CGD is an inherited disorder of phagocyte function in which generation of superoxide by the respiratory burst oxidase (see Fig. 21-9) in neutrophils, monocytes, macrophages, and eosinophils is absent or markedly deficient.[771,954-959] The disorder occurs at an estimated minimum incidence of approximately 1 in 200,000 to 250,000 individuals, thus making it the most common clinically significant disorder of phagocyte function that is inherited.[957] CGD is due to mutations in any one of four essential subunits of the respiratory burst oxidase (Table 21-15; also see Fig. 21-9 and Table 21-7). Though originally described as an X-linked recessive disorder affecting boys,[957,960-964] approximately a third of CGD cases are inherited as an autosomal recessive trait[965,966] (see Table 21-15). In more than 90% of patients, superoxide production by activated phagocytes is undetectable. A respiratory burst 1% to 10% of normal is observed in the remaining patients, who are often referred to as having "variant" CGD.[966-969] Other aspects of phagocyte

*In this nomenclature, the first letter represents the mode of inheritance (X-linked [X] or autosomal recessive [A]), whereas the number indicates the *phox* component that is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (⁰), diminished (⁻), or normal (⁺) as measured by immunoblot analysis. NBT, nitroblue tetrazolium.

function are normal in CGD, including adherence, ingestion, and degranulation.[970-972]

Clinical Manifestations

CGD is associated with a distinctive clinical syndrome that provides clear evidence for the importance of the phagocyte respiratory burst in host defense and the inflammatory response (for reviews, see elsewhere[957,973-981]). Patients suffer from recurrent, often severe purulent bacterial and fungal infections, often caused by organisms not ordinarily considered pathogens. The other and distinctive hallmark of this disorder is a propensity for the development of chronic inflammatory granulomas that can be widely distributed in tissues. This feature of the disease, at least in part, reflects a role for NADPH oxidase–derived superoxide as a cofactor in the oxidative cleavage of tryptophan to L-kynurenine by indolamine 2,3-dioxygenase (IDO), an important immunomodulatory pathway that otherwise downregulates inflammation.[982,983] The majority of patients with CGD manifest symptoms within the first year of life,[957,977] although some may remain relatively symptom free until later in childhood or even adult life.[984-990]

Table 21-16 summarizes the types of infections and infecting organisms most frequently encountered in CGD.[957,974,975,977-979,991,992] The major sites of infection are those that come into contact with the external environment—the lungs, skin, gastrointestinal tract, and lymph nodes draining these organs. Hematogenous seeding can lead to liver abscesses or osteomyelitis. The most common pathogens include *S. aureus*, *Aspergillus* species (most often *A. fumigatus* but occasionally *A. nidulans*),[992-994] and a variety of gram-negative bacilli, including *Serratia marcescens* and various *Salmonella* species. Members of the *Burkholderia cepacia* complex are aggressive and potentially lethal pathogen in CGD.[957,995,996] *Burkholderia* species that cause infection in CGD include *B. cenocepa-*

cia, *B. gladioli*, and *B. mallei*, which causes melioidosis in East Asian countries.[995,996] In many febrile illnesses, no organism can be identified despite extensive culturing. In such cases it is important to look carefully for the presence of unusual microbes that can occasionally cause serious infections in CGD (see Table 21-16 and references).[985,992,997-1004] Of note, disseminated *Mycobacterium bovis* infection has been reported after bacille Calmette-Guérin (BCG) vaccination in CGD,[1005] and infections with other atypical mycobacteria are also reported in CGD.[1006] A newly identified member of the gram-negative Acetobacteraceae family named *Granulobacter bethesdensis*, heretofore not associated with human disease, was identified in a CGD patient with recurrent fever and a chronic necrotizing deep lymphatic infection.[1007]

Pneumonia is most frequently caused by *S. aureus*, *Aspergillus* species, and enteric bacteria. It is common for an organism to not be identified even in lung biopsy specimens. Complications of pneumonia include empyema or lung abscess. Suppurative lymphadenitis, usually involving the cervical nodes, is especially common in younger patients and is typically caused by *S. aureus* and enteric bacilli such as *Serratia* and *Klebsiella*. Staphylococcal skin infections are also common. Hepatic and perihepatic abscesses, usually caused by *S. aureus*, are surprisingly frequent and should suggest the diagnosis of CGD if it has not already been made.[1008-1010] Bone infections can be particularly problematic in CGD and are caused by either direct spread of infection from contiguous sites or hematogenous spread from more distant locations.[957,1011] The former type of osteomyelitis is usually seen in the ribs and vertebral bodies as a result of invasion by pulmonary *Aspergillus*.[1011] The latter type is more frequently seen in peripheral long and small bones and is typically caused by *S. marcescens*, *Nocardia* species, and *S. aureus*.[1011] Perirectal infections are extremely difficult to treat in CGD and can lead to fistula formation.[1008] The

The relative frequencies of different types of infections in CGD are estimated from data pooled from several large series of patients in the United States, Europe, and Japan. See text for references. These series encompass approximately 550 patients with CGD after accounting for overlap between reports. The list of infecting organisms is also arranged according to the data in these reports and is not paired with the entries in the first column.

