of an 18-week-old pig showing normal anatomy of the turbinates.*

forms, a whole spectrum of atrophic changes may be observed; occasionally the turbinates are bizarrely shaped (Fig. 34.10), which may represent some degree of regrowth of the conchae (Done 1985). Another gross change that may be observed is bowing or buckling of the nasal septum (Fig. 34.11); this is not uncommon and is often associated with BS, facial distortion, and/or asymmetrical atrophy. Irregular formation of the ossa nasales and maxillares also occurs in PAR (de Jong 1985) and should not be neglected (Figs. 34.10 and 34.11).

Exudate may be found in the nasal cavity but is not a constant finding. The amount and character depend on the age of the lesion and the type of infection. The exudate consists of variable amounts of mucopurulent to purulent material, possibly flecked with blood. The mucosa lining the frontal sinus is sometimes inflamed, and the sinus itself may contain mucopurulent material. The bones surrounding the nasal cavity may have undergone thinning or may be irregularly shaped to some

extent. Hyperplasia/hyperostosis can be observed in older pigs (de Jong 1985).

Assessment of Turbinate Atrophy. The varying severity of the atrophic changes has led to the development of methods of quantitative assessment, but unfortunately, no one system has gained universal acceptance. Subjective scoring of snouts (e.g., on a 0–5 scale as in the British system; Anon. 1978) has proved very useful in evaluating treatment and monitoring schemes. As well as wide variation between systems, there is also considerable interobserver variation within a system (D'Allaire et al. 1988). At least one reason for this is probably the clinicians' unwillingness to score a herd as having PAR, despite a degree of mild atrophy, when there has never been any clinical evidence of disease. Today, bacteriologic or serologic tests are necessary to confirm downgrading of the health status of a herd (e.g., when toxigenic *P. multocida* is present). The cutoff point between normality and being affected is imprecise, and the condition should not be regarded as a simple all-or-nothing phenomenon (Done 1985). The situation in many herds with only mild atrophy probably represents only the effects of a normally transient and often-resolving hypoplastic rhinitis without the progression characteristic of clinical PAR (see Definition above).

Objective measures of assessing atrophy on a continuous scale have also been developed, including a morphometric index (area of free space as a percentage of total cross-sectional area of snout section) (Done et al. 1984). Such systems provide parametric data suitable for analysis, but as diagnostic tools they offer few advantages over subjective snout scoring (Collins et al. 1988, 1989).

Histologic Changes

Depending on the type of process active at the time of necropsy, acute, subacute, or chronic histologic changes may be observed.

The pathognomonic lesion of PAR by toxigenic *P. multocida* is a fibrous replacement of the bony plates of the ventral conchae (Done 1983a; Elling and Pedersen 1983; Martineau-Doize et al. 1990). Additionally, there may be a variable metaplasia of the respiratory epithelium and inflammation of the mucosal lamina propria; subacute cases of rhinitis in conventional pigs will show various mixtures of degenerative, inflammatory, dystrophic, and reparative processes. In SPF pigs infection with toxigenic *P. multocida* does not induce a typical inflammatory reaction but does induce toxic alterations. The histologic changes in pigs with PAR that show retarded growth have been described by Yoshikawa and Hanada (1981).

Lesions in parenchymatous organs may also be present in cases of severe infection with toxigenic *P. multocida* (de Jong 1983a; Rutter 1983). Parenteral injections with *P. multocida* toxin induced liver cirrhosis, renal failure, marked decrease of peripheral blood lymphocytes without lysis, and growth retardation (Becker et al. 1986; Williams et al. 1986; Cheville et al. 1988).

Bronchopneumonia. Pneumonic lesions occur principally in young pigs and have a characteristic scattered monolobular or bilobular distribution, mainly in the apical and cardiac lobes. Affected areas are initially dark red, become brown, then yellowish brown after a time and develop a contracted appearance. The lesions are associated with the *B. bronchiseptica* element of the complex.

Histologically, the pneumonic lesions in bordetellosis are characteristic. Detailed descriptions of the histopathology of experimental *B. bronchiseptica* bronchopneumonia are given by Duncan et al. (1966b) and Meyer and Beamer (1973) in conventional and germfree swine, respectively. The lesions from these experimental cases are similar to those of field cases. Briefly, the most severe cases affect the pneumonic vasculature, and there are areas of extensive alveolar hemorrhage with necrosis and interlobular edema. In areas where hemorrhagic changes are less extensive, there is an acute inflammatory reaction with cellular infiltration, principally with neutrophils. There is an accompanying bronchiolitis with neutrophilic exudate. As the lesions age, vascular changes become less prominent and epithelialization of the alveoli, fibroblastic activity, and deposition of collagen occur. Large alveolar macrophages are present in some alveoli.

DIAGNOSIS

Bordetella bronchiseptica

Although the clinical signs are suggestive of infection, a definitive diagnosis of bordetellosis in pigs is only possible by the bacteriologic examination of lung washings, lungs at postmortem, or nasal secretions. Nasal secretions are best collected on cotton-tipped swabs with ei-

ther metal or elastic plastic stems. Wooden-stemmed swabs and swabs with quick-breaking plastic stems should be avoided, since sudden movement of the pig may break the shaft. The live pig should be adequately restrained and the external nares cleaned. Swabs are carefully inserted in a naris with a gentle rotating motion and pushed carefully along the ventral meatus so as to avoid trauma to the delicate turbinates. The swabs are then submitted for laboratory examination, preferably in a bacteriologic transport medium or a phosphate buffered saline solution (PBS) under cool conditions (±4°C).

The organism grows well on blood agar or MacConkey agar plus 1% glucose, but its isolation from field specimens is often complicated by the overgrowth of other organisms (Smith and Baskerville 1979); hence, culture on more selective media is recommended. Procedures for isolating and identifying the organism from field specimens from pigs are given by Farrington and Switzer (1977), Smith and Baskerville (1979), and Rutter (1981). Selective media to isolate both *B. bronchiseptica* and *P. multocida* on the same plate are discussed below under the detection of *P. multocida*.

The serologic diagnosis of bordetella infection by the detection of agglutinating antibodies in the serum has been described. The various methods of antigen preparation, details of some of the tests employed, and their interpretation have been reviewed by Giles and Smith (1983). Agglutinating antibodies to *B. bronchiseptica* are widespread in the pig population, but although their detection by serologic tests can be useful in making a herd diagnosis of bordetellosis, these are not commonly employed for routine diagnostic purposes, since, practically, serologic tests offer few advantages over the culture of nasal swabs.

Pasteurella multocida

Clinical Diagnosis. When the full range of clinical signs is present, a preliminary diagnosis of PAR on clinical signs alone is possible, but none of the snout deformations by themselves are pathognomonic for PAR. Animals showing lateral deviation of the snout and/or marked BS, especially at an age of 10–12 weeks, almost always have pronounced turbinate atrophy (Bercovich and de Jong 1976; de Jong 1985; Kobisch and Pennings 1989). However, when these signs are not apparent or are of decreasing prevalence (e.g., following treatment), it is not possible for even experienced observers to assess the extent of turbinate atrophy in the live animal. The presence of a few twisted snouts or sneezing alone is not sufficient evidence to justify a diagnosis of PAR (see Definition).

Radiographic Diagnosis. Radiographic examination of the snout has been developed to facilitate improved diagnosis of turbinate atrophy in the live animal; a suitable procedure is described by Done (1976). In some

countries this method has enjoyed widespread popularity, but it is beset with technical difficulties and problems in interpretation of the radiographs. The method may not detect mild lesions reliably, and its value has been questioned (Eikelenboom et al. 1978; Webbon et al. 1978); furthermore, pigs must be sedated, anesthetized, or physically immobilized, and the procedure is costly and time-consuming. With experience, however, some observers consider radiographic examination a useful aid (Schöss 1983). The same disadvantages apply to rhinoscopy (Plonait et al. 1980). Modern methods such as computerized tomography, used as a diagnostic tool for PAR, facilitate the macroscopic grading of the nasal structures in live pigs of any age (Jolie et al. 1990).

Postmortem Diagnosis. The prevalence and severity of turbinate atrophy are best estimated by examination of snouts after slaughter. Snouts should be transversely sectioned at the level of the first/second upper premolar; sectioning cranial to this should be avoided, since this will reveal a different pattern of turbinate development. Pigs of 4 weeks old or older that died during weaning or prefattening can present turbinate atrophy at an early stage, and cross-sectioning can be carried out with a simple iron saw by qualified local veterinarians during regular herd inspections. Material from tonsils, lungs, and the nose can be sent to laboratories to ensure a proper diagnosis. To make a preliminary herd diagnosis, pigs have to be examined at slaughter at regular intervals. As many pigs as practical should be examined; between 20 and 30 per time is suggested by Goodwin (1988). Atrophy is scored on subjective grading systems (Bendixen 1971; Anon. 1978; Done 1983a, b; de Jong 1985). With low levels it is not possible to define a single cutoff point as representing freedom from PAR. An acceptable level for an individual (toxigenic *P. multocida*–infected) herd is a matter of reasoned clinical judgment but must be one in which the economic effects of the disease are minimal (Goodwin 1988). A monitoring scheme that could serve as a useful model with a diagrammatic representation of snout grading is described by Goodwin (1980). Computerized versions have been developed by Collins et al. (1988), Barfod et al. (1990), and Jolie and Thacker (1990).

Cultural and Serologic Diagnosis. Today, a definite diagnosis of PAR cannot be based solely on clinical and pathomorphologic observations but requires laboratory tests (Pedersen 1983). Detection of the two most significant bacterial pathogens is possible by the culture of nasal and tonsillar swabs or tonsillar biopsies. The live pig should be adequately restrained and the external nares cleaned; slender cotton-tipped swabs with plastic or metal shafts should be inserted with slight rotation deep into both sides of the nasal cavity. Swabbing the tonsillar surface or tonsillar biopsies can aid the isola-

tion and differentiation of *P. multocida* and toxigenic *P. multocida* (Van Leengoed et al. 1986; de Jong et al. 1988; Ackermann et al. 1994). Swabs should be transported to the laboratory within 24 hours, preferably in a transport medium under cooled conditions (4–8°C). Nutrient transport media that support the growth of fast-growing contaminants are best avoided, but sterile phosphate-buffered saline is suitable (Pedersen 1983).

Detection of *P. multocida* (and *B. bronchiseptica*).   Special selective media are described on which both *B. bronchiseptica* and *P. multocida* can grow (de Jong and Borst 1985; de Jong 1994; Moore 1994).

The cultural isolation of *P. multocida* from nasal swabs and the testing of their toxigenicity are detailed by Pedersen (1983). When the nasal cavity is heavily infected with *P. multocida*, the organism can be recovered on simple blood agars (Smith and Baskerville 1983). However, field specimens frequently contain low numbers of organisms, and the other nasal flora may mask the presence of *P. multocida* on nonselective media. Mouse inoculation greatly improves the recovery rate from field specimens, but a good in vitro method would be preferable. Some selective media are described by Smith and Baskerville (1983), Rutter and Luther (1984), de Jong and Borst (1985), Leblanc et al. (1986a, b), Chanter and Rutter (1989), Avril et al. (1990), and de Jong (1994). Evidence suggests that the tonsil is the preferred habitat for *P. multocida* in the pig, and improved detection rates may be achieved by the collection of tonsillar swabs or biopsies in combination with nasal swabs (de Jong et al. 1988). Tonsils and lungs can also be collected in the slaughterhouse and examined in the laboratory. Swabs from noses of pigs sampled after immersion in the hot-water tank are unsatisfactory for the detection of toxigenic *P. multocida* (Chanter and Rutter 1989).

When clinical severe PAR is first detected in pigs, infection by toxigenic *P. multocida* actually occurred weeks or months earlier. The detection of the toxigenic *P. multocida* from these pigs can be difficult. Therefore, it is recommended to also examine clinically less severely affected pigs in such groups or pens.

Detection of *P. multocida* Toxin.   The central etiologic importance of toxigenic strains of *P. multocida* is that classification of field isolates into PAR toxin-positive or toxin-negative strains is necessary in understanding the epidemiology of the disease. The toxin is thermolabile, dermonecrotic in the guinea pig and lethal for the mouse when administered intraperitoneally. All three tests give broadly comparable results; the methods are described by de Jong (1980, 1985), Pedersen (1983), and Rutter (1983), respectively. An in vitro system of detection by assessing the cytopathogenic effect in monolayers of Vero cells or embryonic bovine lung cells has been developed (Pennings and Storm 1984; Rutter and Luther

1984). Today, enzyme-linked immunosorbent assays (ELISAs) are replacing the earlier tests (Foged et al. 1988). DNA probes have been developed to detect the gene responsible for toxin production in toxigenic *P. multocida* (Andresen et al. 1990; Kamps et al. 1990; Lax and Chanter 1990). The use of polymerase chain reaction (PCR) tests is becoming of interest in diagnosis and in proposals for eradication of toxigenic *P. multocida* in PAR-diseased herds (Nagai et al. 1994; de Jong 1994; de Jong et al. 1996).

P. multocida Serotypes.   Determination of the capsular serotype of *P. multocida* is also often useful for epidemiological purposes; most toxin-positive strains are type D, although toxin-positive type A strains also occur. In some regions the toxigenic type D is prevalent, in others it seems to be type A (Cowart and Backstrom 1984; Iwamatsu and Sawada 1988; Pijoan et al. 1988). The usual method of capsular serotyping is the indirect hemagglutination test with rabbit antisera (Carter 1955). The hyaluronidase test (Carter and Rundell 1975) and acriflavine test (Carter and Subronto 1973) are simpler methods for the detection of type A and D strains, respectively, but not all porcine isolates are typeable by these methods (Pedersen 1983). Piliation, hemagglutination, and capsular serotypes did not show a correlation with toxin production (Trigo and Pijoan 1988). An atypical *P. multocida* strain producing a toxin similar to the dermonecrotic toxin of *P. multocida* subs*p. multocida* has been described in cattle (Kamp et al. 1990). Not only the capsule and somatic structure are of epidemiological interest; the phage types and plasmid types are also interesting tools with which to follow the distribution pattern of the different toxigenic strains (Lugtenberg et al. 1984; Nielsen and Rosdahl 1988, 1990; Hoje et al. 1990; Rubies et al. 1996).

Serologic Tests.   Although agglutinating antibodies to *B. bronchiseptica* can be detected in pig serum (Giles and Smith 1983), this is of little diagnostic value. Serologic tests to detect antibodies against toxigenic *P. multocida* resulting from vaccination or infection have been described (de Jong and Akkermans 1986; Bechmann and Schöss 1990; Foged et al. 1990; Schimmelpfennig 1990). The toxin in natural infection is a weak immunogen, and antibodies to it take 3 months or longer to detect and only then in some pigs (Bording et al. 1990; Van Diemen et al. 1994b). This means that serology may only be of importance in detecting antibodies in the sow population. A skin test has been described to detect antibodies in sow herds that have been infected (Schimmelpfennig and Jahn 1988; Breuer and Schimmelpfennig 1990).

In the skin test the purified concentrated toxin is applied intradermally in one or different concentrations. Neutralization of the toxin indicates the presence of antibodies as a response to the infection or vaccination

with toxigenic *P. multocida*. Difficulties in application and in the identification of the correct amount of toxin per dose have limited the use of the skin test in practice.

Differential Diagnosis. Sneezing in young pigs occurs in herds with active PAR, but it is not diagnostic itself, since it regularly occurs due to uncomplicated bordetellosis or porcine cytomegalovirus infection (Rondhuis et al. 1980). Both agents are widely spread in the pig industry and can cause severe mucous membrane damage, which is necessary for colonization by toxigenic *P. multocida*. The frequency of severe sneezing can be used in clinical monitoring of PAR (Kobisch and Pennings 1989). Influenza, PRRS, and pseudorabies are other viruses causing damage to the nasal mucosa.

A variety of other conditions (reviewed by Done 1977) may cause facial deformity in pigs; these are likely to cause confusion in clinical and postmortem diagnosis, since malformations of the turbinates can be observed. A localized bacterial infection entering via wounds may produce a paranasal abscess (bull nose) in young pigs.

Problems with Diagnosis. Should pigs from a herd with no clinically apparent disease that have no obvious growth retardation but show mild turbinate atrophy at slaughter be considered to be suffering from PAR or NPAR? It is suggested that when BS, lateral deviation, and poor growth are obvious within the herd and atrophy at slaughter is marked, the herd should be suspected of having clinical PAR. Conversely, where no turbinate atrophy is seen in slaughtered pigs, the herd must be regarded as clinically free from PAR. However, defining the status of herds where mild atrophy occurs in the absence of clinical disease presents problems, since there is no satisfactory single cutoff point between affected and unaffected herds (Goodwin 1988). These low levels of atrophy have been regarded as representing degrees of subclinical PAR but are probably better viewed as indicating risk of developing clinical PAR. The level of atrophy deemed satisfactory or acceptable for a given enterprise is often a matter of reasoned clinical judgment. With the help of bacteriologic and serologic investigations this problem can be avoided (see Definition).

BS can occur as a breed-associated characteristic in certain lines of the Large White/Yorkshire breed. Breed-associated BS increases with age and cannot be influenced by a medication program intended to combat the influence of a bordetella and/or a pasteurella infection in these pigs. The breed-associated level of BS can easily be assessed by such a medication method. All BS grading higher than this lower genetic level may be a result of PAR or NPAR. A warning limit can be chosen (e.g., at an age of 8–12 weeks) to allow early selection of clinically diseased animals and to limit further damage in grower or fattening pigs as well as in the younger pigs that will follow such groups.

Breed-associated BS is easily distinguished from PAR by the absence of turbinate atrophy, except where regeneration of the turbinates has occurred.

Sows and gilts kept in stalls often bite, chew, or play with bars or drinkers, and this can give rise to asymmetric bone development causing protrusion of the lower jaw or mandibular misalignment. These conditions can be confused with the facial deformity of AR, especially in the older pig, but careful inspection should reveal that the lower jaw is abnormally placed rather than that the snout is shortened or laterally deviated. A useful technique is to draw an imaginary line between the center of the ears and eyes and project it forward onto the snout. Some sows keep their snouts more to one side. This can cause misinterpretation. By pressing the molar teeth on top of each other and comparing the diastema between the incisor teeth in the upper and lower jaw, distortion can be noticed clinically at an early stage. This method can be carried out in combination with the BS-grading method. With thin nasal swabs an increase in internasal space can be observed clinically, but some experience is necessary for the interpretation.

TREATMENT

The effective treatment of an outbreak of NPAR or PAR requires a selected combination of management, environmental, chemotherapeutic, and vaccination procedures. No one combination is equally applicable to all affected herds. The overall aims of treatment are (1) to reduce the prevalence and load of the important specific bacterial infections (bordetellosis and pasteurellosis) in young pigs by sow vaccination, medication of feed, and antibiotic treatment of piglets; (2) to treat growing pigs with an acute rhinitis to reduce the weight of bacterial infection and severity of the hypoplastic changes and maintain efficient growth and feed utilization; and (3) to manipulate housing, ventilation, and management to improve the overall environment for the pigs (de Jong and Bartelse 1980; Smith 1983).

Management and therapeutic measures to control bordetellosis in commercial pig herds are required or usually deemed necessary by experienced clinicians only in herds where this infection is associated with clinically significant disease, whether rhinitis, bronchopneumonia, or infectious PAR. The mere presence of the infection within an ordinary commercial herd is not, on its own, sufficient ground for initiating therapeutic measures against it.

The sulfonamides were the first drugs to be used successfully in this respect (Switzer 1963) and are still widely employed, either alone or in combination with antibiotics, or potentiated with trimethoprim. Bronchopneumonia in piglets should be treated with parenteral injections of sulfadoxine or sulfadiazine at 12.5 mg/kg with trimethoprim at 2.5 mg/kg daily for 3–5 days.

Alternatives to the sulfonamide drugs have been examined. Most porcine isolates of *B. bronchiseptica* appear to be sensitive to the tetracyclines (Sisak et al. 1978; Smith et al. 1980; Pijpers et al. 1989), and these drugs, particularly a long-acting formulation of oxytetracycline given by parenteral injection to young pigs, appear to be suitable for the control of bordetellosis.

The new fluoroquinolones are also active against porcine *B. bronchiseptica* (Hannan et al. 1989).

Antibiotic Resistance

The in vitro activity of 12 sulfonamide drugs against *B. bronchiseptica* was compared by Mengelers et al. (1989), who showed that the minimum inhibitory concentration (MIC)50 ranged from 0.5 to 8 µg/mL. Against a selection of the pathogenic respiratory bacteria of swine, sulfamethoxazole had the highest antimicrobial activity, and sulfamezathine had an overall low activity. Isolates of *B. bronchiseptica* from pigs have been shown to have transmissible R factors that carry antibiotic resistance (Terakado et al. 1974).

Medication

Sows and Piglets. To reduce the prevalence and severity of nasal infection acquired from dams, the feed of the sow can be medicated during the final month of gestation. Sulfadimidine (sulfamethazine) (400–2000 g/ton) and oxytetracycline (400–1000 g/ton) are the products most widely used.

Suckling piglets are best medicated by strategic injections of antibacterial agents in therapeutic dosages four to eight times during the first 3–4 weeks of life. The most useful are potentiated sulfonamides, oxytetracycline, and penicillin/streptomycin.

If bordetellosis is the major infection in suckling piglets, potentiated sulfonamides are the drugs of choice (12.5 mg/kg sulfadiazine or sulfadoxine + 2.5 mg/kg trimethoprim). Injections of oxytetracycline (20–80 mg/kg) once or twice a week are also clinically effective for PAR (de Jong and Oosterwoud 1977; Mefford et al. 1983). The long-acting formulation (20–80 mg/kg) may be the preferred product and is best given once or twice a week during each of the first 3 or 4 weeks of life. If the organism is not resistant, the drug is effective against pasteurellosis, since, experimentally, long-acting oxytetracycline has reduced the prevalence of nasal infection and the severity of turbinate atrophy induced by *P. multocida* (Gois et al. 1983b); although other researchers prefer doxycycline (Pijpers et al. 1988). In the Netherlands, intranasal spraying of oxytetracycline in a 5% solution is used in piglets twice a week, when starting the treatment. If effective after 2–3 months, a reduction from twice to once a week can be recommended (de Jong 1983b). This withdrawal of medication also depends on the average antibody titer against the toxin of *P. multocida* in the dams resulting from the vaccination program.

Other antibiotics to which *P. multocida* may be sensitive and that are frequently used in therapeutic concentrations against pneumonia caused by pasteurellosis include penicillin/streptomycin (20,000 IU/10–25 mg/kg), tylosin (10–25 mg/kg), lincomycin/spectinomycin (50/100 mg/kg), ampicillin (10–20 mg/kg), amoxicillin (10–20 mg/kg), spiramycin (25 mg/kg), quinolone derivatives (0.5–5 mg/kg), cephalosporins (1–5 mg/kg), and tiamulin (10–20 mg/kg) (Plonait and Bickhardt 1988). The benefits of the treatments have not been critically evaluated as far as nasal and pulmonary protection and/or elimination of the toxigenic *P. multocida* are concerned.

Weaners and Growers. The PAR in weaned pigs that leads eventually to marked turbinate atrophy at slaughter can be controlled to some extent by medication of weaner and/or grower rations or by the addition of antibiotics to the drinking water. Such medication also assists in the maintenance of growth and efficiency of feed utilization in the face of active PAR, but as might be expected, medication is always much more effective when the pigs' environment is improved. Various antibacterial agents alone or in combination are effective. The sulfonamides are frequently included in rations because of their known efficacy against bordetellosis. Their use and the problems of the development of drug resistance are of great concern.

Well-established drugs or combinations suitable for the control of PAR are (1) sulfadimidine (sulfamethazine) (400–2000 g/ton) in feed or sulfathiazole (0.08–0.13 g/L) in the drinking water; (2) chlortetracycline (165 g/ton), sulfadimidine (sulfamethazine) (165 g/ton), and penicillin G (83 g/ton) in feed; (3) tylosin (100 g/ton) and sulfadimidine (sulfamethazine) (100 g/ton) in feed; (4) carbadox (50 g/ton) and sulfadimidine (sulfamethazine) (100 g/ton) in feed; (5) oxytetracycline in feed (400 g/ton) or in drinking water (0.18 g/L) (Giles 1986). Various other antibacterial agents, alone or in combination, also have broadly similar beneficial effects on PAR lesions and help to maintain growth. For example, the following have been demonstrated as clinically effective in feed: lincomycin (220 g/ton); lincomycin (220 g/ton) and sulfamethazine (550 g/ton); lincomycin, spectinomycin, and amoxicillin trihydrate (10–20 g/ton).

When a number of drugs are used in feed, a decrease of bioavailability can occur, which may result from the amount of calcium, the feed processing, and the water ration given to the treated pigs (Counotte et al. 1984; Froe 1990; Sutter and Wanner 1990). The availability of some of these drugs and the regulations regarding their use in food-producing animals vary between countries.

Selection of an appropriate antibiotic or combination depends partly on cost, legislation, and clinical experience but should also be related to the antibiotic sensitivity patterns of *B. bronchiseptica* and *P. multocida*

isolates and the established MICs (Pijpers et al. 1988; Fales et al. 1990; Awad-Masalmeh et al. 1994). Differences in MIC between *P. multocida* type D and type A strains may occur in the same herd (Schimmelpfennig 1990). In a severe outbreak, treatment should be directed at pigs of all age groups other than those immediately destined for slaughter; as the severity declines, reducing antibiotic use for the older fatteners should be the first priority. The appropriate withdrawal times before slaughter must always be adhered to. It is usually necessary for pigs at risk to receive medicated feed for a minimum of 4–5 weeks and frequently for longer periods, depending on the results of the vaccination program and the improvement in housing, ventilation, and management.

Vaccination

Sows. Vaccination of the sow induces a significant degree of passive colostral protection against *B. bronchiseptica* in the serum of her suckling piglets (Koshimizu et al. 1973; Smith et al. 1982); in the field, this protection will often persist until about the time of weaning. The colostral protection afforded by sow vaccination is thus an effective aid in controlling *B. bronchiseptica* infections among populations of young suckling piglets; in herds where early piglet infection occurs and rhinitis and/or bronchopneumonia develop in young pigs, sow vaccination should be recommended. Initially two doses should be given 6 and 2 weeks before farrowing, followed by revaccination at 2 weeks before each subsequent farrowing. Bordetella vaccines which induce toxin-neutralizing antibodies and pilus antibodies are of interest.

In a prolonged vaccination scheme for gilts and the sow and boar population, the number of *B. bronchiseptica* carriers is reduced. This in combination with the increased colostrum protection and all-in/all-out procedures in the farrowing and weaner sections may be helpful in producing *B. bronchiseptica*–free offspring or in reducing the *B. bronchiseptica* colonization in such populations. These procedures also reduced bordetella pneumonia. In NPAR herds the use of combined bordetella and pasteurella vaccines is not recommended, because the antibodies against the pasteurella toxin lead to suspicion of PAR in such herds. Downgrading the health status could be the result.

Vaccination of the sow with a potent *B. bronchiseptica* vaccine is an effective way to reduce the prevalence and severity of nasal bordetellosis in suckling and weaned piglets (de Jong 1985) but exerts only a limited effect on clinical PAR (Giles and Smith 1983). Pathogenic determinants important in vaccines include the toxigenic characters, the pilus-producing factor, and outer-membrane proteins. Lack of antibody to some of these properties seems to influence the reduction of *B. bronchiseptica* in sows and piglets.

B. bronchiseptica/P. multocida vaccines have been evaluated experimentally and in the field. In some countries combined vaccines are available commercially. Such vaccines have reduced the prevalence of clinical PAR (Schuller et al. 1980; Baars et al. 1982; de Jong et al. 1984) but do not eliminate the condition. As might be expected, the thermolabile toxin for *P. multocida* appears to be an important determinant in eliciting protection, because experimental vaccination of sows with crude toxin significantly protected their offspring against PAR (Baars et al. 1982, 1986; Pedersen and Barfod 1982). The specific importance of the toxoid fraction has been elucidated (Nagy et al. 1986; Foged et al. 1989; Frymus et al. 1989; Chanter and Rutter 1990).

The antigens and mechanisms of protection against toxigenic *P. multocida* infection and associated disease have yet to be fully defined; reports show that toxoid preparations of *P. multocida* produce an antitoxin response, with an effect on colonization (Chanter and Rutter 1990). Claims made for *B. bronchiseptica* vaccines in the control of AR were not fully substantiated in field use (Giles and Smith 1983); thus, a rush to develop further combined vaccines without full appraisal of the required antigens is undesirable.

Some of the currently available combined *B. bronchiseptica/P. multocida* vaccines may be of benefit in controlling bordetellosis and toxigenic pasteurellosis and in reducing the prevalence and severity of PAR when combined with housing and management changes (de Jong et al. 1984). The marked reduction in toxigenic *P. multocida* in the nose following vaccination with a potent toxoid vaccine requires further evaluation to determine whether the expression of high antibody levels can eradicate toxigenic *P. multocida*. Vaccination of sows with combined vaccines can be as effective as piglet medication. However, neither procedure constitutes a means of protection against the condition nor necessarily obviates the need for medication. Such a vaccination program, once started in an infected herd, has to be maintained, at least for many years.

Piglets. Vaccination of older pigs undoubtedly produces an active humoral response but its value is debatable, since the main effects of the infection occur in younger animals. Specific measures against *B. bronchiseptica* infection should be directed toward preventing the infection from arising in suckling pigs (by management, sow vaccination, or chemotherapy) or mitigating its effects in young pigs (by management and/or chemotherapy).

B. bronchiseptica vaccine has been widely employed. Although some observers have concluded that it has little benefit against clinical PAR and is generally less effective than sow vaccination (Giles and Smith 1982, 1983), in some countries (notably the United States) the procedure nevertheless still enjoys fairly widespread use. *B. bronchiseptica/P. multocida* bacterin vaccines are also widely employed, but the composition of many of them

means that they may be of little benefit in the field. In a study in which both sows and piglets were inoculated with a combined vaccine, Mefford et al. (1983) demonstrated that vaccination alone did not influence turbinate atrophy and only marginally improved profitability.

Only vaccination of the piglets born of inadequately vaccinated or unvaccinated dams is of value in the case of *P. multocida* toxoid vaccines. When sows are properly vaccinated and produce good levels of antitoxic antibodies, piglets may not respond to vaccination. If the dams show good titers, the colostral protection in pigs can last for 3–4 months. Vaccinations of the young breeding stock can be started after this age. A high antitoxin titer seems to reduce colonization by toxigenic *P. multocida*.

The additional use of therapeutics (e.g., long-acting oxytetracycline) in piglets significantly reduced turbinate atrophy at slaughter and markedly improved profitability (Pejsak et al. 1990). Furthermore, some commercially available vaccines contain neither toxigenic strains nor *P. multocida* toxoid, the manufacturers only claiming efficacy against pneumonic pasteurellosis.

Housing and Husbandry

Medication and vaccination procedures should never be introduced without concurrent attempts to improve swine management and husbandry. Although the non-infectious factors that contribute to the severity of PAR are inadequately defined quantitatively, steps should always be taken to reduce their influence. All-in/all-out systems are favored for farrowing, weaner, and preferably fattener management; the age of the sow herd can be allowed to rise and the introduction of large numbers of infected new gilts can be avoided; stocking density can be reduced; strict hygiene measures should be implemented; and correct ventilation rates should be maintained to reduce the airborne concentration of bacterial pathogens, noxious gases, and dust. Steps should also be taken to reduce factors that stress young pigs, including large temperature variations, chilling, and drafts. Replacement breeding stock should not only be free from clinical signs of disease but also be raised in herds free from infections with toxigenic *P. multocida*; introduced weaners should be free from active rhinitis and the associated sneezing and typical BS. Newly purchased stock should originate from herds free from toxigenic *P. multocida*, be isolated (quarantined), be tested bacteriologically or serologically for freedom from toxigenic *P. multocida*, and be integrated slowly. Severely affected pigs with obvious and severe growth retardation should be culled. Vaccination programs should be started if breeding stock free from toxigenic *P. multocida* infection is brought into infected herds. Vaccination can reduce colonization by toxigenic *P. multocida* when infection cannot be avoided. Such an AR vaccination program needs to be carried out continuously in the whole sow population of the infected herd. Effective vaccination with potent vaccines in sows alone can also limit the economic damage in weaners. The risk to breeders, multipliers, and fatteners of becoming infected by toxigenic *P. multocida* can be limited by asking for or giving guarantees that the pigs bought or sold originate directly from herds certified free from the organism. This certification can be carried out under governmental legislation. Only by means of such a system of enforced restrictions can the spread of toxigenic *P. multocida* via sales or auctions be prevented.

Depopulation

Depopulation and restocking with swine from a source known to be free from toxigenic *P. multocida* are often the only viable solution. Buildings should be thoroughly cleaned and disinfected, then fumigated and left empty for 2 weeks to 2 months, depending on the efficacy and quality of the hygiene program. Eradication of rats, mice, and birds must be carried out properly and continually. Replacement pigs should be bought from sources known to be free from PAR and toxigenic *P. multocida* infection, based on clinical, abattoir, bacteriologic, and/or serologic monitoring.

PREVENTION

Since *B. bronchiseptica* is widely prevalent in the pig population, its total exclusion from a herd is only possible by the development of an SPF system or by medicated and segregated early-weaning methods and the strict maintenance of an effective barrier. *B. bronchiseptica* is often one of the first agents to infect an SPF herd.

Vaccination

B. bronchiseptica vaccines have been developed and used in several countries in an attempt to control both the infection and the clinical condition AR by immunologic methods. Killed whole-culture vaccines with aluminum salt adjuvants were the first to be available commercially and have been licensed for use in several countries since the 1970s. Other types of vaccine have also been investigated, including live avirulent strains (Krüger and Horsch 1992) and subunit vaccines, but generally have not been used widely in practice. Killed whole-culture adjuvanted vaccines were at one time widely employed in pig herds because several reports, mainly from the United States and Japan (e.g., Nakase et al. 1976; Goodnow 1977; Goodnow et al. 1979), indicated that such products were highly effective in the control of field outbreaks of clinical PAR. In Europe, however, these benefits were much less obvious (Bercovich and Oosterwoud 1977; Pedersen and Barfod 1977; Giles and Smith 1982). Later, further studies from the United States also concluded that such bordetella vaccines are of limited efficacy in the overall control of PAR. A critical review of bordetella vaccines (Giles and Smith 1983) concluded that,

as single antigens, their beneficial effects in the control of PAR are indeed limited and the previous claims for their usefulness overstated. In the light of new knowledge, combined vaccines have been developed consisting of *B. bronchiseptica*/*P. multocida* bacterins or *B. bronchiseptica* bacterin combined with *P. multocida* toxoid. Such vaccines are of use in the field, provided their limitations are fully realized by the clinician.

Single bordetella vaccines should be used to limit the influence of bordetellosis or NPAR but not in PAR-diseased herds.

PAR can be prevented effectively only by rearing swine free from the specific infections required for disease to develop. The adoption of an SPF system of production and the maintenance of an effective microbiologic barrier are the only sure ways of achieving this. Medicated early weaning (Alexander et al. 1980) may well be a viable alternative to the established methods of producing SPF stock free from toxigenic *P. multocida* (James 1989; Blaha et al. 1990; Larsen et al. 1990). Traditional vaccination or medication regimes applied to infected herds are not likely to create herds free from the infections; thus, the infected herds pose a serious threat to free herds in their neighborhood and also pose risks to other branches of animal production, such as poultry, rabbits, goats, sheep, and cattle (Nielsen et al. 1986; Frymus et al. 1996). In a preventive disease control program, eradication schemes have to be carried out in all types of herds and in all kinds of animals infected with toxigenic *P. multocida*. *B. bronchiseptica* appears to be very widespread in the pig population, but the prevalence of infection with toxigenic strains of *P. multocida* is less well defined. A positive correlation exists between the prevalence of toxigenic strains of *P. multocida* in a herd and the known occurrence of PAR (de Jong 1983b; Nielsen 1983; Pedersen 1983; Cowart and Backstrom 1984; Leblanc et al. 1986b; Bechmann and Schöss 1988; Cowart et al. 1989), although the mere presence of this infection does not always mean clinical disease. The potential risk of clinical PAR developing in a herd could be eliminated simply by ensuring that pigs are free from toxigenic *P. multocida* infection. Therefore, it is desirable to monitor breeding herds for this pathogen and to take steps to reduce its dissemination and introduction into unaffected herds. It is definitely beneficial to maintain herds with no history of PAR and low scores of atrophy at slaughter behind effective barriers or to bring in pigs only from sources known to be free from the condition. Breeding companies that sell and export pigs from infected herds, inadequately monitored for infectious diseases like PAR, are involved more and more in financial claims by new clients who will not accept the cost of medication and vaccination and the degradation of the health status of their own breeding herds. Because aerogenic spread has been described (Baekbo and Nielsen 1988; Stehmann et al. 1989) and spread of infection may be possible from surrounding herds, special attention to

air filtration and decontamination systems (Rutter et al. 1986; Voets et al. 1986b) could be necessary if distances become too small (probably within 200–2000 m, depending on the size of the surrounding herds). PAR has also been found in outdoor systems. Prevention of toxigenic *P. multocida* infection in outdoor systems can be difficult. Prevention by artificial insemination seems possible, but some risks exist when the antibiotics used in the semen diluter do not eliminate the toxigenic pasteurellae (Overby 1990).

Monitoring

Commercial producers should be aware of the current disease status of their herds. This applies to herds that have past or present evidence for the clinical condition, as well as to producers who need to monitor the effects of control measures or whose herds have remained free from the condition and who appreciate early warning of any change in herd status. Hence, ideally, herds need monitoring systems that can quantify not only the presence but also the effects of PAR (Done 1983b), especially in the case of an infected herd. Since this disease is not a simple all-or-nothing condition, merely relying on the presence of clinical disease disguises moderate to low levels of infection and recognizes it too late for the introduction of prophylactic measures.

Parameters that can be usefully measured are indirect production or economic data, such as liveweight gain or efficiency of feed utilization, and clinical/pathological data related to PAR, including the amount of sneezing, the incidence of facial distortion, and the two most useful criteria, the prevalence and extent of BS in weaned pigs and the prevalence and severity of turbinate atrophy at slaughter. The latter is the most popular in some countries. In large, modern slaughterhouses the gathering of snouts and cross sections is difficult; in such situations a scoring system on longitudinally opened snouts can be useful (Visser et al. 1988). Sophisticated methods of monitoring have been developed, one of which is the plotting of cumulative-sum charts with decision boundaries, since it gives early signals of deterioration or improvement. Done (1983b) has reviewed the methods of monitoring PAR. Use of computer technology in slaughterhouses and on pig farms means that important disease-monitoring systems may be effectively employed without laborious clerical work (Collins et al. 1988). Because the antibody titer against the toxin of *P. multocida* correlates with increased protection against turbinate atrophy (Sorensen et al. 1990), serologic monitoring becomes of interest in determining a possible increase in PAR risk when a decrease in the titers occurs in herds with a sow vaccination program. A program in which only sows are vaccinated can also protect the pigs during the fattening period. Recent investigations have shown a relationship between antitoxin titers and some protection against colonization by toxigenic pasteurellae (Chanter and Rutter 1990). Modern methods for the

detection of toxigenic *P. multocida* by DNA probes from samples of noses, tonsils, or lungs may soon become useful in monitoring systems (Kamps et al. 1990). Positive results have already been achieved by bacteriologic (Schöss 1982; Schöss and Thiel 1984; de Jong et al. 1988) or serologic monitoring (de Jong et al. 1988; Bechmann and Schöss 1990; Foged et al. 1990; Schimmelpfennig 1990).

Toxigenic *P. multocida* can be eliminated from infected breeding farms after intensive vaccination for a period of more than 5 years. These regularly vaccinated sows produce high anti–*P. multocida* toxin titers. During this period the replacement gilts and boars must be bought from herds free from toxigenic *P. multocida*. The replacements should be introduced into the infected sow population only after being vaccinated several times with an atrophic rhinitis toxoid (ART) vaccine. The herd vaccination program needs to be continued until the last sow from the infected population has left the farm, which generally takes about 5 years. Methods to shorten such periods by selecting and slaughtering the toxigenic *P. multocida* carriers are being developed with the help of the new PCR techniques. First attempts have been partially successful (de Jong 1994; de Jong et al. 1994, 1996; de Jong and Braamskamp 1994).

Selecting carrier sows in nonvaccinating herds by bacteriological procedures and by the (DAKO) ELISA test or the PCR test and removing them have been described as successful in creating infection-free sow herds (Alt et al. 1996).

35 Brucellosis

A. P. MacMillan, Heidi Schleicher, John Korslund, and William Stoffregen

Brucellosis of pigs is an infectious disease that has been recognized as a specific entity since 1914, when Traum (1914) isolated the organism from aborted porcine fetuses in Indiana, but for many years it was thought to be caused by an exceptionally pathogenic form of *Brucella abortus* until Huddleston (1929) named the infectious agent, *B. suis*, as a separate species. Brucellosis occurs in most countries throughout the world where pigs exist in the wild or domesticated state.

In the United States porcine brucellosis was recognized as a major disease, causing considerable economic loss during the 1920s–1950s. Since that time, changes in management combined with regulatory programs to eradicate the disease have gradually eliminated brucellosis as a major disease problem from large areas of the country. As of late 2004 all states except Texas were in Stage III (Free) status of the Swine Brucellosis Control/ Eradication Program. All outbreaks of infection in domestic herds have been attributed to feral swine exposure for several years, including those in Texas. In fiscal year 2004, there were only 2 small-herd isolated outbreaks reported in the U.S. swine population, both feral-related (Holland and Barton 2004*).* The disease is essentially eradicated in the commercial production swine herd in the United States.

Swine brucellosis appears to be widespread in South America, where it is predominantly caused by biovar 1. In Europe (apart from Britain and Scandinavia, which are brucellosis free), there is a general low prevalence of porcine brucellosis. In Africa, the disease is reported by some countries, but the number of pigs on the continent is not large, and the true position is not entirely clear. Asia, particularly Southeast Asia, seems to have a generally high prevalence of the disease, predominantly caused by biovar 3 in south China and Singapore and by biovar 1 elsewhere. In Australia the disease is confined to feral pigs in Queensland (Alton 1990).

Porcine brucellosis also has noteworthy public health implications. Until recently the source of the majority of human brucellosis has been *Brucella suis*–infected pigs (Fox and Kaufmann 1977). The public health hazard caused by porcine brucellosis is of proportionately greater significance than the risk from bovine brucellosis primarily because *B. suis* (biovars 1 and 3) appears to have a much higher degree of pathogenicity for humans than *B. abortus*. There also tend to be higher numbers of *B. suis* organisms in the tissues, providing a greater exposure to persons who come in contact with infected pigs. As pigs do not produce dairy products, the incidence of *B. suis* in humans is almost entirely occupational: in farmers, veterinarians, abattoir workers, and individuals, such as hunters, having direct contact with feral swine. Interestingly, although the infection of cattle with *B. suis* is rare, Cook and Noble (1984), working in Australia, reported several cases, probably contracted following contact with feral pigs. Persistent excretion in the milk may give rise to human epidemics (Borts et al. 1943). *B. suis* infection of a ram has been reported by Paolicchi et al. (1993), who suggest that this may represent a public health hazard.

ETIOLOGY

The genus *Brucella* comprises six nomen species: *B. abortus*, *B. melitensis*, *B. suis*, *B. neotomae*, *B. ovis*, and *B. canis* (Brinley-Morgan and McCullough 1974; Alton et al. 1975). In addition to the traditional six species, recent identifications of *Brucella* organisms in marine mammal species have led to the provisional speciation of *B. cetaceae* and *B. pinnipediae* (Cloeckaert et al. 2001). The genus appears to be genetically very homogeneous (Verger et al. 1985) but does not appear to be closely related to any other animal pathogens (de Ley et al. 1987). The first three nomen species are further divided into 8, 3, and 5 biovars, respectively. The principal hosts for *B. melitensis* are goats and sheep; for *B. abortus*, cattle, bison, and elk; for *B. neotomae*, desert wood rats; for *B. ovis*, sheep; for *B. canis*, dogs; for provisionally named *B. cetaceae*, dolphins, porpoises, and minke whale; and for provisionally named *B. pinnipediae*, seals. The most

common host for *B. suis* biovars 1 and 3 is the pig, and these biovars are worldwide in distribution. *B. suis* biovar 2 occurs in Europe, where the hosts are pigs and the European hare (*Lepus capinensis*), which can form a reservoir for occasional outbreaks in both wild and domestic pigs. The disease in pigs caused by biovar 2 differs slightly from that caused by biovars 1 and 3 in that miliary brucellosis of the uterus is a feature, and unlike them, it does not appear to be pathogenic for humans. *B. suis* biovar 4 is enzootic in reindeer and caribou (*Rangifer* spp.) in Siberia, Alaska, and Canada and is apparently not pathogenic for pigs although it causes many cases of human brucellosis. *B. suis* biovar 5 causes murine brucellosis.

B. suis is the only recognized *Brucella* species that causes systemic or generalized infection leading to reproductive failure in pigs. Pigs can be infected naturally or experimentally with other *Brucella* species, but a characteristic of the infection is almost invariably a symptomless, self-limiting localized infection of lymph nodes regional to the point of entry. It should be noted, however, that the differentiation of biovars of *Brucella* must be accomplished using methods only available in large reference centers, and this probably accounts for the frequent reports before the early 1960s of the isolation of *B. melitensis* from pigs (Alton 1990).

Bacteriological examination is often of great assistance in aiding a diagnosis, but it must be remembered that handling *B. suis* in the laboratory is extremely hazardous unless appropriate precautions are taken. The genus *Brucella* belongs to Hazard Group III and should be handled in a Class I/III safety cabinet within Containment Level III accommodation by staff with adequate training and experience.

Primary isolations of *B. suis*, like the other species in the genus, appear as small, convex, translucent, honeycolored colonies on the surface of clear agar media after incubation at 37°C for 2–7 days. Colonies grown on more opaque agar media types may appear pearl-colored. All *Brucella* species and biovars, except *B. ovis* and *B. canis*, occur naturally with smooth colonial morphology. *B. ovis* and *B. canis* always occur as rough forms, even on primary isolation. All smooth forms of

brucellae may dissociate into intermediate, rough, or mucoid forms under certain artificially induced environmental conditions. This dissociation frequently occurs if cultures are left for a long period without being subcultured, and it renders them incapable of being assigned to species or biovar. Microscopically, *Brucella* organisms are small, gram-negative bacilli or coccobacilli and are nonmotile and arranged singly. *B. suis* organisms from different sources may vary considerably in size but are generally 0.4–0.8 by 0.6–3.0 μm.

Several commercially available agar media are suitable for isolation and propagation of *B. suis*; those more commonly used include tryptose, trypticase-soy, Albimi, serum dextrose, Farrell's, and potato infusion. The addition of serum to the media to a final concentration of 5% frequently enhances the growth of brucellae, particularly on primary isolation. Increased carbon dioxide tension is not required for growth of *B. suis*. A more complete discussion of biotyping procedures, biovars, and formulation of growth media, as well as descriptive characteristics of the entire genus, can be obtained from Alton et al. 1988.

In general, all biovars of *B. suis* have a noticeably greater urease and catalase activity than other species of *Brucella*. Classification of *B. suis* into biovars is based on the combined findings of a variety of conventional and specialized tests. Briefly, *B. suis* biovar 1 produces large amounts of hydrogen sulfide, whereas biovars 2, 3, 4, and 5 produce little or none; growth of biovars 1, 2, and 5 is inhibited to a greater degree by basic fuchsin than growth of biovars 3 and 4; *B. suis* is not lysed by routine test dilutions (RTD) of Tbilisi *Brucella* phage but may be partially lysed by 10,000 × RTD; using monospecific antisera for the dominant A and M antigens, *B. suis* biovars 1, 2, and 3 are A dominant, while biovar 4 is AM (the only distinguishing feature separating biovars 3 and 4), and biovar 5 is M dominant (Table 35.1).

As the oxidative metabolic characteristics of all *B. suis* biovars are very similar, there are insufficient differences for differentiation.

Among the *B. suis*, only biovars 1 and 3 are known to occur in pig-raising areas of the United States. Until 1946 the only recognized cause of pig brucellosis in the

United States was the organism now known as *B. suis* biovar 1. At that time, *B. suis* biovar 3 (originally classified as American *B. melitensis*) was first isolated from tissues of infected pigs by S. H. MacNutt (Borts et al. 1946). For a period of time, reported isolations of *B. suis* biovar 1 had become comparatively less frequent, while isolations of *B. suis* biovar 3 had become more frequent. However, recent isolations of *B. suis* from feral swine have been identified as biovar 1, and both *B. suis* biovars 1 and 3 are most likely still present within the United States.

EPIDEMIOLOGY

Most evidence indicates that most *B. suis* infection is transmitted to susceptible animals through direct association with infected pigs. In this species, the most important routes of infection are through the alimentary and genital tracts. The habits of pigs and usual character of the disease strongly suggest that the alimentary tract is the most common portal of entry. Pigs of all ages may eat food or drink fluid contaminated with discharges from infected pigs. Piglets are frequently infected by nursing infected dams, and when breeding pigs are confined together, aborted fetuses and fetal membranes are readily consumed. Brucellosis is a venereal disease in pigs, and sows are readily infected when mated with infected boars or when artificially inseminated with semen containing *B. suis*. Experimentally, pigs are readily infected by conjunctival or intranasal exposure with suspensions of *B. suis*. It is possible that organisms could also enter through scarified or, possibly, intact skin.

The survival of brucellae under environmental conditions is a relatively important factor in transmission of the disease. The survival rate of brucellae is similar to that of other nonsporing gram-negative bacteria and as such is extremely variable depending on prevailing conditions. Experimental evidence indicates that *B. suis* is readily killed by pasteurization, 2–4 hours of direct sunlight, and the most commonly used disinfectants. *Brucellae* can survive in organic matter at freezing or near-freezing temperatures in excess of 2 years. Consequently, efforts to eliminate brucellosis from pig-raising premises must include an effective sanitation program (Luchsinger et al. 1965). The most suitable methods for preserving *Brucella* organisms for long periods are lyophilization and/or storage at subfreezing temperatures.

There are few known reservoirs of *B. suis* infection other than infected domestic pigs. Only the European hare and feral pigs have been established as significant potential reservoirs. The European hare was incriminated as a natural host for *B. suis* biovar 2 as early as 1954 (Bendtsen et al. 1954) and is apparently responsible for periodic outbreaks of brucellosis of pigs in Europe. Feral pigs in the southeastern United States, and to a much lesser extent elsewhere (Drew et al. 1992), have been discovered to have a high rate of serologic reactors, with isolation of *B. suis* biovar 1 from some animals (Wood et al. 1976; Becker et al. 1978). Extensive studies conducted in Florida showed that although only some populations are infected, the incidence within these groups is usually high (Leek et al. 1993). The epidemiological importance of feral pigs in the maintenance of porcine brucellosis depends largely on the degree of contact between wild and domestic pigs (Nettles 1991). If pig management systems in regions where feral pigs exist prevent contact, *B. suis* infection in feral pigs may be of greater public health importance than a threat to the pig industry. There have been numerous instances of *B. suis* infection or seropositivity in rodents or carnivorous species trapped near areas where brucellosis in domesticated pigs has occurred. However, general indications are that these species acquired infection from the pigs and are terminal hosts of the infection. With few or no exceptions, epidemiological investigation of newly infected pig herds has revealed the source as another herd of domesticated pigs.

Experimental studies have shown that pigs can be infected with *B. suis* biovar 4, *B. abortus*, *B. melitensis*, *B. canis*, and *B. neotomae*. However, there has been no evidence that these organisms invade the genital tract, are transmissible between pigs, or localize in any tissues other than lymph nodes draining the site of infection. All available evidence indicates that these biovars or species are not highly pathogenic for pigs, pigs are not likely to show clinical evidence of disease, and the infection is self-limiting and usually persists less than 60 days. Nevertheless, these infections do have importance for public health. In particular, pigs are associated with *B. abortus* infection in packinghouse workers.

Pigs infected with *B. suis* biovars 1, 2, or 3 can serve as a source of infection for other domesticated animal species. *B. suis* infection can occur naturally in horses, cattle, and dogs. Although the most common brucella infection in horses is *B. abortus*, fistulous withers and other syndromes have been recorded as caused by *B. suis* when horses were associated with infected pigs. Cattle are rarely infected with *B. suis*; when infection does occur, the characteristic infection is mastitis, with *B. suis* organisms excreted in the milk representing a public health risk. It can cause an acute infection in dogs, with pregnant bitches frequently aborting. There is some evidence that *B. canis*, a significant pathogen in dogs, evolved from *B. suis* biovar 3.

PATHOGENESIS

Available literature and comparative studies indicate that the pathogenesis of *B. suis* biovars 1, 2, and 3 is very similar (Thomsen 1934; Hutchings 1950; Hoerlein et al. 1954; Deyoe 1967). Differences are generally related to factors such as method of exposure, infecting dose, age and breed of pigs, and possibly minor differences between

strains of the same biovar. However, the characteristics of the disease produced are usually indistinguishable.

Regardless of the route of infection, the organism must be able to attach to and penetrate the mucosal epithelium, although the mechanisms for this have not yet been fully elucidated. Following the initial penetration, submucosal aggregations of lymphocytes and plasma cells form in response. Invading organisms are carried to local lymph nodes, although it is not known whether they travel as free organisms or within phagocytes, and infected nodes become enlarged due to lymphoid and reticuloendothelial hyperplasia and infiltration. *Brucella* organisms surviving regional node colonization enter a phase of bacteremia, now protected from humoral immune mechanisms by their intracellular location within neutrophils and macrophages.

In *B. suis* infection of pigs, bacteremia is an invariable finding in acute stages of the disease if frequent blood samples are collected and examined bacteriologically. In general, the onset of bacteremia ranges from 1–7 weeks after exposure, with a mean of about 2 weeks post exposure. Bacteremia persists an average of about 5 weeks and is generally continuous during that time. Intermittent bacteremia in individual pigs has been observed to be as brief as 1 week to as long as 34 months. It is this bacteremia that is probably responsible for the wide range of tissues secondarily infected during the course of the disease.

Within a short time after the bacteremia stage, *B. suis* can be isolated from a large number of sites in the body (Deyoe and Manthei 1967). The entire lymphatic system is often affected for a period of time. With increasing time after exposure, the sites of localization of the organism tend to be reduced in number. Among lymph nodes, the most frequent sources of *B. suis* are mandibular, gastrohepatic, internal iliac, and suprapharyngeal, in that order, depending essentially on the route of infection. Organs of the genital system containing high levels of erythritol, a sugar promoting the growth of brucellae, become involved in many pigs and may remain persistently infected. The placenta is a privileged site, and brucellae localize in the rough endoplasmic reticulum of the chorionic trophoblasts. Despite severe placental infection, only mild inflammation of the endometrium is observed. The spleen, liver, kidney, bladder, mammary gland, and brain may be involved (Jubb et al. 1985), although not as regularly as lymph nodes. Other significant sources of *B. suis*, particularly in chronically infected pigs, are joint fluids and bone marrow.

The response to invasion of *B. suis* becomes evident with the appearance of humoral antibody, activation of the cell-mediated immune system, and development of microscopic lesions. These manifestations may occur simultaneously but usually are subsequent to the appearance of detectable bacteremia; bacteremia may precede detectable antibody levels possibly by as much as 6–8 weeks. As pigs recover from *B. suis* infection (i.e., when viable organisms are no longer present in their tissues), other manifestations, such as antibody levels, cellular hypersensitivity, and microscopic lesions, recede and disappear also. Unfortunately, many pigs remain permanently infected.

In a series of experiments, infection was established in 248 sexually mature pigs (Deyoe 1972a). They were killed at various intervals after exposure to *B. suis* and their tissues subjected to thorough bacteriological examination. Three-fourths of the pigs in each group of females had recovered from infection by 4–6 months or longer after exposure, whereas the recovery rate in males never exceeded 50%. In contrast, Goode et al. (1952) and Manthei et al. (1952) isolated *B. suis* from only 12 of 474 adult pigs exposed as suckling pigs. This information demonstrates beyond doubt that the majority of pigs infected with *B. suis* will eventually recover spontaneously. Nevertheless, sufficient numbers of permanently infected animals will remain to serve as a continual source of infection.

CLINICAL SIGNS

Clinical evidence of *B. suis* infection varies considerably in different herds. The majority of affected herds may have no signs of brucellosis recognizable by the herd owner. The classic manifestations of pig brucellosis are abortion, infertility, orchitis, posterior paralysis, and lameness. Infected pigs fail to show any persisting or undulating pyrexia. Clinical signs may be transient and death is a rare occurrence.

Abortions may occur at any time during gestation and are influenced more by the time of exposure than by the time of gestation. The rate of abortion is highest in sows or gilts exposed via the genital tract at the time of breeding (Deyoe and Manthei 1969). Abortions have been observed as early as 17 days following natural insemination by boars disseminating *B. suis* in the semen. Early abortions are usually overlooked under field conditions, and the first indication is a large percentage of sows or gilts showing signs of estrus 30–45 days after the service that resulted in conception. Little or no vaginal discharge is observed with early abortions. Abortions that occur during the middle or late stages of gestation are usually associated with females that acquire infection after pregnancy has advanced past 35 or 40 days. The persistence of genital infection in females varies considerably.

A small percentage of sows have been shown to shed *B. suis* in vaginal discharges for as long as 30 months. However, the majority ceased shedding organisms within 30 days. A clinically apparent abnormal vaginal exudate is seldom observed in sows that have uterine infection except just prior to and for a short time after abortion. The majority of female pigs eventually recover from genital infection.

When genital infection in sows persists only a short

time after abortion, parturition, or breeding to an infected boar and the sows are permitted two or three estrous cycles of sexual rest, subsequent conception rates and reproductive capacity are usually very good.

Genital infection tends to be more persistent in boars than in sows. Some infected boars do not develop a localized genital infection. However, boars that do develop genital infection seldom recover from it. Pathologic changes in the male accessory glands or testes are generally more extensive and irreversible than in the uterus. Infertility and lack of sexual drive may occur in infected boars and are frequently associated with testicular involvement. More commonly, however, boars have infection in accessory genital glands and as a result disseminate large numbers of *B. suis* in their semen. These boars do not necessarily have reduced fertility (Vandeplassche et al. 1967). In most circumstances, clinically apparent lesions of *B. suis* biovar 1, 2, or 3 infection in boars are seldom encountered.

Clinical brucellosis in suckling and weaning pigs may appear as diskospondylitis associated with posterior paralysis or arthritis. These clinical signs are occasionally observed in any age of pigs.

LESIONS

Macroscopic pathologic changes produced by *B. suis* in pigs are quite variable. Enough abscess formation may occur in affected organs to result in necrosis and desquamation of a significant proportion of the mucous membrane. Generally, the histopathological changes consist of uterine glands filled with leukocytes, cellular infiltration of the endometrial stroma, and hyperplasia of periglandular connective tissue. Diffuse suppurative inflammation is usually present in affected placentas, resulting in purulent, necrotizing placentitis with fibrinous polyserositis. There also may be considerable necrosis of epithelium and diffuse hyperplasia of fibrous connective tissue.

Focal microscopic granulomatous lesions frequently can be observed in livers of pigs with brucellosis, particularly during bacteremic phases of the disease. These foci frequently are necrotic areas infiltrated with lymphocytes, macrophages, neutrophils, and giant cells, with sheets of histocytic and epithelioid cells with a central zone of caseous or coagulative necrosis. The lesions are usually partially or completely enclosed by a fibrous capsule. The necrotic portions of the granulomas are heavily infiltrated with neutrophils, and liquefaction and mineralization may occur (Enright 1990). Aborted fetuses may exhibit purulent hepatitis as well.

These lesions are not specific for brucellosis, since similar hepatic lesions are associated with other bacterial infections.

Microscopic lesions of bones are sometimes caused by *B. suis* infection. These occur both in vertebrae and in long bones. The lesions are most frequently located ad-

jacent to the epiphyseal cartilage and usually consist of caseous centers surrounded by a zone of macrophages and leukocytes and often by an outer zone of fibrous connective tissue.

Focal areas of chronic lymphocytic and macrocytic inflammation or focal abscesses are found infrequently in kidneys, spleen, brain, ovaries, adrenal glands, lungs, and other tissues of infected pigs (Deyoe 1968).

DIAGNOSIS

The most accurate and possibly the most sensitive method of diagnosis of porcine brucellosis is isolation of *Brucella* organisms by direct culture methods. It has been shown that routine culture of a small sample of lymph nodes from carcasses will reveal as many positives as serologic diagnosis (Alton 1990; Rogers et al. 1989). This is a very practical survey strategy, as virtually all the produce of the industry passes through abattoirs and the material can be removed without damage to the carcass. Culture of other material that becomes available is often fruitful, such as vaginal swabs or products of abortion, semen samples or castrated testicles, the contents of swollen joints, and blood samples. However, culture is often not feasible because of inadequate or unavailable laboratory facilities and trained personnel (Deyoe 1969). *B. suis* can readily be grown on all the normal *Brucella* media in the absence of added CO_2, the techniques being fully described by Alton et al. (1988).

Detection of *B. suis* antigen in tissues of infected pigs has been investigated, primarily using fluorescent antibody (FA) techniques. The general conclusion has been that brucellae are seldom detectable in lymph node impression smears with FA procedures because of the relatively low numbers of organisms typically present (Deyoe 1972b). Nevertheless, FA tests could probably be useful for examining aborted materials, since large numbers of *B. suis* are typical in such specimens. More recently, potentially sensitive methods for the detection of the presence of brucellae, such as the polymerase chain reaction (PCR), are gradually being introduced into routine use and may, in the future, prove a valuable method of diagnosis in certain situations (Lealklevezas et al. 1995).

Serologic procedures to detect antibodies against brucellae in infected pigs are generally the most practical and most common means of diagnosis, but the results obtained are far from perfect. Market pig surveys have shown that as many as 18% of normal pigs may react at the 1:25 level when plate agglutination tests are used (Deyoe 1969). On the other hand, some pigs produce little or no antibody against brucellae. Because of variation in the stage of disease, an infected herd of pigs will nearly always contain some infected animals that have no detectable brucella antibody. Some strains of *B. suis* apparently do not stimulate antibody production as well as others (Deyoe 1967). Pigs exposed to a minimal

infective dose of *B. suis* generally have a prolonged incubation period before significant quantities of antibody are produced.

Because of the foregoing factors, current serologic tests are much less effective for the diagnosis of individual pigs than they are in cattle. However, most serologic tests are entirely adequate as herd tests. Characteristically, infected herds include a majority or large numbers of infected individuals. Because of close contact between animals and the tendency of brucellosis to spread rapidly through a herd, 50–80% is a common morbidity range (Spencer and Mattison 1975). When large herds have only a single serologic reactor disclosed during a herd test, it can generally be concluded that *B. suis* infection is not present.

Numerous serologic tests are available or have been investigated for use in diagnosis of porcine brucellosis (Alton et al. 1988). Many of these were developed for diagnosis of bovine brucellosis and have been adapted for testing pig sera. Most tests utilize *B. abortus* whole-cell antigens. Since the commonly used antigen strains *B. abortus* 1119-3 and S99 have the same or very similar surface lipopolysaccharide complexes as smooth *B. suis*, the standardized antigens produced and distributed by the Animal and Plant Health Inspection Service (APHIS) of the USDA and by the Central Veterinary Laboratory, Weybridge, United Kingdom, are equally useful for diagnosis of both bovine and porcine brucellosis. This has been confirmed by extensive laboratory testing of pig sera with both *B. abortus* and *B. suis* antigens.

The original test methods for the diagnosis of porcine brucellosis were tube and plate agglutination procedures. Interpretation of results was based on the finding that most infected pig herds contained one or more animals with more than 100 international units (IU) of agglutination. It is now known that serum agglutination tests (SAT), although sensitive, are not sufficiently specific to be reliable diagnostic tools when used alone. Some of the inaccuracies can be overcome in situations where frequent and repeated testing is practicable and the trend of antibody titers can be determined.

Reducing the pH of antigen-serum mixtures to 3–4 was also found to reduce nonspecific agglutination while not affecting agglutination caused by serum from infected animals. This led to the development of methods classified as buffered brucella antigen tests, in which stained brucella antigen is buffered at pH 3.65. The buffered brucella antigen became the basis of the brucellosis card test and similar procedures such as buffered plate antigen and Rose-Bengal tests (RBT). These tests are the most practical method of diagnosis for porcine brucellosis at present, are possibly still the preferred method for large-scale surveillance testing, and are "prescribed tests for international trade" (Office International des Epizooties 1997). They have a distinct advantage over standard agglutination tests because they are relatively unaffected by nonspecific agglutinins and are

generally as sensitive as any other serologic test for diagnosis of porcine brucellosis.

Other tests, such as the Rivanol precipitation–serum agglutination, 2-mercaptoethanol, and complement fixation tests (CFT), are frequently used for the diagnosis of brucellosis in pigs and are very useful in confirming results of card tests. The above tests very seldom or never detect IgM brucella antibodies in pig serum; therefore, they are highly specific. However, the relative sensitivity of these methods is usually low in early stages of brucellosis. By the time the antibody response peaks and thereafter in chronic stages, the Rivanol, mercaptoethanol, and CFT methods are generally as sensitive as the card test. An evaluation of a range of serologic tests on culture-positive pigs was reported by Rogers et al. (1989). The sensitivity of the RBT was 79%; of the CFT, 49%; and of the SAT, 51%. The specificity of the RBT was reported to be 98% based on the results of testing over 30,000 serum samples. Other studies generally confirm the low levels of diagnostic sensitivity achievable (Ferris et al. 1995; Payeur et al. 1990).

The Particle Concentration Fluorescence Immunoassay (PCFIA) is a competitive immunoassay for IgG1, IgG2, and IgM antibodies which has been reported to have a sensitivity of 80% and specificity of 89% (Ferris et al. 1995). The PCFIA interpretation ranges for swine have been established as a ratio of Sample to Negative Control signal (S/N) of 0.0 to 0.5 for reactors, 0.51 to 0.70 for suspects, and greater than 0.70 for negatives.

Recently, the Fluorescence Polarization Assay (FPA) has also been evaluated for the detection of Brucellosis in swine (Nielsen and Gall 2001). The FPA test is based on the size and rotation rate of molecules in solution and the depolarization of light by these molecules (see Nielsen and Gall 2001 for a complete description.) One study in swine has shown the FPA to have a sensitivity of 94% and a specificity of 97% (Nielsen et al. 1999). The FPA test is currently being incorporated as an official test into the USDA Swine Brucellosis Control/Eradication program.

Limited investigation of the enzyme-linked immunosorbent assay (ELISA) has been conducted, and it appears that this method may be equal or slightly superior to other serologic procedures for diagnosis of porcine brucellosis in the future (Office International des Epizooties 1997). Further investigation of this test for use in eradication campaigns is warranted.

Regardless of the serologic test used for diagnosis, detection of 80–90% of infected pigs must be regarded as the best that can be achieved at present.

Experimental studies reviewed by Corbel (1985) have shown that infection with organisms of several other genera can produce antibodies reactive in brucellosis diagnostic tests. These organisms include *Escherichia coli* serogroup O:157, Salmonella serobiovars of Kaufman-White group N, and most importantly *Yersinia enterocolitica* serogroup O:9. Infection of pigs

with this latter organism has often been confirmed, and the cross-reaction that results (the dominant O polysaccharide antigen is chemically identical to the A antigen present on the surface of all smooth brucellae) is highly significant. In some situations, yersiniosis poses a greater threat to the agricultural industry than does brucellosis itself, due to the confusion with brucellosis in diagnosis and the consequent effect on the export trade. Great Britain has always been free from *B. suis* infection and enjoys a thriving export trade as a result of the generally high health status of its stock. During the 7 years prior to 1988, the number of pigs tested for export certification giving a CFT reaction of greater than 20 international complement-fixation test units (icftu) never exceeded 0.004%, whereas the figures for 1988, 1989, and 1990 were 0.42%, 0.70%, and 1.5%, respectively. Since 1988, at least 4% of exporting herds have had more than 5% CFT positive reactions, with some herds reaching levels of more than 50% of animals tested failing at this level. *Y. enterocolitica* O:9 has been isolated from many herds involved, and despite extensive investigation, *B. suis* has not been recovered (Wrathall et al. 1991).

Lymphocyte transformation tests have been used to measure cell-mediated immune responses in infected pigs on a limited scale (Kaneene et al. 1978). There was high correlation between recovery of *B. suis* from tissues and detectable lymphocyte stimulation responses. However, the complexity of the method probably eliminates it from consideration as a diagnostic tool except in special cases.

Tests for delayed hypersensitivity, using intradermal injection of brucella allergens, have been studied, but results have not stimulated much enthusiasm in the United States. However, they are of similar accuracy to serologic tests and would be more appropriate for farm testing in some circumstances, although they are more difficult to apply and read and would not be applicable in testing programs for market pigs. In the face of cross-reactions caused by *Y. enterocolitica* O:9, the use of such tests is perhaps the most specific method of diagnosis. Skin tests are used frequently for diagnosis of porcine brucellosis in many countries, particularly in Eastern Europe.

One of the most important aids to diagnosis is an adequate herd history. Good records of clinical manifestations, movement of animals, additions to the herd, breeding records, and illnesses in persons working with the pigs provide invaluable information necessary to arrive at a diagnosis of brucellosis. Accurate epidemiological information is an essential supplement to laboratory tests.

TREATMENT

No treatments, such as antibiotic therapy, dietary supplements, or other chemotherapy, have been proven effective and economically feasible in curing pigs of brucellosis. Large doses of tetracyclines, streptomycin, or sulfonamides given over relatively long periods have been investigated. In some trials these antibiotics alone or in combination appeared promising. In general, however, antibiotic therapy was effective in limiting the bacteremic stage of the disease, but after therapy was discontinued, viable *B. suis* was still present in tissues. Although treatments have not been effective in eliminating all organisms from the host, chemotherapy in carefully selected circumstances could probably suppress multiplication of *B. suis* in vivo sufficiently to alleviate clinical manifestations and shedding of organisms. Even though such an approach may have limited practicability, it could have beneficial effects in an infected herd and should not be dismissed as useless.

PREVENTION

Immunity

Safe and reliable vaccines that produce serviceable immunity against brucellosis in pigs have not been developed. Significant resistance can be stimulated, but persistence of immunity has been a limiting factor (Deyoe 1972a). Interest in vaccination of pigs in the United States has declined along with the decline in incidence of the disease. With the present incidence of porcine brucellosis in the United States, the cost of developing and applying vaccination cannot be justified.

There have been no basic studies specifically directed toward the mechanism of immunity against *B. suis* infection in pigs. Nevertheless, one must assume from the overwhelming evidence accumulated in research on brucellosis in other species that the fundamental mechanism is a cell-mediated immunity, with humoral immunity having only a minor or nonexistent role.

Investigations into antibrucella immunity in pigs can be summarized as follows:

1. Some pigs are naturally resistant to brucella infection, and this resistance could be enhanced markedly by selective breeding programs (Cameron et al. 1941) if all other genetic factors could be ignored.
2. Some pigs infected with virulent *B. suis* will recover from the disease, but subsequent resistance induced by the virulent infection may be transient, as most will be susceptible to reexposure probably within 6–12 months after the initial infection. Commonly, many pigs, especially boars, become persistently infected with *B. suis*.
3. Trials with attenuated *B. suis* or *B. abortus* strain 19 have been unsuccessful in producing a persistent immunity with products considered to be safe for use.
4. Bacterins or extracts of killed *B. suis* have generally been ineffective in stimulating immunity or else there has been no conclusive evidence that the persistence of immunity is adequate.

Control Measures

Experiences in control of porcine brucellosis indicate that eradication of the disease from pigs in the United States is desirable and feasible. Marked reduction in the incidence of the disease has occurred since 1950. One significant factor in this reduction has been the tendency for pig production to become more specialized and less a part of diversified farming operations. Consequently, the occurrence of reproductive disease in pigs has become proportionately more important, confinement systems and closed herds have eliminated many opportunities for interfarm spread of disease, and larger units have eliminated the "community boar" in most instances. Another important instrument in control of porcine brucellosis has been the establishment and maintenance of validated brucellosis-free herds, particularly purebred herds or those selling breeding stock. Implementation of effective surveillance programs such as identification and testing of market pigs (sows and boars) has been instrumental in locating and eliminating large numbers of infected herds. Finally, it has been found that whenever recommended procedures to eradicate brucellosis from an individual herd or an enzootic area are conscientiously followed, there is very seldom any recurrence of the disease in that locality (e.g., Spencer and Mattison 1975).

The current brucellosis eradication program in the United States is a joint state-federal and livestock industry program. The program is administered, supervised, and funded by cooperative efforts between state and federal animal health regulatory agencies. This program is now nearing successful completion, with all states and U.S. territories, except Texas, in Stage III (Free) status. Texas will likely gain equal status once Uniform Methods and Rules are revised to reflect federal-state-industry consensus to remove loosely managed feral-exposed domestic herds from commercial herd classification.

The swine brucellosis eradication program has evolved to recognize that the organism will continue to exist indefinitely in the feral swine reservoir and associated transitional swine population. Transitional swine are defined as those feral swine that are captive or swine that have reasonable opportunities to be exposed to feral swine (USDA 2003). Efforts are now concentrated on effective separation of commercial production swine from transitional and feral swine, with adequate surveillance and testing of at-risk populations to assure compliance. The Pseudorabies Eradication Program now requires each state to file a Feral-Transitional Swine Management Plan, outlining its plans for dealing with feral swine pseudorabies virus threats. This plan will address swine brucellosis infection threats from feral swine populations as well. Swine brucellosis will be considered but one of many swine pathogens to be controlled by effective management and biosecurity measures against potential feral-transitional swine infections.

36 Clostridial Infections

J. Glenn Songer and David J. Taylor

Clostridia are large, gram-positive, spore-forming rods, and are strict–to–oxygen-tolerant anaerobes. *Clostridium perfringens* types A and C, *C. difficile*, *C. tetani, C. novyi, C. botulinum,* and occasionally *C. chauvoei* and *C. septicum*, are primary pathogens of swine, but may also invade existing wounds or lesions (Table 36.1). Many maintain a residence in the intestinal tract, and postmortem invasion of other tissues can confuse diagnosis.

ENTERIC INFECTIONS

Clostridium perfringens
Production of the so-called major toxins [alpha (CPA), beta (CPB), epsilon (ETX), and iota (ITX)] divides *C. perfringens* into five toxinotypes (Table 36.2). Strains of type A are widespread in the intestines of warm-blooded animals and in the environment, and others tend to be present in lower numbers in normal animals.

Type C Enteritis. *Clostridium perfringens* type C infection occurs in all swine-producing areas of the world (Field and Gibson 1955; Szent-Ivanyi and Szabo 1955; Barnes and Moon 1964; Hogh 1965; Matthias et al. 1968; Plaisier 1971; Morin et al. 1983; Azuma et al. 1983). Type C causes frequently hemorrhagic, often-fatal, necrotic enteritis in young piglets. Hallmark lesions are profound mucosal necrosis and emphysema in small intestine, sometimes extending into cecum and proximal colon.

Etiology and Epidemiology. Type C is a primary pathogen but can apparently colonize lesions of other diseases, such as transmissible gastroenteritis (TGE). Types B (Bakhtin 1956) and D (Harbola and Khera 1990) have apparently been isolated from type C-like syndromes, but given the vagaries of the in vivo typing system, it may be prudent to confirm these reports before accepting types B and D as even rare causes of severe enteritis in neonatal pigs.

Infection can be transmitted piglet-to-piglet, but the ultimate source is likely the intestine of the sow. Preventing introduction of disease by screening of replacement stock is likely not a viable option. Type C in normal sow feces accounts for only a tiny percentage of the total population of *C. perfringens*; it nearly always goes undetected by any but highly specialized methods, which are impractical for screening large numbers of animals. Piglets may act as enrichment vessels, in which small numbers of type C outcompete other bacteria and multiply to large numbers, with resulting disease production.

The organism persists in the environment as vegetative cells or spores, and the latter are resistant to heat, disinfectants, and ultraviolet light. Environmental organisms cycle through nonvaccinated piglets over long periods.

Disease is most common in 3-day-old piglets, but may appear as early as 12 hours after birth and is rarely seen in pigs older than one week (Bergeland et al. 1966; Meszaros and Pesti 1965; Matthias et al. 1968). Type C enteritis occurs epizootically in nonvaccinated populations (Bergeland et al. 1966) and prevalence of affected litters can reach 100%. The case fatality rate varies with the form of the disease, but 100% mortality in litters of nonimmune sows is not unusual, and total herd mortality may be as high as 50–60% (Bergeland et al. 1966; Hogh 1967b). When herd immunity rises, due to exposure of sows to infected piglets, disease may become enzootic. Milder cases occur over a period of months in individual herds, but continued appearance of acute disease usually indicates a deficiency in herd immunity (e.g., repeated introduction of naive gilts or sows) or failure of piglets to receive adequate levels of specific antibody in colostrum.

Clinical Signs and Lesions. Clinical signs vary according to immune status and age of affected piglets. Most *peracutely affected piglets* develop hemorrhagic diarrhea, accompanied by staining of the perineum. Piglets become weak, move with reluctance, and rapidly become moribund, risking crushing by the sow. Rectal temperature falls to 35°C and abdominal skin may blacken be-

C. chauvoei	Blackleg

36.1. *Necrohemorrhagic jejunitis in a 1-day-old piglet with peracute* C. perfringens *type C enteritis.*

36.2. *Villus of the jejunum early in the course of* C. perfringens *type C infection in a 12-hour-old piglet. Numerous bacilli are present beneath the desquamated epithelium in the area of the epithelial basement membrane (H&E).*

fore death. Many are found dead within 12–36 hours of birth. Death occurs in some animals without diarrhea being seen. The abdominal wall is often edematous when cut, but the most immediate and striking findings are intensely hemorrhagic small intestines (Figure 36.1) and bloodstained fluid in the abdominal cavity. Lesions are typically in jejunum and ileum; they may extend anterior to within a few centimeters of the pylorus and posterior to the proximal colon, or may affect only a few centimeters of jejunum. Gross mucosal lesions are reddish or black in color, with intense hemorrhage and gas bubbles in the intestinal wall. Mesenteric lymph nodes may be reddened. Contents of the affected area contain blood and may be found as far distal as the rectum. Microscopic examination reveals necrotic jejunal villi and a surface covered by a carpet of large gram-positive bacilli. Crypt epithelium may be necrotic, and there is profuse hemorrhage throughout the mucosa and submucosa (Figures 36.2 and 36.3).

Acutely affected piglets may survive for 1–2 days after onset of clinical signs, but usually die shortly thereafter. They have reddish-brown diarrhea containing gray shreds of tissue debris, may be dehydrated, with loss of body condition, and there may be scalding of the perineum and adherent reddish feces. Nursing is minimal, and these piglets rapidly lose condition and become gaunt and weak. Gross lesions (refer to Figure 36.1) are usually localized, and emphysema may be observed in a sharply demarcated portion of jejunum. This portion of intestine may be loosely adherent to adjacent segments by acute fibrinous peritonitis (Figure 36.4), and intes-

tinal wall is usually thickened and yellow or grayish; contents may be bloodstained and contain necrotic debris. Deposition of urate crystals in kidney is common. Microscopic examination reveals loss of most villi, and those surviving are necrotic and covered with bacteria. The exposed submucosa is also carpeted by bacteria,

Table 36.2. Production of so-called major toxins by types of *Clostridium perfringens* and associated diseases

Toxin Type	Major Diseases	Major Toxins
A	Food poisoning, poultry necrotic enteritis, lamb enterotoxemia, porcine neonatal necrotizing enterocolitis, bovine neonatal hemorrhagic enteritis	alpha
B	Lamb dysentery, ovine chronic enteritis, bovine/equine hemorrhagic enteritis	alpha, beta, epsilon
C	Fowl necrotic enteritis, hemorrhagic or necrotic enterotoxemia in piglets, lambs, calves, goats, foals, acute enterotoxemia ("struck") in adult sheep	alpha, beta
D	Ovine enterotoxemia, caprine enterocolitis, bovine enterotoxemia (calves, possibly adults)	alpha, epsilon
E	Bovine (possibly ovine) neonatal enterotoxemia	alpha, iota
36.3. *Jejunum of a piglet with peracute* C. perfringens *type C enteritis. There is acute necrosis of the mucosa and massive hemorrhage in the submucosa (H&E).*

36.5. *Jejunum of a piglet with acute* C. perfringens *type C enteritis. The mucosa is completely necrotic, and there is emphysema of the submucosa and tunica muscularis (H&E).*

36.4. *Acute* C. perfringens *type C enteritis in a 3-day-old piglet. An emphysematous segment of upper jejunum (left) is held together by acute peritonitis. Mucosal necrosis of the lower jejunum (right) is seen from the serosal surface.*

36.6. *Subacute form of* C. perfringens *type C enteritis in a 6-day-old piglet. The entire jejunum is lined with a necrotic membrane.*

shed epithelial cells, fibrin, and degenerating inflammatory cells. Submucosal vessels are necrotic and many contain thrombi and emphysema may be evident in submucosa, tunica muscularis, and under the serosa (Figure 36.5). Large gram-positive bacteria may be present in deeper layers of intestinal wall.

Diarrhea in *pigs with subacute disease* is nonhemorrhagic. These animals remain active, alert, and appetant, but become progressively emaciated; they may be thin and dehydrated at the time of death, usually at about 5–7 days of age. Stools are often yellow initially, but then become clear, with flecks of necrotic debris. There may be adhesions between affected areas of small intestine, and intestinal wall is thickened and friable. The mucosal surface is covered by a tightly adherent necrotic membrane which may be seen from the serosal surface as longitudinal grayish-yellow bands (Figure 36.6).

Chronic cases usually have intermittent diarrhea for more than a week. Feces are yellow-gray and mucoid, and tail and perineum may be fecal-stained, and although these piglets remain alert and vigorous, they may die after several weeks or be euthanized because of unthriftiness. Lesions may resemble those in subacute disease, but may not be obvious from the serosa. There may be local thickening of intestinal wall and well-defined areas (in many cases only 1–2 cm in length) to which necrotic membrane is adherent. Deeper layers of the intestinal wall show evidence of chronic inflammation (Figure 36.7).

Pathogenesis. *Clostridium perfringens* has a very short generation time, and type C organisms can multiply to numbers approaching 10^8–10^9 per gram of contents in only a few hours (Ohnuna et al. 1992). Attachment to jejunal epithelial cells at villous apices (Arbuckle 1972; Walker et al. 1980) is followed by desquamation of these
36.7. *Ileum of a piglet with chronic* C. perfringens *type C enteritis. The mucosa is replaced by a necrotic membrane containing a variety of bacterial species. The submucosa, tunica muscularis, and serosa are infiltrated by chronic inflammatory cells (H&E).*

cells and proliferation of the organism along the basement membrane. Necrosis of the villous lamina propria is extensive, and hemorrhage accompanies necrosis. The necrotic zone advances to involve crypts, muscularis mucosa and submucosa, and occasionally the muscular layers. Perforation of intestinal wall leads to emphysema (sometimes with thrombosis) in muscle layers, beneath the peritoneum, and in mesenteric lymph nodes. Bacteria remain adhered to necrotic villi or are shed into intestinal lumen with cell debris and blood, and sporulation may be observed (Kubo and Watase 1985).

The lethal and necrotizing beta toxin (CPB) is the key factor in pathogenesis of type C infections (Warrack 1963; Hogh 1967a). Toxoid vaccines protect against infection, but it is worth noting that these are crude, containing many clostridial antigens other than beta toxoid. Experimental evidence for the primacy of CPB in pathogenesis is equivocal. Disease was reproduced by oral administration of toxin, but in pigs subsequently found to be infected with the organism (Field and Goodwin 1959). Typical lesions appeared in gut loops inoculated with broth cultures of type C (Bergeland 1972), but necrosis was not produced by inoculation with CPB alone. There are numerous potentially confounding factors in much of the published literature, including use of older pigs as experimental animals; trypsin secretion deficiencies and colostral protease inhibitors probably account for susceptibility of piglets less than 4 days old.

Death is primarily due to effects of intestinal damage and toxemia. CPB has been detected in both intestinal contents and peritoneal fluid of affected pigs. Toxin-containing preparations administered IV in high doses cause sudden death, and lower doses cause polioencephalomalacia, adrenal cortical necrosis, nephrosis, and pulmonary edema. Hypoglycemia and secondary bacteremia due to *C. perfringens* or *E. coli* may raise the

mortality rate (Field and Goodwin 1959; Hogh 1967b).

Beta2 toxin (CPB2), produced by most or all porcine type C isolates, may also play a role in pathogenesis (see below, under "Type A Enteritis").

Diagnosis. Compatible clinical signs, pattern of mortality, and nature of gross and microscopic lesions are sufficient basis for a presumptive diagnosis of type C enteritis. Diagnosis of chronic disease may depend upon a more-detailed history of infection in the herd, elimination of other causes of necrotic enteritis, and detection of type C organisms in lesions. Coccidiosis *(Isospora suis)* and other causes of villous atrophy, such as rotavirus infection, TGE, and porcine epidemic diarrhea, may cause lesions which become colonized by *C. perfringens* type C. It is especially important in subacute and chronic cases to distinguish type C infections from those caused by *C. perfringens* type A, and this can be done only by bacteriologic culture and toxin detection or genotyping.