★Infections most frequently seen at initial evaluation.

rare pathogen *Chromobacterium violaceum* is found in brackish waters and is an uncommon but potentially serious cause of soft tissue infection, pneumonia, or sepsis in CGD patients in the southern part of the United States.[999,1000,1012] *C. violaceum* infection in northern areas has also been reported.

It has long been recognized that patients with CGD are particularly susceptible to organisms that contain catalase, which prevents the CGD phagocyte from scavenging microbially generated H_2O_2 for phagosomal killing.[1013] Thus, infections with streptococci or *Haemophilus* species, which are typically catalase negative, are not problematic in CGD. Another possible link among the organisms with increased virulence in CGD is that they are resistant to the nonoxidative killing mechanisms of the phagocyte mediated by antibiotic proteins contained within the various granule compartments.[282,1014,1015]

The chronic conditions associated with CGD are responsible for many of the major complications seen with this disorder and are summarized in Table 21-17. This includes the formation of granulomas, which are believed to reflect a chronic inflammatory response to inadequate phagocyte killing or digestion and are a distinctive feature of CGD. These lesions contain a mixture of lymphocytes and inflammatory macrophages, some of which may have a foamy lipoid cytoplasm that has a characteristic yellow-brown color. Though not pathognomonic of CGD, the presence of such macrophages in granulomas or other tissue sites should suggest the diagnosis of CGD.[961,962,964,1016] The tendency toward granulomatous inflammation is believed to reflect in part a dysregulated inflammatory response in the absence of

respiratory burst–derived oxidants; it leads to abnormally high level of cytokines and other proinflammatory mediators, in addition to delayed neutrophil apoptosis at inflammatory sites.[1017-1019] These abnormalities have recently been linked to defective superoxide-dependent cleavage of tryptophan to L-kynurenine by IDO.[983] Proinflammatory stimuli upregulate IDO expression in den-

dritic cells and phagocytes, and IDO-catalyzed tryptophan metabolism then downregulates the inflammation by suppressing γδ T-cell activity and mediating the production of IL-17 after initial activation of the innate immune response.[982] Inefficient degradation of debris in the absence of oxidants is also likely to be a contributing factor to the chronic inflammation in CGD.[1019-1021] Granulomatous inflammation can develop independent of active infection.[1019]

Granuloma formation can lead to obstructive symptoms in the upper gastrointestinal tract, including gastric outlet obstruction that can be confused clinically with pyloric stenosis.[1008,1009,1022-1024] A chronic ileocolitis syndrome resembling Crohn's disease is seen in approximately 5% to 10% of patients and can lead to a debilitating syndrome of diarrhea and malabsorption.[1009,1024,1025] Chronic inflammatory lesions have been identified in the urinary bladder walls of some patients and can cause a chronic cystitis that can be manifested as dysuria, penile pain, and decreased urine volume.[1026-1030] In one study of 60 CGD patients, 11 cases of granulomatous inflammation of the bladder wall, ureters, or urethra were seen, accompanied by stricture formation in the latter two sites.[1031] Hydronephrosis can occur as a complication of obstruction.

Other chronic inflammatory complications of CGD include lymphadenopathy, hepatosplenomegaly, and an eczematoid dermatitis,[975,977,1032] along with hypergammaglobulinemia, anemia of chronic disease, and short stature (see Table 21-17). Gingivitis and ulcerative stomatitis can occur.[1033] Chorioretinitis[1034,1035] and destructive white matter lesions in the brain have also been described.[1036,1037] Glomerulonephritis has been reported.[1038,1039] Occasionally, either discoid or systemic lupus erythematosus, juvenile rheumatoid arthritis, or sarcoidosis may develop.[1040-1045] Subtle defects in CGD memory B cells[1046,1047] may influence the development of autoimmune disease in CGD.

The severity and pattern of complications of CGD are heterogeneous, which may partly reflect the heterogeneity of molecular defects (see later) and whether any residual respiratory burst oxidase function is present. However, a severe clinical course can occur in some patients in the latter "variant" category that is indistinguishable from what is observed in patients with complete absence of phagocyte superoxide production.[969,1048] On the other hand, some individuals with undetectable levels of respiratory burst activity can experience relatively few symptoms and have intervals of years between severe infections. Hence, polymorphisms in oxygen-independent antimicrobial systems or other components regulating the innate immune response are likely to play an important role in modifying disease severity in CGD. Specific polymorphisms in the MPO, MBL, and FcγRIIa genes are associated with a higher risk for granulomatous or autoimmune/rheumatologic complications in CGD.[1049] Patients with p47[phox] deficiency overall tend to have milder disease, possibly because of very small but detectable levels of superoxide production.[957,1050]

Heterozygous carriers of the CGD trait are generally asymptomatic, but there are several important exceptions. Carriers of the autosomal recessive forms of CGD have a normal phagocyte respiratory burst and are free from infection. Carriers of X-linked CGD, on the other had, typically have two populations of circulating neutrophils and monocytes—some with normal respiratory burst activity and others with none[1051-1057]—because of random X-chromosome inactivation.[1058,1059] In most X-linked carriers, these two populations are approximately equal in number, but occasionally individuals have an unusually small percentage of either abnormal or normal cells. If the number of functioning neutrophils is less than 10% to 15%, the carrier often suffers from some of the infectious complications of CGD.[969,986,1051,1060] Clinical problems more commonly seen in female carriers of X-linked CGD are aphthous ulcers or discoid lupus erythematosus.[1042,1061] In a 1991 review of the literature,[1042] 22 cases were summarized from 11 reports. Clinically, the carriers had discoid-like skin lesions (13 of 22 patients), photosensitivity (13 patients), and recurrent aphthous stomatitis (12 patients). In a few, polyarthritis, arthralgia, and Raynaud's phenomenon were also observed. Serologic testing for lupus was generally negative, as were immunofluorescence studies of biopsied lesions. Interestingly, all the reported cases were carriers of X-linked CGD. Discoid lupus–like lesions have also been reported in five autosomal recessive CGD patients.[1040,1041,1062] Because the lupus skin lesions typically do not appear to develop unless there is at least a subpopulation of nonfunctioning phagocytes, it has been hypothesized that autoantibodies to antigens from incompletely destroyed microbes may be responsible for the syndrome.[1042]

Molecular Basis of CGD

CGD is classified according to the respiratory burst oxidase subunit that is affected (see Table 21-15). Nomenclature has also been adopted for an abbreviated designation within each major genetic subgroup that includes the mode of inheritance and level of *phox* protein expression. The genes or corresponding cDNA (or both) of all four subunits have been cloned and their chromosomal locations mapped (see Fig. 21-9 and Table 21-7).[310,719,955,1063,1064] In two large studies of 140 pedigrees in the United States and Europe, defects in the X-linked gene for the gp91[phox] subunit of flavocytochrome *b* accounted for approximately two thirds of cases, with the remainder being due to autosomal recessive inheritance of defects in p47[phox] (25%), p67[phox] (5%), and p22[phox] (5%).[957,965,966] However, deficiency of p47[phox] has been reported to account for only 7% of cases of CGD in Japan.[1065]

Mutations in Flavocytochrome *b*. That CGD might result from a genetic defect in an electron-transporting cytochrome was first suspected from reports that neutrophils obtained from the majority of CGD patients lacked a low-potential cytochrome *b*.[725,1066,1067] It is now known

that the respiratory burst cytochrome is a flavocytochrome composed of two subunits and contains both flavin and heme groups that mediate the transfer of electrons from NADPH to molecular oxygen to generate superoxide.[301,1068] The cytochrome has two subunits, a 91-kd glycoprotein (gp91[phox]) that is the site of mutations in X-linked CGD and a 22-kd polypeptide (p22[phox]) that is defective in a rare subgroup of patients with autosomal recessive inheritance of CGD. Formation of the gp91[phox]/p22[phox] heterodimer appears to be important to stabilize each subunit within the phagocyte, and absent expression of both subunits is typically seen in both forms of cytochrome-negative CGD.[308,1069,1070]

The gene encoding gp91[phox] was mapped to Xp21.1 by its linkage to the X-linked form of CGD.[1071] It was the first human gene to be cloned on the basis of its chromosomal location,[310] an approach referred to as positional cloning or "reverse genetics." The gp91[phox] gene (termed *CYBB*) contains 13 exons and spans approximately 30 kilobases (kb) in the Xp21.1 region of the X chromosome.[310,1071,1072] Mechanisms that regulate phagocyte-specific transcription of this gene include a repressor protein, known as CCAAT displacement protein (CDP), that binds to DNA sites upstream of the promoter to block transcription in nonphagocytic or undifferentiated myeloid cells.[1072] Some regulatory elements appear to be located relatively long distances from the coding portion of the gp91[phox] gene.[1072,1073]

Defects in the gene for gp91[phox] X-linked CGD are very heterogeneous[956,958,1065,1074,1075] and, with few exceptions, are associated with absence of both the flavocytochrome heterodimer (X91^0) and respiratory burst activity. Mutations in the gp91[phox] gene have been identified in more than 400 patients with X-linked CGD. An international registry, CYBBbase, is accessible at http://bioinf.uta.fi.[756,1076] In general, each mutation is unique to a given kindred, although some have been seen in several unrelated pedigrees. The overall heterogeneity of mutations and lack of any predominant genotype indicate that CGD is due to many different mutational events without any founder effect, as expected for a formerly lethal disorder. Approximately 10% to 15% of cases of X-linked CGD are caused by new germline mutations.[1074]

The majority of X-linked CGD patients have mutations limited to only one or several nucleotides, which results in missense, mRNA splicing site, frameshift, or nonsense mutations. A small percentage of patients with X-linked CGD express a small amount of residual flavocytochrome *b* (X91$^-$) associated with low levels of superoxide production. In addition, individuals have been reported who have normal levels of a dysfunctional flavocytochrome *b* (X91$^+$). Some of the mutations that result in normal levels of a dysfunctional flavocytochrome affect gp91[phox] domains that either participate in oxidase assembly[1077,1078] or are involved in its redox function.[955,956,958,988,1075,1079-1081]