Laboratory aspects of diagnosis include bacteriologic culture and examination of smears of intestinal contents and mucosal lesions and histological sections of intestine for large, gram-positive rods. *Clostridium perfringens* is not an efficient sporulator, but ovoid-to-eccentric spores are sometimes observed. Colonies after 24 hours' incubation on horse or bovine blood agar are usually 3–5 mm in diameter, grayish, and circular; on primary isolation, these may be mixed with smaller colonies, which are smoother and have a gumdrop-like morphology. The organism usually produces an inner, complete zone of hemolysis, caused by theta toxin (perfringolysin O, PFO), and a less-complete outer zone caused by CPA. Identification to species is based in addition upon biochemical characteristics and production of toxins.

Microscopic lesions are almost pathognomonic. Diagnosis can be confirmed by demonstration of CPB in eluates of hemorrhagic intestinal contents or in peritoneal fluid. Mouse protection tests are seldom used today, having been replaced by enzyme immunoassays (Havard et al. 1992). PCR methods to detect genes for the major toxins are an acceptable substitute for toxin detection in typing of isolates, and can provide useful supportive findings in diagnosis (Buogo et al. 1995; Songer and Meer 1996; Meer and Songer 1997).

In the absence of methodology to detect toxins in pathologic specimens, bacterial isolation and genotyping are useful aids in establishing a diagnosis. In most cases, type C is isolated in large numbers and in pure culture from scrapings of the intestinal mucosa. Results may be misleading in rare situations, in that type C can be found as a secondary agent, colonizing lesions of TGE and other viral diseases. Cultures may be negative in chronic cases, and when positive usually yield a mixture of type C and type A organisms. Thus, it is important to determine genotype or phenotype of multiple primary isolates. Diagnosis must, in some cases, be based upon

findings in the herd as a whole, rather than from examination of individual diseased animals.

Treatment and Prevention. Treatment is of little use in animals with clinical signs (Szabo and Szent-Ivanyi 1957; Hogh 1967b), and prophylaxis is the preferred approach. Passive immunization with equine antitoxin can be useful for protection of litters of nonimmune sows in an outbreak, and protection may last as long as 3 weeks (Ripley and Gush 1983). Antitoxin should be injected parenterally as soon after birth as possible. Oral antimicrobials, such as ampicillin or amoxicillin, may also be given prophylactically, beginning immediately after birth and continuing daily for 3 days. There are reports of antimicrobial resistance in *C. perfringens*, and tetracycline resistance plasmids have been identified (Rood et al. 1985). However, the organism remains uniformly susceptible to penicillins. Ceftiofur may be an alternative for treatment of piglets, and bacitracin methylene disalicylate can be administered to sows before and after farrowing to prevent infection of piglets.

Prevention is best achieved by vaccination of sows with type C toxoid, at breeding or midgestation and 2–3 weeks before farrowing (Kennedy et al. 1977). Commercial toxoid vaccines are quite effective, and instituting a vaccination program usually eliminates the disease within one farrowing cycle. Tenfold reductions in mortality are common (Ripley and Gush 1983), assuming normal responses of the sow to vaccination (Matishek and McGrinley 1986) and ingestion of adequate colostrum. Booster injections should be given about 3 weeks before subsequent farrowings. Toxoid may also be of value in protecting weaned pigs (Meszaros and Pesti 1965).

Type A Enteritis. *Clostridium perfringens* type A is part of the normal flora of the swine intestine (Mansson and Smith 1962), but is also a cause of enteric disease, both in neonatal piglets and, occasionally, in weaned pigs (Jestin et al. 1985). Disease has been reported worldwide (Amtsberg et al. 1976; Ramisse et al. 1979; Nabuurs et al. 1983; Secasiu 1984; Collins et al. 1989). There is a continuing association of type A with hemorrhagic bowel syndrome, but this etiologic link is not supported by experimental evidence.

Etiology and Epidemiology. *Clostridium perfringens* type A resembles type C in culture, but it produces CPA as its sole major toxin (refer to Table 36.2). Recent information (Bueschel et al. 2003; Waters et al. 2003) suggests a role for beta2 toxin (CPB2) in porcine clostridial enteritis, and nearly all type A strains from this condition produce this protein (Bueschel et al. 2003; Waters et al. 2003; see below). Clinical signs have been reproduced experimentally (Johannsen et al. 1993a).

Human clostridial food poisoning usually occurs when enterotoxigenic (CPE-producing) strains grow in slowly cooling meats following cooking. Involvement of CPE-producing strains in animal disease is apparently uncommon (Estrada Correa and Taylor 1989; Damme-Jongsten et al. 1990; Miwa et al. 1997; Collins et al. 1989). Food poisoning strains probably originate most commonly in poultry; porcine strains can also be fully enterotoxigenic, so pigs may also be a source. In general, *cpe* is chromosomal in human strains and plasmid-borne in animal strains.

Disease occurs usually during the first week, and it is assumed that sows are the source of infection for piglets. Antibody is widespread in finishing pigs and in sows (Estrada Correa and Taylor 1989). However, it should be understood that it is not possible to differentiate between normal flora type A strains and those which cause disease, with the possible exception of *cpb2* positivity. Furthermore, it may be that, under the right conditions, *any* strain of type A can cause disease. Type A is ubiquitous in gut contents and in soil, although most of these strains are *cpb2* negative. Thus, discussion of the epidemiology of type A enteric infections amounts to little (or nothing) more than speculation.

As noted previously, *C. perfringens* is an inefficient sporulator, but spores are nonetheless likely to be important in maintaining the organism in the environment. The organism can also be isolated from pig feed.

Clinical Signs and Lesions. Piglets develop creamy or pasty diarrhea within 48 hours of birth, displaying rough hair coat and fecal staining of the perineum (Johannsen et al. 1993a). Diarrhea lasts for up to 5 days, and feces become mucoid and sometimes pink. Most piglets recover, but are stunted, sometimes through the entire growing and finishing period. Disease has been reproduced in gnotobiotic colostrum-deprived and conventional pigs (Johannsen et al. 1993).

On postmortem, small intestine is flaccid, thin-walled, and gas-filled, with watery contents and no blood. Mucosal inflammation is mild, occasionally with adherent necrotic material. Large intestine may be distended, with whitish, pasty contents, but without lesions. Microscopic lesions in piglets may include superficial villous tip necrosis and accumulation of fibrin, but villi may also be completely normal in appearance (Figure 36.8). Jejunal and ileal lesions may be heavily colonized with *C. perfringens* (Nabuurs et al. 1983), although it is common to find masses of organisms in the lumen (Johannsen et al. 1993c). Capillaries may be dilated, but there is no hemorrhage.

Mucosal necrosis and villous atrophy are superficial in infections by enterotoxigenic *C. perfringens* (Nabuurs et al. 1983; Estrada-Correa and Taylor 1989; Collins et al. 1989). Signs in experimental infections range from creamy diarrhea and emaciation with low mortality to profuse, bloodstained diarrhea, enteritis, and death (Olubunmi and Taylor 1985). Morphology of small intestinal villi and enterocytes are normal, and there are no colonic or cecal lesions, but numerous spore-
36.8. *Association of* C. perfringens-*like organisms with villus tips and accumulation of large numbers of organisms in jejunal lumen in* C. perfringens *type A infection in a 3-day-old piglet (Jane Christopher-Hennings).*

bearing, gram-positive rods are found in the lumen or apposed to epithelial cells at tips of villi.

Enterotoxigenic strains have been linked to diarrheal disease in growing pigs, and in these cases onset and the severity of diarrhea correlate with presence of CPE in feces. Affected pigs develop serum antibodies to CPE (Jestin et al. 1985).

Pathogenesis. Type A can be isolated from any normal piglet's first feces, and although pathogenesis of infections is poorly understood, it is likely multifactorial. Numbers in ileum and jejunum reach 10^8–10^9 per gram of contents, producing CPA, CPB2, and possibly other toxins. Attachment and invasion do not occur in experimental infections (Johannsen et al. 1993c). Intestinal epithelial necrosis occurs in experimental infections, but may not be apparent in natural cases; absence of gross and microscopic lesions suggests that type A enteritis is mainly a secretory diarrhea.

There is no direct information on the role of specific toxins in pathogenesis. There are no consistent changes in gut loops inoculated with purified CPA, but slight edema of villi occurs when 6-hour-old piglets are given 80–800 mouse lethal doses (Johannsen et al. 1993b). The specific role of CPB2 in pathogenesis is unknown, but its strong association with enteric disease in pigs suggests that it is at least a marker of virulence (Gibert et al. 1997; Herholz et al. 1999; Bueschel et al. 2003). Few isolates from normal pigs contain *cpb2*, but >90% from porcine neonatal enteritis strains are positive, and the gene is rarely silent (Bueschel et al. 2003). CPE causes villous necrosis and fluid secretion into intestinal lumen. Anti-CPE antibody is present in colostrum, and disease associated with CPE commonly occurs in weaned pigs after maternal antibody disappears (Estrada Correa and Taylor 1989).

Diagnosis. Diagnosis of type A enteritis is seldom unequivocal. The most useful findings are compatible clinical signs and isolation of large numbers of *C. perfringens* from affected jejunum or ileum. Genotyping almost invariably reveals type A organisms with *cpb2*. Microscopic examination may reveal organisms intimately associated with the mucosa, or they may be massed in the lumen. Detection of CPA in gut contents is also supportive, but tests are not widely available. Commercial assays for CPE are prone to false positives, but diarrhea has been associated with fecal CPE titers >1:32 (Popoff and Jestin 1985). Failure to demonstrate other agents is also supportive.

Treatment and Prevention. Treatment with antimicrobials is more likely to be successful than in cases of type C infection. Vaccination against type A is possible via custom biologics, and products available in some countries for immunization of other species are used off-label in pigs. Commercial vaccines do not include CPE toxoid. Growth promoters, such as avoparcin (Taylor and Estrada Correa 1988) and salinomycin (Kyriakis et al. 1995), have been used in feed, and bacitracin methylene disalicylate can be used prophylactically in sows or for treatment of piglets (Madsen 1995).

Clostridium difficile-Associated Disease (CDAD)

Etiology and Epidemiology. Human *C. difficile*-associated disease (CDAD) accounts for one-fourth of all cases of antibiotic-associated diarrhea (Bartlett 1992; Bartlett et al. 1978; Borriello and Wilcox 1998; Johnson et al. 1999). Spores germinate in ileum, cecum, and colon (Kelly et al. 1984), and vegetative cells fill empty niches and produce toxins. Disease presents as diarrhea, colitis, pseudomembranous colitis, or fulminant colitis (Kelly et al. 1984).

CDAD also occurs in antibiotic-treated hamsters (Libby et al. 1982) and guinea pigs and neonatal foals (Jones et al. 1988), and is emerging as a cause of enteritis in neonatal pigs. More than one-third of piglets submitted for diagnosis of enteritis in major swine-producing areas of the U.S. have uncomplicated CDAD and mixed infections occur in a further 20–25% (Songer et al. 2000). Prevalence in a production system was 47.6% on a per litter basis, and 90% of herds were infected (J.G. Songer and K.W. Post, unpublished observations).

Clinical Signs, Lesions, and Pathogenesis. Typical CDAD affects piglets 1–7 days of age born to gilts or multiparous sows. They present with a history of early-onset scours, occasionally with respiratory distress and sudden death (with hydrothorax and/or ascites). Gross lesions usually include mesocolonic edema (Figure 36.9), and large intestines may be filled with pasty-to-watery yellowish feces. Extensive sampling in CDAD-affected herds has revealed that two-thirds of litters and more
36.9. *Mesocolonic edema in a 4-day-old piglet with* C. difficile *infection (J. Glenn Songer).*
36.10. *Colitis in neonatal* C. difficile *infection. Neutrophils entering the colonic lumen form the so-called "volcano" lesion (J. Glenn Songer).*

than one-third of individual pigs are toxin positive in an infected barn. Piglets without enteric signs may be toxin positive (Yaeger et al. 2002; Waters et al. 1998). Focal suppuration in colonic lamina propria is the hallmark lesion, and colonic serosal and mesenteric edema and infiltration of mononuclear inflammatory cells and neutrophils into the edematous areas is common. Segmental erosion of colonic mucosal epithelium and volcano lesions (exudation of neutrophils and fibrin into lumen) may occur (Figure 36.10) (Songer et al. 2000). Pathogenesis of CDAD in domestic animals is likely mediated by the monomeric toxins A (TcdA, 308 kDa, an enterotoxin) and B (TcdB, 270 kDa, a cytotoxin).

Diagnosis. The gold standard for diagnosis of porcine CDAD is detection of TcdA and TcdB in feces or colonic

contents. The reference method is measurement of neutralizable cytotoxicity in monolayers of Chinese hamster ovary cells, but most laboratories now use commercially available enzyme immunoassays. Culture for *C. difficile* can be somewhat challenging, in that this organism is more strictly anaerobic than some clostridia (Songer et al. 2000; Post et al. 2002). Most isolates are fully toxigenic, but some produce only TcdB or no toxins at all. Gross lesions are minimal, but careful microscopic examination of colon and cecum reveals suppurative foci, as described above. Colitis due to other causes is relatively rare.

Treatment and Prevention. Immunoprophylaxis of CDAD in domestic animals has not been studied, but precedent in other species suggests that immunity will be antitoxic. Antibodies against TcdA prevent toxin binding in mouse and hamster models, eliminating secretion, inflammation, and clinical disease (Allo et al. 1979). AntiTcdB antibodies also participate (Kink and Williams 1998; Viscidi et al. 1983). No commercial product is available, but some have attempted to prevent CDAD by use of custom biologics. Results of in vitro antimicrobial susceptibility testing suggest that virginiamycin administered to sows before and after farrowing might be useful for prophylaxis, and tylosin may be effective in treatment of piglets.

CELLULITIS AND GAS GANGRENE

Clostridial wound infections are characterized by acute inflammation, edema, and extensive tissue emphysema and local tissue necrosis. Inflammation spreads rapidly from the primary site, often with terminal generalized sepsis. *Clostridium septicum, C. perfringens* type A, *C. novyi,* and *C. chauvoei* are most likely to cause porcine clostridial cellulitis and gas gangrene.

Clostridium septicum Infection (Malignant Edema)

Etiology and Epidemiology. *Clostridium septicum* appears to be the most common etiologic agent of clostridial cellulitis and gas gangrene of swine. It is an anaerobic gram-positive rod, which forms oval subterminal spores, is found in soil and feces (Finegold et al. 1983; Kahn 1924; Princewill 1985; Princewill and Oakley 1976), and is a frequent postmortem invader (MacLennan 1962). Incidence of malignant edema is particularly high on certain premises that have had large populations of livestock for many years, suggesting that there is a buildup of spore numbers in the environment of these farms.

Clinical Signs and Lesions. *Clostridium septicum* causes malignant edema, which has an acute course and is often fatal in less than 24 hours. Hemorrhage, edema, and necrosis develop as the infection spreads along mus-

cular fascial planes. Common sites include the inguinal and ventral abdominal region, the head and ventral cervical area, and the shoulder. There is reluctance to bear weight on affected limbs, and skin overlying the swollen area has a blotchy reddish-purple discoloration. Tissues that are initially painful and warm, with pitting edema, become rapidly crepitant and cold. In the terminal stage, affected swine lie in lateral recumbency and commonly make a groaning noise during forced expiration.

Swelling at the primary infection site (Figure 36.11) overlies subcutaneous edema that is colorless with focal hemorrhages or uniformly sanguinous. Adjacent skeletal muscle may be edematous, with essentially normal color, or may be black, dry, and crepitant (Figure 36.12). Affected muscle may have a butyric odor comparable to that in ruminant blackleg (*C. chauvoei* infection). Regional lymph nodes are enlarged and hemorrhagic, and may be emphysematous. Acute flbrohemorrhagic

36.11. C. septicum *infection. The grossly swollen area involves the entire left rear leg and extends cranially to the umbilicus. The overlying skin has a blotchy reddish-purple discoloration.*

36.12. *Rear leg of a pig with* C. septicum *infection. There is prominent subcutaneous edema. The infection extends into the ham, which has foci of black, dry necrotic muscle.*

peritonitis is common, the spleen is slightly enlarged, and there is moderate pulmonary edema and congestion. Varying amounts of blood-tinged fluid and fibrin may be found in the pleural cavity and pericardial sac.

Postmortem accumulation of subcutaneous gas progresses until the subcutis of the entire carcass is emphysematous. Focal postmortem lysis of the liver, evidenced by grayish-tan foci, are evident within several hours after death. These foci become confluent, giving the liver a uniform tan color with numerous gas bubbles. Microscopically, edematous subcutis contains large numbers of degenerating acute inflammatory cells and bacteria. Septic thrombi in subcutaneous veins and lymphatics are commonly found (Figure 36.13). Affected skeletal muscle fibers undergo coagulation necrosis with fragmentation and lysis, and bacteria are readily found between degenerating muscle fibers (Figure 36.14).

Pathogenesis. Most cases result from wounds, and tissue damage at the site of inoculation favors initial establishment of the infection. Lesions are largely the result of the necrotizing effect of alpha toxin. Hyaluronidase

36.13. *Acute septic thrombophlebitis involving the subcutaneous vein of a pig with* C. septicum *infection. The thrombus contains many long slender rods and degenerating leukocytes (H&E).*
36.14. C. septicum *infection of the rear leg of a pig. Skeletal muscle fibers are undergoing fragmentation and lysis. The adjacent connective tissues are edematous and emphysematous and contain bacteria and degenerating inflammatory cells (H&E).*

may cause disappearance of the endomysium (Aikat and Dible 1960), which may aid spread of the infection through muscle. Toxemia is probably the ultimate cause of death. Alpha toxin is a pore-former (Ballard et al. 1993) and intravenous infusion specifically affects coronary and pulmonary circulation and causes pulmonary edema (Kellaway et al. 1941).

Diagnosis. Presumptive diagnosis is based upon gross lesions. Laboratory confirmation is based on pathologic findings, exclusion of other diseases, and identification of the organism. Bacteria are seen in direct smears of affected subcutis or muscle, and fluorescent-labeled antibody staining is a rapid and accurate method to positively identify *C. septicum* (Batty and Walker 1963). Bacteriologic culture is an alternative method, but is time-consuming and often less reliable than immunofluorescence (Martig 1966). Swarming of *C. septicum* may cause small numbers of the organism to appear predominant, resulting in a false-positive diagnosis.

Treatment and Prevention. Prevention is preferred to treatment, given the fulminant clinical course. It is important to practice good sanitation and prevent injuries. Infection may be iatrogenic, and adequate sanitary procedures should be followed when making injections or performing surgery. On premises where the disease recurs, immunization could be considered, although this is uncommon in swine. Antibodies to somatic and toxin antigens provide lifelong immunity, although there are differences in immunogenicity by vaccine and host species (Green et al. 1987). Treatment with antibiotics may be successful if given early (Zeller 1956). Experimental prophylactic use of tetracycines, penicillin, or chloramphenicol prevents disease in mice, although their effectiveness was greater when administered at the inoculation site than when given systemically (Taylor and Novak 1952).

Clostridium perfringens Type A Infection (Gas Gangrene)

Etiology and Epidemiology. Most cases of *C. perfringens*-associated myonecrosis are apparently caused by type A strains. The source is usually endogenous, and few cases are nontraumatic. High intraherd incidence in young piglets is often a complication of injection of iron-containing preparations for prevention of nutritional anemia. Anecdotal evidence supports a view that such injections create a tissue microenvironment that favors growth of *C. perfringens* (Jaartsveld et al. 1962; Taylor and Bergeland 1992) in pure or mixed culture. The case fatality rate approaches 50%.

Clinical Signs and Lesions. Affected animals have marked swelling of the entire affected limb, and in the case of piglets with iatrogenic infections, the swelling extends cranially to the umbilical area. The skin overly-

ing the swollen area has a dark reddish-brown discoloration. There is extensive edema, and a copious quantity of gas may be found in muscle and subcutis. The inflammatory exudate is stained by the injected iron preparation and the lesion usually has a putrid odor. Postmortem decomposition is rapid, and livers of pigs dead more than a few hours may have conspicuous gray foci of lysis that surround minute gas bubbles. Acute thrombophlebitis may be evident microscopically, and muscle fibers undergo fragmentation and liquefaction necrosis.

Uterine gangrene and decomposition of its contents may follow dystocia and bungled attempts to assist in delivery. Foul-smelling, reddish, watery vulval discharge may be seen, and death ensues in 12–24 hours. The uterus and its contents are usually dark green or black, malodorous, and contain gas bubbles. There may be foul-smelling reddish fluid in the peritoneal cavity. Decomposition of the remainder of the carcass is rapid, and lesions in other sites are rarely identified.

Pathogenesis. Spores germinate and vegetative cells multiply in ischemic tissue and infection spreads to healthy muscle. CPA and PFO toxins play local and systemic synergistic roles in myonecrosis (Awad et al. 2000), although the entirety of our knowledge in this area comes from studies in mice. The protective effect of CPA-containing toxoids against gas gangrene has been long known, and antibodies against native CPA and its C-terminus protect mice against challenge with toxin or multiple LD_{50} of spores (Titball et al. 1993; Williamson and Titball 1993).

Diagnosis. Diagnosis is based on clinical and pathologic findings, together with isolation and identification of *C. perfringens.* Gram-stained smears of the lesion are helpful in estimating the relative numbers of bacteria. Isolation of the organism is easily accomplished by anaerobic incubation for 18–24 hours on blood agar or egg yolk agar.

Prevention and Treatment. Prevention of gas gangrene requires prevention of deep, contaminated wounds and prompt treatment of any such wounds with systemic penicillins. Treatment may be successful if instituted early in the course of the disease. Infection of mice was prevented by administration of penicillin coincident with *C. perfringens,* but if the antimicrobial was delayed by as little as 3 hours, the survival rate was appreciably lowered (Hac and Habert 1943). Clinically ill pigs may recover following penicillin injection (Jaartsveld et al. 1962).

Specific immunization of domestic animals against infection by type A in North America is focused at present upon anti-CPA immunity, and both toxoids and bacterin:toxoids are widely available elsewhere in the world.

Clostridium chauvoei Infection (Blackleg)

Etiology and Epidemiology. *Clostridium chauvoei* is a pleomorphic, anaerobic, gram-positive rod that readily forms central to subterminal spores. It causes blackleg (Burke and Opeskin 1999; Kuhnert et al. 1996), an emphysematous, necrotizing myositis of ruminants and other domestic species (refer to Table 36.1), which resembles malignant edema.

Clinical Signs and Lesions. Pigs are generally quite resistant to *C. chauvoei* infection, and there have been very few substantiated reports of disease in swine. Blackleg has occurred in swine kept under poor hygienic conditions on premises with previous losses of cattle from blackleg (Sterne and Edwards 1955; Gualandi 1955), although *C. septicum* may also be involved in these cases. Disease may follow consumption by swine of meat from blackleg-affected calves (Eggleston 1950), and in these cases, swelling of the face and throat were prominent. Lesions are perhaps more common in limbs (Mavenyengwa and Matope 1995). Signs include high fever, anorexia, depression, and lameness, with crepitant lesions and sudden death. Lesions are often dry and emphysematous at the center, but edematous, hemorrhagic, and necrotic at the periphery, with little leukocytic infiltration.

Pathogenesis. Pathogenesis of *C. chauvoei* infection in pigs is poorly understood. Infection may be by the oral route, rather than beginning as a wound infection. The organisms may lie dormant in various tissues until a microenvironment favorable for their growth is generated, such as by tissue damage from bruising. The roles of alpha toxin, which is necrotizing, hemolytic, and lethal, and beta toxin, a DNase (Ramachandran 1969), remain undefined. Flagellar expression is associated with virulence, and phase variation occurs in motility and flagellation (Tamura et al. 1995); flagella are apparently protective antigens (Kojima et al. 2000; Verpoort et al. 1966).

Diagnosis. A diagnosis of blackleg can be made only by bacterial identification, due to similarities in the clinical presentation and pathology of *C. septicum* and *C. chauvoei* infections. The fluorescent antibody test, applied to direct impression smears of infected tissue, is a rapid and practical method of identification (Batty and Walker 1963). Bacterial isolation may be difficult in decomposing specimens, since *C. chauvoei* is easily overgrown by other bacteria, including *C. septicum*.

Treatment and Prevention. Prevention of *C. chauvoei* infection involves minimizing exposure to the organism. *Clostridium chauvoei* is not a common soil organism, but anecdotal evidence suggests that keeping swine on known contaminated premises or allowing them to eat carcasses of ruminants dead of blackleg are risk factors.

Clostridium novyi Infection (Sudden Death)

Etiology and Epidemiology. *Clostridium novyi* is an anaerobic, spore-forming, gram-positive rod that is generally the largest of the clostridia encountered in swine. Types A and B are involved in swine infections (Itoh et al. 1987; Duran and Walton 1997).

Clinical Signs and Lesions. *Clostridium novyi* has been associated with sudden death in swine (Batty et al. 1964), with unusually rapid postmortem decomposition. Necropsy findings include rapid postmortem tympany, submandibular swellings, bloodstained fluid in pleural, pericardial, and peritoneal cavities, serosal hemorrhages, and splenic enlargement. The hallmark is perhaps marked hepatic degeneration and emphysema, often referred to as "aerochocolate liver." Its bronze color and the presence of large numbers of small gas bubbles are common (Duran and Walton 1997). The organism can be demonstrated in various tissues, including liver, heart, and blood.

The disease affects large finishing pigs and breeding stock, principally sows, and was recorded more frequently in spring, in older, periparturient sows of parity greater than 4 in moderate to good condition (Duran and Walton 1997).

Pathogenesis. Livers of normal sows often yield *C. novyi* when subjected to bacteriologic culture, although the route by which the organism reaches the liver has not been documented. The conditions under which dormant spores germinate are also unknown. Pathogenesis is likely mediated by the lethal, necrotizing alpha toxin. A so-called large clostridial cytotoxin (Busch et al. 2001; Selzer et al. 1996), it is produced by strains of types A and B. Beta toxin, a phospholipase related to CPA of *C. perfringens*, is produced in small quantities by type B strains. Systemic effects, with acute or peracute death, follow dissemination of alpha toxin (Elder and Miles 1957). Cardio-, neuro-, histo-, and hepatotoxic effects result in edema, serosal effusion, and hepatic necrosis (Elder and Miles 1957; Cotran 1979; Rutter and Collee 1967).

Treatment and Prevention. The disease can be controlled by reducing the incidence of pneumonias, metritis, and enteritis in affected groups of pigs, coupled with vaccination of finishing pigs and sows against the disease using alum-adjuvanted vaccines such as those readily available for sheep. Zinc bacitracin (200 ppm in feed twice daily) may reduce mortality in sows (Marco 1995). Prompt carcass disposal by incineration or deep burial may reduce spore contamination of the environment.

Diagnosis. Diagnosis of *C. novyi* infection in swine is difficult, since suspect cases are usually found dead, and the interval between death and necropsy introduces the possibility of postmortem invasion. Other possible causes of death should be excluded, but disease should

be suspected when there is a history of sudden death and typical necropsy findings. Subcutaneous edema is particularly notable in cervical and inguinal regions. Pulmonary edema and tracheal froth, serofibrinous or serosanguinous exudates in pericardial and pleural cavities, and unusually rapid decomposition with accumulation of gas in the liver are all common. Gas bubbles in the liver in an otherwise fresh carcass are particularly significant (Duran and Walton 1997).

The organism is rapidly identified by fluorescent antibody staining of direct smears of infected tissue. It is the most fastidious of the clostridia commonly encountered in swine, but it can be isolated (Itoh et al. 1987; Duran and Walton 1997; J.G. Songer and K.W. Post, unpublished observations).

Treatment and Prevention. Given that definition of the syndrome is sudden death, treatment is not a factor in management of the disease. It may be possible to prevent disease by feeding bacitracin methylene disalicylate in the periparturient period. Prevention may also be achievable by use of bacterin:toxoids or toxoids, and second-generation vaccines may be based upon native or recombinant alpha (Amimoto et al. 1998) or beta toxoids.

NEUROTOXIGENIC CLOSTRIDIA

Tetanus

Tetanus is caused by *C. tetani* and is characterized by toxin-mediated, uncontrollable spasms of voluntary muscles. Swine of all ages may be affected, but most cases involve young pigs and originate with castration wounds or umbilical infection.

Etiology and Epidemiology. *Clostridium tetani* is a slender, anaerobic, gram-positive rod. It forms terminal spores, which are ubiquitous in the environment. Spores often enter via traumatic wounds, including those from tail-docking. Castration is a risk factor for infection, and sows may be infected by contamination of uterine prolapses.

Clinical Signs and Lesions. Tetanus is characterized by generalized skeletal muscle spasms. The incubation period ranges from several days to several weeks. In general, cases with a short incubation period run a more acute and fulminating course with a higher fatality rate than cases with a long incubation period.

The earliest sign is a stiffened gait, but the disease progresses rapidly over 1–2 days. Ears become erect, the tail extends straight out posteriorly, the head is slightly elevated, and there may be protrusion of the nictitating membrane. The pig becomes incapable of walking, and the skeletal muscles are very firm on palpation. Ultimately, the pig lies in lateral recumbency in opisthotonus, with both thoracic and pelvic limbs extended

36.15. *Generalized tetanus in a 10-day-old pig that apparently resulted from umbilical infection. The ears are erect and the limbs are rigidly extended.*

and directed posteriorly (Figure 36.15). Tetanic spasms proceed from periodic to continuous and are noticeably heightened by sudden sensory stimuli, such as noise, touch, or movement. Tachycardia and increased respiration rate are common terminal signs, and white froth may be present around the mouth and external nares.

Many factors may contribute to the eventual death of the affected pig. In acute cases, respiratory failure resulting from severe skeletal muscle spasms is likely to be the single most important factor. Prolonged recumbency and nutrient deprivation may be factors in animals with a relatively long survival time. No lesions specific for tetanus are found at necropsy. Conspicuous abrasions of the skin over pressure points may be seen, and there may be pulmonary congestion and edema.

Pathogenesis. Development of tetanus depends upon the presence of *C. tetani* in a tissue environment that will support spore germination, vegetative cell growth, and toxin production. Spores usually gain entrance via a deep penetrating wound. Spore germination is facilitated by the presence of foreign bodies or facultative anaerobes which reduce Redox potential (Eh) in tissue. Bacterial multiplication and tetanospasmin (TeNT) production is enhanced by tetanolysin, a cholesterol-binding toxin, which inhibits neutrophil and macrophage chemotaxis and causes local tissue necrosis. Spores may remain latent in healed wounds for 10 years or more. *Clostridium tetani* is not invasive and remains localized at the primary site of infection. The most commonly reported location of tetanus infection in swine is castration wounds (Kaplan 1943).

Toxin-containing vesicles pass by retrograde axonal transport along the motor nerve fibers from neuromuscular junctions at the site of the infection, acting eventually on the inhibitory neurons in the ventral horn of the spinal cord. The toxin consists of a light chain that is enzymatic (a zinc-dependent endopeptidase) and a heavy chain that binds to receptors. The L chain cleaves synaptobrevin, a protein involved in the exocytosis of neurotransmitters by neurons, resulting in tetany.

Diagnosis. Diagnosis is based upon typical clinical signs. An obvious area of infection (e.g., a castration wound or umbilical abscess) may be apparent. The organism may be isolated by bacteriologic culture or identified by immunofluorescence (Batty and Walker 1963), but this is usually not necessary if there is adequate antemortem clinical observation of the affected animals.

Treatment and Prevention. There is no practical way to eliminate spores from soil, so control is directed toward prevention of wound contamination by soil or feces. Good sanitation in the farrowing house, treatment of the umbilical cord with antiseptics soon after birth, and prompt clipping of the canine incisors are recommended preventive measures against neonatal tetanus. Sharp objects that may cause skin wounds should be removed from the environment. Because most tetanus in swine follows castration, particular emphasis should be placed on proper surgical technique, with the provision of clean quarters for the pigs after castration to prevent undue contamination of the castration wound by soil or feces.

Passive immunization with tetanus antitoxin, prophylactic use of antibiotics, and/or active immunization with tetanus toxoid may be indicated. Prophylactic use of large doses of long-acting penicillin or tetracycline may be superior to antitoxin in preventing experimental tetanus in mice, if treatment is instituted within a few hours after infection (Veronesi 1966). Active immunity may be obtained from a single injection of alum-precipitated tetanus toxoid, and excellent protection for a year or more can be expected if three doses are given several weeks apart.

Prognosis is poor, and there is little evidence that treatment by currently practical methods is of real benefit (Mihaljevic 1966; Kaplan 1943). Various suggested treatments include reopening castration wounds and flushing them with hydrogen peroxide, administration of antitoxin in an attempt to neutralize toxin not already fixed by nervous tissue, administration of antibiotics, and the use of tranquilizers or barbiturates as muscle relaxants.

Botulism

Clostridium botulinum produces eight types of botulinum neurotoxin (BoNT) (Smith 1979; Linial 1995; Smith 1977) which have unique geographic distribution and species susceptibility patterns (Smith 1977; Shapiro et al. 1998; Smith and Milligan 1979; CDC 1998; Hatheway 1990, 1995). Thus, botulism is a toxicosis characterized by rapidly progressive flaccid paralysis. Swine are highly resistant to botulism, and there are few authentic reports of naturally occurring botulism in this species.

Etiology and Epidemiology. Botulism spores are ubiquitous in soil throughout the U.S. (Smith 1979; Whitlock and Williams 1999; Kelch et al. 2000). Disease in other species is associated with forage (Kinde et al. 1991; Whitlock 1997; Wichtel and Whitlock 1991; Ricketts et al. 1984; Franzen et al. 1992; Kelly et al. 1994), contamination of grain by decomposing animal carcasses (Whitlock and Williams 1999; Divers et al. 1986; Enfors et al. 1975; Galey et al. 2000), or transport of BoNT by ravens or crows feeding on a decomposing carcass (Schoenbaum et al. 2000). Type D botulism has been linked to pica, in which phosphorous-deficient animals consume bones of confederates dead of botulism (Dobereiner et al. 1992). Prevalence may be associated with the quantity of organic matter in the soil, and factors such as fertilization with manure may increase bacterial numbers. Botulism in swine is rare, so there are few recorded toxin sources, but type C disease due to consumption of dead fish (Beiers and Simmons 1967) and swill and decomposing brewers waste (Doiurtre 1967) have been reported.

The organism is a strictly anaerobic, gram-positive bacillus (Smith and Holdeman 1968), which forms oval, usually subterminal, spores. Growth is perhaps optimal at about 30°C.

Eating habits of nonconfined pigs should make them likely candidates for botulism, but there appears to be innate resistance when toxin is administered by the oral route. The swine intestine may have a low permeability for botulinum toxin (Dack and Gibbard 1926b; Scheibner 1955; Smith et al. 1971).

Clinical Signs and Lesions. The latent period between consumption of toxic material and onset of signs ranges from 8 hours to 3 days or more, largely determined by the amount of toxin consumed (Beiers and Simmons 1967; Smintzis and Dunn 1950). Initial signs are weakness, incoordination, and staggering, with weakness appearing first in the forelegs, followed by involvement of the hindlegs and general motor paralysis and dilation of the pupils of the eyes (Smith et al. 1971). The clinical effect is progressive flaccid paralysis of voluntary muscles, which manifests in the end as lateral recumbency with complete flaccidity. Other clinical signs include anorexia, reduced vision or complete blindness, aphonia, excessive salivation, involuntary urination, and deep labored breathing (Smintzis and Dunn 1950; Beiers and Simmons 1967).

No specific lesions are found at necropsy. Significant findings might include presence in the stomach of the material suspected as the toxin source and the occurrence of aspiration pneumonia as a result of paralysis of the muscles of deglutition (Beiers and Simmons 1967).

Pathogenesis. Botulinum toxin relative potency varies among toxin types, and amounts of toxin produced varies with strain. Botulism occurs after ingestion of preformed BoNT or by dissemination of toxin from a wound or focus of clostridial multiplication in the gastrointestinal tract (Hatheway 1995; Swerczek 1980;

Bernard et al. 1987). Absorption varies among species and with different areas of the intestine (May and Whaler 1958).

Botulinum toxin is composed of an enzymatic light chain (a zinc-dependent endopeptidase) and a heavy chain that binds to receptors and facilitates internalization. The light chain cleaves proteins involved in exocytosis of neurotransmitters by neurons. Toxin types B, D, and F cleave synaptobrevin, types A and E act on SNAP-25, and type C toxin acts on syntaxin, at the myoneural junction, preventing muscular contraction. Death is generally ascribed to asphyxia resulting from paralysis of the muscles of respiration.

Diagnosis. Toxin is detected inconsistently in serum or plasma of acutely affected animals, and this may be a manifestation of relative sensitivity of various species. Gross or histological lesions are usually absent, although inhalation pneumonia may occur due to an abnormal deglutition reflex. Affected animals are dysphagic and will usually have relatively empty gastrointestinal tracts. A diagnosis of botulism should be considered in afebrile, alert animals with progressive weakness and recumbency. Because the pig apparently is quite highly resistant to botulism, a diagnosis should be made only after thorough investigation and exclusion of other possible diagnoses (Beiers and Simmons 1967).

Isolation and identification of *C. botulinum* may also be of some value in establishing the diagnosis (Narayan 1967; Muller 1967; Yamakawa et al. 1992).

Treatment and Prevention. If botulism is suspected, an effort should be made to find the toxin source and prevent further consumption of any remaining suspect material by the herd.

Antitoxin is the only specific treatment for botulism, and it has been effective in reducing mortality in humans when given after consumption of food suspected to contain toxin (Lamanna and Carr 1967; Burgen et al. 1949). Therapy in animals demands use of polyvalent antitoxins that incorporate the types most commonly present in a geographic area. Therapy aimed at reducing continued absorption of toxin from the intestine (administration of magnesium sulfate) may be helpful.

Prevention requires eliminating opportunities to consume potentially toxic material, such as spoiled garbage and decomposing animal tissue. Prophylactic immunization with toxoids is not practical in swine because of the infrequent occurrence of the disease.

37 Erysipelas

Richard L. Wood and Louise M. Henderson

The bacterium *Erysipelothrix rhusiopathiae*, a small gram-positive rod, is a primary pathogen of swine and turkeys as well as a sporadic cause of disease in humans and other species. It is the causative agent of swine erysipelas (SE) (Sneath et al. 1986), which is manifested most commonly by acute or subacute septicemia and chronic proliferative lesions. The disease is worldwide in distribution and of economic importance throughout Europe, Asia, and the Australian and American continents.

The identification of SE as a disease entity began in 1878 when Koch isolated from an experimental mouse an organism that he called "the bacillus of mouse septicemia." In 1882–1883 Pasteur and Thuillier briefly described the organism isolated from pigs with *rouget*. In 1886 Löffler published the first accurate description of the causative agent of *Schweinerotlauf* and described the infection in swine. In the United States the recorded history of SE began when Smith (1885) isolated the causative organism from a pig. Serious outbreaks were reported in South Dakota in 1928; by 1959 acute SE had been reported in 44 states. Since that time the prevalence of SE apparently had decreased overall (Wood 1984); but in 2001, SE reemerged in the midwestern U.S. (Opriessnig et al. 2004).

E. rhusiopathiae also causes polyarthritis of sheep and lambs and serious death losses in turkeys and marine mammals, including dolphins. It has been isolated from body organs of many species of wild and domestic mammals and birds as well as reptiles, amphibians, and the surface slime of fish. In humans *E. rhusiopathiae* causes erysipeloid, a local skin lesion that occurs chiefly as an occupational disease of persons engaged in handling and processing meat, poultry, fish, and lobsters as well as of rendering-plant workers, veterinarians, game handlers, leather workers, and laboratory workers. The organism occasionally is isolated from cases of endocarditis in humans and rarely causes acute septicemic disease.

ETIOLOGY

E. rhusiopathiae is a gram-positive bacillus with a tendency to form elongated filaments. Plasmid DNA has been detected in some strains of *E. rhusiopathiae*, but the functions of the plasmid are unknown (Noguchi et al. 1993). The morphology of *E. rhusiopathiae* is variable. In smears made directly from tissues in cases of acute infection, the organism appears as slender, straight or slightly curved rods, 0.2–0.4 by 0.8–2.5 µm, occurring singly or in short chains (Figure 37.1). An occasional coccoid or clubbed form may be seen. Palisades and angular formations ("snapping division") are common. The organism is nonmotile, non–spore-forming, non-acid-fast, and produces no flagella. It stains readily with ordinary dyes and is gram-positive but is easily decolorized. After several subcultures on an artificial medium, filamentous forms of the organism begin to appear and may predominate in old cultures or in chronic lesions. Filamentous forms are somewhat thickened, are greatly elongated (4–60 µm), and may form a mass resembling mycelia, especially in a liquid medium (refer to Figure 37.1). The filamentous forms sometimes have a beaded appearance when Gram's stain is used. Growth of *E. rhusiopathiae* at 37°C in a nutrient broth appears at 24 hours as a faint turbidity with no pellicle. Growth is much heavier in broth enriched with serum. In gelatin stabs incubated at 22°C for 4–8 days, growth produces a test-tube brush appearance.

Colonies of *E. rhusiopathiae* on agar media at 48 hours are tiny (less than 1 mm), transparent, and vary from smooth to rough, (refer to Figure 37.1). Colonies of most strains have entire edges, but some strains form colonies that are slightly larger and have somewhat undulate edges. Granulelike structures usually appear under a colony just below the surface of the agar. Dissociation from smooth to rough form may occur during the development of a colony, producing a sector (refer to Figure 37.1); the morphology of cells from these
SMOOTH   INTERMEDIATE   ROUGH

37.1. *Cellular and colonial morphology of* Erysipelothrix rhusiopathiae. *Upper row: ×1200, crystal violet; lower row: ×32. (Courtesy National Animal Disease Center, Ames, Iowa.)*

intermediate forms will include a variety of shapes from short, curved rods to short filaments. Most strains of *E. rhusiopathiae* produce a narrow zone of partial hemolysis on blood agar, usually with a greenish color. Rough colonies do not induce hemolysis. *E. rhusiopathiae* produces acid but no gas from certain fermentable carbon compounds and produces hydrogen sulfide along the stab in triple-sugar iron agar (Vickers and Bierer 1958; White and Shuman 1961). Most, if not all, strains have one or more common heat-labile antigens, which are proteins or protein-saccharide-lipid complexes. Heat-stable antigens consisting of peptidoglycan fragments from the cell wall form the basis for identification of various serovars within the species. The serovars are identified by precipitin reactions with specific hyperimmune rabbit sera, usually in a gel double-diffusion system. Most isolates of the organism (75–80%) from swine fall into two major serovars designated 1 and 2 (Wood and Harrington 1978; Takahashi et al. 1996). About 20% of isolates make up a group of less-common serovars. Under a numerical system introduced by Kucsera (1973), a total of 26 serovars have been described so far (Kucsera 1973; Wood et al. 1978; Nørrung 1979; Xu et al. 1984, 1986; Nørrung et al. 1987; Nørrung and Molin 1991). Strains that do not possess the specific antigen are referred to as serovar N. Pulsed-field gel electrophoresis (PFGE) has been used to characterize field isolates and vaccine strains, with 23 PFGE patterns identified from

20 characterized strains (Opriessnig et al. 2004). Using PGFE to genotype is easy to perform and allows characterization without the need to rely on difficult-to-obtain antisera.

E. rhusiopathiae is a facultative anaerobe; some strains grow better in an atmosphere of reduced oxygen containing 5–10% carbon dioxide. It will grow at temperatures of 5–42°C. Optimum growth occurs at 30–37°C and at a pH range of 7.4–7.8. Growth is enhanced by serum, glucose, protein hydrolysates, or surfactants such as Tween-80. The organism is fastidious, requiring a complex medium, but no specific nutrient requirements are known. It is relatively resistant to adverse conditions and somewhat resistant to drying and can remain viable for several months in animal tissues under a variety of conditions. It can persist in frozen or chilled meat, decaying carcasses, dried blood, or fish meal. It is remarkably resistant to salting, pickling, and smoking and can survive several months in cured and smoked hams. The organism can survive in swine feces or fish slime for 1–6 months if temperatures remain below 12°C. It is sensitive to penicillin and usually to the tetracyclines; it is quite resistant to polymyxin B, neomycin, and kanamycin and is relatively resistant to streptomycin and the sulfonamides (see the section on treatment). It is killed readily by common disinfectants, heat (15 minutes at 60°C), and gamma irradiation.

Another species, *E. tonsillarum*, has been identified

(Takahashi et al. 1987a). This species is distinguished from *E. rhusiopathiae* by DNA homology. Protein profiles using sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) demonstrated differences between the strains but were unable to establish sufficient differences to support identification to a species (Bernath et al. 2001). Phenotypic characteristics of the two species are indistinguishable by the usual diagnostic bacteriologic methods. *E. tonsillarum* has been isolated from a variety of sources, including the tonsils of healthy swine. Reported isolates have little or no virulence for swine and are not considered significant in the etiology of SE.

EPIDEMIOLOGY

The most important reservoir of *E. rhusiopathiae* is the domestic pig. Carriers can discharge the organism in their feces or oronasal secretions, and swine affected with acute erysipelas shed profusely in feces, urine, saliva, and nasal secretions. The large variety of wild mammals and birds known to harbor *E. rhusiopathiae* provides an extensive reservoir (Wood and Shuman 1981; Shuman 1971). Various species of domestic animals from which the organism has been isolated provide an additional potential reservoir. The agent can be found in the soil; however, Wood (1973) and others have found no evidence of maintenance of the organism in test soils, and current evidence indicates that soil provides only a temporary medium for transmission of *E. rhusiopathiae*. Swine between 3 months and 3 years of age are generally most predisposed to SE, most likely due to naturally acquired passive immunity in the young and active immunity following subclinical infection or vaccination in older animals. Suckling pigs of immune sows are immune to infection up to several weeks of age. There is no experimental evidence that susceptibility to SE is related to genetics of the animal; however, naturally acquired active immunity induced by previous infection, often with organisms of low virulence, is not uncommon. The role of parasites in transmission of disease has not been well defined, but the poultry red mite has been shown to carry the agent (Chirico et al. 2003).

SE can occur with other swine diseases, but the significance of preexisting infectious disease as a predisposing factor is uncertain. Parasitic infestations have been reported to increase the severity of clinical SE. In addition, Cysewski et al. (1978) showed that the susceptibility of swine to acute SE can be enhanced by subclinical toxicity from aflatoxin in the feed. This treatment also interfered with vaccination efficacy. Environmental and stress factors such as nutrition, ambient temperature, and fatigue, particularly sudden changes in these conditions, have long been linked to the appearance of SE. A number of molecular techniques may provide useful tools for epidemiological investigations. SDS-PAGE can be utilized for such purposes (Bernath et al. 1998).

PATHOGENESIS

Investigations using germfree pigs have demonstrated that *E. rhusiopathiae is* the sole causative agent of SE and does not require the presence of any other infectious agent for its disease-producing ability. The organism can gain entry to the body by a variety of routes. Infection through ingestion of contaminated feed and water is considered a common mode. The organism can readily gain access to the body through the palatine tonsils or other lymphoid tissue but entrance is probably not limited to these areas. Natural infection can result from infected skin wounds, and experimental infection can be easily accomplished by inoculation of scarified skin (Shuman 1951).

Acute systemic SE begins with bacteremia, which quickly results in clinical signs of generalized infection (septicemia). A nonsystemic infection consisting only of a local skin lesion may occur upon cutaneous exposure to a strain of low virulence or with partial immunity. In such cases the organism is eliminated without inducing septicemia and the lesion disappears. In the more typical systemic infection caused by virulent organisms, bacteremia usually develops within 24 hours after exposure. The organism usually can no longer be cultured from blood or most body organs after a few days but may persist in the joints and in lymphoid tissue such as tonsils, Peyer's patches, and spleen.

According to Schulz et al. (1975b, 1977), pathogenesis of the early septicemic phase consists of changes involving capillaries and venules of most body organs, including synovial tissues. As early as 36 hours after subcutaneous exposure, swelling of endothelium, with adherence of monocytes to vascular walls and evidence of widespread hyaline thrombosis was observed. This process was referred to as a shocklike generalized coagulopathy leading, within 4 days, to fibrinous thrombosis, diapedesis, invasion of vascular endothelium, and deposition of fibrin in perivascular tissues leading to connective-tissue activation in joints, heart valves, and blood vessels.

In severe acute SE, hemolysis is commonly observed. Ischemic necrosis of perivascular tissues may occur, caused by interference with microcirculation. Drommer et al. (1970) observed a high incidence of encephalomalacia in acute experimental SE and theorized that certain strains of the organism are endotheliotropic and damage the endothelial cell barrier in the central nervous system (CNS). Mild, delayed hypersensitivity responses to *E. rhusiopathiae* can be elicited and transferred by lymphoid cells. It is doubtful, however, that delayed hypersensitivity has a significant part in the pathogenesis of acute SE.

Information on the pathogenesis of chronic SE is derived primarily from studies on development of the arthritic lesion, which has stimulated interest because of its apparent similarity to the lesion of rheumatoid

arthritis of humans. According to observations by Schulz et al. (1975a, 1977), the joint lesion in chronic SE begins with acute synovitis that may occur as early as 4–10 days after exposure. Within 3 months, fibrinous exudation, proliferation, and pannus formation occur, developing further into severe fibrosis and destruction of articular cartilage in 5–8 months. During this time, the organism can be found sequestered within chondrocytes in addition to its presence in synovial tissue and fluid (Franz et al. 1995). The earliest changes in the synovial tissue are described as consisting of coagulopathy and fibrinous exudate into perivascular tissues. Fibrin deposited during the vascular phase, not bacterial colonization, is believed to act as mediator of the subsequent connective-tissue proliferation. Affected joints are culture-negative after 3–6 months; yet the arthritic lesions usually undergo a progressive development that can continue at least 2 years. Hypersensitivity may be a significant factor in the chronic proliferative and destructive changes but probably not in initiation of the lesion. The porcine homologues of intracellular adhesion molecule-1 (ICAM-1)F and MHC class II, which are not constitutively expressed on porcine chondrocytes, appear to be induced as a result of arthritis and support the use of the model for immunopathological studies (Davies et al. 1994).

There is evidence that the bacteria do not entirely disappear from chronically affected joints, and the long-term progressive lesion may occur in response to the continued presence of either whole bacterial cells or their antigens. Schulz et al. (1977) reported that living *E. rhusiopathiae* was occasionally isolated from such joints for up to 2 years. Furthermore, they stated that *E. rhusiopathiae* antigen could be detected by immunofluorescence, and whole or fragmented bacteria could be seen with the electron microscope in culturally negative joints. Denecke and Trautwein (1986) reported detection of *E. rhusiopathiae* in arthritic joints microbiologically and immunohistologically for up to 3 years. Specific antibodies to the organism have been detected in synovial fluid of chronically arthritic joints and apparently are produced locally by plasma cells in the synovial tissue, which can assume a lymphoid function. It is not known whether the chronicity of the joint lesion is maintained entirely by specific immune reactions against *E. rhusiopathiae* antigen or whether superimposed autoimmune reactions are involved.

A preponderance of evidence exists to indicate that erysipelatous arthritis is initiated by active infection of the joint. Mild synovitis and arthritis have been induced in rabbits and rats by massive intravenous or intra-articular injections with nonliving whole cells or fractions of the organism (White et al. 1975; Hermanns et al. 1982), but the lesions were not as severe as those typically caused by infection. White et al. (1975) suggested that the mild response induced by such antigens may predispose the joint to infection during a subse-

quent transient septicemia. Studies on the pathogenesis of endocarditis indicate that the valvular lesions begin with vascular inflammation and myocardial infarcts, possibly resulting from bacterial emboli. These processes, together with exudation of fibrin, lead to destruction of valvular endocardium.

The mechanism by which *E. rhusiopathiae* incites disease processes is not clearly understood, but considerable evidence indicates that neuraminidase, an enzyme that specifically cleaves alpha-glycosidic linkages in neuraminic acid (sialic acid), a reactive mucopolysaccharide on surfaces of body cells, is a factor. The amount of enzyme produced by the strain seems to increase as virulence increases (Müller 1981). Specific antibody activity against *E. rhusiopathiae* neuraminidase has been demonstrated in sera of swine with chronic SE and commercial equine antierysipelas antibody. Neuraminidase activity could be a major factor mediating the widespread vascular damage, thrombosis, and hemolysis described (see the section on pathogenesis of acute SE). The ability to adhere to cell surfaces may also play a role in the pathogenicity of *E. rhusiopathiae*, and there is evidence that the process involves neuraminidase. Takahashi et al. (1987b) reported that virulent strains of the organism adhered better to porcine kidney cells in vitro than did avirulent strains. Nakato et al. (1987) reported that neuraminidase was essential for adherence of *E. rhusiopathiae* bacteria to vascular endothelial cells.

Although neuraminidase activity may be largely responsible for the pathogenicity of *E. rhusiopathiae* and may be a virulence factor, other virulence factors play an important role in disease processes. The virulence of *E. rhusiopathiae* is related to the organism's ability to resist the action of phagocytes, and resistance to phagocytosis is correlated with the presence of a protective capsulelike structure on the surface of virulent strains but not on avirulent mutants (Shimoji et al. 1994).

In the U.S., reports of field cases frequently have described serovar 1 (usually subserovar 1a) as the predominant isolate from acute septicemic disease and serovar 2 as the most common isolate from subacute and chronic cases of SE. However, experimentally, all clinical forms of SE can be induced readily in susceptible swine by strains of serovar 1 or 2. The less-common serovars (3 through 26; N) tend to have low virulence for swine.

CLINICAL SIGNS

The clinical signs of SE can be divided into three general classifications: acute, subacute, and chronic. In addition, subclinical infection can occur in which no visible signs of acute disease are evident but which can lead to chronic SE.

Acute SE is characterized by sudden onset, sometimes with sudden death. Other animals in the herd may have temperatures of 104–108°F (40–42°C) and over, and those with the higher temperatures may show

signs of chilling. Some pigs may appear normal and yet have temperatures of 106°F (41°C). In surviving pigs, temperatures usually return to normal within 5–7 days. Affected animals withdraw from the herd and will be found lying down. When approached, they resent being disturbed but usually will get up and move away. This usually is accompanied by squealing; when walking, they show a stiff, stilted gait. Upon stopping, they may be seen to shift their weight in an apparent effort to ease the pain in their legs. If left alone, they will soon lie down carefully. Pigs showing severe depression are nevertheless usually aware of activities around them. They may show some resentment at being disturbed but will make little or no effort to rise. Upon being forced to get up, they may stand for only a few moments before lying down again. While standing, the feet are carried well under them and the head is hung dejectedly, giving the back line a marked arched appearance. Others will not be able to stand even when assisted. Most affected animals will show partial or complete inappetence. Bowel movements are usually retarded and the feces firm and dry in pigs of market age and older, although as the disease progresses, a diarrhea may appear in younger animals. Abortion may occur in sows that contract acute or subacute SE during pregnancy.

Characteristic cutaneous lesions (urticarial, or "diamond-skin" lesions) appear as early as the second, and usually by the third, day after exposure to *E. rhusiopathiae* (Figure 37.2). On the light-skinned pig they can be seen as small, light pink to dark purple areas that usually become raised, are firm to the touch, and in most instances are easily palpated. In animals with dark-pigmented skin, one must rely mainly on palpation, although the weltlike lesions may be detected by observing raised areas in the hair coat. The lesions may be few in number and easily overlooked or so numerous it would be difficult to count them all. An animal also may die before recognizable urticarial lesions are evident. Individual lesions, by extension of the borders, assume a characteristic square or rhomboid shape. In acute nonfatal erysipelas, these lesions may spread considerably but will gradually disappear within 4–7 days after their first appearance, with no subsequent effect other than a superficial desquamation to mark the site. The intensity of skin lesions has a direct relationship to the outcome of the disease. Light pink to light purplish-red lesions are characteristic of acute nonfatal SE, whereas angry dark purplish-red lesions usually precede death of the animal. In acute fatal disease, extensive dark purplish discoloration often occurs over the belly, ears, tail, posterior aspect of the thighs, and jowls. Infrequently, severely affected pigs do not die, and skin necrosis may follow the severe cutaneous lesions. The areas of necrotic skin are dark, dry, and firm and eventually become separated from the healing underlying tissue. Affected areas, particularly the ears and tail, will eventually slough, and secondary infection may occur.

37.2. *Typical rhomboid urticarial lesions ("diamond-skin" lesions) of SE. (Courtesy National Animal Disease Center, Ames, Iowa.)*

Subacute SE includes signs that are less severe in their manifestations than the acute form. The animals do not appear as sick; temperatures may not be as high and may not persist as long; appetite may be unaffected; a few skin lesions may appear that may be easily overlooked; and, if visibly sick, the animals will not remain so for as long as those acutely ill. Some cases of subacute SE are so mild as to remain unnoticed.

Chronic SE may follow acute or subacute disease or subclinical infection and is characterized most commonly by signs of arthritis, or, occasionally, signs of cardiac insufficiency that are most noticeable following exertion, sometimes causing sudden death. Chronic arthritis results in joints that show various degrees of stiffness and enlargement, sometimes as early as 3 weeks after infection. Interference with locomotion ranges from a slight limp to complete refusal to put weight on the limb, depending upon the extent of damage. Arthritis is the most important clinical manifestation of SE from an economic standpoint. The condition not only affects growth rate but is responsible for significant losses of prime cuts at slaughter.

LESIONS

Rhomboid urticarial lesions ("diamond-skin" lesions) are characteristic of acute SE, and when generalized (refer to Figure 37.2), they are a reliable indicator of septicemia. This observation is important in meat inspection as well as in field diagnosis. Most lesions of acute SE are similar to those of septicemia caused by a variety of organisms.

In acute SE, macroscopic lesions include evidence of diffuse cutaneous hemostasis, which is often prominent, particularly in the skin of the snout, ears, jowls, throat, abdomen, and thighs. The lungs may be congested and edematous. Petechial and ecchymotic hemorrhages may be seen on the epicardium and in the musculature of the atria, particularly the left atrium. Catarrhal to hemorrhagic gastritis is common, and

hemorrhage of the serosa of the stomach may be present. The liver usually is congested. The appearance of the spleen is of particular note, for it may be congested and markedly enlarged, particularly in animals affected for several days. Petechial hemorrhages may be present in the cortex of the kidneys. The appearance of the lymph nodes will depend upon the degree of involvement in the area they drain. There is some degree of enlargement with moderate to marked congestion; subcapsular hemorrhage of peripheral nodes may be seen after several days of illness. The mucosa of the urinary bladder usually appears normal but may present areas of congestion. A histologic examination of skin lesions reveals damage to the capillaries and venules, with perivascular infiltration by lymphoid cells and fibroblasts. The pathologic changes occur in the papillae and upper layers of the derma. Blood vessels of the papillae are congested and may contain microthrombi and bacteria. The papillae may also present focal necrotic areas as a result of circulatory stasis. Vascular lesions can be seen in the heart, kidney, lung, liver, nervous system, skeletal muscle, and synovial membranes. Cellular response consists predominantly of mononuclear leukocytes and macrophages. Neutrophils may appear but do not predominate. Purulent lesions are not characteristic.

Affected lymph nodes usually show acute hyperplastic lymphadenitis, with hyperemia and hemorrhage. In some nodes there may be evidence of thrombosis and necrosis of small blood vessels and capillaries. Hemorrhagic nephritis with inflammatory changes in glomeruli may be seen occasionally. In addition, necrosis of renal tubules with hyaline and granular casts has been reported. Focal accumulations of mononuclear cells may be seen in subcapsular sinuses of the adrenal cortex. Lesions of skeletal muscle may occur, associated with vascular lesions. These consist of a segmented hyaline and granular necrosis of muscle fibers, which may be followed by fibrosis, calcification, and regeneration. Lesions of the CNS have been described, consisting of angiopathies with disturbances in permeability,

degeneration of neurons, swelling of endothelial cells, and malacic foci in the cerebrum, brain stem, and spinal cord.

Leukocytosis may occur in field cases of SE that last for several days or possibly from mixed bacterial infection, but in uncomplicated acute SE a leukopenia accompanied by a relative lymphocytosis is characteristic during the first 3–5 days. There may be a relative increase in the number of eosinophils. Hemoglobin and hematocrit values decrease during acute disease, followed later by the appearance of nucleated erythrocytes. The sedimentation rate increases. Changes during acute SE include a decrease in glucose and increases in glutamic oxaloacetic transaminase activity, blood creatinine, and blood urea nitrogen.

The predominant lesion of chronic SE is a proliferative, nonsuppurative arthritis, occurring most commonly in hock, stifle, elbow, and carpal joints with occasional spondylitis. Vegetative proliferation on heart valves is less common. Animals affected with chronic arthritis have an enlargement of one or more joints, most readily visible in hock and carpal joints. The joint capsule is thickened with fibrous connective tissue. The joint cavity contains an excessive amount of serosanguinous synovial fluid, which may be slightly cloudy, indicating a small amount of purulent material. The presence of frank pus, however, is not characteristic of the lesion. The synovial membrane presents varying degrees of hyperemia and proliferation (Figure 37.3), which gives the tissue a swollen, somewhat granular appearance, and often takes irregular forms, producing fringes ("tags") that project into the joint cavity. These fringes may be caught between the articulating surfaces and produce severe pain. The proliferating tissue also may extend across the surface of articular cartilage, forming a pannus that leads to destruction of the articular surface and eventually to fibrosis and ankylosis of the joint. Lymph nodes associated with arthritic joints are usually enlarged and edematous. Vegetative endocarditis consists of proliferative granular growths on the

37.3. *Synovitis and arthritis of chronic SE in a hock joint 8 weeks after exposure to* E. rhusiopathiae. *Note hyperemia and proliferation of synovial tissue. (Courtesy National Animal Disease Center, Ames, Iowa.)*

heart valves and may be accompanied by lesions resulting from cardiac insufficiency. Other internal organs may show chronic inflammatory changes such as infarcts of kidneys and spleen. Enlargement of the adrenal gland has been reported.

Lesions of the synovial tissue may vary in severity, from slight perivascular accumulation of mononuclear cells to an extensive proliferative process. The typical synovial lesion in chronic SE is characterized by pronounced hyperplasia of the synovial intima and subintimal connective tissue, with vascularization and accumulation of lymphoid cells and macrophages, forming a villous pad of inflammatory tissue. Deposition and organization of fibrin may be seen. As the lesion progresses, proliferation of fibrous connective tissue becomes more prominent, and long fronds of hyperplastic synovium may be seen. The surface lining may become necrotic, with deposition of a fibrinous to fibrinopurulent exudate. Some tendency to follicle formation may be evident in the heavy accumulations of lymphoid cells. There may be erosion of the articular cartilages along with periostitis and osteitis. In old lesions ankylosis of the involved joint by fibrous adhesion may be accompanied by calcification. Vegetative growths on the heart valves are composed of granulation tissue and superimposed masses of fibrin. Connective tissue proliferation occurs with additional fibrin formation, which can be the source of emboli.

DIAGNOSIS

Clinical and bacteriologic examinations are useful to diagnose acute SE, which often cannot readily be differentiated clinically from other septicemic diseases (Miniats et al. 1989). Nevertheless, certain clinical features of an outbreak in a herd are more characteristic of SE than of other diseases if viewed in combination. For example, the following are presumptive of SE: a history of a few sudden deaths with no prior evidence of illness; several others sick with high temperatures and apparent stiffness in legs; reluctance of sick pigs to move but unexpected vitality when aroused; and clear, alert eyes. Other characteristic signs include a fair appetite in some visibly sick animals; normal to dry feces; death or recovery of sick animals within a few days; and, when present, the characteristic rhomboid skin lesions. Marked improvement within 24 hours after treatment with penicillin supports the diagnosis. At necropsy the presence of an enlarged spleen is suggestive.

Isolation of *E. rhusiopathiae* from the acutely affected animal provides a definitive laboratory diagnosis of SE. Hemoculture is a useful diagnostic aid in living animals, but specimens should be taken from several affected animals in the herd, because the presence of the organism in the blood may vary. At necropsy of a pig that has died in the acute phase, the organism is easily cultured from a variety of body organs (heart, lungs, liver, spleen, kid-

neys, joints). If the illness has persisted for several days, however, the organism often can no longer be cultured from internal organs but may still be found in the joints. Under these conditions it is important to take several specimens of fluid and synovial tissue from as many synovial sacs of a joint as possible, because the organisms may be present in small numbers and limited to certain areas.

Culture of *E. rhusiopathiae* from tissue specimens is relatively simple. In addition to use of blood agar, selective culture methods for isolation of the organism from contaminated specimens are described elsewhere (Cottral 1978). The use of immunofluorescence for rapid identification of *E. rhusiopathiae* has been reported; however, the method is not in widespread use for routine diagnostic purposes (Harrington et al. 1974).

A variety of serologic tests have been used in attempts to diagnose SE. These include plate, tube, and microtitration agglutination; passive hemagglutination; hemagglutination inhibition; complement fixation; enzyme-linked immunosorbent assay (ELISA); and indirect immunofluorescence. An agglutination test involving the use of growing culture as antigen was developed by Wellmann (1955). Most recently, a serological assay using nitrocellulose impregnated with a 65 kDa antigen has been developed (Chin et al. 1992). No serologic test has proved useful for routine diagnosis of acute infection or to determine immune status but may have some value in detection of chronic infection, primarily on a herd basis. Microtitration agglutination, growth agglutination, and ELISA are probably the most reliable for this purpose. It can be concluded that serologic testing has limited practical application in clinical diagnosis of SE in the field. The chief value of serologic procedures resides in research. Polymerase chain reaction (PCR) methods have improved the detection of *E. rhusiopathiae* in clinical and environmental samples. The use of these techniques for routine diagnosis is growing.

TREATMENT

The treatment of SE with hyperimmune serum, usually obtained from horses, was introduced in 1899, several years after it had been developed for use in conjunction with live-culture vaccination. Until the introduction of antibiotics nearly 50 years later, the administration of antiserum was the only effective treatment available. Polyclonal and monoclonal antiserum directed against protective antigens have been shown to protect animals from challenge with virulent strains of *E. rhusiopathiae* if administered early.

It is generally accepted that the treatment of choice for acute erysipelas is administration of penicillin; treatment early in an acute outbreak usually results in dramatic response within 24–36 hours. Specific treatment regimens generally involve giving penicillin alone or in combination with other antibiotics or anti-

serum (occasionally both) to provide a longer action. For example, long-acting penicillin (available under various proprietary names), consisting of a combination of 150,000 units procaine penicillin G and 150,000 units benzathine penicillin G/cm^3, may be given intramuscularly at a single dose of 5000–10,000 units/pound (454 g) to visibly sick pigs. The entire herd may be treated with tetracycline in the drinking water: 500 mg/gallon, 132 mg/l until 5 days after no sick pigs are observed or given antiserum if the outbreak is very severe. As an alternative, long-acting penicillin may be given in severe outbreaks, and procaine penicillin G in less severe cases. The use of antiserum for treatment of suckling pigs is a fairly common practice. Although penicillin has been consistently found to be the most effective antibiotic for treatment of acute SE, satisfactory results have been reported also with tetracyclines (including chlortetracycline and oxytetracycline), lincomycin, and tylosin. The organism is sensitive in vitro to erythromycin, but this antibiotic has been reported to be relatively ineffective in vivo. Streptomycin, dihydrostreptomycin, chloramphenicol, bacitracin, polymyxin B, neomycin, and sulfonamides are not effective against SE. Some isolates of the organism from swine have been found to be resistant to tetracyclines. There is no practical treatment for chronic SE. Experimentally, the administration of antiinflammatory agents has provided some alleviation of the effects of chronic arthritis, and they may be used in treatment of especially valuable individual animals. Initiation of a vaccination program in herds where outbreaks occur is strongly recommended.

PREVENTION

Prevention of SE is best accomplished by sound practices of herd health management, including a program of immunization. Swine should be raised according to sound husbandry practice relative to nutrition, housing, and condition of lots and pastures, and they should be observed regularly for deviations from their usual attitude. Replacements should be obtained from clean sources. The recent introduction of a new boar is a relatively common historical finding preceding acute outbreaks of SE in a herd. Newly purchased animals should be isolated for at least 30 days. It is advisable to eliminate chronically affected swine from the herd, as they can remain carriers of the organism indefinitely. Good sanitation is important in general herd management and is essential following the cessation of an outbreak. Walls and floors should be cleaned and disinfected. Phenolic, alkali, hypochlorite, or quaternary ammonium disinfectants are effective against the organism but must be applied to clean surfaces.

A variety of veterinary biologics developed for the purpose of inducing immunity to SE are licensed for use in the U.S. Active immunization can be induced using either live attenuated vaccines or killed bacterins. Bacterins are inactivated whole-cell or subunit preparations and have been used in the U.S. since 1953. Many licensed bacterins are made from selected strains of serovar 2 that produce a soluble immunogenic product when grown in a complex liquid medium containing serum. This substance, most of which is released into the medium, has been described as a glyco-lipoprotein (White and Verwey 1970). The most active component of the immunogenic substance has been identified as a protein fraction with a molecular weight of 64–66 kDa (Timoney and Groschup 1993; Sato et al. 1995; Goodman 1996; Zarkasie et al. 1996). The properties of the 64–66 kDa immunogenic substance have been the subject of a number of studies. A monoclonal antibody recognizing the 64–66 kDa (and a 43 kDa degradation product) immunogen was developed in 1992 and shown to provide passive protection to mice and swine challenged with virulent *E. rhusiopathiae* (Henderson et al. 1993b). An affinity purified protein, shown to be 99% pure by HPLC, that was derived using the monoclonal antibody was also shown to protect pigs from challenge. The 64 kDa immunogen has since been identified as Spa A.1, a cell surface protein, and the protective immunogenic region has been shown to reside within the N-terminal two-thirds of the SpaA.1. region (Shimoji et al. 1999).

Conventionally attenuated live vaccines, developed by passage through rabbits or chicken embryos, by air-drying, or by growth in media containing acridine dyes resulting in low virulence for swine, were first licensed in the U.S. in 1955. They stimulate immunity in swine by limited multiplication in the body, with very few or no clinical disease. Passive protection or antiserum given concomitantly may interfere with development of immunity following vaccination. Manufacturers generally do not recommend use of serum with their attenuated products except when immediate protection is necessary, as in the case of suckling pigs being given both vaccine and serum during a herd outbreak. In this case, repeated vaccination at weaning is recommended. Treatment with antibiotics that affect replication of *E. rhusiopathiae* should be discontinued at least 8–10 days before vaccination with attenuated vaccines. Attenuated vaccines are usually given by injection or administered orally in drinking water. In some parts of Europe and the former Soviet Union, vaccination by aerosol has been practiced. Acapsular mutants of *E. rhusiopathiae* may be useful for the development of live vaccines (Shimoji et al. 1998).

Lysate bacterin, first reported in 1953, has been used in the U.S. since 1955. It is similar to whole-culture bacterin except that the bacterial cells have been lysed. Bacterins are given by subcutaneous or intramuscular injection; a second (booster) injection in 3–5 weeks is generally recommended. Some studies have demonstrated that the immunity induced by bacterins may not

protect animals for sufficient periods of time to reach market weight from challenge (Henderson et al. 1992). Subsequently, some manufacturers have demonstrated longer duration of immunity for their bacterins; this information is available on the label of the product. An enzyme-linked immunosorbent assay (ELISA) has been developed for use in potency testing of bacterins. The assay uses a monoclonal antibody to the protective 64–66 kDa protein and reduces the use of animals in testing bacterin potency (Henderson et al. 1993b). An alternative ELISA has been developed for detection of a protective antibody response in mice to replace the mouse challenge model for potency testing of erysipelas bacterins (Imada 2003).

Temporary passive immunity can be induced by administration of commercially available polyclonal antiserum as well as monoclonal antibody to the 64–66 kDa protein fraction. Pigs given antiserum by subcutaneous or intravenous administration receive immediate passive protection, which persists for about 2 weeks. Antiserum may be useful during a herd outbreak for temporary protection of suckling pigs until they are old enough to be vaccinated.

The mechanism of immunity to *E. rhusiopathiae* infection is not clearly defined, but serologic responses play a key role in immunity. Studies have shown that virulent *E. rhusiopathiae* bacteria opsonized with immune serum were readily eliminated by polymorphonuclear leukocytes (Sawada et al. 1988) and by macrophages (Shimoji et al. 1996). Nonopsonized virulent organisms were resistant to phagocytosis. Immunity induced by vaccination may not always prevent chronic SE. Many investigators agree that vaccination has little effect on the incidence of arthritis caused by *E. rhusiopathiae*, although this observation is difficult to evaluate in the field, since SE vaccination is not universally practiced in the U.S. Some believe vaccination actually causes an increase in arthritic lesions by initiating a state of hypersensitivity to subsequent contact with the organism. An alternative explanation for the failure of vaccination to prevent arthritis may exist, however. The organism may be carried to synovial tissues by loaded macrophages soon after exposure, thereby escaping the opsonic effects of humoral immunity (Drommer et al. 1970). Sequestration of the bacteria in chondrocytes (Franz et al. 1995) might provide similar protection from immune mechanisms. It is possible that certain uncommon serovars of *E. rhusiopathiae* may be refractory to the immunity induced in swine by standard SE vaccines. However, such serovars are usually isolated from healthy carrier pigs or nonporcine sources, and none have been directly associated with cases of acute SE in the field.

Vaccination provides a worthwhile means of control when used with other good management practices. A regular vaccination program for both breeding and market animals is recommended. Because of the ubiquity of *E. rhusiopathiae*, together with its poorly understood ability to exist in nature, the possibility of eradication of the organism seems remote.

38 *Escherichia coli* Infections

John M. Fairbrother and Carlton L. Gyles

Introduction

J. M. Fairbrother

The genus *Escherichia* is named after the German pediatrician Theodor Escherich (1857–1911). It is classified with the family *Enterobacteriaceae*, which belongs to the gram-negative facultatively anaerobic rods. The species *Escherichia* (*E.*) *coli* includes normal inhabitants of the gastrointestinal tract and strains causing a broad variety of intestinal and extraintestinal diseases in swine.

BACTERIOLOGY

E. coli are gram-negative, peritrichous flagellated rods of variable length and with a diameter of about 1 μm. Colonies on solid media reach their full size within 1 day of incubation. Their appearance may vary from smooth to rough or mucoid. A wide range of selective media is available for growth of *E. coli*. Some strains produce hemolysins. Species identification relies mainly on biochemical characters, bearing in mind that there are exceptions with every single biochemical character. Commercially available identification kits therefore make use of up to 50 characters to achieve a high level of accuracy. The interpretation may be facilitated by computer-assisted processing of the data. The determination of DNA relatedness, the scientific base of discrimination between species, is restricted to research laboratories.

SEROTYPING

There are several ways to subdivide the species into types. So far, serotypes have shown the best association with certain virulence traits. Complete serotyping includes determination of O (somatic), K (capsular or microcapsular), H (flagellar), and F (fimbrial) antigens. Unlike salmonellae, only a small percentage of *E. coli* isolates are typeable with available antisera, since sero-

typing has been limited to isolates of proven or suspected pathogenicity. Presently, at least 175 O, 80 K, 56 H, and over 20 F antigens are officially recognized.

In diagnostic laboratories serotyping is often reduced to one or two classes of antigens and to a limited spectrum of antisera. This may be quite suitable, since in a given region, animal species, and organ, pathogenic serotypes maintain their characteristic antigenic makeup. Thus one may deduce the complete serotype from a simple slide agglutination with a living culture. Serotyping is diagnostically helpful in communicable types of disease caused by a limited number of serotypes, such as postweaning *E. coli* diarrhea and edema disease.

VIRULENCE FACTORS

Bacterial traits involved in pathogenesis are called virulence factors. The nomenclature for pathogenic *E. coli* has evolved over the last few years. The term "pathotype" is now used to identify types of *E. coli* on the basis of their virulence mechanism, as indicated by the presence of virulence factors that characterize the method by which disease is caused. This system identifies broad classes of pathogenic *E. coli*, such as enterotoxigenic *E. coli* (ETEC), edema disease *E. coli* (EDEC), and attaching and effacing *E. coli* (AEEC) and these classes are referred to as pathotypes (Gyles and Fairbrother 2004). Potent exotoxins trigger the secretion of fluid into the gut lumen in ETEC infections and are responsible for systemic pathology caused by EDEC strains. Endotoxin is present in the outer membrane of most *E. coli* strains. Its significance is well documented only in extraintestinal infections, such as septicemia, mastitis, and urinary tract infections.

Many *E. coli* infections require the colonization of

mucous membranes. With ETEC and EDEC, adhesion to the small intestine is mediated by extracellular proteinaceous appendages, which are called fimbriae, fimbrial adhesins (F antigens), or pili and are highly host-specific. In some strains capsular polysaccharide has been shown to enhance the ability to colonize. AEEC colonizing the lower gastrointestinal tract adhere by an attaching and effacing mechanism. In the pig, colonization of the urinary tract has received little attention to date.

In extraintestinal sites, *E. coli* have to resist the natural bactericidal activity of serum, a characteristic called serum resistance. Some *E. coli* utilize high-affinity iron-uptake systems to compete with the host for available iron. A given pathogenic strain may exhibit a whole set of virulence factors, that is, more than one toxin and even more than three adhesins. Detection of more virulence factors can be expected.

GENETICS OF VIRULENCE

Very specific sets of virulence factors are needed to cause a particular disease. Thus, strains causing enteric diseases are usually not associated with extraintestinal infections and vice versa. Detection of virulence factors is important for the identification of pathogenic *E. coli* and the term virotype is now used to refer to the combination of these factors for a particular isolate. Many virulence factors examined so far are plasmid determined. This applies in particular to hemolysins, toxins, and adhesins of ETEC. In strains from most extraintestinal infections, however, the genes encoding for fimbriae, cytotoxins, and hemolysin are chromosomally located. In the laboratory, plasmids can easily be transmitted from donor to recipient strains. However, such exchanges of genetic material do not appear to play a major role in the field. The genetic makeup of pathogenic *E. coli* strains is remarkably stable. This may be because a whole set of virulence factors is involved in the virulence of a particular strain, and certain recipient strains may not express transmitted plasmid-determined functions. The clinically important development of antimicrobial resistance is an exception to this observation.

The time-consuming and sometimes cumbersome assays for detection of virulence factors are increasingly being replaced by hybridization and polymerase chain reaction (PCR) techniques for the detection of the genes encoding these factors.

ECOLOGY

The particular ecology of pathogenic *E. coli* strains has been somewhat neglected. Intestinal infections caused by ETEC and EDEC are often contagious. The same strain is usually found in many sick pigs and often in consecutive batches of pigs. When edema disease spread through Denmark, 63% of the outbreaks were connected by trade of pigs to one single infected breeding herd (Jorsal et al. 1996). On the other hand, clinical edema disease occurred in no more than 5% of the herds with trading contacts. These strains may sometimes appear in healthy pigs without overt disease. They are usually shed in high numbers for only a few days. The ensuing dramatic decrease seems to be due to the development of local immunity.

Extraintestinal infections, however, do not behave like communicable diseases. Individual pigs in a given herd are affected most often by different strains. Mixed infections by more than one strain are frequent. In humans, the fecal flora is obviously the reservoir of such pathogenic strains. Most extraintestinal infections in the pig are also endogenous. For example, in 18 out of 67 sows with mastitis, *E. coli* of the same O types present in samples of mammary secretion were isolated from the feces (Awad-Masalmeh et al. 1990).

The primary habitat of *E. coli* in the pig is the gastrointestinal tract. The *E. coli* flora of individual pigs is extremely complex. When strains were distinguished by the combined application of O serogrouping, biotyping, and resistance pattern, up to 25 strains were identified in the gastrointestinal tract of one individual (Hinton et al. 1985). Numerically dominant strains change at intervals from 1 day to several weeks, leading to successive waves of dominant strains (Katouli et al. 1995). Proliferation of *E. coli* takes place mainly during the passage through the small intestine. Subsequent increases in bacterial numbers from the ileum to the rectum is minimal or absent (McAllister et al. 1979). Numbers in the large intestine fluctuate around 107 colony-forming units/g. However, *E. coli* contribute less than 1% to the total bacterial count. When found elsewhere (feed, water, soil, etc.), *E. coli* are derived from this habitat, usually by fecal contamination. Long survival times in the environment are promoted by low temperature and sufficient available water, among other factors. In an experiment with five slurry samples, a porcine *E. coli* O139:K82(B) strain remained viable for between 5 and more than 11 weeks (Burrows and Rankin 1970).

Neonatal *Escherichia coli* Diarrhea

J. M. Fairbrother

Diarrhea has become an economically important disease in pigs as a result of increasing intensification of farrowing management. It may be classified into three main entities: neonatal diarrhea (within the first few days of birth), young piglet diarrhea (from the first week of birth to weaning), and postweaning diarrhea. *Escherichia coli* is the most important etiologic agent of neonatal and postweaning diarrhea. Etiologic agents of diarrhea in young piglets are more numerous and include transmissible gastroenteritis virus, rotavirus, coccidia, and *E. coli* (Biehl and Hoefling 1986). A less frequently encountered manifestation of enteric *E. coli* infection is an acute shock syndrome which provokes gross lesions of hemorrhagic gastroenteritis. Neonatal diarrhea in pigs has been reviewed by Alexander (1994).

ETIOLOGY

Neonatal diarrhea associated with *E. coli* is observed most commonly in pigs aged from 0–4 days. Causative strains produce one or more enterotoxins and are referred to as ETEC. ETEC adhere to the small intestinal mucosa in neonatal pigs by means of one or more of the fimbrial adhesins F4 (K88), F5 (K99), F6 (987P), or F41 (Table 38.1). They may also produce an adhesin involved in diffuse adherence (AIDA). They colonize the small intestine and produce one or more of the enterotoxins STa (STI), STb (STII), EAST1, or LT. Until recently, the most commonly observed ETEC in cases of neonatal diarrhea belonged to the classic serogroups O149, O8, O147, and O157, were F4-positive, and produced the enterotoxins LT and STb (Harel et al. 1991; Soderlind et al. 1988; Wilson and Francis 1986). An increasing number of ETEC of serogroups such as O8, O9, O64, and O101 which are F5-, F6-, and/or F41-positive and mainly produce the enterotoxin STa, or less often STb, are now being isolated. These ETEC cause diarrhea mainly in pigs aged from 0–6 days, and to a lesser extent in older pigs, whereas F4-positive ETEC may be isolated in diarrheic pigs from birth to the postweaning period. F4-positive ETEC now predominantly belong to the serogroup O149, also the main cause of postweaning diarrhea.

Table 38.1. Predominant *E. coli* pathotypes, virotypes, and O serogroups associated with neonatal diarrhea

Pathotype	Virotypes	O Serogroups
ETEC	STa:F5:F41, STa:F41, STa:F6, LT:STb:EAST1:F4, LT:STb:STa:EAST1:F4, STb:EAST1:AIDA	8,9,20,45,64, 101,138,141, 147,149,157

Source: The *Escherichia coli* Laboratory, Université de Montréal.

Enteric colibacillosis complicated with shock also occurs in young pigs before and after weaning. *E. coli* associated with this disease either (1) are ETEC and commonly belong to serogroups O149, O157, and O8, which are F4-positive, produce STb and LT, but only occasionally produce Shiga toxin (Stx2e) (Faubert and Drolet 1992), or (2) produce Stx2e and are associated with edema disease. The latter will be discussed in a later section.

EPIDEMIOLOGY

The occurrence of *E. coli* diarrhea depends on an interaction between the causative bacteria, environmental conditions, and certain host factors. Only *E. coli* that carry virulence factors as described in the previous section and that are ingested in large numbers are able to cause diarrhea. The newborn pig, on leaving the uterus and before reaching the teats of the sow, encounters the heavily contaminated environment of the farrowing crate and the skin of the dam, resulting in ingestion of microbes from the intestinal flora of the sow. Thus, in conditions of poor hygiene or in a continuous-farrowing system, a buildup of pathogenic *E. coli* in the environment could lead to an outbreak of neonatal *E. coli* diarrhea. The colostrum contains nonspecific bactericidal factors and specific antibody (IgG and IgA) that inhibit the adherence of pathogenic *E. coli* in the intestine. If the dam has not been exposed to the pathogenic *E. coli* present in the environment of the piglets, specific antibodies are not present in the colostrum, and the

piglets are susceptible to infection. Similarly, when individual piglets do not have access to colostrum, due to injury or inability to compete or due to agalactia or insufficient teats of the sow, they are more susceptible to infection. Ambient temperature in the farrowing house is also very important. In pigs kept at temperatures of less than 25°C, intestinal peristaltic activity is greatly reduced, and passage of bacteria and protective antibodies through the intestine is delayed (Sarmiento 1983). Increased numbers of pathogenic *E. coli* in the intestinal tract of these pigs result in a more severe diarrhea than in pigs kept at 30°C.

PATHOGENESIS

In the presence of the appropriate predisposing environmental conditions and host factors, pathogenic *E. coli* proliferate in the intestine and cause diarrhea by means of specific virulence factors. Pathogenesis will be discussed with respect to the *E. coli* pathotypes defined by the production of these factors.

Enterotoxigenic *E. coli*

Most pathogenic *E. coli* produce one or more fimbrial adhesins that mediate their attachment to specific receptors on mucosal epithelial cells and in the adjacent mucous layer. These fimbriae (or pili) are hairlike appendages extending from the bacterial cell and consist of structural protein subunits that, in many cases, act as a support for a separate adhesive protein found at the tips of the fimbriae. Fimbriae are classified by serologic reactivity or by receptor specificity, the latter being manifested by agglutination of red blood cells from different animal species. The nomenclature for fimbriae has been very diverse. For example, the first fimbrial adhesins demonstrated on porcine ETEC were thought to be capsular antigens and were named K88 and K99. A more standardized nomenclature based on serologic activity in crossed immunoelectrophoresis and using an F designation has been proposed (Orskov and Orskov 1983) and is now widely accepted. Hence, K88 and K99 are now called F4 and F5, respectively. The latter nomenclature will be used in this chapter.

Although an increasing number of fimbrial adhesins have been described (more than 30), most fimbrial adhesins, with the exception of F1 (type 1) common fimbriae, are associated with *E. coli* of particular serogroups isolated from specific animal species. F1 fimbriae are found on most *E. coli* isolates and cause an agglutination of guinea pig red cells which is inhibited by D-mannose. Their role in attachment of porcine ETEC to the intestinal mucosa is still unclear (Jayappa et al. 1985; To et al. 1984).

F1 has been found in the absence of any other known fimbrial adhesins on certain diarrheagenic ETEC strains (Broes et al. 1988). The four important fimbrial adhesins of neonatal porcine ETEC are F4 (K88), F5 (K99), F6

(987P), and F41. F4 (K88) fimbriae have been divided into three variants, F4ab, F4ac, and F4ad, based on serologic cross-reactions (Guinée and Jansen 1979). Many ETEC isolates produce more than one fimbrial adhesin, and common combinations are F5 and F6, F5 and F41, and F4 and F6. Production of fimbriae is controlled by genes on the bacterial chromosome (F1, F41) or on plasmids (F4, F5, F6). Many fimbriae, such as F1 and F6, undergo phase variation and may be very poorly expressed after several passages in culture conditions. Other fimbriae (F5 and F41) undergo quantitative variation and are only well expressed in culture media low in glucose or alanine, such as Minca medium (Guinée et al. 1977).

The adhesin involved in diffuse adherence (AIDA), an autotransported 100-kDa mature protein, was originally detected in *E coli* isolates from humans with diarrhea, and has been detected recently in *E. coli* strains from pigs with diarrhea (Mainil et al. 2002; Niewerth et al. 2001). ETEC isolates of the STb or STb:EAST-1 virotypes from neonatal or weaned pigs may be AIDA-positive and induce diarrhea in neonatal pigs (Ngeleka et al. 2003).

Fimbriae adhere to specific receptors on the cell membrane of intestinal epithelial cells and to specific receptors or nonspecifically in the mucus coating the epithelium. ETEC producing fimbriae F5, F6, and F41 mostly colonize the posterior jejunum and ileum, whereas F4-positive ETEC tend to colonize the length of the jejunum and the ileum. Certain pigs do not have receptors for the F4 adhesin on intestinal epithelial cells and are thus resistant to infection by F4-positive ETEC (Sellwood et al. 1975). This genetic resistance to infection is inherited in a simple Mendelian way, and the allele for the receptor is dominant. Subsequent studies have demonstrated at least five pig phenotypes, based on susceptibility of brush borders of different pigs to adherence of isolates producing the different variants F4ab, F4ac, and F4ad (Bijlsma et al. 1982; Hu et al. 1993). The loci encoding porcine intestinal receptors for F4ab and F4ac are closely linked on chromosome 13 (Edfors-Lilja et al. 1995). A similar genetic resistance has not been observed for the other fimbriae of neonatal porcine ETEC. On the other hand, there appears to be an age resistance to infection by F5-and F6-positive isolates, which is not observed for F4-positive isolates. Piglets are most susceptible to infection with F5- and F6-positive ETEC during the first several days of life and subsequently become more resistant. This susceptibility could be related to a reduction of the number of receptors present on intestinal epithelial cells with age in the case of F5 (Runnels et al. 1980). F6-mediated intestinal colonization in older pigs is thought to be inhibited by preferential binding of bacteria to F6 receptors present in the mucus rather than to those on the intestinal epithelium (Dean-Nystrom and Samuel 1994).

ETEC adhering to the intestinal mucosa produce enterotoxins that change the water and electrolyte flux of

the small intestine and may lead to diarrhea if the excess fluid from the small intestine is not absorbed in the large intestine. Two major classes of enterotoxin are produced by porcine ETEC: heat-stable toxin (ST), which is resistant to heat treatment at 100°C for 15 minutes, and heat-labile toxin (LT), which is inactivated at 60°C for 15 minutes (Guerrant et al. 1985). ST has been further divided into STa and STb based on solubility in methanol and biological activity (Burgess et al. 1978). The gene for EAST1, which is related to STa, has been recently reported in ETEC isolates from pigs. The *E. coli* enterotoxins have been reviewed in detail elsewhere (Gyles and Fairbrother 2004).

LT is a high–molecular-weight toxin complex that consists of five B subunits able to bind to ganglioside receptors on the intestinal epithelial cell surface and a biologically active A subunit (Gill et al. 1981). After binding, the latter activates adenylate cyclase, which stimulates the production of cyclic AMP. High levels of cyclic AMP in the cell result in increased secretion of Cl, Na, HCO_3, and water into the intestinal lumen. Excessive secretion will lead to dehydration, metabolic acidosis, and eventually death. Two subgroups of LT, LTI and LTII, have been described (Holmes et al. 1986). Only LTI is neutralized by anticholera toxin. LT produced by porcine isolates belongs to the LTI subgroup. The LT produced by human and porcine ETEC has been designated LTh and LTp, respectively, based on slight differences in the genes coding for the toxin.

STa (STI, ST1, and ST mouse) is a small, nonimmunogenic protein with a molecular weight (MW) of 2000 (Lallier et al. 1982). STa binds to a guanylyl cyclase intestinal epithelial receptor (De-Sauvage et al. 1991) and activates guanylate cyclase, which stimulates production of cyclic GMP. High levels of cyclic GMP in the cell inhibit the Na/Cl cotransport system and reduce the absorption of electrolytes and water from the intestine (Dreyfus et al. 1984). STa is active in infant mice and young piglets of less than 2 weeks of age but is less active in older pigs. This could be due to differences in the concentration of intestinal receptors with age (Cohen et al. 1988). As with LT, STa produced by human and porcine ETEC has been designated STah and STap, respectively, based on differences in the genes coding for the toxin.

STb (STII, ST2, ST pig) is a small, 5000 MW protein that is antigenically and genetically unrelated to STa and is poorly immunogenic (Dubreuil 1997). STb stimulates cyclic-nucleotide-independent fluid secretion in the gut (Kennedy et al. 1984), which is independent of the cyclic nucleotides but appears to be mediated by prostaglandin E_2 and possibly other secretagogues (Harville and Dreyfus 1995; Peterson and Whipp 1995). STb is inactivated by trypsin and, in the presence of trypsin-inactivator, is active in intestines of mice, rats, and calves (Whipp 1990). STb is found in 74% of all porcine ETEC isolates (Moon et al. 1986). The role of STb in the development of diarrhea has been questioned (Casey et al. 1998), although ETEC producing only STb can induce diarrhea in experimentally infected newborn pigs (Fairbrother et al. 1989), and STb induces some villous atrophy in pig intestinal gut loops (Rose et al. 1987).

EAST1 was first identified in enteroaggregative *E. coli* isolated from humans and was subsequently reported in ETEC from pigs with diarrhea (Yamamoto and Nakazawa 1997). It is commonly found in F4-positive ETEC strains from pigs with diarrhea and in F18:Stx2e strains from pigs with edema disease (Choi et al. 2001). EAST1 is a 38 amino acid peptide of 4100 Da that is different from STa and STb, although it shares 50% homology with the enterotoxic domain of STa (Savarino et al. 1993) and appears to interact with the STa receptor guanylate cyclase C to elicit an increase in cGMP. Hence, the mechanism of action of EAST1 is proposed to be identical to that of STa. However, the role of EAST1 in the development of diarrhea has not yet been defined.

Attaching and Effacing *E. coli*

Porcine AEEC attach to the intestinal mucosa and cause lesions similar to those observed for enteropathogenic *E. coli* (EPEC) isolated from human infantile diarrhea (Hélie et al. 1990). They attach intimately to the intestinal epithelial cell membrane by means of a bacterial outer-membrane protein termed "intimin" or "EPEC attaching and effacing factor" (Eae), efface the microvilli, and invade the epithelial cells (Zhu et al. 1994).

CLINICAL SIGNS

Enteric *E. coli* infection is usually manifested by diarrhea, the severity of which depends on the virulence factors of the *E. coli* and the age and immune status of the piglets. In severe cases, clinical signs of dehydration, metabolic acidosis, and death are observed. In certain cases, particularly in young animals, the infection may be so rapid that death occurs before the development of diarrhea.

Neonatal diarrhea may first be observed 2–3 hours after birth and may affect single pigs or whole litters. Gilt litters are more often affected than sow litters. A large number of piglets in a farrowing house may be affected and mortality may be very high in the first few days of life. Diarrhea may be very mild with no evidence of dehydration or may be clear and watery. The feces vary in color from clear to whitish or various shades of brown. The fecal material may just dribble from the anus down the perineum and be detected only by close examination of the perineal area. In very severe outbreaks, a small proportion of affected animals may vomit. In severe cases, 30–40% of total body weight may be lost as fluid into the intestinal lumen and result in signs of dehydration. The abdominal musculature is flaccid and atonic, the pigs are depressed and sluggish, the eyes may be sunken, and the skin may be bluish-gray

in color and resemble parchment in texture. The loss of fluid and weight results in the exaggerated appearance of the bony prominences. These animals usually die. In more chronic or less severely affected cases, the anus and perineum may be inflamed from contact with the alkaline fecal material. Pigs with less severe dehydration may continue to drink and, if treated appropriately, may recover with only minimal long-term effects.

Diarrhea in pigs from the neonatal to the postweaning period is similar to that observed in neonatal piglets but tends to be less severe. Morbidity may be the same as in the neonatal period but mortality is invariably lower. The feces vary from grayish to whitish in unweaned piglets to brownish in recently weaned piglets. Enteric colibacillosis complicated by shock, when associated with ETEC strains, occurs both in unweaned pigs from a few days of age and in recently weaned pigs (Faubert and Drolet 1992). Apparently healthy pigs die suddenly or decline rapidly with cyanosis of the extremities. A yellowish to brownish diarrhea is sometimes observed.

LESIONS

Few specific pathological changes may be attributed to enteric *E. coli* infection. Gross lesions that may be observed include dehydration, dilation of the stomach (which may contain undigested milk curd or feed in the case of postweaning diarrhea), venous infarcts on the greater curvature of the stomach, and dilation of the small intestine with some congestion of the small-intestinal wall. In cases of ETEC infection complicated by shock, characteristic lesions include marked congestion of the small-intestinal and stomach walls and blood-tinged intestinal contents.

Histologic lesions depend on the category of *E. coli* involved. In ETEC infections, layers of *E. coli* are observed adhering to the mucosal epithelial cells of most of the jejunum and ileum in the case of F4-positive ETEC isolates, and of the posterior jejunum and/or the ileum in the case of other ETEC isolates. Adhering bacteria may be found only in the crypts of Lieberkühn, or more often covering the crypts and the tips of the villi. On transmission electronmicroscopy, bacteria are usually located approximately half a bacterial width away from the microvilli, and fimbriae may sometimes be visualized between the bacteria and the microvilli (Figure 38.1). Histological lesions, if observed, may include vascular congestion in the lamina propria with some hemorrhages into the intestinal lumen, increased numbers of neutrophils and macrophages in the lamina propria and migrating into the lumen, and some villous atrophy. In cases of ETEC enteric infection complicated by shock, *E. coli* are found adhering to the mucosal epithelial cells of the small intestine. Congestion, some hemorrhages, and in severe cases villous necrosis and microvascular fibrinous thrombi are observed in the lamina propria of the stomach, small intestine, and colon.

38.1. *Electron micrograph of attachment of E. coli 987P positive strain in the intestine.*

In pigs infected with AEEC isolates, a multifocal colonization of the brush border of mature enterocytes by *E. coli* arranged in palisades with enterocyte degeneration and light to moderate inflammation of the lamina propria is observed, mostly in the ileum (Hélie et al. 1990). Colonization is most intense in the duodenum and cecum, bacteria are sometimes observed in intracytoplasmic vacuoles in enterocytes, and there is a light to moderate villous atrophy in the small intestine. On transmission electronmicroscopy, bacteria are intimately attached to the cytoplasmic membrane of mature enterocytes and arranged in regular palisades, parallel to the microvilli, with effacement of adjacent villi (Figure 38.2). The bacterial cell wall and the apical cell membrane of the enterocyte are separated by a narrow, regular gap of 10 nm at the cupping pedestal, and apical dense regions are seen at attachment sites.

DIAGNOSIS

Enteric *E. coli* infection in young, unweaned pigs must be differentiated from other common infectious causes of diarrhea in pigs of this age group. These include *Clostridium perfringens*, transmissible gastroenteritis virus, rotavirus, and coccidia. More than one etiologic agent may be associated with a particular animal or outbreak. A presumptive diagnosis may be made by determination
38.2. *Electron micrograph of AEEC lesions.*

of the fecal pH. Secretory diarrheic fluid as a result of enteric ETEC infection has an alkaline pH, whereas that from diarrhea associated with malabsorption as a result of transmissible gastroenteritis virus or rotavirus infection is acid.

Diagnosis of enteric *E. coli* infection is based on clinical signs, histopathological lesions, and the presence of gram-negative organisms usually closely adhering to the small-intestinal mucosa (Wilson and Francis 1986). This diagnosis is strengthened by the isolation of *E. coli* of the appropriate serogroup or, more important, possessing one or more of the above-mentioned virulence factors. Production of enterotoxins and cytotoxins may be ascertained by detection of toxin biological activity. STa activity is determined in the infant mouse test, STb activity in pig and rat ligated gut loops, and LT and Stx in cell culture assays. Fimbrial adhesins may be detected by serologic assays such as slide agglutination, immunofluorescence, and ELISA, using rabbit polyclonal antisera. However, F5 and F41 are only produced when *E. coli* are grown on special minimal media, and F6 is often poorly produced in in vitro conditions. Alternatively, *E. coli* adhering to the intestinal mucosa may be demonstrated directly in infected pigs by examination of frozen sections using indirect immunofluorescence or by examination of formalin-fixed, paraffin-embedded tissues using the immunoperoxidase technique.

Recent technological advances have greatly improved the detection of *E. coli* virulence factors (Wray and Woodward 1994). Use of monoclonal antibodies has led to more specific, sensitive, and reproducible assays for the detection of STa, F4, F5, F6, and F41. Such antibodies may be used in diagnostic kits for the rapid detection and identification of pathogenic *E. coli* directly in the feces or intestinal contents of affected piglets. Currently, genotypic analysis is more commonly used to define the virotypes involved in an infection. Colony hybridization probes and the multiplex polymerase chain reaction (PCR) have been developed for the detection of the genes coding for the fimbrial adhesins and enterotoxins of swine ETEC isolates (Francis 2002; Frydendahl 2002; Osek 2001; Wray and Woodward 1994). There is a high correlation between the results of the standard serologic and biological assays and those of gene probes for the detection of fimbrial adhesins and enterotoxins of swine ETEC isolates (Harel et al. 1991). Gene probe techniques often involve the use of radioactivity and thus must be performed in controlled laboratory conditions. Multiplex PCR amplification may be used to rapidly detect the genes encoding for the virulence factors of pathogenic *E. coli* associated with diarrhea in pigs, either following enrichment culture or directly in the feces or intestinal contents (Tsen et al. 1998). The latter approach is more rapid and indicates the presence of pathogenic *E. coli,* but it does not permit the identification of specific virotypes, as is possible when isolates are tested. However, the traditional approach for identification of pathogenic *E. coli* by serotyping will still be necessary, at least in reference laboratories, in order to monitor changing trends and to identify new, emerging *E. coli* virulence determinants that could gain importance due to the pressure of vaccination of sows against the currently predominant determinants.

TREATMENT

Treatment of enteric *E. coli* infection should be aimed at removal of the pathogenic *E. coli*, correction of their harmful effects, and provision of optimal environmental conditions. Therapy should be rapidly instituted to be as effective as possible. It is important to confirm the diagnosis of *E. coli* infection by culture and to perform antibiotic sensitivity tests, because antibiotic sensitivity varies greatly among *E. coli* isolates (Table 38.2). A broad-spectrum antibiotic treatment could be used initially until the results of antibiotic sensitivity are known. In vitro resistance of *E. coli* isolates to a wide range of antimicrobial agents has dramatically increased over the last several years. In newborn piglets, treatment with antibiotics may be on an individual or litter basis, by mouth or parenteral injection. Commonly used antibiotics are ampicillin, apramycin, ceftifur, gentamycin, neomycin, spectinomycin, furizoli-

Table 38.2.   Sensitivity to antimicrobial agents of *E. coli* isolates from pigs aged from 0 to 7 days with diarrhea in Quebec

Antimicrobial Agent	*n* = 38 % Sensitive Isolates
Amikacin	100
Ampicillin	46
Apramycin	79
Ceftiofur	92
Cephalothin	70
Enrofloxacin	100
Gentamycin	63
Neomycin	56
Spectinomycin	41

done, and potentiated sulfa drugs. An alternative approach to the treatment of enteric *E. coli* infection is the use of bacteriophages, an approach that has been successful experimentally but has not been extensively applied in the field.

Fluid therapy, consisting of electrolyte replacement solutions containing glucose given orally, is useful for the treatment of dehydration and acidosis. Drugs which inhibit the secretory effects of enterotoxin, such as chlorpromazine and berberine sulfate, may be useful for the treatment of diarrhea, although many of these drugs have undesirable side effects. The use of such antisecretory drugs as bencetimide and loperamide, alone or in combination with antibacterial agents, has also been suggested (Solis et al. 1993).

It is important to ensure that younger piglets are maintained at a constant temperature of 30–34°C and that recently weaned pigs are held in a draft-free environment at a constant temperature of about 29.5°C.

PREVENTION

A program for prevention of enteric *E. coli* infection should be aimed at reduction of numbers of pathogenic *E. coli* in the environment by good hygiene, maintenance of suitable environmental conditions, and provision of a high level of immunity. Because most pathogenic *E. coli* belong to a limited number of serogroups, enteric *E. coli* infection could be eliminated from some herds.

Husbandry

One of the most important factors in prevention of enteric *E. coli* infection is the maintenance of piglets at an adequate environmental temperature (30–34°C for unweaned pigs), free of drafts, and on a low–heat-conducting floor. This is particularly true for piglets of below-average weight, who lose heat more rapidly because they have a greater skin surface area per unit body weight.

Good hygiene in the farrowing area leads to a reduction in the numbers of *E. coli* being presented to the piglet to a level that it is able to control through its own defense mechanisms.

Farrowing-crate design is important because it affects the position at which feces are deposited by the sow. In crates that are too long, the feces are deposited over a large area of the available floor space, thereby increasing the heavily contaminated area. Ideally, the crate should be adjustable, allowing for a shorter crate for gilts than for sows. Crates on raised, perforated floors allow fecal material to drop through and away from the piglets, and litters farrowed onto such floors have a noticeably lower incidence of diarrhea than those on solid concrete floors.

A dry, warm environment reduces the moisture available to enhance the survival of *E. coli*. This is largely affected by ventilation rates, although if room temperature is too high, sows tend to try and spread water over their lying area to cool themselves, thereby defeating other hygienic procedures. The sow should be at a temperature of approximately 22°C, necessitating a warmer creep area for the piglets.

Quarantine should be used to control the introduction of different *E. coli* virotypes or other infectious agents into the herd. Animals in the herd will have little immunity to *E. coli* fimbrial antigens with which they have not had contact. Farrowing crates should be thoroughly cleaned and disinfected between litters. An all-in/all-out farrowing system with thorough disinfection of the farrowing room between batches will reduce the *E. coli* population in the environment.

Diet may be modified in order to reduce colonization of the intestine by *E. coli* (Thomlinson and Lawrence 1981). Feeding of cultures of *Streptococcus faecium* to young pigs may reduce the incidence of diarrhea (Morkoc et al. 1984).

Immunity

Immunity to enteric *E. coli* infections is humoral and is initially provided through the maternal colostrum, lactogenic antibodies in the milk of the sow, and subsequently by a local intestinal immune response. Specific antibodies inhibit bacterial adherence to receptors on the intestinal epithelial cells and neutralize the activity of the enterotoxins or cytotoxins produced by *E. coli*.

Colostrum from the sow contains high levels of immunoglobulin G (IgG), which rapidly decrease during lactation and IgA becomes the main immunoglobulin class (Bourne 1976). The latter protects the gut against *E. coli* infection. It appears that most IgA, IgM, and IgG in the milk of the sow is produced within the mammary gland. During pregnancy, a proportion of the lymphocytes stimulated by antigens in the intestine migrate to the mammary gland and produce specific antibody against enteric pathogens. These antibodies are actively transported to the colostrum and then the milk during lactation.

The newborn piglet begins to synthesize specific immunoglobulin and develop intestinal immunity during the first week of life (Butler 1973). At first, IgM predominates, but after 12 weeks, it is replaced by IgA as the most important immunoglobulin class in the intestine (Bianchi et al. 1999). Thus, during the first weeks of life, colostrum is the main source of immunologic protection for the piglet.

Breakdown in the protection provided by colostrum may occur for several reasons. If the dam has not been exposed to ETEC present in the environment of the piglets, her colostrum will not contain the specific antibodies necessary for protection against adherence and proliferation of ETEC. Also, any disease process causing agalactia in the sow will diminish transfer of colostrum. Generalized systemic infection may cause a total reduction in colostrum production, whereas mastitis or injured teats may affect production in one or several glands. Piglets failing to receive colostrum due to deformities, infection, small size, or damage at birth will also be more susceptible to ETEC infection.

Maternal vaccination has been one of the most effective ways of controlling neonatal ETEC diarrhea in piglets. Identification of virulence factors important in the pathogenesis of ETEC diarrhea and application of recombinant DNA technology have resulted in the production of more efficient vaccines over the last several years. One of the earliest vaccination techniques consisted of taking the small-intestinal contents from a piglet with diarrhea, culturing it in milk, and feeding the culture to pregnant sows, usually about a month before parturition (Kohler 1974). This technique is effective, conferring an immunity lasting throughout the suckling period, and is still used, particularly in the United States.

Commonly used commercially available vaccines are given parenterally and may be killed whole-cell bacterins or purified fimbrial vaccines. Both of the latter types of vaccines appear to work equally well (Fahy 1987). Bacterins usually contain strains representing the most important serogroups and producing the fimbrial antigens F4, F5, F6, and F41 (Nagy 1986). They are usually given parenterally at about 6 weeks and 2 weeks prior to parturition. Addition of the common fimbrial antigen F1 to a fimbrial bacterin appeared to have been protective in one study (Jayappa et al. 1985) but was not protective in another study (To et al. 1984). Recombinant DNA technology has enabled the production of large quantities of purified fimbrial antigens for use in parenteral vaccines for immunization of the dam (Clarke et al. 1985).

In cases where vaccination is ineffective, it is important to identify the serotypes involved for possible inclusion into an autogenous bacterin. Further characterization of these isolates may identify new or variant fimbrial adhesins important in the pathogenesis of ETEC diarrhea. An alternative approach to the problem of emerging ETEC negative for the known fimbriae has been the use of vaccines containing the nontoxic form of the enterotoxin LT-B conjugated to the nonimmunogenic STa (Klipstein 1986). Following conjugation, STa becomes immunogenic, and this vaccine has given protection in experimental animals. Addition of these components to fimbrial vaccines will provide protection against emerging ETEC with new fimbrial antigens in neonates and against ETEC negative for the known fimbrial antigens and commonly found in older pigs. Isaacson (1994) has recently reviewed the use of vaccines for the prevention of *E. coli* diseases.

Finally, a novel approach to the prevention of ETEC diarrhea in piglets could be the oral administration of exogenous proteases such as bromelain (Mynott et al. 1996). Such proteases can inhibit attachment of F4-positive ETEC to the intestinal mucosa due to modification of the receptor attachment sites.

Postweaning *Escherichia coli* Diarrhea and Edema Disease

J. M. Fairbrother and C. L. Gyles

Postweaning *Escherichia coli* diarrhea and edema disease are treated in one section because they often both occur in the same age group of pigs, the causative bacteria share certain virulence factors, and some strains of *E. coli* can cause both diseases. There are also important differences in the two diseases.

E. coli postweaning diarrhea (PWD) is a communicable diarrhea mediated by enterotoxins and observed mainly after weaning. It is also called "postweaning enteric colibacillosis."

Edema disease (ED) is a communicable enterotoxemia caused by certain *E. coli* that colonize the small intestine and produce a protein toxin that enters the bloodstream and damages vessel walls in certain tissues. The names "edema disease," "bowel edema", and "gut edema" were coined because edema of the submucosa of the stomach and the mesocolon is often a prominent feature of the disease.

E. coli PWD and ED may occur independently, but they may also occur in a single outbreak or in the same pig. The early history of the two diseases has been extensively reviewed by Sojka (1965).

E. coli is an important cause of death in weaned pigs. Losses due to PWD are reported worldwide, whereas mortality due to ED does not appear to be as great in North America as is observed in Europe.

ED bears some similarity to the human diseases caused by enterohemorrhagic strains of *E. coli* (EHEC), which produce closely related, but not identical, Shiga toxins. However, the human EHEC strains colonize the intestine by a mechanism distinct from edema disease *E. coli* (EDEC) (Tzipori et al. 1986). Serotypes associated with ED are different from those of EHEC that cause disease in humans.

ETIOLOGY

PWD and ED are caused by strains of *E. coli* that possess certain adhesion factors enabling the bacteria to colonize the small intestine and that produce one or several exotoxins. Nearly all of these *E. coli* are alpha-hemolytic. Most of them belong to a very limited number of serotypes. In a given area, the serotypes are closely associated with a rather constant set of fimbrial adhesins and toxins. Thus, the serogroup O139 has been found worldwide to produce the fimbrial variant F18ab. Strains of this serogroup from Australia always cause PWD, whereas those from Europe typically induce ED. The serogroup O149 has been found worldwide to produce the fimbrial variant F4ac and to induce PWD.

At present, by far the most predominant serogroup of *E. coli* associated with PWD in pigs is O149. The most important virotypes and O serogroups of *E. coli* associated with PWD throughout the world are found in Table 38.3. These virotypes usually have either F4 or F18 as fimbrial adhesin. Some F4- and F18-negative virotypes have been identified by The *Escherichia coli* Laboratory in Quebec and by others (Frydendahl 2002) in *E. coli* from pigs with PWD. The role of these virotypes in the development of diarrhea has not yet been established. Some differences in the predominant virotypes have been observed from country to country. For example, the fimbrial adhesins F4 and F18 were detected in 45% and 39%, respectively, of isolates from pigs with PWD or

Table 38.3. Important pathotypes, virotypes, and O serogroups of *E. coli* causing disease in postweaning pigs

Disease	Pathotype	Virotypes	O Serogroups
Postweaning diarrhea	ETEC	LT:STb:EAST1:F4, LT:STb:STa:EAST1:F4, STa:STb, STa:STb:Stx2e[1]:F18ac, STa:F18ac, LT:STb, STb:EAST1:AIDA, LT:STb:STa[1]:EAST1:F4[1]: AIDA[1]:Stx2e[1]:F18ac, AIDA:F18ac	8, 38, 139, 141, 147, 149, 157
Postweaning diarrhea	EPEC	Eae:EAST1[1]	45, 103

[1]Not always present.

ED in Denmark during 1999–2000 (Frydendahl 2002). Of the F4-positive isolates, all were O149: two-thirds were of virotype LT:STb:EAST1:F4 and one-third were of virotype LT:STa:STb:EAST1:F4. The F18 isolates were much more heterogeneous, the most common serotype/virotype profiles being O149:LT:STb:EAST1:F18, O138:STa:STb:F18, O138:LT:STb:EAST1:Stx2e:F18, and O139:Stx2e:F18. More than half of the ETEC isolated from pigs with diarrhea in South Dakota, U.S., in 2001–2002 were of virotypes LT:STb:F4, STa:STb:F18, or STa:STb:Stx2e:F18, F4 isolates being slightly more prevalent than F18 isolates (Francis 2002). On the other hand, the predominant fimbrial adhesin found in ETEC isolated from pigs with diarrhea in Quebec, Canada, both in diagnostic cases from 1994 to 1998 (Fairbrother et al. 2000) and in a study of 17 farms with at least 15% diarrhea in pigs in the first 3 weeks postweaning (personal observations 2002), was F4. In both studies, about half of ETEC isolates produced F4. All F4-positive isolates were O149, half being of virotype LT:STb:EAST1:F4, half being of virotype LT:STa:STb:EAST1:F4. Only 2% of isolates were F18-positive and were mostly of virotype STa:STb. All other ETEC produced neither F4 nor F18, the most common virotypes being STa:STb and STb:EAST1:AIDA. AIDA has been detected recently in *E. coli* strains from pigs with edema disease or postweaning diarrhea, particularly in strains of the virotypes Stx:F18 and F18 alone (Mainil et al. 2002). AIDA is encoded by genes present on a plasmid, possibly the same as that containing the *fed* genes that encode F18 fimbriae. ETEC isolates of the STb or STb:EAST-1 virotypes from weaned pigs may also be AIDA-positive (Ngeleka et al. 2003).

The antigenic variants of F18 fimbriae were serologically determined using 380 isolates from fatal cases of PWD and ED in Germany (Wittig et al. 1995). Variants F18ab and F18ac were found in 40% and 35%, and F4 in 14%, of the isolates. The remaining isolates were negative for F18 and F4.

An interesting evolution in the virotype of O149 isolates has been observed. In retrospective studies in Canada, it has been observed that O149 strains isolated before 1990 were predominantly of virotype LT:STb: EAST1 (Fontaine et al. 2002; Noamani et al. 2003). Since 1990, a new virotype, LT:STa:STb:EAST1, has appeared and is now either as prevalent as (Fontaine et al. 2002; Frydendahl 2002) or has almost replaced (Noamani et al. 2003) the old virotype. This trend may not be universal, because most O149 strains isolated from 4- to 6-week-old weaned pigs with diarrhea in Poland (Osek 2003) were of the LT:STb:EAST1 virotype, and the new virotype did not appear to be prevalent in the 2001–2002 South Dakota study (Francis 2002).

PWD and ED are mediated by toxins—enterotoxins in the case of *E. coli* PWD, and Shiga toxin in the case of ED. It is noteworthy that ETEC and EDEC strains may occur in pigs in the absence of PWD or ED. In these cases, the pathogenic *E. coli* constitute a low percentage of the fecal *E. coli*. In contrast, in disease, they constitute most or all of the *E. coli* in the feces.

A more detailed description of the enterotoxins is given in the preceding subchapter. The term "Shiga toxin" (Stx2e) is a synonym of Shiga-like toxin, verotoxin, edema disease principle, neurotoxin, and vasotoxin. MacLeod and Gyles (1990) developed a purification scheme resulting in a homogeneous preparation of Stx2e free of endotoxin. As little as 3 ng of pure Stx2e per kilogram of body weight administered intravenously to young pigs induces disease. Clinical signs and gross and microscopic lesions are characteristic of ED, thus confirming that Stx2e and EDP (edema disease principle) are identical. Incubation time and severity of disease are directly related to the toxin dose.

Enteropathogenic *E. coli*

An enteric syndrome distinct from classic PWD was described by several investigators. It is characterized by attaching and effacing lesions caused by *E. coli* (AEEC). The clinical outcome of the infection is difficult to evaluate, because mixed infection, such as with F4-positive ETEC, often occurs. The AEEC do not possess any virulence factors of classic PWD or ED strains (Zhu et al. 1994). Their virulence attributes are dealt with in the

subchapter on neonatal *E. coli* diarrhea. Experimental infection of gnotobiotic pigs allows reproduction of the lesions (Figure 38.2). Several predisposing factors, such as a weaner diet containing soya and field peas or Porcine Reproductive and Respiratory Syndrome (PRRS) virus infection, may enhance bacterial colonization and development of attaching and effacing lesions (Neef et al. 1994, personal observations). AEEC will not be further dealt with in this chapter.

Comprehensive overviews of *E. coli* and its role in animal disease may be found elsewhere (Gyles 1994; Gyles and Fairbrother 2004).

EPIDEMIOLOGY

The epidemiologies of PWD and ED have many features in common. The age group primarily affected by PWD and/or ED depends on the weaning age. There are some differences between *E. coli* with F4 and those with F18. The former can cause neonatal, preweaning, and postweaning diarrhea, most often in the very first days after weaning. In farms where husbandry measures at weaning, such as addition of higher levels of protein of animal source, plasma, acidifying agents, and zinc oxide are being used, peaks of diarrhea and enteric colibacillosis complicated by shock may be observed often at 3 weeks after weaning, or even at 6–8 weeks after weaning, at the time when the pigs enter the growing barns (Fairbrother, unpublished observations). The latter, however, more often cause disease between 5 and 14 days after weaning (Svendsen et al. 1974) or after introduction to fattening herds. Unweaned piglets can also be affected by *E. coli* diarrhea and ED. In suckling pigs, the severity of the disease depends on antibody titers in the milk of the sow (Sarmiento et al. 1988b).

The morbidity in an affected herd is extremely variable. Within a particular litter it may be up to 80% or more, but the average is 30–40%. With ED, the case fatality rate ranges from 50% to over 90%. The course of the disease in the herd varies from 4–14 days, the average being slightly under a week. The disease disappears as abruptly as it appears. Recurrence on premises is common (Kurtz et al. 1969). With PWD the case fatality rate and the mortality tend to be lower. In untreated herds, the latter may attain 26% (Svendsen et al. 1974).

The environment of the weaner unit appears to be the most likely source of pathogenic *E. coli* strains. Unweaned pigs may acquire infection in the farrowing house, presumably from the same source, and carry it into the weaning unit. Routine cleaning and disinfection are usually insufficient to break the cycle of infection (Hampson et al. 1987). Under experimental conditions, however, transmission can be prevented by strict hygienic measures (Smith and Halls 1968; Kausche et al. 1992). The minimal infectious dose is not known. In transmission experiments with a F4-positive ETEC strain, airborne transmission between pigs in wire cages

1.5 m apart was repeatedly observed (Wathes et al. 1989). Outbreaks tend to involve only one strain of F4-positive *E. coli* at any one time. Occasionally, two potential pathogens are isolated, but one usually predominates. Multiple infections of herds involving more than one serogroup were detected in 47% of 84 herds (Awad-Masalmeh et al. 1988).

The spread of pathogenic *E. coli* is presumed to occur via aerosols, feed, other vehicles, pigs, and possibly other animals. Introduction of new pathogenic strains of *E. coli* into closed primary specific pathogen free (SPF) herds with a high isolation standard was observed at intervals of 1–2 years. Once a site is contaminated with a particular strain, it can remain so for an extended period. The serotypes associated with postweaning diseases tend to be similar in broad geographic areas. When ED entered Denmark in 1994, it spread from one SPF breeding herd by trade of pigs to at least 37 other herds. The close clonal relationship of the causal strains was confirmed (Aarestrup et al. 1997; Jorsal et al. 1996). Another 22 herds became infected without known trading contact.

PATHOGENESIS

For the sake of clarity, intestinal colonization and toxemia will be presented separately. However, there may be mutual interactions.

Colonization of the Small Intestine

E. coli causing PWD and/or ED enter the animal by ingestion and, when present in sufficient numbers, colonize the small intestine following bacterial attachment to receptors on the small intestinal epithelium or in the mucus coating the epithelium, by means of specific fimbrial adhesins. These bacteria then proliferate rapidly to attain massive numbers to the order of 10^9 in the midjejunum to the ileum. The degree of colonization determines whether disease results from infection. Adhering microcolonies or layers of bacteria were observed on the small-intestinal mucosae of pigs experimentally infected with two strains of O group 139 (Figure 38.3) (Bertschinger and Pohlenz 1983; Methiyapun et al. 1984; Bertschinger et al. 1990). EDEC adhere to the brush border similarly to ETEC. Some of the known factors influencing colonization by pathogenic *E. coli* are discussed here.

Brush border receptors for pathogenic *E. coli* are not present in every pig. Genetic resistance resulting from lack of receptors for F4 was first described by Sellwood et al. (1975) (see section on neonatal colibacillosis). The receptor for F18 fimbriae is also controlled in a single locus, and the presence of a receptor is dominant over absence (Bertschinger et al. 1993). The receptor for F18 is distinct from the receptor for F4. The genes for the F4 receptor were determined on chromosome 13 (Guérin et al. 1993), whereas the genes for the F18 receptor were lo-
38.3. *Bacteria adhering patch-wise to microvilli of small-intestinal epithelium of a weaner 6 days after oral inoculation with a culture of E. coli O139:K12:H1.*

cated on chromosome 6 close to the locus for stress susceptibility. In a high proportion of the Swiss pig population, resistance against stress is linked to susceptibility to adhesion of *E. coli* with F18 fimbriae (Vögeli et al. 1996). In view of the low prevalence of stress-susceptible pigs, the frequency of pigs with the F18 receptor would be predicted to be high. This has been confirmed in a number of studies.

Fimbrial receptors are thought to be glycoconjugates that are subject to modulation by feed lectins such as constituents of leguminous plants (Kelly et al. 1994). It may be speculated that feed-induced changes of the receptor are involved in the reduced susceptibility to colonization by F18-positive *E. coli* in the first days after weaning (Bertschinger et al. 1993). Endogenous as well as orally administered proteases may reduce the receptor activity for F4 fimbriae (Mynott et al. 1996). Receptors for F4 are fully expressed from birth to adult age, whereas the F18 receptor is not yet fully expressed by piglets under about 20 days of age (Nagy et al. 1992). Hence, *E. coli* with F18 fimbriae do not cause disease in neonatal pigs. Constant expression of receptors may underlie the earlier appearance after weaning of *E. coli* strains with F4 in herds where F4- and F18-positive strains are endemic.

Loss of milk antibodies appears to contribute significantly to susceptibility of pigs to *E. coli* enteric infections in the postweaning period (Deprez et al. 1986, Sarmiento et al. 1988b).

A variety of viruses infect the porcine intestine and may thereby change the bacterial environment. Dual infection of pigs with rotavirus and with an ETEC strain without F4 results in a more severe diarrhea than inoculation with either agent alone (Lecce et al. 1982). The investigators concluded that viral damage of the epithelium favors colonization by *E. coli*. Infection by the PRRS virus results in a decreased efficacy of the immune system, permitting ETEC to cause a septicemia leading to death (Nakamine et al. 1998).

An acid environment has an inhibitory effect on *E. coli*. The pH of the stomach contents falls after weaning (Risley et al. 1992). Several investigators found that the pH of the jejunum cannot be reduced by acidification of the feed. The pH close to the jejunal brush border is slightly acid and highly regulated. It is not influenced by the pH of the chyme (McEwan et al. 1990).

Veterinary practitioners and farmers were convinced many years ago that nutritious feed would play an important role in development of disease. Thus ED was named "protein intoxication." Smith and Halls (1968) inoculated pigs on various feed regimens with an O141:K85ac EDEC strain. They found that severe feed restriction resulted in much lower fecal numbers of the bacteria and absence of disease. A similar effect was achieved by feeding pigs ad libitum on a diet extremely rich in fiber and low in nutrients. The authors concluded that the physiological state of the intestinal epithelium might influence bacterial adhesion. These experiments were extended by Bertschinger et al. (1978) using an O139:K12 EDEC strain. The findings of Smith and Halls (1968) were confirmed. However, the poor diets inhibited growth of the pigs. When these diets were replaced by a conventional type of feed, colonization and clinical disease developed. The inhibitory effect of the poor diet was abolished by supplementation with fish meal but not with starch or fat. The precise mechanism behind these phenomena remains to be elucidated.

Low room temperature in the weaner rooms was proposed as being responsible for a more severe course of PWD (Wathes et al. 1989). Under experimental conditions, ED was not aggravated by cold stress (Kausche et al. 1992).

Diarrhea

The mechanisms by which enterotoxins induce diarrhea are described in the preceding section (neonatal *E. coli* diarrhea). Almost all *E. coli* involved in fatal cases of PWD produce LT (Imberechts et al. 1994). Pigs colonized about 12 days after weaning with ETEC producing one or both heat-stable enterotoxins develop diarrhea only exceptionally (Sarrazin and Bertschinger 1997). This difference between neonates and weaned pigs may be explained at least in part by the marked increase of antisecretory factor beginning a few days after weaning (Lange et al. 1993).

Enterotoxemia

Highly purified Stx2e induces a disease indistinguishable from ED when administered intravenously to pigs (MacLeod and Gyles 1990). Stx2e produced by EDEC in the intestine is absorbed into the circulation and can bind to globotetraosyl ceramide on red blood cells. Thus, vessels are subjected to prolonged toxin exposure (Boyd et al. 1993). By immunological methods the toxin can be detected in endothelial cells of small blood vessels of the intestine and in microvillous membranes of enterocytes at the base of the villi (Waddell et al. 1996).

The most consistent injury observed in natural cases, after injection of partially purified toxin (Clugston et al. 1974b; Gannon et al. 1989) and in pigs inoculated orally with live cultures (Methiyapun et al. 1984; Kausche et al. 1992) is a degenerative angiopathy of small arteries and arterioles. The edema fluid found in various tissues is low in protein and could be the result of a mild increase in vascular permeability. Information on pathophysiology of ED is scarce. Clugston et al. (1974a) observed an increase of blood pressure after intravenous administration of EDP. Hypertension developed later than clinical edema and was therefore thought to be the result of vascular injury rather than its cause. Hypertension might exacerbate the lesions in the already damaged vessels. The development of injuries in the nervous system may be due to hypoxia resulting from impaired blood flow (Clugston et al. 1974b).

A distinct type of ED is characterized by terminal bloody diarrhea and hemorrhagic lesions in the cardiac region of the stomach, the ileum, and the large intestine (Figure 38.4) (Bertschinger and Pohlenz 1983). According to Gannon et al. (1989) and MacLeod and Gyles (1990), acute hemorrhagic gastroenteritis occurs in some of the pigs to which a high dose of Stx2e is administered. Epithelial necrosis secondary to necrosis of small arteries and arterioles may be responsible for luminal hemorrhage.

CLINICAL SIGNS

Postweaning Diarrhea

In the spontaneous outbreaks caused by an *E. coli* strain of O149 without F4 investigated by Svendsen et al.

38.4. *Extended hemorrhages and minor mesenteric edema in the colon of a pig that developed bloody diarrhea 5 days after inoculation with a culture of E. coli O139:K12:H1.*

(1974), the first manifestation of PWD was sudden death of one or several pigs as early as 2 days after weaning. At the same time, feed consumption of the affected batch of pigs dropped markedly, and a watery diarrhea developed. At the onset, some pigs exhibited a characteristic quivering of the tail. The rectal temperature was normal. Affected pigs became dehydrated and depressed. They ate irregularly, but even in the terminal stage of the disease, they tried to drink. Many pigs showed cyanotic discoloration of the tip of the nose, the ears, and the abdomen. Even severely affected pigs tried to move around with staggering, uncoordinated movements. The peak of mortality occurred 6–10 days after weaning. Surviving pigs recovered well. Some pigs were completely spared from the disease.

In pigs experimentally infected with a strain with virulence factors F4, LT, and STb, diarrhea started 1–2 days after inoculation and was fulminating and fatal in some of the pigs, whereas others survived after diarrhea of 3–4 days' duration (Sarmiento et al. 1988a). The pigs lost some weight in the first 2 days after inoculation. From the fifth day on, the growth curve of susceptible pigs resumed a course parallel to that of genetically resistant pigs. The latter were not colonized and remained free from any symptoms.

Postweaning Diarrhea Combined with Edema Disease

Smith and Halls (1968) described the disease experimentally induced with a strain of serogroup O141:K85a,c, obviously a producer of Stx2e and of enterotoxin(s). The

first sign was anorexia, which started at the onset of shedding bacterial numbers above 10^9 colony-forming units (CFU)/g of feces 3 (2–5) days postinoculation (PI) and was observed in most pigs. Anorexia lasted for several days in the pigs that recovered and until euthanasia in the pigs killed when death was imminent. Diarrhea appeared on day 4 (1–8) PI. Usually it was severe but of short duration. It was rarely fatal. In most pigs diarrhea was no longer present when signs of nervous involvement became apparent, that is, on day 6 (5–13) PI. Swollen eyelids were seen at about the same time. Ataxia was accompanied with varying degrees of mental confusion and was usually progressive. Affected pigs soon became completely recumbent. Severe dyspnea was usually present at this final stage. Most of the pigs with ataxia had to be killed on the day the signs of impairment of the nervous system appeared. Pigs were moribund 7 (5–13) days PI. The rectal temperature always remained within the normal range.

Edema Disease

A similar disease was seen in pigs inoculated with a nonenterotoxigenic ED strain of serotype O139:K12:H1 (Bertschinger et al. 1978). However, diarrhea was not associated with colonization and a more pronounced edema developed in some cases. In such cases ears, subcutaneous tissue over the frontal bones, nose, and lips were swollen (Figure 38.5). In mild cases, subcutaneous edema was accompanied by pruritus, which disappeared after recovery. In some pigs with or without dyspnea, respiration was accompanied by a snoring sound.

Watery diarrhea with clots of fresh blood became apparent in a few pigs at the terminal stage (Bertschinger and Pohlenz 1983). Hemorrhagic colitis developed also

38.5. *Edematous swelling of eyelids, forehead, and lips, breathing through open mouth, and inability to rise in a weaner 4 days after oral inoculation with a culture of E. coli O139:K12:H1.*

in pigs to which high doses of toxin Stx2e were administered (MacLeod et al. 1991).

Chronic ED occurred in a variable, but mostly low, proportion of pigs recovering from acute attacks of ED or *E. coli* PWD (Bertschinger and Pohlenz 1974; Nakamura et al. 1982). The condition was called cerebrospinal angiopathy before its association with ED became apparent. For periods varying from days to several weeks after intestinal infection, growth stops, and sick pigs often show unilateral nervous disturbances such as circling movements, twisting of the head, or atrophy of limb muscles with progressive weakness. Subcutaneous edema is rare. Affected pigs should be destroyed. Subclinical ED was observed in most pigs surviving for 2 weeks after inoculation with a strain of *E. coli* O139 positive for Stx2e and STb. The pigs were clinically normal but developed vascular lesions. No pigs were allowed to survive beyond the 2 weeks (Kausche et al. 1992).

LESIONS

Postweaning Diarrhea

Gross Lesions. Pigs dead from *E. coli* PWD are generally in good condition but severely dehydrated with sunken eyes and some cyanosis. Lungs look pale and dry, as observed in well-bled pigs (Svendsen et al. 1974). The stomach is often distended with dry feed. Variable hyperemia of the gastric mucosa is often noted in the fundic region. The small intestine is dilated, slightly edematous, and hyperemic. The contents vary from watery to mucoid, with a characteristic smell. The mesentery is heavily congested. Contents of the large intestine most often look light greenish or yellowish and are mucoid to watery. Pigs dying late in an outbreak look emaciated and exhibit a strong smell of ammonia. There are irregularly shaped superficial ulcerations in the fundic region of the stomach and similar lesions of smaller size in the large intestine. The feces look yellow and pasty. The fluid from the anterior chamber of the eye may give a positive reaction for urea.

Some authors use the terms "hemorrhagic gastroenteritis" or "enteric colibacillosis complicated by shock" to describe a form of *E. coli* diarrhea characterized by severe congestion of the gastric fundus and the small intestine with or without blood-tinged contents of the small intestine and sometimes the upper large intestine, but only exceptionally with bloody feces (Faubert and Drolet 1992). This type of lesion was always caused by *E. coli* with F4 fimbriae. The syndrome of enteric colibacillosis complicated by septicemia was recently reproduced in gnotobiotic pigs and deletion of the gene for LT resulted in reduction of F4-mediated colonization, reduced dehydration, and less frequent septicemia (Berberov et al. 2004).

Microscopic Lesions. Bacteria adhering to the ileal and less consistently to the jejunal surface are always

seen. The bacterial layers are restricted to villi and look patchy (Sarmiento et al. 1988a; Casey et al. 1992; Faubert and Drolet 1992). The mucosa and the epithelium appear intact. Some investigators have reported increased numbers of neutrophils in the superficial lamina propria. In pigs with enteric colibacillosis complicated by shock, severe congestion of the gastric and small-intestinal mucosae is commonly associated with microvascular fibrinous thrombi. Necrosis of villi with marked infiltration of neutrophils occurs in severe cases. There is only occasional hemorrhage in the lamina propria of the jejunum and the ileum (Svendsen et al. 1974; Faubert and Drolet 1992).

Edema Disease

Gross Lesions. Pigs dead of ED are mostly in good condition, somewhat pale, and the bodies retain a fresh appearance. Edema at specific sites is variable and may be absent in some animals. Subcutaneous edema may occur. Edema in the submucosa of the stomach is characteristic when present and is located in the region of the glandular cardia (Figure 38.6). It may vary from being barely detectable to 2 cm or more in thickness. The edema fluid is usually serogelatinous and occasionally may be bloodstained adjacent to the mucosa. If severe, the edema may extend into the fundic submucosa. Inflammatory edema associated with acute ulceration of the esophageal cardia must not be confused with that of ED.

Edema of the gallbladder is sometimes seen. The mesocolon is a common site for edema. Careful inspection of the pericardial, pleural, and peritoneal cavities may reveal occasional whitish fibrin strands and a slight increase in serous fluid. The mesenteric and colic nodes vary in appearance from normal to being swollen, edematous, and congested. Typically, the stomach is full of
38.6. Edematous swelling of glandular mucosa of the cardiac region and gelatinous submucosal edema of the cut stomach wall from a field case from which E. coli O139:K12:H1 was isolated.

dry, fresh-looking feed, and the small intestine is relatively empty. Colonic contents may be diminished in amount. It may be inferred that this is a manifestation of delayed gastric emptying, since some animals have a period of anorexia before death. Also, it has been shown experimentally that pigs with ED may eat very little for 48 hours before death and at necropsy have full stomachs (Smith and Halls 1968). The suggestion that some pigs with ED are affected by constipation also agrees with these observations.

The lungs may display varying degrees of edema and a characteristic, patchy, sublobular congestion. In some cases this may be the only observable lesion. Cases with laryngeal edema have also been observed. A few epicardial and endocardial petechiae may occur. This lesion must not be confused with mulberry heart disease.

In some pigs with spontaneous or experimental ED, a form of hemorrhagic gastroenteritis occurs, which is quite different from that described with *E. coli* PWD. In addition to marked edema, the edematous submucosa of the cardiac region of the stomach and the mucosa of the lower small and upper large intestine show extensive hemorrhage. Watery diarrhea with clots of coagulated blood occurs shortly before death in some of these pigs (Bertschinger and Pohlenz 1983). Endothelial swelling, vacuolation and proliferation, microthrombus formation, subendothelial fibrin, medial necrosis, and perivascular edema were detected in such cases (Methiyapun et al. 1984). The similarity to human hemorrhagic colitis is striking.

If the causative strain of *E. coli* is also capable of producing enterotoxin, lesions of postweaning diarrhea may be added, and edema may be mild or absent.

Microscopic Lesions. Patchy layers of adhering bacteria are present throughout the small intestine early in the course of ED (Bertschinger and Pohlenz 1983; Methiyapun et al. 1984; Bertschinger et al. 1990). Contrasting with *E. coli* PWD, the colonization has often disappeared when pigs with ED become moribund (Smith and Halls 1968).

The most important microscopic lesions are those of a degenerative angiopathy affecting small arteries and arterioles (Clugston et al. 1974b; Kausche et al. 1992). The lesions may occur in many organs and tissues. The dense arterial network in the mesocolon adjacent to the colic lymph nodes is frequently affected. The early acute lesion is one of necrosis of smooth muscle cells in the tunica media characterized by pyknosis and karyorrhexis of nuclei and hyaline change in cytoplasmic elements. In the walls of some affected vessels, fibrinoid material is deposited (Figure 38.7). Swelling of endothelial cells has also been observed. In acute experimental cases, edema of the leptomeninges and perivascular spaces has been demonstrated. In older lesions, there may be proliferation of adventitial and medial cells (Figure 38.8).
38.7. Arterioles in submucosa of the urinary bladder: (left) normal; (right) fibrinoid or hyaline change, acute experimental ED (Clugston et al. 1974b).
38.8. Submucosa of cardial gland region of the stomach 17 days after inoculation with EDP (edema disease principle containing STL-IIe); arteriole with proliferative arteriopathy (Clugston et al. 1974b).

Vascular lesions may be difficult to detect in acute cases, but in surviving pigs or those affected subclinically, they are more readily apparent (Kausche et al. 1992). Thrombosis is not usually a feature of uncomplicated naturally occurring ED.

In pigs that have recovered from natural outbreaks or survived for several days following acute signs, there are lesions of focal encephalomalacia in the brain stem together with lesions in the small arteries and arterioles (Kurtz et al. 1969; Kausche et al. 1992). These are thought to be the result of vascular injury leading to edema and ischemia. A cerebrospinal angiopathy of pigs has been recognized as a clinicopathologic entity for some years. Its microscopic features are those described above as well as the occurrence of eosinophilic, Periodic Acid Schiff (PAS)–positive droplets around affected vessels. This angiopathy is most likely a manifestation of edema disease (Bertschinger and Pohlenz 1974).

DIAGNOSIS

Postweaning Diarrhea

Postweaning diarrhea is a very complex disease with multiple etiologies (see Chapter 3). Occurrence of diarrhea early after weaning, marked dehydration, and at least some mortality are characteristics in the field allowing a preliminary diagnosis of ETEC. The gross lesions, including the characteristic smell, are also helpful. The final diagnosis requires detection of ETEC (see neonatal *E. coli* diarrhea), which are shed in high numbers. Hemolysis is not a valid criterion for identification of ETEC. Laboratories not equipped for the determination of virulence factors should at least use serotyping of living cultures with OK-antisera against serotypes most prevalent in a given region.

Edema Disease

The diagnosis of acute ED is based on sudden appearance and on clinical signs of neurologic disease in thriving pigs 1–2 weeks after weaning. In the live pig the most important and constant diagnostic sign is partial ataxia or a staggering gait. Subcutaneous edema in the palpebrae and over the frontal bones is also a cardinal sign when present. At necropsy the characteristic lesions of edema, when present, are helpful in confirming the diagnosis but may be absent in a significant number of cases, especially when severe diarrhea has preceded ED. Diagnosis of ED in adult pigs (Imberechts et al. 1996) may require additional efforts, such as histopathology and postmortem examination of more than one pig.

Bacteriologic examination of the small intestine and colon usually yields pure or nearly pure cultures of hemolytic *E. coli*. However, bacterial numbers may have declined in more protracted cases (Bertschinger and Pohlenz 1983). In contrast to ETEC infections, a negative bacteriologic result therefore does not exclude the

diagnosis of ED. Serologic identification of the common serotypes associated with ED is additional evidence. Serotyping is essential, because hemolytic *E. coli* not associated with other virulence factors are frequently encountered in the intestinal flora and may be present in high numbers. Polymerase chain reaction (PCR) amplification of the genes for Stx2e and F18 fimbriae may be used to obtain a rapid and definitive identification of EDEC.

Subacute or chronic ED is diagnosed by the demonstration of arteriopathy and eventually lesions of focal encephalomalacia.

In cases of sudden death, differential diagnosis includes microangiopathia dietetica and circulatory failure, as seen after severe fighting. When pigs show signs of neurological disease, viral encephalitis (enteroviral polioencephalomyelitis, pseudorabies) and bacterial meningoencephalitis (*Streptococcus suis, Haemophilus parasuis*) as well as water deprivation should be considered.

TREATMENT

Much less is known about the treatment of these diseases than about pathogenesis and about treatment of neonatal colibacillosis.

Antimicrobial Therapy

Chemotherapeutic control of bacterial proliferation is therapeutically much more effective in *E. coli* PWD than in ED, because in the latter, toxin has already been absorbed into the circulation and become bound to its receptor when clinical signs become visible. The development of bacterial resistance against a wide range of antimicrobial drugs (Table 38.4) renders this approach uncertain. It is not possible to give universal data on resistance, because the situation varies in different pig populations depending on the antimicrobials preferentially used.

Sick pigs must be treated parenterally. They eat and drink very little, even if they stand close to the creep and to the drinking nipple. Substances must be selected that reach the intestinal lumen, such as amoxicillin/clavulanic acid, fluoroquinolones, cephalosporins, apramycin, ceftiofur, neomycin, or trimethoprim. Testing bacterial resistance is indispensable if there is a herd problem.

Supportive Therapy for PWD

The supportive therapy has to counteract dehydration and acidosis. Attractive rehydration fluid should be offered for spontaneous intake or injected intraperitoneally if the pig is anorectic. Such fluids may contain glucose, glycine, citric acid, and potassium dihydrogen phosphate in an isotonic solution (Bywater and Woode 1980). Uptake should be equal to the loss (i.e., up to 25% of the body weight).

Table 38.4. Sensitivity to antimicrobial agents of *E. coli* O149 isolates from pigs with PWD or ED in Switzerland and PWD in Quebec

Antimicrobial Agent	% Sensitive O149 Isolates	
	Switzerland[1] *n* = 59	Quebec[2] *n* = 52
Ampicillin	73	36
Amoxicillin/clavulanic acid	100	NT[3]
Cefoxitin	100	NT
Streptomycin	37	NT
Spectinomycin	19	NT
Neomycin	81	73
Apramycin	93	58
Gentamicin	91	81
Tetracycline	47	0
Chloramphenicol	81	NT
Enrofloxacin	100	98
Colistin[4]	100	NT
Ceftiofur	NT	100
Sulfonamide	15	NT
Trimethoprim	73	NT
Trimethoprim-sulfamethoxazole	NT	30
Furazolidone	100	NT

[3]Not tested.
[4]Modified agar dilution technique (Bertschinger et al. 1996).

Edema Disease

There is little likelihood of saving the lives of pigs with advanced signs such as severe subcutaneous edema, respiratory distress, or inability to rise. Evaluation of therapy is difficult because the severity of the illness cannot be quantified. Numerous remedies have been recommended in the past and have then been abandoned.

PREVENTION

Breeding of Resistant Pigs

This is the approach to prevention that may be most effective and economical in the long term. Work in this direction is in progress. It will be important to avoid co-selection of unwanted traits closely linked with loci coding for the F4 and the F18 receptors. It cannot be predicted whether additional types of adhesive fimbriae or new variants of known types will emerge that could bind to yet unidentified receptors.

Eradication of EDEC

The transmissible character of *E. coli* PWD and ED is evident. In Denmark most of the recent spread of ED followed the routes of the pig trade (Jorsal et al. 1996). It was logical to start an eradication program involving depopulation of affected farms and disinfection of the buildings (Johansen et al. 1996b). With one exception, the 15 farms participating in this program remained free of clinical disease for a minimum of 4–7 months. They are

under continuing surveillance. Some problems render this approach risky. The tools to prove the absence of pathogenic *E. coli* from a given herd are not yet adequate. Also, *E. coli* has a high tenacity in the environment.

Immunoprophylaxis

Acquired immunity may result in protection against intestinal colonization and/or against effects of the toxins. Weaned pigs can be protected passively or actively.

Passive Immunity. A daily dose of 525 mL, but not of 270 mL, milk obtained from sows in late lactation fed to weaned pigs completely inhibited colonization, whereas pigs fed the same amount of cow's milk shed high numbers of the EDEC bacteria (Deprez et al. 1986). Spray-dried porcine blood plasma fed at a dose of 90 g per pig/day had a similar inhibitory effect that lasted only as long as the plasma was fed, and the inhibitory effect could be improved by vaccination of the donor pigs (Deprez et al. 1990, 1996). Immune protection against colonization with F4- and F18-positive *E. coli* may be attained by feeding eggs produced by vaccinated hens (Imberechts et al. 1997; Marquardt et al. 1999). It remains to be shown whether the antibody-containing egg powder can be produced at an acceptable price.

Active Immunity. Few commercial vaccines are available for the prevention of postweaning *E. coli* PWD and ED. Injectable vaccines, such as those administered to sows for the prevention of neonatal diarrhea, stimulate mostly the systemic rather than mucosal immunity, giving rise to circulating antibodies which do not reach intestinal bacteria in high enough levels to be very effective (Van den Broeck et al. 1999). Such vaccines may even suppress the mucosal immune response upon subsequent oral infection with a pathogenic *E. coli* (Bianchi et al. 1996). Several approaches for the control of postweaning *E. coli*–associated diarrhea are currently being investigated. Most of these control strategies are specific for the adhesin or O serogroup of the causative *E. coli*. Hence, an accurate diagnosis and identification of the adhesin type is essential to assure a more effective control of the diarrhea. New vaccination strategies include the oral immunization of piglets with live attenuated avirulent *E. coli* strains carrying the fimbrial adhesins. Such vaccine strains may be administered to weaned piglets in the drinking water or to unweaned piglets by oral dosing at least 1 week prior to the expected onset of diarrhea, to allow the intestinal colonization by these bacteria and induction of local intestinal antibodies which will block the adherence of the pathogenic *E. coli* and hence prevent the development of diarrhea. This approach appears to be effective for the control of both F4 and F18 *E. coli*–associated diarrhea, using a vaccine strain carrying the appropriate adhesin. A large scale on-farm study in the United States has demonstrated a decreased mortality and reduced use of antimicrobials fol-

lowing oral administration of a live nonenterotoxigenic F4 *E. coli* strain to pigs immediately following weaning (Fuentes et al. 2004). Pigs that have been colonized by an F18 ETEC producing STI and STb are protected against recolonization by a heterologous ETEC sharing no other antigens with the immunizing strain except F18 fimbriae. However, the cross-protection between strains with fimbrial variants F18ab and F18ac may not be very high (Bertschinger et al. 2000). Current research is aimed at the oral administration of purified F4 fimbriae, instead of the whole bacteria, as a vaccine for the control of outbreaks of *E. coli*–associated diarrhea in weaned pigs (Van den Broeck et al. 1999). Use of such a subunit vaccine results in a specific mucosal immune response in the intestines and a significant reduction in fecal excretion of the pathogenic F4.

In the pig, the small intestine is the major site of IgA and IgM production. IgM is more a mucosal isotype than in other animal species and probably has an important role in mucosal immunity (Bianchi et al. 1999). In the porcine lamina propria, the frequency of IgM secreting cells is similar to that of IgA secreting cells at 4 weeks of age and increases thereafter. The shift from IgM to IgA as predominant mucosal isotype is at about 12 weeks of age. Vaccines for preventing PWD should activate the mucosal immune system and evoke antigen-specific IgA or IgM responses in order to induce a protective mucosal immunity (Van den Broeck et al. 1999).

Gannon et al. (1988) did not detect neutralizing antibody against Stx2e in the sera of neonatal pigs and weaned pigs from herds with and without ED. However, pigs do mount an antibody response; Wieler et al. (1995) showed that pigs that had survived an outbreak of ED had antibodies reacting in an ELISA to the B subunit of Stx2e.

Active immunity against intravenous challenge with Stx2e was induced in young pigs by a toxoid vaccine prepared from an ultrasonic lysate of an EDEC by treatment with glutaraldehyde (Dobrescu 1982). A similar toxoid was used for vaccination of pigs 1 week before weaning (Awad-Masalmeh et al. 1989). The vaccine conferred highly significant protection against ED after the pigs were orally challenged with EDEC serogroup O139:K12. Vaccinated principals shed lower numbers of the inoculated bacteria and had better weight gains than placebo-vaccinated littermates.

A toxoid prepared by treatment of Stx2e with formaldehyde was not completely free of toxic activity. Therefore, the toxin was modified by site-directed mutagenesis of the *stx2e* gene. The genetically modified toxin was found to have no deleterious effect on the growth of vaccinated pigs, and it prevented overt and subclinical ED when vaccinated pigs were challenged with an *E. coli* O139:F18 positive for Stx2e and STb (Bosworth et al. 1996). A different approach was chosen by MacLeod and Gyles (1991), who detoxified purified Stx2e with glutaraldehyde. An adjuvanted experimental vaccine was evaluated in two herds infected by a strain of *E. coli*

O139:F18, Stx2e. Mortality due to ED was significantly reduced, and daily gain in the nursery was significantly improved. Deaths caused by ETEC in one of the herds were not prevented (Johansen et al. 1996a). These toxoid vaccines are not yet commercially available.

Chemoprophylaxis

At present, preventive feed medication is practiced in a majority of the affected herds in most countries despite serious drawbacks such as nonacceptance by the consumer, impaired buildup of immunity, and selection of resistant bacteria. Resistance is often induced within days or a few weeks. Isolates from *E. coli* PWD and ED show the highest rate of resistance within porcine *E. coli*. Besides the classes of antimicrobials mentioned above for parenteral therapy, the aminoglycosides and colistin are widely used. The latter has the advantages of high stability, low toxicity, absence of infectious resistance, and slow development of resistance. With colistin, resistance cannot reliably be detected by the agar diffusion technique (Bertschinger et al. 1996). Investigators have reported that oxytetracycline reduces the adhesion of *E. coli* at concentrations below the minimum inhibitory concentration. Sarmiento and Moon (1988) reported that *E. coli* PWD induced by a tetracycline-resistant strain takes an identical course in pigs eating feed with and without tetracycline.

Zinc oxide offers an alternative to antimicrobials. Feeds with contents between 2400 and 3000 ppm of zinc reduce diarrhea and mortality and improve growth. The activity is explained by an antibacterial effect (Holm and Poulsen 1996). However, environmental considerations should be included in discussions of zinc oxide at such high levels.

Dietary Measures

Restriction of feed intake, high-fiber diets, or ad libitum feeding of fiber have been reported as effective deterrents to the development of ED and postweaning diarrhea (Smith and Halls 1968; Bertschinger et al. 1978; Rantzer et al. 1996). The nutritive value of the feed may be reduced by increasing fiber content to 15–20% and reducing crude protein and digestible energy to one-half of the normal values (Bertschinger et al. 1978). The addition of fiber to normal diets may be beneficial. Dunne (1975) advocated feeding high-quality alfalfa coupled with restriction of daily feed intake. To be effective, nutrient intake has to be low enough to maintain daily gain below 1% of body weight in the 2 weeks after weaning. Such diets prevent colonization and impair the development of immunity in the same way as antimicrobials. Later outbreaks are frequently seen.

A lower mortality due to *E. coli* enterotoxemia and improved weight gains were reported after introduction of rations with a reduced acid-binding capacity. A similar effect is ascribed to organic acids. Others were unable to reduce the mortality due to ED by the inclusion of a mixture of organic and inorganic acids in the feed (Johansen et al. 1996b). This result is not surprising in view of the highly regulated pH close to the mucosal surface (McEwan et al. 1990).

An improved weight gain and lower frequency of scours was observed in early weaned (10 days of age) pigs fed a spray-dried porcine plasma (SDPP)–based diet (Owusu-Asiedu A et al. 2002). This was partly attributed to the presence of specific anti-ETEC antibodies in the SDPP. In another study, addition of SDPP to the ration of weaned pigs did not prevent losses due to experimental challenge with an ETEC strain, although improved weight gain was observed (Van Dijk et al. 2002). However, the lack of effect on losses could be due to the severity of the experimental model.

Exogenous as well as endogenous proteases lower the activity of intestinal F4 receptors. Bromelain, a protease from pineapple stems, applied orally to pigs reduced the binding of F4-positive ETEC to brush borders in a dose-dependent manner (Mynott et al. 1996). The efficacy in a clinical situation remains to be demonstrated.

Scandinavian workers have shown that antisecretory factor reverses secretory diarrhea induced by heat-labile enterotoxin. The levels of antisecretory factor in the blood plasma can be increased by addition of glucose and of some amino acids to the feed. Treated weaner pigs were reported to have a lower incidence of diarrhea and a greater weight gain (Göransson et al. 1993). Antisecretory factor probably exerts its effects on the enteric nervous system (Hansen and Skadhauge 1995).

Bacterial Probiotics

In recent investigations *Enterococcus faecium*, *Lactobacillus* sp., and *Bacillus cereus* strain "toyoi" were fed to experimentally infected (De Cupere et al. 1992) and to naturally infected (Johansen et al. 1996b) pigs. No preventive effect was recorded. Schulze (1977) confirmed earlier comparative quantitative studies of the gastrointestinal flora in weaned and in unweaned pigs, where no evidence was found for an interdependence between *E. coli* and the other components of the flora.

General Management

Management of the weanling pig should minimize environmental and other forms of stress such as unnecessary mixing of litters, chilling, transportation, and assignment to new pens. Wathes et al. (1989) observed a higher incidence of scours and greater mortality due to *E. coli* PWD in experimentally infected pigs kept at 15°C than in controls at higher temperatures. The experiment was not perfectly conclusive because genetic resistance was neglected.

Systemic Infection
J. M. Fairbrother

Escherichia coli may induce systemic infections, such as septicemia, or localized extraintestinal infections, such as meningitis or arthritis, resulting from bacteremia (Fairbrother and Ngeleka 1994; Fairbrother et al. 1989; Morris and Sojka 1985). Septicemia due to *E. coli* may be primary, occurring predominantly in newborn to 4-day-old pigs, or secondary, when associated with diarrhea or other compromising diseases in young pigs.

ETIOLOGY

Only a relatively small number of *E. coli* serogroups have been reported in natural cases of septicemia. Serogroups O6, O8, O9, O11, O15, O17, O18, O20, O45, O60, O78, O83, O93, O101, O112, O115, and O116 have most commonly been identified in isolates associated with septicemia (Morris and Sojka 1985; Nielsen et al. 1975a; Fairbrother et al. 1989). Other gram-negative bacteria such as *Klebsiella* spp. and *Pseudomonas* spp. have been reported to be associated with systemic infections in pigs (Nielsen et al. 1975b). In a 4-year study at the *Escherichia coli* Laboratory from 1989 to 1992, the most commonly observed serogroups in isolates from cases of primary septicemia were O9 (10%) and O20 (18%) (Fairbrother and Ngeleka 1994). Serogroups O1, O18, O60, O78, O101, O141, and O147 were isolated in relatively lower numbers (2–4% each), but 49% of isolates were nontypeable. Not all *E. coli* isolates are able to cause septicemia in colostrum-deprived piglets (Meyer et al. 1971; Murata et al. 1979).

The characteristics of *E. coli* involved in porcine septicemia have not been greatly studied. However, septicemia-inducing strains may express virulence determinants, which include fimbriae, polysaccharide capsule and O-antigen capsule, lipopolysaccharide (LPS), the aerobactin system, hemolysin, and other cytotoxins (Table 38.5). Fimbrial adhesins associated with *E. coli* isolates from piglets with septicemia include the $F165_1$, $F165_2$ (Contrepois et al. 1989; Fairbrother et al. 1986), and other fimbriae of the P, S, and F1C fimbrial families (Dozois et al. 1997).

ETEC may be associated with secondary septicemia, particularly in older piglets. These isolates most frequently belong to the virotypes listed in Table 38.3.

The virulence determinants most frequently associated with isolates from primary septicemia in pigs or isolates inducing septicemia in newborn colostrum-deprived pigs are $F165_1$, $F165_2$, or other fimbriae of the P, S, and F1C fimbrial families, production of colicin V, production of the siderophore aerobactin, and resistance to the bactericidal effects of serum (Fairbrother and Ngeleka 1994). Isolates from cases of primary septicemia

Table 38.5.   Important pathotypes, virulence factors, and O serogroups of *E. coli* causing extraintestinal disease in pigs

may occasionally produce cytotoxic necrotizing factor (CNF1).

EPIDEMIOLOGY

Primary septicemia is most often seen as sporadic cases and rarely in the form of a small outbreak (Nielsen et al. 1975a). The disease may occur throughout the suckling period, with exceptional cases in pigs up to 80 days old. Epidemiology of the secondary systemic infection is determined by the underlying disease.

PATHOGENESIS

Primary neonatal septicemia occurs in piglets lacking immunity, due either to an absence of ingested colostrum or to ingestion of colostrum lacking specific antibody. The disease may develop after bacterial invasion of the respiratory or the gastrointestinal tract in the nonimmune host. Contamination of the umbilicus after birth may also lead to colisepticemia. However, the intestine is considered as a major route of *E. coli* invasion since the disease can be experimentally induced by oral or intragastric administration of the organisms (Ngeleka et al. 1993).

Secondary septicemia may develop after invasion of the host by ETEC, but in most cases development of primary neonatal septicemia is associated with intestinal permeability to macromolecules, to some defect of the immune system (e.g., low levels of maternal colostrum), to low birth weight, and to sublethal malformations (Gyles and Fairbrother 2004; Murata et al. 1979).

Bacteria may pass through the mucosa of the alimentary tract, probably by endocytic uptake into intestinal epithelial cells or through the intercellular spaces formed by lateral plasma membranes of adjacent epithelial cells, to locate in the mesenteric lymph nodes before entering the bloodstream. This bacterial invasion may result in a generalized infection (septicemia, polyserositis) with bacteria disseminated in different extraintestinal organs such as lung, liver, spleen, kidney, brain, and heart blood, or in a localized infection (meningitis or arthritis) (Morris and Sojka 1985). In the sow, a puerperal sepsis may be induced by an enteric *E. coli* soon after farrowing (Sojka 1965).

Septicemia may be produced experimentally in colostrum-deprived piglets by intragastric inoculation with isolates of porcine origin (Fairbrother and Ngeleka 1994; Ngeleka et al. 1993). However, the disease can also be reproduced in piglets with isolates from other sources, such as calves, cats, and poultry (Fairbrother et al. 1993; Murata et al. 1979; Meyer et al. 1971). Animals may develop fever, anorexia, diarrhea, dyspnea, or nervous signs, due in part to the effect of bacterial endotoxin or cytotoxins or to the effects of inflammatory cytokines induced by these bacterial products (Nakajima et al. 1991; Jesmok et al. 1992).

The role of some of the virulence determinants associated with *E. coli*–inducing septicemia is only partially understood. LPS, K capsule and O-antigen capsule, and production of siderophores such as aerobactin are thought to allow the bacteria to invade the host and escape its defense mechanisms. These determinants increase bacterial resistance to the bactericidal effect of complement and to phagocytosis and allow bacterial growth in body fluids with low concentrations of free iron (Crosa 1989; Ngeleka et al. 1992, 1993).

Fimbriae appear to be important for the survival and spread of bacteria within the host and subsequent bacterial pathogenicity, in part by promoting bacterial resistance to the bactericidal effects of phagocytosis (Ngeleka et al. 1992, 1993, 1994). One mechanism for this resistance appears to be an inhibition of the oxidative response (Ngeleka and Fairbrother 1999).

CLINICAL SIGNS

Clinical signs of infection include depression, lameness, reluctance to move, anorexia, rough hair coat, and labored respiration (Nielsen et al. 1975a). The affected piglets may show sternal recumbency and the abdomen may be somewhat distended. Sometimes piglets become unconscious, with convulsions and paddling movements; they may be in good bodily condition but cyanosis of the extremities may be observed. Some piglets are found dead whereas others are comatose without any sign of diarrhea. These clinical signs may develop within 12 hours after birth and piglets can die within 48 hours (Taylor 1989). In older piglets, the clinical signs may include periodic scouring or other ailments that precede the onset of acute septicemia with clinical signs resembling those in the newborn pigs.

LESIONS

In acute primary septicemia, there may be no gross lesions other than congestion of the intestine, the mesenteric lymph nodes, and the extraintestinal organs. In subacute cases, subserous or submucosal hemorrhages and fibrinous polyserositis with gross signs of pneumonia are usually observed, often accompanied by fibrinopurulent arthritis and meningitis (Morris and Sojka 1985; Waxler and Britt 1972). Histological examination of the lung reveals interalveolar interstitial pneumonia with edema and neutrophilic infiltration, but alveoli are free of exudates. In secondary septicemia resulting from enteric colibacillosis, icterus, petechial hemorrhages in the serosal membranes, and splenomegaly accompanied by severe diarrhea and dehydration can be observed in some cases (Svendsen et al. 1975). In many cases of secondary systemic *E. coli* infection, presumably occurring at a very late stage in the underlying disease, the changes are slight or no lesions at all are recorded.

DIAGNOSIS

Systemic colibacillosis is generally suspected with the appearance of the clinical signs described above. However, in the case of polyserositis, a differential diagnosis between *Mycoplasma hyorhinis* and *Haemophilus parasuis* has to be made. In the former infection, gross lesions can be detected more than 6 days after infection. Mortality is lower than in *E. coli* infection. In polyserositis due to *E. coli*, the exudates encountered in piglets are serofibrinous or fibrinopurulent, whereas in *H. parasuis* infections they tend to be serofibrinous. In the central nervous system and joints, these exudates are fibrinopurulent to purulent (Waxler and Britt 1972). Infection due to *H. parasuis* is rarely seen in the early suckling period but is more common in piglets of 2–3 months of age. However, differential diagnosis can be established after a careful microbiological examination. In most of the cases, postmortem examination and bacteriology are useful for identifying the infection. Diagnosis of primary systemic colibacillosis is strengthened by the isolation in pure culture or by the predominance of *E. coli* in extraintestinal tissues, particularly *E. coli* of one of the above-mentioned serogroups or, more important, possessing one or more of the virulence factors, such as adhesins of the P or S families, serum resistance, or production of aerobactin (Table 38.5). The genes for these virulence factors may be detected by hybridization probes and the multiplex polymerase chain reaction (PCR), as described in the section on neonatal diarrhea. Diagnosis of secondary systemic colibacillosis is strengthened by the isolation in pure culture or by the predominance in extraintestinal tissues of *E. coli* possessing the genes for one or more of the enterotoxins LT, STa, or STb and possibly one of the fimbrial adhesins associated with ETEC, particularly F4.

PREVENTION AND TREATMENT

Inadequate hygiene and poor environmental temperature control increase the likelihood of infection. Thus, prevention of infection should focus on reduction or elimination of significant pathogenic *E. coli* populations in the environment of the piglets and in providing a plentiful supply of colostrum at birth. Hygiene, especially washing and disinfection of the farrowing pens, will efficiently contribute to reduction of the infection. Young piglets should be maintained at an even temperature of 35°C for the first week of life. They must be kept dry and warm in clean surroundings. Affected piglets should be treated if necessary, and other litters of susceptible age watched. However, in the case of small outbreaks, careful monitoring of the causative serogroup(s) and autovaccination of the pregnant sows might be beneficial.

Treatment may be attempted after diagnostic confirmation of *E. coli* infection and antibiotic sensitivity testing. Meanwhile, parenteral or oral administration of broad-spectrum antimicrobials to affected piglets is rec-

ommended while waiting for results of diagnostic tests. This treatment may be useful in subacute cases of infection but is mostly ineffective after the appearance of clinical signs. However, the remaining piglets in the litter and affected piglets and littermates in adjacent litters should be treated.

Coliform Mastitis
J. M. Fairbrother

The term "coliform mastitis" (CM) is used to refer to puerperal mastitis in the pig, underlining the parallel of this disease with CM in the cow (Bertschinger 1999). Other terms used to denominate CM and related conditions are discussed in Chapter 4 of this book. In one study, it was found that 59 of 72 agalactic sows (82%) had gross lesions of mastitis (Ross et al. 1981).

CM has a worldwide distribution. Hermansson et al. (1978) reported an average incidence of postpartum agalactia of 12.8%, individual herds varying from 0.5–50%. In a Danish study, on farms with a high management level, an incidence of 9.5% of mastitis-metritis-agalactia (MMA) among 72,000 farrowings was observed (Jorsal 1986). In these studies, the precise incidence of CM was not determined. In another study, *E. coli* or *Klebsiella pneumoniae* was isolated from 79% of the 131 mammary complexes with mastitis examined in herds with an MMA problem (Wegmann et al. (1986).

Economic loss due to CM is difficult to estimate, being multifactorial. In the affected sows, mortality is low, and it is difficult to assess the cost of extra care and of treatment. On the other hand, the mortality in piglets nursing multiparous sows with MMA has been reported to be as high as 55.8%, compared to 17.2% in piglets nursing healthy sows (Bäckström et al. 1984) and 21% compared to 17% in another study (Madec et al. 1992). Mortality of piglets may result from lengthened farrowing time, crushing by the sow, starvation, and impaired immunity to infectious agents because of insufficient uptake of colostral immunoglobulins. The average milk yield of three sows affected with CM on the first 2 days after farrowing was about half the yield of healthy sows, and the piglets of the sick sows lost some weight (Ross et al. 1975). Piglets sucking glands with mastitis of sows with subclinical CM had smaller weight gains only for days 1–4 postpartum (Bertschinger et al. 1990).

ETIOLOGY

The term "coliform," when used in the context of mastitis, refers to the bacterial genera *Escherichia*, *Klebsiella*,

Enterobacter, and *Citrobacter*. However, the methods used for identification in several studies were not adequate to determine the genera and even less the species of the bacterial isolates. *E. coli* was the organism most often identified in either milk samples or affected mammary tissue (Ringarp 1960; Armstrong et al. 1968; Bertschinger et al. 1977a; Ross et al. 1981; Wegmann et al. 1986). No one serotype has been associated with *E. coli* isolated from the milk of sows with CM (Morner et al. 1998). The virulence factors of *E.coli* from CM are not well known, although serum resistance and ability to bind to fibronectin have been associated with these isolates. Nevertheless, *E. coli* isolates from sows with mastitis are very heterogeneous, as shown by random amplified polymorphic DNA genotyping (Ramasoota et al 2000). *Klebsiella*, mostly *K. pneumoniae*, was prevalent in the cases investigated by Ross et al. (1975) and Jones (1976). *Staphylococcus epidermidis* and a variety of streptococci have also been found in the mammary glands of sows with signs of mastitis, either mixed with coliforms or as pure cultures. Nevertheless, noncoliform organisms were rarely associated with microscopic lesions of mastitis (Bertschinger et al. 1977a; Ross et al. 1981).

EPIDEMIOLOGY

CM of the sow appears to be noncontagious. Multiple serological types of isolate from cases of mastitis may be found within a herd and even within distinct glands of one sow. A significant proportion of subcomplexes harbor more than one type (Bertschinger et al. 1977a; Awad-Masalmeh et al. 1990). The great variety of coliform bacteria associated with CM indicates an abundant reservoir of potentially pathogenic bacteria. The coliforms causing mastitis may originate from the flora of the sow as well as from the environment. In about one-third of the sows with mastitis, identical isolates were found in mastitic glands, the uterine contents, and the urinary bladder (Bertschinger et al. 1977a). The intestinal flora of the sow, the oral flora of the neonatal piglet, and environmental bacteria may significantly contribute to contamination

of the nipples. Awad-Masalmeh et al. (1990) found identical O serogroups of *E. coli* in mammary secretion and in feces of about one-fourth of 67 sows with CM. Muirhead (1976) considered the bedding of the sow of paramount importance. Dung and urine contaminate the udder. *Klebsiella* spp. may also originate from wood shavings used for bedding. Bertschinger et al. (1990) compared 12 farrowings each in conventional farrowing crates and in an experimental pen where the sows could lie down in a clean resting area. Sows in the experimental pen had much lower counts of coliform bacteria on their teat ends and an incidence of intramammary *E. coli* infections 10 times lower than that of the sows in the crates.

PATHOGENESIS

Invasion of the Mammary Gland

Mastitis was reproduced in the sow by intramammary instillation of not more than 120 organisms of a strain of *K. pneumoniae*. Following massive external contamination of the nipples with the same strain, the bacteria were recovered from 60 out of 142 subcomplexes examined. External contamination of the nipples was as successful on gestation day 111 as 2 hours after completion of farrowing (Bertschinger et al. 1977b). It is largely unknown at what time spontaneous invasion of the cistern takes place. McDonald and McDonald (1975) found significant numbers of coliform bacteria in about one-fourth of mammary glands cultured immediately prior to parturition. In a sequential examination of the mammary secretions, *E. coli* was isolated from 30 glands. In 17 of these glands, the bacteria were detected before the first piglet was born (Bertschinger et al. 1990). New infections appeared not later than day 2 postpartum.

The bacteria are located in the ductular and alveolar lumina, either free or within phagocytic cells. Little adhesion to surfaces is observed. At postmortem examination the causative bacteria are frequently isolated from regional lymph nodes, whereas isolations from the liver, spleen, or kidney are rare (Armstrong et al. 1968; Bertschinger et al. 1977a, b; Ross et al. 1981).

Multiplication of bacteria in the mammary secretion is controlled by antimicrobial mechanisms. The antimicrobial activity of cow's milk is due to a variety of inhibitors acting in concert and conferring on the dry udder a nearly total resistance to coliform proliferation (Bramley 1976). A lower opsonic activity observed in mammary secretions of sows at parturition (Osterlundh et al. 1998), as well as a lower phagocytic capacity of polymorphonuclear (PMN) cells in colostrum as compared to in milk (Osterlundh et al. 2001) may explain the increased susceptibility to the development of CM at parturition. CM is a self-curing disease. The bacteria generally disappear between 1 and 6 days after parturition (Wegmann and Bertschinger 1984; Bertschinger et al. 1990). In severe cases, however, they persist in necrotic foci throughout lactation (Löpfe 1993).

Mammary Inflammation

CM in the sow is associated with massive accumulation of neutrophils in the lumina of affected glands. Simultaneous induction of CM in several mammary subcomplexes of sows from which the piglets had been removed resulted in severe leukopenia within 24 hours (Bertschinger et al. 1977b). Intracisternal instillation of identical bacterial inocula following a highly standardized protocol led to a spectrum of reactions ranging from very severe local and general signs to subclinical mastitis (Löpfe 1993; Mossi 1995). Severe reaction is the consequence of massive and persistent multiplication of inoculated bacteria. In the experiments of Löfstedt et al. (1983) susceptibility to experimental infection was associated with impaired function of circulating neutrophils. The cause of the impaired neutrophil function is still a mystery. Magnusson et al. (2001) showed that sows were more susceptible to experimental infection immediately prior to parturition than at 4 days before parturition, the number of neutrophils in the blood being greater in the former. This suggests a role for the number of circulating neutrophils at the time of infection in the development of clinical CM in the sow. Nevertheless, Osterlundh et al. (2002) have shown in experimental inoculation studies that impaired chemotactic or phagocytic capacity of blood granulocytes does not appear to be involved in susceptibility of sows to develop clinical CM at parturition. Cytological findings in the secretion must be interpreted with caution. Mammary glands not chosen by a piglet undergo involution soon after parturition. Involution is accompanied by an increase in the total somatic cell count as well as in the proportion of PMN cells (Wegmann and Bertschinger 1984). In some sows many glands show increases of total somatic and of PMN cells in the absence of cultivable bacteria (Bertschinger et al. 1990).