Relatively large deletions in Xp21.1 involving *CYBB* and adjacent loci have been described in a few rare patients.[310,1071,1082-1085] These individuals have complex phenotypes that include CGD and McLeod's syndrome (mild hemolytic anemia with acanthocytosis associated with depressed levels of Kell antigens because of defects in the red cell antigen K^x), with or without concomitant Duchenne's muscular dystrophy and retinitis pigmentosa. Patients with the McLeod phenotype may develop anti-Kell antibodies when transfused with red blood cells, which can make future transfusion very difficult. Nerve and muscle disorders related to Kell expression in nonerythroid tissues can also develop in these patients.[1086,1087] Smaller deletions of the gp91[phox] gene have been reported as well.[1075]

Mutations affecting the regulation of gp91[phox] transcription are rare and have been identified in two unusual phenotypes. In one type, described in two unrelated kindreds, affected males have two distinct populations of neutrophils.[1048] One population has normal respiratory burst activity and accounts for 5% to 15% of the circulating phagocytes and myeloid progenitor cells, whereas the other population, which accounts for the remainder of the cells, lacks a respiratory burst entirely. Affected males had a severe clinical course.[1048] Sequencing of the gp91[phox] gene identified a point mutation in the promoter sequence that was located 57 bp upstream of the normal transcription initiation site in one kindred and 54 bp upstream in the other.[1060] Another unusual patient with X-linked CGD had normal levels of gp91[phox] expression and function in circulating eosinophils, but this patient's neutrophils, monocytes, and B lymphocytes had markedly reduced levels of gp91[phox].[1088] Molecular analysis identified a mutation 53 bp upstream of the transcription start site in this kindred.[1089] These mutations disrupt the binding of several transcriptions important for normal expression of the *CYBB* gene,[1089,1090] thus suggesting that gp91[phox] gene expression is dependent on this region of the promoter in all but a subset of granulocytes.

Mutations in the gene for the p22[phox] subunit of flavocytochrome *b*, designated *CYBA*, are an uncommon cause of autosomal recessive CGD (see Table 21-15). The *CYBA* locus resides at 16q24 and contains six exons that span 8.5 kb.[1063] The genetic defects that have been identified in this flavocytochrome subunit are heterogeneous and range from a large interstitial gene deletion[1063] to point mutations associated with missense, frameshift, or RNA-splicing defects.[776,958] In all but one case, p22[phox] is not expressed (A22^0 CGD). A proline-to-glutamine substitution in a cytoplasmic domain of p22[phox] is associated with normal levels of flavocytochrome *b* and a nonfunctional oxidase (A22$^+$ CGD).[1079] This mutation disrupts a proline-rich docking sequence in p22[phox] that binds to a pair of SH3 domains in the p47[phox] domains and is required for assembly of the active oxidase complex.[301,1068] The proline substitution in p22[phox] is the one example of a genetic disease caused by disruption of protein-protein interactions mediated via SH3 domains. A kindred with X-linked agammaglobulinemia caused by

deletion of the SH3 region of Bruton's tyrosine kinase has also been reported.[1091]

Mutations in Cytosolic Factors. A key discovery in unraveling the molecular basis of the different genetic subgroups in CGD was the observation that both the plasma membrane and the cytosol were required to reconstitute a catalytically active oxidase in a cell-free assay.[1092-1095] Complementation analysis using this assay identified two different subgroups of CGD in which the defect involved a cytosolic protein rather than the membrane-bound flavocytochrome b.[1096,1097] Mutations in the gene encoding a cytosolic phosphoprotein, p47^{phox}, account for approximately a fourth of all cases of CGD in the United States and Europe, whereas in Japan the incidence is only approximately 7%.[724,1065] Inherited defects in the p67^{phox} gene also account for a small subgroup of autosomal recessive CGD (see Table 21-15). Neither p47^{phox} nor p67^{phox} appear to participate directly in electron transfer but act in a regulatory role. The p47^{phox} subunit is believed to function as an "adaptor" protein important for efficient recruitment of p67^{phox} translocation to the flavocytochrome. Consistent with this role, substantial amounts of superoxide can be generated from neutrophil membranes in vitro, even in the absence of p47^{phox}, provided that high concentrations of p67^{phox} and Rac-GTP are supplied.[300]

The gene for p47^{phox}, termed *NCF1* (for neutrophil cytosolic factor 1), resides on chromosome 7[1098] and contains nine exons spanning 18 kb.[1099] In contrast to other forms of CGD, the majority of p47^{phox}-deficient CGD is due to a single type of mutation, a GT deletion at the beginning of exon 2 that results in a frameshift and premature translational termination.[1099,1100] Most patients are homozygous for this mutation without any history of consanguinity, although a few compound heterozygotes have been described with a missense mutation accompanying the GT deletion.[1101] The high frequency of the GT deletion appears to reflect the fact that humans have highly and closely linked conserved pseudogenes for p47^{phox} that contain the GT deletion.[1102] Some individuals also have a gene-pseudogene-pseudogene chimera.[1103] Recombination or gene conversion events between the authentic p47^{phox} gene and its pseudogene or pseudogenes lead to a nonfunctional p47^{phox} allele containing the GT deletion.[1104] All reported patients with p47^{phox} gene mutations do not express this protein (A47^0). Perhaps because p47^{phox} is an adaptor protein rather than directly involved in activating electron transport, A47^0 neutrophils can still generate very small but detectable amounts of superoxide, which may account for the overall milder course of this genetic subgroup.[957,1050]