Systemic Reaction

The systemic signs of CM are brought about by the bacterial endotoxin. An outline of the systemic changes is given in Chapter 4. CM in the absence of systemic reaction is often revealed by methodical examination of mammary secretion (Wegmann 1985; Bertschinger et al. 1990; Persson et al. 1996b).

Immunity

CM apparently does not result in protection against homologous reinfection (Bertschinger and Bühlmann 1990). Ringarp (1960) reported a higher incidence in sows than in gilts, as well as repeated occurrence, up to 10 times, in individual sows.

CLINICAL SIGNS

Ross et al. (1975) described the clinical findings in sows with proven CM and demonstrated changes quite similar to those described earlier in sows with lactational

failure. Interpretation of clinical parameters is rendered difficult by the presence of subclinical CM in apparently healthy sows (Nachreiner and Ginther 1972; Middleton-Williams et al. 1977; Persson et al. 1996b).

The initial signs are most often detected on the first or second day and more rarely on the third day after farrowing. However, they may be observed as early as during parturition (Martin et al. 1967). The first symptoms are body temperature response, listlessness, weakness, and loss of interest in the piglets. Affected sows prefer sternal recumbency. In severe cases they become stiff, do not stand up, and may even become comatose. Consumption of feed and water is either reduced or absent. Body temperature is moderately elevated and only rarely exceeds 42° C. Afebrile cases have been reported; although the temperature was not taken continuously and temperature peaks may have been missed. On the other hand, many normal sows will have rectal temperatures that exceed the 39.7°C limit on the day of parturition and for 2 days thereafter (King et al. 1972). In affected sows, respiratory and heart rates are increased. In general, symptoms do not last for more than 2–3 days.

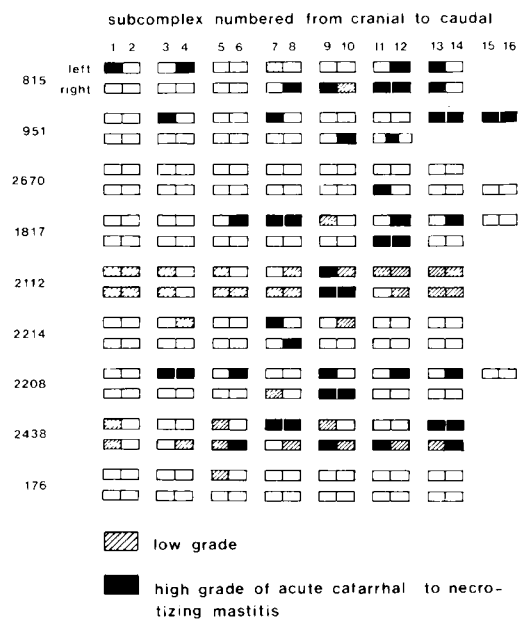
The behavior of the piglets is very helpful in the early detection of lactational failure. Undernourished piglets look gaunt. They frequently try to suck, move from nipple to nipple, nibble at litter, and lick urine from the floor. If access to the nipples is given by the sow, the periods of suckling are shortened. After suckling, the piglets wander instead of resting in close contact with their littermates.

Precise localization of mammary lesions is often not possible because reddening and heat of the skin extend over several subcomplexes. The reliable clinical assessment of the state of the actual mammary tissue is rendered difficult by subcutaneous fat and considerable subcutaneous edema. If palpable, the mastitic tissue is firmer and palpation may cause pain. The red color of the skin is blanched by finger pressure, which causes a depression of the tissue lasting for some time. Mere clinical examination will at best detect some of the affected subcomplexes (Persson et al. 1996b). The inguinal lymph nodes may be swollen.

The fluid expressed from a nipple originates from more than one subcomplex, because two or, rarely, three teat canals end in each nipple. Therefore, in samples taken from a nipple, secretion from the unaffected, productive subcomplex dominates. The exudate from inflamed subcomplexes looks serous to creamy, like pus. It may contain clots of fibrin or blood. The pH is of limited diagnostic value (Ross et al. 1981; Persson et al. 1996b), but cytological examination allows differentiation between healthy and mastitic complexes at least during the first 48 hours after parturition (Wegmann and Bertschinger 1984). Because mastitis is a local process, samples must be taken from individual complexes and not pooled. The threshold value of the total cell count varies depending on the investigator. Bertschinger et al. (1990)

suggested 5×10^6 cells per mL and fewer than 70% PMN. In a recent study, Persson et al. (1996a) proposed 10×10^6 cells per mL. However, these authors did not distinguish between sucked and unsucked glands. Involution of some glands starts as early as 1 day after parturition (Wegmann and Bertschinger 1984). It leads to a significant increase of the total cell count accompanied by a transient increase of up to 60% of the proportion of PMN cells. As a consequence, cytological distinction between involution and mastitis may be difficult or impossible between 2 and 7 days postpartum (Wegmann 1985). Bacteriological examination of the secretion may be necessary in unclear cases. Infection persisting for several days is limited to severely affected complexes (Löpfe 1993).

LESIONS

Despite the high incidence of CM, there are not many reports of necropsy findings (Martin et al. 1967; Jones 1976; Middleton-Williams et al. 1977; Ross et al. 1981). In general, lesions are confined to the mammary glands and regional lymph nodes. The subcutaneous tissue may be edematous over affected parts of the udder. For reliable demonstration of mastitis, Middleton-Williams et al. (1977) recommended a longitudinal section at the level of the nipples through each row of glands. Using this technique, irregularly scattered foci of mastitis were detected in 1–23 subcomplexes (Figure 38.9). The appearance of affected mammary tissue varied from slightly increased firmness and grayish discoloration to sharply demarcated, red-mottled, hard, and dry areas


38.9. *Distribution and intensity of histologic lesions on nine field cases of CM (modified from Middleton-Williams et al. 1977).*
38.10. *Acute CM of one subcomplex adjacent to unaltered glandular tissue in longitudinal cut surface: (a) subcutaneous edema, (b) demarcation from adjacent subcomplex, (c) mottled appearance of affected tissue.*

(Figure 38.10). The secretion was sparse and sometimes mixed with clots.

Histological examination permitted the detection of additional lesions that had not been recognized at gross examination. In every case there was an acute purulent exudative mastitis with congestion. An extreme variability in severity ranging from a small number of neu-trophils in the alveolar lumina to severe purulent infiltration with necrosis was obvious (Figure 38.11). The severity of the lesions varied not only between but also within subcomplexes, where unaffected tissue was found adjacent to severely inflamed areas. Acute purulent lymphadenitis was present in the inguinal and iliac lymph nodes (Middleton-Williams et al. 1977). A sequential study of the microscopic lesions following experimental intracisternal inoculation revealed in severe cases the persistence throughout lactation of abscesslike large necrotic foci surrounded by granulomatous connective tissue (Löpfe 1993). A predilection of microscopic lesions for certain areas within a given complex was not evident. The mucosa lining the cisternae was not affected.

DIAGNOSIS

Any hypogalactia at the beginning of lactation arouses suspicion of CM. The diagnosis may be supported by fever, anorexia, reluctance to stand up, lying on the gland, and disinterest in the piglets. In severe cases some affected glands may be reddened, swollen, and firm, and the secretion may look abnormal. A reliable rapid test for use on the farm is not available. Due to the higher cell content of sow milk, tests developed for use with the cow cannot be recommended. Bacteriological and cytologi-

cal examinations of the secretion are valuable only if all glands are sampled or if affected glands are known. The differential diagnosis of CM is reviewed in Chapter 4.

TREATMENT

Therapeutic measures are usually not taken before the sow shows signs of dysgalactia. Thus, treatment may at best shorten the period of underfeeding of the piglets.

Chemotherapy is complicated by the heterogeneous pattern of antimicrobial susceptibility of individual isolates, not only within a herd but also within a sow. Therefore, sensitivity testing is of little value in individual cases.

The pharmacokinetics of antimicrobials has received only limited attention. One injection of 20 mg/kg body weight of a slow-release formulation of oxytetracycline results in milk levels not surpassing 2 µg/mL, that is, just above the minimum inhibitory concentration (MIC) of susceptible *E. coli* (Schoneweis et al. 1982). Enrofloxacin, a quinolone antibiotic, given at 2.5 mg/kg body weight orally twice daily, is concentrated in colostrum and milk to mean levels of 1.2 µg/mL, which is 20 times higher than the MIC (Oliel and Bertschinger 1990). Awad-Masalmeh et al. (1990) tested 107 strains of *E. coli* isolated from sows with CM from 43 herds and found no resistance to enrofloxacin (Table 38.6). Therapeutic trials are generally difficult to evaluate because the curative effect is not quantified and is often difficult to distinguish from spontaneous improvement. Options for supportive therapy are discussed in Chapter 4.

Much attention should be given to the piglets. They may either be fostered by other sows or remain with their mother and receive a milk substitute. Sweetened condensed milk diluted with water 1:1 can be used instead of commercial products. A sterile 5% glucose solution at a dose of approximately 15 mL can be repeatedly injected intraperitoneally every several hours, or a more concentrated solution may be administered intragastrically. When the pig obtains insufficient amounts of milk, protection against chilling is particularly important.

PREVENTION

Hygiene Measures

Muirhead (1976) and Jones (1979) suggested that protection of the teats from bacterial contamination might be an effective prophylaxis of CM. Bertschinger et al. (1990) performed a prospective study of farrowing in two types of pens. They concluded that the density of the coliform flora on the teat apex reflects the degree of contamination of the lying area. Optimal prophylaxis is achieved by designing farrowing accommodation in such a manner that the sow is prevented from lying down in her own excreta. On the other hand, washing and disinfection of the pen and of the newly housed sow contribute much less to efficient prophylaxis. If cases of CM accumulate, the bedding materials should be checked.

Nutrition of the Sow

Drastic reduction of the sow's ration shortly before parturition is a widespread practice. In a carefully designed long-term study using pairs of full siblings, the reduction of the daily feed allowance from 3.2 to 1.0 kg of a commercial-type feed lowered the incidence of agalactia from 26.6% to 14.4% (Persson et al. 1989). Udder changes were observed in a high percentage of the agalactic sows, and significant numbers of bacteria were found in more than 80% of the agalactic sows. The two feed regimens did not influence the total cell count, the PMN levels, or the pH of the secretion (Persson et al. 1996b). Plonait et al. (1986) reported a corresponding observation. Experimentally induced CM takes a similar course with sows on high and low rations (H. U. Bertschinger and A. Bühlmann, unpublished data). This finding led to the suggestion that feed reduction might act through reduced exposure of the teats to microbial infection due to the much smaller amounts of feces and urine contaminating the lying area.

Immunoprophylaxis

Vaccination is not a promising method for control of mastitis. Induction of specific immunity is hampered by the wide range of antigenic types of coliforms isolated from sows with CM. Use of an *E. coli* bacterin induced poor protection in sows against intramammary challenge with the same strain used to prepare the bacterin (R. Ross, Ames, Iowa, unpublished data, 1982).

In the cow, there is considerable evidence that vaccination with an R-mutant of *E. coli* results in a dramatically reduced incidence of CM (Tyler et al. 1993). Vaccination has little impact on the frequency of new infections but decreases the incidence of overt disease. No reports have appeared to date on the efficacy of such vaccines in the sow.

Table 38.6.   Sensitivity to antimicrobial agents of coliform isolates from mammary glands in Switzerland and Austria

| | % Sensitive Isolates | | |
| | Switzerland | | Austria |

Hormones

Some investigators found an extended period of gestation in sows developing lactational failure. The length of gestation can be controlled by use of prostaglandins. However, the prophylactic application led to conflicting results. Studies focusing on CM are not known.

Chemoprophylaxis

At present, chemoprophylaxis appears to be the most promising method of control where accommodation cannot be improved. The prevalence of drug resistance (Table 38.6) and the wide variety of bacteria associated with the disease in a given herd must be considered when the drug is selected. Feed medication should be replaced by individual application of the drug in a small amount of feed because the feed consumption of the sow in the periparturient period is quite variable. Minimizing the period of treatment helps postpone the emergence of drug resistance. In field trials, the morbidity from MMA was reduced from 30% to 12% by giving 0.4 g trimethoprim, 1 g sulfadimidine, and 1 g sulfathiazole/150 kg body weight twice a day. The treatment began on gestation day 112 and lasted for 4 days regardless of the day of farrowing (Bollwahn 1978). Six intramuscular injections of apramycin (6.25 mg/kg) at 12-hour intervals reduced the severity of experimentally induced mastitis (Ross and Zimmermann 1982).

Oliel and Bertschinger (1990) evaluated the effect of oral chemoprophylaxis with enrofloxacin on experimentally induced CM. Three glands of each sow were inoculated with *E. coli* and three glands with *K. pneumoniae*. Eight sows were not treated (treatment I), eight sows received 2.5 mg (treatment II), and eight sows received 5.0 mg/kg body weight twice a day (treatment III). The inoculated bacteria were reisolated in treatment I from 100%, in treatment II from 10%, and in treatment III from 2% of the inoculated glands. A beneficial effect on milk productivity would be expected but could not be demonstrated because the control sows did not develop systemic signs.

Urinary Tract Infection

J. M. Fairbrother

Urinary tract infection (UTI) is present whenever any of the typically sterile sections of the urinary tract are colonized by microbes. UTI may or may not be accompanied by clinically manifest or subclinical disease. In the pig, specific UTI caused by *Actinobaculum suis* (Chapter 9) is distinguished from nonspecific UTI caused by a variety of microbes, the subject of this chapter. According to Liebhold et al. (1995), a nonspecific UTI often predisposes for *A. suis* infection.

UTI is the predominant cause of death in pigs over 1 year of age (Häni et al. 1976). In a survey of culled sows, significant bladder colonization was detected in 17% of the sows, and 80% of the colonized bladders exhibited histological lesions of cystitis (Colman et al. 1988).

Many authors have suggested a relationship between bacteriuria and reproductive disorders, including MMA. Sows developing MMA have a much higher prevalence of UTI in the preceding gestation period than sows with a normal puerperium (Miquet et al. 1990). According to Petersen (1983), examination of urine in late pregnancy allows recognition of sows at risk to develop MMA at a subsequent farrowing. However, similar prevalences of UTI in herds with and without MMA were reported by Becker et al. (1985). Potential pathogenetic relations between UTI and MMA were discussed in detail by Berner (1988).

ETIOLOGY

A. suis is often associated with severe cases of urinary tract disease. Nonspecific UTI may be caused by one or more of a number of bacterial species, often including *E. coli*. In one study of sows with acute urinary tract disease, *A. suis* was the bacterial species most commonly detected, mostly together with two or three other bacterial species, such as *E. coli*, *Streptococcus* sp., *Staphylococcus epidermidis*, *Klebsiella* sp., *Pseudomonas* sp., *Aeromonas* sp., and *Bacteroides* sp. (Stirnimann and Tschudi 1985). *A. suis* was also the bacterial species most commonly detected, mostly in mixed infections, in cases of pyelonephritis (Carr and Walton 1993). In this study, the isolation of large numbers of *E. coli* in the upper urinary tract was associated with linear renal scarring.

In a study of sows with severe acute urinary tract disease, mostly cystitis and often with pyelonephritis, *A. suis* was detected in fewer cases and *E. coli* was the prin-

cipal pathogen, followed by streptococci and *Pseudomonas* (Stirnimann 1984). In another study, half of the sows with a significant bacteriuria but no pyelonephritis were infected with enterobacteria and streptococci but were free from *A. suis* (Liebhold et al. 1995).

In a study of aspirates taken at a slaughterhouse from sow bladders, *E. coli* was the most commonly isolated bacterial species, mostly in pure culture (Colman et al. 1988). *S. aureus*, *S. hyicus*, *E. faecalis*, *E. faecium*, *S. dysgalactiae,* and diverse gram-positive bacteria were also isolated, but to much lesser extent. Cystitis was present in most of the examined bacteriologically positive sows. *A. suis* was not detected in this study.

The urinary tract is a dynamic microbiological ecosystem. Dominant bacterial species change spontaneously in a significant proportion of sows surveyed over prolonged periods (Berner 1990). These changes become more frequent when sows are treated with antimicrobials.

EPIDEMIOLOGY

Nonspecific UTI behaves like a noncontagious infectious disease of endogenous origin. In dogs, *E. coli* isolates from urine and from rectal samples of the same individual show identity in phenotypic and genotypic tests (Low et al. 1988). Corresponding studies with the pig are lacking. The fecal flora may achieve access to the urinary tract more efficiently in females than in males. Under intensive confinement conditions, sows' vulvas are often placed in direct contact with feces (Smith 1983). The dog-sitting position helps to force fecal material into the vagina. Sows resting for long periods void urine at longer intervals. However, housing conditions have not yet been studied with respect to UTI.

The age distribution of UTI favors the concept of continuous exposure to fecal contamination. The prevalence of UTI increases from 18% in young sows with 1–3 litters to 38% in older sows with 7 and more litters (Becker et al. 1985).

PATHOGENESIS

In humans and in dogs colonization of the lower genital tract and of the urinary tract by uropathogenic *E. coli* is greatly facilitated by fimbrial adhesins, particularly Type 1 and P fimbriae (Gyles and Fairbrother 2004). Similarly, P fimbriae and mannose-sensitive hemagglutination indicative of type 1 pili, were found in *E. coli* isolates from the urine of pigs with bacteriuria (de Brito et al. 1999). It is assumed that most agents ascend through the urethra (Smith 1983). Invasion is favored by the short, wide urethra of the female pig, the relaxation of the sphincter muscle in late pregnancy and puerperium, trauma to the urethra and bladder at coitus and parturition, abnormal bacterial colonization of the sinus urogenitalis and the genital organs, incomplete closure of the vulva, and catheterization of the bladder

(Berner 1988). Repeated examination of individual sows led to the conclusion that asymptomatic bacteriuria may temporarily deteriorate to cystitis with spontaneous remission (Berner 1988). Liebhold et al. (1995) assumed that nonspecific infection promotes colonization of the bladder by *A. suis*. Carr et al. (1990) postulate that bacterial colonization leads to shortening and deformation of the ureteric valve and thereby promotes vesicoureteric reflux. The latter could be easily demonstrated postmortem in cases of acute pyelonephritis.

Serum antibody against the infecting *E. coli* strain can regularly be detected in sows with pyelonephritis, less often in sows with cystitis, and rather rarely in sows with asymptomatic bacteriuria (Wagner 1990). *E. coli* strains may persist in the urinary tract despite high antibody concentrations in the urine.

UTI predisposes to MMA in one of several ways (Berner 1988). Ascending invasion of the uterus at parturition and of the mammary glands from contamination of the lying area appears most likely. However, other routes cannot be ruled out. Identical OK serotypes of *E. coli* were found in the urinary bladders and in the uteri of 3 sows and in the bladder and mammary gland of 1 out of 9 sows with MMA killed for postmortem examination (Bertschinger et al. 1977).

CLINICAL SIGNS

In the vast majority of nonspecific UTI cases there are no clinical signs (Berner 1988). Akkermans and Pomper (1980) concluded from an extended field study that sows with a significant bacteriuria tend to wean small litters, have increased intervals between litters, show a lower fertility rate, and exhibit an inferior body condition. In many sows with cystitis, careful observation reveals abnormal urination (Becker et al. 1988). The sows stand in one place before they void urine in small quantities with straining. They are more often seen in a dog-sitting position. Proteinuria, macrohemoturia, and pH increases are more prevalent in sows infected with *A. suis* than with *E. coli* (Liebhold et al. 1995).

Vulval discharge may appear as dried deposits around the vulva, on the underside of the tail, or more often as a pool on the floor underneath the sows (Dial and MacLachlan 1988a). The discharge may be mucoid, mucohemorrhagic, or purulent and is observed most often during the final phase of urination. However, discharge may result from inflammation of any part of the urogenital tract. Significant discharge is more often the consequence of endometritis than of UTI.

Severe pyelonephritis becomes clinically manifest during the first 2 weeks postpartum in 40% of the cases (Stirnimann 1984). Typical cases exhibit a rectal temperature below 38.0°C, a heart rate over 120, polypnoea, cyanosis, ataxia, and more rarely generalized tremor (Stirnimann and Tschudi 1985). The blood concentrations of urea and creatinine are higher than normal.

LESIONS

Berner (1981) examined 118 culled sows for bacteria and lesions. Twenty-six out of 29 sows with a UTI presented a cystitis, and 12 sows presented an additional pyelonephritis.

The gross lesions of cystitis begin as focal or diffuse mucosal hyperemia (Dial and MacLachlan 1988b). Subsequently, there may be mucosal ulceration with fibrinopurulent exudate over affected areas. The bladder wall becomes thickened. Similar lesions occur in the ureters and the renal pelvis if infection ascends the urinary tract. In pyelonephritis the inflammatory process extends into the renal parenchyma. Wedge-shaped foci extend from the distorted pelvis to the cortex. Fibrosis of the kidneys may occur with time.

Microscopic bladder lesions can be found even in sows with nonspecific UTI and no proteinuria. They consist of a prominent goblet cell proliferation and of intraepithelial cysts containing a few granulocytes. The epithelial layer is infiltrated with neutrophils, whereas mononuclear cells dominate in the lamina propria (Liebhold et al. 1995).

DIAGNOSIS

Mere clinical examination of the animal is of little value in the diagnosis of UTI (Stirnimann 1984); urine must be examined in most cases. Bacteriology of the urinary tract is complicated by the presence of the normal flora colonizing the vagina and the distal part of the urethra. Therefore, distinction between contamination and infection is based on the number of bacteria in the urine. A viable count of 10^5 CFU/mL is interpreted as indicative of infection and 10^4 CFU/mL as suspicious. Dip slides (i.e., commercially available slides covered by bacterial culture media) give satisfactory quantitative results (Akkermans and Pomper 1980). Nevertheless, dip slides have the shortcoming that anaerobes such as *A. suis* and slow growers will be missed.

Catheterization of the sow is possible (Stirnimann 1984) but does not circumvent contamination and involves the risk of setting up a new UTI. Voiding can be induced by rousing the sows in the morning before feeding time (Becker et al. 1985). When collecting midstream urine, the attendant should avoid contact with the urine, which may contain zoonotic agents such as leptospires.

Diagnostic test strips are applicable to the urine of pigs, except for nitrite. The sensitivity of the latter test is too low due to the low nitrite concentration in porcine urine (Becker et al. 1985). The most useful parameters are protein, hemoglobin, and pH. In cases due to *A. suis*, the pH is strongly alkaline (greater than 8.5) (Carr et al. 1995). Cytological examination may allow discrimination between bacteriuria, cystitis, and pyelonephritis. The presence and concentrations of antibodies in the urine are not well correlated with the severity of the condition (Wagner 1990). Test strips permit the rapid determination of blood urea (Liebhold et al. 1995). Concentrations greater than 10 mmol/L indicate uremia.

TREATMENT

Nearly all the treatments recommended in the literature are aimed at elimination of the bacteria by antimicrobials. The variable susceptibilities of the diverse bacteria involved and the frequent acquisition of R factors pose considerable problems (Table 38.7). With regard to the observed changes of infecting bacterial species or types in the course of antimicrobial treatments, Berner (1990) recommended the use of either broad-spectrum or combined antimicrobials and suggested intensifying the search for alternative strategies.

Becker et al. (1988) treated 9 sows twice daily for 2 weeks via feed with sulfadimidine 1.0 g, sulfathiazole 1.0 g, and trimethoprim 0.4 g/sow. Significant bacteriuria was present in 2 sows 1 week after the treatment and in 3 sows 7 weeks later. The same substances applied over 4 days gave greatly inferior results. Gentamicin, 2.5 mg/kg body weight, was injected intramuscularly to 15 sows on the first day, followed by 2.0 mg on the next 3 days. One week after this treatment, 10 sows were free of significant bacteriuria. The authors concluded that prolonged treatment should be preferred. Antimicrobial resistance was not checked.

Treatment of severely affected sows was reported by Stirnimann (1988). Injection of ampicillin 3 g/sow daily

Table 38.7.   Sensitivity to antimicrobial agents of significant isolates from porcine UTI in Belgium and Switzerland

| | % Sensitive Isolates | | |
| | Belgium[1] | | Switzerland[2] |
Antimicrobial Agent	Gram-Negative $n = 62$	Gram-Positive $n = 18$	E. coli $n = 21$
Penicillin G	NT[3]	44	NT
Penicillinase-stable Penicillins	NT	72	NT
Ampicillin	68	44	71
Amoxycillin/clavulanic acid	100	72	NT
Streptomycin	40	44	NT
Neomycin	98	61	86
Spectinomycin	85	72	NT
Gentamicin	100	61	100
Tetracycline	47	61	33
Chloramphenicol	82	83	67
Nitrofurane	95	94	14
Sulfonamide	37	50	52
Trimethoprim	76	61	NT
Trimethoprim and sulfonamide	NT	NT	76
Macrolide	NT	61	NT
Lincomycin	NT	72	NT

for 4 days or of the same antibiotic combined with novaminsulfon 10 g/sow was compared. The combined treatment led to a smaller number of emergency slaughters. Subclinical UTI persisted in about half of the successfully treated sows.

Dial and MacLachlan (1988b) concluded that treatment of urogenital infections of swine generally is frustrating.

PREVENTION

Results of long-term prospective studies are not available. Berner (1988) recommended that all pregnant sows be checked repeatedly for UTI and that positive sows be treated with antimicrobials shortly before parturition. Smith (1983) suggested medicating all dry sows on problem farms for 7–10 days at 6-week intervals. The interval between treatments can be increased gradually as experience dictates. Antibiotics such as tetracyclines or a suitable form of penicillin have been successfully used in the diet. In view of the disappointing results reported by Berner (1990), these recommendations should be viewed with caution.

According to Wagner (1990), immunoprophylaxis holds little promise. Thus, Smith (1983) and Carr et al. (1995) recommended the reduction of environmental exposure by improving fecal drainage and housing conditions. These factors as well as the role of water intake should be further investigated. Frequency of urination was increased by giving access to an exercise yard and by increasing water intake, which was achieved by a salt content of 1% in the diet (Smith 1983).

39 Exudative Epidermitis

H. C. Wegener and E. W. Skov-Jensen

Exudative epidermitis (EE) has been known by its clinical signs for over 160 years (Spinola 1842). The classic disease occurs as an acute or peracute infection in suckling and newly weaned piglets in which a generalized epidermitis may lead to dehydration and death. Early occurrence and distribution have been comprehensively reviewed by Jones (1956), who provided a good description of the disease and its effects on production. It has been recorded in most pig-rearing countries in both piglets and weaners. Major studies have been carried out by Sompolinsky (1953), Jones (1956), Underdahl et al. (1963, 1965), L'Ecuyer (1966), L'Ecuyer and Jericho (1966), Hunter et al. (1970), and Wegener and Skov-Jensen (1992). The condition is of sporadic occurrence in all countries but may be of great importance in individual herds, especially in newly established or repopulated herds (Pepper and Taylor 1977).

ETIOLOGY

Staphylococcus hyicus is the causal agent of the generalized form of the disease seen in piglets. Although it is present in profuse culture in lesions in adult pigs, the disease has not been reproduced in that age group. Strains of *S. hyicus* can be divided into virulent and avirulent types with regard to the ability to reproduce EE experimentally in piglets (Wegener et al. 1993). Both types can be present simultaneously on the skin of diseased, as well as healthy, piglets (Park and Kang 1986; Wegener et al. 1993). The production of an exfoliative toxin appears to be the single most important virulence determinant of *S. hyicus* (Amtsberg 1979; Sato et al. 1991; Wegener et al. 1993; Andresen et al. 1993; Andresen et al. 1997). However, a range of other factors may also be necessary, but not sufficient, to render *S. hyicus* capable of causing EE in piglets.

S. hyicus was first described by Sompolinsky (1953) as *Micrococcus hyicus;* it was then defined as a staphylococcus by Baird-Parker (1965). *S. hyicus* was separated into *S. hyicus* subsp. *hyicus* and *S. hyicus* subsp. *chromogenes,* a nonpathogen, by Devriese et al. (1978). *S. hyicus* subsp. *chromogenes* was subsequently elevated to species *S. chromogenes* by Hajek et al. (1986), making *S. hyicus* the taxonomically correct designation for the causal agent of EE. The organism is a gram-positive coccus that forms 3–4 mm porcelain-white nonhemolytic colonies on sheep blood agar after 24 hours' incubation. It is coagulase negative using the slide test and is heat-stable DNase, lipase, and hyaluronidase positive, and mannitol and acetoin negative. These biochemical characteristics are of value in distinguishing the organism by conventional means from other staphylococci found in pigs (Devriese 1977). A selective indicator medium described by Devriese (1977) which utilizes the lipase activity as the indicative principle can be very useful for isolation of *S. hyicus* from pathological samples.

S. hyicus may be isolated from a range of other animals, including ruminants and fowl (Devriese et al. 1978). Phenotypic and genotypic differences from porcine isolates suggest that *S. hyicus* from other animals may belong to separate ecovars (Devriese et al. 1978; Schleifer 1986; Takeuchi et al. 1988). Their virulence with regard to EE is not known.

EPIDEMIOLOGY

EE has been described from all major pig-producing countries, and the incidence has been reported to be increasing in some regions (Anon. 1991; Wegener 1992). This increase may reflect changes in pig production toward larger units, earlier weaning, and higher animal densities. The disease may occur sporadically and with low morbidity among litters in some pig herds, whereas in others it reaches epidemic proportions affecting all litters. This suggests that immunity plays an important part in the cause of the disease in the individual animal as well as in the herd. The significance of immunity in relation to EE has, however, not been thoroughly investigated.

The disease occurs most commonly following the

introduction of carrier animals to a nonimmune herd and affects successive litters of piglets, usually those born to nonimmune sows. All litters in an affected herd may be affected, and up to 70% of affected piglets may die. Outbreaks are usually self-limiting and last for 2–3 months but may persist or recur if nonimmune sows are brought into infected buildings or exposed to infected animals. Outbreaks may start among the weaned piglets, possibly as a result of mixing nonimmune litters and litters of immune carriers, and then spread to the farrowing section of the herd.

S. hyicus can frequently be recovered from the nasal mucosa of healthy pigs, from the conjunctiva, the skin of the snout or ear, and from the vagina in gilts and sows (Hajsig et al. 1985; Wegener and Skov-Jensen 1992). *S. hyicus* strains indistinguishable from those present in the vaginas of sows have been recovered from the skin of their offspring, suggesting that colonization takes place during passage through the birth canal (Wegener and Skov-Jensen 1992).

S. hyicus is very resistant to adverse conditions (as most staphylococci are) and can persist in the environment for long periods. The organism can persist for weeks on fittings and surfaces, and it has been recovered from the air of infected units at levels up to $2.5 \times 10^4/m^3$, suggesting that airborne transmission is possible (Wegener 1992). Other species such as horses, dogs, cattle, goats, and chickens may be of little importance as sources of infection for pigs.

PATHOGENESIS

Application of pure cultures of virulent *S. hyicus* to the scarified skin of a nonimmune pig is sufficient to reproduce the disease (Underdahl et al. 1965; L'Ecuyer and Jericho 1966), but it can also be produced by subcutaneous injection in specific pathogen free (SPF) piglets (Underdahl et al. 1965; Wegener et al. 1993). Conventional animals may be resistant to such applications, suggesting that immunity may be an important protective factor. Studies indicate that other elements of the skin flora, especially other staphylococci, may contribute to this resistance to colonization (Allaker et al. 1988). Trauma from fighting, unclipped teeth, rough bedding, or pen walls leading to exposure of dermis may allow the organism to establish infection, although *S. hyicus* may also be able to penetrate the epidermis directly.

The earliest changes are seen as skin reddening accompanying the multiplication of the organism on the skin surface and its growth between the corneocytes of the epidermis, where microcolonies develop. Inflammation, marked hyperplasia of the stratum corneum, and invasion by neutrophils occur, with an increase in thickness of the epidermis, followed by its erosion. The stratum germinativum becomes disorganized and penetrates deeply into the dermis. Clinical signs develop in gnotobiotic piglets when the number of organisms on the skin ex-

ceeds $10^5/cm^2$ (Allaker et al. 1988). *S. hyicus* may adhere to fibronectin in the dermis by fibronectin-binding proteins on the bacterial surface (Lämmler et al. 1985).

The phagocyte-opsonin system is the pig's first active line of defense against the infection. Many *S. hyicus* strains harbor determinants that may protect them from phagocytosis: protein A, present in the cell wall of most porcine *S. hyicus* strains, reduces opsonization by binding immunoglobulins at the Fc terminal (Takeuchi et al. 1990), and a capsule present in all virulent but not all avirulent strains of *S. hyicus* inhibits phagocytosis by neutrophils and macrophages (Wegener 1990). All porcine *S. hyicus* strains coagulate pig plasma, suggesting a potential for forming aggregates which may increase protection of the bacterium against phagocytosis. In addition, the production of catalase may protect the bacterium from being killed by the phagocytic cells. All of these properties may contribute to overcoming the initial immune response of the piglet.

The most important factor in the pathogenesis is probably the production of an exfoliative toxin of approximately 30 kDa. Crude or purified exfoliative toxin, which is demonstrable in culture supernates of the organism, can reproduce the skin alterations seen in clinical EE when injected subcutaneously in piglet skin locally (Wegener et al. 1993; Andresen et al. 1993; Sato et al. 1991). There are different antigenic variants of the toxin; however, they all seem to exert the same activity in pig skin (Andresen et al. 1997). The effect of the purified toxin is separation of the cells in the epidermis, notably separation of cells in the upper stratum spinosum, allowing for rapid intraepidermal spread of the bacteria (Andresen et al. 1993). Exfoliation of the skin is accompanied by excess sebaceous secretion and serous exudate. *S. hyicus* is present in large numbers in the skin and may be isolated from the draining lymph nodes and blood. The mortality associated with this disease results from dehydration and possibly also septicemia.

Exudative epidermitis shares many similarities with the human infection called the staphylococcal scalded skin syndrome, which is a *Staphylococcus aureus* infection of the skin of neonates. The infection leads to a local or a generalized exfoliation of the epidermis and excessive sebaceous secretion and is caused by strains of *S. aureus* capable of producing exfoliative toxins. Two variants of the toxin are known: ET-A, which is encoded by a gene located on the chromosome, and ET-B, which is plasmid encoded. The exfoliative toxins of *S. aureus* and *S. hyicus* have different species specificity. ET-A and ET-B affect the skin of humans and mice but not pigs, whereas the exfoliative toxin of *S. hyicus* affects pigs and chickens but not mice.

CLINICAL SIGNS

Piglets usually develop the disease between 4–6 days and 5–6 weeks of age. Clinical signs begin with dejection

39.1. *Generalized exudative epidermitis in a 3-week-old piglet.*

and a reddish or coppery skin color. Thin, pale brown scales of exudate develop in the axillae and groin and within 3–5 days spread to all parts of the body and rapidly become dark in color and greasy in texture (Fig. 39.1). The skin of affected piglets often feels hot, the hair coat is matted, and exudate may extend to the eyelashes. Ulcers may occur in the mouth, and separation of horn may occur at the bulbs of the heels. Anorexia and dehydration are features of this disease. Severely affected piglets lose weight rapidly and may die within 24 hours; death usually occurs within 3–10 days. There is no pruritis, and fever is not common.

Not all piglets in a litter are affected to the same extent, and some individuals will suffer from chronic disease in which smaller areas of the body are involved (Fig. 39.2). Mildly affected piglets may have a yellowish skin,

39.2. *A single piglet with generalized exudative epidermitis among only mildly affected or unaffected littermates.*

appear hairy, and have only a few flakes of exudate in the axillae or groin or near facial scratches or damage on the knees or adjacent to badly clipped teeth. Growth depression is marked in survivors, and productivity of the herd may be depressed by up to 35% during an outbreak and up to 9% in the year following infection (Pepper and Taylor 1977). Disease in adults varies in severity but occurs as localized lesions on the back or flanks. Mild forms may appear as brownish areas of EE, but in some cases, there may be ulceration (Smith et al. 1990).

LESIONS

Gross Lesions

Early lesions of the infection include reddening of skin and the presence of a clear exudate. The abdominal skin can be peeled off by slight rubbing. Early lesions are usually present around the mouth, eyes, and ears as well as on the abdomen. Later cases are covered by a thick brownish, greasy, and odorous layer due to dirt and feces sticking to the affected skin. During the recovery phase, the skin is dry and crusted for a period of several days to weeks. The carcasses of pigs that have died from EE are dehydrated and emaciated. The superficial lymph nodes are usually edematous and swollen. Most animals have empty stomachs, and urate crystals may be seen in the medulla of the kidney on section. There is often an accumulation of mucoid or crystalline material in the pelvis of the kidney, and pyelonephritis may be present.

Microscopic Lesions

Early changes of the epidermis are exfoliation, exocytosis, crust formation, and formation of vesicles and pustules classified as an "intraepidermal vesicular and pustular dermatitis." In the later stages, acanthosis (hyperplasia of the epidermis) is observed (Fig. 39.3). In the dermis, perivascular inflammation occurs (Andresen et al. 1993). In histological sections of the skin, bacterial microcolonies may occur in the keratinized layer of the epidermis.

Bacteriology

S. hyicus can usually be isolated from the lesions, from the superficial lymph nodes, and frequently also from the liver and spleen of untreated cases but may be difficult to demonstrate on nonselective culture media if treatment has been given or if secondary infection by *Proteus* sp. and *Pseudomonas aeruginosa* has occurred. The use of a selective indicative agar facilitates isolation of *S. hyicus* from pathological samples (Devriese 1977). Both virulent and avirulent strains of *S. hyicus* can be isolated as mixed cultures from the skin, lymph nodes, and organs of diseased piglets (Wegener 1992). Whether the avirulent strains take any active part in the establishment or course of the infection remains unknown.
39.3. *Histological section of skin of pig with generalized exudative epidermitis (original magnification ×1200). Changes present in the epidermis are exfoliation, exocytosis, crust formation, formation of vesicles and pustules classified as an "intraepidermal vesicular and pustular dermatitis," and acanthosis (hyperplasia of the epidermis). In the dermis, perivascular inflammation can be seen.*

DIAGNOSIS

The clinical signs are generally sufficient to reach a diagnosis in young piglets. The lack of fever or of pruritis and the generalized nature of the lesions, their appearance, and the variation in severity within an affected litter are all features suggestive of the disease. Confirmation may be obtained by histological and bacteriological means. It may be necessary to confirm the identity of the staphylococci isolated as *S. hyicus* by conventional bacteriological means (Devriese 1977) or by use of strip tests such as the Staph-Zym test (Lämmler 1989). These have the advantage of revealing the identity of non–*S. hyicus* staphylococci.

S. hyicus from pigs are very heterogeneous with regard to phago-, sero-, and DNA fingerprinting types (Wegener 1993a; Park and Kang 1987). Diagnosis is complicated by the simultaneous presence of up to 8 different types of *S. hyicus* on diseased piglets. Wegener (1993b) found that each diseased piglet on average harbored 1.9 different phage types and 2.3 different antibiotic resistance patterns among 10 randomly selected isolates of *S. hyicus* recovered from the skin. Only a slightly lower diversity was observed for strains recovered from the liver or the spleen of the animals. In the absence of simple methods to differentiate virulent from avirulent

strains in the diagnostic laboratory, all types of *S. hyicus* should be regarded as potentially virulent. Thus, antimicrobials for therapy which affect all types present should be chosen. Similarly, autogenous vaccines should be prepared from all types present on the diseased animals.

Diagnosis is less easy when the lesions are mild, localized around predisposing lesions such as fight wounds, or have been treated. The demonstration of *S. hyicus* and response to antimicrobials may help confirm uncomplicated disease of this type, but the organism may be present in lesions caused by a number of initiating agents.

Other skin conditions that may be confused with EE include swine pox (localized lesions, rarely fatal), mange (pruritis, demonstration of mites), ringworm (expanding superficial lesions, isolation of fungus), pityriasis rosea (expanding circles, nonfatal, lesions not greasy), zinc deficiency (weaners, symmetrical dry lesions), dermatosis vegetans (inherited in Landrace, fatal pneumonitis), and local wounds such as facial fight wounds and abraded knees in piglets and crate injuries in adults. The organism may be isolated from other pathologic conditions such as arthritis in piglets (Noda and Fukui 1986) and cystitis in sows as well as from the skin of healthy pigs.

TREATMENT AND PREVENTION

Treatment is most successful if carried out early in the disease; severely affected animals may not respond. The effect of systemic treatment is reduction in the severity of the skin lesions, development of only superficial lesions, and promotion of the healing process. *S. hyicus* is frequently resistant to antibiotics. This resistance has been shown to be predominantly mediated by plasmids (Wegener and Schwarz 1993). Combinations of trimethoprim and sulfonamides or lincomycin and spectinomycin have been shown to have good in vitro activity against *S. hyicus* (Wegener et al. 1994). Antimicrobial treatment should be accompanied by the provision of a fluid replacer or at least clean water for affected piglets and by local treatment with antibiotics or skin disinfectants such as cetrimide, hexocil, or Virkon X in order to speed recovery and prevent spread of the infection. Treatment may have to be continued for at least 5 days, and clinically affected piglets may make a slow recovery or remain stunted.

Vaccination of sows with autogenous bacterins made from strains isolated on the affected farm may be of value in protecting the litters of newly purchased sows when given before farrowing. Antibodies can effectively neutralize the effect of the exfoliative toxin in the skin. It is possible that the toxin may be able to serve as a single protective antigen; however, this has not yet been shown under field conditions. Therefore, autogenous vaccines should be prepared from both the bacterial cells and the culture supernatant, which contains the exfoliative toxin.

The incidence of the disease may be reduced by clipping the teeth of litters at risk, by ensuring that pen surfaces are not abrasive, and by providing soft and dry bedding, such as softwood sawdusts or chaffed straw. Sows entering farrowing accommodation should be washed and disinfected and placed in clean, disinfected, or fumigated pens. Prompt treatment of local lesions on both sows and piglets may also help.

40 *Haemophilus parasuis*

Vicki J. Rapp-Gabrielson, Simone R. Oliveira,
and Carlos Pijoan

Once considered a sporadic disease of young pigs compromised by stress, porcine polyserositis and arthritis (Glässer's disease), caused by *Haemophilus parasuis*, has emerged as one of the significant bacterial diseases affecting swine throughout the world. Adoption of new production technologies resulting in high-health-status herds and the emergence of new respiratory syndromes have contributed to an increase in prevalence and severity of the disease. Disease management with antibiotics, vaccination, and other strategies is not always successful in countering production losses due to *H. parasuis* infection. It has long been known that the immune status of a herd is a determinant of pathogenic outcome of infection (Nielsen and Danielsen 1975). However, the heterogeneity among *H. parasuis* strains is striking, and a better understanding of the association of these phenotypic and genotypic differences with virulence potential and protective immunity has emerged in recent years.

ETIOLOGY

Glässer (1910) first reported the association of a small gram-negative rod with fibrinous serositis and polyarthritis of swine. Initially, the causative agent was identified as *Haemophilus suis* by Hjärre and Wramby (1943) and as *Haemophilus influenza suis* by Lecce (1960). The name was changed to *H. parasuis* based on demonstration that the organism did not require X factor (haemin or other porphyrins) for growth (Biberstein and White 1969; Kilian 1976). The taxonomic position of *H. parasuis* within the Pasteurellaceae is still uncertain, due to a lack of nucleic acid homology with other *Haemophilus* species (De Ley et al. 1990; Dewhirst et al. 1992). Taxonomic studies on the NAD-dependent swine Pasteurellaceae based on nucleic acid hybridization or 16s rRNA gene sequencing have led to the classification of 6 bacterial species (Møller at al. 1996). However, considerable genetic, biochemical, serological, and virulence differences exist among strains provisionally clas-

sified as *Actinobacillus minor*, *Actinobacillus porcinus,* and *Actinobacilus indolicus*, indicating that these may represent groups of similar organisms rather than clearly defined species (Kielstein et al. 2001). Considerable genotypic heterogeneity has also been demonstrated among *H. parasuis* strains (Smart et al. 1988; Rapp-Gabrielson et al. 1992a; Blackall et al. 1997; Rafiee et al. 2000; Ruiz et al. 2001; Oliveira et al. 2001b; De la Puente Redondo et al. 2003; Oliveira et al. 2003a). It has been proposed that more than one bacterial species may be represented by strains identified as *H. parasuis* (Morozumi et al. 1986; Dewhirst et al. 1992).

Microscopically, *H. parasuis* cells are small, nonmotile, pleomorphic rods, varying from single coccobacilli to long, thin, filamentous chains. A capsule can usually be demonstrated, but expression is influenced by in vitro culture (Rapp-Gabrielson et al. 1992b). Thus, the significance of reports associating lack of capsule with virulence needs further investigation (Kobisch and Desmettre 1980; Morozumi and Nicolet 1986a; Kielstein 1991). Nicotinamide adenine dinucleotide (NAD, or V factor) is required for growth and can be supplied by heated blood (chocolate agar) or by satellitic growth in the vicinity of a streak of a staphylococcus strain. After 24–48 hours' growth, colonies are small, translucent, and nonhemolytic on blood agar.

The existence of serovars was first reported by Bakos et al. (1952). In subsequent years, expansion of this serotyping scheme by other investigators led to several proposals for new serovars (Schimmel et al. 1985; Morozumi and Nicolet 1986b; Nicolet et al. 1986; Kielstein 1991; Rapp-Gabrielson and Gabrielson 1992). Presently, 15 serovars based on immunodiffusion (ID) are recognized (Kielstein and Rapp-Gabrielson 1992). The type-specific antigen is heat-stable polysaccharide (Morozumi and Nicolet 1986b) presumed to be capsule or lipopolysaccharide (LPS). Although some geographic differences are apparent, serotyping of isolates from Japan, Germany, Australia, the United States, Canada, Spain, and Denmark shows serovars 4, 5, and 13 to be

Sources: Morikoshi et al. 1990; Rapp-Gabrielson and Gabrielson 1992; Kielstein and Rapp-Gabrielson 1992; Blackall et al. 1996; Kielstein and Wuthe 1998; Rúbies et al. 1999; Rafiee and Blackall 2000; del Rio et al. 2003; Oliveira et al. 2003; Tadjine et al. 2004a; Angen et al. 2004.

[a]Differences between the type strains and field isolates for serovars 7 and 10 have been reported and these serovars cannot always be distinguished by ID (Rapp-Gabrielson 1995, unpublished; Blackall et al. 1996; Rafiee and Blackall 2000; Tadjine et al. 2004).

[b]Only tested for *H. parasuis* serovars 1–7.

[c]Typed by Indirect Hemagglutination (IHA).

most prevalent (Table 40.1). Serovar 15, which is of low prevalence in most countries, was identified in 65% of outdoor units in Hungary/Romania/Serbia (Docic and Bilkei 2004). A large percentage of isolates are nontypeable, indicating that some isolates may not express sufficient type-specific antigen, the presence of antigenic diversity within serovars, or the existence of additional serovars. More recently, indirect hemaglutination (IHA) may also be used to serotype *H. parasuis* (del Rio et al. 2003; Tadjine et al. 2004a; Angen et al. 2004). Initial reports indicated that the IHA technique reduced the percentage of nontypeable isolates from 30% to less than 10% compared to ID. However, Turni and Blackall (2005) reported that a similar high percentage of field isolates were nontypeable by ID and IHA. Discordant results were evident for almost 36% of the isolates they examined, and the IHA test did not identify some serovar 4, 5, 13, and 14 field isolates. They recommend that ID be used as the primary typing method, with IHA as a secondary test.

The heterogeneity of *H. parasuis* isolates can also be demonstrated based on genomic fingerprints by Enterobacterial Repetitive Intergenic Consensus polymerase chain reaction (ERIC-PCR) testing (Figure 40.1) (Rafiee et al. 2000; Ruiz et al. 2001; Oliveira et al. 2003a). With this technique, extensive strain variation within serovar groups has been demonstrated. Analysis of strains from the United States identified at least 12 different strains among serovar 4 isolates. The remaining serovar groups contained either 1 (serovar 5), 2 (serovars 1, 3, and 7), 3 (serovars 12 and 14), or 4 (serovar 2) different strains. There was also high genetic diversity among nontypeable isolates, and at least 18 different strains were identified (Oliveira et al. 2003a).
40.1. Haemophilus parasuis *genotyping by means of ERIC-PCR. Three clusters of genetically related strains are shown in the dendrogram (A, B, and C). The scale represents the percent of similarity between strains.*

EPIDEMIOLOGY

The pig is the natural host for *H. parasuis*. This organism is commonly isolated from nasal secretions and tracheal swabs of healthy swine (Bertschinger and Nicod 1970; Harris et al. 1969; Smart et al. 1989; Cu et al. 1998) and from the lungs of pigs with pneumonia, but not generally from normal lungs (Little 1970; Møller et al. 1993). In conventional herds, *H. parasuis* is one of the earliest and most prevalent bacterial isolates from nasal swabs of pigs at 1 week of age (Kott 1983).

Historically, Glässer's disease has been considered a sporadic disease of young swine compromised by stress. However, the epizootiologic picture in specific pathogen free (SPF) or high-health-status herds that represent an immunologically naive population is much different (Nielsen and Danielsen 1975; Baehler et al. 1974; Menard

and Moore 1990). Introduction of *H. parasuis* may result in systemic disease of high morbidity and mortality, affecting swine at any stage of production. In conventional herds that use segregated early weaning (three-site production), late infection with a virulent *H. parasuis* strain can have severe consequences if it occurs when maternal immunity is no longer present. Presently, *H. parasuis* is one of the most serious problems associated with mixing swine from different herds or introduction of new breeding stock into a herd (Smart et al. 1989; Menard and Moore 1990).

There is support for *H. parasuis* as a contributor in the swine respiratory disease complex as a predisposing agent, a secondary invader, or a primary pathogen involved in pneumonia. Demonstration of purulent rhinitis associated with *H. parasuis* colonization supports a possible role as a predisposing factor for other viral and bacterial pathogens (Gois et al. 1983; Vahle et al. 1995, 1997). In pneumonia, *H. parasuis* has often been assumed to be an opportunistic secondary invader, causing disease only in association with other viral or bacterial agents. Such a relationship was evident after accidental infection of pigs experimentally inoculated with pseudorabies virus with *H. parasuis* serovar 4 (Narita et al. 1994). Isolation of *H. parasuis* from pneumonia has increased substantially in recent years and is believed to be associated with the increased prevalence of mycoplasma pneumonia as well as viral respiratory pathogens such as porcine reproductive and respiratory syndrome (PRRS) virus, swine influenza virus, and porcine respiratory coronavirus. *H. parasuis*, in combination with *Mycoplasma hyorhinis*, was isolated from 51.2% of lungs from PRRS-infected swine (Kobayashi et al. 1996). Although an association between PRRS virus and *H. parasuis* appear to be evident in the field, the potential interaction between these two agents has not been substantiated in experimental in vitro or in vivo models (Solano et al. 1997; Cooper et al. 1995; Segalés et al. 1998, 1999). However, Solano et al. (1998) reported that in later stages of infection, pulmonary alveolar macrophages from PRRS virus–infected pigs had a decrease in ability to kill *H. parasuis*. A recent study indicated that pigs harboring a virulent *H. parasuis* strain may develop pneumonia by this agent following PRRS virus challenge (Oliveira et al. 2004d). Several reports support field observations that *H. parasuis* may be a primary agent in pneumonia without the involvement of other pathogens (Pöhle et al. 1992; Barigazzi et al. 1994; Solano et al. 1997; Brockmeier 2004; Müller et al. 2003).

The pathogenic potential of *H. parasuis* strain(s) occurring in a herd is also a factor in the severity and progression of systemic disease. Serovars and strains commonly isolated from upper respiratory sites in swine are not commonly isolated from systemic sites (Bloch 1985; Rapp-Gabrielson 1993; Oliveira et al. 2003a). There may be a subpopulation of *H. parasuis* strains occurring in the respiratory tract that is capable of invading systemi-

Table 40.2. Virulence of strains representing *H. parasuis* serovars for SPF swine

H. parasuis Serovar	No. of Strains Evaluated	Virulence[a]

[a]Swine inoculated intraperitoneally with 5×10^8 colony-forming units.

cally and causing disease (Rapp et al. 1986; Rapp-Gabrielson 1993).

An association between serovar and isolation from polyserositis was apparent in several studies (Bakos et al. 1952; Morozumi and Nicolet 1986b; Kielstein 1991; Oliveira et al. 2003a; Docic and Bilkei 2004). Differences in virulence among serovars were demonstrated by inoculation of SPF or cesarean-derived, colostrum-deprived (CDCD) swine and guinea pigs with strains representing the 15 serovars (Rapp-Gabrielson et al. 1992b, 1995; Kielstein and Rapp-Gabrielson 1992; Nielsen 1993; Amano et al. 1994, 1996). In these studies, strains representing some serovars were highly virulent and strains representing other serovars were of lesser virulence or avirulent. Virulence of field isolates was consistent with that of the reference strain, indicating a causal relationship between serovar and virulence (Table 40.2). However, the demonstration that two serovar 14 strains differed in virulence for CDCD pigs indicates that factors other than serovar contribute to the virulence potential of a strain (Rapp-Gabrielson et al. 1995).

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of whole-cell and outer-membrane (OM) proteins also demonstrates phenotypic heterogeneity among strains (Morozumi and Nicolet 1986a; Rapp et al. 1986; Morikoshi et al. 1990; Rosner et al. 1991; Rapp-Gabrielson et al. 1992a; Ruiz et al. 2001; Oliveira and Pijoan 2004a). These reports indicate a possible association of virulence potential with specific protein patterns, particularly with the presence of 36–38 kDa proteins. However, the precise relationship between protein pattern, serovar, genotype, and virulence potential is complex. Heterogeneity of *H. parasuis* LPS has been demonstrated by SDS-PAGE patterns and immunoblotting with monoclonal antibodies, but LPS patterns have not been associated with virulence (Zucker et al. 1994, 1996; Hueller et al. 1999). Filamentous structures presumed to be fimbriae have been demonstrated on some *H. parasuis* strains, but their role in adhesion or pathogenicity remains to be defined (Münch et al. 1992).

A cell-associated neuraminidase that may function as a virulence factor has been characterized for *H. parasuis* (Lichtensteiger and Vimr 1997, 2003). The future understanding of virulence factors and differences among *H. parasuis* strains lies in newer molecular techniques, such as differential display reverse transcription-polymerase chain reaction (DDRT-PCR), which has recently been used in a search for virulence-associated genes (Hill et al. 2003). The development of new molecular techniques has made significant contributions to an understanding of the epidemiology within a herd and between related herds (reviewed by Oliveira and Pijoan 2004b). Although there is a high genetic diversity among strains affecting unrelated herds, only 2–3 prevalent strains are normally involved in mortality within a herd or related herds (Rafiee et al. 2000; Ruiz et al. 2001; Oliveira et al. 2003a, 2004c). These prevalent strains may persist in affected herds for periods of up to 1 year (Oliveira et al. 2003a, 2004c).

PATHOGENESIS

To overcome the influence of natural infection and maternal antibodies, experimental challenge models using CDCD or naturally farrowed, colostrum-deprived pigs have been developed (Rapp-Gabrielson et al. 1995; Oliveira et al. 2003b). Vahle et al. (1995) examined sequential events in infection by inoculating CDCD pigs intranasally with a virulent strain of *H. parasuis*. Within 12 hours postinoculation, *H. parasuis* was isolated from the nasal cavity and trachea; within 36 hours, from blood cultures; and at 36–108 hours, from systemic tissues. Early colonization of the middle and caudal nasal cavity and trachea was also demonstrated by immunohistochemistry and transmission electron microscopy (Vahle et al. 1997). Colonization was associated with purulent rhinitis, focal loss of cilia, and acute cell swelling within the nasal and tracheal mucosa. In vitro infection of nasal turbinate explants also resulted in marked reduction in ciliary activity and damage to ciliated epithelial cells (Vahle 1996). Bacterial cells were not closely associated with cilia or epithelium, and the mechanism of colonization or cellular destruction was not defined. The observation by these investigators that *H. parasuis* preferentially colonizes the nasal cavity and trachea, and not the tonsil, is in concordance with the ability to isolate *H. parasuis* from the nasal cavity, but not tonsil or lung specimens, from slaughterhouse pigs (Møller et al. 1993). Other studies, however, have demonstrated that *H. parasuis* may not only be isolated from the tonsil of healthy pigs (Oliveira et al. 2001a; Raßbach 1992), but it can also be detected in tonsillar tissue by immunoperoxidase stain and electron microscopic examination (Amano et al. 1994). A recent study suggests that prior infection of the nasal cavity with *Bordetella bronchiseptica* may increase nasal colonization by *H. parasuis* (Brockmeier 2004). However, the role of increased colonization by *H. parasuis* on pathogenesis of infection still remains to be defined.

Mucosal injury may enhance invasion. Microbial and host factors involved with systemic infection are not known; however, the virulence of some strains is remarkable. Intratracheal inoculation of less than 100 colony-forming units of strains representing several serovars caused systemic disease and death in CDCD pigs within a few days (Rapp-Gabrielson et al. 1995). Bacteremia is apparent in pigs in the early stages of infection (Vahle et al. 1995). Septicemic lesions consist of petechiae or ecchymoses in the liver, kidney, and meninges; high levels of endotoxin are detected in plasma, and fibrinous thrombi are present in many organs (Amano et al. 1994). Subsequent replication at multiple serosal surfaces produces the typical fibrinosuppurative polyserositis, polyarthritis, and meningitis observed in field cases (Amano et al. 1994; Vahle et al. 1995). Endotoxin shock and disseminated intravascular coagulation (DIC) may be involved in acute deaths (Amano et al. 1997). Pneumonia was not prominent in one challenge model, even though *H. parasuis* was isolated from the lung (Vahle et al. 1997). Pneumonia was also not evident following inoculation of the reference strains of serovars 1, 4, or 5 (Amano et al. 1994). Differing observations on the ability of *H. parasuis* to produce pneumonia may be due to differences per se in the challenge models, the doses administered, or pathogenic potential of the strains examined.

CLINICAL SIGNS AND LESIONS

Clinical presentation is dependent on the location of inflammatory lesions. In naive herds or pigs, onset is rapid, occurring a few days after exposure. Clinical signs include pyrexia and apathy followed by inappetence and anorexia. Dyspnea, pain (evidenced by squealing), swollen joints, lameness (Figure 40.2A), tremor, incoordination, cyanosis, recumbency, and death may follow. Abortion in gilts and chronic lameness in boars may be sequelae to acute infection. Even if infection of gilts is controlled by antibiotic treatment, pigs in subsequent farrowings may experience severe disease (Menard and Moore 1990). In conventional herds, chronic infections in nursery pigs may result in poorly performing pigs. Cough, dyspnea, weight loss, lameness, and rough hair coat are the primary clinical signs.

Primary macroscopic lesions are a serofibrinous to fibrinopurulent exudate at single or multiple serosal surfaces, including the peritoneum, pericardium, and pleura (Figure 40.2B); articular surfaces, particularly the carpal and tarsal joints, and the meninges may also be involved (Hjärre 1958; Amano et al. 1994). Microscopically, the exudate consists of fibrin, neutrophils, and lesser numbers of macrophages (Figure 40.3) (Vahle et al. 1995). Less commonly, *H. parasuis* infection may result in acute septicemic disease in which cyanosis, sub-
40.2. *Clinical signs and macroscopic lesions characteristic of* Haemophilus parasuis *systemic infection. (A) Lameness. (B) Polyserositis characterized by fibrinous exudate on serosal surfaces (peritoneum and pericardium).*

cutaneous and pulmonary edema, and death can occur without the typical serosal inflammation (Riley et al. 1977; Peet et al. 1983; Desrosiers et al. 1986). Fasciitis and myositis (Hoefling 1991) and purulent rhinitis (Gois et al. 1983; Vahle et al. 1995) have also been reported.

DIAGNOSIS

Diagnosis is usually based on herd history, clinical signs, and necropsy. Bacterial isolation, necessary for confir-

mation, is not always successful. This is due in part to the fragility and fastidious growth requirements of *H. parasuis* relative to other bacteria that may also be present in the specimen. Retrospective analysis of submissions to diagnostic laboratories in Ontario indicate that the true incidence of disease may be tenfold higher than reported, due in part to the inability to confirm the presence of *H. parasuis* from submitted specimens (Miniats et al. 1986). Detection of *H. parasuis* in clinical specimens by PCR or in-situ hybridization is useful for diagnosis when isolation is negative (Segalés et al. 1997; Calsamiglia et al. 1999; Oliveira et al. 2001b; Jung and Chae 2004; Jung et al. 2004). Although these newer molecular techniques may help define the role of *H. parasuis* in the disease process, they are not widely available as diagnostic tools. PCR must be interpreted with caution since the technique does not differentiate between virulent and avirulent organisms. Isolation is still necessary for further characterization of field isolates by serotyping and genotyping (Oliveira and Pijoan 2004b). Necropsies should be performed not only on pigs with severe clinical signs and lesions but also on pigs in the acute phase of disease, prior to administration of antibiotics. Isolation rates are considerably higher when samples are collected from euthanized pigs rather than from pigs found dead (Oliveira et al. 2002). The best chance for isolation is by culturing several serosal surfaces or exudates, cerebrospinal fluid, and heart blood, even if lesions are mild or not apparent. *H. parasuis* can be recovered from these fluids when inoculated into a transport medium prior to shipment to the diagnostic laboratory (Mendez-Trigo and Trigo 1996; del Rio et al. 2003a). Although somewhat laborious for routine diagnosis, special dilution techniques followed by plating on selective media containing antibiotics have been used successfully for culturing *H. parasuis* in high numbers from

Note: *A. minor* was formerly known as *Haemophilus* taxon "Minor Group"; *A. porcinus* was formerly known as *Haemophilus* sp. taxons D or E; *A. indolicus* was formerly known as *Haemophilus* sp. taxon F. Taxon C has infrequently been isolated from swine.

Key: + indicates greater than 90% of isolates are positive; −, less than 10% of isolates positive; ±, variable reactions among isolates.

respiratory specimens (Møller and Kilian 1990; Møller et al. 1993; Kirkwood et al. 2001). The use of defibrinated horse blood and tryptose blood agar base, rather than bovine or sheep blood and trypticase soy agar, also appears to enhance growth.

Biochemical tests are required to distinguish *H. parasuis* from other NAD or V factor–dependent organisms belonging to the family *Pasteurellaceae* that have been isolated from swine (Table 40.3). Occasionally misidentified as *H. parasuis*, these other NAD-dependent organisms are present in high numbers in the nasal cavity, tonsils, or lungs and are generally believed to be of low pathogenic potential (Møller and Kilian 1990; Møller et al. 1993; Chiers et al. 2001). However, recent analysis of *A. minor, A. porcinus*, and *A. indolicus* strains indicate that it is not uncommon for these organisms to be isolated in pure culture from lungs with inflammatory changes and that their possible role in respiratory disease should be reevaluated (Kielstein and Wuthe 1998; Kielstein et al. 2001).

Several different strains, distinguishable by genotype or serovar may be present in a herd, or even in different specimens from a single pig (Smart et al. 1989; Rapp-Gabrielson and Gabrielson 1992; Rapp-Gabrielson 1993; Kirkwood et al. 2001; Oliveira et al. 2003a). Thus, recovery from systemic sites or gross lesions is the only assurance that the isolate obtained is involved in the disease process. Serotyping and genotyping, critical to an understanding of the epidemiology of the disease outbreak and immune response to infection or vaccination, are available only at a few diagnostic laboratories.

Differential diagnosis should include septicemic bacterial infections caused by *Streptococcus suis, Erysipelothrix rhusiopathiae, Actinobacillus suis, Salmonella choleraesuis* var. kunzendorf, and *Escherichia coli. Mycoplasma hyorhinis* polyserositis and arthritis in 3–10-week-old pigs produces lesions similar to *H. parasuis*. The signifi-

cance of *H. parasuis* in bronchopneumonia can be ascertained only after identification of other viral and bacterial pathogens that may be involved in the multifactoral disease process.

TREATMENT

Prophylactic use of antibiotics or therapeutic oral medication may be of little value in severe *H. parasuis* outbreaks (Madsen 1984; Wiseman et al. 1989; Menard and Moore 1990). High antibiotic doses should be administered parenterally as soon as clinical signs have manifested, and all pigs in the affected group, not just those showing signs, should be treated (Desrosiers et al. 1986). Penicillin has been considered the drug of choice, but one study reported an increasing resistance to penicillin has been reported (Kielstein and Leirer 1990). Most *H. parasuis* strains are also sensitive in vitro to ampicillin, ceftiofur, ciprofloxacin, enrofloxicin, erythromycin, florphenicol, gentamicin, spectinomycin, tiamulin, tilmicosin, and potentiated sulfas (Kielstein 1985; Trigo et al. 1996; Vonaltrock 1998; Wissing et al. 2001; Aarestrup et al. 2004). In some regions, a number of strains show higher resistance to tetracycline, erythromycin, streptomycin, kanamycin, gentamicin, sulfonamide, and lincosamide (Trigo et al. 1996; Wissing et al. 2001). Oral amoxicillin, either administered through the water or as a feed additive, may be the drug of choice, but is effective mostly when given before clinical signs become apparent.

PREVENTION AND IMMUNITY

Because nasal mucosa of baby pigs may be colonized before 1 week of age, elimination of *H. parasuis* by early weaning alone is unlikely to be successful. Clark et al. (1994) evaluated several medicated early-weaning strate-

gies and found that *H. parasuis* could be eliminated only when parenteral and oral administration of high doses of antibiotics to baby pigs was a part of the treatment. Elimination of *H. parasuis* from a herd may not be desirable, inasmuch as subsequent mixing of naive pigs with pigs harboring *H. parasuis* during later stages in production may result in a disease course with devastating economic losses. Introduction of new breeding stock from a herd with a different health background should include isolation and acclimation periods long enough to allow for development of protective immunity from either vaccination or natural exposure.

Maternal and natural immunity are critical factors for controlling the disease process (Nielsen and Danielsen 1975; Blanco et al. 2004). Swine previously exposed to nonpathogenic *H. parasuis* strains develop resistance to subsequent challenge with virulent strains (Nielsen 1993). Vaccination of gilts resulted in protective maternal immunity for up to 4 weeks when weaned piglets were challenged with the same serovar contained in the bacterin (Solano et al. 1998; Solano-Aguilar et al. 1999; Baumann and Bilkei 2002; Hoffmann and Bilkei 2002). Because of the septicemic nature of the disease, antibodies are probably a major protective immune mechanism. Tadijine et al. (2004b) characterized two mononoclonal antibodies that recognized an OM protein epitope or an LPS-associated polysaccharide epitope, both of which were common to all *H. parasuis* isolates. They demonstrated that both antibodies were involved in protecting mice against lethal infection and that antibodies to these same epitopes occurred in sera from naturally infected swine.

Controlled exposure has been proposed as an alternative technique to control disease in the field (Pijoan et al. 1997; Oliveira et al. 2001a, 2004c). The main objective of this technique is to expose young piglets to a low dose of the prevalent *H. parasuis* strains involved in herd mortality while pigs are still protected by maternal immunity, thus allowing the piglet to develop natural immunity. Although this technique has been shown to effectively reduce nursery mortality, there are legitimate concerns regarding the safety of exposing young pigs to live, virulent *H. parasuis*. Sow vaccination may reduce the risks of systemic infection in exposed piglets. Concurrent PRRS virus infection may predispose pigs to systemic infection by the *H. parasuis* strain used for colonization (Oliveira et al. 2004d).

There are numerous reports of successful disease control by vaccination with commercial or herd-specific (autogenous) bacterins (Nielsen and Danielsen 1975; Riising 1981; Wiseman et al. 1989; Menard and Moore 1990; Schimmel et al. 1992; Kirkwood et al. 2001; Takahashi et al. 2001). There are also instances where bacterins are not efficacious, and these may be due to lack of cross-protection for the strain or serovar involved in the disease process or when the timing of vaccination is inappropriate. Cross-protection against other virulent strains is not always evident in experimental challenge models (Miniats et al. 1991; Kielstein and Raßbach 1991; Rapp-Gabrielson et al. 1997). Although cross-protection is primarily a concern for commercial bacterins, autogenous bacterins may also lack efficacy because of the presence of more than one strain or serovar or the subsequent introduction of a new strain into the herd. Several factors should be taken into account when selecting isolates to be included in autogenous bacterins. Isolates recovered from systemic sites are preferred and genotyping can be used to define the clusters of genetically related strains affecting the herd. A representative isolate from each prevalent cluster should be included in the autogenous bacterin. Isolates recovered from new clinical cases should be genotyped and compared with those included in the vaccine (Oliveira et al. 2002, 2004c).

Efficacy of vaccination against challenge with different strains of the same serovar, as well as cross-protection against some heterologous serovars, has been demonstrated. A commercial bacterin containing *H. parasuis* serovars 4 and 5 has been shown to protect against experimental challenge with strains representing serovars 12, 13, or 14, but not against serovar 2 (Rapp-Gabrielson et al. 1996, 1997). Lack of cross-protection between serovar 2 and 5 bacterins was also reported by Takahashi et al. (2001). A bacterin containing *H. parasuis* serovar 5 that is commercially available in Europe showed some cross-protection against serovars 1, 12, 13, and 14 (Bak and Riising 2002).

Strains representing nine serovars, as well as nontypeable strains, have been demonstrated to be virulent. Demonstration that virulent strains may not protect against challenge with different strains of the same serovar, or even against challenge with the homologous strain, indicates that the protective antigens may not be identical to the virulence factors or the type-specific antigens (Kielstein and Raßbach 1991; Rapp-Gabrielson et al. 1997). Because of the heterogeneity of strains with pathogenic potential and the current lack of understanding of protective antigens and virulence factors, it is unlikely that any bacterin will provide cross-immunity against all strains of etiologic significance in the swine population. Control programs may include vaccination and antibiotic treatments but also should address management practices to reduce or eliminate other respiratory pathogens, tighten weaning age and pig flow, and eliminate mixing of pigs at all stages of production.

41 Leptospirosis

W. A. Ellis

Leptospirosis is a cause of reproductive loss in breeding herds and has been reported in swine from all parts of the world; however, knowledge of the incidence and economic impact of the disease is largely confined to the intensive pig industries of the Northern Hemisphere, Australia, New Zealand, Argentina, and Brazil.

Endemic infection in a herd of swine may produce little evidence of clinical disease, but when it is first introduced into a susceptible breeding herd, or during periods of waning herd immunity, it can cause very appreciable losses through abortion, the full-term birth of dead pigs or of weak pigs of reduced viability, or infertility.

Leptospires persist in the kidneys and genital tracts of carrier swine and are excreted in urine and genital fluids. Survival outside the host is favored by warm, moist conditions. Transmission is by direct or indirect contact with a carrier animal.

Interruption of transmission from an infected pig or other host to the pig is the critical factor in control.

Leptospirosis is an occupational zoonosis of those who work with pigs.

ETIOLOGY

Leptospirosis of swine is a disease caused by a variety of morphologically similar, but antigenically and genetically distinct, small, motile, aerobic spirochetes belonging to the genus *Leptospira*. They are thin, helical, motile, gram-negative organisms that are often hooked at one or both ends. They spin constantly on their long axis. They range in length from about 6 to 20 μm, with an amplitude of approximately 0.1–0.15 μm and a wavelength of about 0.5 μm. Under adverse nutritional conditions, leptospires may be greatly elongated, whereas under conditions such as high salt concentrations or in aging culture or tissues, leptospires may form coccoid forms of about 1.5–2 μm in diameter (Faine 1994). They divide by binary fission. They stain poorly with aniline dyes. Unstained cells are visible only by dark-field microscopy. In a suitable liquid environment, motility is

accomplished by rotating along the long axis, but this changes to an undulating action in semisolid media. They require special media containing mammalian serum or albumin for cultivation.

The major structural components are an outer envelope, which surrounds a cell wall or peptidoglycan complex, and two polar endoflagella (originating subterminally at each end).

The taxonomy of the leptospires has been through a period of change which continues to cause considerable confusion to those not intimately acquainted with the subject. Until recently a single genus *Leptospira* was recognized in the family *Leptospiraceae*. Two groupings were recognized within the genus: those found in animal species (the parasitic strains) and those found in water (the saprophytic strains). These two groupings, which were referred to as the *interrogans* and *biflexa* complexes, can be differentiated by their growth requirements and biochemical reactions. Only the parasitic strains are of medical and veterinary interest.

For taxonomic purposes and as an aid to epidemiological studies, the parasitic leptospires were divided into serogroups on the basis of antigenic relationships as determined by cross-agglutination reactions and were further subdivided into serovars by agglutination-absorption patterns. About 23 serogroups are recognized, containing approximately 212 serovars.

The advent of genetic typing methods has provided rapid, reproducible typing protocols. The current recommendations on the taxonomy of leptospires (Ellis 1995) recognized eight species of pathogenic leptospires within the family *Leptospiraceae*. They are *Leptospira interrogans, L. borgpetersenii, L. inadai, L. kirschneri, L. noguchii, L. meyer, L. weilii,* and *L. santarosai.*

The species definition is based on a level of DNA-DNA homology of at least 70% and 5% or less divergence in DNA relatedness. Taxonomy at the subspecific level continues to be based on serovars as defined by Dikken and Kmety (1978), but other valid methods which give results comparable to conventional serotyp-

ing can be used for their identification. Such methods include monoclonal antibody agglutination profiles, factor analysis, and analyses in which restriction-fragment length polymorphisms or rRNA gene restriction patterns are used in pulsed-field gel electrophoresis analyses. The term "type" is used to indicate strain differences at the subserovar level (Ellis 1995).

Molecular Biology

The genus *Leptospira* is characterized by a guanine plus cytosine (G+C) ratio of 35–41 mol% in its chromosomal DNA, depending on species. The published genome size has varied between 3100 and 5000 kb depending on the techniques used to measure it and reflecting differences between strains. The *Leptospira interrogans* serovars *icterohaemorrhagiae* and *pomona* have two circular chromosomes: the large (4400–4600 kb) and the small (350 kb) replicons are regarded as chromosomal because the essential asd gene is located on the smaller unit. *Leptospira interrogans* strains contain two 23S and 16S rRNA genes but only one 5S rRNA gene. The 5S rRNA gene is highly conserved among the pathogenic leptospires.

There are differences in the global distribution of some of the *Leptospira* species: *L. interrogans, L. borgpetersenii,* and *L. kirschneri* have a worldwide distribution, whereas *L. noguchii* and *L. santarosai* are found mainly in North and South America, and *L. weilii* is found mainly in China and eastern Asia. Strains that cause disease in pigs are found mainly in the *L. interrogans* and *L. borgpetersenii* species.

EPIDEMIOLOGY

The epidemiology of swine leptospirosis is potentially very complicated, since swine can be infected by any of the pathogenic serovars. Fortunately, only a small number of serovars will be endemic in any particular region or country. Furthermore, leptospirosis is a disease that shows a natural nidality, and each serovar tends to be maintained in specific-maintenance hosts. Therefore, in any region, pigs will be infected by serovars maintained by pigs or by serovars maintained by other animal species present in the area. The relative importance of these incidental infections is determined by the opportunity that prevailing social, management, and environmental factors provide for contact and transmission of leptospires from other species to pigs.

Pigs act as maintenance hosts for serovars belonging to the *Pomona*, Australis, and *Tarassovi* serogroups, while strains belonging to the *Canicola, Icterohaemorrhagiae,* and *Grippotyphosa* serogroups are among the more commonly identified incidental infections in swine.

Pomona Infection

Serovar *pomona* has been the most common serovar isolated from pigs worldwide. Infection with this serovar has been extensively studied and it provides a suitable model with which to illustrate general concepts of swine leptospirosis. Many strains of serovar *pomona*, especially those of type kennewicki found in the United States and Canada, are adapted to swine. Serovar *pomona* has been the cause of widespread clinical disease in swine in North and South America, Australia, New Zealand, parts of Asia, and Eastern and Central Europe and is endemic in many of these regions. Such strains are apparently absent from the more westerly parts of Europe. Furthermore, not all strains of serovar *pomona* are adapted to pigs nor are the other serovars of the *Pomona* serogroup, but they have rodent hosts (Sebek et al. 1983).

In parts of North America, the prevalence of *pomona* infection in pigs has fallen from the high levels observed in the 1950s and early 1960s: no carriers were detected in a 1989 meat-plant survey carried out in Iowa (Bolin and Cassells 1992). In contrast, Baker et al. (1989) recovered serovar *pomona* (type kennewicki) from almost 10% of pigs in a small survey in Canada.

Leptospires have a particular affinity for the kidneys of infected pigs, where they persist, multiply, and are voided in urine. This characteristic is very important in the transmission of infection.

Infection is introduced into a susceptible herd by three possible routes: the introduction of infected stock, exposure to a contaminated environment, or contact with an alternative infected animal vector (Hathaway 1983). Carrier pigs are probably the most common route of introduction. Replacement gilts (Edwards and Daines 1979) or infected boars (Kemenes and Suveges 1976) have been identified as important means of introducing infection.

The importance of free-living species as possible sources of *pomona* infection of pigs depends on geographical location. In North America, the skunk has been incriminated as a source of *pomona* outbreaks in pigs (Mitchell et al. 1966).

Once *pomona* has been introduced into a pig population, a high prevalence of infection is established. Only low infective doses are required to transmit infection (Chaudhary et al. 1966a, b). If direct contact is prevented, indirect contact through contaminated effluent, water, or soil ensures transmission (Michna 1970; Buddle and Hodges 1977; Kingscote 1986). The presence of moisture is critical for indirect transmission; the organisms cannot withstand dessication, but when infected urine is deposited in damp soil or water with a pH around or slightly on the alkaline side, the organisms may survive for extended periods (Mitscherlich and Marth 1984).

During the initial herd infection, clinical disease may occur in all ages of sows.

Following the initial establishment of infection, an endemic cycle typical of that in a maintenance host population is set up (Hathaway 1981). Piglets are passively protected in the first weeks of life by colostrum-

derived immunoglobulins from infected dams (Fish et al. 1963; Bolt and Marshall 1995a). The duration of this passive protection depends primarily on the quantity of immunoglobulins received in colostrum (Chaudhary et al. 1966b). A study of grower pigs in New Zealand has shown that leptospiral infection becomes apparent in piglets from 12 weeks of age, and by slaughter up to 90% may be infected. The intensity of leptospiruria is greatest in the first 3–4 weeks of infection, after which it declines and becomes intermittent (Bolt and Marshall 1995a, b). Infection between groups of fattening pigs is often by urine-contaminated effluent from a common drainage system (Buddle and Hodges 1977).

In herds with endemic infection, clinical disease is usually restricted to gilts that either have been reared in isolation since weaning and reintroduced into the herd or, more commonly, have been brought in from an uninfected herd.

Tarassovi Infection

There is much less information available on the epidemiology of *tarassovi* infection in pigs. The pig acts as a maintenance host for some strains of *tarassovi* found in Eastern Europe and Australia. In these regions, it does not spread as rapidly in a pig population as does *pomona* (Kemenes and Suveges 1976), but endemic infection is readily maintained (Ryley and Simmons 1954b; Kemenes and Suveges 1976).

Many strains of *tarassovi* have been recovered from free-living animals (Anon. 1966, 1975) and these may give rise to incidental pig infections. For example, *tarassovi* has not been recovered from swine in the United States, but there is serologic evidence of infection in pigs (Cole et al. 1983) in the southeastern states, where it has been isolated from racoons, skunks, and opossums (McKeever et al. 1958; Roth 1964).

Australis Infection

Serovar *bratislava* and to a lesser extent the closely related serovar *muenchen* have emerged as major swine-maintained leptospiral infections in the last few years. Serologic data have indicated widespread *bratislava* infection in Germany (Weber and Fenske 1978), the United Kingdom (Hathaway and Little 1981; Hathaway et al. 1981), Czechoslovakia (Propopcakova et al. 1981), the Netherlands (Bercovich et al. 1983), Sweden (Sandstedt and Engvall 1985), Denmark (Jensen and Binder 1989; Nissen 1989), the United States (Hanson 1985, 1987), Canada (Kingscote 1988), Austria (Loimayr 1990), Australia (Chappel et al. 1992), Brazil (Oliveira et al. 1994), and South Africa (Potts et al. 1995). There is, as yet, no information from Russia but it would be reasonable to assume that infection is now present in all major pig-rearing countries.

Serovar *bratislava* was first recovered from a pig in the Netherlands by Hartmann et al. (1975) (Ellis 1992) and has now been recovered from pigs in the United

Kingdom (Ellis et al. 1986a, b, c), the United States (Ellis and Thiermann 1986; Bolin and Cassells 1990, 1992), and Germany (Schonberg et al. 1992).

The epidemiology of these strains is poorly understood. There are specific pig-adapted strains, strains that are maintained by pigs, dogs, horses, and hedgehogs, and strains that are found only in wildlife.

Two very distinct serologic profiles may be seen in endemically infected herds. In indoor sow units infected with pig-adapted strains of *bratislava*, the prevalence of sows with antibody titers of greater than 1:100 in the microscopic agglutination test (MAT) is usually very low, although many sows will have titers of less than 1:100. This is thought to result from infection being primarily due to venereal transmission. In contrast, in units where the sows are kept outside, the seroprevalences (≥1:100) may be greater than 50%. This is thought to be due to the sows being infected systemically as a result of exposure to infected rodent urine.

Although the renal-carrier state does become established, urinary excretion is poor compared with *pomona* excretion, and transmission within the fattening house is inefficient. Important additional carrier sites have been identified, namely, the upper genital tracts of sows and boars (Ellis et al. 1986b, c; Power 1991; Bolin and Cassells 1992). Venereal transmission is thought to play an important role in the spread of *bratislava* infection.

Canicola Infection

Although organisms belonging to the *Canicola* serogroup have been recovered from swine in at least 11 countries (Hanson and Tripathy 1986), little is known of the epidemiology of *canicola* infection in pigs. The dog is the recognized maintenance host for this serovar and is the probable vector whereby this serovar enters a piggery, although a report from Peru (Paz-Soldan et al. 1991) incriminates wildlife as the source of an outbreak in sows. The long period of leptospiruria observed in infected pigs (at least 90 days) (Michna 1962) and the ability of *canicola* to survive for up to 6 days in undiluted pig urine (Michna 1962) suggest that there would be an opportunity for intraspecies transmission, but no studies have been done on this subject (Hathaway 1983).

Icterohaemorrhagiae Infection

Serologic evidence of *Icterohaemorrhagiae* serogroup infection has been reported in many countries but few isolations have been made from pigs (Hathaway 1985). It appears that both serovars *copenhageni* and *icterohaemorrhagiae* may be involved. The maintenance host for these serovars is the brown rat (*Rattus norvegicus*), and it is probable that *copenhageni* and *icterohaemorrhagiae* are introduced to susceptible stock via an environment contaminated with infected rat urine. Field investigation suggests that transmission between swine is inefficient (Hathaway 1985). Schnurrenberger et al. (1970) found that urinary excretion lasted less than 35 days in natu-

rally infected pigs, while Fennestad and Borg-Petersen (1966) failed to demonstrate leptospiruria in experimentally infected pigs. Low prevalences of renal infection have been found in those microbiological surveys in which Icterohaemorrhagiae strains have been recovered; Hathaway et al. (1981) reported a 0.7% prevalence in England, and McErlean (1973) found a 0.4% prevalence in Ireland. It is believed, in the absence of supporting isolation data, that vaccine-induced antibodies are responsible for the seroprevalences of *icterohaemorrhagiae* observed in the United States.

Grippotyphosa Infection

Serovar *grippotyphosa* infection is maintained by wildlife hosts, and incidental infection of pigs gives rise to low prevalences of antibodies in swine in various regions, particularly Eastern and Central Europe and the United States. It has been recovered from pigs in the former USSR (Gorshanova 1964) and the United States (Hanson et al. 1965, 1971).

Hardjo Infection

Serovar *hardjo* infection is maintained by cattle worldwide, and where cattle and pigs come in close contact, the opportunity arises for infection in pigs to occur. There are now reports of the isolation of *hardjo* from pigs in the United Kingdom (Hathaway et al. 1983; Ellis et al. 1986a) and the United States (Bolin and Cassells 1992). Persistence in renal tissue was not a feature of experimental infection (Hathaway et al. 1983); therefore, intraspecies transmission is unlikely.

Sejroe Infections

Serovar *sejroe,* which is maintained by small rodents, has also been isolated from swine in Europe (Brandis 1956; Fuzi et al. 1957; Combiesco et al. 1958), and another serovar in this group (serovar *balcanica*) has been recovered from swine in the former USSR (Matveeva et al. 1977).

PATHOGENESIS

The most important route of natural infection has not been determined; however, it is thought to be via the mucous membranes of the eye, mouth, or nose (Alston and Broom 1958; Alexander et al. 1964; Michna and Campbell 1969). Infection via the vaginal route is also possible (Ferguson and Powers 1956; Chaudhary et al. 1966a). Transmission of leptospires through milk from an infected dam has been demonstrated experimentally (Tripathy et al. 1981). A period of bacteremia, which may last for a week, begins 1 or 2 days after infection. During this period leptospires can be isolated from most organs of the body and also from cerebrospinal fluid. This primary bacteremic phase ends with the appearance of circulating antibodies, which are detectable usually after 5–10 days (Hanson and Tripathy 1986). A secondary bacteremic period (after 15–26 days) has been reported in experimental *hardjo* infection (Hathaway et al. 1983).

Antileptospiral agglutinins appear at detectable levels in the blood at approximately 5–10 days after infection and reach maximum levels at around 3 weeks (Ryley and Simmons 1954b; Ferguson and Powers 1956; Morse et al. 1958). Peak titers vary considerably (1:1000 to 1:100,000 in the MAT), and these may be maintained for up to 3 weeks, after which a gradual decline occurs. Low titers may be detectable for several years in many animals.

Following the period of leptospiremia, the leptospires localize in the proximal renal tubules, where they multiply and are voided in the urine. The duration and intensity of urinary shedding vary from pig to pig and with the infecting serovar. In the case of *pomona* infection, the intensity of excretion is highest during the first month of shedding, when more than a million leptospires may be present in each milliliter of urine (Morse et al. 1958); leptospiruria is very constant during this period (Hodges et al. 1979). A variable period of intermittent, low-intensity leptospiruria then ensues, and this may last for up to 2 years in some cases (Ryley and Simmons 1954a; Morse et al. 1958; Mitchell et al. 1966). Low levels of antibody may be detected in the urine of pigs (Morse et al. 1958), but the immunologic mechanism whereby infection is ultimately eliminated from the kidneys is not known.

Leptospires also localize in the uterus of pregnant sows, and abortion, production of stillborn pigs, and neonatal disease frequently result from intrauterine infections occurring in the last half of the gestation period. Abortions and stillbirths usually occur 1–4 weeks following infection of the gilt or sow (Hanson and Tripathy 1986), by which time most sows have developed detectable antibody titers. Since pig fetuses are capable of producing antibodies during the latter stages of gestation, some stillborn piglets will have detectable titers.

The pathogenesis of reproductive disease is poorly understood, but some authors believe that transplacental infection, occurring during the very limited period of maternal leptospiremia, is the sole cause (Fennestad and Borg-Petersen 1966). While this may be true for systemic infections such as *pomona*, the low antibody titers detected in sows aborting *bratislava*-infected fetuses has led to the hypothesis that infection occurs as a result of waning uterine immunity being unable to prevent transplacental infection by leptospires present in the genital tract. The possibility of transplacental infection during leptospiremia appears to increase with the stage of pregnancy (Wrathall 1975). From midpregnancy onward, it is likely that the majority of fetuses in a litter at risk will become infected. Fennestad and Borg-Petersen (1966) have suggested that horizontal transmission to littermates not infected during the period of maternal leptospiremia may also occur. Once the placental barrier is breached, septicemia results in large numbers of leptospires in all fetal tissues (Preston and Morter 1960). It is unlikely that placental insufficiency plays a role in

fetal death (Wrathall 1975); abortion is probably initiated by toxic products released from dead and autolyzing fetuses.

An additional feature seen in *bratislava* infection but not reported for the other swine leptospiral infections is the persistence of leptospires in the oviduct and uterus of nonpregnant sows (Ellis et al. 1986c; Ellis and Thiermann 1986; Bolin and Cassells 1992) and in the genital tracts of boars (Ellis et al. 1986b).

CLINICAL SIGNS

The vast majority of swine leptospiral infections are subclinical. Two groups of pigs are most likely to experience clinical infections: the young piglet and the pregnant sow.

Acute Leptospirosis

This phase usually coincides with the period of bacteremia (Morse et al. 1958; Sleight and Lundberg 1961; Chaudhary et al. 1966a, b). In experimental infections, many pigs exhibit transient anorexia, pyrexia, and listlessness at this time (Hanson and Tripathy 1986). However, the mild nature of these signs means that in natural infections, especially in endemically infected herds where perhaps only one or two animals may be affected, this phase of infection usually goes unrecognized.

There have been a few reports of jaundice and hemoglobinuria in naturally occurring outbreaks (Ferguson et al. 1956), particularly in cases of infection in piglets under 3 months of age by strains belonging to the Icterohaemorrhagiae serogroup (Klarenbeek and Winsser 1937; Field and Sellers 1951; Urban and Androsov 1976). A high proportion of these undergo spontaneous recovery within a week of when symptoms develop. The small number of such reports suggests that this more severe form of disease is rare.

Chronic Leptospirosis

Abortions, stillbirths, and the birth of weak piglets of reduced viability are primary signs of chronic leptospirosis, particularly *pomona* infection, in pigs (Bohl et al. 1954; Fennestad and Borg-Petersen 1966) and it is this aspect of leptospirosis that can cause considerable economic loss. Weak litters have been reported as a feature of Icterohaemorrhagiae infection (Neto et al. 1997).

Information as to the importance of leptospirosis as a cause of abortion in national swine herds is not available, and if it were, it must vary from country to country depending on prevalence, epidemiological, and management factors, including the implementation of control measures. From the limited information available, it would appear that even in countries where vaccination has been widely practiced, leptospirosis is a common cause of swine abortion. In Ontario, for example, 6% of swine abortions were attributed to *pomona* infection (Anon. 1986). Endemic *tarassovi* infection was consid-

ered to be the cause of a 3% abortion rate in herds in Poland investigated by Wandurski (1982). Acute outbreaks can still give rise to severe losses; Saravi et al. (1989) described an outbreak in a herd in which 19% of pregnant sows aborted, while the number of dead piglets/sow rose from 8% prior to the outbreak to 28% during the outbreak. Differences in strain pathogenicity also contribute to different prevalences of clinical abortion in infected herds (Nagy 1993).

A very high prevalence of serovars belonging to the Australis serogroup has been observed in aborted pig litters in part of the United Kingdom. Ellis et al. (1986a) isolated either serovar *bratislava* or *muenchen* from 71% of the litters they examined. Similar strains have also been recovered from aborted piglets in the United States (Bolin and Cassells 1990), where a high prevalence in aborted fetuses has also been noted (Bolin et al. 1991). Rehmtulla et al. (1992) reported fetal *bratislava* infection following abortions in 16% of sows in a herd in Ontario. Egan (1995) reported fluorescent antibody test (FAT) positive prevalences ranging from 5% to 23% in diagnostic submissions in Ireland. Published experimental evaluations of the significance of such microbiological findings are not available. There has, however, been an absence of significant isolations of other abortifacient agents from these cases, and the farrowing rate and the number of live piglets born/sow improve significantly following either *bratislava* vaccination (Frantz et al. 1989) or the use of an antibiotic medication program (Ellis 1989). Van Til and Dohoo (1991) failed to demonstrate a relationship between positive serology and stillbirths.

Following abortions due to *pomona*, there does not appear to be any subsequent limitation on reproductive performance, even in pigs that remain infected for long periods (Ferguson and Powers 1956; Mitchell et al. 1966; Kemenes and Suveges 1976).

Infertility is a feature of *bratislava* infection. An analysis of serologic and clinical data by Hathaway and Little (1981) has shown a statistically significant relationship between Australis serogroup titers and infertility in sows. Similar associations have been observed by Jensen and Binder (1989) and Van Til and Dohoo (1991). Split-herd trials, carried out using a *bratislava* bacterin, have demonstrated significant improvements in sow fertility (Frantz et al. 1989).

LESIONS

The main pathological changes are essentially the same for all infections, with the primary lesion being damage to the membranes of the endothelial cells of small blood vessels.

In acute leptospirosis there are no pathognomonic gross changes. Pathological changes in acute *pomona* infection are very limited, reflecting the mild nature of acute clinical disease. Hanson and Tripathy (1986) re-

ported little gross or histopathological change in swine killed during the acute phase of leptospirosis. Burnstein and Baker (1954) reported that petechial and ecchymotic hemorrhages could be seen in the lungs of some pigs, and histological examinations have revealed minor renal tubular damage, focal liver necrosis, lymphocytic infiltration of the adrenal glands, and meningoencephalitis with perivascular lymphocytic infiltration (Burnstein and Baker 1954; Sleight et al. 1960; Chaudhary et al. 1966a).

In chronic leptospirosis, lesions are confined to the kidneys and consist of scattered small gray foci, often surrounded by a ring of hyperemia. Microscopic examination shows these lesions to be a progressive focal interstitial nephritis (Burnstein and Baker 1954; Langham et al. 1958; Cheville et al. 1980). The interstitial leukocytic infiltrations, which consist mainly of lymphocytes, macrophages, and plasma cells, may be extensive in some areas. Focal damage may also involve glomeruli and renal tubules. Some affected glomeruli are swollen, some atrophic, and others are replaced by fibrosis. The Bowman's capsule may be thickened, containing eosinophilic granular material (Langham et al. 1958). Tubular changes involve atrophy, hyperplasia, and the presence of necrotic debris in the lumen in some areas. Occasionally, petechial hemorrhages may be present in interstitial spaces.

Older lesions mainly consist of fibrosis and interstitial infiltration. Chronic lesions with accompanying acute inflammatory changes are still noticeable as long as 14 months postinfection (Morter et al. 1960).

Experimental studies indicate leptospires can invade the mammary gland of pigs and produce a mild, focal nonsuppurative mastitis (Tripathy et al. 1981).

The gross pathology of fetuses aborted as a sequela of *pomona* infection is nonspecific and includes edema of various tissues, serous or bloodstained fluid in body cavities, and sometimes petechial hemorrhages in the renal cortex (Ryley and Simmons 1954b; Fennestad and Borg-Petersen 1966; Wrathall 1975). These changes are probably the result of intrauterine autolysis. Jaundice may be seen in some aborted piglets (Hathaway et al. 1983). Focal necrosis, presenting as small grayish-white spots, is a frequent finding in the liver (Ryley and Simmons 1954b; Fish et al. 1963; Fennestad and Borg-Petersen 1966). Histological examination may reveal small foci of interstitial nephritis.

Placentas from aborted fetuses are grossly normal (Fish et al. 1963; Fennestad and Borg-Petersen 1966).

DIAGNOSIS

A diagnosis of leptospirosis in swine may be required not only for the clinician to confirm leptospirosis as a cause of clinical disease but also for other reasons, such as (1) the assessment of the infection and/or the immune status of a herd for the purposes of a control or eradication program on either a herd or a national basis; (2) epidemiological studies; or (3) a determination of the infectivity status of an individual animal to assess its suitability for international trade or for introduction into an uninfected herd.

The mild, often inapparent, clinical signs of acute leptospirosis make clinical diagnosis difficult; therefore, diagnosis is usually based on the results of laboratory procedures.

Laboratory diagnostic procedures for leptospirosis fall into two groups. The first group consists of tests for antibody detection; the second contains the tests for the demonstration of leptospires in pig tissues. The selection of tests to be carried out depends on the purpose for which a diagnosis is to be made and the resources available.

Serologic Tests

Serologic testing is the most widely used method for diagnosing leptospirosis, and the MAT (Cole et al. 1980; Faine 1982) is the standard serologic test. The minimum antigen requirements are that the test should employ representative strains of all the serogroups known to exist in the particular country, plus those known to be maintained by pigs elsewhere.

The MAT is used primarily as a herd test. To obtain useful information, at least 10 animals or 10% of the herd, whichever is the greater (Cole et al. 1980), should be tested. A retrospective diagnosis of both acute leptospirosis and *pomona* abortion may be made when the majority of affected animals have titers of 1:1000 or greater. Increasing the sample size and sampling a number of different cohorts markedly improve epidemiological information, investigations of clinical disease, assessments of vaccination needs, and public health tracebacks.

As an individual-animal test, the MAT is very useful in diagnosing acute infection; rising antibody titers in paired acute and convalescent serum samples are diagnostic. The presence of antibody in fetal serum is diagnostic of leptospiral abortion.

The MAT has severe limitations in the diagnosis of chronic infection in individual pigs, both in the diagnosis of abortion and in the identification of renal or genital carriers. Infected animals may have MAT titers below the widely accepted minimum significant titer of 1:100 (Ellis et al. 1986b, c).

Other serologic tests have been described for use in pigs, especially ELISA-based tests, but none of these have gained widespread acceptance for use as diagnostic tests.

Demonstration of Leptospires in Pig Tissues

The isolation of leptospires from, or their demonstration in, the internal organs (such as liver, lung, brain) and body fluids (blood, cerebrospinal, thoracic, and peritoneal) of clinically affected animals gives a definitive diagnosis of acute clinical disease or, in the case of a

fetus, a diagnosis of leptospiral abortion and probable chronic infection of its mother.

Their presence in the male or female genital tract, the kidney, or urine, in the absence of evidence of generalized infection, is diagnostic of chronic infection. Failure to demonstrate leptospires in the urine of a pig does not rule out the possibility of the animal being a chronic renal carrier; it merely indicates that the pig was not excreting detectable numbers of leptospires at the time of testing.

Isolation. Isolation, especially from clinical material, is difficult and time-consuming and is a job for laboratories specializing in the identification of isolates. Isolation from renal carriers is very useful in epidemiological studies to determine which serovars are present in an animal species or in a particular group of animals or geographic location.

The isolation of leptospires is the most sensitive method of demonstrating their presence, provided that antibiotic residues are absent, that tissue autolysis is not advanced, and that tissues for culture have been stored at a suitable temperature (4°C) and, in the case of urine, at a suitable pH since collection.

Culture should be carried out in a semisolid (0.1–0.2% agar) bovine serum-albumin medium containing either Tween 80 (Johnson and Harris 1967) or a combination of Tween 80 and Tween 40 (Ellis 1986), and preferably a small amount of fresh rabbit serum (0.4–2%) if the more fastidious leptospires such as *bratislava* are to be isolated. A dilution culture method should be used (Ellis 1986). Contamination may be controlled by a variety of selective agents (e.g., 5-fluorouracil, nalidixic acid, fosfomycin, and a cocktail of rifamycin, polymyxin, neomycin, 5-fluorouracil, bacitracin, and actidione). The use of selective agents will reduce the chance of isolation where there are only small numbers of viable leptospires. Culture media containing 5-fluorouracil at levels between 200 and 500 μg/mL should be used as transport media for the submission of samples (Ellis 1990).

Cultures should be incubated at 29–30°C for at least 12 weeks, preferably for 26 weeks (Ellis 1986). They should be examined by dark-ground microscopy every 1–2 weeks.

Other Methods of Demonstrating Leptospires. Leptospires do not stain satisfactorily with the aniline dyes, and silver-staining techniques lack sensitivity and specificity (Baskerville 1986). Dark-ground microscopy of fetal fluids or urine has been widely used in the diagnosis of leptospirosis and can be a useful tool in the hands of an experienced diagnostician, but many tissue artifacts can be mistakenly identified as leptospires.

The demonstration of leptospires by immunochemical tests (immunofluorescence, immunoperoxidase, and immunogold) is more suited to most laboratory situations; however, these tests are "number-of-organisms" dependent and lack the sensitivity of culture. They provide no information as to the infecting serovar (Ellis 1990) and require high-IgG-titer antileptospire sera, which are not available commercially. Immunofluorescence is the method of choice for the diagnosis of fetal leptospirosis. There have been a number of polymerase chain reaction methods published, but so far these have failed to deliver the promised increase in sensitivity which the underlying technology should theoretically deliver (Taylor et al. 1997).

PREVENTION AND CONTROL

Interruption of transmission from an infected pig or other host to a pig is the critical factor in control. Control of leptospirosis depends on the combined use of three strategies: antibiotic therapy, vaccination, and management. Unfortunately, not all these options are available in every country; for example, vaccines are not available in many Western European countries, including the United Kingdom, and problems of antibiotic residues may make the use of antibiotic therapy difficult in other situations. In the United States, the most useful antibiotic for leptospiral control/treatment programs, streptomycin, is no longer available for veterinary use. Control programs must therefore be modified to meet local conditions.

Vaccination induces immunity of relatively short duration. Immunity to infection is probably never 100% and, at best, lasts little more than 3 months (Kemenes and Suveges 1976; Ellis et al. 1989); immunity to clinical disease is believed to last somewhat longer, although the exact duration is not known. Vaccination will markedly reduce the prevalence of infection in a herd (Wrathall 1975; Kemenes and Suveges 1976) but will not eliminate infection (Hodges et al. 1976; Edwards and Daines 1979; Cargill and Davos 1981). Given the widespread use of tetracycline medication of feed in parts of Europe to control *bratislava* infection and all the attendant residue problems, there is an urgent need for the marketing of an effective *bratislava* vaccine in Europe.

Antibiotics alone will not eliminate pig-maintained leptospiral infections from the individual carrier animal or control infection in herds. Despite claims by some authors that either systemic streptomycin at 25 mg/kg body weight (Dobson 1974; Alt and Bolin 1996) or oral tetracyclines at levels of 800 g/ton of feed (Stalheim 1967) will eliminate carriers, others have reported that these regimes do not work (Doherty and Baynes 1967; Hodges et al. 1979). Recent work into the use of alternative antibiotic therapy regimes indicates that oxytetracycline (40 mg/kg for 3 or 5 days), tylosin (44 mg/kg for 5 days), or erythromycin (25 mg/kg for 5 days) may be effective in eliminating *pomona* from the kidneys of experimentally infected pigs (Alt and Bolin 1996).

The main management factor in the control of lep-

tospirosis is the prevention of direct or indirect contact with free-living vectors or other domestic stock. Strict biosecurity should be implemented and rodent control programs instigated in and around the production complex. When faced with an outbreak of clinical disease, the best option is to treat both affected and at-risk stock with streptomycin at 25 mg/kg body weight, to immediately vaccinate the at-risk stock, and then to introduce a regular vaccination program. If vaccination is not an available option, then a feed medication program, using either chlor- or oxytetracycline at 600–800 g/ton of feed, should be introduced. This ration is fed either continuously or on a 1-month-on/1-month-off basis. Alternatively, it may be fed for two periods of 4 weeks in the year, preferably one in the spring and the other in the autumn.

The use of artificial insemination is an important tool in the control of *bratislava* infection.

ZOONOSIS

Leptospirosis is an important occupational zoonosis of those who work with pigs, especially farmers and those involved in slaughtering pigs. Pigs are now being produced for intended xeno grafting. It is important to remember the potential risk to recipients posed by pig-associated leptospirosis (Bjoersdorff et al. 1995).

42 Mycoplasmal Diseases

Eileen L. Thacker

Mycoplasma hyopneumoniae and the pneumonia associated with it remain a concern to the swine industry throughout the world. *M. hyopneumoniae*, associated with enzootic pneumonia, is also considered to play a primary role in the porcine respiratory disease complex (PRDC), a continuing problem to swine producers. Other important pathogenic mycoplasmas include *M. hyorhinis,* which induces polyserositis and arthritis, and *M. hyosynoviae*, also a cause of arthritis in grow-finish pigs. Although the majority of other swine mycoplasmas, including *M. flocculare, M. sualvi, M. hopharyngis,* and several species of *Acholeplasma* can be isolated from swine, they appear to be nonpathogenic.

MYCOPLASMAL PNEUMONIA OF SWINE

Both Mare and Switzer in the U.S. (1965) and Goodwin et al. in the U.K. (1985) isolated *M. hyopneumoniae* in 1965. Since that time the role of *M. hyopneumoniae* in the induction of chronic pneumonia in pigs throughout the world continues to be problematic to the swine industry. Pneumonia caused by *M. hyopneumoniae* alone is mycoplasmal pneumonia. However, enzootic pneumonia is the most common term used because it describes the epidemiology pattern of the disease in combination with the various other etiological agents or lesions involved. Enzootic pneumonia is characterized by infection with *M. hyopneumoniae* and other pathogenic bacteria, such as *Pasteurella multocida, Streptococcus suis, Haemophilus parasuis,* or *Actinobacillus pleuropneumoniae* (APP). When combined with porcine respiratory and reproductive syndrome virus (PRRSV), porcine circovirus type 2 (PCV2) and/or swine influenza virus (SIV), a syndrome known as the porcine respiratory disease complex (PRDC) has emerged as a serious health problem to the swine industry. Infection with *M. hyopneumoniae,* independent of terminology, is associated with respiratory disease and reduced productivity in pigs.

Etiology

Culture and isolation of *M. hypneumoniae* is slow and complex. It can be grown in medium (Friis 1975); however, culture and identification is tedious, time consuming, and often unsuccessful. Contamination by other bacteria or other mycoplasmas, especially *M. hyorhinis,* will often preclude successful culture and isolation of the organism. Media and methods for isolation of *M. hyopneumoniae* were reviewed by Ross and Whittlestone (1983).

In culture, *M. hyopneumoniae* grows slowly compared to other porcine mycoplasmas, producing turbidity and an acid color shift to the media 3–30 days after inoculation of the media. Inoculation of solid agar medium and incubation in a 5–10% carbon dioxide atmosphere results in barely visible colonies after 2–3 days incubation. The organism must be differentiated from other swine mycoplasmas, and the nonpathogenic *M. flocculare* has many morphological, growth, and antigenic similarities to *M. hyopneumoniae.*

Antigenic diversity between *M. hyopneumoniae* isolates was first identified by Frey (1992) and further supported by Artiushin and Minion (1996) and Kokotovic (1999). Recent studies have further demonstrated differences in virulence between field isolates of *M. hyopneumoniae* (Strait et al. 2003; Vicca et al. 2002, 2003).

Epidemiology

Transmission of *M. hyopneumoniae* by carrier swine is the most common source of infection in field conditions. Isolation of the organism in nasal samples from infected pigs was demonstrated by Goodwin (1972). More recently, the use of polymerase chain reaction assays (PCR) have confirmed the presence of the organism in the nasal cavity of infected pigs (Calsamiglia et al. 1999, 2000; Kurth et al. 2002; Mattsson et al. 1995)). In addition, it was demonstrated that transmission of the organism can occur between penmates, independent of age (Etheridge et al. 1979; Piffer and Ross 1984). The

slow growth characteristics and fastidious nature of *M. hyopneumoniae* would suggest that transmission between herds would be difficult. However, numerous researchers have documented the infection or reinfection of herds. As early as 1985, Goodwin found that herds that were less than 3.2 km apart could infect each other (Goodwin 1985). A number of studies of the Danish specific pathogen free (SPF) systems found that most reinfections occurred in the autumn and winter and when SPF herds were close to non-SPF herds (Jorsal and Thomsen 1988). More recently, risk factors identified with reinfection of *M. hyopneumoniae*-free herds in Switzerland include the presence of finishing farms, large mixed breeding-finishing farms, infected neighbors, and the close proximity of pig transport parking sites to the farm (Hege et al. 2002). Airborne transmission of *M. hyopneumoniae* has also been documented (Stark et al. 1998; Thomsen 1992).

The transmission of *M. hyopneumoniae* in many herds occurs by sow-to-pig exposure (Calsamiglia and Pijoan 2000; Rautiainen and Wallgren 2001). After infection is established, transmission between penmates occurs. Differences in exposure times as well as production systems have been investigated and identified (Sibila et al. 2004; Vicca et al. 2002). These studies demonstrated that numerous factors including housing styles and ventilation, management practices including stocking density, climatic conditions, and 1- or 2-site production systems versus 3-site systems can influence the transmission and dynamics of disease within a herd. In the majority of herds, transmission among penmates occurs at weaning. In continuous-flow systems, *M. hyopneumoniae* and other respiratory pathogens may be transmitted in large numbers at that time. However, overt signs of mycoplasmal pneumonia are typically not observed in pigs under 6 weeks of age, although all ages of pigs are susceptible (Piffer and Ross 1984). Exceptions to the typical age of pneumonia has been shown to occur experimentally in the presence of PRRSV, where an increase in the percentage of mycoplasmal pneumonia occurred within 10 days of experimental infection with *M. hyopneumoniae* (Thacker et al. 1999). Use of early weaning strategies, where pigs are weaned at 7–10 days of age and removed to an isolated site significantly reduced, but does not always completely eliminate, the vertical transmission from sows (Dritz et al. 1996).

The incidence of mycoplasmal pneumonia varies between countries. A recent survey of U.S. swine populations in the National Animal Health Monitoring Survey (NAHMS) (USDA 2001) found that swine producers in the U.S. felt *M. hyopneumoniae* was a concern in 19.6% in nursery pigs on 29% of the farms surveyed. In large swine operations with more than 10,000 pigs, mycoplasma associated disease was important in 52.7% of the sites with nursery pigs and 68% sites with finisher pigs. A diagnosis of *M. hyopneumoniae* was made in over 50% of the sites. Other countries have indicated the prevalence of herds with pneumonia consistent with mycoplasma ranging between 38% and 100% (Guerrero 1990). The exact prevalence of pneumonia due to *M. hyopneumoniae* is often difficult to ascertain due to the complication of co-infections with other respiratory pathogens including *P. multocida,* PRRSV, SIV and PCV2.

Eradication strategies for *M. hyopneumoniae* have been implemented in various countries with differing success. An eradication program using partial depopulation, consisting of a 2-week period during which no animals younger than 10 months were allowed on the farm, has been used successfully in a number of European countries including Switzerland, Denmark, Sweden, and Finland (Baekbo et al. 1996; Heinonen et al. 1999; Rautiainen et al. 2001; Zimmerman et al. 1989). In a follow-up to the Swiss eradication program, it was determined that 2.6% of the farms became reinfected, which is a considerable reduction over the time prior to the implementation of the eradication program (Hege et al. 2002). However, the reinfection rate in Switzerland that attempted eradication on a national level is indicative of the difficulty in successful eradicating the organism on a wide scale basis.

Economic losses due to mycoplasmal pneumonia have been associated with reduced daily weight gain (DWG), increased mortality, reduced feed efficiency and increased costs due to medication. A review article found that the DWG was reduced from 2.8% to 44.1% in 24 different studies (Straw et al. 1989). Pointon et al. (1985) found the growth rate of pigs in contact with *M. hyopneumoniae*-infected pigs was reduced by 12.7%. Information related to the exact amount of economic loss and percentage of pneumonia can often be difficult to interpret. Scheidt et al. (1990) found no correlation between average daily gain and severity of pneumonia at slaughter. Paisley et al. (1993) reported that mycoplasma-like pneumonia, as well as other respiratory lesions, was related to reduced mean daily gain. However, they concluded that lesions present at slaughter were responsible for only 9–27% of the variation and suggested that the remaining variation was due to factors such as environment, feed, genetics, and management systems.

Pathogenesis

The pathogenesis of *M. hyopneumoniae* is complex and consists of two separate methods of causing disease and affecting the overall health of the host. Colonization of the airways by *M. hyopneumoniae* begins with the binding of the organism to the cilia of epithelial cells in the airways of the pig (Zielinski and Ross 1992). Although the exact method of adherence of the organism to the cilia has not been fully identified, a number of proteins involved with adhesion have been identified. A protein, P97, has been recognized by Zhang, et al. (1994, 1995) to be involved in adherence of *M. hyopneumoniae* to the cilia, because monoclonal antibodies to this protein can

block adherence to the organism in vitro. While P97 has been recognized as important in adherence to the cilia, vaccination against this protein alone has not produced protection against clinical disease or colonization in vivo (King et al. 1997). The P97 gene has been cloned and the binding region has been identified (Hsu et al. 1997; Hsu and Minion 1998). However, it has been determined that variation in this gene due to the addition or subtraction of repeated amino acids may result in alteration of the protein, making recognition by the immune system and thus immunization difficult (Wilton et al. 1998). Other glycoproteins (Chen et al. 1998) and cell surface features are probably also involved in the binding of the organism to the cilia (Zielinski and Ross 1992). Colonization of the cilia by *M. hyopneumoniae* results in ciliostasis, clumping and loss of cilia (DeBey and Ross 1994), and loss of epithelial cells and bronchial goblet cells (DeBey et al. 1992). Colonization of the airways by *M. hyopneumoniae* results in a significant reduction in the ability of mucociliary apparatus to function and clear the airways of debris and invading pathogens, especially bacteria. This is thought to be an important mechanism for the increased colonization of the airways by respiratory bacteria, including *P. multocida, B. bronchiseptica*, *A. pleuropneumoniae*, *A. pyogenes,* and other bacteria. This co-infection of *M. hyopneumoniae* with bacteria results in enzootic pneumonia.

The virulence factors associated with *M. hyopneumoniae* are largely unknown and appear to be extremely complex. The genome of one isolate has recently been sequenced (Dr. F. C. Minion, Iowa State University, personal communication), which should facilitate the identification of the genes and proteins that are important in the induction of disease and immunity. Virulence factors that contribute to attachment/colonization, cytotoxicity, competition for substrates, and evasion and modulation of the respiratory immune system remain unknown. The various mechanisms of pathogenesis involved with *M. hyopneumoniae* infection are probably not due to a single gene, but rather to a multitude of gene products that will need to be identified.

The complex, chronic pathogenesis of *M. hyopneumoniae*-mediated respiratory disease appears dependent on the alteration or modulation of the respiratory immune response. Immunopathologic changes are a major component of mycoplasmal pneumonia, although little is known about the mechanisms of how the organism induces the immune and inflammatory responses associated with disease. The microscopic lesions associated with mycoplasmal pneumonia are characterized by an infiltration of the peribronchiolar and perivascular areas with mononuclear cells consisting of both macrophages and lymphocytes. This infiltration of both B and T lymphocytes over time can result in the formation of lymphoid nodules with germinal-like centers. The infiltration of mononuclear cells in association with *M. hyopneumoniae* infection impacts all of the components of the immune system, including macrophages from the innate immune system and B and T lymphocytes of the adaptive immune response. Pulmonary alveolar macrophages infected with both *M. hyopneumoniae* and APP were shown to have reduced phagocytic capability (Caruso and Ross 1990). *M. hyopneumoniae*-infection also induces macrophages to produce proinflammatory cytokines, including interleukin (IL)-1, IL-6, IL-8, and tumor necrosis factor (TNF) alpha, both in vivo (Asai et al. 1993, 1994; Thacker et al. 2000) and in vitro (Thanawongnuwech et al. 2001). Recent research has demonstrated that IL-10 and IL-12 levels are also increased in the bronchoalveolar lavage fluid 28 days after experimental infection with *M. hyopneumoniae* (Thanawongnuwech and Thacker 2003). Production of proinflammatory cytokines increases the inflammation in the lung, which further reduces the respiratory immune system's ability to control other pathogens in the respiratory tract. Although an inflammatory response is important in the control of pathogens, the tissue injury and disease subsequent to *M. hyopneumoniae* infections appears to be caused more by the response from the host than the organism itself.

In addition to affecting macrophages, *M. hyopneumoniae* has an impact on both B and T lymphocytes. Evidence of the immunosuppressive effect of *M. hyopneumoniae* to nonspecific mitogens has been reported (Kishima and Ross 1985). A subsequent study found nonspecific stimulation (mitogenic) of lymphocytes by the organism (Messier and Ross 1991). Tajima et al. (1984) further confirmed the role of the immune system in the pathogenesis of mycoplasmal pneumonia by demonstrating that the pneumonia was less severe in thymectomized pigs treated with antithymocyte serum and inoculated with *M. hyopneumoniae*. These results suggest that a cell-mediated immune mechanism may be important in the development of pneumonia. However, in the same study *M. hyopneumoniae* was isolated from the spleen of one of the thymectomized pigs, indicating that containing and controlling invasion and systemic spread of the organism by T lymphocytes is crucial in preventing systemic spread of the organism. The alterations of the various effector cells in the respiratory immune system by *M. hyopneumoniae* in infected pigs is probably important in the ability of the organism to persist and cause disease in pigs.

Onset of mycoplasmal pneumonia may be dependent on the intensity of infection and the number of organisms that colonize the respiratory tract and the presence of other pathogens in the respiratory tract that contribute to disease. Recent research has determined that different isolates have different virulence capabilities that influence their ability to induce disease (Strait et al. 2003; Vicca et al. 2003). The incubation period for experimental infection as well as acute infections in the field is 10–14 days. Under natural field conditions it is more difficult to pinpoint the exact time of infection

and thus the incubation period. Disease has been reported to occur as early as 2 weeks of age (Holmgren 1974), but more commonly it spreads slowly within the herd, and pigs begin showing clinical disease associated with mycoplasmal pneumonia at 3–6 months of age.

An important role of *M. hyopneumoniae* in swine respiratory disease is its interaction with other pathogens. Infections with *M. hyopneumoniae* alone induce a mild chronic pneumonia; however, in conjunction with other pathogens; the respiratory disease becomes a severe problem consistent with PRDC in the field. Numerous studies have investigated the impact of co-infections of other pathogens and *M. hyopneumoniae.* In most cases, it is the co-infecting organism that has an increased severity and potentially duration of disease associated with *M. hyopneumoniae.* Ciprian et al. (1994) did a nice review of the interaction of *M. hyopneumoniae* with the various bacteria of the respiratory tract. Enzootic pneumonia, attributed to *M. hyopneumoniae,* is centered on the interaction with other bacteria, including *P. multocida* and APP. With secondary bacterial infections, the pneumonia consistent with *M. hyopneumoniae* infection appears more severe resulting in enzootic pneumonia. In contrast, combination with viral respiratory pathogens, including PRRSV and PCV2, has changed the character of respiratory disease and has resulted in the term porcine respiratory disease complex (PRDC). In a first study investigating the interaction of *M. hyopneumoniae* and PRRSV, Van Alstine (1996) did not see a strong interaction between the two. However, since that time, Thacker et al. (1999) demonstrated that the viral pneumonia induced by PRRSV was significantly increased in both severity and duration when both pathogens were present. In this study, it was found that the presence of PRRSV resulted in increased acute mycoplasmal pneumonia. Similar findings were observed in the presence of pseudorabies virus (PRV) (Shibata et al. 1998). Recently it has been demonstrated that *M. hyopneumoniae* increases the pneumonia associated with concurrent infection with PCV2 (Opriessnig et al. 2003). In contrast, the interaction of *M. hyopneumoniae* with SIV lacks the interaction observed with the other viruses, and although the severity of pneumonia at the peak of infection is increased, the potentiation observed with PRRSV and PCV2 did not occur (Thacker et al. 2001). This interaction with other pathogens is probably the most important role that *M. hyopneumoniae* plays in swine respiratory disease.

Clinical Signs

Mycoplasmal pneumonia is chronic in nature with a high morbidity and a low mortality. Clinically it is characterized by a dry, nonproductive cough, although the presence or absence of cough is variable with individual animals. Experimentally, onset of clinical signs characterized by coughing, occurs within 7–14 days post infection; however, with natural infection clinical disease

onset is less predictable (Robert 1974; Sorensen et al. 1997; Vicca et al. 2002). Onset of clinical signs in a herd tends to be gradual, with coughing within the herd lasting weeks to months. The presence of other clinical symptoms, such as fever, decreased appetite, labored breathing or prostration, is due to secondary pathogens. Many pigs with mycoplasmal pneumonia may appear unthrifty and feed intake is reduced, but overall the pigs remain normal in appearance.

Lesions

The macroscopic lesions of mycoplasmal pneumonia consist of purple to gray areas of consolidation of the cranial-ventral portions of the lung. The lesions tend to be in the ventral portions of the cranial and middle lobes, the accessory lobe, and the cranial ventral portions of the caudal lobes of the lungs; however, they can be spread throughout the lungs in severe cases. In the absence of secondary infections, the lesions tend to be focal and fairly well demarcated. In the presence of other organisms, the lesions become more diffuse and depending on the agent, difficult to differentiate from the other pathogens. When the lung tissue is cut, the consistency of the lung is thick and heavy although not excessively firm. A catarrhal exudate is often present in the airways. The regional lymph nodes are usually firm and enlarged.

Microscopic lesions are characteristic of a chronic pneumonia. Early in the disease process, accumulations of neutrophils in the airways are present microscopically. As the disease progresses, lymphocytes and monocytes infiltrate the peribronchiolar, peribronchial, and perivascular regions. Interstitial pneumonia may also be observed, with airways filled with cellular debris. Alveoli may contain eosinophilic fluid consistent with edema and increased numbers of mononuclear and polymorphonuclear cells. More advanced lesions can consist of lymphoid nodules associated with the airways. In recovering lesions, alveoli are collapsed and emphysematous and lymphoid nodules are common. The severity of the microscopic lesions increases with increased numbers of secondary pathogens as well as in pigs housed in poor environments with inadequate management strategies. Neither macroscopic nor the microscopic lesions are specific for *M. hyopneumoinae,* and other respiratory pathogens, including bacterial invaders and swine influenza virus (SIV) must be ruled out.

Diagnosis

Macroscopic lesions associated with mycoplasmal pneumonia combined with the onset of clinical disease and coughing lead to the suspicion of *M. hyopneumoniae* infection. It is important to remember however that the clinical signs, macroscopic and microscopic lesions, are not specific for mycoplasmal pneumonia, so other differential assays must be done to confirm the role of the organism in respiratory disease in a herd.

The pathogenesis of disease due to *M. hyopneumoniae* makes accurate diagnosis of the organism challenging. The organism's location on the mucosal surface of the respiratory tract, gene expression variation and ability to modulate the respiratory immune response can make the diagnosis of mycoplasma pneumonia difficult. Although culture and isolation are considered the "gold standards" for detecting *M. hyopneumoniae,* isolation of the organism is difficult due to its requirement for specialized media and its slow growth properties, often requiring 4–8 weeks to grow to measurable levels (Friis 1975). Difficulty in culturing the organism is increased by the additional requirement for swine serum negative for *M. hyopneumoniae* antibodies. Due to the slow growth in culture, contamination by other swine mycoplasmas or bacteria may preclude the growth and isolation of *M. hyopneumoniae*. Combined, these factors make isolation and growth of the organism expensive, difficult and impractical. Culture is not recommended as a diagnostic technique and failure to isolate the organism under field conditions should not be used to deny the presence of the organism within a herd.

Serology is the most common tool used to determine the presence or absence of an organism within a herd situation and *M. hyopneumoniae* is no exception. However, as with most diagnostics associated with *M. hyopneumoniae*, interpretation of serological results can be challenging. Numerous studies have compared the various assays as well as their association with lung lesions and protection against disease. Originally complement fixation (CF) assays were used to detect antibodies to *M. hyopneumoniae*. However in several comparison studies, it was determined that an indirect ELISA assay was more efficacious at detecting antibody than the CF assay (Bereiter et al. 1990; Piffer et al. 1984). Currently, ELISA assays are the most commonly used assay to detect antibodies to the organism. Serology is best suited to screening for infected herd status or evaluating vaccine responses. Care must be taken in their use on an individual animal basis, as well as in evaluating for vaccine compliance. Three ELISA assays are currently used in the United States to detect mycoplasmal serum antibodies. Indirect ELISA assays include the Tween-20 assay (Bereiter et al. 1990; Nicolet et al. 1980) and the HerdCheck *Mycoplasma hyopneumoniae* ELISA assay (Idexx Laboratories, Westbrook, Maine). The DAKO *Mycoplasma hyopneumoniae* ELISA (DAKO corporation, Carpenteria, California) is a blocking ELISA based on an antigenic internal protein. A recent study using serum from experimentally infected pigs found that all three assays had excellent specificity in recognizing antibody negative samples and thus few false positive results are observed (Erlandson et al. 2002). In contrast, the sensitivity of the assays was low and ranged from 37–49%. This low sensitivity results in a low negative predictive value and a high percentage of false negative results. Of the assays assessed, the DAKO ELISA was the most con-

sistent in identifying infected pigs; however, a combination of assays appeared to improve the predictive ability of the tests. Sorensen et al. (1997) found similar results of high specificity and low sensitivity in *M. hyopneumoniae* ELISA assays. In addition, recent research has found that the assays varied in their ability to detect antibodies induced in pigs experimentally infected with different field isolates of the organism (Strait et al. 2003; Vicca et al. 2002). To further complicate the serological diagnosis of *M. hyopneumoniae*, *M. flocculare* antibodies can cross-react with a number of the serological assays and must be considered in the diagnostic workup within a farm. A study of nine naturally infected Danish swine herds found that most pigs seroconverted in the growing-to-finishing units and the association of lung lesions at slaughter and seroconversion was complex (Andreasen et al. 2000, 2001). It was demonstrated that pigs seroconverting to *M. hyopneumoniae* close to slaughter had the highest percentage of pneumonia and early seroconversions appeared to be related to pleuritic lesions in the cranio-ventral regions of the lung (Andreasen et al. 2001). In addition, concurrent infection with PRRSV (Thacker et al. 1999), SIV (Thacker et al. 2001), or PCV2 (Opriessnig et al. 2003) appear to increase *M. hyopneumoniae* antibody levels. Antibody levels following vaccination with *M. hyopneumoniae* bacterins may vary depending on the vaccine, the infection status of the pig, and the serological assay used (Erlandson et al. 2002; Thacker 2001). No correlation between vaccine-induced antibody levels and protection from colonization and disease has been observed (Djordjevic et al. 1997; Thacker et al. 1998).

In addition to assessing serum samples for the presence of antibodies to *M. hyopneumoniae*, colostrum has been used to document freedom of a herd from infection (Rautiainen et al. 2000). Detection of antibodies in colostrum occurred weeks prior to clinical outbreak of mycoplasmal pneumonia in one case (Sorensen et al. 1993). However, sampling colostrum within the first 2 hours after farrowing is required for the most accurate detection of antibodies, which decreases the practicality under typical field situations. In addition, it has been demonstrated that parity is important in the accurate detection of antibodies in colostrums, with high-parity sows being a better source for the detection of antibodies to assess the herd status (Rautiainen et al. 2000).

Accurate diagnosis of *M. hyonpneumoniae* has increased with the development of polymerase chain reaction (PCR) assays (Artiushin et al. 1993; Calsamiglia et al. 1999; Harasawa et al. 1991; Mattson et al. 1995; Stark et al. 1998; Stemke 1997; Stemke et al. 1994; Verdin et al. 2000). The various collection sites and potential uses of PCR to detect infection accurately have been investigated (Calsamiglia and Pijoan 2000; Calsamiglia et al. 2000, Kurth et al. 2002; Sorensen et al. 1997). On the basis of these studies, lung tissue and bronchial washings appear to be among the most reliable collection

sites, and detection of the organism from the nasal cavity appears more variable. To increase the sensitivity of the assay, nested PCR assays using two sets of primers are typically used. This results in an assay capable of picking up as few as four to five organisms. Although the ability to detect these low numbers of organisms may assist in the detection of *M. hyopneumoniae* on a herd basis, the potential for contamination may be problematic. It has been documented that PCR assays are capable of detecting the organism in the air of production units housing pigs infected with *M. hyopneumoniae* (Stark et al. 1998). In addition, recent research investigating the variability of the genetics of different field isolates of *M. hyopneumoniae* has documented potential differences in our ability to detect the organism through the use of PCR (Strait et al. 2003). These results suggest that additional research is required to determine the accuracy of detection of *M. hyopneumoniae* by PCR under field conditions.

Detection of *M. hyopneumoniae* by either fluorescent antibody (FA) or immunohistochemistry (IHC) assays is typically performed in diagnostic laboratories (Amanfu et al. 1983; Opriessnig et al. 2003). Frozen tissues are required to detect *M. hyopneumoniae* by FA assay, making sample collection problematic in the field. In situ hybridization of fixed tissues has also been described, although used less commonly (Kwon and Chae 1999). Because in situ hybridization and IHC assays can be performed on fixed tissues, these assays are more practical for samples collected on the farm. It is critical that the samples collected for all of these assays include airways with ciliated epithelial cells so the organism can be detected.

Ultimately the assay used to diagnose *M. hyopneumoniae* is dependent on whether it is to determine infection status as an aid in determining intervention strategy timing or to assess whether a herd is free of the organism in eradication protocols. Serology alone would be a poor choice to confirm that a herd is negative for *M. hyopneumoniae*, and PCR assays are not usually required to determine timing of vaccination or therapy, which can be based primarily on the occurrence of clinical disease. Sorensen et al. (1997) compared duration of disease and evaluation of four diagnostic assays, including serology and PCR following experimental challenge. He reported similar predictive values between all of the assays. Thus, for the greatest degree of accuracy on detecting the organism, multiple diagnostic procedures are probably required. The sensitivity and specificity of each of the assays should be considered both for accurate interpretation of clinical signs and serological and PCR test results, and according to the information required by the veterinarian and producer.

Treatment

Antibiotics against *M. hyopneumoniae* can help control the disease, but do not eliminate the organism from the respiratory tract nor heal existing lesions. A number of studies have assessed the efficacy of a number of antibiotics, including various quinolones (Hannan et al. 1989), tylosin, oxytetracycline (Cooper et al. 1993), and tilmicosin (Thacker et al. 2001), among others using a number of different testing systems (Tanner et al. 1993; Ter Laak et al. 1991; Williams 1978; Wu et al. 1997) to evaluate the susceptibility of each antimicrobial agent in vitro. In these studies, the quinolones tended to be highly effective; tiamulin, danfloxacin, chlortetracycline, lincomycin, tilmicosin, and other antibiotics were active against the organism, but many of these appeared to mycoplasmastatic rather than 'cidal. However, care must be taken when comparing in vitro antibiotic studies on *M. hyopneumoniae* to their performance in the pig, due to the location of the organism on the cilia within the airways. In order for an antibiotic to be effective against the organism, it must be able to achieve significant levels within the mucous and fluids of the respiratory tract.

Studies assessing antibiotic efficacy in vivo have also been performed, occasionally with conflicting results. *M. hyopneumoniae* lacks a cell wall, which precludes the effectiveness of antibiotics that would interfere with cell wall synthesis, such as penicillin, ampicillin, amoxicillin, and cephalosporin. Other antibiotics that would have little efficacy against *M. hyopneumoniae* include polymyxin, erythromycin, streptomycin, trimethoprim, and sulphonamides. The ability of *M. hyopneumoniae* to develop resistance to antibiotics is unknown; however, it has been reported in the field that resistance to the tetracyclines can occur (Maes et al. 1996). Tiamulin has been reported to reduce the severity of experimentally induced and naturally acquired mycoplasmal pneumonia (Hannan et al. 1982). In a separate study, Ross and Cox (1988) failed to observe beneficial effects of tiamulin on macroscopic or microscopic lesions or *M. hyopneumoniae* antigens detected by FA. Research has demonstrated that use of chlortetracycline in the feed administered prior to challenge reduces both the severity of pneumonia as well as the number of organisms (Thacker et al. 2001). Other studies have demonstrated the beneficial effects of tiamulin (Hsu et al. 1983), tilmicosin and tylosin (Mateusen et al. 2001), and doxycycline (Bousquet et al. 1998) on weight gain and clinical disease. However, these were field trials, and pigs were infected with multiple pathogens making assessment of antibiotic impact on *M. hyopneumoniae* more difficult to interpret. However, results of antibiotic use in the treatment of *M. hyopneumoniae* are often disappointing because the organisms tend to reappear after the medication is discontinued. In addition, infection with secondary pathogens makes therapy more challenging and often results in the need to use multiple antibiotics to control all of the various pathogens associated with respiratory disease. The successful use of combination therapies with antibiotics has also been reported (Burch et al. 1986; Stipkovits et al. 2001).

Antibiotics as a therapy for mycoplasmal pneumonia are best used during periods of stress in the life of the pig, including weaning or mixing. Knowing the other pathogens present in the respiratory tract is critical for the success of therapy as well as determining the optimal timing for the best results. Administration of medication prior to or early following exposure to the organism is also important for success in using medication as an aid in controlling mycoplasmal pneumonia. Overall, prevention of the development of mycoplasmal pneumonia is the only effective method for decreasing the economic impact of *M. hyopneumoniae* within a swine herd.

Prevention

Effective prevention and control of mycoplasmal pneumonia, enzootic pneumonia, or PRDC is based on providing an optimal environment for the pigs, which includes adequate quality of air, ventilation, ambient temperature, and the appropriate number of animals housed in the available space. Management practices such as all in/all out pig flow, medicated and segregated early weaning, and multisite operations further facilitate control of respiratory disease associated with *M. hyopneumoniae* infection. In addition, Maes et al. (1996) recommended other management strategies that help limit the impact of *M. hyopneumoniae* on pig production. These include a balanced and stable sow herd with fewer than 30% replacement gilts; closing the herd or minimizing the number of sources used to procure pigs; multisite production; biosecurity to prevent the spread and introduction of disease; reduction of stress on pigs; optimal stocking density; and adequate ventilation, air quality and room temperature.

Eradication has become a goal for many production systems. The Swiss have used a program referred to earlier to eradicate the organism from the country (Zimmerman et al. 1989). Other protocols for eradication of the organism within a herd include medicated early weaning protocols where the sow is treated with antibiotics and the pigs weaned at 6 days of age (Alexander et al. 1980), and segregated early weaning with the use of multisite operations to decrease significantly the number of organisms transmitted from the sow to the pigs (Harris 1990). Using pigs that have been produced by cesarean section–derived, colostrum-deprived (CDCD) pigs to repopulate a herd is the only method guaranteed to produce *M. hyopneumoniae*-free pigs consistently. In all cases, reexposure and reinfection have been problems in maintaining *M. hyopneumoniae*-free pigs.

Vaccines against *M. hyopneumoniae*, produced from adjuvanted whole-cell or membrane preparations are commonly used to control the clinical disease associated with mycoplasmal pneumonia. Numerous commercial vaccines are now used throughout the United States and the world. More than 85% of the herds in the U.S. vaccinate with mycoplasma vaccine (USDA 2001). Numerous studies have been performed demonstrating the efficacy of these vaccines under both field and experimental settings. Currently in the U.S. both single- and dual-dose vaccination protocols are used successfully to control disease. The appropriate use of either of these strategies is based on a number of factors, including overall health of the farm, time of clinical disease associated with *M. hyopneumoniae*, level of maternal antibodies, and circulation of PRRSV virus in the herd.

The economic benefit of mycoplasma vaccination has been demonstrated in a number of studies (Dohoo and Montgomery 1996; Jensen et al. 2002; Maes et al. 1999). Analysis of the immune response induced by *M. hyopneumoniae* bacterins has demonstrated reduction in percentage of lung lesions, production of serum antibodies, production of local IgG and IgA in the respiratory tract, and reduction of proinflammatory cytokines (Djordjevic et al. 1997; Kobisch et al. 1987; Kristensen et al. 1981; Messier et al. 1990; Ross et al. 1984; Sheldrake et al. 1993; Thacker et al. 1998, 2000). In addition, the effectiveness of antibiotic use in conjunction with vaccination has been demonstrated as an efficacious method to reduce the clinical disease associated with *M. hyopneumoniae* infection (Mateusen et al. 2001, 2002). Vaccine failure has been reported in the field and the impact of maternal antibodies has been investigated. It appears that maternal antibody levels against *M. hyopneumoniae* inhibit vaccine efficacy only if levels of antibodies are very high (Jayappa et al. 2001; Thacker et al. 1998, 2000; Thacker and Thacker 2001). However, a major cause of decreased mycoplasma vaccine efficacy is the presence of PRRSV during or shortly after vaccination (Thacker et al. 2000). Vaccination against *M. hyopneumoniae* reduced the increased severity of PRRSV pneumonia in conjunction with mycoplasmal pneumonia; however, the presence of PRRSV, either through infection or use of a modified live vaccine, significantly decreased the efficacy of the vaccine against *M. hyopneumoniae*-induced disease. The current vaccines are effective in reducing the clinical disease associated with mycoplasmal pneumonia including percentage of lung lesions and coughing; however, they do not prevent colonization of the organism in the host (Thacker et al. 2000). Investigation of new vaccines is actively occurring, including the use of aerosol and feed-based vaccines as well as subunit vaccines (Fagan et al. 1996, 2001; Frey et al. 1994; Lin et al. 1991; Murphy et al. 1993).

M. HYORHINIS

Polyserositis, arthritis, and otitis are clinical disorders associated with *M. hyorhinis* infection. The organism is ubiquitous within the swine population and also a common cell contaminant in cultured cell lines from humans and all species of animals.

Etiology

If present, *M. hyorhinis* is typically the first mycoplasma that grows in culture when investigating mycoplasmal diseases in pigs. The protocol and media for isolation and growth of *M. hyorhinis* is well summarized by Ross and Whittlestone (1983). The presence of the organism in pigs frequently prevents the isolation of other mycoplasmas.

Epidemiology

M. hyorhinis is a common pathogen in swine production units, with pigs becoming infected from either the sows or older pigs in system. Ross and Spear (1993) demonstrated that the organism could be isolated from the nasal secretions of 10% of sows and 30–40% of weanling pigs. It is considered a normal member of the upper airways of young pigs (Ross and Young 1993). Following exposure, the organism spreads quickly through the upper respiratory tract and can frequently be isolated from the lungs and eustachian tube. The majority of infected pigs have no apparent clinical disease, although many clinical diseases, including pneumonia, arthritis, polyserositis, eustachitis, and otitis, have been described in conjunction with *M. hyorhinis* infection.

Pathogenesis

Little is known about the pathogenesis of *M. hyorhinis.* Like *M. hyopneumoniae*, *M. hyorhinis* adheres to ciliated epithelial cells within the upper and lower respiratory tract of pigs. Little is known about the virulence factors of *M. hyorhinis.* Within the respiratory tract, pneumonia has been reported to be associated with some strains of *M. hyorhinis* (Ross 1992). In addition, infection with *M. hyorhinis* can result in otitis media (Kazama et al. 1989; Morita et al. 1999). The presence of the organism in the auditory tube may impair the mucociliary apparatus as the organism adheres to the cilia of the epithelial cells. This enables ascending infection with other bacteria such as *P. multocida* and *A. pyogenes*. Co-infection of the respiratory tract with other pathogens, including PRRSV (Kawashima et al. 1996) or *B. bronchiseptica* (Gois et al. 1977) has been suggested as being important for the increased respiratory disease that occasionally occurs with *M. hyorhinis* infection.

Although *M. hyorhinis* is a common inhabitant of the respiratory tract of pigs, much of the disease is associated with invasion of the organism systemically resulting in polyserositis and arthritis. The mechanism that enables the *M. hyorhinis* to leave the respiratory tract and induce systemic disease is currently unknown, although the presence of other pathogens or stress may facilitate the spread of the organism systemically. Once systemic, the organism produces polyserositis and polyarthritis in pigs less than 8 weeks of age, and infection in 3–6-month-old pigs typically results in only arthritis (Potgieter et al. 1972; Potgieter and Ross 1972).

Isolation of the organism from areas of polyserositis or arthritis is most successful during the acute stages of disease. It may be possible to isolate the organism later in infection and the organism has been shown to persist as long as 6 months in some joints. In a study of arthritis in Canada, 56 of 153 joints with arthritis were positive for bacteria and 5 of those were a *Mycoplasma* sp, with 3 confirmed as *M. hyorhinis* (Hariharan et al. 1992). This suggests that, although infection with the organism is potentially capable of inducing arthritis in pigs, it is not a frequent cause. Genetic differences in the susceptibility of pigs to experimental inoculation with *M. hyorhins* has been suggested and appears to be related to the production of proinflammatory cytokines (Magnusson et al. 1998; Reddy et al. 2000).

Clinical Signs

The polyserositis associated with *M. hyorhinis* infection generally occurs in 3–10-week-old pigs, although occasionally it can occur in older animals. Typically evidence of disease occurs 3–10 days after exposure or the precipitating cause of the systemic spread of the organism. Pigs become unthrifty in appearance with roughened hair coat, slight fever, depression, reduced appetite, reluctance to move, difficulty breathing, abdominal tenderness, lameness, and swollen joints. The acute clinical signs begin to resolve after 10–14 days depending on the severity of the clinical disease. Some pigs continue to do poorly or die acutely. If arthritis is involved, lameness and swollen joints will persist for 2–3 months, although many pigs will remain lame up to 6 months later. In addition, conjunctivitis has been associated with *M. hyorhinis* infection (Friis 1976).

Lesions

The polyserositis of the acute phase of the disease consists of fibrinopurulent pericarditis, pleuritis, and occasionally peritonitis. Over time, the membrane lesions consist of fibrous adhesions and thickened, cloudy, rough serosal membranes. Acute arthritis is associated with painful and swollen joints with increased amounts of serosanguineous synovial fluid. The synovial membranes are swollen and hyperemic. Over time, the synovial fluid increases in amount and fibrous adhesions occur. The lesions appear less active, although erosion of cartilaginous surfaces and pannus formation may occur.

Otitis due to *M. hyorhinis* is characterized by the appearance of mycoplasmas among the cilia in the auditory canal.

Diagnosis

The diagnosis of clinical disease in association with *M. hyorhinis* is commonly made by the appearance of the serofibrinous to fibinopurulent lesions, although other pathogens such as *H. parasuis* and *S. suis* can cause similar lesions. The organism can be isolated during the acute and subacute stages of disease. Freshly necropsied

animals will increase the success in isolating the organism as autolysis reduces the chances of culturing *M. hyorhinis.*

PCR assays capable of detecting *M. hyorhinis* have been used to assist in differentiating the various mycoplasma species isolated from field cases; however, they are not routinely performed as a diagnostic procedure (Taylor et al. 1984, 1985).

Treatment

In vitro antibiotic susceptibility for *M. hyorhinis* has been shown to many antibiotics. However, treatment of clinically affected animals is usually unsuccessful because the majority of the lesions are chronic in nature and elimination of the organism does little to reduce the adhesions and inflammation. Treatment with tylosin or lincomycin may be beneficial (Ross 1992).

Prevention

Control programs should stress preventing the other medical conditions that may predispose the animals to the systemic spread of *M. hyorhinis.* No published information is available on the ability of antibiotics to reduce clinical disease and no vaccine is currently available on a commercial basis.

M. HYOSYNOVIAE ARTHRITIS

M. hyosynoviae-induced arthritis has been recognized throughout the world with reports from the United States (Ross and Duncan 1970), England (Blowey 1993; Roberts et al. 1972), Germany (Ross et al. 1977) and Denmark (Nielsen et al. 2001). It was demonstrated in 1995 that 8–9% of synovial fluid samples from Danish slaughter pigs with nonpurulent arthritis were positive for the organism (Buttenshon 1995), and Friis et al. (1992) isolated the organism from 20% of arthritic lesions of pigs in a Danish abattoir.

Etiology

A review of isolation techniques and the media required for isolating *M. hyosynoviae* are reported in Ross and Karmon (1970). Isolation of the organism is often complicated because of overgrowth by *M. hyorhinis* and bacteria. A selective media has been described that facilitates the ability to isolate *M. hyosynoviae* in the presence of *M. hyorhinis* (Friis 1979). Recent research has identified genetic variation between isolates of the organism with several genotypically distinct variants occurring in a single herd (Kokotovic et al. 1999, 2002).

Epidemiology

M. hyosynoviae colonizes the respiratory tract of pigs (Friis et al. 1991) and is primarily located in the upper portions (Ross and Spear 1973). The organism can persist in carrier swine indefinitely in the tonsils (Friis et al. 1991; Ross and Spear 1973). Although present in infected sows, the organism is not transmitted to the pigs until 4–8 weeks of age (Ross and Spear 1973). Large numbers of the organism are shed only during the acute phase of infection and only intermittently from persistently infected sows (Ross and Spear 1973). It is unknown why the organism can't be isolated from pigs younger than 4 weeks of age; however, it does allow pigs to be obtained that are free of the organism.

Following infection of a few pigs at 4–8 weeks of age, it is thought the organism is spread throughout the pens from either acute or chronically infected animals (Hagedorn-Olsen et al. 1999). The rate of spread may be related to environmental factors as well as stocking density.

Pathogenesis

The acute phase of infection with *M. hyosynoviae* lasts 1–2 weeks, during which time the organism spreads systemically to the joints and various tissues throughout the body. Arthritis can occur after an incubation period of 4–9 days and the mycoplasma can be isolated from the joints during the acute phase, which is 1–2 weeks after the occurrence of lameness and typically 2–3 weeks post exposure. The subacute and chronic phases occur 3–16 weeks after clinical arthritis, during which time the tonsils remain infected and viable organisms can persist in joint and lymph nodes. Infection of pigs from chronically infected animals through pen contact may not result in the systemic spread of the organism, but infect the tonsils only. This suggests that animals are initially infected through the tonsils, which may then result in systemic spread (Hagedorn-Olsen et al. 1999). In a study by Hagedorn-Olsen et al. (1999), septicemia was found in 90% of experimentally infected pigs, 12 of 23 pigs developed clinical arthritis, and 20% of the joints from which the organism was isolated appeared normal, demonstrating that infection does not always result in clinical disease. Differences in genetics, body structure, management practices, and environment appear to play a role in determining whether clinical arthritis will result following infection with *M. hyosynoviae* (Ross 1973). Osteochondrosis or trauma-induced bursal lesions (Nielsen et al. 2001) may predispose pigs to arthritis induced by *M. hyosynoviae*.

Clinical Signs

Clinical lameness associated with *M. hyosynoviae* typically occurs in 3–5-month-old pigs. The lameness appears acutely and may occur in more than one leg. One study found only hindlegs were involved in clinical lameness associated with the organism (Nielsen et al. 2001). Rectal temperatures remain normal, and pigs may exhibit a slight reduction in appetite with an accompanying weight loss. Often soft fluctuating to no joint swelling is observed, with no evidence of suppurative arthritis.

Acute signs persist for 3–10 days after which the

lameness gradually decreases in severity. Many animals recover with no further lameness or may exhibit stiffness of motion. Continued clinical signs are often due to osteochondrosis as well as *M. hyosynoviae*-induced arthritis. Mortality is low and morbidity ranges form 1–50% in affected herds (Ross 1992).

Lesions

Proliferation, swelling, edema, and hyperemia of synovial membranes are common in *M. hyosynoviae*-infected joints. Increased volumes of synovial fluid that is serofibrinous to serosanguineous in nature are frequently observed. Lame pigs may have cloudy to brownish-colored synovial fluid. The periarticular tissues surrounding the affected joint are often edematous. In chronic phases the joint membranes may be thickened with fibrosis with pannus formation occurring. Cartilaginous changes may be associated with either *M. hyosynoviae* infection or due to osteochondrosis. Pseudocysts or calluses on the cranial surface of the carpal joint or the plantar and lateral surface of the tarsal joint may occur (Nielsen et al. 2001). Microscopically, acute lesions are characterized by edema, hyperemia, hyperplasia of synovial cells, and perivascular infiltration with mononuclear cells, including lymphocytes, monocytes, and macrophages. As the infection progresses, increased numbers of plasma cells and lymphocytes are present, followed by fibrosis as the joint heals (Hagedorn-Olsen et al. 1999).

Diagnosis

Acute lameness in 10–20-week-old pigs that is not responsive to penicillin is suggestive of *M. hyosynoviae* (Ross 1992). Isolation of the organism from the joint that exhibits lesions consistent with *M. hyosynoviae* infection is required for a definitive diagnosis. Animals with a disease profile consistent with *M. hyosynoviae* infection and in the acute phase of the disease should be selected for diagnostic procedures. Joint fluids from several animals should be collected from live animals or at slaughter or necropsy.

Serology can be used to detect antibodies to the organism. Both complement fixation and ELISA assays have been described, although these assays are not generally available in the U.S. (Hagedorn-Olsen et al. 1999; Zimmermann and Ross 1982). Pigs with subclinical infections may develop antibodies in the absence of disease, so the use of paired serum samples collected during the acute and subacute or chronic phase of disease should be used to ascertain that the antibody levels are increasing with the clinical disease.

Treatment

An in vitro study demonstrated that enrofloxacin, lincomycin, tetracycline, and tiamulin are all active against the *M. hyosynoviae* (Aarestrup and Friis 1998). In the same study, isolates collected between 1968–1971 ap-

peared to be highly susceptible to tylosin activity, and isolates collected in 1995–1996 were divided between highly susceptible and relatively resistant, suggesting the development of resistance to tylosin by some isolates (Aarestrup and Friis 1998). Earlier studies had documented that *M. hyosynoviae* was sensitive to tylosin, lincomycin (Zimmermann and Ross 1975), and valnemulin (Hannan et al. 1997). In addition, Burch et al. (1984) demonstrated that the use of tiamulin and lincomycin was effective in improving production parameters and reducing lameness in a herd that was experiencing clinical disease associated with *M. hyosynoviae*. However, in a study of 9 Danish herds, treatment had no apparent impact on the outcome of clinical disease, with the majority of lameness resolving independent of the antibiotic therapy used (Nielsen et al. 2001).

MYCOPLASMA HAEMOSUIS (SUIS) (EPERYTHROZOON SUIS)

With the advent of molecular biology, *Eperythrozoon suis* has recently been reclassified as a member of the Mollicutes family based on the physical characteristic of the organism and the 16s ribosomal RNA gene sequences. Initially renamed *Mycoplasma suis,* it has been proposed to be called *M. haemosuis* and will be used in this chapter (Neimark et al. 2002). Independent of name, the organism remains the cause of anemia in pigs.

Etiology

M. haemosuis was originally observed as "a rickettsia-like or anaplasmosis-like disease in swine" characterized by icteroanemia, respiratory distress, weakness and fever occurring in 2–8-month-old pigs (Doyle 1932). In 1950, Splitter and Williamson described the organism responsible for the clinical disease observed earlier by Doyle and named the organism *Eperythrozoon suis* because of its similarity to similar organisms in cattle and sheep. Originally described as two species, *E. suis* and *E. parvum* due to differences in appearance, it was later determined that they were the same organism at different stages of maturity (Liebich and Heinritzi 1992; Zachary and Basgall 1985).

M. haemosuis were originally classified in the family Anaplasmataceae due to biologic and phenotypic characteristics that were not consistent with regular bacteria (Moulder 1974). However, there was always a suspicion that they were a member of the class Mollicutes based on their lack of intracellular parasitism, small size, lack of cell wall, resistance, and susceptibility to tetracyclines (Tanaka et al. 1965). This was confirmed in 1997 when Rikihisa, et al. (1997) sequenced the 16s rRNA gene sequences of the organsims. The gene sequences were found to have little in common with other Rickettsial organisms, instead being closer to other mycoplasmal species (Johansson et al. 1999). As a result, it was proposed that *E. suis* be named *Mycoplasma suis* (Neimark et

al. 2002). However, rather than naming the organism after the species it was suggested that the name *M. haemosuis* be used (Neimark et al. 2001).

M. haemosuis is round to oval with an average diameter of 0.2–2 μm that adheres to the surface of erythrocyte membranes (Liebich and Heinritzi 1992; Zachary and Basgall 1985). It has not been cultured in media in the absence of cells to date.

Epidemiology

The disease has been reported to be widespread in the Midwestern U.S. (Splitter 1950a). Smith et al. (1977) tested 10,000 swine sera and found approximately 20% of the animals were seropositive at a titer of 40 or more using an indirect hemagglutination assay (IHA) (Smith and Rahn 1975). Morbidity ranges from 10–60% and mortality may reach up to 90% in association with acute disease (Anthony et al. 1962). Morbidity due to subclinical infection is much lower as is mortality and difficult to measure. Recently a PCR assay has been developed and a small study found that 29% of the serum of 60 pigs tested were positive for the organism (Messick 2004). Clinical disease is often closely associated with outbreaks of other infectious diseases present in the herd.

Transmission of the organism can be through direct exposure by oral uptake of blood and blood components by such practices such as licking wounds, cannibalism, or uptake of blood-contaminated urine. Indirect transmission also occurs by means of vectors, including ectoparasites and blood-sucking insects, and by nonliving vectors such as contaminated needles, surgical instruments, or snares. Transmission by semen occurs only in the case of blood contamination and thus is rare (Heinritzi 1999).

The incubation period in experimentally infected and splenectomized pigs is between 3 and 30 days. This results in an acute phase of the disease. However, a carrier state that can recrudesce is also possible (Splitter 1950b).

Pathogenesis

The initial decrease in PCV, total RBC count, and hemoglobin concentration observed with *M. haemosuis* infection is due to massive parasitism of RBC. The resulting reduction in RBC numbers may contribute to the development of anemia and bilirubinemia. Infected RBCs are more fragile, have altered membranes, and are recognized as abnormal and removed from the circulation by the spleen. In addition to the direct damage to RBC membranes, the host immune response appears to play a role in both acute and chronic forms of the anemia associated with *M. haemosuis*. This is due to the presence of autoantibodies present to the RBCs (Smith 1992). The production of cold-reacting agglutinins is directed at sialoglycoconjugates on the RBC membranes (Feizi and Loveless 1996). It has been suggested that the host's immune response may exacerbate the hemolytic episodes.

A prerequisite for RBC agglutination is some type of membrane injury and blood from pigs with both spontaneous and experimentally produced infection agglutinated in the cold (Hoffman et al. 1981). The mechanism used by *M. haemosuis* to adhere to RBCs is unknown.

In the acute phase, an increased bleeding potential is observed occasionally resulting in a consumptive coagulopathy. The greater the number of RBCs affected by the organism, the more striking the changes. Similar effects on blood coagulation are not observed with latent infection with *M. haemosuis* (Plank and Heinritzi 1990). During acute infection, hypoglycemia and blood acidosis can occur due to the metabolic activity of the organism (Heinritzi 1999).

In addition to the changes in the RBCs, research has demonstrated that *M. haemosuis* infection results in a transient hyperglobulinemia that increases the IHA titers. Lymphocyte responses to the nonspecific mitogens, phytohemagglutinin, pokeweed, and *E. coli* lipopolysaccharide was reduced after massive parasitemia. This may be one of the mechanisms for the increased occurrence of diseases of the respiratory and enteric tracts observed following infection (Zachary and Smith 1985). Further support of the impact that the organism has on the immune response is demonstrated by the increased difficulty in controlling other diseases in *M. haemosuis*-infected herds (Henry 1979).

Clinical outbreaks may increase in frequency in infected herds, but eventually a certain equilibrium is reached between the organism and the pigs that results in minimal disease that can be attributed directly to *M. haemosuis*. This equilibrium can be disrupted by other pathogens, stress, or inadequate management practices resulting in a clinical outbreak, which makes management critical in controlling the disease in an infected herd. The primary importance of a *M. haemosuis* infection within a herd is the impact the infection has on production parameters.

Clinical Signs

M. haemosuis infection can cause acute hemolytic disease and death in young pigs, prepartum sows, and stressed weaned and feeder pigs (Henry 1979; Smith 1992). Pigs of any age can exhibit disease in association with *M. haemosuis*. Pallor, fever, occasional icterus, and cyanosis of the extremities, especially the ears, are observed clinically during the acute phases of the disease. More commonly, mild anemia and poor growth rates are observed in weaned and feeder pigs. Infection of sows may result in fever, anorexia, lethargy, decreased mild production, and poor maternal behavior. Clinical disease in sows typically occurs within 3–4 days of introduction to the farrowing room or immediately after farrowing.

Chronic infections in animals with low or undetectable numbers of parasites results in uthriftiness, pallor, and occasionally skin hypersensitivities character-

ized by urticaria. Chronic *M. haemosuis* infections have been associated with decreased reproduction, resulting in sows with anestrus, delayed estrus, early embryonic death, and abortions. However, Zinn et al. (1983) found no appreciable impact on sow reproductive performance, but did see a reduced rate of gain in pigs farrowed from sows with high IHA titers.

In all cases, secondary bacterial or viral infections, poor management strategies, including overcrowding, poor environmental conditions, and the presence of parasites contribute to the severity of disease associated with *M. haemosuis* infection. Frequent injections and vaccinations can also be an important factor in spread of the organisms as well as subsequent reinfection. The use of oral treatment with tetracycline in treatment of other diseases can mask the clinical signs.

Diagnosis

Diagnosis is based on clinical signs, hematology results, demonstration of the organism, IHA assays for antibodies, and PCR. Prior to the development of PCR assays, the best diagnostic test to detect or confirm latent infection in carrier animals was by splenectomizing a potentially infected pig or by inoculation of a splenectomized pig with blood from suspected pigs.

Serological assays include the IHA assay (Smith and Rahn 1975). The production of antibodies occurs in waves, with each reinfection or recrudescent episode resulting in the production of new antibodies. However, the antibody titers persist only 2–3 months resulting in frequent false negative results (Heinritzi 1999).

More recently a PCR assay has been developed that is more sensitive and allows increased detection of pigs that are either carriers or subclinically infected (Messick et al. 1999).

Treatment

The treatment of choice is oxytetracycline at a dose of 20–30 mg/kg administered parenterally (Heinritzi 1999). Acutely ill pigs require parenteral treatment due to lack of adequate feed consumption. Administration of oxytetracycline at times of stress or treatment in infected herds may help prevent acute disease. However, treatment does eliminate the organism from the pig. Oral chlortetracycline therapy can reduce the incidence of anemia, although will not prevent outbreaks. Supportive therapy and iron injections (200 mg iron dextran/pig) will help recovery and minimize mortality.

Prevention

Supportive and prophylactic measures should be included with therapy (Claxton and Klunish 1975). Stopping the spread of the organism and preventing reinfection are critical to controlling disease in the herd. Parasitic control and hygiene are critical for disease control. Transmission by needles and surgical instruments must be minimized by changing needles between sows and litters.

No vaccines are available and if a herd is *M. haemosuis*-free, new additions should also be from herds negative for the organism. Negative status can be assumed if serologic or PCR tests from serum of pigs in the farrowing unit are negative or if transfusion from at least 10 blood samples into splenectomized pigs has no effect.

OTHER MYCOPLASMAS FROM SWINE

A number of mycoplasmas are present in swine that are of less importance to the industry than those discussed earlier in this chapter. These include mycoplasmas that are typically in other species, strains that are not normally associated with disease in swine, and acholeplasmas, which are common in a wide variety of animals and plants.

A species of mycoplasma that is frequently isolated from swine, but considered nonpathogenic is *M. flocculare.* It was first isolated from the respiratory tract of pigs in Denmark (Friis 1972). Since that time, the organism has been isolated by researchers in the U.K., Sweden, and the U.S. (Armstrong and Friis 1981). It was demonstrated that *M. flocculare* is capable of inducing lymphocytic infiltrations in the nasal tissues and peribronchial areas (Friis 1973). These findings were later confirmed by Armstrong et al. (1987). However the role of *M. flocculare* in respiratory disease in the field remains poorly defined. *M. flocculare* is of primary importance to the swine industry due to its antigenic similarities to *M. hyopneumoniae,* which can complicate their differentiation both antigenically following culture and isolation and more importantly, serologically (Bereiter et al. 1990). However, it has been confirmed using molecular techniques that the two organisms differ genetically (Blank and Stemke 2001).

Infection of the genitourinary tract with mycoplasmas in many animal species is common; however, little evidence has been presented reporting similar findings in swine. Shin et al. (2003) demonstrated a cytopathic species of *M. hyorhinis* that was thought to be a cause of abortions in sows.

Other species of mycoplasmas that have been isolated from swine include *M. sualvi, M. hyopharyngis, M. arginini, M. bovigenitalium, M. buccale, M. gallinarum, M. iners, M. mycoides,* and *M. salivarium.* In addition to mycoplasmas, Acholeplasmas have occasionally been isolated from the respiratory tract of swine (Gois et al. 1969). Acholeplasmas differ from Mycoplasmas by having a larger genome and being capable of growing in media that lacks sterols (Ross 1992). No importance in their presence of pigs has been demonstrated.

43 Pneumonic Pasteurellosis

Carlos Pijoan

Pneumonic pasteurellosis, the result of *Pasteurella multocida* infection of the lung, is the common final stage of enzootic pneumonia or porcine respiratory disease complex (PRDC). This syndrome is one of the most common and costly diseases of pigs, especially when they are raised under confinement. Published data suggest that pneumonic lesions at slaughter are very common, even in well-managed herds. Reports on the prevalence of pigs with pneumonic lesions at slaughter has varied from as low as 30% to as high as 80% in various studies through the years. Recent data from the United States found a prevalence of 75% of pigs with pneumonia and 13% with pleuritis in a sample of 6634 pigs inspected, with all herds studied showing some animals with lesions (Bahnson 1994), which highlights pneumonia as the most frequent lesion seen at slaughter.

Pneumonia in pigs also appears to be a very costly disease, although the actual cost has been difficult to calculate and has varied widely in published results. Noyes et al. (1990) performed a radiographic study of pigs' lungs in a commercial herd in order to evaluate lifetime pneumonia and found a significant correlation between the extent of lifetime pneumonic lesions and the weight of the animals at 180 days. Bahnson (1994) compared batches of finishing pigs sent to slaughter. The batch with the highest pneumonia scores had a 7.8% lower rate of gain than the batch with the lowest score, a difference that has considerable economic impact.

Pneumonic pasteurellosis occurs worldwide and in all climates and husbandry conditions. Specific-pathogen-free (SPF) schemes, especially at the national level, do achieve a degree of control, presumably through the eradication of *Mycoplasma hyopneumoniae.* However, *P. multocida,* which is a common inhabitant of the pig's nasal flora, is extremely difficult to eradicate and can be found in most high-health-status herds, such as SPF or minimal-disease herds. Since pasteurellae can interact directly with other agents, elimination of mycoplasmas does not give an absolute guarantee of controlling pneumonia.

A more recent strategy for raising high-health-status pigs has been to use a combination of segregation of the offspring together with early weaning. This program of segregated early weaning (SEW) has been extremely successful in controlling and minimizing most of the common diseases that affect the pig. However, its impact on pneumonic pasteurellosis has been variable. In most farms and groups of pigs, pneumonia at slaughter has decreased to negligible levels. However, some farms have presented with severe pneumonia during the late finishing stages, around 16–18 weeks of age. This late pneumonia has been attributed mostly to infection by *M. hyopneumoniae,* but *P. multocida* is also commonly isolated. SEW, at least when used with weaning at 15 days, does not eliminate *P. multocida* from the offspring. Elimination of *M. hyopneumoniae* is more variable and unpredictable, probably dependent on sow immunity, and is most probably the predisposing trigger for pneumonia in these systems.

ETIOLOGY

P. multocida is a gram-negative coccobacillus, 0.5–1 4× 1–2 μm in size. The organism is a facultative anaerobe, growing well in most enriched media. It is oxidase positive, nonmotile, indole positive, and urease negative. It does not grow well in MacConkey and is nonhemolytic and does not require X and V factors. These reactions are helpful in differentiating *P. multocida* from a group of closely related bacteria that are also involved in pulmonary diseases of pigs, namely, *P. haemolytica, Actinobacillus suis,* and *A. pleuropneumoniae.*

P. multocida has five capsular serotypes, A, B, D, E, and F of which A, B, and D have been reported in swine. Serotype B however, is atypical in that it produces a much more severe disease. It is also rare, confined to regions of Southeast Asia, China, and India (Verma 1988). It has not been reported from natural outbreaks in pigs in North America or Europe. The most common serotype isolated from pneumonic lungs is A, although a variable proportion of serotype D strains is also found

(Pijoan et al. 1983a, 1984; Kielstein 1986; Hoie et al. 1991; Rubies et al. 1996). *P. multocida* also has 16 somatic serotypes; strains of serotypes 3 and 5 are commonly detected in pigs, with strains A:3, A:5, D:5, and D:3 being the most prevalent, in that order.

Virulence Factors

The virulence factors of *P. multocida* are not well defined. In particular, the importance of the dermonecrotic toxin (DNT) is unresolved. This toxin is central to the production of atrophic rhinitis (see Chapter 34) when only toxigenic strains of *P. multocida* are involved in the disease. Toxigenic strains of *P. multocida* from lungs were first reported by Pijoan et al. (1984). Since then, a number of authors have found increasing numbers of toxigenic strains (both type A and type D) in pneumonic lungs. Some reports (Kielstein 1986; Iwamatsu and Sawada 1988) show that between 25% and 45% of strains isolated from lungs are toxigenic. Kielstein (1986) found that toxigenic strains were frequently isolated from acute cases but not from slaughterhouse lungs, suggesting enhanced virulence. However, Baekbo (1988) postulated that toxigenicity was not important in determining the virulence of *P. multocida* in experimentally infected animals.

The role, if any, of toxigenicity in pneumonic pasteurellosis is still under debate. For example, Hoie et al. (1991) found that 94% of serotype A and 90% of serotype D isolates from pneumonic lungs were toxigenic. In contrast, Rubies et al. (1996) found no toxigenic strains (either A or D) in 218 isolates from pneumonic lungs in Spain.

The capsule appears to be an important virulence factor, especially in serotype A, for it may help the organism avoid phagocytosis by alveolar macrophages, at least in vitro. Maheswaran and Thies (1979) reported that *P. multocida* uptake by swine alveolar macrophages was very low, even in the presence of opsonins. Similar results were found by Fuentes and Pijoan (1986). More recent work, however, suggests that little capsule is expressed when the organisms are grown under iron-restricted conditions (Jacques et al. 1994). These growth conditions mimic the scenario found in vivo. Thus, the relevance of the capsule to virulence may have been overestimated in the past.

Some strains of *P. multocida* are able to produce pleuritis and abscessation in experimentally infected pigs (Pijoan and Fuentes 1987). The virulence factors that distinguish these strains from less virulent pneumonic strains are not defined. However, Iwamatso and Sawada (1988) found that strains of serotype D or toxigenic strains (of both serotypes) were associated with abscesses but not with pleuritis.

Mucosal Colonization

The colonization of mucous surfaces by *P. multocida* has received some attention lately, as it is of paramount im-

portance in understanding the pathogenesis of this organism. Jacques (1987) found that both serotypes A and D adhered poorly to isolated tracheal epithelial cells, although serotype A strains were more adherent. He later showed that serotype A strains adhered mostly to ciliated epithelial cells. Pijoan and Trigo (1989) also found sparse colonization by serotype A and D strains but found that serotype D strains adhered mostly to nonciliated cells. Trigo and Pijoan (1988) and later Issacson and Trigo (1995) found that some strains, in particular toxigenic ones, had detectable pili on their surface, although the role of these structures in adhesion is still under debate. In contrast to their poor attachment to epithelial surfaces, *P. multocida* strains have been shown to attach readily to nasal mucus, raising questions as to where normal attachment and colonization take place.

The presence of capsule has been shown to decrease the attachment of *P. multocida* to respiratory tract mucus, as well as to cultured tracheal rings (Jacques et al. 1993). On the other hand, the same group has reported that preinfection of tracheal rings with *Bordetella bronchiseptica* enhanced subsequent attachment by *P. multocida* (Dugal et al. 1992). Some other authors, however, have had difficulties in confirming that *P. multocida* attached to immobilized mucus (Issacson and Trigo 1995).

Mucosal colonization of suckling pigs is becoming a very important issue in SEW systems. It has been postulated (Pijoan 1995) that pigs weaned early (at 15 days of age or less) are not homogeneously colonized with organisms such as *P. multocida* and *M. hyopneumoniae*. As a result, pigs are weaned into isolated nurseries in populations that have a variable prevalence of colonized animals. Populations with low prevalence of colonization are at risk of developing severe clinical disease, because some pigs in the population will become infected very late, at a time when no maternal immunity is available. This could explain why SEW systems sometimes present with delayed PRDC (the "18-week wall") (Dee 1997).

EPIDEMIOLOGY

The epidemiology of *P. multocida* is not well understood. The organism is present in practically all herds and can be readily isolated from the nose and tonsils of normal, healthy individuals. Transmission of the disease by aerosols has been postulated but is unlikely to be of importance. Baekbo and Nielsen (1988) measured airborne *P. multocida* in herds suffering from atrophic rhinitis. They were able to isolate the organism in 29 of 44 herds studied. However, the low number of organisms isolated (144 CFU/mL) led them to conclude that there was no relationship between the number of organisms recovered and the severity of the clinical problem.

Although aerosol transmission may occasionally occur within the herd, it is probable that nose-to-nose contact is the common route of infection. Both vertical and horizontal transmission occur, although within

farms most transmission appears to be horizontal, with one strain predominating in pneumonic lungs (Zhao et al. 1993). This suggests the existence of *P. multocida* strains of variable virulence, with one of the more virulent strains producing most of the disease within a population. External sources of the organism include mice and other rodents, although chickens and chicken manure have also been postulated as sources. These are probably not common sources of the organism in modern swine farms, however.

PATHOGENESIS

Experimental infections with *P. multocida* are very difficult to produce. Healthy pigs will readily tolerate large doses of organisms instilled intranasally or even intratracheally. Pulmonary clearance is very effective, and the bacteria cannot be reisolated 30 minutes after challenge. Recent work demonstrating that little capsule is present in vivo has clarified the apparent disparity between the poor phagocytosis observed in vitro and the ready clearance of bacteria found in healthy animals. Experimental models of the disease have used serotype B organisms (Farrington 1986), previous infections with immunosuppressive virus or mycoplasmas (Fuentes and Pijoan 1986; Ciprian et al. 1988), or massive instillation of infected fluids into the lung (Hall et al. 1988). This has led to the conclusion that *P. multocida* is not a primary agent of pneumonia but rather follows infections with other agents. Vaccination against hog cholera virus (Pijoan and Ochoa 1978) and infection with Aujezsky's virus (Fuentes and Pijoan 1987) or *M. hyopneumoniae* (Ciprian et al. 1988) have all been shown to predispose the pig to superinfections with *P. multocida*. In contrast, porcine reproductive and respiratory syndrome (PRRS) virus could not be shown to interact with *P. multocida* in the production of pneumonia (Carvalho et al. 1997).

Once established, the organism stimulates a rapid suppurative reaction, characterized by neutrophil infiltration. This is probably a host reaction to bacterial lipopolysaccharide, which stimulates the release of inflammatory cytokines. Death is uncommon, probably the result of endotoxic shock and respiratory failure.

CLINICAL SIGNS

The clinical signs vary in severity depending on the strain of *P. multocida* involved, together with the immune status of the animals.

Acute Form

This form is most commonly associated with serotype B strains. It is rare and is never seen in Europe or North America. The animals show dyspnea, labored breathing with abdominal "thumps" (sudden contractions of the abdomen), prostration, and high fever (up to 42.2°C, 108°F). Mortality may be high (5–40%) in these cases;

dead and moribund animals may show purplish discoloration of the abdominal region, suggesting endotoxic shock.

Subacute Form

This is associated with *P. multocida* strains that produce pleuritis. In these cases, cough and abdominal breathing can be detected in grower or finishing pigs up to market weight. Cough in this age pig is usually the hallmark of severe disease. Clinically, this form of the disease is very similar to pleuropneumonia due to *A. pleuropneumoniae* (see Chapter 33). The main distinguishing feature is that pleuritic pasteurellosis rarely results in sudden death. Rather, pigs become extremely emaciated but may survive for a long time. Recently, outbreaks of PRDC in finishing pigs (about 16–18 weeks of age) on farms using SEW methods has resulted in cough and abdominal breathing in pigs but usually not pleuritis (Dee 1997).