The gene for p67^{phox}, *NCF2*, which has been mapped to the long arm of chromosome 1,[1105] spans 37 kb and contains 16 exons.[1106] Mutations identified in p67^{phox}-deficient CGD are heterogeneous and typically result in absent p67^{phox} expression (A67^0 CGD).[1107-1111] In one patient, in whom a triplet nucleotide deletion resulted in

an in-frame deletion of lysine 58, a nonfunctional form of p67^{phox} was expressed that failed to translocate and was unable to bind to Rac.[1112]

Diagnosis

A diagnosis of CGD is suggested by the characteristic clinical features (see Tables 21-16 and 21-17) or by a family history of the disease. Because the severity and onset of the disease can vary considerably among patients, CGD should still be considered in adolescents and adults with an unusual site of infection or organism typical of CGD (see Table 21-16). The diagnosis of CGD is established by demonstrating an absent or greatly diminished neutrophil respiratory burst. It is important to have testing performed on appropriately handled blood samples and by experienced laboratories to avoid inconclusive or false-normal results.

Many different methods have been used to monitor respiratory burst activity. Assays include those that monitor chemiluminescence or fluorescence when superoxide is released from activated phagocytes.[1054,1055,1113,1114] One of the simplest and most accurate techniques is the nitroblue tetrazolium (NBT) test, in which neutrophils in freshly isolated blood are stimulated to undergo a respiratory burst in the presence of NBT.[1052,1053,1115,1116] When reduced by electrons donated from superoxide, the water-soluble, yellow tetrazolium dye is converted to deep blue, insoluble formazan deposits that precipitate on any cell that undergoes a respiratory burst. NBT reduction can be evaluated quantitatively on cells in suspension[1115] or, preferably, by examination of neutrophils and monocytes that have adhered to a microscope slide (the NBT slide test).[1052,1053] As shown in the NBT slide test in Figure 21-11, stimulated neutrophils and monocytes are normally strongly stained with NBT formazan deposits (panel B). Cells from patients with X91^0, A22^0, A47^0, and A67^0 CGD fail to stain with NBT (an X91^0 patient is shown in panel C), whereas patients with variant forms of the disease show light staining (an X91$^-$ patient is shown in panel E). In addition to X91$^-$ CGD neutrophils, weak staining in the NBT test and a small but measurable level of dihydroxyrhodamine 123 (DHR 123) fluorescence (see later) can be seen in A47^0 cells and reflects a small amount of residual oxidant production. The NBT slide test can also diagnose the carrier states of either X91^0 or X91$^-$ CGD because a mixed population of NBT-positive and NBT-negative (or weakly NBT stained) cells is observed (Fig. 21-11D and F). Failure to detect a mixed population of formazan-staining cells does not necessarily rule out the X-linked carrier state because nonrandom inactivation of cells with the mutant X chromosome can occur by chance. A normal maternal NBT test may also indicate that there has been a de novo mutation in the germline of a parent[1074,1098] or that the patient has one of the autosomal recessive forms of CGD. Intermediate levels of NBT reduction are not seen in the phagocytes of autosomal recessive carriers. Flow cytometric assays of oxidase activity, such as those

FIGURE 21-11. Evaluation of chronic granulomatous disease (CGD) with the nitroblue tetrazolium (NBT) test. Photomicrographs are shown of NBT tests performed on normal cells (at rest and after stimulation with phorbol myristate acetate [PMA]) and on PMA-stimulated cells from X91⁰ and X91⁻ CGD patients and their mothers (who are carriers). Dense formazan crystals are seen in all the normal phagocytes after stimulation (**B**) but are absent from resting cells (**A**). The CGD patients are seen to have homogeneous populations of cells that either do not respond (X91⁰, **C**) or respond only minimally (X91⁻, **E**) to PMA. In contrast, NBT tests on CGD carriers show heterogeneous populations of cells that respond either normally or in a fashion similar to that of the abnormal cells from their offspring (**D** and **F**). In the case of the maternal carrier shown in **F,** the cells with normal deposits of formazan (*arrow*) are intermixed with cells containing minimal amounts of formazan (*arrowheads*) identical to those seen in her affected male child (**E**). *(Reprinted from Smith RM, Curnutte JT. Molecular basis of chronic granulomatous disease. Blood. 1991;77:673-686.)*

based on the conversion of DHR 123 to rhodamine 123,[1113,1114] are increasing in use for the diagnosis of CGD and, like the NBT test, provide both quantitative measurements of oxidant generation and cell-by-cell distribution of activity. The DHR 123 assay for neutrophil respiratory burst activity is available in many referral centers and reference laboratories and can be performed on blood collected in heparin and stored overnight.