Chronic Form

This is the most common form of the disease, characterized by occasional cough, thumping, and low or nonexistent fever. Animals affected are usually in the later stages of the nursery or are growers (10–16 weeks of age). The signs are indistinguishable from those following *M. hyopneumoniae* infections, for *P. multocida* causes the continuation and exacerbation of primary mycoplasmosis.

LESIONS

Lesions of *P. multocida* are confined to the thoracic cavity and are superimposed on those of *M. hyopneumoniae*. Typically, anteroventral consolidation of the lung is seen, together with froth in the trachea. There is a clear line of demarcation between affected and healthy lung tissue. The affected portion of the lung will have discoloration ranging from red to grayish-green, depending on the course of the infection (Figure 43.1).

Severe cases may present varying degrees of pleuritis and abscessation. Pleural adhesions to the thoracic wall are common in these cases, and the pleura has a translucent, dry appearance (Figures 43.2, 43.3). This is useful in differentiating pneumonic pasteurellosis from actinobacillus pleuropneumonia, in which moist, yellowish pleural adhesions with massive fibrin infiltration are more common (Pijoan 1989).

Histologically, a lobular, exudative bronchopneumonia is found. Severe bronchopneumonia, alveolar epithelial hyperplasia, and the presence of abundant neutrophils are seen with mucopurulent exudate in the bronchial lumen and in alveolar spaces. These lesions are not specific to *P. multocida* infections and are similar for most bacterial pneumonias.

Evidence has also been presented for a relationship between pasteurella-induced bronchopneumonia and the presence of disseminated focal nephritis (Butten-

43.1. *Pneumonic pasteurellosis. Lung consolidation is anteroventral with a clear demarcation line between affected and healthy tissue.*

schon 1991). The author concluded that the two diseases are connected by a process of dissemination from the pulmonary lesions.

DIAGNOSIS

Since the lesions of *P. multocida* infection are not pathognomonic, they cannot be used as the only criteria to establish a definite diagnosis. The history of the outbreak, histopathology, and isolation of the organism should be used to confirm the original presumptive diagnosis. Serology has not proven effective for diagnosis, and no serologic test is routinely available for *P. multocida* infections.

P. multocida is a relatively easy organism to culture, provided proper specimens are submitted to the laboratory. Specimens yielding the best isolations include swabs of tracheobronchial exudate and affected lung tissue obtained from the border area between affected and normal tissue. Nasal swabs have also been shown to be good samples for isolation of *P. multocida* (Schoss and Alt 1995). Swabs should be immersed in an appropriate transport medium, such as Stuart's. Lung samples should be obtained as aseptically as possible. All samples should be refrigerated (but not frozen) until cultured.

Culture of *P. multocida* can be successfully achieved in laboratories with minimal facilities. Good-quality specimens will yield the organism on direct culture onto blood agar or glucose agar plates. If the samples are more contaminated, they can be serially diluted tenfold in brain-heart infusion (BHI) broth, grown overnight, and then plated (Pijoan et al. 1983b). Alternatively, selective media can be used: Ackermann et al. (1994) successfully isolated *P. multocida* from tonsils and turbinates of adult pigs using blood agar with 3.75 U/mL of bacitracin, 5 µg/mL clindamycin, 0.75 µg/mL gentamicin, and 2.25

43.3. *Lung from a case of pleuritic pasteurellosis. Note anteroventral, well-demarcated lesions, together with the presence of multiple abscesses. There is extensive interlobar adhesion.*

μg/mL of amphotericin B. Isolation can also be enhanced by injecting the specimen intraperitoneally into mice and then recovering the pasteurellae 24 hours later from liver and ascitic fluid.

Differential diagnosis must include influenza virus, *A. pleuropneumoniae, B. bronchiseptica, Salmonella choleraesuis,* and pure *M. hyopneumoniae* infections. Accurate clinical differentiation based on the epidemiology and lesions can be readily achieved for some of these conditions but may be difficult in cases of influenza, *B. bronchiseptica,* or *M. hyopneumoniae.* In these cases, histology and bacterial culture will be needed. Ramirez and Pijoan (1982) and Straw (1986a) have published tables for the differential diagnosis of these conditions.

TREATMENT

Treatment of *P. multocida* field infections with antibiotics is usually difficult or unsuccessful. This is partly due to widespread antibiotic resistance in *P. multocida* isolates in the United States and also to difficulties in achieving adequate antibiotic concentrations in consolidated, pneumonic lung.

A variety of antibiotics and antibiotic combinations have been commonly used (Farrington 1986). These include parenteral antibiotics such as oxytetracycline, 11 mg/kg; long-acting oxytetracycline, 20 mg/kg; procaine penicillin, 66,000 units/kg; benzathine penicillin, 32,000 units/kg; tiamulin, 10–12.5 mg/kg; and ampicillin, 6.6 mg/kg. Many of these drugs, however, are becoming increasingly less efficient due to widespread antibiotic resistance. Treatment via feed antibiotics has also been suggested, although, as in the case of other pneumonias, it is probably not very effective.

Cote et al. (1991) found some plasmid-mediated resistance to streptomycin and sulfonamides among 29 field isolates investigated. Gutierrez Martin and Rodriguez Ferri (1993) studied 59 Spanish isolates, finding good activity with penicillins, aminoglycosides, tetracyclines, erythromycin, colistin, and rifampicin, with some resistance to tylosin, vancomycin, and tiamulin. They reported that third-generation cephalosporins and fluorinated quinolones were the most effective drugs. Raemdonck et al. (1994) found good minimum inhibitory concentrations (MIC) for danofloxacin, ceftiofur, and trimethoprim-sulfonamide; they found variable to high resistance to erythromycin, gentamicin, lincomycin, oxytetracyclines, and spectinomycin. Finally, Salmon et al. (1995) tested isolates from several countries and found the best activity with cephalosporins and enrofloxacin, with poor activity shown in vitro by erythromycin, sulfamethazine, spectinomycin, and lincomycin.

The effectiveness of all these antimicrobials will vary considerably depending on strain susceptibility. Since *P. multocida* readily exhibits resistance to various antimicrobials, antibiograms should be performed before instituting treatment.

As in other respiratory infections, antibiotics are more effective when used as prophylactic, rather than therapeutic, agents. Tetracyclines alone, tetracyclines combined with sulfamethazine or sulfathiazole or penicillin, and tylosin combined with sulfamethazine have been recommended for this purpose. It is probable that the most effective compound in these mixtures is sulfamethazine. This antimicrobial has been the focus of controversy over residues. Because of this, its use has been severely limited and monitored. Tiamulin (40 ppm in feed) has been shown, in a number of trials, to improve average daily gain. However, since pneumonic lesions are not significantly reduced by this antibiotic (Pott and Edwards 1990), the mode of action by which these improvements are obtained is unclear. Tiamulin has been found to be of variable effectiveness against *P. multocida.* It is therefore probable that its main effect in pneumonia lies in the control of *M. hyopneumoniae.*

Some new antibiotics with claims for *P. multocida* treatment are not available in the United States but are

used extensively in other countries. These include injectable lincomycin-spectinomycin, some cephalosporins, and various quinolones including enrofloxacin and danofloxacin. Injectable ceftiofur is available in the United States, however, and it has been shown by a number of authors to have good activity against *P. multocida*.

PREVENTION

Management Approaches

Since antibiotic therapy is often unsuccessful and even when successful may not prove cost-effective, prevention of pneumonia has received much attention. Prevention is usually obtained through changes in management. The management techniques that result in decreased pneumonia have been reviewed by several authors (Pijoan 1986; Straw 1986b). Caution must be taken when implementing these recommendations, since they derive mostly from retrospective epidemiological studies and not from experimental data. Also, they are intended to reduce pneumonia as a whole (and other respiratory problems) and do not differentiate between conditions of different etiology.

Management changes can be directed either at modifying the pigs' environment or at reducing the possibilities of spreading the organism.

Environmental changes such as increasing ventilation flow rate, decreasing ammonia, and minimizing temperature fluctuations and dust are usually recommended. Some of these recommendations are antagonistic; increasing airflow, especially in winter, results in a decrease of both temperature and humidity, with an increase in dust. Most of these changes have not proven valuable in controlled, experimental conditions. Noyes et al. (1986) found that decreasing ventilation below minimal recommended levels (0.5 CFM/pig) had no effect on weaned pigs inoculated with both *B. bronchiseptica* and *P. multocida*. Similarly, Rafai et al. (1987) found that cold stress, even though it reduced immune function in suckling pigs, had no effect on the course of an experimental *P. multocida* infection. Environmental changes frequently entail extensive remodeling. They are, therefore, expensive to institute and maintain. It is not clear that these changes are cost-effective in terms of reducing respiratory disease.

On the other hand, considerable improvement may be obtained by instituting management changes that reduce the spread of the organism. These include the following:

1. Segregated early weaning: SEW has a major impact on pneumonia and, when properly done, will reduce or eliminate pneumonia from most groups of pigs. This is probably based on the control of *M. hyopneumoniae,* which in many herds is virtually eliminated. Early weaning probably has less effect on *P. multocida*, since

it has been shown that pigs are colonized as early as 10 days of age. Occasional farms or groups of pigs will experience acute outbreaks of pneumonia.

2. All-in/all-out production: In farms where SEW is not possible, efforts should be made to institute an all-in/all-out production program. Several workers have shown that this type of production system markedly decreases the incidence of pneumonia.

3. Closed herds: Minimizing the purchase of outside pigs, especially fatteners, will result in a decrease of pneumonia and other respiratory conditions. However, the pressure to improve genetics in modern farms has forced most producers to purchase their breeding animals. It has become increasingly important to evaluate the health status of the farm from which these animals are purchased, in order to minimize the probability of introducing disease.

4. Minimal mixing and sorting: This is a source of stress to the pigs, while also intensifying the probabilities of disease transmission. Pigs should be mixed as few times as possible during their productive life.

5. Reduction in building and pen size: Smaller rooms and smaller pens both have been shown to reduce levels of pneumonia. Rooms should have a maximum of 250 pigs, and pens a maximum of 20–25 pigs each. This again is difficult to achieve in modern farms. However, the recent trend of building wean-to-finish barns, where pigs are only mixed once, at weaning, will probably have a positive effect in decreasing pneumonia.

6. Reduction in animal density: Decreasing animal density has been shown by many authors to reduce levels of pneumonia. It is important therefore to find a reasonable compromise between densities that are appropriate for the animals' health and those that maximize returns on the building's cost.

Vaccination

Although several killed vaccines for the prevention of pneumonic pasteurellosis are available, their effectiveness is questionable. Since no reliable model of experimental disease exists, potency testing is usually performed in mice. It is doubtful, therefore, that this model truly replicates the disease in the pig. Under field conditions, clinicians frequently have disappointing results with these vaccines, and they do not appear to be cost-effective.

Some modern approaches to vaccination against *P. multocida* have been reported recently. The use of purified lipopolysaccharide (LPS) antigen and the use of *aro* A gene deletion mutants both resulted in protection against homologous, but not heterologous, challenge (Adler et al. 1996). The use of a cloned, 87 kDa outer-membrane protein had similar limitations (Ruttolo and Adler 1996). Cross-protection has been reported in chickens with the use of a protein preparation from cells grown under iron-deprived conditions, which mimic

the in vivo environment (Wang and Glisson 1994). However, none of these fraction vaccines are commercially available or have been tested in pigs, where the disease is not septicemic as it is in chickens and mice. Therefore, there is at present no successful commercial vaccine against *P. multocida* in the pig.

OTHER PASTEURELLA INFECTIONS IN PIGS

Several authors have sporadically isolated *P. haemolytica*–like organisms from cases of severe necrotizing pleuropneumonia. The lesions seen are similar to those found in *A. pleuropneumoniae* infections but tend to be less severe. In this regard, they are also similar to lesions reported from *A. suis*. A new nicotinamide adenine dinucleotide (NAD)-independent biotype of *A. pleuropneumoniae* has now been recognized, and it is very probable that many of these severe pneumonias are related to these two organisms rather than to *P. hemolytica*.

All these organisms are very similar and differ in minor biochemical reactions such as indole formation or V-factor requirement. Bisgaard (1984) did a comprehensive study of these strains and concluded that they differed from *P. haemolytica* sensu stricto. Since the lesions produced (and the serologic reactions) are indistinguishable from *A. pleuropneumoniae,* it is possible that some field outbreaks have been misdiagnosed. At present, it is very difficult to assess the true prevalence and economic impact of these strains.

44 Proliferative Enteropathies

Steven McOrist and Connie J. Gebhart

Proliferative enteropathies (PE; also known as *ileitis*) are a group of acute and chronic conditions of widely differing clinical signs but with a common underlying pathological change visible at necropsy: a thickening of the mucosa of the small intestine and colon. Histologically, the affected tissues show marked proliferation of immature epithelial cells of the intestinal crypts, forming a hyperplastic to adenoma-like mucosa. These proliferating cells invariably contain numerous intracytoplasmic *Lawsonia intracellularis*, an obligate intracellular bacterium.

In growing pigs with uncomplicated proliferation of the mucosa, the condition is chronic proliferative enteropathy, also known as *porcine intestinal adenomatosis (PIA)* or *ileitis*. In some pigs, these changes can be mild and subclinical or, alternatively, can have additional changes superimposed on this basic lesion, including a necrotic enteritis, a granulomatous regional ileitis, or an acute proliferative hemorrhagic enteropathy (PHE, Rowland and Lawson 1975). The chronic, subclinical and acute hemorrhagic forms of PE are now important enteric diseases in the modern pig industry.

The lesions of PE were first described in pigs in Ames, Iowa, by Biester and others in the 1930s (Biester and Schwarte 1931; Biester et al. 1939) and were subsequently found to occur in other major pig-raising areas throughout the world, but it was not until 1973 that Alan Rowland and Gordon Lawson, investigating major outbreaks occurring in Scotland, developed a productive research program (Rowland and Rowntree 1972; Rowland and Lawson 1974). They found that whenever these proliferative changes in pigs were studied either ultrastructurally or using silver stains, intracellular bacteria were consistently present within the abnormal proliferating cells (Rowland and Lawson 1974). These bacteria lie free in the apical cytoplasm of infected epithelial cells and are not membrane-bound during the important stages of infection. The identity of these bacteria and their etiologic role in PE in pigs were finally resolved in 1993 with successful culture of the intracellular organism and the reproduction of the disease in pigs using a pure culture of this agent (Lawson et al. 1993; McOrist et al. 1993). Also in 1993, its taxonomic position was clarified (Gebhart et al. 1993); its definitive name is *Lawsonia intracellularis* (McOrist et al. 1995a).

Pathological changes closely resembling porcine PE and caused by intracellular Lawsonia species have been described in a wide range of host species as single case reports, including in macaques (Klein et al. 1999; Cooper and Gebhart 1998). However despite obvious infection opportunities, no case of PE or Lawsonia infection has been detected in humans. Natural disease outbreaks are reported in the laboratory hamster (Frisk and Wagner 1977; Williams et al. 1996; Lavoie et al. 2000), in the laboratory rabbit (Schoeb and Fox 1990; Duhamel et al. 1998), in deer (Drolet et al. 1996), and in ratite birds (Cooper et al. 1997; Lemarchand et al. 1997), but importantly, other farm birds and wild-type mice appear resistant (Collins et al. 1999; McOrist et al. 2003a). Experimental transmission studies, in situ immunostaining and DNA analysis across species have demonstrated that the one bacterial species can infect the intestinal cells of a wide variety of host species (Lawson and Gebhart 2000). The common infection among laboratory rabbits hampers simple production of specific polyclonal antibody. However, there is currently no evidence to link these other hosts directly with the onset of disease in farmed pigs. The disease has been detected in wild pigs (Sus scrofa) living in central Europe (Tomanova et al. 2002).

ETIOLOGY

The cause of PE is the obligately intracellular bacterium, *L. intracellularis*, which preferentially grows within the cytoplasm of intestinal epithelial cells. This bacterial growth is invariably accompanied by localized proliferation of infected immature crypt epithelial cells. It has not as yet been cultivated in cell-free media, due to a metabolic requirement for preformed mitochondrial

triphosphates or a similar energy source. Some earlier literature refers to the intracellular bacterium as a Campylobacter-like organism; however, that designation was based only on its morphologic similarity to that genus.

L. intracellularis forms curved to straight vibrioid-shaped rods with either tapered or rounded ends and measure 1.25–1.75 μm in length by 0.25–0.43 μm in width. It has a typical gram-negative trilaminar outer envelope. No fimbriae or spores have been detected. A long, single, polar flagellum and darting motility has been observed in some isolates co-cultured on cell lines, but only when the bacteria are located extracellularly. It has a small, single circular genome and 3 plasmids, totalling 1.72 million bp and 1,324 orf. It possesses the small genome, cell-dependent respiration, low G+C%, and significant expression of the gro EL heat shock proteins commonly seen in other symbiont intracellular bacteria (Dale et al. 1998; McOrist and Gebhart 2004). Despite being placed in the Desulfovibrionaceae family on DNA sequence analysis, it does not appear to have sulfate reduction capacity. In vitro culture of *L. intracellularis* requires co-culture on a transformed cell line such as intestinal epithelial cells, in a microaerobic atmosphere of 82.2% nitrogen, 8.8% carbon dioxide, and 8% oxygen at 37°C (Stills 1991; Lawson et al. 1993). Isolates of *L. intracellularis* from pigs and those from a variety of origins and other host species (hamster, horse, deer) show a very high degree (>98%) of similarity among DNA sequences in key taxonomic sites and in their outer membrane proteins, indicating that a single "strain" of *L. intracellularis* may occur (Cooper et al. 1997; Al-Ghamdi 2003).

Experimental transmission studies using pure cultures of *L. intracellularis* as oral-challenge inocula for conventional pigs and using gnotobiotic pigs predosed with a minimal bacterial flora of nonpathogenic enteric species have resulted in reproduction of the specific lesions of PE (McOrist et al. 1993, 1994). Exposure of pigs to crude, or partially filtered, homogenized diseased mucosa resulted in reproduction of specific intestinal lesions and clinical disease in early challenge trials (Roberts et al. 1977; Mapother et al. 1987; McOrist and Lawson 1989a). This strategy was later revived into a well-chararacterized mucosal homogenate challenge exposure model for reproduction of PE in conventional pigs (Winkelman et al. 2002; Guedes and Gebhart 2003a, b). Intestinal lesions that develop as a result of artificial exposure to various isolates have had all the characteristics of the field disease, including the presence of mucosal proliferation and intracellular bacteria (McOrist et al. 1993; Guedes and Gebhart 2003a, b). *L. intracellularis* isolates derived from American or European origins and from acute or chronic lesions have proved capable of producing typical chronic or acute PE lesions (Mapother et al. 1987; Knittel et al. 1996), indicating that the differing clinical expression of PE cases

(PIA, subclinical, PHE) are due to dosage and host response differences, not to separate bacterial strains.

EPIDEMIOLOGY

The disease is worldwide in distribution and occurs commonly in all pig-raising regions and in all pig farm management systems, including outdoor ones (McOrist et al. 2003b). The incidence of lesions in pigs at normal slaughter age is generally low, at 0.7–2.0%, and therefore unreliable for farm monitoring (Rowland and Hutchings 1978; Christensen and Cullinane 1990; Jensen et al. 1999).

The development and widespread use of Lawsonia-specific PCR suitable for fecal samples and serology methods has enabled a clearer understanding of the widespread prevalence and epidemiology of PE on pig farms. Recent surveys in Europe, Asia, and the Americas have indicated that practically all pig farms have at least a low level of infection and that some 20–40% of pig farms have a notable level of clinical and/or subclinical cases (Moller et al. 1998; Kim et al. 1998; Stege et al. 2000; Bane et al. 2001; Jacobsen et al. 2003; Marsteller et al. 2003).

Comparison of management systems with the onset of infection indicates that on pig farms with age-separation of groups (so-called multisite farm systems) *L. intracellularis* infection occurs rarely in breeding stock and is usually delayed in grower-finishers until they are 12–20 weeks old (Just et al. 2001; Bronsvoort et al. 2001; Chouet et al. 2003). This delayed infection may be associated with the onset of PIA or PHE cases, but antibiotic usage may complicate this simplistic pattern.

In contrast, on single-site farms with a continuous pig flow between different groups (so-called farrow-to-finish systems) there is early postweaning infection at approximately 5 to 7 weeks old, with frequent occurrence of related subclinical and clinical problems (PIA). Infection of piglets probably occurs soon after maternally derived passive immunity wanes, via positive feces exposure. The infection can then amplify over the next few weeks in groups of postweaned "nursery" pigs. In these farms, levels of recent exposure of at least 10% are also evident among healthy breeding females of all parities, with some (<5%) of these exposed sows shedding detectable *L. intracellularis* in their feces. Where group housing of breeding females occurs, this rate of recent exposure consistently rises above 30%, presumably due to higher contamination of the bedding (Stege et al. 2000; Chouet et al. 2003).

It is likely that the environment of many pig farms, particulary the grower-finisher areas, contains a sustained level of *L. intracellularis* infection "embedded" in the fecal material, fomites, pens, insects, and walkways in the buildings. This acts to reintroduce the infection to many new groups of pigs at various ages. However, even with use of the best diagnostic tests, it can be diffi-

cult to establish exactly when a group infection and/or its related clinical outbreak of ileitis starts on any given farm (Hammer 2004). In other words, the infection can build up slowly or quickly, with variations in the time of disease onset on different farms and, importantly, on the same farm between different groups in the same building or pens (Philips et al. 1998; Hammer 2004). The highest levels of exposure in all farms are usually seen in older finisher pigs (Moller et al. 1998; Marsteller et al. 2003). Transmission of positive feces from this contaminated area to other areas of a farm, such as those containing breeding animals, would occur more commonly on single-site farms. Modes of this transmission probably include passive transfer of feces on boots or fomites, such as within rodent feet. Although cross-species transmission of *L. intracellularis* infection has been demonstrated experimentally, an active role of infected vectors has not yet been clearly demonstrated on any *L. intracellularis*–infected farm.

Clinically important outbreaks of acute PHE are now very apparent and frequent, probably due to the persistence of this obvious and often fatal disease in the face of "high health" strategies, such as multisite farms and medicated early weaning (Guedes et al. 2002a). Particular management situations are thought to lend themselves to outbreaks of acute PHE. Young adults (4–12 months old) within boar and gilt performance testing stations, gilts within breeding programs that involve transportation to new units, and the movement and mixing of boars and gilts into breeding groups are commonly associated with PE outbreaks. Although this often partly reflects changes in exposure and use of antibiotics at these times, the occurrence of major stressors, such as extreme weather conditions, is a common feature prior to many outbreaks.

Overall epidemiologic features of PE include: *L. intracellularis* can remain viable in feces at 5 to 15°C for 2 weeks (Collins et al. 2000), the infectious dose is relatively low (McOrist et al. 1993; Guedes et al. 2003) and fecal excretion may be high in some infected "spreader" pigs (Smith and McOrist 1997; Guedes et al. 2002a). Sanitation methods are incompletely understood. Of 6 disinfectants tested in one study (Collins et al. 2000), only quaternary ammonium (3% cetrimide QA) and iodine-based (1% povidone-iodine) compounds showed full bactericidal activity. Isolates appeared somewhat resistant to a 0.33% phenolic mixture. In herds with endemic chronic PE, feces from infected pigs or on the boots of workers can clearly provide the likely source of new infections. Rigorous removal of feces from boots and between batches of pigs in buildings capable of complete "all-in/all-out" is likely to be more effective at control of PE than reliance on slatted floors and sunken pits for feces removal (Smith et al. 1998; Bane et al. 2001). It is possible but not considered likely that feces from infected gilts or sows are responsible for regular transmission to their progeny.

PATHOGENESIS

PE can be reproduced by exposing susceptible pigs to *L. intracellularis* or to diseased mucosa containing these intracellular bacteria (Roberts et al. 1977; McOrist and Lawson 1989; McOrist et al. 1993, 1994; Guedes and Gebhart 2003a). In typical oral challenge exposure studies of postweaned pigs (4 weeks old) with a standard inoculum of 10^8 *L. intracellularis* bacteria, numerous intracellular bacteria can be visualized in the developing proliferative intestines and feces 1–3 weeks following inoculation with a peak of infection and lesions 3 weeks after challenge. In most of these pigs, intestinal infection, proliferative lesions and excretion persists for approximately 4 weeks, but in some exposed pigs, excretion may persist for at least 10 weeks (Smith and McOrist 1997; Guedes et al. 2002a). At the peak of infection 3 weeks after challenge, moderate diarrhea and histologic lesions of PE are usually observed in 50% and 100%, respectively, of animals challenged with this inoculum. Infection and lesions in the large intestine generally occur a week or two after small intestinal infection following oral challenge (Guedes and Gebhart 2003b). Naive pigs of a wide age range (neonates to grower-finishers) are susceptible to oral challenge.

PE develops initially as a progressive proliferation of immature epithelial cells populated by numerous intracellular bacteria. In most cases, no significant inflammatory reaction occurs and the organisms remain in the epithelium at this stage. In severe cases of PE, *L. intracellularis* can also be observed in the mesenteric lymph node and tonsils (Roberts et al. 1980; Jensen et al. 2001), but these appear to be secondary sites. In vivo and in vitro studies have elucidated some of the early events in bacteria-cell interaction (McOrist et al. 1989b, 1995b; Lawson et al. 1995). Bacteria associate with the cell membrane and then quickly enter the enterocyte via an entry vacuole. Specific adhesins or receptors have not been identified, but *L. intracellularis* may possess a type III secretion system. The entry vacuole rapidly breaks down (within 3 hours), and the bacteria flourish and multiply free (not membrane-bound) within the cytoplasm. The entry of bacteria into cells is dependent on cell, but not necessarily bacterial, viability—that is, a type of induced phagocytosis (Lawson et al. 1995). The mechanism whereby the bacteria cause infected cells to fail to mature, but continue to undergo mitosis and form hyperplastic crypts, is not yet understood fully. It may reflect an inhibition of the normal crypt cell differentiation process, as regulated locally at the crypt neck. *L. intracellularis*–infected intestinal crypts can become enormously elongated and often branched. Loss of body protein and amino acids into the intestinal lumen and the reduced nutrient absorption by the intestinal mucosa lacking mature enterocytes are the likely causes of the reduction in weight gain and feed conversion efficiency seen in pigs affected with chronic uncomplicated

PE lesions (Rowan and Lawrence 1982; Gogolewski et al. 1991).

Early lesions contain very few infiltrating inflammatory cells, probably not above the normal for pig intestines (McOrist et al. 1992). Affected epithelial cells contain a large accumulation of intracellular IgA (Lawson et al. 1979; McOrist et al. 1992), and intestinal lavages contain a high level of Lawsonia-specific IgA (Guedes et al. 2002c). Macrophage ingestion of *L. intracellularis* in developing lesions probably leads to a typical Th1 type immune cell response in the lamina propria (McOrist et al. 1992; MacIntyre et al. 2003). Both cell-mediated and humoral responses occur in the blood of affected pigs (McOrist and Lawson 1993; Knittel et al. 1998; Guedes and Gebhart 2003b). These are first detectable 2 weeks after exposure and can persist for up to 3 months in acutely infected pigs (Guedes et al. 2002c). It is therefore likely that animals exposed to *L. intracellularis* show a specific immune response.

Degenerative and reparative changes may be superimposed on the basic enterocyte proliferation, probably due to local secondary bacterial infections. Inflammatory changes range from a superficial fibrinous reaction to extensive, deep, coagulative necrosis, which is the lesion of necrotic enteritis. In some pigs a substantial granulation tissue reaction may occur, leading to fibrous tissue infiltration and muscular hypertrophy, which is the lesion of regional ileitis.

Acute hemorrhagic PE (PHE) is marked by severe bleeding into the lumen of the intestine, but with underlying lesions of chronic PE. The hemorrhage occurs concurrently with the widespread degeneration and desquamation of many epithelial cells and leakage from the capillary bed. PHE has been reproduced in older naive pigs, challenged once with a high dose of *L. intracellularis*, indicating a host rather than bacterial effect. The pathogenesis of this lesion has not yet been determined fully.

CLINICAL SIGNS

Clinical cases of chronic PE are observed most commonly in the postweaned pig between 6 and 20 weeks of age. In many cases of chronic PE in growing pigs, the clinical signs are slight to subclinical, and little more is seen than variation in pig performance with a failure to sustain growth despite normal feed intake. Ileal lesions are a consistent feature of these pigs. In some pigs there may be a degree of anorexia, characterized by curiosity about food but refusal to eat. Thus, affected animals vary from the clinically unremarkable to those showing marked dullness and apathy. Diarrhea, when present, is generally moderate, with loose, sloppy to watery stools of normal grey-green color; this is probably a feature of only a proportion of pigs affected with chronic PE. Blood or mucus are not features of chronic PE diarrhea. When chronic or subclinical PE is suspected in a herd,

milder cases can be relatively common but difficult to detect. Therefore, such farms should be inspected for apparent wasting of well-grown animals with anorexia and irregular diarrhea, with variable sizes of growing pigs in a group. Records should be carefully examined to detect changes in average weight gains and feed conversion efficiency in the postweaned group (Roberts et al. 1979; Gogolewski et al. 1991). More severely affected cases are often associated with varying degrees of inflammatory or necrotic change in the affected mucosa, and those that develop necrotic enteritis show severe loss of condition and often scour persistently.

Unlike chronic PE, cases of acute hemorrhagic PE occur more commonly in young adults 4–12 months old, such as breeding gilts, and present a clinical picture of acute hemorrhagic anemia. Black tarry feces are often the first visible clinical sign and these may become loose. However, some animals die without fecal abnormality and show only marked pallor. Probably around half of the animals clinically affected will die, the remainder recovering over some weeks. Pregnant animals that are clinically affected may abort, the majority within 6 days of the onset of clinical signs, with some residual reproductive losses possible (McOrist et al. 1999). Progeny from acutely affected breeding females are not protected from acquiring PE (Guedes et al. 2002a).

In most cases of uncomplicated chronic PE, recovery occurs 4–10 weeks after the onset of clinical signs with a return of appetite and growth rate to normal levels. However, although progress to slaughter weight can take place despite extensive lesions (Rowland and Hutchings 1978; Jensen et al. 1999), there will be a reduction in average weight gain, causing a significant extension of the time pigs take to reach market weight, with a consequent cost burden. The increase in feed required per unit weight gain in affected pigs is also a major cost in extra feed requirements. Careful feed and weight measurements during challenge studies have established that average weight gains are reduced 6–20% in affected pigs, and the increase in feed required per unit gain is 6–25%, compared to normal pigs (Gogolewski et al. 1991; McOrist et al. 1996b, 1997). The costs in increased "variation" in a group of pigs destined for breeding programs or a specific market target can be significant. The economic losses due to PE have been estimated from its negative impacts on slaughter weight, feed conversion efficiency, space utilization, breeding problems, and morbidity-mortality effects, totaling at from U.S. $0.50 to over U.S. $1 per affected growing pig, depending on the variable prices for pigs, building spaces and feed (McOrist et al. 1997; Veenhuizen et al. 2002).

LESIONS

Chronic PE

Chronic PE in growing pigs occurs most commonly in the terminal 50 cm of the small intestine and the upper

third of the proximal colon. In severe cases, the lesions will extend to the jejunum, cecum, and lower large intestine. The magnitude of the proliferation varies widely, but in the developed lesions the wall is visibly thickened and the overall diameter increased. In minor lesions, the area of the terminal ileum that is 10 cm proximal from the ileocecal valve should be carefully examined as the most likely site of infection. Care is needed to distinguish minor lesions from contracted mucosa over the Peyer's patches. Some subserosal and mesenteric edema is common, and the normal corrugated pattern of the serosal surface is emphasized. The mucosal surface is moist but not mucoid, sometimes with flecks of inflammatory exudate loosely adherent. The affected mucosa itself is thrown into deep folds, longitudinal or transverse (Figure 44.1); similar changes in the large intestine may result in apparent plaque or polyp formation.

   Histologically, the mucosa is composed of enlarged, branching crypts lined with immature epithelial cells. Compared to normal crypts, which are 1 cell layer thick, affected crypts are often 5, 10, or more cells thick (Figure 44.2). Numerous mitotic figures occurring throughout the crypt are evident. Other nuclei of affected cells may appear as enlarged vesicular structures or densely staining elongated spindles. Goblet cells are absent, and their reappearance in deep glands is an indication of impending resolution. In uncomplicated disease, the lamina propria is normal.

   Silver staining, specific immunostaining or electron

microscopy of affected intestinal sections reveals intracellular *L. intracellularis*, often in considerable numbers, lying in the apical cytoplasm of the affected epithelial cells (Figure 44.3). In recovering lesions, the organisms become aggregated and may be extruded in degenerate cells into the lumen or be consumed by activated macrophages in the lamina propria. Many cases show little evidence of inflammatory reaction. The recovering lesions are notable for the resumption of development of a population of mature epithelium, with goblet cells in the deep crypts, and a rapid disappearance of the adenomatous cells from the surface (McOrist et al. 1996a).

Necrotic Enteritis

This is evident as coagulative necrosis with marked inflammatory exudation superimposed on an established lesion of PE. Yellow-gray cheesy masses that adhere tightly to the jejunal-ileal mucosa are present and may closely follow the original thickened mucosal architecture for some distance. Histologically, the coagulative necrosis is clearly defined, with fibrin deposits and degenerative inflammatory cells. Diagnosis is confirmed

by the presence of remnants of the proliferative epithelium observed in the deep layers.

Regional Ileitis

This is recognized as a smoothly contracted, almost rigid length of lower small intestine; hence the traditional name "hose pipe gut" (Figure 44.4). The mucosa may contain ulceration, with granulation tissue and islands of surviving mucosa adjacent. The most striking feature is hypertrophy of the outer muscle coats. Regional ileitis lesions are now considered relatively rare.

Acute Hemorrhagic PE

Hemorrhagic PE generally affects the terminal ileum and colon. The affected intestine is thickened, dilated, and somewhat turgid with serosal edema. The lumen of the ileum and colon usually contains one or more formed blood clots, often with no other bloody fluids or feed contents evident. The rectum may contain black, tarry feces of mixed blood and digesta (Figure 44.5). The mucosal surface of the affected portion of intestine shows little gross damage except for the marked hyperplastic thickening. Bleeding points, ulcers, or erosions are not observed. Histological examination demonstrates extensive degeneration, congestion, and hemorrhage within the proliferative epithelium. There is marked accumulation of bloody cellular debris containing numerous *L. intracellularis* organisms above the af-

fected mucosa and in the lumina of affected intestinal crypts (Figure 44.6).

DIAGNOSIS

Because of the difficulty of culturing *L. intracellularis*, it has been necessary to develop alternative methods for its detection. Confirmation of a clinical diagnosis of PE may be obtained by demonstration of *L. intracellularis* in feces, either by a PCR assay using *L. intracellularis*–specific primers (Jones et al. 1993) or by using specific hyperimmune rabbit polyclonal antibody or, preferably, a specific anti–*L. intracellularis* monoclonal antibody (McOrist et al. 1987; Guedes and Gebhart 2003c) incorporated into immunoassay techniques. Pigs with active lesions are usually found to be excreting the agent over several weeks (Knittel et al. 1998; Kim et al. 1998; Guedes et al. 2002c). However, fecal analysis is unlikely to prove sufficiently sensitive for the diagnosis of all infections. The PCR assay can detect 10^2–10^5 organisms per gram of feces, depending on the DNA extraction method and type of assay used (nested or direct). Animals 6–10 weeks old usually have the highest prevalence rates for screening of single-site farms. Older animals are usually sampled only during outbreaks of acute PE. Feces should be stored at 4°C or below for either test.

Methods described for the serologic diagnosis of PE have employed whole bacterial antigen incorporated into an indirect immunofluorescence assay (Lawson et al. 1988; Knittel et al. 1998) or an immunoperoxidase assay (Guedes et al. 2002b). Those assays used bacteria extracted from affected intestines or cultured *L. intracellularis*. Results from serologic assays suggest that the serum antibody response in pigs to *L. intracellularis* is specific and involves IgM and IgG. Although detectable antibody responses relate well to the presence of lesions, exposure to infection may not induce significant seroconversion in all cases. Although blood collection is considerably more time-consuming than feces collection, the serotests are probably cheaper to perform and more amenable to high throughputs.

At necropsy, the use of modified Ziehl-Neelsen stain or the Giminez stain on mucosal smears to demonstrate the intracellular organisms is a simple presumptive technique, requiring minimal time and equipment (Love et al. 1977). Histopathological examination of affected tissues will reveal the distinctive morphology of the proliferative lesions. Specific identification of *L. intracellularis* in these lesions can be achieved by immunohistochemical staining of fixed embedded tissues (Lawson et al. 1985; McOrist et al. 1987; Guedes et al. 2002c). In the absence of specific immunological reagents, silver-staining techniques will clearly show the presence of intracellular bacteria (Figure 44.7). Modifications of the Warthin-

Starry silver impregnation technique (Young 1969) are satisfactory for routine use. The affected crypts need to be examined carefully at high magnifications due to the small size of *L. intracellularis*. Where electron microscopic facilities are available, the presence of the intracellular organism can be confirmed.

Cultivation of the obligate intracellular *L. intracellularis* in the laboratory requires establishment of a suitable cell line, such as IEC-18 rat enterocytes or IPEC-J2 pig enterocytes and the addition of purified *L. intracellularis* from pig intestines in the presence of antibiotics to retard the growth of other bacteria (Lawson et al. 1993; McOrist et al. 1995b). Maintenance and passage of the organism in co-culture require suitable microaerobic atmospheres and cell lysis conditions, respectively (Lawson et al. 1993). Most cells in a monolayer are typically infected with around 50 cytoplasmic bacteria (Figure 44.8), causing no apparent cytopathic effect.

TREATMENT AND PREVENTION

In vitro evaluations via a cell culture approach of the minimum inhibitory concentration of 20 antimicrobial agents and the minimum bactericidal concentration of 10 of these suggested a rather broad range of antibiotic groups with potential activity against *L. intracellularis* (McOrist et al. 1995c; McOrist and Gebhart 1995). However, challenge exposure and controlled field evaluations of treatment and prevention measures in commercial pigs have indicated that macrolides, lincosamides, and pleuromutilins are the most effective antibiotics, when given at an adequate dosage rate per kg of bodyweight (McOrist et al. 1996b, 1997; Walter et al. 2001; Schwartz et al. 1999; Winkelman et al. 2002). In the U.S., some quinoxalines are also available and effective. Acquired resistance to these active drug groups has not been proven in *L. intracellularis* (McOrist 2000). Apparent medication failures with these drugs are most likely to occur in pigs with ileitis that are underdosed on a bodyweight basis, such as breeding pigs with a low feed intake, or when pigs are medicated before or after actual peaks of infection. Antimicrobial drugs now known to be inherently ineffective against *L. intracellularis* in clinical cases of PE include the penicillins, bacitracin, aminoglycosides such as neomycin, virginiamycin, and the ionophores. Nonantibiotic therapies such as copper or zinc compounds or feed acidifiers have also shown no evidence of efficacy.

Various approaches to medication are possible, depending on the age and type of pigs involved. Treatment of acute PE in breeding herds requires a vigorous approach. Treatment needs to include both the clinically affected and the in-contact animals (which may be the whole herd). The preferred treatment would be tiamulin (120 ppm) or tylosin (100 ppm) for 14 days, delivered orally via a water-soluble formulation or an in-feed premix or by intramuscular injection of an equivalent dose to affected and in-contact pigs.

Severe chronic clinical disease manifested as wasting pigs with or without necrotic enteritis will often appear to be moderated by the use of tylosin, lincomycin, or tia-

mulin (or carbadox where available). If sufficient numbers of clinical cases are occurring in growing pigs, the removal of affected animals to separate accommodation, with supportive therapy, may limit losses. Controlled field trials now suggest that incorporation of in-feed or water-soluble antibiotics for control achieves best results if given just prior to the peak period of *L. intracellularis* infection; on many single-site farms this is around 8–11 weeks of age (McOrist et al. 1999, 2000). Medication of older pigs, such as breeding stock, is not likely to eliminate the infection from their progeny or from other groups. Because infection and PE disease can vary in the time of onset on different farms and between batches on the same farm, in-feed antibiotics for treatment might be added too late to stop damaging clinical signs and poor performance (Hammer 2004). Alternatively, if they are added too early, groups of "clean" pigs are not getting the chance to develop active immunity to the disease and may remain naive and susceptible to later severe acute PE cases.

Despite the short time since the elucidation of the cause of PE, its endemic nature, major economic impact, and variable time of onset persuasively indicate that a vaccine approach is the most logical for long lasting control. Oral administration of a single low titer dose ($10^{4.9}$ TCID$_{50}$/dose) of an attenuated live vaccine (Enterisol Ileitis, Boehringer Ingelheim) to young pigs provided significant levels of protective immunity against subsequent challenge with virulent heterologous *L. intracellularis* (Kroll et al. 2004). This was confirmed by a significant reduction ($p <0.05$) in the primary parameter of gross and microscopic lesions in the ileum of vaccinates. This protection was independent of the route of oral administration chosen (individual oral drench or drinking water delivery to a group). Significantly improved weight gains and reduced fecal shedding of *L. intracellularis* were also noted after vaccine administration, particularly if given via drinking water. This vaccine has rapidly grown to widespread usage where available, with no safety concerns identified. Killed or subunit vaccine types are not available.

Where vaccine is unavailable, animals such as replacement breeding stock that are to be introduced into infected transport situations or into infected premises could be allowed a period of exposure followed by therapeutic levels of antimicrobial agents to impede the occurrence of clinical disease. The preferred treatment would be tiamulin (120 ppm), tylosin (100 ppm) or lincomycin (110 ppm), delivered orally via a stabilized in-feed premix for 14 days. Following the transport or on-farm period of exposure, no more than 2–3 weeks should elapse before the introduction of antibiotics (Love and Love 1977). Such an approach is most suited to the management of acute PE in young adult animals. However, even with this type of program, PE may occur in medicated animals following the end of therapy.

It remains a matter of concern that acute and chronic PE continue to be serious problems in high-health-status, minimal-disease herds, often with early weaning and high-quality commercial breeding lines in place. It cannot be overemphasized that in most conventional herds, the absence of clinical PE, even over a period of years, is no guarantee of freedom from the infection and disease. Apparently clean animals from such herds may be responsible for the introduction of PE into a hitherto uncontaminated environment, often followed by an explosive outbreak of acute hemorrhagic PE and later by a low level of endemic chronic PE.

45 Salmonella

R. W. Griffith, K. J. Schwartz, and D. K. Meyerholz

Members of the genus *Salmonella* are notorious for their ability to infect a broad range of hosts, which is a major factor in their success as pathogens. Taylor and McCoy (1969) observed that salmonellae have been isolated from virtually all vertebrate hosts from which they have been sought, with the possible exception of fish in unpolluted waters. Although many of the more than 2400 salmonella serotypes have a broad host range and are widely distributed, several serotypes are quite adapted to a single host species, most notably *S. typhi* (humans), *S. dublin* (bovine), and *S. choleraesuis* (swine). Many serotypes are not associated with overt disease and appear to have limited host and geographical range.

Salmonella infections of swine are of concern for two major reasons. The first is the clinical disease (salmonellosis) in swine that may result, and the second is that swine can be infected with a broad range of salmonella serotypes that can be a source of infection of pork products.

Salmon and Smith (1886) first associated salmonellae with disease when they described *S. choleraesuis* as the putative cause of classical swine fever (hog cholera). The identification and, in many swine-producing areas, eradication of the viral etiology of classical swine fever, relegated *S. choleraesuis* to an opportunistic pathogen in swine. The dramatic increase in salmonellosis during the 1980s in North America underscored the pathogenic potential of *S. choleraesuis* for swine.

Disease associated with host-adapted *S. choleraesuis* is referable to septicemia, enterocolitis, or bacteremic localization as pneumonia and hepatitis (Baskerville and Dow 1973) or occasionally as meningitis (Reynolds et al. 1967; McErlean 1968), encephalitis (Wilcock and Olander 1977c), and abortion (Schwartz and Daniels 1987). Only a handful of other serotypes are associated with disease in swine, usually as a cause of enterocolitis, the most notable being *S. typhimurium*. Reported rarely, *S. typhisuis* is associated with caseous lymphadenitis (Barnes and Bergeland 1968).

ETIOLOGY

The genus *Salmonella* is a morphologically and biochemically homogeneous group of gram-negative, motile, non–spore-forming, facultatively anaerobic bacilli with peritrichous flagella. The reservoir for salmonellae is, typical of the family *Enterobacteriaceae,* the intestinal tract of warm-blooded and cold-blooded animals.

Salmonellae are hardy and ubiquitous bacteria. They multiply at 7–45°C; survive freezing and desiccation well; and persist for weeks, months, or even years in suitable organic substrates. Salmonellae were reported to survive in meat-meal fertilizer for 8 months (Mittermeyer and Foltz 1969) and in manure oxidation ditches for 47 days (Will et al. 1973). Survival is greatly shortened below pH 5.0 (Henry et al. 1983). Numerous reports of prolonged survival in water have been cited (Williams 1975; Wray and Sojka 1977; Pokorny 1988). The bacteria are readily inactivated by heat and sunlight as well as by common phenolic, chlorine, and iodine-based disinfectants (Rubin and Weinstein 1977). Ability to survive in the environment, as well as prolonged carrier states in innumerable hosts, ensures the widespread distribution of this genus worldwide.

Techniques for isolation of salmonellae vary widely, depending on the nature of the suspect material and sometimes with the specific serotypes sought. In sewage, feed, and polluted water, where salmonella numbers are likely to be low compared to other organisms, well-documented and sometimes elaborate techniques of pre-enrichment, selective enrichment, and selective plating are commonly used (Groves et al. 1971; Edwards and Ewing 1972; Skovgaard et al. 1985; Vassiliadis et al. 1987). It is important to note that some of the enrichment media are detrimental to the growth of certain serotypes of salmonellae. For example, Rappaport-Vassiliadis is commonly used for enrichment of food and environmental samples but is known to restrict the growth of those serotypes that are host-adapted. Occasionally enrichment techniques may be necessary for

the isolation of salmonellae from tissues or feces of carrier animals in which numbers are low, but in clinically affected animals the populations are such that direct plating of internal organs on routine selective and differential enteric media such as brilliant green agar and MacConkey agar are usually adequate (Committee on Salmonella 1969). The isolation of salmonellae is not sufficient for definitive diagnosis of salmonellosis, particularly if elaborate isolation techniques are required, since subclinical infections and environmental contamination are common. Isolation techniques for various types of specimens are detailed in most standard texts on clinical microbiology. Epidemiological investigations of zoonotic outbreaks occasionally demand more sophisticated techniques of phage typing, plasmid characterization, mapping of outer-membrane proteins (OMP), or DNA analysis to trace a specific isolant.

S. choleraesuis is the type species for the genus *Salmonella* as described by Salmon, although it is now more commonly isolated as the hydrogen sulfide–producing variant *kunzendorf*. There is considerable disagreement over the nomenclature of the genus *Salmonella* and several proposals for altering it have been made. Convention is to refer to each of the over 2400 distinct serotypes as though it is a species. Serotype identification uses the Kauffmann-White schema, based on antigenic differences in somatic (O), surface or capsular (Vi), phase 1 flagellar, and phase 2 flagellar antigens determined by agglutination serology. Complete serotyping is laborious and is available at only a few reference laboratories. Most laboratories use commercially available antisera to determine the O antigen groups of isolates for rapid and preliminary identification. The serogroup designation will help predict the serotype present or, at least, can be used to rule out those serotypes found in other serogroups (Table 45.1).

In contrast to the large number of serotypes isolated from carcasses and pork products, disease in swine is almost always caused by either the hydrogen sulfide–producing variant of *S. choleraesuis* variety *kunzendorf* or by *S. typhimurium*. The former has been and continues to be the most frequent serotype causing disease in swine (Levine et al. 1945; Lawson and Dow 1966; Morehouse 1972; Wilcock et al. 1976; Mills and Kelly 1986; Schwartz and Daniels 1987; Schwartz 1997a), generally manifested as septicemia.

S. typhimurium is the second most frequently isolated serotype from diseased swine, usually associated with enterocolitis. Disease caused by *S. typhimurium* occurs with greater than expected frequency in what could be considered unusually clean herds: university research herds, testing stations, closed specific pathogen free (SPF) herds, or purebred breeding herds (Heard et al. 1965; Gooch and Haddock 1969; Lynn et al. 1972).

Table 45.1. Serogroups of selected salmonella serotypes and ranking of frequency of isolation from diseased pigs, swine sources, and humans

Serogroup	Serotype	Isolations from Diseased Pigs (Schwartz 1997a)	Isolations from Swine Sources (Ferris and Frerichs 1996)	Isolations from Humans (CDC 1996)

E_4	*S. senftenberg*			
G_2	*S. worthington*			

Presumably, this is because of introduction to a previously immunologically naive population, a situation occurring with increasing frequency in modern production units using age-segregated rearing. This organism is also frequently isolated as a sequel to other enteric or debilitating diseases.

Localized epizootics of disease caused by the biochemically atypical *S. typhi*suis have been reported in the American Midwest (Barnes and Bergeland 1968; Andrews 1976) and at least historically in Europe (Barnes and Sorensen 1975). This organism grows poorly in standard selective media for salmonella isolation, but the disease produced by *S. typhisuis* is so characteristic that outbreaks are not likely to remain unnoticed (Barnes and Bergeland 1968).

Other serotypes are occasional causes of disease in swine but are usually transient and associated with predisposing factors, including other intestinal disturbances or disease, circumstances that allow immunologically naive pigs to be exposed to very large doses, or debilitated and immunologically compromised pigs. A variety of serotypes may be isolated from diarrheic piglets in the immediate postweaning period, but most are usually associated with concurrent enteric pathogens, inappropriate diets, poor hygiene and environment, or debilitation. The isolation of uncommon serotypes of salmonellae from diarrheic pigs generally warrants further diagnostic investigation. *Salmonella heidelberg* has been associated with postweaning diarrhea, with lesions more typical of enterotoxigenic diarrheal disease than typical salmonellosis (Reed et al. 1985). Reports of naturally occurring disease, such as those for *S. dublin* (Lawson and Dow 1966; McErlean 1968) and *S. enteritidis* (Reynolds et al. 1967), should support the isolation of the offending serotype with clinical and pathologic evidence of salmonellosis. In the case of both *S. dublin* and *S. enteritidis*, the reports were of meningitis in suckling pigs.

EPIDEMIOLOGY

The reservoir for salmonellae is the intestinal tract of warm- and cold-blooded animals. Salmonellae have mastered virtually all of the attributes necessary to ensure wide distribution, including abundant reservoir hosts, efficient fecal shedding from carrier animals, persistence within the environment, and the effective use of transmission vectors (feed, fomites, vehicles, etc.). Inapparent, long-term carriers that can shed salmonellae in feces continuously or intermittently, often in high numbers, are common in most host species. Shedding of the organism can be exacerbated by a long list of stressors, including commingling of pigs, transportation, concurrent diseases, and food deprivation.

The epidemiology of salmonella infections in swine is two relatively separate problems: salmonella infection of pork carcasses and retail products and infections that

cause salmonellosis in swine. Infection of swine by one or more serotypes is common, but primary clinical disease caused by serotypes other than *S. choleraesuis* or *S. typhimurium* is uncommon. It is important to understand that swine can be infected with a variety of serotypes that do not cause disease in swine but do represent a source of infection for pork products.

Extrapolation of epidemiological data from experimental studies where a single serotype with predetermined dose is administered to naive healthy pigs is not likely to represent field situations, where there are multiple serotypes, varying doses, intermittent exposures, variable host resistance, many management variables, and various intercurrent infections and diseases. Similarly, disease prevalence surveys must be carefully scrutinized to be sure that infection is not equated with disease, that multiple isolations are recorded from a single source, and that a source of infection is not inaccurately implicated.

Salmonellae in Pork

Data collected from various countries indicate salmonellae to be present in 0–48% of carcasses (Riley 1970; Nottingham et al. 1972; McCaughey et al. 1973; Gustafson et al. 1976; Tacal and Lawrence 1980; Morse and Hird 1984; Jayarao et al. 1989; Carr et al. 1996) and 0–30% of retail pork products (Gooch and Goo 1971; Surkiewicz et al. 1972; Roberts et al. 1975; Banks and Board 1983; Silas et al. 1984; Fukushima et al. 1987; Anon. 1994). The marked variation is probably due, in part, to real variation in contamination and, in part, to differences in methods of survey and methods of meat processing. The high level of infection demonstrated in some of the studies is apparently the result of abattoir cross-contamination in holding pens prior to slaughter. There also may be some mechanical transfer of contamination among carcasses by dehairing machines, scalding tanks, and polishers (Galton et al. 1954; Hansen et al. 1964; Kampelmacher et al. 1965; Williams and Newell 1970; Michaud 1978; Morgan et al. 1987). Although much of the salmonella contamination of pork products occurs within abattoirs, infected pigs leaving the farm are considered the original source of abattoir infections. The stress of transport and feed deprivation increases shedding from inapparent carriers, which then contaminate the environment of the truck and abattoir (Williams and Newell 1970). The prevalence of infection within the group continues to increase with increasing length of stay in the pens prior to slaughter, rising by about 50% for each 24-hour period (Craven and Hurst 1982; Morgan et al. 1987). It should be noted that *S. choleraesuis* is rarely associated with contamination of carcasses and pork products, although this may be an artifact of the isolation methods used. Although unusual as a cause of human disease, *S. choleraesuis* is particularly severe when it does occur (Cherubin 1980).

There is currently an explosion of investigational

activity related to issues of food safety, including salmonella contamination of a variety of foods. Salmonellosis is considered to be one of the most common food-borne illnesses in humans. There has been an increased public awareness of microbiological hazards of food and improved monitoring. Although salmonella contamination of poultry and beef products exceeds that of pork, salmonella control programs in swine will continue to be a primary focus of food safety initiatives. Salmonella reduction programs are becoming commonplace, with long-range goals to include the production and marketing of salmonellae-free pork products. Numerous, dynamic programs are in place utilizing hazard analysis and critical control point (HACCP) principles. Those programs that have been in place for a sufficient period of time, such as the Danish program, have significantly reduced the rate of salmonella infection in pork products (Nielsen et al. 1995). Fortunately, most of the methods useful for preharvest salmonella reduction in swine populations are related to sound management practices that also improve the overall health of a swine operation. The Danish program using serology to identify salmonella-infected herds and thereby control the introduction of shedding swine into the abbatoir has not been as successful as originally hoped.

Salmonellosis in Swine

Most salmonellosis outbreaks occur in intensively reared weaned pigs, and although disease in adults and suckling pigs is infrequent, infection is not (Gooch and Haddock 1969; Wilcock et al. 1976). The low frequency of salmonellosis in suckling pigs presumably results from lactogenic immunity, since neonatal swine are susceptible to oral challenge with salmonellae and develop a disease comparable to that in weaned pigs (Wilcock 1978). Disease occurs worldwide but varies markedly in estimated prevalence, morbidity, and mortality. This may be from incautious extrapolation of data gathered from microbiological surveys applied to actual disease incidence. In one correlative study in Indiana in 1974–1975, salmonellosis accounted for 19% of 327 consecutive porcine necropsies (Wilcock et al. 1976). In contrast, Hooper and Troutt (1971) reported that salmonella infection was considered the major disease process in only 2% of samples submitted in Missouri between 1967 and 1969. During a 4-year period in Ireland, salmonellosis was the diagnosis in 4.4% of 2180 swine necropsies (Lawson and Dow 1966). In Taiwan, salmonellae were isolated from about 10% of scouring pigs and 48% of fatal diarrheas or septicemias in weaned pigs (Hsu et al. 1983). A survey of diagnostic submissions to the Iowa State University Veterinary Diagnostic Laboratory from 1994 through 1996 revealed salmonellae to be present in 11% of 9109 porcine pneumonia cases, 9% of 3320 enteric cases, and 58% of 1612 cases of porcine bacterial septicemia (Schwartz 1997a).

Host-adapted *S. choleraesuis,* isolated almost exclusively from diseased swine, is the most common cause of salmonellosis in swine, and is usually manifested as septicemia. Midwestern U.S. diagnostic laboratories and veterinarians reported an increasing frequency of salmonellosis due to *S. choleraesuis* from 1981 to 1990 and a decreasing frequency from 1991 to 1997 (Schwartz 1997b). The recent decrease in the Midwest is likely due to improvements in swine management and husbandry and the advent of efficacious attenuated live vaccines. Regional variation in salmonellosis incidence is loosely correlated to pig density, husbandry practices, and, in particular, commingling of pigs of different ages and/or origins.

S. typhimurium accounts for most of the remaining cases of salmonellosis in swine. This serotype has worldwide distribution and is not host-specific. Enterocolitis is the primary disease referable to this serotype, most commonly seen in pigs with concurrent debilitating illnesses, in conditions of poor hygiene that allow exposure to high doses of the organism, or where immunologically naive pigs are exposed to sufficiently large doses. The latter situation appears to be more frequently encountered with modern production systems utilizing age-segregated production.

The attribution of primary pathogenic status to other serotypes should be made with caution. Most other serotypes are transient, sporadic causes of disease and often cannot be associated with disease experimentally without unique, qualifying criteria. *S. heidelberg* has been associated with catarrhal enterocolitis in young pigs, with enterotoxigenic properties leading to accumulations of large amounts of fluid in the small intestine and colon as a rather unusual presentation of salmonellosis (Reed et al. 1985).

Sources of Infection

The number of potential sources of salmonella infection for a population of swine is seemingly endless. A task force study in the United States did not reach a consensus as to the most important source of salmonellae for pigs (Bixler 1978), in large part due to the diversity and the biology of the genus *Salmonella*. In general, the source of salmonellae virulent for swine is most likely to be other swine or environments contaminated by swine. *S. choleraesuis* is the most frequent porcine isolate from clinically ill pigs, but it is a very infrequent isolate from pig feeds or nonporcine salmonella reservoirs. The conclusion seems clear that infected, shedding pigs and contaminated environments are the major sources of new infections of *S. choleraesuis*. Vertical (dam to offspring) and horizontal transmission both occur. Feed contamination and nonporcine species have not been implicated as a source of *S. choleraesuis* infection of swine.

The source of infection for other serotypes is less clear, since the host and vector range for salmonellae is broad and they have amazing capability to persist in en-

vironments outside the host. For serotypes other than *S. choleraesuis*, pigs should be thought of as biological filters for the low numbers of various salmonella serotypes present in feed, water, or litter contaminated by birds, rodents, or other animals. There may be exceptions to this; for example, *S. derby* seems to be very common in some abattoir surveys of swine. Evidence linking sources of contamination to primary clinical outbreaks, without other concurrent diseases or predisposing conditions, is generally lacking. Feed containing ingredients of animal origin is widely accepted as a source of salmonella infection to herds, but it should be emphasized that ingredients of vegetable origin can also be a source of salmonellae-contaminated feed. Water is not as likely a source of infection unless surface water is used for consumption or pigs have access to recycled lagoon water. Birds, insects, rodents, and pets can all act as carriers, as can bedding and litter (Allred et al. 1967; Williams et al. 1969; Nape and Murphy 1971). In a survey in the United States, salmonellae were isolated from feed or feed ingredients from 14 of 30 farms and 36 of 1228 samples (Harris et al. 1997). The isolation of salmonellae from feed was significantly associated with the lack of bird-proofing, with on-farm feed preparation, and with the housing of pigs in facilities other than total confinement, for all stages of production. Interestingly, salmonella isolation from complete feeds was more frequent from pelleted feeds than from ground feed. No *S. typhimurium* was isolated from feed samples in this study.

Transmission, Shedding, and Carrier State

Because of the dynamic relationship between salmonellae, host, and environment, and because infection does not equate with disease, definitive statements regarding transmission, shedding, and carrier states are apt to be misinterpreted, if not erroneous. Salmonella transmission and shedding within differing populations of animals in an endless variety of environmental, feeding, and management situations result in countless unique situations that cannot be experimentally reproduced. In general, fecal-oral transmission is the most likely mode of transmission of virulent salmonellae. Salmonella can be recovered from the intestinal tract of pigs within several minutes of oral exposure. Transmission can occur from pig to pig, contaminated environment to pig, or dam to offspring. Oral-pharyngeal secretions may contain salmonellae, largely due to the fact that tonsils become rapidly contaminated with salmonellae following oral transmission. This may allow nose-nose transmission. Aerolized secretions, feces, or contaminated dust particles make the potential for aerosol transmission for short distances quite real.

Salmonella infection of swine herds is much more common than disease. Longitudinal Dutch studies suggest that about 25% of herds are never infected, 24% are constantly infected, and 50% are infected most of the time. There appear to be infection cycles, with the endemic salmonellae having an ecological advantage over newly introduced salmonella serotypes. Infection occurs in the first weeks after arrival or commingling and reaches a maximum of 80–100% prevalence within another 2–3 weeks. About 5–30% of the pigs are still excreting salmonellae at the end of the finishing period. In 1995, the National Animal Health Monitoring Service (NAHMS) reported 30–60% of U.S. herds infected with at least one serotype of *Salmonella*, with the greatest percentage of postive herds found in the southeastern United States and in herds marketing greater than 10,000 head annually.

During acute disease, pigs will shed up to 10^6 *S. choleraesuis*/g feces (Smith and Jones 1967) or 10^7 *S. typhimurium* (Gutzmann et al. 1976). The minimum disease-producing dose of either serotype has not been established in field situations, but disease is difficult to reproduce experimentally at low doses. There is one report of moderate disease following oral inoculation of 10^6 cells (Dawe and Troutt 1976), but most authors report successful experimental disease production with doses of 10^8–10^{11} cells unless pigs are artificially stressed by injection of dexamethasone or in some other manner. Pigs infected with 10^3 organisms remained clinically normal but uninoculated pigs in the same pen did become clinically ill (Gray et al. 1996). It is likely that dose (and perhaps virulence) is magnified when pigs are infected and sequential (pig-to-pig) transmission occurs in field situations, so that the initial infective dose in the field is considerably less than that required in experimental situations. High animal density, stress of transport, and intercurrent nutritional or infectious disease are assumed to increase the shedding by carriers as well as the susceptibility of exposed pigs (Committee on Salmonella 1969). Pigs with nondetectable shedding of salmonellae can begin shedding within hours of an applied stress. The transmission demonstrated between feeder pigs also occurs between pigs during market transport and lairage at abattoirs, with infection rates proportional to time spent in transport and lairage (Hurd et al. 2001a; Hurd et al. 2001b). It is likely that catecholamines are released in association with stress, resulting in decreased gastric acid production and increased intestinal motility. Increases in stomach pH increase the likelihood that salmonellae will survive passage through the stomach and will access and replicate in the intestine and colon.

Outbreaks of salmonellosis are usually characterized by spread from pen to pen. Situations of spread from pen to distant pen are likely because of vectors or caretaker transmission. When all animals sicken simultaneously, a common source such as feed, bedding, water, or a contaminated environment should be suspected. Salmonella infections tend to be more prevalent in continuous-flow systems than in barns managed by principles of all-in/all-out. Prevalence is also higher in

barns with open flush-gutters than in those with slotted floors, with the highest rates of infection observed in outdoor finishing systems (Davies et al. 1997).

Numerous studies in a variety of host species with a potpourri of serotypes have demonstrated prolonged carrier states following infection. The pattern of shedding and the duration of the carrier state after clinically apparent disease have been studied only in group-housed pigs with no barrier to repeated reinfection (Wilcock and Olander 1978; Wood et al. 1989). After experimental infection, *S. typhimurium* was isolated from feces daily during the first 10 days post infection and frequently during the next 4–5 months. When slaughtered 4–7 months after initial infection, over 90% of pigs were positive for *S. typhimurium* in the mesenteric lymph node, tonsil, cecum, or feces (Wilcock and Olander 1978; Wood et al. 1989; Wood and Rose 1992; Fedorka-Cray et al. 1994). *S. newport* has been shown to persist in mesenteric lymph nodes for 28 weeks. Infection of individual animals may be relatively short-lived (less than 8 weeks), but organisms may circulate within a population and between pigs and the environment for extended periods of time.

S. choleraesuis given by either the intranasal or the intragastric route has been demonstrated to persist within ileocolic junction, lymph nodes, tonsils, lungs, and colon for at least 12 weeks (Gray et al. 1995). Infection with low doses of *S. choleraesuis* produced a shorter period of infection than infection with moderate or high doses. *S. choleraesuis* has been shown to persist for at least 3 months in wet feces and 6 months in desiccated feces.

The influence of antibiotics on the frequency and duration of shedding of salmonellae in pigs has received little attention. In human enteric salmonellosis, the use of antibiotics has long been recognized to prolong the carrier state (Dixon 1965; Aserkoff and Bennett 1969). In pigs with enterocolitis, antibiotics do not reduce the duration or the magnitude of fecal shedding, but neither are they reported to prolong or intensify shedding (Finlayson and Barnum 1973; DeGeeter et al. 1976; Gutzmann et al. 1976; Wilcock and Olander 1978; Jones et al. 1983; Jacks et al. 1988). In contrast, vigorous antibacterial therapy early in the course of septicemia caused by *S. choleraesuis* may significantly reduce the magnitude and duration of fecal shedding (Jacks et al. 1981).

PATHOGENESIS

The clinical and pathological features of salmonella infections are extremely variable. Severity is influenced by serotype, virulence, natural and acquired host resistance, and route and quantity of the infective dose. Over 200 virulence factors have been associated with salmonellae but few have been completely characterized. Generally, those that promote virulence in pathogenic

salmonellae are involved in adhesion, invasion, cytotoxicity, and resistance to intracellular killing, often working in combination to promote disease. Despite distinct differences in clinical signs, many parallels can be drawn between *S. choleraesuis* and *S. typhimurium* when discussing pathogenesis.

Although large doses (greater than 10^7) are required to induce disease experimentally, intraluminal replication may be important with small inocula. Disease is facilitated by factors such as peristaltic impairment, interference with intestinal flora, and elevation of gastric pH (Clarke and Gyles 1993). Replication to about 10^7 organisms/g of intestinal content is required for lesion production in pigs infected with *S. typhimurium*, a finding that probably also applies to other serotypes causing enterocolitis. Alterations in normal intestinal defenses by antibiotic-induced changes in normal flora or cold-induced alteration in intestinal motility may reduce the amount of replication required for disease or increase the ease of salmonella replication (Bohnhoff et al. 1954). Infection with *S. choleraesuis* may not require such massive luminal proliferation as prerequisite for disease, because it is inherently more invasive than other serotypes, can infect via the pharyngeal tonsil, and regularly causes signs of septicemia 24–72 hours before the onset of diarrhea (Smith and Jones 1967; Cherubin et al. 1974; Wilcock 1979; Reed et al. 1986).

The ability to invade is a requirement for pathogenesis and is encoded by a serotype-specific plasmid (Helmuth et al. 1985). Removal of this plasmid results in a lack of ability to invade but has no effect on ingestion or killing by murine macrophages, LPS production, or serum resistance (Gulig and Curtiss 1987). During the invasion process there is induction of synthesis of new proteins that probably enhance intracellular survival (Finlay et al. 1989). Peroxidase-antiperoxidase immunoenzymatic labeling and immunogold labeling techniques have demonstrated that *S. typhimurium* has a low tendency to invade the enteric mucosa and does not have a predilection for any specific intestinal location. While many epithelial cell types (enterocytes, M-cells, goblet cells) in the jejunum and ileum may be invaded, the predominant portal of entry into the submucosa may occur at Peyer's patches (Meyerholz et al. 2002; Meyerholz et al. 2003; Schauser et al. 2004). *S. choleraesuis* locates preferentially in the colon on the luminal surface of ileal M cells of Peyer's patches (Pospischil et al. 1990). Invasion is by endocytosis by M cells of gut-associated lymphoid tissue as well as enterocytes. Attachment of the bacteria to epithelial receptors triggers microfilament-controlled uptake, vacuole formation, vacuole transport through the cell cytoplasm, and entry into the lamina propria via exocytosis through the basement membrane (Takeuchi 1967; Takeuchi and Sprinz 1967). Passage through the epithelium causes mild and transient enterocyte damage. Salmonellae can synthesize over 30 proteins that are selectively induced

during infection of macrophages, making them facultative intracellular bacteria (similar to *Brucella, Mycobacterium,* and *Listeria*) that can survive within macrophages and neutrophils in the lamina propria (Roof et al. 1992a, b). Spread to mesenteric lymph nodes is rapid, occurring within 2 hours of inoculation of ligated intestinal loops or 24 hours after oral challenge (Reed et al. 1985, 1986). Knockout mice (CD18⁻) have been used to show that CD18⁺ phagocytes are important in the dissemination of the organism to the spleen and liver (Vazquez-Torres et al. 1999). Two leading cell candidates for this systemic transport are the macrophages and dendritic cells (Vazquez-Torres et al. 2000). Recent in vitro work has suggested that dendritic cells are capable of producing tight junction proteins to penetrate the epithelium and sample luminal bacteria including *Salmonella* (Rescigno et al. 2001). Concurrent with bacillary spread is the appearance of an acute, predominantly macrophagic, inflammatory reaction and prominent microvascular damage with thrombosis within the lamina propria and submucosa. Other routes of systemic invasion may be important. When administered intranasally to esophagotomized pigs, *S. choleraesuis* demonstrated primary colonization of the lung within 4 hours (Fedorka-Cray et al. 1995; Gray et al. 1995).

Early intestinal inflammation is considered a key feature of pathogenesis for enteric forms of salmonellosis. Neutrophil recruitment and transmigration across the epithelium is considered the most significant component (McCormick et al. 1995). Caspase-1 can act as a proinflammatory agent by cleaving interleukin-1 beta and interleukin-18 into active molecules (Fantuzzi and Dinarello 1999). SipA has also been shown to contribute to the inflammatory response by activation of phosphokinase C (Lee et al. 2000). Salmonella-induced activation of inflammatory mediators such as nuclear factor kappa B and phosphokinase C results in basolateral secretion of interleukin-8 and apical secretion of pathogen-elicited epithelial chemoattractant (Eaves-Pyles et al. 1999; Lee et al. 2000). These molecules act as chemokines promoting the transepithelial migration of neutrophils into the intestinal lumen (Gewirtz et al. 1999). In contrast, several studies using rabbits, monkeys, calves, or pigs have demonstrated fluid secretion independent of mucosal necrosis or inflammation (Giannella et al. 1973; Rout et al. 1974; Kinsey et al. 1976; Clarke and Gyles 1987). These studies present evidence that, at least early in the disease, the diarrhea is the result of decreased sodium resorption and increased chloride secretion due to cholera-like and shiga-like enterotoxins. Secretion stimulated by prostaglandins elaborated by endotoxin-stimulated neutrophils may also be important (Stephen et al. 1985). Toxic effects of certain OMPs, as well as lipid A associated with the LPS, are also important mediators of cell damage. Survival within phagocytes is an important attribute of virulent salmonellae, the mechanism of which is not clear. Sal-

monellae which possess smooth LPS, O side chains, and a complete LPS core are more resistant to phagocyte killing.

Mucosal inflammation and necrosis, as well as septicemia, occur in concert with the diarrhea but perhaps independently of it. Microvascular thrombosis and endothelial necrosis in the submucosa and lamina propria are consistent early lesions in porcine salmonellosis (Lawson and Dow 1966; Wilcock et al. 1976; Jubb et al. 1993; Reed et al. 1986), probably in response to locally produced endotoxin. Salmonellae are not directly associated with the damaged vessels but direct the events from the protected intracellular niche of macrophages in the surrounding submucosa or lamina propria (Takeuchi and Sprinz 1967). Mucosal ischemia as a result of the microvascular thrombosis is probably a major contributor to the mucosal necrosis so typical of salmonellosis in all species. The second major contribution to mucosal necrosis is probably from the chemical products of mucosal inflammation. The systemic signs and lesions of septicemic salmonellosis, in swine almost exclusively *S. choleraesuis* infection, are most commonly attributed to endotoxemia from bacterial dissemination. The complex biology of endotoxin is beyond the scope of this chapter, and readers should consult Wolff (1973), Elin and Wolff (1976), or Cybulsky et al. (1988). Briefly, endotoxin interacts with plasma and with leukocytes to initiate inflammation and fever. Most of the effects are mediated by interleukin-1, a lymphokine produced by macrophages stimulated by the endotoxin (Rubin and Weinstein 1977). Endotoxins have either direct effects on tissue or effects via an array of cytokine mediators.

CLINICAL SIGNS, PATHOLOGICAL FINDINGS, AND DIAGNOSIS

The clinical signs of porcine salmonellosis are referable to septicemia or to enterocolitis, and this section describes each syndrome separately. Pigs surviving acute septicemia may develop clinical signs due to bacteremic localization: pneumonia, hepatitis, enterocolitis, and, occasionally, meningoencephalitis. Pigs initially suffering from enterocolitis may later develop chronic wasting disease or, occasionally, rectal stricture.

The most available salmonella diagnostic method is bacterial isolation and identification, which, along with compatible lesions, remains the basis for diagnosis. Other tests using more sophisticated technology, including polymerase chain reaction (PCR), are not required for routine diagnosis. PCR currently has value as a screening tool but has a relatively high cost and currently lacks sensitivity without preenrichment. Detection of salmonellae does not constitute diagnosis of salmonellosis.

Serology is becoming increasingly available, usually in the form of an ELISA test. Most tests use surface anti-

gens such as OMP or LPS. These tests, some of which use mixed antigens containing both OMP and LPS or antigens from several serotypes, thus far appear to lack specificity and sensitivity for individual-animal diagnosis but are useful for herd screening (Baum et al. 1996). A mixed-ELISA test using meat juice at slaughter to detect antibody to a broad range of serotypes has been useful in categorizing the level of salmonella infection in herds in Denmark (Nielsen et al. 1995; Mousing et al. 1997).

Septicemic Salmonellosis

This form of disease, usually caused by *S. choleraesuis*, occurs mainly in weaned pigs less than 5 months of age but may be seen occasionally in market swine, suckling piglets, or adult breeding stock either as a septicemia or as a cause of abortion.

Clinical Signs. Pigs ill with *S. choleraesuis* are inappetent, lethargic, febrile with temperatures of 105–107°F (40.5–41.6°C) and may have a shallow, moist cough with slight expiratory dyspnea. Icterus may be apparent. The first evidence of disease may be finding pigs reluctant to move, huddled in the corner of a pen, or even dead, with cyanosis of extremities and abdomens. Diarrhea is not usually a feature of septicemic salmonellosis until the third or fourth day of disease, when watery yellow feces may be seen. In most outbreaks, the case fatality rate is high; morbidity is variable but is usually less than 10%. Outbreaks are frequently associated with stressful situations. The duration of the disease in individual pigs, as well as the duration and severity of each epizootic, is unpredictable but will be prolonged without successful intervention. Evaluation of therapeutic regimens in naturally occurring outbreaks is difficult, making response to therapy a poor diagnostic criterion. Disease spread is by ingestion of contaminated feces or nasopharyngeal secretions, with an incubation period ranging from 2 days to at least several weeks. Surviving pigs may remain carriers and fecal shedders for at least 12 weeks.

Gross Lesions. Lesions at necropsy include cyanosis of ears, feet, tail, and ventral abdominal skin; congestion progressing to infarction of gastric fundic mucosa; splenomegaly with less severe hepatomegaly; and moist, swollen gastrohepatic and mesenteric lymph nodes. Lungs are firm and resilient, diffusely congested, often with interlobular edema and perhaps hemorrhage; cranioventral bronchopneumonia is not uncommon. Icterus can be severe, although not consistently present (Fig. 45.1). An inconsistent, subtle lesion is miliary, random white foci of necrosis in the liver. In pigs surviving the first few days of disease there may be serous to necrotic enterocolitis. The features of the intestinal lesion are described more fully in the section on salmonella enterocolitis. Petechial hemorrhages, when present, are usually best seen in the renal cortex or on the epicardium.

Microscopic Lesions. The most diagnostic lesion of systemic salmonellosis is the presence of paratyphoid nodules in the liver. These are clusters of histiocytes amid foci of acute coagulative hepatocellular necrosis, corresponding to the white foci seen grossly. These lesions are often present (Lawson and Dow 1966) and unique for this disease, although other agents can produce suppurative or necrotic foci in liver. Other lesions typical of salmonellosis include fibrinoid thrombi in

45.1. *Splenomegaly, hepatomegaly, and swollen mesenteric lymph nodes from S.* choleraesuis *infection.*

venules of gastric mucosa, in cyanotic skin, in glomerular capillaries, and less regularly in pulmonary vessels. There is hyperplasia of reticular cells of spleen and lymph nodes as well as generalized swelling of endothelial cells and histiocytes typical of gram-negative sepsis. A similar diffuse histiocytic interstitial pneumonia is present in lung. A complete discussion of the pathology of septicemic salmonellosis can be found in Lawson and Dow (1966) and Jubb et al. (1993).

Diagnosis. The diagnosis of septicemic salmonellosis cannot be made on the basis of clinical signs alone, which are similar to those of other causes of septicemia in pigs, particularly *Erysipelothrix rhusiopathiae, Streptococcus suis, Actinobacillus suis,* or death due to classical swine fever or *Actinobacillus pleuropneumoniae.* Gross lesions of splenomegaly, hepatomegaly, lymphadenopathy, interstitial pneumonia, or focal hepatic necrosis are very suggestive of septicemic salmonellosis, but are not seen in every case. In most situations, definitive diagnosis requires the isolation of large numbers of salmonellae from tissues of affected pigs, almost invariably *S. choleraesuis* var. *kunzendorf.* Samples of lung, liver, or spleen often yield pure cultures of the organism on brilliant green, bismuth sulfite, blood agar, or MacConkey agar. Enrichment techniques are seldom required unless the organs have been contaminated by feces or careless handling or have autolysis, in which case tetrathionate broth at 42–43°C is the enrichment medium of choice. Selenite broth is inhibitory for *S. choleraesuis* and should be avoided (Edwards and Ewing 1972). Attempts to isolate salmonellae from animals that have received antimicrobial therapy are often unrewarding. Intestine or feces are not reliable specimens for isolation of the organism in pigs with acute septicemia. Differential diagnosis must include agents associated with the particular systems affected, including those that may cause septicemia, pneumonia, hepatitis, encephalitis, or enterocolitis (Schwartz 1991).

Salmonella Enterocolitis

Salmonellosis manifested as enterocolitis is most frequent in pigs from weaning to about 4 months of age. Disease may be acute or chronic and can usually be ascribed to *S. typhimurium* (including variety copenhagen) or, less frequently, to *S. choleraesuis.* Although isolation of other serotypes of salmonellae from pigs with diarrhea occurs with some frequency, implication of serotypes other than *S. choleraesuis, S. typhimurium,* and perhaps *S. heidelberg* as primary pathogens should be done with caution.

Clinical Signs. The initial clinical sign is watery yellow diarrhea, initially without blood or mucus. The disease may spread rapidly to involve most pigs in a pen within a few days. The initial diarrhea in an individual pig usually lasts 3–7 days, but it typically may recur for second and third bouts, giving the impression of a waxing and waning diarrheal disease of several weeks' duration. Blood may appear sporadically in the feces but rarely with the profuseness typical of swine dysentery or hemorrhagic porcine proliferative enteropathy (PPE). Affected pigs are febrile, have decreased feed intake, and are dehydrated, paralleling the severity and duration of the diarrhea. Mortality usually is low and occurs only after several days of diarrhea, presumably as the result of hypokalemia and dehydration. Most pigs make complete clinical recovery but a portion may remain as carriers and intermittent shedders for at least 5 months. A few pigs may remain unthrifty and, occasionally, may develop rectal strictures.

Gross Lesions. In pigs that have died of diarrhea, the major lesion is focal or diffuse necrotic enteritis, colitis, or typhlitis. The lesion is seen as adherent gray-yellow debris on the red, roughened mucosal surface of an edematous spiral colon, cecum, or ileum (Fig. 45.2). Colon and cecal contents are bile stained and scant, often with

45.2. *Coalescing colonic ulcers from* S. typhimurium *infection.*

black or sandlike gritty material. Mesenteric lymph nodes, especially ileocecal nodes, are greatly enlarged and moist. The gross lesion may extend to involve the descending colon and rectum. The necrosis may be seen as sharply delineated button ulcers, particularly in resolving lesions. Necrotic ileitis has historically been attributed to several agents, including *Salmonella,* but in confirmed cases of salmonellosis, ileal involvement usually is seen as reddening and slight roughening of the mucosa, suggesting mild superficial necrosis. Salmonellae associated with necrotic enteritis may be a sequel to PPE. Lesions of septicemia may be present in those cases involving *S. choleraesuis.* In cases of *S. typhimurium* enterocolitis, the liver and spleen are not enlarged except by terminal congestion.

Microscopic Lesions. The typical enteric lesion is necrosis of cryptal and surface enterocytes that varies from focal to diffuse. The lamina propria and submucosa contain numerous macrophages and moderate numbers of lymphocytes; neutrophils are numerous only in the very early lesions. Thrombi containing fibrin, platelets, and leukocytes are numerous (Fig. 45.3). The necrosis frequently extends to involve muscularis mucosa, submucosa, and lymphoid follicles. *Balantidium coli* is commonly present in necrotic debris of chronic cases. In the ileum, necrosis is usually quite superficial and is often seen as villous atrophy. The Peyer's patches may be necrotic in acute disease, but in pigs dying of the naturally occurring disease, lymphoid hypertrophy or even regenerative hyperplasia is more common. The liver may contain paratyphoid nodules but not with the consistency or the necrosis usually seen in the septicemic disease. A more complete discussion of the pathology can be found in Wilcock et al. (1976), Reed et al. (1986), and Jubb et al. (1993).

Diagnosis. The differential diagnosis of diarrhea in weaned pigs must include salmonellosis, swine dysen-

tery, and PPE due to *Lawsonia intracellularis.* Other viral, bacterial, or parasitic diseases capable of causing diarrhea include rotaviral and coronaviral enteritis, postweaning colibacillosis, trichuriasis, and coccidiosis. Salmonellosis concurrently present with other diseases is not uncommon.

Typical acute swine dysentery is distinguished from salmonellosis on the basis of the mucoid and bloody diarrhea in otherwise alert swine with dysentery, contrasted with depression and profuse yellow diarrhea of salmonellosis. PPE may be seen as acute intestinal hemorrhage or acute to chronic diarrhea with mucosal proliferation or necrosis. Differentiation among the three diseases at necropsy is primarily by recognition of differences in lesion distribution rather than by differences in character. Salmonellosis is usually in colon and occasionally small intestine, may be focal, and always involves marked mesenteric lymphadenopathy. The lesion of swine dysentery is diffuse, shallow, and restricted to large intestine; lymph node enlargement is absent or mild. In PPE ileal involvement usually overshadows the milder colonic lesions, and the mucosa underlying the necrotic membrane is markedly hyperplastic (Table 45.2). Whipworms (*Trichuris suis*) may also cause diffuse mucohemorrhagic colitis.

The diagnosis of salmonellosis is confirmed by microbiological and histological examination. The wide distribution of environmental salmonellae makes isolation alone unreliable for disease diagnosis, and a positive isolation should always be supported by appropriate lesions before a diagnosis of salmonellosis is made. A pool of ileum and ileocecal lymph node should enable detection of virtually all active or recently recovered cases, although tissues such as tonsil or cecal wall will usually yield positive cultures as well (Wilcock et al. 1976; Wood et al. 1989). From live animals, large (10 g) aliquots of feces or pharyngeal tonsil scrapings are preferable to rectal swabs for isolation, with tetrathionate enrichment the method of choice.
45.3. *Histological section showing deep colonic ulceration and inflammation from* S. typhimurium *infection.*

Table 45.2.   Differential diagnosis of enterocolitis in swine at necropsy

Condition	Ileal Lesion	Colonic Lesion	Ileocecal Nodes	Extraintestinal Lesions
Salmonellosis	Mild, usually no pseudo-membrane	Focal to diffuse, deep necrotic lesions	Always enlarged two to five times normal	Variable, gastric infarction, interstitial pneumonitis, miliary hepatic necrosis
Swine dysentery	Absent	Superficial and usually diffuse necrosis, blood and/or mucus	Often normal, slight enlargement	None except gastric fundic infarction in natural deaths
Porcine proliferative enteritis	Varies from hemorrhagic to necrotic or proliferative	Milder than in the ileum, usually only the proximal spiral colon	Variable with stage of disease	None

Other Syndromes

Salmonellae are occasionally involved in disease outbreaks in which the clinical signs may not suggest salmonellae as the etiologic diagnosis. Outbreaks of neurologic disease resembling classical swine fever or pseudorabies have been reported (Wilcock and Olander 1978), and brain lesions sometimes occur with septicemic salmonellosis. The lesion in the brain is necrotic vasculitis and perivascular granulomatous lesions resembling typical paratyphoid nodules (Fig. 45.4). Rectal strictures in growing pigs have been ascribed to defective healing of ulcerative proctitis caused by *S. typhimurium* (Wilcock and Olander 1977a, b). The stricture reportedly represents fibrosis in an area of persistent ischemia, with the rectum predisposed because of a normally precarious blood supply (Fig. 45.5).

Infection with the fastidious, swine-adapted serovar *S. typhisuis* causes a relatively specific chronic syndrome of diarrhea and wasting in which caseous lymphadenitis, histiocytic interstitial pneumonia, or suppurative bronchopneumonia is added to the typical necrotic colitis (Barnes and Bergeland 1968; Andrews 1976; Fenwick and Olander 1987). In some pigs the intestinal lesions may have healed, leaving the lymphoid and pulmonary lesions to be distinguished from tuberculosis and infection with *Arcanobacterium pyogenes* (Barnes and Sorensen 1975).