With the exception of classic X-linked disease in a male whose mother is a carrier, determining the specific oxidase gene affected in a given CGD patient (see Table 21-15) requires additional studies. Genetic (DNA) testing for all four subgroups of CGD is now available commercially. Other assays, available in research laboratories, include immunoblot analysis of *phox* protein expression in neutrophil extracts, flavocytochrome *b* spectroscopy, and functional analysis of membrane and cytosol fractions in the cell-free oxidase assay. In a male with absent flavocytochrome *b* without clear evidence of a maternal carrier, it is necessary to search for the mutation in both the gp91^{phox} and p22^{phox} genes by DNA sequencing or another method of analysis. Identification of the specific genetic subgroup of a patient is useful primarily for pur-

poses of genetic counseling and prenatal diagnosis. In prenatal testing for suspected X-linked CGD, further analysis is not necessary if the fetus is determined to be a 46,XX female.

Prognosis and Treatment

The prognosis for patients afflicted with CGD has continued to improve since the disorder was first described in the 1950s, at which time almost all patients died in childhood.[960-962] In one retrospective review of 38 patients monitored between 1964 and 1989, actuarial analysis showed a 50% survival rate through the third decade of life.[1117] In another retrospective study of 48 patients monitored between 1969 and 1985 in Paris, the actuarial survival rate was 50% at 10 years of age, with a prolonged plateau thereafter.[978] Further refinements in treatment and the use of prophylactic antimicrobials, coupled with the introduction of IFN-γ therapy, have continued to improve the prognosis for CGD.[1118,1119] Despite the lack of prospective data examining the long-term impact of these newer management strategies, it is generally agreed that a large majority of patients should survive well into their adult years. The overall mortality for all patients

with CGD in the United States, including adults, was estimated to be 5% per year for X-linked CGD and 2% per year for autosomal recessive CGD in a recent retrospective analysis.[957] The most common causes of death were pneumonia or sepsis (or both) as a result of infection with *Aspergillus* species or *B. cepacia*.[957,980] A single-institution study involving 76 younger patients reported an overall mortality of 1.5% per year.[1119] As already noted, patients with a deficiency of p47^{phox} have often been noted to exhibit milder disease than those with flavocytochrome-negative CGD, possibly because of small amounts of residual superoxide produced.[1050,1120]

A multifaceted therapeutic approach has been responsible for the greatly improved prognosis in CGD. The cornerstones of current management include (1) prevention and early treatment of infections; (2) use of prophylactic antibacterial and antifungal therapy; (3) early use of parenteral antibiotics, including antifungal drugs, augmented by surgical drainage or resection of recalcitrant abscesses; and (4) the use of prophylactic rIFN-γ.

Several approaches can be used to prevent infections. Patients with CGD should receive all routine immunizations (including live virus vaccines) on schedule and an influenza vaccine yearly. Cuts and skin abrasions should be promptly cleaned with soap and water and rinsed with a 2% solution of hydrogen peroxide. The frequency and severity of rectal infections can be greatly reduced by avoiding constipation and soaking early lesions in warm, soapy water. Flossing and professional dental cleaning can help prevent gingivitis and periodontitis. The risk of *Aspergillus* infection can be decreased by avoiding marijuana smoke[1121] and decaying plant material (e.g., rotting wood, mulch, hay), both of which often contain numerous *Aspergillus* spores.[1122]

The prophylactic use of antibiotics for bacterial and fungal infections is another important component in the management of CGD. Retrospective studies showed that chronic prophylaxis with trimethoprim-sulfamethoxazole (5 mg/kg/day of trimethoprim given in one or two doses) can decrease the number of bacterial infections in patients with CGD without increasing rates of fungal infection or infection with pathogens resistant to trimethoprim-sulfamethoxazole.[978,1120] Dicloxacillin (25 to 50 mg/kg/day) can be used in sulfa-allergic patients, although there are relatively few data documenting its efficacy. Itraconazole is used for prophylaxis against fungal disease. A prospective study found an incidence of 3.4 *Aspergillus* infections (lung) per 100 patient-years as compared with 11.5 in a historical control group that did not receive any prophylaxis.[1123] A subsequent randomized, double-blind, placebo-controlled study further documented the efficacy of itraconazole for prophylaxis of fungal infections in CGD.[1124] Daily itraconazole is therefore now recommended for all CGD patients (200 mg daily if 13 years or older or if weighing at least 50 kg or 100 mg daily if younger than 13 years or weighing less than 50 kg). Liver function tests should be monitored in patients receiving itraconazole.

rIFN-γ is another cornerstone of current management that reduces the frequency of serious infection in patients with CGD.[1119,1125-1127] rIFN-γ enhances many aspects of normal phagocyte function, including nonoxidative microbial killing. The recommended dose of rIFN-γ in CGD is 0.05 mg (50 μg)/m^2 or 0.0015 mg/kg if less than 0.05 m^2, given three times a week subcutaneously. A multicenter double-blinded, placebo-controlled phase III trial first established that rIFN-γ was an effective and well-tolerated treatment that reduces the infectious complications of CGD in all four genetic subgroups,[1128] a result that has continued to be supported by longer follow-up phase IV studies.[1119,1126,1127] The main conclusions of the original study are summarized in Table 21-18. Patients receiving rIFN-γ had a 70% reduction in the number of serious infections during the study period. These beneficial effects were independent of age, mode of inheritance, and concomitant use of prophylactic antibiotics. The most common side effects were mild fever, headache, and other flu-like symptoms. No additional adverse effects, including any increased incidence of chronic inflammatory complications, have been noted with longer periods of prophylactic rIFN-γ (>10 years).[1119] On average, these patients are averaging one serious infection per patient every 4 to 5 years.

The beneficial effect of rIFN-γ in most CGD patients is not fully understood but appears to be achieved by enhancing nonoxidative antimicrobial pathways and other phagocyte functions. For example, administration of rIFN-γ to normal volunteers increases expression of FcγR1 and enhances phagocytosis.[1129] Overall, no difference was found in neutrophil superoxide production and killing of *S. aureus* in CGD patients receiving either rIFN-γ or placebo.[1128,1130] However, because rIFN-γ increases levels of gp91^{phox} mRNA expression,[1131] increased superoxide production and bacterial killing can be seen in some patients with variant X-linked CGD (see X91$^-$ in Table 21-15).[1131-1134] One site of action of rIFN-γ, at least in X91$^-$ patients, appears to be granulocyte-monocyte precursor cells in the bone marrow.[1132,1134]

A frequent shortcoming in the treatment of patients with CGD is failure to treat potentially serious infections promptly or long enough with the appropriate parenteral antibiotics. CGD patients do not always have typical symptoms and signs, even with serious infections, and fever and leukocytosis can be absent. An elevated sedimentation rate is often present and can be very useful both as a clue to the presence of significant infection and for monitoring the response to therapy.[991] Therapy should be directed initially at characteristic pathogens. In the absence of a diagnostic culture, a broad-spectrum gram-negative antibiotic effective against *B. cepacia* should be administered in conjunction with a potent antistaphylococcal agent (e.g., a combination of nafcillin and ceftazidime). If the site of infection, the offending pathogen, or both are not known and the patient is severely ill and not responding to the initial therapy within 24 to 48 hours, an aggressive search for the underlying infection should

TABLE 21-18 Summary of the Phase III Study Establishing the Efficacy of Recombinant Interferon-γ for Infection Prophylaxis in Chronic Granulomatous Disease

Variable	TREATMENT GROUP		P Value
	Interferon	Placebo	
Number of patients	63	65	
Patient years on study	52.1	50.9	
Age ± SD (yr)	14.3 ± 10.1	15.0 ± 9.6	
Number of patients with at least one serious infection	14 (22%)	30 (46%)	.0006
Serious infections per patient-year	0.38	1.1	
Total number of serious infections	20	56	<.0001
Number of hospital days per patient-year	8.6	28.2	
	Percentage without Serious Infection*		
Age			
<10 yr (52 patients)	81	20	
≥10 yr (76 patients)	73	34	
Inheritance			
X-linked (86 patients)	79	33	
Autosomal (42 patients)	71	39	
Prophylactic antibiotics			
Yes (111 patients)	78	33	
No (17 patients)	69	28	

The table shows a summary of the final results of a phase III randomized, double-blind, placebo-controlled study in which 128 patients with CGD received either recombinant interferon-γ (50 mg/m^2 per dose) or placebo by subcutaneous injections three times per week for an average duration of 8.9 months (a controlled trial of interferon gamma to prevent infection in chronic granulomatous disease. The International Chronic Granulomatous Disease Cooperative Study Group. N Engl J Med. 1991;324:509-516). The major end points of the study were time to the first serious infection and the number of such infections. A serious infection was defined as an event requiring hospitalization and parenteral antibiotics.

*The bottom portion of the table shows the Kaplan-Meier estimates of the cumulative proportion of patients free from serious infections for 12 months (after randomization) with adjustment for stratification factors.

be conducted, including bronchoscopy or open biopsy, if indicated. In ill patients, therapy for fungi, *Nocardia* species, and *B. cepacia* may have to be given empirically. *B. cepacia* is notorious for causing persistent fevers followed by bloodstream dissemination from the lung or other sites that results in sudden septic shock. *B. cepacia* generally responds to ceftazidime or meropenem,[995] which are most effective if given before dissemination into the bloodstream. Proven or suspected fungal infections have been treated with amphotericin B in the past, although its use is being replaced with newer azole antifungal agents such as voriconazole.[1135-1137] Even when appropriate antibiotics are used, infections often respond slowly and should generally be treated with an antibiotic course that is more prolonged than for a patient with normal neutrophil function. Some infections may require many months of therapy, particularly *Aspergillus*, but staphylococcal infections as well. Surgical drainage or resection can play a key role in the management of lymphadenitis, osteomyelitis, and abscesses of the liver, lungs, kidney, brain, and rectum. Finally, granulocyte transfusions may be helpful in the treatment of recalcitrant or life-threatening infections.[991,1138,1139]