TREATMENT

With either septicemic or enteric salmonellosis, the goals of treatment in an outbreak of salmonellosis are to minimize the severity of clinical disease, prevent spread of infection and disease, and prevent recurrence of the disease in the herd. With salmonellosis the attainment of these goals is particularly difficult. Both *S. choleraesuis* and *S. typhimurium* are often resistant in vitro to many antibacterial agents used in swine (Barnes and Sorensen 1975; Wilcock et al. 1976; Blackburn et al. 1984; Schultz 1989; Fales et al. 1990; Schwartz 1997a). During clinical disease, the organism inhabits a protected intracellular niche inaccessible to many common antibacterials. The use of various antibiotics to treat enteric salmonellosis is widely advocated (Morehouse 1972; Barnes and Sorensen 1975; Blood et al. 1979), but much of the information to support this recommendation has been taken from trials designed to test the prophylactic efficacy of drugs, not their therapeutic efficacy. Thus, pigs on medicated feed, when inoculated orally with salmonellae, have the antibiotic already present in the gastrointestinal tract to interact with the salmonellae, resulting in milder disease because of what amounts to a decreased inoculum. In the few trials designed specifically to test antibacterial drug efficacy against clinical enteric salmonellosis, such therapy was considered to have little merit (Heard et al. 1968; Gutzmann et al. 1976; Olson et al. 1977; Wilcock and Olander 1978). Although not therapeutic, oral medications may decrease efficiency of transmission and have a prophylactic effect on pigs not yet affected. Antimicrobials are ordinarily administered at maximum permissible levels in feed or, preferably, water. Ideally, the choice of antibacterial agent should be based on in vitro susceptibility testing of isolates from each outbreak. Since medication often must be initiated before such results are available, choices must be based on previous experience and results of controlled trials.

In contrast, vigorous therapy early in the course of septicemia caused by *S. choleraesuis* has been reported to significantly reduce the duration and severity of disease (Jacks et al. 1981). In that report, therapy was initiated after inoculation but prior to the onset of clinical signs. Evaluation of efficacy under field conditions is difficult because of the unpredictability of the disease and because husbandry changes often accompany the use of antibacterials in an outbreak. Reports and practitioner communications from the American Midwest, however, suggest that visibly affected animals respond to aggressive therapy with parenteral antimicrobials (Schwartz 1991). Mass medication of the population at risk to decrease severity of disease and transmission of salmonellae is also widely practiced. The choice of an appropriate antimicrobial is aided by antibiograms and previous herd experience. In the absence of either, amikacin, gentamicin, neomycin, apramycin, ceftiofur, and trimethoprim-sulfonamide are effective in vitro against most isolates (Barnes and Sorensen 1975; Wilcock et al. 1976; Mills and Kelly 1986; Schultz 1989; Evelsizer 1990; Fales et al. 1990, Schwartz 1997b). Antiinflammatory agents are sometimes administered to critically ill animals to combat the effects of endotoxin (Schwartz and Daniels 1987; Schultz 1989; Evelsizer 1990).

Most salmonella antimicrobial resistance is plasmid-mediated. Of concern is the recent emergence of an *S. typhimurium* definitive type 104 (DT 104), isolated primarily from bovine and human populations, that has chromosomally integrated multiple antimicrobial resistance (Low et al. 1997). This isolate has a higher morbidity and mortality in humans than other *S. typhimurium* organisms and is increasing in prevalence in human and bovine populations. Carrier swine are generally asymptomatic. Although evidence linking emergence of such isolates to veterinary medical practices is generally lacking, the impact will affect public health initiatives as well as the availability of therapeutic agents for food-producing animals. It should be emphasized that salmonella control programs that rely strictly on antimicrobials are doomed to failure.

In addition to antimicrobial therapy, the successful treatment of salmonellosis relies heavily on routine husbandry procedures recommended for control of infectious diseases. The diarrheic pig contaminates its environment and is the single most important source of infection for other pigs. Removal and isolation of sick animals, minimizing exposure to infective material by scrupulous pen sanitation, frequent cleaning of water bowls, and restriction of animal or staff movement from potentially contaminated to clean areas are necessary. Efforts to modify management and environment to decrease crowding and stress and increase pig comfort are essential adjuncts to specific therapy.

PREVENTION

Prevention of infection of swine with salmonellae is not currently possible. Infection does not necessarily result in disease, and pigs may not sicken with disease until severely stressed long after initial exposure. The control of disease expression rests on efforts to minimize the exposure dose and to maximize pig resistance. The carrier pig and contaminated feed or environment are the most significant sources of infection to pigs, and pigs are most likely to develop disease during periods of stress or when exposed to massive numbers of salmonellae. The commingling and transport of weanling pigs from different sources to finishing farms enhance activation of latent carriers and ensure exposure of stressed pigs to salmonellae (Allred 1972). The source of host-adapted *S. choleraesuis*, which is rarely, if ever, isolated from feed or feed ingredients, would seem to be limited to carrier pigs and facilities previously contaminated with this serotype. The fact that many outbreaks occur in facilities with

good sanitation suggests that other stresses probably contribute to occurrence of the disease. Management practices that allow filling of grower and finishing rooms with single-source and single-age pigs are beneficial. Minimizing the variety of stresses often involved in acute outbreaks requires constant attention to details of management and husbandry, including proper animal density; dry, comfortable pens and temperatures; and adequate ventilation. On farms with enzootic disease, modifications to the facility and environment and implementation of management practices that emphasize all-in/all-out production should precede a prophylactic drug program. Antibiotics are probably useful as aids in preventing occurrence of disease when used prophylactically, but their use will not prevent infection and when relied upon for prevention of disease will eventually fail.

Nutritional approaches to prevent or alleviate swine salmonellosis include feeding of propionic or other volatile fatty acids, mannose, lactose, probiotics, and heavy metals. Although all of these practices are based on a sound theoretical basis and are reported to be successful experimentally or in other species, evidence for their efficacy in swine is lacking. Anecdotal reports suggest acidification of rations or water to be of some benefit.

As with other facultative intracellular bacteria, live vaccines that stimulate cell-mediated immunity are the most likely to be protective for salmonellae in swine. Historically, an attenuated live *S. choleraesuis* vaccine was used widely in the United Kingdom for many years but was withdrawn when *S. choleraesuis* infection decreased in that country to negligible proportions. Recently, the introduction of effective and safe modified live attenuated vaccines for *S. choleraesuis* has had a major impact on the occurrence of systemic salmonellosis in North America. The isolates used in these vaccines are either naturally occurring avirulent *S. choleraesuis* or are derived from repeated passage through porcine neutrophils, the product of which was demonstrated to have been cured of a 50 kb virulence plasmid necessary for intracellular survival (Roof et al. 1992b; Kramer et al. 1987, 1992). When given at weaning, vaccine protected pigs for at least 20 weeks (Roof and Doitchinoff 1995) against homologous serotypes, with some cross-protection suggested with heterologous serotypes.

Partial protection can be obtained with bacterins, primarily because of the nonspecific mitogenic and immunostimulant effect of LPS (Fenwick et al. 1986). Killed vaccines for *S. typhimurium* are safe, but the bulk of the evidence suggests that they have little efficacy in preventing disease following strong challenge because resistance to disease rests primarily on cell-mediated immunity (Collins 1974; Davies and Kotlarski 1976). Extrapolation of information from experience in humans (Hornick et al. 1970; Welliver and Ogra 1978) and calves (Bairey 1978) suggests, however, that use of a po-

tent killed vaccine may increase the dose necessary to cause disease and may offer some protection from septicemic salmonellosis, in which humoral immunity may play a role.

Monitoring herds for salmonellae has not been commonly practiced. The detection of carrier animals is difficult because of the unpredictability of fecal shedding. The detection of salmonellae by bacterial culture of feces and tonsils of diarrheic pigs in the nursery would likely be the most rewarding for identification of infected herds. However, even repeated negative fecal or tonsilar cultures do not guarantee that a herd or individual is not a salmonella carrier and thus a potential shedder. The use of salmonella serology can determine if an animal has had previous exposure to salmonellae, but this has little relevance to the carrier status or to the probability of shedding. Food safety concerns have stimulated renewed interest in serology as a method to determine the salmonella infection status of groups of market swine. This technology offers the possibility of sensitive and specific methods to identify infected herds, but it is not yet useful for determining the infection status of individual pigs.

46 Porcine Colonic Spirochetosis / Intestinal Spirochetosis

David J. Hampson and G. E. Duhamel

Porcine colonic spirochetosis (PCS), also known as porcine intestinal spirochetosis, is a spirochete-associated colitis that occurs mainly in weaner and grower pigs. The disease results from infection with a weakly hemolytic anaerobic intestinal spirochete that is distinct from *Brachyspira hyodysenteriae*, the agent of swine dysentery (Taylor et al. 1980; Zuerner et al. 2004). The spirochete causing PCS is now named *Brachyspira pilosicoli* (Ochiai et al. 1997), although it has also been referred to as "*Anguillina coli*" (Lee et al. 1993), "*Serpulina coli*" (Duhamel et al. 1993), a group IV weakly hemolytic intestinal spirochete (Fellström and Gunnarsson 1995) and, most recently, *Serpulina pilosicoli* (Trott et al. 1996a).

Infection with *B. pilosicoli* usually causes a mild to moderate typhlocolitis accompanied with either watery diarrhea or stools with the consistency of "wet cement," sometimes containing mucus. Based on the severity and extent of the colonic damage, affected pigs display variable loss of condition and reduced growth rate. Individual infected pigs may show increased time to reach market weight, thus disrupting efficient production flow through commercial units (Duhamel 1998).

A common histologic feature in the early phase of PCS is the presence of focal areas of inflammation in the cecum, colon, and/or rectum, where large numbers of spirochetes may be found attached by one cell end to the apical surface of the epithelium, forming a "false brush border" (Taylor et al. 1980; Girard et al. 1995) (Figure 46.1). This characteristic attachment of *B. pilosicoli* also is found in natural disease in other hosts, including humans (Trivett-Moore et al. 1998), nonhuman primates (Duhamel et al. 1997; Duhamel et al. 2003), dogs (Duhamel et al. 1996), domestic chickens (Trampel et al. 1994; McLaren et al. 1997; Stephens and Hampson 2001), and various species of wild birds (Webb et al. 1997; Jansson et al. 2001). Because isolation of *B. pilosicoli* from feces does not always correlate with the presence of diarrhea or end-on epithelial attachment of the spirochetes, the significance of identifying the spirochete needs to be interpreted in the context of a complete diagnostic investigation (Thomson et al. 1998). Experimental challenge studies in susceptible pigs have clearly shown that *B. pilosicoli* is associated with all of the clinical and pathological changes seen in spontaneous PCS (reviewed by Duhamel 2001).

PCS was first described by Taylor and colleagues (1980), who challenged 7- to 8-week-old susceptible weaned pigs with a weakly beta-hemolytic intestinal spirochete (strain P43/6/78[T]). The pigs developed a mucoid diarrhea containing flecks of blood, and lesions of colitis. This spirochete initially was thought to be a strain of the nonpathogenic weakly beta-hemolytic intestinal spirochete *Brachyspira innocens*, but it is now recognized as the type strain of the species *B. pilosicoli*. PCS with or without end-on attachment of spirochetes to the colonic mucosa has since been experimentally reproduced in pigs in several independent investigations, using other strains of *B. pilosicoli* besides P43/6/78[T] (e.g., Trott et al. 1996b; Thomson et al. 1997; Duhamel 1998; Jensen et al. 2000; Jensen et al. 2004a). PCS is increasingly recognized as an important cause of colitis worldwide. Reasons for this include the increased availability of improved diagnostic methods for differentiation of *B. pilosicoli* from other intestinal spirochetes, the withdrawal of routine antimicrobial growth promoters that might otherwise have been supressing the growth of *B. pilosicoli*, and the fact that other major intestinal diseases such as salmonellosis and swine dysentery are now better controlled in many countries (Duhamel 1996). It is likely that at least some of the cases of "nonspecific colitis" reported in the United Kingdom may have been caused by *B. pilosicoli*, although a noninfectious, diet-responsive colitis also appears to exist (Wood 1991). PCS has been reported in most major pig-producing countries, including Australia (Hampson 1990; Lee et al. 1993), Belgium (Castryck et al. 1997; Hommez et al 1998a), Brazil (Barcellos et al. 2000a), Canada (Jacques et al. 1989; Girard et al. 1995), Denmark (Møller et al. 1998), Finland (Heinonen et al. 2000), France (Pronost et al. 1999), Germany (Verspohl et al. 2001), Korea (Choi

et al. 2002), Spain (de Arriba et al. 2002), Sweden (Fellström et al. 1996), the United Kingdom (Taylor et al. 1980; Thomson et al. 1998; Thomson et al. 2001), and the United States (Ramanathan et al. 1993; Duhamel et al. 1995a). Much of the research concerning PCS has been undertaken in the last decade, and many important aspects of the disease are still poorly understood, including detailed epidemiology, virulence determinants of the spirochete, and pathogenesis of infection—including the role of host immune and inflammatory responses. The overall economic impact of PCS also has not been critically evaluated.

ETIOLOGY

Brachyspira pilosicoli is the etiologic agent of PCS (by definition), but, in the field, mixed infections with other enteric pathogens frequently occur. *B. pilosicoli* has a characteristic spirochete morphology and a general appearance similar to other species in the genus *Brachyspira* (formerly *Serpulina*). It is 6–10 µm long, 0.25–0.30 µm wide, and characteristically has 4–7 periplasmic flagella attached at each cell end, and pointed ends (Figure 46.2). The spirochete has a pronounced corkscrew like motility that helps it penetrate and move through mucus overlying the colonic epithelium. The outer envelope of the spirochete contains a semirough type lipooligosaccharide, and this is serologically heterogeneous among different strains (Lee and Hampson 1999). A number of outer membrane proteins and lipoproteins of *B. pilosicoli*

have been described, but more work is needed to define their potential role in disease, including whether they may be involved in attachment and/or in generating protective immunity (reviewed by Trott et al. 2001).

Brachyspira pilosicoli is cultured under the same anaerobic conditions as those described for *B. hyodysenteriae* (see Chapter 48). After 3–5 days incubation on trypticase soy blood agar, *B. pilosicoli* forms a thin spreading surface haze surrounded by a zone of weak beta-hemolysis. For isolation, plates containing colistin (25 µg/ml), vancomycin (25 µg/ml), and spectinomycim (400 µg/ml) are widely used (CVS; Jenkinson and Wingar 1981). The inclusion of rifampicin and spiramycin, sometimes recommended for the isolation of *B. hyodysenteriae,* inhibits the growth of *B. pilosicoli* and thus is not recommended (Duhamel and Joens 1994; Duhamel et al. 1995b; Trott et al. 1996c). Slicing the agar prior to primary inoculation, as reported for *B. hyodysenteriae* (Olson 1996), can improve the recovery of *B. pilosicoli*. However, by contrast with *B. hyodysenteriae*, a zone of enhanced hemolysis, or ring phenomenon, is not usually seen with *B. pilosicoli*. Once isolated, the spirochete grows readily in various liquid media, such as in a prereduced anaerobically sterilized (PRAS) medium based on trypticase soy broth (Kunkle et al. 1986) and in Brain Heart Infusion broth.

In the last decade, the taxonomy of the porcine intestinal spirochetes has undergone considerable revi-

sion (Hampson and Trott 1995; Hampson and Stanton 1997). Currently there are four species of weakly beta-hemolytic anaerobic spirochetes recognized as colonizing pigs, of which only *B. pilosicoli* is confirmed to be a pathogen. Other porcine intestinal spirochetes of unusual phenotypes and uncertain taxa also have been reported (Thomson et al. 2001). Although *B. pilosicoli* contains a copy of the *hlyA* gene that encodes a hemolysin in *B. hyodysenteriae* (Hsu et al. 2001), it is believed that this is either not expressed in *B. pilosicoli* or expressed in a form that results in reduced hemolytic activity (Zuerner et al. 2004).

Until recently the four named weakly hemolytic *Brachyspira* species colonizing pigs belonged to the genus *Serpulina*, but in 1997 the strongly hemolytic *Serpulina hyodysenteriae* and weakly hemolytic *S. innocens* and *S. pilosicoli* were transferred to the genus *Brachyspira* (Ochiai et al. 1997; Validation list 1998). Unfortunately, two weakly beta-hemolytic spirochete species of pigs, *Serpulina intermedia* and *Serpulina murdochii* (Stanton et al. 1997), were not officially transferred. Nevertheless, by general agreement among spirochete scientists, they are now "unofficially" referred to as *Brachyspira intermedia* and *Brachyspira murdochii* (Hampson 2000). These four species of weakly hemolytic intestinal spirochete have a similar appearance on blood agar and can be differentiated only by biochemical and genetic typing techniques. *B. innocens*, *B. intermedia*, and *B. murdochii* have not been shown to cause disease in experimentally infected conventional pigs and are generally considered to be nonpathogenic commensals in pigs (Lee et al. 1993; Jensen et al. 2000). On the other hand, certain strains of avian *B. intermedia* are pathogenic in commercial chickens (Hampson and McLaren 1999), and a porcine strain caused cecal damage in experimentally infected 1-day-old chicks (Trott and Hampson 1998). Additionally, *B. intermedia* can cause lesions when inoculated into isolated porcine colonic loops (Binek and Szynkiewicz 1984) and on occasions has been associated with diarrhea in pigs in the field (Fellström and Gunnarsson 1995). Overall, however, it remains doubtful whether *B. intermedia* is a cause of enteric disease in pigs. Some strains of *B. innocens* isolated from pigs with diarrhea have been shown to cause diarrhea and lesions when inoculated into gnotobiotic pigs (Neef et al. 1994), but again whether or not they are capable of causing significant disease under field conditions (for example, under certain specialized circumstances) remains uncertain. The identification of virulence determinants among *Brachyspira* species should help resolve some of these questions. Currently, the main significance of the commensal weakly hemolytic intestinal spirochetes is that their presence may complicate attempts to diagnose PCS and/or swine dysentery. Recently, a *Brachyspira*-like spirochete was found associated with lesions of colitis in experimentally infected pigs in Finland. Surprisingly, this spirochete hybridized with a nucleic acid probe against *Leptospira* but not with a *Brachyspira* probe (Jensen et al. 2004b). The significance of this finding is not clear, but if such organisms exist and are widespread they also could complicate attempts to diagnose spirochete-associated colitis.

EPIDEMIOLOGY

The detailed epidemiology of PCS has not been fully determined. Infection is believed to occur by the fecal/oral route, and, as previously shown with swine dysentery, PCS in naive herds may be introduced by carrier pigs. *B. pilosicoli* can persist in the environment; therefore, the disease can recur between batches of pigs if the premises are not adequately cleaned and disinfected. In fact, *B. pilosicoli* can survive in spiked feces kept at different temperatures for longer than *B. hyodysenteriae* (Barcellos et al. 2000b). Oxberry et al. (1998) showed that *B. pilosicoli* can survive in lake water at 4°C for 66 days, again surviving longer than *B. hyodysenteriae*. Other studies have shown that *B. pilosicoli* remains viable for 119 days in soil and 210 days both in soil with 10% pig feces and in pig feces kept at 10°C (Boye et al. 2001). The spirochete is susceptible to many commonly used disinfectants, but the efficacy of some of these products is reduced in the presence of organic matter, such as feces (Corona-Barrera et al. 2004a).

Various studies have demonstrated that *B. pilosicoli* may be isolated from pigs during any period of the growing stage, but infection is most common and significant in weaner and grower pigs. Lack of availability of serologic assays has hampered progress in determining antibody titers indicative of exposure in live animals. Instead, detection of *B. pilosicoli* in live animals is usually accomplished by bacteriological culture of feces as described above, followed by identification of suspected bacterial growth using amplification of *Brachyspira* species-specific nucleotide sequences by the polymerase chain reaction (PCR), as described below.

Using these detection techniques, the prevalence of *B. pilosicoli* among herds in different geographic regions has been estimated. In a study in Sweden, *B. pilosicoli* was isolated from 6 of 7 (85.6%) herds with diarrhea, and from only 1 of 8 herds without diarrhea (Fellström et al. 1996). In a survey conducted in the U.K. between 1992 and 1996 that involved 85 pig farms with colitis and diarrhea, *B. pilosicoli* was identified as the primary etiological agent on 21 (25%) units, and formed part of a mixed infection on another 23 (27%) units (Thomson et al. 1998). In a follow-up investigation conducted between 1997 and 1999 on 98 farms with problems of diarrhea and enterocolitis, *B. pilosicoli* was the primary etiologic agent in 18 (18.4%) units, and was involved as part of a mixed infection in 24 (24.5%) units—indicating that PCS continues to be a significant problem in the U.K. (Thomson et al. 2001). In Denmark, *B. pilosicoli* was isolated from 10 of 72 (13.9%) herds with diarrhea and

from none of 26 herds where diarrhea was not a problem (Møller et al. 1998). In a subsequent study of 79 randomly selected herds, 15 (19.0%) were found to contain grower pigs colonized by *B. pilosicoli*, with these having a within-herd prevalence rate of 5–10% (Stege et al. 2000). In a survey conducted in Finland in 1997, *B. pilosicoli* was isolated from 14 of 50 (28%) high health status farms (Heinonen et al. 2000), whereas a survey conducted in 1998 in Brazil revealed *B. pilosicoli* in the feces of growers in 7 of 17 (41.2%) farms where diarrhea was a problem (Barcellos et al. 2000a). A recent study from Sweden revealed that the presence of *B. pilosicoli* and *L. intracellularis* was significantly associated with herds having poor performance in growing pigs (Jacobson et al. 2003). Collectively, these studies indicate that a variable, but often very high, proportion of farms that have persistent diarrhea are also infected with *B. pilosicoli*, whereas farms without diarrhea have very low or no infection. The specific prevalence values obtained in individual surveys must be interpreted with caution, because they can be influenced by several factors, including the concurrent administration of antibiotics, the age of the pigs examined, the methods of collection and handling of specimens, the limitations of culture and identification methods used, and the degree of contamination with other fecal organisms, all of which can affect the ability to detect *B. pilosicoli*.

Relatively few detailed epidemiologic studies have examined the within–herd pattern of *B. pilosicoli* infection. Recently, Oxberry and Hampson (2003) conducted cross-sectional and cohort studies on two Australian farms with PCS. Their study demonstrated that the on-farm epidemiology of *B. pilosicoli* can be highly variable. The prevalence on farm A (>2,000 sows) was 2.4%, with infection largely confined to grower/finisher pigs. All isolates obtained were identical—a situation that resembles swine dysentery, where all infections on a farm usually can be attributed to a single strain of *B. hyodysenteriae*.

On farm B, an 80-sow research farm that received replacement pigs from farm A, the prevalence among growers and finishers was 12.2%, and weaners also were infected. Here, not only was the prevalence higher, but the 10 isolates obtained were genetically heterogeneous, comprising seven different genetic types. The results were consistent with those from a small farm investigated in an earlier study, where nine genotypes of *B. pilosicoli* were identified among 14 isolates obtained from different pigs (Trott et al. 1998). The presence of multiple *B. pilosicoli* genotypes within certain farms might explain why PCS commonly recurs in convalescent animals or in those that have been treated with antimicrobials. In such cases, reinfection may be with a different strain, possibly having different antigenic determinants, antimicrobial susceptibilities, or potential to colonize and cause disease. Porcine strains of *B. pilosicoli* with different pathogenic potentials probably do exist (Thomson et al. 1997; Jensen et al. 2004a).

The extensive genetic diversity of strains from within the species *B. pilosicoli* is well established (Lee and Hampson 1994). Members of the species apparently are capable of undergoing genetic recombination and re-arrangements (Trott et al. 1998; Zuerner et al. 2004), perhaps in part associated with the activity of a generalized transducing bacteriophage (Stanton et al. 2003). A recent study of strain diversity among isolates from pig herds in Finland revealed that most farms had their own distinct genotypes of *B. pilosicoli*, whilst it was rare to find the same genotype on different farms (Fossi et al. 2003). Interestingly, the within-farm genotypes appeared fairly stable, because three farms that were re-examined after 3 years still had the same genotypes of *B. pilosicoli* present.

In the study of Oxberry and Hampson (2003), on farm B, *B. pilosicoli* also was detected in chickens, effluent pond water, and wild ducks on the effluent pond. An isolate from the pond belonged to the same genetic type as one from a pig, a finding consistent with a previous observation suggesting that feral waterbirds may contaminate water supplies and so represent a potential source of *B. pilosicoli* infection for pigs (Oxberry et al. 1998). Although it is well established that rodents can be persistent carriers of *B. hyodysenteriae*, they appear less likely to serve as a biologic reservoir of *B. pilosicoli*. To date there appears to be only one report of a natural infection of a feral mouse with *B. pilosicoli* (Fellström et al. 2004). The apparent rarity of this occurrence may relate to the fact that it is difficult to obtain colonization of laboratory mice with *B. pilosicoli* unless they receive specialized diets that increase fermentation in the large intestine (Sacco et al. 1997; Jamshidian et al. 2004).

In addition to pigs, a wide range of animal species may be naturally infected with *B. pilosicoli* (reviewed by Duhamel 2001), and typical clinical signs and lesions associated with PCS have been recorded in all host species, including humans. Although isolates from pigs, dogs, birds, and humans are genetically closely related (Lee and Hampson 1994; Trott et al. 1998), clear evidence for zoonotic transmission has not been obtained. Nevertheless, human strains of *B. pilosicoli* can cause disease when inoculated into conventional pigs (Trott et al. 1996b) and can colonize 1-day-old chicks (Duhamel et al. 1995a; Trott et al. 1995; Muniappa et al. 1997; Muniappa et al. 1998; Trott and Hampson 1998) and adult chickens (Jamshidi and Hampson 2003). Therefore, the potential for cross-transmission of *B. pilosicoli* between humans and animals cannot be discounted. Colonization of humans with *B. pilosicoli* is usually associated with either an immunocompromised state or poor hygiene, such as occurs in developing communities where fecal contamination of water supplies is often found (Margawani et al. 2004; Munshi et al. 2004). Consequently, industry workers who are healthy are unlikely to be at risk of developing disease from contact with pigs with PCS.

PATHOGENESIS

The pathogenesis of PCS is not well understood but is thought to differ from swine dysentery in several aspects (Johnston et al. 1999). Infection is often associated with the presence of large numbers of spirochetes attached by one cell end to the luminal surface of colonic and cecal epithelial cells. Additionally, the colitis associated with PCS is usually much less severe than swine dysentery and resembles the early stages of that disease.

As with swine dysentery, *B. pilosicoli* colonization and/or expression of disease can be influenced by the pig's diet. An analysis of risk factors on farms revealed that reduced prevalences can result from using home-mixed and/or nonpelleted diets (Stege et al. 2001). Reducing the energy and protein content of the diet also has alleviated clinical problems (Spearman et al. 1988; Wilkinson and Wood 1987). Addition of carboxymethylcellulose to a weaner pig diet, to experimentally increase the viscosity of the intestinal contents, enhanced colonization with *B. pilosicoli* (Hopwood et al. 2002). The authors speculated that high levels of soluble non-starch polysaccharide ("soluble fiber"), such as are present in grains like barley and rye, may similarly increase viscosity and enhance *B. pilosicoli* colonization. Consistent with this, pigs fed diets based on cooked white rice (highly digestible and low in soluble fiber) have shown reduced colonization with *B. pilosicoli* compared to pigs fed conventional diets (Hampson et al. 2000; Lindecrona et al. 2004). In the study of Lindecrona and co-workers (2004), feeding pigs a pelleted diet rather than meal increased the risk of colonization, but feeding fermented liquid feed or lactic acid did not influence colonization.

In order to be able to colonize, *B. pilosicoli* cells need to be able to penetrate and move through the mucus overlying the colonic mucosa. Cells of *B. pilosicoli* are motile, but are not attracted to colonic mucin in the same way as are virulent strains of *B. hyodysenteriae* (Milner and Sellwood 1994), and their chemotactic response appears to be modulated by the presence of certain substrates in the growth medium (Witters and Duhamel 1999). Pigs convalescent from PCS have serum IgG antibodies to a membrane lipoprotein of *B. pilosicoli* that is homologous to MglB, the glucose and galactose transport and chemoreceptor lipoprotein present in the pathogenic spirochetes *Borrelia burgdorferi*, the cause of Lyme disease, and *Treponema pallidum*, the syphilis spirochete (Zhang et al. 2000). As this protein is involved in motility-regulated signal transduction of the spirochete and is recognized by pigs recovered from PCS, it must be expressed during infection, perhaps during scavenging of glycoconjugate present in colonic mucin. Hence it likely plays a role in mucosal association.

Following experimental inoculation, *B. pilosicoli* may be shed in the feces within 2–7 days, although the incubation period may range up to 20 days. In the initial stage of infection, *B. pilosicoli* cells can adhere in large numbers to the surface of cecal and colonic epithelial cells, resulting in effacement of the microvilli and disruption of the terminal web microfilaments. Attachment occurs to only mature apical enterocytes between crypt units, and spirochetes do not attach to immature cells deeper within intestinal crypts (Trott et al. 1996b). Epithelial cell damage results in an increase in the crypt cell mitotic rate, crypt elongation, and the replacement of the mature columnar epithelium by squamous or cuboidal cells. Erosion of the epithelium is evident grossly as small adherent nodules on the surface of the mucosa (Figure 46.3).

B. pilosicoli cells have been observed inside dilated colonic crypts (Trott et al. 1996b), invading through tight junctions between colonic enterocytes, within
46.3. *Colonic mucosa of a chronic case of porcine colonic spirochetosis. Note the coalescing erosions accompanied by mucosal hyperemia and hemorrhage.*

goblet cells (Thomson et al. 1997), and within the lamina propria (Duhamel 2001). The presence of *B. pilosicoli* within crypts and the lamina propria is associated with neutrophilic exocytosis (crypt abscesses) and colitis characterized by edema, with a mixed infiltrate of neutrophils and lymphocytes within the lamina propria and occasionally extending further into the gut wall. In chronic infections, the lamina propria is infiltrated with large numbers of monocytes, lymphocytes, and plasma cells (Duhamel 2001). Invasion has been observed both concurrent with and independent of attachment of spirochete cells to the epithelium. In humans, *B. pilosicoli* has been isolated from the bloodstream of individuals with severe clinical disease or impaired immunity, in association with colitis (Trott et al. 1997; Kanavaki et al. 2002). Although a systemic spread or spirochetemia with *B. pilosicoli* has not been directly observed in pigs, its occurrence cannot be excluded.

The epithelial damage followed by local invasion and subsequent colitis combine to cause an increase in the water content of the cecal and colonic contents, together with excess mucus production and occasionally flecks of blood. Erosion of the epithelium leading to replacement by immature cells may reduce available surface area of the colon for absorption of water, electrolytes, and volatile fatty acids, and consequently affect feed conversion efficiency and weight gain (Duhamel 1998; Thomson et al. 1997).

Besides the "virulence life-style" genes of *B. pilosicoli* involved in motility and chemotaxis, other virulence determinants that might contribute to the disease have yet to be identified. A search for the attachment and invasion determinants encoded by the *inv*, *ail*, and *yadA* genes of *Yersinia enterocolitica*, the *eae* gene from enteropathogenic *Escherichia coli*, and a virulence plasmid of *Shigella flexneri* failed to identify similar genes in *B. pilosicoli* (Hartland et al. 1998). Although the attachment of *B. pilosicoli* to epithelial cells has been confirmed using intestinal epithelial cell lines in vitro, to date putative adhesins or host cell receptors have not been identified (Muniappa et al. 1998). At least three different protease activities, including a subtilisin-like serine protease similar to that of other gram-negative bacteria have been found in the membrane of *B. pilosicoli* (Muniappa and Duhamel 1997; Dassanayake et al. 2004). However, the role of these enzymes in disease, if any, has not been determined. Identification of virulence determinants in *B. pilosicoli* has been hampered by a lack of genomic information for this spirochete. Furthermore, unlike the case with *B. hyodysenteriae*, no successful gene inactivation experiments have been described for *B. pilosicoli*.

The host immune mechanisms that may be directed against *B. pilosicoli* have not been determined. In early studies, agglutinating serum antibodies were demonstrated in pigs recovered from experimental infection (Taylor et al. 1980). The development of serum IgG anti-bodies against whole cell extracts and membrane preparations of *B. pilosicoli* has been recorded 2–7 weeks after challenge inoculation of conventional weaned pigs (Zhang et al. 1999; Zhang et al. 2000; Zhang and Duhamel 2002). However, in another study, significant titers against whole cell preparations of *B. pilosicoli* were not found within 18 days following experimental infection of pigs, even though colonization and mild colitis were present (Hampson et al. 2000).

Gnotobiotic pigs (Neef et al. 1994), 1-day-old chicks (Duhamel et al. 1995a; Trott et al. 1995; Muniappa et al. 1998; Trott and Hampson 1998), adult chickens (Jamshidi and Hampson 2003), and mice (Sacco et al. 1998; Jamshidian et al. 2004) have been used as experimental models of *B. pilosicoli* infection. In various experimental infections of conventional pigs, between 17% and 100% of pigs have become infected, with 17–67% developing diarrhea and 8–100% exhibiting lesions of colitis (reviewed by Duhamel 2001). Not all colonized or diseased pigs have shown end-on attachment of spirochetes to the colonic epithelium (Thomson et al. 1997).

CLINICAL SIGNS

PCS has a clinical presentation similar to other forms of colitis and to the early stages of swine dysentery. It is commonly seen in the immediate postweaning period and in recently mixed growers placed on a new diet, but can be observed in finishers and occasionally pregnant sows and recently introduced breeding stock. PCS may affect groups of pigs of the same age in a unit or be present in pigs of mixed age on the same farm. It is not uncommon to observe various manifestations of PCS in weaners, growers, and finishers on the same farm. As a result of the large functional capacity of the cecum and colon, not all infected animals develop diarrhea; however, subclinical infections still may result in depressed growth rates.

The first clinical signs are hollowing of the flanks and the passage of loose, sometimes sticky feces that adhere to the pen floor. The consistency of the feces then changes to that of wet cement or porridge and may take on a glistening appearance. These may be the only clinical signs observed in finishers. Weaner and grower pigs usually develop a watery to mucoid diarrhea which is green or brown in color and occasionally characterized by thick tags of mucus and, rarely, flecks of blood. Diarrhea is usually self-limiting and lasts between 2 and 14 days, although some animals may relapse and again develop clinical signs after convalescence or treatment.

Affected pigs appear unthrifty, have fecal staining of the perineum, have a tucked-up appearance, and are sometimes febrile, but usually continue to eat. Pigs with PCS may have concurrent illness, particularly intestinal diseases such as swine dysentery, salmonellosis, or proliferative enteropathy. Mixed infections occur com-

monly in the field (Duhamel et al. 1995a; Girard et al. 1995; Møller et al. 1998; Thomson et al. 1998; Stege et al. 2000; Stege et al. 2001; Thomson et al. 2001). Pigs with uncomplicated PCS that develop loose feces may show significant loss of condition, decreased feed conversion, and delays in reaching market weight (Thomson et al. 1997; Thomson et al. 1998). Mortality is generally not a feature of PCS.

LESIONS

Gross Lesions

Gross lesions associated with PCS are limited to the cecum and colon and may be very subtle, particularly in the early stages of the disease. Postmortem examination soon after the onset of clinical signs often reveals a flaccid, fluid-filled cecum and colon with an edematous serosal surface and enlarged mesenteric and colonic lymph nodes. The large intestinal contents are abundant and watery green or occasionally yellow and frothy. Mild congestion and hyperemia of the mucosal surface might be apparent, with occasional erosions and necrotic foci. Inflammation in the later stages may result in multifocal erosive, ulcerative, or mucohemorrhagic colitis, but it is not as severe as that observed in swine dysentery. The mucosa becomes thickened, and local ecchymotic or petechial hemorrhages may be apparent on the surface. In chronic cases and in resolving lesions, the hemorrhages are covered by small tags of adherent fibrin, necrotic material, and digesta, which appear as conical scales adherent on the surface of the mucosa (see Figure 46.3). This material may be dislodged by rinsing, and can be found as a deposit after decanting the washings (Johnston et al. 1999).

Microscopic Lesions

PCS has been described as a catarrhal, multifocal, erosive or ulcerative colitis. Lesions are generally confined to the mucosa and submucosa, but may extend into the muscularis. The mucosa is thickened, edematous, and occasionally hyperemic and is characterized by the presence of dilated, elongated intestinal crypts filled with mucus, cellular debris, and degenerate inflammatory cells (Figure 46.4). The crypt cell mitotic rate is increased, and immature, cuboidal, or squamous epithelium may be present on the surface of the mucosa between crypt units. Where columnar epithelium is still present on the surface of the colon, it may be covered by a dark fringe of spirochetes attached by one cell end (see Figure 46.1). Silver stains (Muniappa et al. 1997), and more specifically either immunohistochemical staining with specific antibodies (Webb et al. 1997) or fluorescent in situ hybridization with specific oligonucleotide probes (Boye et al. 1998; Jensen et al. 2000), can be used to confirm the presence of spirochetes attached to the surface of colonic enterocytes, within dilated intestinal crypts, and occasionally within the lamina propria. The protozoan *Balantidium coli* is often seen in large numbers on the surface of the colon in pigs with PCS (Taylor et al. 1980; Trott et al. 1996b).

Electron Microscopy

Using transmission electron microscopy, polar-attached spirochetes with 4–7 periplasmic flagella may be observed invaginated into the terminal web cytoplasm, effacing microvilli and disrupting microfilaments without penetrating the host cell plasmalemma (Figure 46.5). Scanning electron microscopy reveals the adherent spirochetes as a patchy fringe on the surface of

Hematoxylin and eosin.*
46.5. *Transmission electron photomicrograph of colon obtained from a pig with spontaneous porcine colonic spirochetosis. Note attachment of large numbers of spirochetes by one of their ends to the apical membrane of enterocytes causing effacement of the microvilli and rarefaction of terminal web microfilaments (arrowheads). Many spirochetes are associated with the mucin at the opening and extending inside the lumen of the crypt (asterisk). Uranyl acetate and lead citrate; Bar = 2.5 μm (Reproduced from Johnston et al. 1999, with permission).*

colonic epithelial cells. Spirochetes also may be observed invading between epithelial cells in the extrusion zone between adjacent crypt units (Duhamel 1996).

DIAGNOSIS

PCS should be suspected when typical clinical signs of mucoid or porridge-like diarrhea without blood and no mortality are found in weaned pigs. The clinical signs of PCS are difficult to differentiate from those associated with the proliferative enteropathies caused by *Lawsonia*

intracellularis. In addition to proliferative enteropathy, PCS may occur concurrently with a number of other intestinal infections, including salmonellosis, postweaning colibacillosis, swine dysentery, yersiniosis, and trichuriasis. All of these should be considered in the differential diagnosis of PCS, as well as nonspecific colitis, an apparently diet-related condition possibly associated with a form of hypersensitivity to pelleted feed (Smith and Nelson 1987).

To obtain a diagnosis, postmortem examination of several affected pigs, including routine histologic and bacteriologic examination, should be undertaken (Johnston et al. 1999). Fecal samples for culture and/or PCR for *Brachyspira* spp. and other pathogens also should be obtained from a cross-section of affected pigs. Swabs taken directly from the colonic wall can be used to prepare wet smears for viewing by phase contrast microscopy, or they can be fixed and Gram-stained, in both cases to look for the presence of large numbers of spirochetes that might suggest a spirochetal etiology. In histologic sections from the cecum and particularly the colon, the presence of spirochetes attached to the colonic mucosa is diagnostic for PCS, but this change is not observed in every case of the disease. Other histologic lesions associated with PCS are often nonspecific, and a definitive diagnosis of PCS requires demonstration of *B. pilosicoli* by bacteriologic culture and/or PCR. While waiting for confirmation of results, medication should be initiated, because sometimes it can take 1–2 weeks to obtain a definitive diagnosis.

The four species of weakly beta-hemolytic spirochetes colonizing pigs can be differentiated from one another and from *B. hyodysenteriae* using a number of simple biochemical tests outlined in Table 46.1. Unfortunately, these tests generally require the growth of pure cultures, a process which can take several weeks to achieve, particularly if the initial plates are heavily contaminated with other fecal flora. In addition, the existence of isolates with unusual phenotypes, such as hippurate negative strains of *B. pilosicoli* (Fossi et al. 2004), can make interpretation difficult. Generally, laboratory

Table 46.1. Differentiation of the five recognized groups of porcine intestinal spirochetes by their hemolyis pattern on Trypticase Soy blood agar, biochemical reactions and utilization of sugars.

Test	*B. hyodysenteriae*	*B. intermedia*	*B. innocens*	*B. murdochii*	*B. pilosicoli*
Hemolysis	strong	weak	weak	weak	weak
Indole	+[a]	+	−	−	−[a]
Hippurate	−	−	−	−	+[b]
API-ZYM	1	1	2	3	4
D-ribose	−	−	−	−	+

+positive reaction; − negative reaction

[a]Indole negative strains of *B. hyodysenteriae* and indole positive strains of *B. pilosicoli* have been recorded.

[b]Hippurate negative strains of *B. pilosicoli* have been recorded.

1 = alpha-glucosidase positive, alpha-galactosidase negative.

2 = alpha-glucosidase positive or negative, alpha-galactosidase positive.

3 = alpha-glucosidase negative, alpha-galactosidase negative.

4 = variable reactions, including positive reactions for both enzymes, beta-glucosidase negative.

confirmation of *B. pilosicoli* can be accomplished using strength of beta-hemolysis, hippurate hydrolysis, metabolism of ribose, and lack of beta-glucosidase activity in the API-ZYM profile (Fellström and Gunnarsson 1995; Trott et al. 1996c). Nowadays, diagnosis is more usually supported by the use of specific polymerase chain reaction (PCR) tests.

Several PCR assays that are based on either a unique 16S rRNA gene sequence (Park et al. 1995; Fellström et al. 1997; Muniappa et al. 1997), a 23S rDNA sequence (Leser et al. 1997), or the NADH oxidase gene (Atyeo et al. 1999) specific for *B. pilosicoli* have been described. When applied to growth harvested from the primary isolation plate, the combined culture/PCR technique is more sensitive than culture alone and can significantly reduce the time taken for a diagnosis, even if there is a large amount of contamination with other fecal microbiota (Atyeo et al. 1998). A recent improvement in diagnosis involves the use of a duplex PCR for the simultaneous detection of both *B. pilosicoli* and *B. hyodysenteriae,* which is applied directly to DNA extracted from the feces (La et al. 2003). Potentially this can be used to give a diagnosis on the day of sample submission. The duplex PCR has been further modified to introduce a *Lawsonia intracellularis* component in the reaction, increasing the range of potential pathogens that it can detect in a single fecal sample (La et al. 2004). When using these fecal PCRs, it is usual also to culture the samples to obtain isolates, so that these can be used for strain-typing and/or determining their antimicrobial susceptibilities.

As previously mentioned, another recent adjunct to diagnosis has been the development of a fluorescent in situ hybridization (FISH) technique, which uses fluorescent oligonucleotide probes specific for sequences present in the 16S or 23S rRNA of *B. pilosicoli* (Boye et al. 1998; Jensen et al. 2000). The advantage of this technique is that identification and localization of the spirochetes associated with the intestinal mucosa can be done simultaneously. Localization of intestinal spirochetes in formalin-fixed and de-paraffinized tissue sections also has been accomplished using immunohistochemical staining with a *Brachyspira*-specific mouse monoclonal antibody (MAB) to FlaB periplasmic flagellar core proteins and the avidin-biotin-alkaline phosphatase complex method (Fisher et al. 1997; Webb et al. 1997; Johnston et al. 1999). These techniques are particularly useful in a research setting when investigating aspects of the pathogenesis of PCS.

A number of other schemes have been developed to detect and/or identify species of weakly hemolytic intestinal spirochetes of swine, as well as *B. hyodysenteriae,* without the need for culture and biochemical analysis. These involve PCR amplification of specific gene sequences, followed by restriction enzyme digestion of the products to give species-specific banding patterns after gel electrophoresis. Genes that have been used in

this way include the 16S rRNA gene (Stanton et al. 1997), the 23S rRNA gene (Barcellos et al. 2000c; Thomson et al. 2001), and the NADH-oxidase gene (Rohde et al. 2002). Indirect fluorescent antibody tests using MABs that have been raised against specific outer-membrane proteins of *B. pilosicoli* also have potential for diagnostic use on feces (Lee and Hampson 1995; Tenaya et al. 1998). Unfortunately, a MAB-based immunomagnetic separation of *B. pilosicoli* from feces did not improve sensitivity of detection above those achieved with standard culture followed by PCR (Corona-Barrara et al. 2004b).

Typing of individual strains of *B. pilosicoli* can provide important epidemiologic information to help devise control measures. Early studies used multilocus enzyme electrophoresis (MLEE) to differentiate intestinal spirochete isolates into species and strains (Lee et al. 1993; Stanton et al. 1996), but this time-consuming technique is no longer commonly used. Pulsed field gel electrophoresis now is the most commonly used strain typing technique for *B. pilosicoli* and gives better strain discrimination than MLEE (Atyeo et al. 1996; Trott et al. 1998; Fossi et al. 2003).

As a result of significant serologic cross-reactivity among the weakly beta-hemolytic intestinal spirochetes, to date no reliable tests are available to measure species-specific serum antibody titers.

TREATMENT AND CONTROL

Although treatment and control of PCS are largely modeled on procedures developed for swine dysentery, some modifications are necessary because of the lesser economic impact of PCS on pig production. No effective vaccines have been developed to date. An autogenous bacterin vaccine induced good systemic antibody titers, but vaccinated pigs still became colonized and developed diarrhea after experimental challenge (Hampson et al. 2000).

Implementation of rational antimicrobial therapy can reduce *B. pilosicoli* infection and maximize productivity while improving the welfare of pigs raised under intensive management. Affected pigs should be treated by water or feed medication at similar levels and lengths of time as recommended for the treatment of swine dysentery (Chapter 48). Parenteral treatment may sometimes be warranted for severely ill pigs.

Although information on the in vitro antimicrobial susceptibility of *B. pilosicoli* is relatively limited, a number of antimicrobials that are effective against *B. hyodysenteriae,* including tiamulin, valnemulin, carbadox, dimetridazole, and to a lesser extent lincomycin, have been shown to have low minimum inhibitory concentration (MIC) values when tested against collections of porcine *B. pilosicoli* isolates (Trott et al. 1996c; Cizek et al. 1998; Duhamel et al. 1998; Hommez et al. 1998b; Fossi et al. 1999; Kinyon et al. 2002; Brooke et al. 2003). Fewer isolates have been found to be susceptible to ty-

losin (Cizek et al. 1998; Hommez et al. 1998b; Kinyon et al. 2002). Olaquindox has been shown to have MIC values of less than 1.0 μg/mL against *B. pilosicoli*, and the organism could not be isolated from herds previously receiving olaquindox in the feed at 100 ppm (Fellström et al. 1996). However, despite its preventive attributes, the use of this agent is now very limited. Resistance to single antimicrobials, particularly tylosin, or to combinations of antimicrobials commonly used for treatment of PCS have been recorded (Kinyon et al. 2002). Of great concern is the recent emergence of *B. pilosicoli* strains resistant to tiamulin among field isolates obtained from pigs in Finland (Fossi et al. 1999) and North America (Kinyon et al. 2002).

Management strategies, particularly those aimed at limiting access of pigs to environments contaminated with manure, can be used to reduce the impact of PCS. Implementation of an all-in/all-out system ("batch production") rather than a continuous flow system of production reduces the risk of infection (Stege et al. 2001). Improved pen hygiene can reduce transmission. Where practical, modification to the diet composition and/or physical form may help control the impact of the infection. The addition of zinc oxide in the feed at 3 kg/tonne can help control PCS (Love 1996). This method also has been effective in controlling uncomplicated cases of nonspecific colitis (Kavanagh 1992). Interestingly, in laying hens, the addition of 50 ppm zinc bacitracin to the diet actually enhanced colonization with *B. pilosicoli* (Jamshidi and Hampson 2002), but whether the same occurs in pigs is not known.

The methods described in Chapter 48 for the elimination of swine dysentery also may be effective for PCS, but because PCS is less severe and has less economic impact than swine dysentery, it generally does not warrant such drastic procedures. Fossi et al. (2001) reported eradicating *B. pilosicoli* from a 60-sow herd by tiamulin treatment, followed by relocation of the breeding herd, thorough cleaning and disinfection of the premises, and then returning the adult animals to the original location. This protocol would be more difficult to follow in larger herds, and the existence of reservoir hosts for *B. pilosicoli*, such as feral waterbirds, presents an ongoing threat of reintroduction of PCS.

Where PCS becomes endemic in a herd, regular periods of treatment with antimicrobials in the feed or water may be required to prevent sudden increases in morbidity due to recent introduction of naive pigs, change of diet, or other periods associated with stress.

As a result of the current global nature of the pig industry and the limited number of available antimicrobial agents with demonstrated efficacy against *B. pilosicoli*, the potential for emergence of resistant strains has become an international concern. To assist future control of PCS, a high priority should be given to monitoring the antimicrobial resistance patterns of *B. pilosicoli*, to improving understanding of the basic mechanisms of re-

sistance, and to investigating the feasibility of producing vaccines or other methods to help control the disease.

47 Streptococcal Diseases

Robert Higgins and Marcelo Gottschalk

Several streptococcal species can be found in tonsils, intestines, and genital tracts of clinically healthy pigs, and some of them are potential pathogens. Among species considered as part of the intestinal microflora in swine, are *S. hyointestinalis* (Devriese et al. 1988), *S. suis, S. alactolyticus* (*S. intestinalis*), and *S. bovis* (Devriese et al. 1994b). *S. suis, S. porcinus*, and *S. dysgalactiae* subsp. *equisimilis* (Vieira et al. 1998) are generally found in tonsils (Devriese et al. 1994b). Vaginal microflora may comprise some of the above mentioned species, as well as *S. hyovaginalis* and *S. thoraltensis* (Devriese et al. 1997). Members of the genus *Enterococcus* such as *E. faecalis, E. faecium, E. durans, E. hirae*, and *E. villorum* are also important members of the intestinal microflora.

In this chapter, the different pathological conditions associated with streptococci and enterococci are presented. A particular emphasis was put on the infections caused by *S. suis* because of their importance in the swine industry during the last 15 years. Efforts were made to synthesize the more recent knowledge about the different aspects of these infections, particularly pathogenesis, clinical signs, diagnosis, and prevention. Importance was also given to the fact that *S. suis* is a zoonotic agent with severe consequences, and that its presence in a wide range of animal species and birds may influence the epidemiology and the control of the infection in swine. Comments about infections caused by other streptococci, such as *S. porcinus* (Lancefield groups E, P, U, and V), *S. dysgalactiae* subsp. *equisimilis* (Lancefield groups C, G, and L), have been included, as well as a discussion of diarrhea associated with enterococci.

INFECTIONS CAUSED BY *STREPTOCOCCUS SUIS*

Etiology and Prevalence
New alpha-hemolytic streptococci from septicemic infections in pigs were first biochemically and serologically characterized by de Moor between 1956 and 1963 as new Lancefield groups R, S, RS, and T (de Moor 1963). In England, Elliott (1966) suggested that de Moor's group S was similar to his PM *Streptococcus* and that both belonged to Lancefield's group D; he proposed the name *Streptococcus suis* serotype 1. In 1975, Windsor and Elliott isolated other porcine streptococci which corresponded to de Moor's group R and named them *S. suis* serotype 2. Isolates reacting with both antisera against serotypes 1 and 2 were designated serotype $\frac{1}{2}$ (originally RS group). Isolations of streptococci belonging to group T from tonsillar, vaginal, and preputial swabs were reported by Clifton-Hadley in 1984. The Lancefield group T reference strain was designated *S. suis* serotype 15 in 1989 (Gottschalk et al. 1989).

Between 1983 and 1995, a total of 32 new serotypes were described, out of a total number of 35 serotypes (Perch et al. 1983; Gottschalk et al. 1989; Gottschalk et al. 1991b; Higgins et al. 1995). Reference strains originated from diseased pigs except for capsular type 14, a human isolate, capsular types 17, 18, 19, and 21 isolated from clinically healthy pigs, capsular types 20 and 31 from diseased calves, and type 33 from a diseased lamb (Gottschalk et al. 1989; Higgins et al. 1995). The designation of *S. suis* as a new bacterial species was made official in 1987 by Kilpper-Balz and Schleifer. This species appeared genetically distinct and displayed no specific relationship with other streptococcal species examined (Chatellier et al. 1998). Genetic diversity among members of the *S. suis* species is important (Chatellier et al. 1999; Hampson et al. 1993), and this should be taken into account in diagnosis, surveillance, and control of the disease.

Initial reports of *S. suis* infections were published by Jansen and Van Dorssen in the Netherlands (1951) and by Field et al. (1954) in England. Since then, *S. suis* has been reported in all countries where the swine industry is important, and for more than 15 years, infections associated with this microorganism have been observed in both traditional and modern intensive swine operations. Most *S. suis* organisms isolated from diseased pigs

belong to a limited number of serotypes, often those between 1 and 8 (Galina et al. 1992; Higgins and Gottschalk 2001; Hogg et al. 1996; Kataoka et al. 1993; Reams et al. 1996). Although serotype 2 isolates predominate in most countries, the situation may be different depending on the geographical location. For example, the prevalence of this serotype recovered from diseased animals in Canada remained relatively low (below 25%) during the last 10 years (Higgins and Gottschalk 2001). This situation is very different from that observed in some European countries, where serotype 2 was frequently isolated in France, Italy, and Spain (Berthelot-Hérault et al. 2000; Wisselink et al. 2000). In this regard, it may be hypothesised that European and North American serotype 2 strains of *S. suis* possess a different virulence potential (Gottschalk and Segura 2000). In Japan, serotype 2 was also the most prevalent serotype (28%) (Kataoka et al. 1993).

Some strains belonging to less common serotypes have also been associated with severe cases of infection. Serotype 9 was reported to be most frequently isolated in Belgium, The Netherlands and Germany (Wisselink et al. 2000) and associated with outbreaks of septicemia, meningitis, and pneumonia in weaned pigs (Orr et al. 1989; Gogolewski et al. 1990). In the United Kingdom, serotype 14 is frequently isolated from piglets presenting clinicopathological findings similar to those associated with serotype 2 (Heath and Hunt 2001). The number of untypeable isolates is in general relatively low (Higgins and Gottschalk 2001). Most of the time, these isolates are recovered from sporadic cases of disease. It seems that there is no justification at the present time for the characterization of new serotypes.

Serotype 2 can also be isolated from clinically healthy pigs, but its prevalence has been reported to be low. British authors showed that in four herds without any history or clinical signs of the disease, two were negative for the presence of type 2, one had a prevalence of 1.5%, and another a prevalence of 20% (Clifton-Hadley et al. 1984). This is in accordance with Canadian studies that reported the presence of this serotype in relatively low number of herds without clinical signs of infection and in a low number of piglets within these herds (Brisebois et al. 1990; Monter Flores et al. 1993). However, the prevalence of a specific serotype may also be underestimated due to the lack of sensitivity of the isolation method used in these studies.

Hogg et al. (1996) noted a higher prevalence of serotypes 9–34 from nasal and vaginal swabs than from tissues taken from diseased pigs. It is noteworthy that several serotypes may be present in the same animal. In one study, 31% of pigs had only one serotype of *S. suis* in their nasal cavities, 38% had two or three serotypes, and 6% had more than four serotypes (Monter Flores et al. 1993). Isolation of multiple serotypes also has to be taken into consideration in diseased animals (see the section on diagnosis).

Epidemiology

Natural Habitat. The natural habitat of *S. suis* is the upper respiratory tract (particularly the tonsils and nasal cavities) and the genital and alimentary tracts of pigs (Devriese et al. 1994b; Hogg et al. 1996; Baele et al. 2001; Cloutier et al. 2003). *S. suis* is also increasingly isolated from a wide range of animal species and birds (Higgins et al. 1990b, 1995; Kataoka et al. 1993; Devriese et al. 1994a), and this may affect some epidemiological aspects of this infection. Finally, its presence in the environment is transitory (see the next section).

Transmission. Transmission of the infection between herds usually occurs by the movement of healthy carrier animals. The introduction of carrier pigs harboring virulent strains (breeding gilts, boars, weaners) into a non-infected herd may result in the subsequent onset of disease in weaners and/or growing pigs in recipient herds. Sows infect their own piglets during the birth process and probably through the respiratory route (Clifton-Hadley et al. 1986b; Robertson et al. 1991; Amass et al. 1997; Cloutier et al. 2003). It appears that although most weaned piglets carry *S. suis* strains, only a few of them carry strains capable of inducing the disease after weaning (Torremorell et al. 1998; Cloutier et al. 2003). It has been reported for serotype 2 and 5 that, even though different strains within the same serotype are present in the herd, only one of them is usually responsible for the clinical cases (Torremorell et al. 1998; Cloutier et al. 2003). For other serotypes, such as serotype 1/2, strains isolated from diseased animals seem to be similar to those recovered from carrier animals in herds without clinical disease (Martinez et al. 2002). Horizontal transmission seems to be significant especially in the presence of clinical signs, with a considerably higher number of bacteria in the environment that would increase transmission either by aerosol or direct contact. Aerosol transmission without nose-to-nose contact has been demonstrated for *S. suis* serotype 2 (Berthelot-Hérault et al. 2001).

S. suis also appears to be also transmitted via fomites (Robertson et al. 1991; Dee and Corey 1993). *S. suis* types 1 and 2 were isolated from the feed troughs of piglets and sows (Robertson et al. 1991). Enright et al. (1987) demonstrated that flies can carry *S. suis* type 2 for at least 5 days and can contaminate materials on which they feed for at least 4 days. Thus, flies could spread infection within farms and between farms. The importance of other animal species or birds as reservoirs or vectors of the infection has still to be determined. Carriage by humans also seems possible (Sala et al. 1989).

Survival in the Environment. Studies on the survival of *S. suis* in the environment have only been carried out with serotype 2. This organism survived in water at 4°C for 1–2 weeks. In experimentally inoculated feces, it sur-

vived at 0°C, 9°C, and 22–25°C for 104, 10, and 8 days, respectively, and in dust for 54, 25, and 0 days, respectively. Thus, at a summertime or weaner-accommodation temperature of 22–25°C, the organism could survive about 8 days in feces but less than 24 hours in dust (Clifton-Hadley and Enright 1984). *S. suis* serotype 2 was shown to survive in pig carcasses left rotting on farms. Survival time was 6 weeks at 4°C and 12 days at 22–25°C, potentially providing a source of infection for indirect spread by, for example, birds, rats, mice, or dogs (Clifton-Hadley et al. 1986c).

With regard to the cleaning of infected pens, disinfectants and cleaners commonly used in piggeries can kill *S. suis* type 2 in less than 1 minute, even at concentrations in distilled water less than those recommended by the manufacturers (Clifton-Hadley and Enright 1984; Robertson et al. 1991). The presence of dirt and organic material protects some organisms from the action of chemical disinfectants, and hence, removal of surface dirt from pens is an important part of the disinfection procedure. *S. suis* type 2 has survived for up to 2 hours at 50°C, but only 10 minutes at 60°C. Hot water may be used, but water from heated pressure washers cools rapidly on pen surfaces and is usually below 50°C. Thus, its value is in diluting contaminating microorganisms and washing away surface dirt rather than in killing by heat (Clifton-Hadley and Enright 1984).

Clinical Signs and Lesions

Even when the pig carrier rate is near 100%, the incidence of the disease varies from period to period and is usually less than 5% (Clifton-Hadley et al. 1986a). However, in the absence of treatment, mortality rates can reach 20% (Cloutier et al. 2003). In most cases, affected animals are generally between 5 and 10 weeks of age, but cases in pigs up to 32 weeks of age and a few hours old have also been described (Nielsen et al. 1975; Reams et al. 1996; MacInnes and Desrosiers 1999; Lapointe et al. 2002; Cloutier et al. 2003). Reams et al. (1996) indicated that in 75% of *S. suis* cases reported in United States, pigs were aged of 16 weeks or less. The earliest sign is usually a rise in rectal temperature to as high as 42.5°C. This may occur initially without any other obvious signs. It is accompanied by a detectable bacteremia or pronounced septicemia, which, if untreated, may persist for up to 3 weeks. During this period, there is usually a fluctuating fever and variable degrees of inappetence, depression, and shifting lameness (Clifton-Hadley et al. 1984).

In peracute cases, pigs may be found dead with no premonitory signs. Meningitis is the most striking feature and the one on which a presumptive diagnosis is usually based. Early nervous signs include incoordination and adoption of unusual stances, which soon progress to inability to stand, paddling, opisthotonus, convulsions, and nystagmus (Staats et al. 1997). The eyes are often staring, with reddening of mucous mem-

branes. Septicemia, arthritis, and pneumonia are less remarkable manifestations of the disease, and a tentative diagnosis may be difficult to make. Among other manifestations of *S. suis* infections, there are endocarditis, rhinitis, abortions, and vaginitis (Sanford and Tilker 1982; Sihvonen et al. 1988). In North America, *S. suis* is, by far, the infectious agent most frequently isolated from cases of endocarditis in pigs. Affected pigs may die suddenly or show various levels of dyspnea, cyanosis, and wasting.

In the United Kingdom, infections due to *S. suis* serotype 2 were primarily associated with septicemia and meningitis in weaned pigs (Windsor and Elliott 1975). In North America, early reports indicated that *S. suis* was predominantly isolated from cases of pneumonia (Koehne et al. 1979; Sanford and Tilker 1982; Erickson et al. 1984). Years later, reports from the United Kingdom mentioned septicemia, meningitis, and polyarthritis, but rarely pneumonia (MacLennan et al. 1996; Heath et al. 1996), whereas pulmonary lesions still predominated in North America (Reams et al. 1994, 1996; Hogg et al. 1996). In the Netherlands, *S. suis* type 2 was associated with pneumonia in 42% of the cases, followed by meningitis, endocarditis, and polyserositis in 18%, 18%, and 10%, respectively (Vecht et al. 1985). *S. suis* isolates belonging to serotypes other than 2 have been recovered from cases of bronchopneumonia in Argentina (Vena et al. 1991), Denmark (Perch et al. 1983), the Netherlands (Vecht et al. 1985), Belgium (Hommez et al. 1986), Finland (Sihvonen et al. 1988), Australia (Gogolewski et al. 1990), Canada (Higgins et al. 1990a; Gottschalk et al. 1991a, b), and the United States (Reams et al. 1994). The role of *S. suis* as a primary agent of pulmonary lesions, in the absence of other pathogens, is still controversial (Staats et al. 1997); so far, only one report indicated the presence of fibrinous pleurisy and bronchopneumonia in specific-pathogen–free piglets experimentally infected with *S. suis* serotype 2 (Berthelot-Hérault et al. 2001). In general, it is considered that neither clinical signs nor gross lesions are associated with specific serotypes (Reams et al. 1996).

Significant microscopic lesions are usually limited to the lung, brain, heart, and joints (Reams et al. 1994). The predominant lesions are neutrophilic meningitis and choroiditis, with hyperemic meningeal blood vessels, fibrinopurulent or suppurative epicarditis and suppurative bronchopneumonia (Sanford and Tilker 1982; Erickson et al. 1984; Reams et al. 1994, 1996). Evidence of encephalitis, edema, and congestion of the brain may be present (Staats et al. 1997). The choroid plexus may have disruption of the plexus brush border and fibrin and inflammatory cell exudates may be present in the ventricles (Staats et al. 1997). Interstitial pneumonia is also seen and is considered a lesion secondary to septicemia (Reams et al. 1994). Microscopic lesions do not seem to be associated with serotype (Reams et al. 1994). Rare cases of fibrinohemorrhagic pneumonia and septal

necrosis have been seen, and it is suggested that certain strains of *S. suis* may cause vascular lesions (Reams et al. 1995). In this regard, it has been reported that hemolysin-positive strains are toxic for endothelial cells (Charland et al. 2000; Vanier et al. 2004). Unusual lesions of hemorrhagic and necrotizing myocarditis and subacute meningoencephalitis and meningoencephalomyelitis have also been reported by Sanford (1987a, b). In cases of arthritis, the carpal and tarsal joints are most commonly affected (Windsor and Elliot 1975).

Virulence Factors and Pathogenesis of the Infection

Most studies on *S. suis* virulence factors have been carried out with serotype 2 strains. Although there is confusion in the description of virulence, researchers agree on the existence of virulent and avirulent strains of this serotype (Gottschalk and Segura 2000). Different opinions or versions about the definition of the virulence of *S. suis* have contributed to hampering the studies on virulence factors of this bacterial species, because the concept of "virulence" may differ depending on the experimental infection model that is used. In fact, there is no universally accepted model, and different research groups use different animal species, pigs with different health status and different ages, different routes of infection, or variable bacterial doses. (Gottschalk et al. 1999a). As a consequence, important discrepancies exist in the literature regarding even the virulence of the same strain (Gottschalk et al. 1999a). One of the most important practical applications of the identification of virulence factors is their use as "virulence markers" to differentiate virulent from avirulent strains. So far, there is no such universal virulence marker for *S. suis*.

Despite the fact that knowledge on virulence factors is limited, the most important candidates in *S. suis* serotype 2 are the capsular polysaccharide (CPS), virulence-related proteins, such as the muramidase-released protein (MRP) and the extracellular factor (EF), the hemolysin or suilysin, and some adhesins (Gottschalk and Segura 2000). The CPS is an important antiphagocytic factor, and these findings significantly changed the studies on the pathogenesis of the meningitis (see below). Despite the fact that the CPS was shown to be a major virulence factor, most avirulent strains are encapsulated indicating that other virulence factors are essential (Charland et al. 1998).

The MRP and EF proteins were originally associated with virulence (Vecht et al. 1991). Variants of these proteins were later described with a series of phenotypes that can be found in several serotypes (Smith et al. 1997). A certain association of these proteins with virulence in European strains seems to exist, and most isolates harboring these factors are virulent. However, the absence of one or both of these proteins cannot necessarily be associated with a lack of virulence. In fact, some European and most virulent North American iso-

lates do not produce these factors (Quessy et al. 1994; Galina et al. 1996; Gottschalk et al. 1998; Berthelot-Hérault et al. 2000). Similar observations have been made with the suilysin, a thiol-activated hemolysin produced by some strains of *S. suis* (Jacobs et al. 1994; Gottschalk et al. 1995). Although some authors reported a high association between virulence and the presence of this toxin (Staats et al. 1999; Tarradas et al. 2001), others showed that this hemolysin is absent in most North American virulent isolates (Gottschalk et al. 1998). Segers et al. (1998) also reported that the suilysin was present in 95% of the strains isolated in Eurasia, but only in 7% of the strains from North America. As is the case for the MRP and EF proteins, a certain association between the presence of the suilysin and virulence may be established, since avirulent suilysin-positive strains have never been reported so far (Gottschalk and Segura 2000). Isogenic mutants lacking either the MRP and EF proteins or the suilysin have been obtained and shown to be as virulent for pigs as the respective parent strain (Smith et al. 1997; Allen et al. 2001).

Adhesins, such as hemagglutinins (Haataja et al. 1993; Tikkanen et al. 1996), an albumin-binding protein (Quessy et al. 1997), an IgG-binding protein (Serhir et al. 1993) and a fibronectin-binding protein (de Greeff et al. 2002), have also been suggested as potential virulence factors. These binding proteins may participate in the establishment of the infection, but their role in the pathogenesis of *S. suis* infections remains to be confirmed.

The mechanisms that enable *S. suis* to disseminate throughout the animal are not well understood. The bacterium could spread systemically from the nasopharynx, occasionally resulting in septicemia and death (Gottschalk and Segura 2000). Both palatine and pharyngeal tonsils are considered as possible portals of entry for *S. suis* with subsequent hematogenous or lymphogenous spread (Madsen et al. 2002). An early theory suggested uptake of bacteria by monocytes, intracellular survival, and invasion of the central nervous system (CNS) by the Trojan horse theory (Williams and Blakemore 1990). Studies carried out by flow cytometry are controversial, with high (Busque et al. 1998) or low (Lun and Willson 2004) levels of phagocytosis. However, most studies carried out during the last decade suggest that bacteria may also use (an)other mechanism(s) to disseminate. It seems that most bacteria remain extracellular and the number of monocytes containing bacteria in septicemic pigs is low ($\leq$2%) (Williams and Blakemore 1990). In addition, the CPS would confer antiphagocytic properties to *S. suis* (Charland et al. 1998; Smith et al. 1999). It is possible that bacteria travel either free in circulation or even externally attached to monocytes (modified Trojan horse theory) (Gottschalk and Segura 2000; Segura and Gottschalk 2002). Bacteria can then reach the CNS via the endothelial cells that form the brain blood barrier

(BBB). It has been recently reported that *S. suis* is able to invade porcine brain microvascular endothelial cells (Vanier et al. 2004). On the other hand, interactions of bacteria with polarized epithelial cells of the choroid plexus (another important cell component of the BBB) may be the consequence of pressure of high-grade constant bacteremia. In fact, disruption of the plexus brush border, with fibrin and inflammatory cell exudates present in the ventricules has been described during natural and experimentally induced *S. suis* meninigitis (Williams and Blakemore 1990). Further studies of interactions between *S. suis* and epithelial cells from the choroid plexus might bring new and relevant information. Finally, studies have pointed out that the inflammatory exudate itself may be detrimental in some cases and have recommended treatment with antiinflammatory medications (Tunkel et al. 1990). In this regard, *S. suis* has been described as being able to induce an important release of proinflammatory cytokines (Gottschalk and Segura 2000; Segura et al. 2002).

Diagnosis

From Diseased Pigs. Presumptive diagnosis of *S. suis* infections is generally based on clinical signs, age of animals, and macroscopic lesions. Confirmation is achieved by the isolation of the infectious agent and microscopic lesions in tissues. When feasible, collection of more than one alpha-hemolytic colony from different tissues of the same animal or from different animals in the same herd is recommended, because multiple serotypes and strains of *S. suis* can be involved (Reams et al. 1996). Amass et al. (1997) suggested periodic culture of CSF from pigs with meningitis to ensure that the strain(s) of *S. suis* causing meningitis in the herd have not changed. This could be very helpful when vaccination is considered. Since *S. suis* may be recovered even from healthy lung tissues (Mwaniki et al. 1994), isolates from tissues other than lungs should be preferred in septicemic cases. In respiratory case accessions, isolation of other infectious agents such as *Pasteurella multocida*, *Actinobacillus pleuropneumoniae*, or *Arcanobacterium pyogenes* is frequent, but pure cultures of *S. suis* are also isolated (Higgins et al. 1990a; Galina et al. 1992). Direct detection of *S. suis* from infected tissues has also been studied. *In situ* hybridization with a probe detecting (without differentiating) serotypes 1–31 was used for detection of *S. suis* in formalin-fixed, paraffin-embedded tissue sections of brain, endocardium, and lung from *S. suis* infected pigs. In addition, immunohistochemical methods for the detection (without differentiation) of serotypes 2 and 1/2 were also reported (Boye et al. 2000). Detection of some serotypes of *S. suis* by PCR has also been reported (Wisselink et al. 2002a). However, these methods are not used in routine diagnosis.

After isolation, biochemical identification of *S. suis* isolates is possible with a minimum of tests when serotyping is available (Higgins and Gottschalk 1990).

Devriese et al. (1991) suggested the use of only two tests on pig isolates: amylase positive and Voges-Proskauer (acetoin) negative. However, this simplified identification scheme can be used only for isolates recovered from diseased or dead pigs and from sites other than the upper respiratory tract.

Serotyping is still an important part of the routine diagnostic procedure. It can be carried out by different techniques, but many laboratories have adopted the coagglutination technique. Since the majority of typeable isolates belong to serotypes 1–8 and 1/2, it is advisable for diagnostic laboratories to only use antisera corresponding to those serotypes and to send untypeable isolates to a reference laboratory (Higgins and Gottschalk 1990; Hogg et al. 1996). Some isolates cross-react with more than one antiserum using the coagglutination, as well as the capsular reaction, tests. The most important cross reactions are serotype 1/2 isolates with antisera against serotypes 1 and 2, and serotype 1 isolates with antiserum against serotype 14 (Gottschalk et al. 1989; Gottschalk and Segura 2000).

Genetic tools could be of valuable help in distinguishing individual isolates of *S. suis*, in establishing the origin of the infection in a given herd, in monitoring the kinetics of an outbreak, or in ensuring that the right strain is included in a vaccine. It was demonstrated that an important diversity existed among *S. suis* isolates even for those belonging to the same serotype (Mogollon et al. 1990). Genomic fingerprinting has allowed the identification of outbreak isolates of *S. suis* serotypes 2 and 5 (Mogollon et al. 1991; Cloutier et al. 2003). One study carried out with isolates from diseased pigs from different regions of Brazil showed the presence of a clonal atypical isolate (Martinez et al. 2003). Conversely, for herds affected with serotype 1/2 strains, clinical manifestations of the disease were more likely to be the result of inherent herd factors than the virulence of a specific isolate (Martinez et al. 2002). Overall, the great genetic heterogeneity of the clinical strains of *S. suis*, the isolation of different strains within the same herd, and the predominance of particular strains in some herds are evidence that infection by *S. suis* is a dynamic process and reinforce the idea that the epidemiology of *S. suis* infection is very complex (Vela et al. 2003). Isolates from different geographical origins seem to be genotypically different. In fact, strains of *S. suis* serotype 2 from Europe (presenting a MRP′, EF′, suilysin′ phenotype) seem to be different from North American strains, which are negative for these markers (Chatellier et al. 1999).

From Clinically Healthy Pigs. As mentioned before, *S. suis* is considered a normal inhabitant of the upper respiratory tract (Baele et al. 2001). Detection of *S. suis* from tonsils has no practical utility. These sites are highly contaminated and traditional bacterial isolation presents a low sensitivity (Gottschalk et al. 1999b). The pres-

ence of *S. suis* in high numbers in nasal cavities may reflect an active transmission of the infection rather than a carrier state (Cloutier et al. 2003). In this regard, it has been reported that the use of selective isolation using immunomagnetic beads coated with serotype 2 specific antibodies significantly increased the isolation rate of this serotype from tonsils when compared to the standard isolation technique (Gottschalk et al. 1999b). This technique has also been used with serotype 5 infected herds (Cloutier et al. 2003). Wisselink et al. (1999) described a PCR for the detection of virulent strains of serotype 1 and 2 from tonsils, but based on the phenotypes EF and MRP, which are not present in North America. Untypeable isolates recovered from tonsils or nasal cavities must be confirmed as being *S. suis* by genetic methods (Okwumabua et al. 2003), since biochemical identification may be misleading.

Different serologic tests for the detection of antibodies against *S. suis* have been evaluated (del Campo Sepulveda et al. 1996; Kataoka et al. 1996). However, these tests are not useful to differentiate infected from noninfected herds and cannot be used routinely. It has been reported that the use of an ELISA test using a protein extract of *S. suis* (homologous strain present in the herd) as coating antigen presented high interest. The development of a strain-specific ELISA allowed the evaluation of the serologic profiles of the maternal antibody levels in piglets to decide the time of vaccination as well as the induction of antibodies after either natural infection or vaccination (Lapointe et al. 2002; Cloutier et al. 2003).

Treatment

The choice of the best antibacterial agent against *S. suis* infections must be based on several criteria such as the susceptibility of the organism, the type of infection, and the mode of administration. Using the Kirby-Bauer method, susceptibility of *S. suis* isolates to penicillin appeared to be high (Kataoka et al. 2000; Han et al. 2001; Marie et al. 2002). The determination of minimal inhibitory concentrations allowed the demonstration of a large number of isolates moderately susceptible to penicillin, but the sensitivity rate to amoxicillin and ampicillin was around 90% (Shryock et al. 1992; Dee et al. 1993; Turgeon et al. 1994). It is now recommended that penicillin be used only in cases where sensitivity tests have shown that *S. suis* is sensitive. Different authors have reported a high degree of resistance of *S. suis* isolates to some antibacterial agents such as tetracycline, clindamycin, erythromycin, kanamycin, neomycin, and streptomycin (Estoepangestie and Lämmler 1993; Dee et al. 1993; Reams et al. 1993; Turgeon et al. 1994). Susceptibility to trimethoprim-sulfamethoxazole appeared to be variable (Sanford and Tilker 1989; Shryock et al. 1992; Turgeon et al. 1994; Kataoka et al. 2000). A Danish study showed a significant serotype-associated difference in the susceptibility to macrolides and tetracycline and demonstrated an increase in resistance

among *S. suis* isolates recovered during the last years to the two most commonly used antimicrobial agents (tylosin and tetracycline) in pig production in Denmark (Aarestrup et al. 1998). Marie et al. (2002) also described a higher proportion of resistance among non-serotype 2 isolates of *S. suis*. On the other hand, Han et al. (2001) did not find any correlation between antimicrobial susceptibility and serotype. MacInnes and Desrosiers (1999) suggested that ampicillin, ceftiofur, gentamicin, tiamulin and a combination of trimethoprim and a sulfonamide would seem to be the most useful antibacterial products for parenteral treatment.

Prompt recognition of the early clinical signs of streptococcal meningitis followed by immediate parenteral treatment of affected pigs with an appropriate antibiotic is currently the best method to maximize pig survival (Amass et al. 1997). Pigs in the early stages of meningitis may be difficult to detect, and groups of pigs should be checked 2–3 times daily. Affected pigs hold their ears back, squint their eyes, or exhibit dog-sitting (Amass et al. 1997). Adjunctive therapy with an antiinflammatory agent is recommended for treatment of *S. suis* meningitis in pigs (Amass et al. 1997). In a segregated early-weaning (SEW) program where postweaning meningitis associated with *S. suis* was observed, excellent results were obtained when piglets, in the very early stages of the disease, were injected with both penicillin and dexamethasone (Clark 1995). In peracute forms of the disease, the response to antibiotic treatment can be poor and it is sometimes advisable to treat all the pigs in a pen when one is affected or found dead (MacInnes and Desrosiers 1999).

Treatment can also be administrated via the drinking water or in medicated feed. However, due to the method of spread of the disease, treatment needs to be started very quickly. Whichever method of medication is to be used, it is important that treatment is continued for at least 5 days (Denicourt and Le Coz 2000).

Prevention

Control of Predisposing Factors. *S. suis* is an example of an emerging infection associated with the intensification of the swine industry. Multiple factors are involved, and among them are the health status of the herd (such as concomitant infections and immunosuppression), the degree of virulence of the *S. suis* strains involved, and the quality of the environment and of the management. It was also reported that minimizing variation in weaning age, with concurrent use of an autogeneous vaccine and antibiotic at processing and weaning, appeared to contribute to a decrease in nursery mortality (Villani 2003).

Overcrowding, poor ventilation, excessive temperature fluctuations, and mixing of pigs with an age spread of more than 2 weeks seem to be the most important stress factors involved in the development of *S. suis* infection in susceptible pigs (Dee et al. 1993). Manage-

ment practices such as all-in/all-out pig flow can help reduce the incidence of the disease. Dividing large buildings into smaller rooms can help minimize temperature fluctuations and the age spread between pigs. Cleaning each room between groups of pigs reduces buildup of microorganisms and improves health status, average daily gain, and feed conversion (Dee et al. 1993).

It is likely that concomitant viral infections could potentiate the development of lesions in infections due to *S. suis*. Iglesias et al. (1992) concluded that clinical disease associated with *S. suis* type 2 was enhanced by concomitant infection with pseudorabies virus. In North America, swine practitioners generally agree with the concept that the infection with the porcine reproductive and respiratory syndrome virus (PRRSV) significantly increases the susceptibility of animals to secondary infections, such as those caused by *S. suis*. This was confirmed by experimental infections (Galina et al. 1994; Thanawongnuwech et al. 2000). In addition, Feng et al. (2001) clearly demonstrated that in utero infection by PRRSV makes piglets more susceptible to infection and disease following challenge by *S. suis* type 2.

Production Technologies. Medicated early weaning and SEW have been used to improve the health status of pigs and to eliminate some infectious organisms (Alexander et al. 1980). It is now accepted that although early weaning can succeed in controlling diseases such as pleuropneumonia and swine dysentery, its capacity to reduce or eliminate early colonizers, such as *S. suis, Haemophilus parasuis,* and *Actinobacillus suis*, is questionable (Pijoan 1996). Control of these problems requires aggressive use of new diagnostic techniques, such as serum profiling, together with some manipulation of sow immunity and disease transmission in the nursery (Pijoan 1996). Other procedures, such as nursery depopulation, are under evaluation (Dee and Joo 1997).

Antimicrobial Preventive Medication. Antimicrobial preventive medication of groups of pigs via feed or water against *S. suis* infections must be based on several considerations. Bioavailability, route of administration (feed or water), competition (overcrowded pens), and serum concentration needed to kill *S. suis* have to be considered prior to prophylactic antimicrobial treatment (del Castillo et al. 1995; Amass et al. 1997).

Procaine penicillin incorporated into the feed was reported to significantly reduce the prevalence of streptococcal meningitis within a herd (McKellar et al. 1987). Oral administration of procaine penicillin G resulted in measurable systemic concentrations, although it is known that in humans, only about one-third of an orally administered dose is absorbed from the intestinal tract. Higher plasma concentrations are obtained with an equivalent dose of phenoxymethyl penicillin (McKellar et al. 1987). Del Castillo et al. (1995) indicated that of all types of oral treatments with penicillin, only

penicillin V in water given to fasted piglets could reach serum concentrations greater than the target concentrations selected for *S. suis* isolates. In the same conditions, penicillin G concentrations were much lower and hardly stayed above the target serum level. In the presence of food, only penicillin V reached the target level, but only in a few piglets. Thus, penicillin should exclusively be orally administered through drinking water to reduce the interference in absorption due to feed (del Castillo et al. 1995).

Amoxicillin is also an antibiotic of choice, since it rapidly achieves high plasma levels, diffuses well into the extracellular space, and most *S. suis* strains present low MIC (Denicourt and Le Coz 2000). In addition, persistence of amoxicillin in lymph nodes and tonsils may be relevant to control pathogens such as *S. suis*. Other authors have reported less conclusive results using experimentally infected animals (Halbur et al. 2000; Schmitt et al. 2001). In these studies, the use of ampicillin and penicillin G did not significantly reduce disease in animals exposed to a co-infection with *S. suis* and SRRPV. Ceftiofur treatment was the only regimen that significantly reduced mortality, recovery of *S. suis* from tissues at necropsy and severity of gross lung lesions.

Immunization. Until now, most vaccines used in the field to protect against *S. suis* infections have been commercial autogenous bacterins and results have been inconsistent (Reams et al. 1996; Torremorell et al. 1997; Halbur et al. 2000). The exact reasons for vaccine failure are still unknown, but possible explanations are degradation of protective antigens or loss of antigenicity of the bacteria caused by heat or formalin processing (Holt et al. 1990a), production of antibodies to antigens not associated with virulence factors (Holt et al. 1988), and weak immunogenicity of the capsulated bacteria (del Campo Sepulveda et al. 1996). Since affected animals are in general between 6 and 10 weeks old, interference with maternal antibodies should be taken into consideration. This was demonstrated by Lapointe et al. (2002) with a serotype 1/2 *S. suis* strain in an autogenous vaccine using sonicated bacteria. The serologic profile revealed that antibody levels against the *S. suis* serotype 1/2 strain varied considerably among 2- and 4-week-old pigs. Differences in antibody levels among piglets in these age groups could be attributed to differences in maternal antibody levels and/or in the rate of absorption of maternal antibodies by the piglets. In that study, it was clear that animals with the lowest levels of antibodies against the strain of *S. suis* serotype 1/2 responded more effectively to vaccination (Lapointe et al. 2002). In addition, the adjuvant used seems to play an important role. Wisselink et al. (2001) showed that a bacterin with a water-in-oil emulsion as an adjuvant presented better results than the same bacterin but with aluminium hydroxide-based adjuvant.

Live avirulent strains have also been tested. Pro-

tection was obtained in pigs following the inoculation of live avirulent *S. suis* serotype 2 strains (Holt et al. 1988; Busque et al. 1997). On the other hand, a live acapsular mutant was shown to fail to provide protection (Wisselink et al. 2002b). Since in some cases, live *S. suis* strains appear to induce a protection similar to that produced by live virulent strains, it is suggested that the important immunogens may be different from *S. suis* virulence factors (Gottschalk and Segura 2000). The use of a reduced dose of virulent *S. suis* also showed good protective results although some residual virulence was observed (Schmitt et al. 2001).

The importance of humoral immunity was well established by succeeding in passively transferring protection against *S. suis* type 2 (Holt et al. 1988, Andresen and Tegtmeier 2001). The role of antibodies against the capsule is still controversial. It was demonstrated that pigs experimentally or naturally infected with *S. suis* type 2 produced only low levels of antibodies against the capsular polysaccharide (del Campo Sepulveda et al. 1996). Andresen and Tegtmeier (2001) obtained high titers of antibodies against the CPS in one of two horses immunized for more than 40 weeks with whole cells of *S. suis* serotype 2. On the other hand, Wisselink et al. (2002b) showed that antibodies against the CPS and other bacterial components are essential for full protection against homologous challenge.

Studies have shown that different *S. suis* type 2 proteins could induce a good protection (Holt et al. 1990b; Quessy et al. 1994). A vaccine using MRP and EF proteins completely protected pigs against a challenge with virulent *S. suis* serotype 2 strains (Wisselink et al. 2001). These results disagree with those presented by Jacobs et al. (1996), who also reported that the suilysin was the only protein giving complete protection against *S. suis* infection. However, as mentioned, these three proteins are not present in all virulent strains (Quessy et al. 1994; Galina et al. 1996; Gottschalk et al. 1998; Berthelot-Hérault et al. 2000).

Most studies have been carried out with piglets. However, vaccination of sows and gilts has also been proposed and shown to be effective to a certain extent (Torremorell et al. 1997; Amass et al. 2000).

Finally, and based on the fact that systemic strains of *S. suis* are rarely found colonizing the upper respiratory tract of sows and gilts, and that a small number of piglets reach the nursery colonized with the herd's systemic strains, it has been suggested that early colonization of young pigs with the systemic strain can be used as a method for disease prevention (Torremorell et al. 1999; Oliveira et al. 2001). These authors showed that although both colonization protocols were successful in getting the piglets colonized, direct inoculation of 5-day-old piglets with the herd's systemic strain of *S. suis* tended to be more effective in reducing the morbidity and mortality than the colonization of piglets by nose-to-nose contact with inoculated sows (Oliveira et al. 2001).

Eradication

Attempts to eradicate the infection have focused only on serotype 2. Medicated early weaning (Alexander et al. 1980) is in general poorly effective, since *S. suis* is a very early colonizer (Torremorell et al. 1998). According to Clifton-Hadley et al. (1986b), only depopulation and restocking with clean pigs will ensure eradication of the infection, and in most herds this is not economic. Mills (1996) described the procedures that were used to establish a purebred minimal-disease herd from gilts found to be carriers of a virulent strain of *S. suis* type 2. Amass et al. (1996), on the other hand, did not recommend such an approach. They emphasized optimization of management and environment of pigs coupled with strategic medication of clinically ill animals for control and prevention of mortality caused by streptococcosis.

Cesarean section can be used to derive pigs free of *S. suis* from infected dams. Strict biosecurity measures are needed and they must include eliminating rodents and flies (Amass et al. 1997).

Considering that the infection is transmitted during farrowing, disease is often associated with respiratory problems and with multiple *S. suis* serotypes, that some less common serotypes are more and more involved in severe outbreaks, that reliable diagnostic or monitoring tools such as serology will not be available in the short term, and, finally, that *S. suis* is now isolated from a wide range of animal species and birds, it would appear reasonable to direct research efforts toward control measures rather than eradication.

Infection in Humans

S. suis is a zoonotic agent which deserves attention. Since the first description in Denmark in 1968 (Perch et al. 1968), nearly 200 human cases of *S. suis* infection have been reported. Several reports indicate "Lancefield group R streptococci"; these cases must be considered as *S. suis* since the latter terminology has been abandoned (Gottschalk and Segura 2000). In general, the *S. suis* disease is considered a rare event in man; however, it has been reported to be "one of the major causes of meningitis in adults in Hong Kong" (Chau et al. 1983). Most cases are caused by serotype 2 strains; but cases due to serotype 4 (one case) and serotype 14 (two cases) strains have also been observed (Gottschalk and Segura 2000; Watkins et al. 2001). Two recently found *S. suis* serotype 1 cases in humans remain to be confirmed because the serotype of these strains was only established using biochemical criteria and was not confirmed with a serologic reaction using specific sera (Kopic et al. 2003). Unfortunately, these isolates are no longer viable to confirm the serotype (J. Kopic, personal communication 2004).

Cases have been reported in The Netherlands, Denmark, Italy, Germany, Belgium, United Kingdom, France, Spain, Sweden, Ireland, Austria, Hungary, Hong Kong, Croatia, Japan, Singapore, Taiwan, New Zealand,

and Argentina (Gottschalk 2004). In the United Kingdom and France, this infection has been listed as an Industrial Disease in 1983 and 1995, respectively (Walsh et al. 1992; Pedroli et al. 2003). Mysteriously, although human cases have been observed in Canada (Michaud et al. 1996), none has been reported in the United States. It seems that the lack of reports on this disease in humans in the U.S. is most probably due to the misidentification of the microorganism (Gottschalk 2004). Even though *S. suis* field isolates readily grow on media employed for culturing meningitis causing bacteria, many laboratories working in human diseases are not aware of this microorganism and it is usually misidentified as enterococci, *Streptococcus pneumoniae, Streptococcus bovis,* viridans group streptococci, or even *Listeria* spp. (Lütticken et al. 1986; Michaud et al. 1996). In many cases, the initial gram stain diagnosis of the cerebrospinal fluid (CSF) specimen is pneumococcal meningitis.

In man, *S. suis* usually produces a purulent or nonpurulent meningitis (Lütticken et al. 1986). In addition, endocarditis, cellulitis, rhabdomyolysis, arthritis, pneumonia, and endopthalmitis have also been reported (Gottschalk 2004). Severe cases of sepsis with shock, multiple organ failure, disseminated intravascular coagulation, and associated purpura fulminans, which lead to death within hours, have also been described (François et al. 1998). One of the most striking features of the infection is the consequence of deafness following *S. suis* meningitis (Lütticken et al. 1986). *S. suis* meningitis may have been missed in the past because of such confusion. *S. suis* infection in humans is observed more frequently in intensive pig farming areas or where people live in close contact with pigs (Strangmann et al. 2002). In fact, in nearly all reported cases, patients had close contact with pigs—as farmers, butchers, abattoir workers—or handled pork products (Arends and Zanen 1988). One documented case of a veterinary surgeon has been reported (Walsh et al. 1992). The most frequent transmission route is through skin abrasions or cuts, although in many cases, no skin laceration could be shown (Michaud et al. 1996). The finding that liquid soap inactivates *S. suis* type 2 in less than 1 minute at a dilution in water of 1 in 500 suggests that washing with soap and water would be a satisfactory way of removing skin contamination (Clifton-Hadley and Enright 1984). Since *S. suis* type 2 can survive in carcasses at 4°C for 6 weeks, chilled or frozen meat could be a hazard long after being butchered.

Information about the occurrence and frequency of human colonization by *S. suis* is scarce, with most data coming from abattoir workers (Strangmann et al. 2002; Sala et al. 1989). In New Zealand, relatively high antibody titer against *S. suis* serotype 2 were reported in people with occupational contact with the pig industry (Robertson and Blackmore 1989). However, these data should be taken with caution since no standardized serological test to detect *S. suis* antibodies exists.

In general, *S. suis* isolates from humans are phenotypically and genotypically similar to those recovered from pigs (Berthelot-Hérault et al. 2002) and they are also susceptible to beta-lactams. Gentamicin appeared also very active against *S. suis*, and a combination with penicillin is recommended in human cases of endocarditis due to this agent (Trottier et al. 1991).

INFECTIONS CAUSED BY BETA-HEMOLYTIC STREPTOCOCCI

Streptococcus porcinus

The name *Streptococcus porcinus* was proposed in 1984 by Collins et al. (1984) to represent streptococci of serological groups E, P, U, and V, which formed a single DNA-DNA homology group. *S. porcinus* has a unique phenotypic profile in addition to serologic differences that can be used to help identify the species. By rRNA sequencing, *S. porcinus* is closely related to the other beta-hemolytic streptococci, such as groups A, B, and C (Facklam et al. 1995).

S. porcinus group E has been associated, particularly in the United States, with a contagious clinical entity in growing pigs known as streptococcal lymphadenitis, jowl abscesses, or cervical abscesses. Transmission is possible by contact, drinking water, or ingestion of food contaminated by abscess discharge or infected feces. The organisms enter the swine host through the mucosa of the pharyngeal or tonsillar surfaces and are carried to the lymph nodes, primarily of the head and neck region, where abscesses are formed (Wessman 1986). Losses due to this disease in the United States were important in the 1960s, but its incidence has since declined. The disease is not recognized as an important economic entity in other countries, where the bacterium represents only a few percent of the microorganisms isolated from abscesses in swine (Wessman 1986). A report of an outbreak from Spain mentioned that 80% of 50 feeder pigs had mandibular and retropharyngeal purulent lymphadenitis (Real et al. 1992). Antibiotic treatment is not usually successful in abscessed swine or in elimination of carriers. Resistance to tetracycline has been recently reported (Facklam et al. 1995; Lämmler and Bahr 1996). Vaccination is possible but has not been widely used since the condition is not widespread.

S. porcinus group E can be isolated from tonsils, pharynx, and nasal cavities of clinically healthy pigs. It is also occasionally found in the vaginal mucus of sows and in the semen and prepuce of boars. It is considered to be more of a secondary invader than a primary pathogen in conditions such as pneumonia, enteritis, encephalitis, and arthritis (Wessman 1986). It was isolated in Canada from the lungs of a 2-year-old pig affected with an abscessative pneumonia, along with other bacterial agents (A. Désilets, personal communication 1995).

S. porcinus groups P, U, and V were isolated by

Hommez et al. (1991) from pig lungs, genital organs, and brains. However, no histological lesions could be associated with their presence. *S. porcinus* groups P and V were associated with abortions in pigs (Plagemann 1988; Lämmler and Bahr 1996). Hommez et al. (1991) cited a report of Hinterdorfer et al. (1990), in which *S. porcinus* group P was associated with hemorrhagic tracheitis in pigs.

Katsumi et al. (1997) found *S. porcinus* in 1.6% of slaughtered pigs with lesions of endocarditis. In 1998, the same authors reported that on a total of 170 beta-hemolytic streptococci isolated from lesions in slaughtered pigs, 22.4% were identified as *S. porcinus*. Of those, 3.0% belonged to group E, 3.0% to group P, 8.2% to group U, and 8.2% were ungroupable (Katsumi et al. 1998).

Streptococcus dysgalactiae subsp. *equisimilis*

In 1984, Farrow and Collins, using DNA-DNA hybridization, DNA base composition, and biochemical tests, indicated that *Streptococcus dysgalactiae*, *S. equisimilis*, and streptococci of Lancefield serologic groups C, G, and L were a single species. In 1996, Vandamme et al. proposed that the name *S. dysgalactiae* subsp. *dysgalactiae* be used for strains of animal origin, and the name *S. dysgalactiae* subsp. *equisimilis* be used for human isolates. However, in 1998, Vieira et al., based on multilocus enzyme electrophoresis typing and genomic DNA relatedness, proposed a new classification for these organisms: alpha- and non-hemolytic streptococci of Lancefield group C are defined as *S. dysgalactiae* subsp. *dysgalactiae*, and beta-hemolytic streptococci belonging to groups C, G, or L are named *S. dysgalactiae* subsp. *equisimilis*.

In swine, members of the *S. dysgalactiae* subsp. *equisimilis* species are all beta-hemolytic streptococci. Although members of the normal flora, they are considered the most important beta-hemolytic streptococci involved in lesions in pigs, and these agents were judged to be of etiological significance in autopsy reports (Hommez et al. 1991). *S. dysgalactiae* group C streptococci are common in nasal and throat secretions, tonsils, and vaginal and preputial secretions (Jones 1976). Vaginal secretions and milk from postparturient sows are the most likely sources of infection for the piglets (Woods and Ross 1977). Streptococci enter the bloodstream via skin wounds, the navel, and tonsils. A bacteremia or septicemia occurs, and the organisms then settle in one or more tissues, giving rise to arthritis, endocarditis, or meningitis. Insufficient consumption of colostrum or milk or inadequate levels of antibodies, especially in gilts, may predispose to disease (Windsor 1978).

Infection is usually first seen in pigs between 1 and 3 weeks of age. Joint swelling and lameness are the most obvious and persistent clinical signs. Elevated temperatures, lassitude, roughened hair coat, and inappetence

may also be noted. Early lesions consist of periarticular edema; swollen, hyperemic synovial membranes; and turbid synovial fluid. Necrosis of articular cartilage may be seen 15–30 days after onset and may become more severe. Fibrosis and multiple focal abscessation of periarticular tissues and hypertrophy of synovial villi also occur. In lame pigs, up to 12 weeks of age, the causative agents of arthritis were, in decreasing order, *S. dysgalactiae* subsp. *equisimilis* (26.3%), *Staphylococcus hyicus* (24.6%), *Arcanobacterium pyogenes* (13.2%), *S. aureus* (7.9%), and *Haemophilus parasuis* (7.9%), and most of the pigs culled for arthritis were under 6 weeks of age (Hill et al. 1996). Hommez et al. (1991) mentioned that *S. dysgalactiae* is frequently isolated from pigs, in which the organisms cause septicemia, arthritis, or valvular endocarditis. In 1997, Katsumi et al. reported the isolation of *S. dysgalactiae* from lesions of endocarditis in 15.2% of slaughtered pigs, and *S. suis* was present in 25.7% of the animals. In 1998, Katsumi et al. mentioned that during a 7-year period, 77.6% of beta-hemolytic streptococci isolated from slaughtered pigs belonged to the *S. dysgalactiae* species. Of those, 45.8% belonged to Lancefield group C, 25.3% to group L, and 6.5% to group G.

Since baby pigs are virtually assured of being exposed to *S. dysgalactiae*, effective preventive measures should be followed. Adequate intake of colostrum may ensure that the piglets receive protective antibodies. Traumatic injuries to the feet and legs should be minimized by reducing the abrasiveness of the floor surface in the nursing area. Beta-hemolytic streptococci are sensitive to beta-lactam antibiotics. Long-acting antibacterial agents may be beneficial, and treatment should be given before the inflammatory process is well advanced (Sanford and Higgins 1992). There are no recent reports about vaccination against groups C or L streptococci. Autogenous bacterins have been used, and a reduction in incidence of arthritis has been reported when sows were vaccinated before farrowing (Woods and Ross 1977).

Enteritis Associated with Enterococci in Piglets

Some enterococcal species that show typical adhesion to the apical surface of the enterocytes of the small intestine of young animals have been described as associated with diarrhea in different animal species (Vancanneyt et al. 2001). Cases have been reported in piglets between 2 and 20 days of age. Most cases were sporadic (Johnson et al. 1983; Drolet et al. 1990), but an outbreak included 90% of the piglets in 16 of 20 litters (Cheon and Chae 1996). Taxonomic studies have shown that most of these enterococci are members of the *E. faecium* species group, mainly *E. durans* and *E. hirae*. In 2001, Vancanneyt et al. reported that some of the *E. hirae* or *E. hirae*-like isolates retrieved from piglets were genetically different from the reference strains and should be represented by a new species, *E. villorum*.

Enterococci are known as part of the intestinal flora, but some strains have the capacity to colonize the mucosal surface of the small intestine extensively. The pathogenesis of enteric disease associated with adherent enterococci is unclear. Adherence occurs with the help of fibrillar projections (Tzipori et al. 1984), and diarrhea is not associated with enterotoxin production or substantial mucosal injury (Cheon and Chae 1996). A decreased activity of brush border digestive enzymes such as lactase and alkaline phosphatase would interfere with digestion and absorption of the brush border (Drolet et al. 1990; Cheon and Chae 1996). Because of the natural resistance of enterococci to some antibacterial agents, antimicrobial susceptibility testing is advised before the institution of a treatment. Due to the lack of knowledge about the clinical and epidemiological aspects of this infection, preventive measures are difficult to establish.

48 Swine Dysentery

David J. Hampson, C. Fellström, and Jill R. Thomson

Swine dysentery (SD) is a mucohemorrhagic colitis affecting pigs primarily during the grow-finish period. The disease can be severe and may cause significant economic loss. SD has been reported worldwide and remains problematic in many major swine-rearing countries. The primary etiologic agent of SD is the strongly beta-hemolytic anaerobic intestinal spirochete *Brachyspira hyodysenteriae*. An emerging issue of concern to veterinarians is the existence of *B. hyodysenteriae* isolates with reduced susceptibility to a number of antimicrobial agents that were formerly effective for the control of SD. The presence of such isolates on certain piggeries, and their possible spread, reduces the options available for controlling SD.

ETIOLOGY

Intestinal Spirochetes and Swine Dysentery

The spirochetal etiology of SD was conclusively demonstrated in the early 1970s (Taylor and Alexander 1971; Glock and Harris 1972), when the causal strongly beta-hemolytic anaerobic spirochete was identified and named *Treponema hyodysenteriae* (Harris et al. 1972). Subsequently, the spirochete was transferred to a new genus *Serpula* (Stanton et al. 1991), then to *Serpulina* (Stanton 1992), and is now classified in the genus *Brachyspira* as *Brachyspira hyodysenteriae* (Ochiai et al. 1997; Validation list 1998). This genus includes four other named species of intestinal spirochete (all weakly beta-hemolytic) that colonize swine, as well as at least four other named or suggested *Brachyspira* species that are known to colonize other animal species or humans (Hampson 2000). Of the porcine intestinal spirochetes, besides *B. hyodysenteriae* only *Brachyspira pilosicoli* is confirmed to be pathogenic in swine, causing an often-mild colitis called "porcine colonic spirochetosis" or "porcine intestinal spirochetosis" (see Chapter 46). The other three species, *Brachyspira innocens, Brachyspira intermedia* and *Brachyspira murdochii* are generally considered to be nonpathogenic commensals in swine. *B. inter-*

media occasionally has been suspected of causing diarrhea in pigs (Fellström et al. 1996), and it is known to cause wet litter and reduced egg production in adult chickens (Stephens and Hampson 2001).

B. hyodysenteriae produces typical signs and lesions of SD when orally inoculated into conventional or specific pathogen free pigs (Taylor and Alexander 1971; Glock and Harris 1972; Harris et al. 1972). Lesions also can be produced with pure cultures of *B. hyodysenteriae* in porcine colonic segments prepared by surgical anastomosis (Hughes et al. 1975), and in isolated ligated porcine colonic loops (Whipp et al. 1978). Mice are frequently used as an experimental model of SD (Joens and Glock 1979). The spirochete has been recovered from naturally infected rheas (a large flightless South American bird) in the United States, in which it causes a necrotizing typhlocolitis (Jensen et al. 1996). Strongly hemolytic spirochetes identified as *B. hyodysenteriae* recently have been isolated from Mallard ducks in Sweden, but whether they cause disease in this species is unclear (Jansson et al. 2004).

Characteristics of *B. hyodysenteriae*

Brachyspira hyodysenteriae is a gram-negative, oxygen-tolerant, anaerobic spirochete. It is 6–8.5 μm long, 320–380 nm in diameter, loosely coiled (Figure 48.1), motile, and
48.1. *Cells of* Brachyspira hyodysenteriae *as viewed under a phase contrast microscope.*

strongly beta-hemolytic on blood agar. It has 7–14 periplasmic flagella inserted at each cell end, and these overlap at the middle of the protoplasmic cylinder. The whole cell, including the periplasmic flagella, is covered by a loose outer membrane (Figure 48.2).

B. hyodysenteriae grows slowly in an anaerobic environment at 37–42°C on trypticase soy agar and on similar agar plates that are fortified with 5–10% defibrinated blood (usually ovine or bovine). After 3–5 days, the spirochetes can be seen as a low flat haze of growth surrounded by a zone of strong beta-hemolysis (Figure 48.3.). The hemolysis can be enhanced by cutting slices into the agar at the time of inoculation (Olson 1996). Different combinations of antibiotics may be incorporated into the agar to make selective plates for isolation of the spirochete from feces (see diagnosis section).

B. hyodysenteriae can be propagated in various anaerobic broth media. Broths are incubated at 37–42°C, and are usually gently agitated on a reciprocal shaker. Growth of 10^8–10^9 cells per mL can be achieved within 2–3 days in the prereduced anaerobic trypticase soy
broth medium of Kunkle et al. (1986), and also in brain heart infusion broth containing 10% (v/v) fetal bovine serum (Stanton and Lebo 1988). The latter authors showed that the addition of 1% O_2 to the anaerobic culture atmosphere enhances growth. *B. hyodysenteriae* can utilize oxygen with the aid of enzymes such as nicotinamide adenine dinucleotide, reduced [NADH] oxidase (Stanton 1997).

Stanton (1997) published a comprehensive description of the metabolic activities of *B. hyodysenteriae* and related intestinal spirochetes. Useful features that can help distinquish *B. hyodysenteriae* from other intestinal spirochete species include their ability to produce indole, their enzymic profile in the commercial API-ZYM kit, and the presence of strong beta-hemolysis (Fellström et al. 1997). Some comparative features of *B. hyodysenteriae* and other porcine spirochetes are tabulated in Chapter 46. It must be emphasized that none of these phenotypic properties can be completely relied upon to provide identification, because strains of intestinal spirochetes with unusual phenotypes are occasionally encountered (Thomson et al. 2001). For example, indole negative strains of *B. hyodysenteriae* recently have been described (Fellström et al. 1999), whilst *B. intermedia* is also indole positive.

The outer envelope of *Brachyspira hyodysenteriae* contains lipooligosaccharide (LOS: a semirough form of the more usual lipopolysaccharide [LPS] of gram-negative bacteria) (Halter and Joens 1988). Baum and Joens (1979) extracted LOS from *B. hyodysenteriae* using hot phenol/water, and used agar gel diffusion to react it with serum from rabbits that had been hyperimmunized with *B. hyodysenteriae*. Doing this, they were able to classify a set of 13 isolates into four LOS serotypes.

Subsequent work uncovered the existence of considerably more antigenic diversity among LOS extracted from other isolates, and the typing system was extended to include new serotypes. The system was then modified to include a number of serogroups, some of which also contained individual serovars (Hampson et al. 1989). The serogroup is identified using unabsorbed sera, and the serovar is then identified using cross-absorbed sera. Currently 11 serogroups are recognized (Hampson et al. 1997). There is no indication that the virulence of an isolate correlates with its serotype, although LOS antigens appear important in stimulating protective immunity (see later section).

A number of attempts have been made to identify outer envelope proteins from *B. hyodysenteriae* (e.g., Chatfield et al. 1988; Joens et al. 1993), mainly in the course of attempts to identify potentially immunogenic molecules for use in vaccine production. Extraction of the outer membrane with Triton X-114 is considered the preferred method to reduce cellular contamination (Sellwood and Bland 1997), although osmotic lysis followed by isopycnic centrifugation also may result in spirochetal extracts that are free of cytoplasmic and flagellar contaminants (Trott et al. 2001). Well-characterized outer membrane lipoproteins include the 16 kDa "SmpA" (Thomas and Sellwood 1993), which has been renamed BmpA (Lee et al. 2000), and the 29.7 kDa BmpB (Lee et al. 2000). BmpB has also been referred to as BlpA, with the encoding gene sequence *blpA* being identified as a component of a locus designated *blpGFEA,* encoding four tandem paralogous *B. hyodysenteriae* genes encoding lipoproteins all of approximately 30 kDa (Cullen et al. 2003). A 39 kDa variable surface protein, encoded by eight linked gene copies, and possibly involved in immune avoidance, also has been described (Gabe et al. 1998; McCaman et al. 2003). A periplasmic ATP-binding cassette involved in iron importation has been characterized, which includes at least three lipoproteins (Dugourd et al. 1999).

Genomic Organization and Population Genetics

A physical and genetic map of the chromosome of the type strain of *B. hyodysenteriae* (B78^T) has been prepared (Zuerner and Stanton 1994). The chromosome is circular and is estimated to be about 3.2 Mbp in size, compared to about 2.45 Mbp for *B. pilosicoli* (Zuerner et al. 2004). Ritchie et al. (1978) demonstrated several different types of bacteriophages on the surfaces of cultures of *B. hyodysenteriae* and *B. innocens* (see Figure 48.2). A generalized transducing bacteriophage (VSH-1) from *B. hyodysenteriae* has been purified and characterized (Humphrey et al. 1997) and is believed to be important in transferring host genes between cells.

Analysis of the population structure of *B. hyodysenteriae* using multilocus enzyme electrophoresis (MLEE) has shown that the species is quite diverse, that it con-

tains numerous genetically distinct strains, and that it includes at least four subgroups with similar phenotypes (including virulence) (Lee et al. 1993). Subsequent analysis of new MLEE data was used to deduce that the species is recombinant, and that it has an epidemic population structure (i.e., epidemic clones exist, which may be widespread) (Trott et al. 1997). In a study using pulsed-field gel electrophoresis (PFGE) to analyze strains from individual farms, it was shown that over the course of several years new strains of *B. hyodysenteriae* may emerge as variants of the original parent strain (Atyeo et al. 1999a). Other than the occurrence of random mutational and recombination events, bacteriophages such as VSH-1 may contribute to this on-farm "micro-evolution" of strains through transduction of new sequences from other *Brachyspira* species or strains. New strains that emerge could have altered phenotypic properties, potentially including altered antimicrobial susceptibility, colonization potential, or virulence. Drifts in antigenicity of surface LOS among isolates on the same farm over a number of years have been recorded (Combs et al. 1992). Interestingly, chromosomal rearrangements and sequence drift also contribute to differences observed between the genomes of *B. hyodysenteriae* and *B. pilosicoli* (Zuerner et al. 2004).

Virulence Attributes

Virulence attributes of *B. hyodysenteriae* are likely to consist of a set of virulence "lifestyle" factors involved in initial colonization and fitness for survival in the microenvironment adjacent to the mucosa of the large intestine, as well as "essential" virulence factors that are required for lesion production. Avirulent isolates of *B. hyodysenteriae* that colonize pigs but do not induce disease have been described in the U.K. and Australia (Lysons et al. 1982; Lee et al. 1993; Thomson et al. 2001), and a study of these may help to define *B. hyodysenteriae* virulence factors. Some of these avirulent isolates have been reported to have a reduced motility in porcine mucus (Milner and Sellwood 1994), suggesting that motility is important in efficient colonization. Recent analysis of other avirulent isolates suggests that some lack a homologue of the *mglB* gene, encoding the glucose-galactose lipoprotein, which is believed to be a chemoreceptor in glucose and galactose chemotaxis (Walker et al. 2002). Both chemotaxis and motility are likely to be important mechanisms in allowing *B. hyodysenteriae* to associate with the gut mucosa (Kennedy et al. 1988). The role of motility in colonization has been confirmed in experiments where *B. hyodysenteriae* strains with disruptions introduced to their flagella genes (*flaA* and *flaB*) had both reduced motility and a reduced ability to colonize (Rosey et al. 1996; Kennedy et al. 1996).

Another likely "lifestyle" virulence factor is the NADH oxidase activity of *B. hyodysenteriae,* which is believed to enhance the spirochete's ability to colonize the

colonic mucosa by protecting it from oxygen toxicity. Consistent with this, *B. hyodysenteriae* strains with an inactivated *nox* gene show a reduced ability both to colonize swine and to cause disease (Stanton et al. 1999).

The hemolytic activity of *B. hyodysenteriae* is considered to be associated with its virulence, and the hemolysin is probably an "essential" virulence factor. Unfortunately, there has been considerable confusion about the nature of the hemolysin(s) involved. Various early studies suggested that *B. hyodysenteriae* hemolysins had molecular weights of 19 kDa, 68 kDa or 74 kDa (reviewed by ter Huurne and Gaastra 1995). The hemolysin or hemolysins were oxygen-stable and resemble another carrier-dependent toxin, streptolysin S. Purified hemolysin is cytotoxic for a number of tissue culture cell lines and to primary pig cells (Kent and Lemcke 1984). It has been shown to damage epithelial cells in porcine ligated intestinal loops (Lysons et al. 1991) and in the murine cecum (Hutto and Wannemuehler 1999). Three different genes (*tlyA*, *tlyB,* and *tlyC*) encoding putative hemolysins of *B. hyodysenteriae* were originally described, based on their ability to induce a hemolytic phenotype in *Escherichia coli* (ter Huurne et al. 1994). More recently, a distinct gene (*hlyA*) has been characterized that encodes an 8.93 kDa polypeptide of *B. hyodysenteriae,* which has hemolytic activity (Hsu et al. 2001). It now appears that the *tly* genes may be regulatory elements, rather than encoding hemolysins themselves. Nevertheless, inactivation of *tlyA* has been shown to reduce both the hemolytic activity and the virulence of *B. hyodysenteriae* (Hyatt et al. 1994). These results emphasize the likely role of hemolysin(s) in the virulence of *B. hyodysenteriae.*

LOS from *B. hyodysenteriae* has some of the same biological properties as LPS from other gram-negative bacteria and is likely to contribute to the pathology observed in SD. Nuessen et al. (1982) showed that *B. hyodysenteriae* LOS extracted by phenol/water was toxic for mouse peritoneal macrophages, increased uptake of red blood cells by murine peritoneal cells via Fc and C3 receptors, acted as a mitogen for murine splenocytes, and generated chemotactic factors in fresh swine serum. Greer and Wannemuehler (1989b) found that endotoxin extracted from *B. hyodysenteriae* by butanol/water had more biological activity than the LOS extracted by phenol/water. It induced interleukin-1 and tumor necrosis factor from murine peritoneal cells and augmenting natural killer activity. Nevertheless, these authors also found that the biological activities of LOS and endoxin from *B. hyodysenteriae* and *B. innocens* were similar, and therefore may not account for the different pathogenic potential of the two species (Greer and Wannemuehler 1989a). Subsequent in vivo studies in mice and pigs demonstrated that *B. hyodysenteriae* endotoxin also can induce production of proinflammatory cytokines such as interleukin-6 (Nibbelink et al. 1997). Other evidence that *B. hyodysenteriae* LOS has a poten-

tial role in virulence came from studies where the outcome of infection in C3H/HeJ mice (hyporesponsive to LPS) was compared to the response in C3H/HeB mice (normal responders) (Nuessen et al. 1983). Lesions were produced in the colons of endotoxin-sensitive mice but not in endotoxin-resistant mice. Nibbelink and Wannemuehler (1991) subsequently obtained similar results and again concluded that the host's response to LOS influences their susceptibility to *B. hyodysenteriae.*

EPIDEMIOLOGY

Distribution of SD

SD is known to have a worldwide distribution, although the incidence of disease varies in different countries and regions, and alters with time. For example, in 1993 Mapother reported that 11% of U.S. herds showed serological evidence of infection with *B. hyodysenteriae,* with there being a 33% prevalence in the major pig producing state of Iowa. Now, even though there have been no recent surveys conducted, there is a general consensus that SD is much less common in the U.S. In part, this reduction in incidence may have resulted from rapid alterations in production systems, with the establishment of new high-health-status herds in nontraditional swine-rearing states, and with larger units, multisite production, and early-weaning systems now predominating.

In contrast to the U.S., SD still seems to be a relatively common and important problem in Europe. In the U.K., a postal survey of 105 pig units conducted in 1996 indicated that 50.5% had had scour problems in grower-finisher pigs in the last 3 years, and overall 10.5% had had a diagnosis of SD made (Pearce 1999). In a separate survey of 85 U.K. pig units where colitis was a problem, conducted in the period 1992–1996, *B. hyodysenteriae* was the primary etiological agent in 6 units (7%), and was isolated with other etiological agents of colitis in 3 other units (3.5%) (Thomson et al. 1988). Subsequently, in the period 1997–1999, Thomson et al. (2001) surveyed another 98 units with colitis problems, and found *B. hyodysenteriae* alone in 13% of these, and forming part of a mixed infection in another 16% of the units. In Denmark, among 72 units with diarrhea problems, 10 (14%) had *B. hyodysenteriae* infection, while the spirochete was not isolated from pigs on another 26 units where diarrhea was not a problem (Møller et al. 1998). In a subsequent study, examining samples from growing pigs in 79 randomly selected herds, only 2 herds (2.5%) were infected with *B. hyodysenteriae,* with a within-herd prevalence of 25–30% (Stege et al. 2000). In Sweden, a survey of diagnostic submissions over the period 1996–2003 indicated that SD remains a substantial ongoing clinical problem (Råsbäck et al. 2004). In parts of Europe, particularly where there are large numbers of pig units in close proximity to each other, the disease may be more widespread. In Poland, fecal samples from 8 of 23 (34.8%) herds with diarrhea were positive for *B.*

hyodysenteriae (Plawinska et al. 2004). In Spain, fecal samples from 86 of 225 (38.3%) herds with diarrhea contained *B. hyodysenteriae*, with a within–herd prevalence of 45.4% (Carvajal et al. 2003). Among 17 herds with diarrhea in Brazil, 6 (35.3%) were infected with *B. hyodysenteriae* (Barcellos et al. 2000a). In Australia, the disease occurs less commonly than it did 10 years ago, but it is still entrenched in certain large units.

There is little published information about the prevalence of SD in other parts of the world, although the disease is certainly present and is highly likely to be causing problems. For example, SD is reported to have been increasing in incidence in Thailand in recent years, possibly as a result of increased governmental regulations on antimicrobial use (Prapasarakul et al. 2004). Concerns have been expressed elsewhere that the incidence of clinical cases of SD will increase in association with restrictions on growth promoter use and the reduced availability and efficacy of other antimicrobials. It is likely that these agents currently may be masking disease in some infected piggeries.

Patterns of Disease in Infected Herds

SD is most commonly observed in grower and finisher pigs, with the disease especially becoming evident a few weeks after pigs are moved from the nursery. This coincides with removal of antimicrobial agents that are frequently administered to weaner pigs to control respiratory and enteric diseases. The disease also is seen in weaners, and may occur in adults, particularly in sows reared outdoors, and occasionally in suckling piglets.

On endemically infected piggeries, clinical signs of SD often recur in a cyclic manner. In large groups of affected pigs, symptoms in individual pigs and in the group as a whole may reappear at 3–4-week intervals. This reappearance often occurs after removal of therapeutic levels of drugs from the water or feed. Asymptomatic pigs also may develop diarrhea following management procedures, such as moving them to new pens, mixing with different animals, weighing, or a change in feed. Stresses such as overcrowding, and exposure to extreme changes in environmental temperatures also may precipitate disease. Where antibiotic medication is routine, any cause of loss of appetite, such as pneumonia, stops the intake of drug and the animal can then succumb to SD. Many pigs that survive the acute phase of the disease do recover from SD, and are capable of resisting subsequent challenge. However, chemotherapy during the acute phase may not allow the pig to initiate an immune response.

In outbreaks of SD, morbidity in weaner pigs may approach 90% and mortality may be 30%, depending on the effectiveness of treatment. The severity in chronically affected herds may be mild, and disease may not be clinically evident, particularly if the herd is being medicated. Under experimental conditions in which pigs are not treated, mortality may reach 50%. The occurrence

and severity of experimentally induced SD is related to a number of things, including the amount of stress on the pig, the quantity of infectious inoculum administered, the growth-phase of the culture (with active log-phase inoculum being most infectious), the diet, the group size, and the weight of the pig (Jacobson et al. 2004).

Sources of Infection

On an endemically infected piggery, transmission of infection to susceptible pigs occurs primarily by ingestion of fecal material that originates either from clinically affected pigs or from asymptomatic pigs that are colonized by the spirochete. This sort of transmission is especially likely to occur in single-site, farrow-to-finish herds with continuous flow and poor on-farm biosecurity. Experimentally, transmission has been accomplished by exposure of susceptible pigs to previously infected animals that have had no clinical signs for 70 days (Songer and Harris 1978). *B. hyodysenteriae* in feces may be transmitted by animal caretakers who did not change clothing or footwear between isolation units containing diseased and healthy pigs. Transmission between pens is also likely to occur in older housing systems where open channels draining excreta run between pens. The infectious nature of this material is emphasized by the fact that lagoon water containing effluent of a herd affected with SD produced the disease when administered to susceptible pigs (Glock et al. 1975).

B. hyodysenteriae is relatively resistant in the environment of a pig house, particularly in feces in moist conditions. For example, Chia and Taylor (1978) demonstrated that *B. hyodysenteriae* will survive in dysenteric feces diluted in water for 48 days at between 0°C and 10°C, although it survived for only 7 days at 25°C, and less than 24 hours at 37°C. In a more recent study, *B. hyodysenteriae* survived for 10 days in soil held at 10°C, but this increased to 78 days in soil in the presence of 10% pig feces, and was 112 days in pure pig feces (Boye et al. 2001). Under laboratory conditions, *B. hyodysenteriae* survives at minus 80°C for more than 10 years.

Other potential reservoirs of infection on a piggery include feral and other animals. For example, *B. hyodysenteriae* was isolated from the feces of a dog that frequented pens containing pigs affected with SD (Songer et al. 1978). The organism also has been isolated from field mice captured on farms on which there were pigs affected with the disease (Joens and Kinyon 1982; Fellström et al. 2004). Hampson et al. (1991) isolated *B. hyodysenteriae* from the cecum of a wild rat living on an Australian piggery where SD was present. Mice probably represent a greater risk for recycling of infection than rats, since experimentally inoculated mice shed *B. hyodysenteriae* in their feces for over 180 days (Joens 1980), and rats apparently shed it for only 2 days (Chia 1977). Under experimental conditions, pigs exposed to the feces of infected mice developed clinical symptoms of SD within 11 days after the first contact with mouse

feces (Joens 1980). *B. hyodysenteriae* has also been isolated from the feet and feces of seagulls frequenting outdoor pig herds in the U.K. (J. R. Thomson, unpublished data). This suggests that transmission of infection between neighboring units by birds is a risk, particularly in outdoor farming systems.

Most new outbreaks of SD are associated with the introduction of asymptomatic carrier pigs into a herd, particularly where these new animals are not quarantined and/or treated prophylactically. However, outbreaks of the disease also occur in herds with no history of introduction of new animals. In these cases infection may be introduced through contaminated feed or animal trucks, or by visitors or others who have had contact with pigs on infected farms. When investigating risk factors for SD, Robertson et al. (1992) found a high odds ratio for infection for both allowing visitors onto farms, and there being rodents present. On the other hand, provision of boots and protective clothing for visitors, and the presence of security fencing around piggeries were protective. Interestingly, the use of home-mixed feed and acquisition of replacement breeders from the same source each year also both were protective.

Molecular Epidemiology

In recent years there has been an increased interest in understanding the molecular epidemiology of *B. hyodysenteriae* infections, particularly in the context of the need to understand and control the dissemination of problematic strains with reduced susceptibility to antimicrobials. The earliest strain-typing method used was serotyping, based on the LOS antigens (Baum and Joens 1979). It soon became apparent that a large number of serologically distinct strains of *B. hyodysenteriae* existed, with, for example, 91 Australian isolates being divided into eight serogroups (Combs et al. 1992). Interest in serotyping was stimulated by the finding that immunity against *B. hyodysenteriae* infection in a porcine colonic-loop model was largely LOS-serotype specific (Joens et al. 1983). In turn, this meant that bacterin vaccines would have to contain strains of the appropriate serotypes for use in a particular area, so these serotypes had to be determined. Subsequently, the use of bacterin vaccines for control of SD has not had great commercial success, so interest in serotyping has waned. Studies using MLEE showed that strains with the same serotype were not necessarily closely related genetically, and closely related strains were not necessarily of the same serotype (Lee et al. 1993). Other DNA-based typing techniques that have been applied to study the molecular epidemiology of *B. hyodysenteriae* include DNA restriction endonuclease analysis (Combs et al. 1992; Harel et al. 1994), DNA restriction fragment polymorphism analysis (Fisher et al. 1997), random amplification of polymorphic DNA (Dugourd et al. 1996), and pulsed-field gel electrophoresis (PFGE) (Atyeo et al. 1999a). The latter technique now is most frequently applied, and, although DNA banding

patterns for *B. hyodysenteriae* are usually not as clear as those for *B. pilosicoli*, PFGE has proved very useful for epidemiological studies—such as tracing strains with reduced susceptibility to tiamulin (Karlsson et al. 2004). All techniques have shown the species to be made up of large numbers of genetically distinct strains. In contrast to the situation with *B. pilosicoli*, generally only one strain of *B. hyodysenteriae* is found on a given infected piggery (Combs et al. 1992). Where two strains are found, one may have emerged as a variant of the original strain (Atyeo et al. 1999a, b). In two separate studies, strain-typing techniques have been used to demonstrate the presence of the same strain of *B. hyodysenteriae* in pigs and rats (Hampson et al. 1991) and pigs and mice (Fellström et al. 2004) on infected piggeries.

FINANCIAL IMPACT

SD causes considerable financial loss due to mortality, decreased growth rate, poor feed conversion, and expenses for treatment. Less tangible costs arise from the necessity to implement preventative measures in herds that do not have the disease, and particularly from the disruption to the supply and movement of pigs when the disease becomes introduced into stock in large breeding company herds. In the latter situation, the company's losses potentially can be enormous. There have been no recent evaluations of these costs, but older figures illustrate how expensive this disease can be. For example, Cutler and Gardiner (1988) considered it to be the most costly endemic pig disease in Australia. Lysons (1983) calculated that in-feed medication for SD cost £1.50–£5.00 ($2.60–8.60) per pig. Wood and Lysons (1988) demonstrated that the feed-conversion efficiency ratio in an infected herd deteriorated by 0.58, a cost increase of £7.31 ($12.60) per pig sold, and the cost of medication was £1.38 ($2.40) per pig. Walter and Kinyon (1990) found that the cost of medicating an infected herd was $8.30 per pig marketed, and that medication costs were reduced to US$0.08 per pig after eradication. Polson et al. (1992) projected the financial impact of SD via four simulation scenarios: SD-free, endemic SD, eradication by medication and disinfection, and total depopulation/repopulation. Net present value, internal rate of return, and benefit/cost ratio were calculated for each simulation scenario over a 10-year period. The profit margin per 100 kg liveweight produced was as follows: SD-free, $7.44; endemic SD, $1.67; eradication, $4.93; and depopulation/repopulation, $0.07. Ten years ago, total national losses to the U.S. swine industry were estimated to be $115.2 million (Duhamel and Joens 1994).

PATHOGENESIS

The pathogenesis of SD is complex and not completely understood. An important feature of the infection is the fact that various species of anaerobic bacteria that nor-

mally form part of the microbiota of the swine colon and cecum act synergistically with *B. hyodysenteriae*, facilitating spirochete colonization and augmenting inflammation and lesion production (Whipp et al. 1979; Joens et al. 1981). The diet consumed by pigs has a strong influence on the density and composition of the colonic microbiota (Durmic et al. 1998; Leser et al. 2000). Consistent with this, and consistent with there being a role for some other members of the normal microbiota in full expression of SD, it has been reported that colonization of *B. hyodysenteriae* can be inhibited by feeding pigs highly digestible diets that result in reduced fermentative activity in the large intestine (Pluske et al. 1996, 1998; Siba et al. 1996). Colonization of the ceca of mice with *B. hyodysenteriae* also can be influenced by diet and by the composition of the microbiota (Suenaga and Yamazaki 1984; Nibblink and Wanneumuehler 1992). Nevertheless, emphasizing the complexity of this situation, similar changes in the colonic microenvironment and/or inhibition of spirochetal colonization in pigs have not always been obtained using experimental diets designed to inhibit *B. hyodysenteriae* colonization (Durmic et al. 2000; Lindecrona et al. 2003).

Pigs become affected with SD following ingestion of dysenteric feces containing *B. hyodysenteriae*. Under experimental conditions an inoculum of 10^5 colonyforming units (cfu) is usually sufficient to produce SD (Kinyon et al. 1977), although much higher dose rates (e.g., 10^{10} cfu) often are used for experimental challenge (e.g., Hampson et al. 1993). Optimal colonization is achieved using actively motile bacterial cells in mid-log phase and repeating the oral challenge daily over 2 or 3 days. Presumably the bacteria normally survive the acidic environment of the stomach protected in feces, and eventually they arrive at the large intestine.

As previously discussed under "Virulence Attributes," spirochetal proliferation and colonization of the mucosa in the large intestine require a number of specialized bacterial features. These include the ability of *B. hyodysenteriae* to survive in the anaerobic environment of the large intestine, to utilize available substrate, to penetrate and move through viscous mucus down a chemotactic gradient into the crypts, and to avoid potential oxygen toxicity at the surface of the colonic mucosa. In infected pigs, the spirochetes may be seen close to epithelial cells in the lumen and crypts of the cecum and colon (Wilcock and Olander 1979a, b). At these sites they stimulate an outpouring of mucus into the lumen. Clinical signs and lesions of SD start to develop as numbers of spirochetes reach $10^6/cm^2$ of mucosa (Hughes et al. 1977; Whipp et al. 1979). Spirochetes first appear in the feces 1–4 days before diarrhea commences (Kinyon et al. 1977). At this time, there is a shift in the composition of the rest of the colonic microflora, from predominantly gram-positive bacteria in healthy animals, to mainly gram-negative organisms in pigs with dysentery (Pohlenz et al. 1984).

It is not known whether spirochetal attachment to epithelial cells is an important feature of the disease. Both Knoop et al. (1979) and Bowden et al. (1989) demonstrated in vitro attachment of *B. hyodysenteriae* to animal cell cultures. Bowden et al. (1989) concluded that the *B. hyodysenteriae* binding adhesins for cultured Henlé intestinal epithelial (HIE 407) cells contain sialic acid residues. In these studies, cellular damage and invasion of the cultured cells did not occur. Although *B. hyodysenteriae* can be seen within epithelial cells, particularly goblet cells, and in the lamina propria of tissues with typical lesions, this invasion does not seem to be essential for lesion production (Glock et al. 1974).

Although the mechanism of tissue destruction in SD has not been fully elucidated, the hemolysin(s) and LOS of *B. hyodysenteriae* may play a role (see section on virulence). These toxic substances presumably act locally to disrupt the adjacent epithelial barrier in the colon, resulting in epithelial sloughing and subsequent submucosal invasion by spirochetes as well as other secondary bacteria and the protozoan *Balantidium coli*. *B. hyodysenteriae* does not invade beyond the lamina propria of the large intestine, and the lack of *B. hyodysenteriae* and significant lesions in other organs implies that the entire pathogenesis of the disease can be directly attributed to the enteric lesions (Kinyon et al. 1980). The primary systemic effects of typical SD are the result of fluid and electrolyte imbalance induced by enteritis. The pathogenesis of peracute deaths is not known, but may be attributable to endotoxin release.

A series of studies have been conducted on the pathophysiology of SD (Argenzio et al. 1980; Argenzio 1981; Schmall et al. 1983). These have shown that, in contrast to what might be expected from histologic interpretations, the diarrhea observed in pigs with SD is not the result of increased mucosal permeability and leakage of protein and extracellular fluid from blood to lumen because of increased tissue hydrostatic pressures. Instead, the fluid loss appears to be the result of colonic malabsorption as a consequence of the failure of the epithelial transport mechanisms to actively transport sodium and chloride ions from lumen to blood. Furthermore, cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) levels in colonic mucosa of infected pigs were normal, but their response to a stimulus (theophylline) was markedly attenuated. Thus, these studies strongly suggest that an enterotoxin and/or prostaglandins released from the inflamed mucosa are not involved in the production of diarrhea. Therefore, the pathogenesis of dysentery is unlike the diarrhea induced by enterotoxigenic *E. coli* or *Salmonella* spp. Consistent with this, Whipp et al. (1978) reported that sterile filtrates of broth cultures of *B. hyodysenteriae* failed to cause fluid accumulation in ligated colonic loops of pigs or in sucking mice. Furthermore, sterile filtrates did not produce changes in Y-1 adrenal cells. Inactivated whole cells and sonically disrupted suspensions of *B. hy-*

odysenteriae also do not cause lesions or fluid accumulation in ligated colonic segments of pigs.

Studies of small-intestinal function in infected pigs indicated that the glucose-stimulated fluid-absorptive mechanism was intact and that no additional small-intestinal secretory component was present. Therefore, the fluid losses are exclusively the result of failure of the colon to reabsorb the animals' own endogenous secretions. Because as much as 30–50% of the extracellular fluid volume of these animals, in the form of endogenous secretions, is presented daily to the colon for absorption, colonic absorptive failure alone is sufficient to explain the progressive dehydration and death associated with the disease. These studies also imply that oral glucose-electrolyte solutions would be useful as a therapeutic measure in restoring these extracellular fluid losses.

CLINICAL SIGNS

The incubation period of SD is variable. Specific reports range from 2 days to 3 months, but the disease usually occurs within 10–14 days in naturally exposed pigs. Diarrhea is the most consistent sign, but the severity may be quite variable. The disease usually spreads gradually through an infected herd, with new animals being affected daily. The course varies not only between individual animals within a herd but also between herds.

Occasional animals are peracutely affected and die after a period of a few hours with little or no evidence of diarrhea. The first evidence of the disease in most animals is soft, yellow to gray feces. Partial anorexia and increased rectal temperature of 104–105°F (40–40.5°C) may be evident in some animals. A few hours to a few days following infection, large amounts of mucus and often flecks of blood are found in the feces. As the diarrhea progresses, watery stools containing blood, mucus, and shreds of white mucofibrinous exudate are seen with concurrent staining of the perineum. The majority of animals recover over a period of several weeks, but their growth rate remains depressed. Where prolonged diarrhea occurs it leads to dehydration with increased thirst, and affected animals become weak, incoordinated, and emaciated. Where death occurs it is associated with dehydration, acidosis, and hyperkalemia. The cause of occasional peracute deaths is not known.

Suckling pigs are not commonly affected, except in older piglets in gilt litters where the gilt has not been exposed to *B. hyodysenteriae*, and in piglets in newly infected herds. Infected piglets may have catarrhal enteritis without hemorrhage.

LESIONS

Gross Lesions

Pigs that have died from SD are often emaciated and may have a rough hair coat with fecal staining. Dehydration is usually evident. A consistent characteristic is the presence of lesions in the large intestine but not in the small intestine, often with a sharp line of demarcation at the ileocecal junction.

Typical changes in the acute stages of SD include hyperemia and edema of the walls and mesentery of the large intestine. Mesenteric lymph nodes may be swollen and small amounts of clear ascitic fluid may be present. White, slightly raised foci on the serosa, particularly in subacute or chronic infections are caused by aggregates of mononuclear cells, mainly lymphocytes in the submucosa that form part of the inflammatory reaction. There is obvious swelling of the mucosa, with loss of the typical rugose appearance. The mucosa is usually covered by mucus and fibrin with flecks of blood, and the colonic contents are soft to watery and contain exudate.

As the condition progresses, the amount of edema within the wall of the large intestine may decrease. Mucosal lesions may become more severe with increased fibrin exudation and may form thick, mucofibrinous pseudomembranes containing blood. As lesions become more chronic, the mucosal surface is usually covered by a thin, dense, fibrinous exudate, often giving the appearance of marked necrosis, which is quite superficial. Lesions can be found in clinically healthy pigs and appear as discrete areas of reddening of the mucosa, usually covered with some mucus, but with colon contents of normal consistency.

The distribution of lesions within the large intestine varies. In some instances the entire organ may be involved, while at other times only certain segments may be affected. Lesions tend to become more diffuse in the later stages of the disease.

Other lesions may include hepatic congestion and hyperemia or congestion of the gastric fundus. However, these lesions are also associated with other diseases and are not specific for SD. The stomach may be full.

Microscopic Lesions

The only significant microscopic lesions are found in the cecum, colon, and rectum. Typical acute lesions include obvious thickening of the mucosa and submucosa due to vascular congestion and extravasation of fluids and leukocytes. There is also hyperplasia of goblet cells, and the epithelial cells at the base of the crypts may be elongated and hyperchromic in appearance. The spirochetes may enter goblet cells in the colonic crypts, and penetrate intercellular gaps in the epithelium (Sueyoshi and Adachi 1990). There is an associated loss of cohesion between colonic enterocytes, with subsequent necrosis and shedding of the epithelium. The organisms may attach to the lumenal surface and enter these disrupted epithelial cells. Increased numbers of various types of leukocytes may be present in the lamina propria, with excessive accumulation of neutrophils in and around capillaries near the lumen. Some spirochetes also may be observed in the lamina propria, particularly around blood vessels. Bleeding occurs from small vessels
48.4. B. hyodysenteriae *in colonic crypt and epithelium (Warthin-Starry; ×750).*

located under areas of eroded epithelium, which also may be invaded by other members of the colonic microbiota. Blood becomes trapped in the overlying mucus, producing the typical blood-flecked appearance of the colonic contents in the acute stages of the disease.

Later changes include accumulation of large amounts of fibrin, mucus, and cellular debris in mucosal crypts and on the lumenal surface of the large intestine. Superficial necrosis of the mucosa may be extensive, but deep ulceration is not typical. Increased numbers of neutrophils may be seen throughout the lamina propria. Large spirochetes with the appearance of *B. hyodysenteriae* are found in the lumen and within crypts at all stages of the disease but are most numerous in the acute phase (Figure 48.4).

Chronic changes are not particularly specific, with less hyperemia and edema being present. There is often more advanced superficial necrosis of the mucosa, which usually has a thick, fibrinous pseudomembrane.

Ultrastructural changes during the early stages of SD

have been characterized. Large numbers of spirochetes with the appearance of *B. hyodysenteriae* are found at the lumenal surface and within crypts (Figure 48.4). Adjacent epithelial cells have lesions, including destruction of microvilli, swelling of the mitochondria and endoplasmic reticulum, loss of other organelles, and decreased density. As damage becomes more pronounced, the epithelial cells often shrink and become dark. *B. hyodysenteriae* invade epithelial cells, goblet cells, and the lamina propria, and may be found in large clusters within some epithelial cells (Figure 48.5), suggesting that intracellular multiplication may occur (Taylor and Blakemore 1971; Glock et al. 1974).

Hematology

Hematologic changes in SD include marked alterations in many measurable factors. Total leukocyte counts may increase, but not consistently. A marked left shift usually occurs, with high numbers of immature neutrophils in circulation. Other changes include early transient increases in erythrocyte sedimentation rates and fibrinogen levels. Packed-cell volumes vary but do not indicate significant blood loss, and total plasma protein may be elevated as a result of dehydration. Serum glutamic-oxaloacetic transaminase levels remain normal.

The most significant changes occur in blood electrolytes. Serum sodium, chloride, and bicarbonate levels decrease, and a marked metabolic acidosis develops, which may be fatal. Terminal hyperkalemia may be noted, and together with acidemia may be a significant cause of death (Glock 1971).

IMMUNITY

Pigs that have recovered from SD may be protected against subsequent experimental challenge with *B. hyodysenteriae* for up to 17 weeks (Olson 1974; Joens et al. 1979). Nevertheless, a proportion of recovered pigs (7–43%) remain susceptible (Jenkins 1978; Joens et al.
48.5. *Electron photomicrograph of* B. hyodysenteriae *invading a colonic epithelial cell (Glock and Harris 1972).*

1979; Rees et al. 1989a), and about 10% may become fully protected only after two previous bouts of disease (Rees et al. 1989a).

As previously stated, immunity to *B. hyodysenteriae* appears to be quite strongly serotype-specific, directed against LOS antigens present in the cell envelope (Joens et al. 1983). Following experimental infection or vaccination with a bacterin vaccine, there is some limited protection against serotypes of *B. hyodysenteriae* other than those to which the animals have been exposed (Kennedy et al. 1992; Nuessen and Joens 1982; Parizek et al. 1985). This suggests that besides being targeted at LOS antigens, protective immune responses also are directed against other spirochetal components that are common to isolates of different serotypes.

Changes occur in both antibody titers and in cell-mediated immunity in pigs with SD, but their importance is unclear. Titers of serum IgG against *B. hyodysenteriae* correlate with the duration of clinical signs, and IgA titers in colonic washes are indicative of recent exposure (Rees et al. 1989b). Neither of these titers is strongly correlated with protection from developing SD (Joens et al. 1982; Fernie et al. 1983; Rees et al. 1989b). Other studies suggest that complement components, in conjunction with immune serum, may be involved in the clearance of *B. hyodysenteriae* from the colon (Joens et al. 1985). Cell-mediated immunity also may be involved in protection, since there is evidence of inhibition of peripheral blood leukocyte migration, a delayed hypersensitivity response, and a T cell proliferative response to *B. hyodysenteriae* antigens in pigs convalescent from SD (Jenkins et al. 1982; Kennedy et al. 1992). In contrast, in mouse models of the disease, no significant changes in T cell subsets in the lamina propria were observed (Nibbelink and Wannemuehler 1990). It seems unlikely that there are immune-mediated components to the lesions of SD, because in mouse models the changes observed in numbers of mast cells in the lamina propria are not correlated with lesion development (Nibbelink and Wannemuehler 1990). Recent studies have identified CD8$\alpha\alpha$ cell proliferation in pigs recovered from SD (Waters et al. 2000a). Most recently, Jonasson et al. (2004) investigated levels of circulating leukocytes and lymphocyte subpopulations in pigs before and after experimentally induced SD. By comparing results from pigs that did or did not succumb to disease, the authors deduced that $\gamma\delta$ T cells and CD8$^+$ cells may be associated with susceptibility to infection, and monocytes and CD4$^+$ CD8$^+$ T cells appear to be the major responding lymphocytes. Further work is required to understand the mechanisms involved in host immunity to *B. hyodysenteriae*.

DIAGNOSIS

Clinical Features
The diagnosis of SD depends primarily on differentiating the condition from other potential causes of diarrhea. Factors that should be considered include history, clinical signs, gross lesions, microscopic lesions, as well as isolation or detection of *B. hyodysenteriae*.

SD may occur as a persistent problem within a herd, with phases of increased or decreased severity. Diagnostic problems are most likely to occur in a herd in which the disease has not been previously diagnosed. History may be helpful because it is not unusual to have an outbreak following the introduction of new (carrier) animals into the herd. Other situations that disrupt the normal environment may also precipitate outbreaks in herds that have been exposed to *B. hyodysenteriae* but in which the overt disease has not been detected.

Clinical signs such as depression, dehydration, and diarrhea with mucus and/or blood in the feces are quite suggestive but offer only presumptive evidence. Temperature increases are too moderate and inconsistent to be of any diagnostic benefit. Hematologic changes as previously described are characteristic, but not sufficiently unique to be of any great differential value.

Necropsy and Histopathological Findings
In acutely infected animals the essential finding at necropsy is diffuse enteritis limited to the large intestine. Mucofibrinous exudate and free blood in the lumen are characteristic of SD, but not pathognomonic. Typical microscopic lesions of mucosal edema and microfibrinous enteritis with superficial erosion, particularly if associated with the presence of numerous spirochetal bacteria, are very suggestive of SD. The organisms can best be demonstrated by staining with Warthin-Starry, Victoria blue 4-R, or Goodpasture stains.

Laboratory Diagnosis
Sample Selection. Diagnostic samples are best taken from several acutely affected animals that have not been medicated. Colonic contents from recently necropsied animals are optimal, but fecal samples obtained from several animals with mucohemorrhagic diarrhea are also satisfactory. Where disease is mild or subclinical, it may be necessary to examine very large numbers of fecal samples before a positive specimen is identified. Fellström et al. (2001) have recommended pooling batches of five rectal swabs to increase the sensitivity of detection in such herds. Samples should be transported to the laboratory with care taken not to let them dry out. Serum samples from convalescent or slaughter-age animals can also be taken where there is access to a laboratory that can evaluate them for specific antibody titers.

Visual Examination of Samples. It is usual to conduct direct examination of smears prepared on slides from colonic mucosa or feces of pigs suspected of being affected with SD looking for the presence of characteristic spirochetal bacteria. Clearly, this cannot distinguish between *B. hyodysenteriae,* the pathogenic *B. pilosicoli,* or other commensal spirochetes. Workers in the United

Kingdom have traditionally utilized an absorbed antiserum in an indirect fluorescent antibody test to detect *B. hyodysenteriae* in such smears (Hunter and Saunders 1977). Unfortunately, even with extensive cross-absorption, it is technically difficult to prepare standard high titer polyclonal sera that are specific for *B. hyodysenteriae,* so false positive reactions can occur using this method. The use of specific monoclonal antibodies, as described by Lee and Hampson (1996), should improve this situation. Unfortunately, attempts to use this monoclonal antibody bound to magnetic beads to extract *B. hyodysenteriae* from feces has not increased the sensitivity of detection over that obtained with other currently used diagnostic techniques (Corona-Barrera et al. 2004).

Culture and Identification. A definitive diagnosis of SD requires specific demonstration of *B. hyodysenteriae* in the colonic mucosa or feces. This has traditionally been done by anaerobic culture, followed by examination of phenotypic properties of the organism. Optimal culture media and conditions are as described earlier under "Characteristics of *B. hyodysenteriae,*" but with the addition of 400 µg/mL spectinomycin and 25 µg/mL each of colistin and vancomycin to the agar to make the medium selective (Jenkinson and Wingar 1981). Alternatively, a more selective medium with lower concentrations of the previous three antimicrobials, but with 25 µg/mL spiramycin and 12.5 µg/mL rifampin also added, is frequently used (Kunkle and Kinyon 1988). Recently it has been suggested that isolation can be improved by briefly preincubating the sample in a selective broth medium prior to plating out (Calderado et al. 2001).

Pigs acutely affected with SD possess large numbers (10^8–10^9/g) of *B. hyodysenteriae* in their colonic mucosa and feces, and these are readily isolated. By contrast, pigs that are asymptomatic may only shed the organism periodically at detectable levels in their feces. Furthermore, medications commonly used to treat or prevent SD may reduce the number of organisms below culturally detectable levels. Therefore, caution must be used in interpreting the results of negative culture results, particularly from fecal samples.

On primary isolation, *B. hyodysenteriae* produces zones of strong beta hemolysis in which colonies are hard to distinguish, but a film of growth in the hemolytic zone is grossly visible. As a routine, plates without evidence of beta hemolysis should be further incubated anaerobically and observed at 48-hour intervals for up to 10 days. False negative culture results can occur for a number of reasons, including inappropriate sample handling or storage between collection and culture—for example, high temperature or freezing, drying out, or delay during transport.

Phenotypic Tests for *B. hyodysenteriae.* After a strongly hemolytic spirochete is isolated, it is usual to examine selected biochemical properties, as described

earlier under "Characteristics of *B. hyodysenteriae.*" It is important to obtain a pure culture of the isolate before phenotypic characterization, which can prove difficult unless microbiology technicians are highly experienced in this field. Mixed spirochete species can be present within the confluent culture growth, and exacting procedures are required to clone individual isolates to purity. Antigen detection–based methods have been described that also may help to confirm an isolate's identity, although these largely have been superceded by PCR testing. Methods include using a fluorescent antibody test with absorbed antiserum (as described for fecal smears), a growth-inhibition test (Lemcke and Burrows 1979), and a rapid slide agglutination test (Burrows and Lemcke 1981).

Nucleic Acid-Based Techniques. In an attempt to increase the sensitivity of detection from clinical material, and to improve the identification process of spirochetal isolates, nucleic acid probes and polymerase chain reaction (PCR) amplification of specific sequences have been developed for *B. hyodysenteriae* and other intestinal spirochetes. Probes have been used to detect 10^5 cells of *B. hyodysenteriae* per gram of pig feces (Jensen et al. 1990), but the technique is quite technically difficult and time-consuming. The use of probes in fluorescent in situ hybridization (FISH) on fixed colonic tissue is, however, a potentially useful tool for examining aspects of the pathogenesis of SD (Boye et al. 1998). The PCR is a simpler technique and generally can detect many fewer organisms. The most usual targets for DNA amplification are the 23S rRNA gene (Leser et al. 1997) and the NADH oxidase gene (Atyeo et al. 1999b). The PCR is usually conducted on growth harvested from the primary isolation plate. Even under these circumstances, where results are obtained in 3–5 days, PCR offers a more rapid, sensitive, and specific approach to diagnosis than does the more routine method of isolation followed by biochemical identification of the spirochetes (Atyeo et al. 1998). Use of PCR on growth from the primary isolation plates also is compatible with obtaining spirochetal isolates for subsequent antimicrobial sensitivity testing and/or strain typing, where required.

Another PCR-based methodology that can be used to detect and identify intestinal spirochetes to species level involves amplification of portions of specific genes, followed by restriction enzyme digestion of the products to give species-specific banding patterns after gel electrophoresis. Genes that have been used in this way include the 16S rRNA gene (Stanton et al. 1997a), the 23S rRNA gene (Barcellos et al. 2000b; Thomson et al. 2001), and the NADH-oxidase gene (Rohde et al. 2002). Unfortunately, in the U.K. "atypical" isolates of *B. hyodysenteriae* have been obtained that fail to amplify in this 23S rDNA PCR (Thomson et al. 2001).

Recently, the basic PCR test has been streamlined, such that it can be conducted as a duplex reaction iden-

tifying both *B. hyodysenteriae* and *B. pilosicoli* in DNA extracted directly from fecal samples (La et al. 2003). Potentially this test gives the opportunity to obtain same-day results, and it is also specific and highly sensitive for detection when applied to spiked fecal samples. It is anticipated that these tests will be improved further by the impending introduction of real-time PCR for *Brachyspira* species.

Molecular-based methods can be used to detect *B. hyodysenteriae* DNA in samples where spirochetes are dead on arrival at the laboratory (spirochetes are present in the sample but show lack of motility). In this case direct extraction of DNA from feces for PCR testing can be done in addition to attempted bacterial culture.

Serologic Assays. Several serologic tests have been reported that detect antibodies to *B. hyodysenteriae* in serum of experimentally affected pigs (reviewed by La and Hampson 2001). Generally these tests have not been based on species-specific antigens and consequently have had low specificity and/or sensitivity. Tests have included microtiter agglutination (Joens et al. 1978), indirect fluorescent antibody, passive hemolysis (Jenkins et al. 1976), and enzyme-linked immunosorbent assays (ELISAs) using various plate-coating antigens (Burrows et al. 1984). The most useful ELISA has used LOS as plate-coating antigen (Joens et al. 1982; Egan et al. 1983). This type of ELISA has proved helpful for use in identifying infected herds, but not for detection of individual pigs with SD. LOS-based ELISA systems also have the disadvantage that they require a knowledge of the serotypes of organisms present in the herds to be tested (Mhoma et al. 1992) so that the appropriate LOS can be used as plate-coating antigen, and consequently they are now rarely used. Recently, an ELISA using recombinant BmpB (the 29.7 Kda outer membrane lipoprotein of *B. hyodysenteriae*) as the plate-coating antigen has been described (La and Hampson 2001). Further work is required to evaluate this ELISA under field conditions before it can be made available for more general use.

Differential Diagnosis

A number of enteric diseases may be confused with SD. Also it is important to realize that SD often occurs concurrently with infections with other enteric pathogens (Møller et al. 1998; Thomson et al. 1998). Proliferative enteropathy caused by *Lawsonia intracellularis* may clinically resemble the signs of SD. However, unlike proliferative enteropathy, SD does not affect the small intestine. A definitive diagnosis of proliferative enteropathy depends on a positive PCR test from feces, herd serology, and/or demonstration of typical pathology including the presence of *L. intracellularis* in crypt enterocytes.

Salmonellosis, in particular infection with *Salmonella enterica* serovar Choleraesuis, easily can be confused with SD because clinical signs and lesions may be quite similar. Hemorrhage or necrosis in parenchymatous organs and lymph nodes may be expected with salmonellosis but not with SD. Mucosal lesions may be found in the small intestine with salmonellosis but not with uncomplicated SD. Deep ulcerative enteric lesions are also much more typical of salmonellosis. The definitive diagnosis depends on lack of *B. hyodysenteriae* in the mucosa of the large intestine and the isolation of *Salmonella* serovars from the intestine or other organs such as lymph nodes or spleen. The mere isolation of *Salmonella* does not constitute a positive diagnosis, since both normal animals and animals with SD may harbor these bacteria.

Trichuriasis may be differentiated on the basis of the presence of numerous *Trichuris suis* in the large intestine and the lack of *B. hyodysenteriae*. Concurrent infections can occur, and possible potentiation of SD by *T. suis* has been postulated.

Gastric ulcers and other hemorrhagic conditions may cause the presence of blood in the feces and confusion with SD. These conditions are easily differentiated at necropsy since they generally involve the anterior digestive tract. Feces also tend to be "tarry" due to digestion of the blood.

"Colitis" is a diet-related disease syndrome of growing pigs that can resemble SD both in clinical signs and in postmortem appearance (Lysons et al. 1988). There has been some confusion over this condition, and some reported cases actually might have been colonic spirochetosis/intestinal spirochetosis, caused by infection with *Brachyspira pilosicoli* (see Chapter 46). Typically, weaner or grower/finisher pigs aged 7 weeks or more are affected. They may develop a watery scour, or sometimes just soft feces, and lose body condition. Lesions are confined to the colon. In the early stages of the disease, the large intestine is filled with liquid contents and there is a mild reddening of the colon. Pigs in which the disease persists can become thin, excrete mucus in the feces, and have a mucofibrinous exudate on the mucosal surface of the colon. To eliminate SD from the diagnosis, it is necessary to autopsy pigs in the early stages of the disease and to carry out extensive screening for the presence of *B. hyodysenteriae*. Clearly, colonic spirochetosis represents the most difficult differential diagnosis, since it so closely resembles mild cases of SD. Although it responds to similar treatment, an accurate diagnosis is important because, in general, it has much less economic impact in individual herds than SD. Furthermore, it appears that aspects of the epidemiology of colonic spirochetosis differ from those described for SD (see Chapter 46).

TREATMENT AND CONTROL

Principles of Antimicrobial Treatment

Prior to implementing medication, the diagnosis of SD should be confirmed. At the same time it is important to

have a clear idea of the overall goal of the treatment and to have a long-term strategy for dealing with the disease on the farm. Eradication should be the preferred option, and this is discussed in a later section.

At present there are only a few effective drugs available for treatment of SD, and in recent years it has become increasingly evident that the development of resistance of *B. hyodysenteriae* strains to antimicrobials such as pleuromutilins presents a potential long-term threat to the pig industry. Therefore, the use of such drugs must be restricted to specific therapy and, specifically, they should be reserved for attempts to eradicate the disease or for use in cases where other drugs or control measures are not effective.

The route of administration of antimicrobials is also an important consideration. Severely affected animals may require parental (intramuscular) treatment for, e.g., 3 days; however, in most cases medication via the drinking water for 5–7 days is the preferable way of treating acute SD. If medication via the water is not possible, in-feed medication for 7–10 days may be considered, although this has the disadvantage that affected animals may have a low feed intake. Medication of acute SD should always be accomplished by free access to drinking water, with or without supplementation with electrolytes. Treatment of acute SD may be followed by in-feed medication at subtherapeutic levels for 2–4 weeks to prevent reinfection.

Medication should be used in conjunction with management practices that reduce the risk of reinfection of medicated pigs and spread of infection to other groups or batches. All-in/all-out management of pig buildings with thorough cleaning and disinfection between batches is an important part of the control process. Ideally, affected batches should be moved to clean buildings at the end of the course of SD medication, thereby breaking the cycle of infection. Careful disposal of infected bedding materials, the use of boot scrubbers and disinfectant footbaths, cleaning and disinfection of equipment used in infected areas and changing of protective clothing are all vital parts of successful control procedures. Furthermore, because outbreaks of SD are often associated with conditions that produce stress, such as pig handling, crowding, transportation, severe weather conditions or dietary changes, it is important to minimize these stresses where possible. Attention also should be paid to the form and composition of the diet, to determine whether this might be predisposing to disease expression (see section on pathogenesis).

A list of the four drugs most commonly used for the treatment of SD—tiamulin, valnemulin, tylosin, and lincomycin—together with their dose rates and potential side effects, is presented in Table 48.1. Based on consideration of pharmacokinetic properties and in vitro susceptibility data, it appears that the pleuromutilins

Table 48.1. Dosage level, duration of administration and side effects for the four drugs most commonly used for the treatment of SD

Drug	Dosage and duration	Side effects
Tiamulin	10mg/kg bw; im for 1–3 days. 8mg/kg bw; po for 5–7days in drinking water. Or: in-feed medication with 100 ppm for 7–10 days, followed by 30–40 ppm for 2–4 weeks.	Rare: erythema. Local reactions at the injection site. Lethal side effects may occur in combination with ionophors.
Valnemulin	In-feed medication 3–4 mg/kg bw for 1–4 weeks.	Adverse effects, including lethargy, depression, erythema, edema, pyrexia, ataxia, anorexia, and deaths have been reported. Lethal side effects may occur in combination with ionophors.
Tylosin	10mg/kg bw; im twice daily for 3–5 days. Or: 5–10 mg/kg bw; po in drinking water for 5–7 days. Followed by: in-feed medication with 100 grams per ton feed for 3 weeks, followed by in-feed medication 40 grams per ton feed.	Diarrhea, pruritus, erythema rectal edema, and prolapse have been reported.
Lincomycin	8mg/kg bw; po in drinking water. Not to be used for more than 10 days and not for use in swine weighing more than 250 pounds (115 kg). In-feed medication 100 grams per ton feed for 3 weeks or until signs of disease disappear, followed by 40 grams per ton. Not for use in swine weighing more than 250 pounds (115 kg).	Rare

Note: The information in this table is an abbreviated summary of product labeling. For information regarding withdrawal times (which vary extensively between countries), review national regulations and product labels. bw = body weight, im = intramuscular, po = per os (oral).

(tiamulin, valnemulin) are the most suitable antimicrobials available for the treatment of SD (Kitai et al. 1979; Messier et al. 1990; Rønne and Szancer 1990; Walter and Kinyon 1990; Weber and Earley 1991; Binek et al. 1994; Molnar 1996; Cizek et al. 1998; Karlsson et al. 2003). Unfortunately, in several countries such as the U.K. (Gresham et al. 1998), the Czech Republic (Lobova et al. 2004) and Sweden (SVARM 2004), a decreased susceptibility to tiamulin among *B. hyodysenteriae* isolates has been reported. Strains with high MICs to pleuromutilins also have been reported from Germany (Rohde et al. 2004). The mechanism(s) of tiamulin resistance by *B. hyodysenteriae* are not known; however, one study indicates that resistance emerges slowly in vitro (Karlsson et al. 2001). Another recent study showed that tiamulin usage was sufficient to select several clones of *B. hyodysenteriae* with decreased tiamulin susceptibility on different farms in Germany (Karlsson et al. 2004). Therefore, to reduce the risk of emerging resistance to pleuromutilins, and if herd records or MIC determinations indicate that other drugs are effective for treatment of SD in a specific herd, such drugs should be preferred over pleuromutilins. The other two commonly used drugs, tylosin and lincomycin, have the disadvantage that high levels of resistance to them have been reported in *Brachyspira* spp., for example by Smith et al. (1991), Binek et al. (1994), Rønne and Szancer (1994), Hommez et al. (1998) and Karlsson et al. (2002, 2003). Macrolide and lincosamide resistance is caused by a single point mutation in the 23S rRNA gene, and tylosin resistance develops within 2 weeks in vitro (Karlsson et al. 1999).

Many other antibacterials, such as bacitracin, spiramycin, gentamicin, dimetridazole, ronidazole, virginiamycin, olaquindox, and carbadox have been used more or less successfully over the years in the treatment and prevention of SD. Unfortunately, the development of resistance by *B. hyodysenteriae* to several of those substances has been reported, and the availability of others is now much reduced internationally. For example, carbadox and olaquindox have been withdrawn from use in the European Union (EU) and in several other countries, while dimetridazole and ronidazole are no longer available either in the EU or the U.S.A. Olaquindox and carbadox usually have low MICs against *B. hyodysenteriae*. Nevertheless, their pharmacokinetic properties result in low concentrations of the drugs in relevant parts of the gastrointestinal tract, and this makes them unsuitable for the treatment of SD—although they work well as an effective prophylaxis (de Graaf et al. 1988).

Hopefully, new drugs, or old substances that have been modified to improve their efficiency, will become available to replace these antimicrobials. For example, acetylisovaleryltylosin (aivlosin), a new macrolide antibiotic, recently was shown to prevent clinical SD, as well as to treat the disease when it was used for in-feed medication (Tasker et al. 2004).

Serious losses also may be prevented, even in exposed herds, by the use of growth promoters with antibacterial potential such as salinomycin and monensin (ionophores). It should be noted, though, that toxicity occurs when ionophores are used with pleuromutilins or with other drugs that potentially interfere with hepatic metabolism. For example, severe side effects have been reported when salinomycin was mixed in the feed with pleuromutilins (Kavanagh 1992). Growth promoters with potential antibacterial effects have the disadvantage that they may mask disease in apparently SD-free herds. They should not be used as a substitute for good management.

Control of Vectors
Studies using strain detection techniques have strongly indicated that mice and rats can act as a reservoir for *B. hyodysenteriae* in pig herds (Hampson et al. 1991; Fellström et al. 2004). Consequently, lack of efficient rodent control may be an important explanation for failures in SD eradication programs. The role of birds as possible vectors for *B. hyodysenteriae* is unclear, but should not be ignored. *B. hyodysenteriae* or isolates similar to *B. hyodysenteriae* are commonly found in the feces of Swedish mallards (Jansson et al. 2004). Whether these avian isolates are capable of causing disease in pigs is not known, although it was not possible to induce SD in pigs challenged with rhea isolates of *B. hyodysenteriae* (Stanton et al. 1997b). Mechanical transmission of infectious material by birds and other possible wildlife vectors is an important risk factor in outdoor pig units where effective control is impossible.

Vaccination for SD
To date vaccination has not played a large role in the control of SD, mainly because of the limited efficacy and availability of such vaccines. Even if available, it is unlikely that they would be used prophylactically in herds free of SD unless there was a perception that the herds were at a high risk of introducing the disease. Generally, if appropriate vaccines were available, they could be used to help manage SD. For example, in herds that were intended to be eradicated, vaccines could be used prior to this to help reduce shedding and environmental contamination. In other infected herds, vaccines could be used to replace or supplement current antimicrobial usage. This would reduce overall herd antimicrobial consumption, and remove selective pressures that might lead to the development of resistance in spirochete strains.

Bacterin vaccines are available commercially in some countries, and may provide a degree of protection against SD (Fernie et al. 1983; Parizek et al. 1985; Hampson et al. 1993; Diego et al. 1995; Waters et al. 2000b). Unfortunately, they tend to be LOS serogroup-specific, which then requires the use of autogenous or multivalent bacterins. Furthermore, they are relatively difficult and costly to produce on a large scale because of the fastidious growth requirements of the spirochete. One

publication reported that immunization with a *B. hyodysenteriae* bacterin actually exacerbated dysentery (Olson et al. 1994). A commercial proteinase-digested bacterin may offer a better level of protection than conventional bacterins, although the cellular immune responses generated by it in pigs were not different from those in bacterin-vaccinated pigs (Waters et al. 2000b).

Several attempts have been made to develop either attenuated or genetically modified live avirulent strains of *B. hyodysenteriae* as vaccines for SD. Naturally avirulent or low-virulence strains have been used experimentally (Hudson et al. 1976), sometimes in combination with bacterins (Lysons et al. 1986), while modified strains have been produced by inducing mutations in genes affecting motility (Rosey et al. 1996; Kennedy et al. 1997), hemolysis (Hyatt et al. 1994), and protection from oxygen toxicity (Stanton et al. 1999). These strains may have a reduced ability to colonize the large intestine, and, probably for this reason, have produced limited protective immunity. To date, none have become commercially available as live vaccines.

The use of recombinant subunit vaccines for the control of SD is an attractive alternative, since the products would be well defined (essential for registration purposes) and relatively easy to produce on a large scale. A recombinant 38-kDa flagellar protein from *B. hyodysenteriae* used as a trial vaccine failed to prevent *B. hyodysenteriae* colonization in pigs (Gabe et al. 1995), but recently the immunogenic 29.7 kDa outer-membrane lipoprotein of *B. hyodysenteriae*, designated BmpB, provided a 50% reduction in incidence of disease in pigs that were vaccinated and then experimentally infected (La et al. 2004). Although protection was not complete, it appears that recombinant vaccines have potential for use in this context. Apart from identifying appropriate recombinant vaccine candidates, a major issue is how to deliver them to pigs in a way to optimize protective immunity in the large intestine. Many different strategies are being considered, but as yet there is no consensus on how best to do this. The large intestine is a difficult site to protect, and ideally a vaccine would prevent colonization rather than just limit the extent of lesion formation. This requires the production of a persistent and effective local immune response.

Elimination of SD

Eradication Programs without Depopulation. In herds with SD, elimination of the disease should always be the aim, both because of the devastating effect of SD on feed-conversion efficiency and for animal welfare reasons. Furthermore, herds with SD represent a potential risk of disease for other pig herds, and a high consumption of antibacterials in infected herds increases the risk of development of antibacterial resistance and spread of resistant strains. Elimination programs have not always proved successful (Muirhead 1984; Wood and Lysons 1988), so, to improve the chances of success, considerable effort must be put into planning, organizing, and achieving the full understanding and cooperation of all personnel involved. Generally, eradication becomes more difficult as herd size increases and as the company operation becomes larger and more complex. Wood and Lysons (1988) suggested that provided that there was a careful selection of herds the chances of an eradication program succeeding were around 80–90%. The cost for elimination of SD has been estimated to be recovered in 6–12 months through improved production and reduced drug usage (Windsor and Simmons 1981; Christensen et al. 1987; Wood and Lysons 1988). Hence successful eradication is of considerable long-term financial benefit to the producer.

Attempts to eliminate SD without total depopulation of pigs from the unit is not recommended unless an effective antimicrobial agent against *B. hyodysenteriae* isolates from the unit is available. It is also important to establish a source of replacement breeding stock that is guaranteed to be free from SD (e.g., herds officially certified as free from the disease). Alternatively, a system of isolation and medication of all replacement stock is necessary before permitting entry to the unit. The introduction of *B. hyodysenteriae* into pig herds primarily occurs with carrier pigs and, unfortunately, at present there are no reliable methods of detecting carrier pigs from infected herds.

Depending on the herd structure, the production model (e.g., batch or continuous production), economical considerations, etc., eradication can be performed in several different manners. These vary from intensive medication of all pigs for a short period, to introduction of medicated-early-weaning and multisite production, through to an ongoing program performed by emptying and disinfecting each herd unit in a cycle, and thereafter introducing medicated animals to cleaned and disinfected units. The eradication period for the latter method may last for several months. General guidelines, partly adopted from Harris and Glock (1981), Baekbo (1998), and Løvens Kemiske Fabrik (1998) follow:

1. The diagnosis should be verified by culture, biochemical tests, and/or PCR.
2. Since the herd may be infected by more than one clone of *B. hyodysenteriae*, several isolates should be tested for their susceptibility to antibacterials available for use in an eradication program. Susceptibility testing should use agar dilution or broth dilution to establish minimum inhibitory concentration (MIC) values. In most cases pleuromutilins will be the agents of choice.
3. Herds practicing a continuous production system should be encouraged to change their production to a planned system based on batch production before the eradication program is performed.
4. The eradication program should be performed during a warm season since the survival time of *B. hyo-*

dysenteriae in the environment is reduced and the efficiency of disinfectants is improved at higher temperatures.

5. The number of animals in the herd should be reduced to as few as possible. Ideally, all weaners, growers, and finishers should be removed from the herd before the start of the program.

6. An efficient rodent and insect control program should be introduced and protective measures taken to stop wild birds from entering buildings where pigs are housed.

7. Dogs and cats should not be allowed within the herd area. Alternatively they should not be allowed to leave the house where they are kept and should be included in the medication program.

8. All possible sanitary measures to reduce environmental contamination with potentially infectious spirochetes should be taken, including thorough cleaning and disinfecting of all areas where pigs are housed or with which they have contact, the watering and feeding systems, all equipment, etc. Cleaning should be performed by high pressure washing with hot water to remove organic matter, followed by disinfection. *B. hyodysenteriae* is sensitive to most of the commonly used disinfectants. Where slatted floors are present, the slats have to be lifted before cleaning/disinfection. Slurry tanks must be emptied and subjected to the same cleaning and disinfection procedures. Effective cleaning and disinfection may be particularly problematic in outdoor production units or units where grower pigs are housed in shelters and bedded on straw or rice hulls over an earth floor. Relocation of cleaned and disinfected outdoor huts to fresh fields and burning any remaining organic material at the old location followed by ploughing and reseeding the ground should be effective in eliminating infection.

9. All sows, gilts, and boars should be medicated through the drinking water or feed for a minimum of 14 days and introduced into cleaned and disinfected buildings. Piglets born during the medication period should be weaned and finished offsite, receiving parenteral treatment with the antimicrobial agent of choice at weaning. All sow and boar accommodation, including the farrowing accommodation must be thoroughly cleaned and disinfected during the medication period. Ideally the program of cleaning should be started in advance of medication so that the buildings are empty for at least 2 weeks after completion of disinfection. Piglets born after the sows have completed the 14-day medication period can be weaned and finished onsite.

10. All replacement of stock should be stopped during the eradication program.

11. Outdoor lots that have held pigs affected with SD should remain free of pigs for a substantial time period (see Sources of Infection). Any liquid feces, such as in pits and lagoons, should be considered to contain infectious *B. hyodysenteriae* for several months, and lagoon water should not be used for recycling until an appropriate time period of 2–3 months has elapsed after an elimination program has been completed.

Depopulation/Repopulation with SD-Free Stock. Total depopulation, cleanup, disinfection, and repopulation with SD-free stock to reestablish an ongoing pig operation should not be made without accurate financial calculations (Wood and Lysons 1988). However, in some situations this alternative is the only method available to eliminate *B. hyodysenteriae* from the herd. The general guidelines described for elimination without depopulation should be carefully followed. Financial evaluations comparing medication/disinfection methods with depopulation/repopulation methods were made by Polson et al. (1992). Elimination without depopulation was financially more attractive than the depopulation/repopulation method. However, the probability of successful eradication would certainly influence the choice of eradication method.

Prevention of SD

Herds that have been established as free of SD and are either closed or maintained in a closed pyramid will remain free of SD if situated in an isolated location and precautions are taken to prevent contamination by feces from carrier pigs or by vectors, especially rodents and birds. Infectious materials may also be carried into a herd by fomites such as workers' boots, farm implements, and feed or animal trucks. However, introduction of new stock represents by far the greatest hazard. A reliable history of the source herd is the only assurance of safety, since no reliable methods of detecting carrier pigs from infected herds exist. Research efforts are being directed at various methods of identification of carrier animals, and it is hoped that sensitive and specific serologic tests or other detection methods will be available in the future. To avoid introduction of SD and other diseases into herds, purchased animals should always be kept in quarantine for at least 3 weeks. Quarantine is a highly recommended procedure, since clinical signs often appear in subclinically affected animals as a result of transportation. During quarantine, the newly purchased animals can be treated to eliminate *B. hyodysenteriae* from the intestinal tract.