Granulomatous inflammation in the esophagus, gastric antrum, and bladder can result in symptoms of obstruction, and in the bowel wall, a syndrome resembling inflammatory bowel disease can occur. These complications can cause considerable morbidity in some patients with CGD and are generally managed with a combination of antibiotics and steroids.[1023,1029,1119,1140-1143] Although the anti-inflammatory effects of steroids are often beneficial in this setting, even at low oral doses (1 mg/kg/day of prednisone),[1143] their use should be carefully monitored because of the additional immunosuppression associated with them. Cyclosporine has also been used to successfully treat a case of intractable gastrointestinal disease, although a serious fungal pneumonia secondary to *Paecilomyces variotii* did develop while taking cyclosporine.[1025] IFN-γ has had no clear role in management of the chronic inflammatory complications of CGD; however, anecdotal reports suggest that it may be beneficial in some patients. A recent study in a mouse model of CGD suggested that combining IFN-γ with L-kynurenine may be beneficial in counteracting the dysregulated inflammatory response in CGD.[983] NADPH oxidase–derived superoxide appears to be an important cofactor in the oxidative cleavage of tryptophan to L-kynurenine by IDO, which is an important immunomodulatory pathway that otherwise downregulates inflammation.[983]

Allogeneic bone marrow transplantation can be used to treat CGD.[398,772,1144-1150] Because of the risks associated with this procedure, marrow transplantation is generally considered only for patients who have frequent and severe infections despite aggressive medical management and also have a fully HLA-matched sibling donor. Nonmye-

loablative conditioning regimens for allogeneic transplantation have also been used successfully in CGD, including several cases with ongoing fungal infections, although graft-versus-host disease can be a significant problem in adult patients.[1148,1150,1151] Cord blood transplants have been reported as well.[1152,1153]

Because CGD results from single-gene defects in proteins expressed in myeloid cells, this disorder is considered to be an excellent candidate for gene replacement therapy targeted at hematopoietic stem cells. Based on the lack of symptoms observed in female carriers of X-linked CGD with as few as 10% to 20% NBT-positive neutrophils, significant clinical benefit may result even if a minority of the phagocyte population is successfully corrected.[959] Studies of bone marrow transplantation and gene therapy in murine CGD have been useful in evaluating the level of correction required to prevent symptoms and have generally confirmed the clinical observations in female X-linked CGD carriers and variant X-linked CGD.[1154-1157] Thus, genetic modification of marrow stem cells may be a useful future therapeutic modality for CGD if obstacles in achieving safe and effective gene delivery can be overcome.[771,1030,1158,1159] Early phase I clinical trials using retroviral vectors for gene therapy for CGD showed "proof of concept" in that oxidase-positive peripheral blood neutrophils were detected, though at very low levels (<0.5%) and disappearing within 9 months.[771,1160] This was not surprising because patients did not receive any preparative regimen and there is no intrinsic selection for gene-corrected cells in CGD. A subsequent clinical trial in Germany for X-linked CGD used a gamma-retroviral vector with a more potent viral long terminal repeat driving expression of the X-linked CGD protein, as well as partially ablative busulfan conditioning.[1161] In the first two patients reported, much higher numbers of oxidase-positive neutrophils (20% to 50%) were seen, along with resolution of chronic infectious complications. However, this high level of correction resulted from expansion of myeloid precursors that harbored vector insertions in genes that are master regulators of myeloid cell growth.[1161] Current efforts at gene therapy for CGD are focused on the development of gamma-retroviral and lentiviral vectors that lack strong viral enhancer sequences to reduce the potential for insertional mutagenesis as a result of activation of neighboring genes.[771,1159]

Glucose-6-Phosphate Dehydrogenase Deficiency

The substrate for the respiratory burst oxidase, NADPH, is generated by the first two reactions of the hexose monophosphate shunt: G6PD (see Fig. 21-7, reaction 8) and 6-phosphogluconate dehydrogenase (6PGD). Because G6PD is the first enzyme in this pathway, its absence results in greatly diminished shunt activity and thus a severe decrease in the availability of NADPH. Consequently, severe G6PD deficiency in neutrophils results in an attenuated respiratory burst and, in some cases, a clinical picture somewhat similar to that observed in CGD.[1162-1165] The key features of G6PD deficiency are summarized in Table 21-19. The organisms causing infection in severely deficient patients are similar to those observed in CGD and are predominately catalase-positive bacteria.

In light of the relatively high frequency of G6PD mutations in the American black and Mediterranean populations,[1166] as well as the fact that leukocyte and erythrocyte G6PD is encoded by the same gene, it might

---

TABLE 21-19	Summary of Neutrophil Glucose-6-Phosphate Dehydrogenase Deficiency
Incidence	Extremely rare
Inheritance	X-linked
Molecular defect	Poorly characterized family of mutations that cause CNSHA in erythrocytes and functional failure of G6PD in neutrophils (possibly kinetic mutants); other rare mutants may also be responsible
Pathogenesis	Severe functional failure of neutrophil G6PD (<5% of normal) leading to an extremely low steady-state concentration of NADPH, which serves as the substrate for NADPH oxidase
Clinical manifestations	CNSHA (hemolytic anemia that occurs even in the absence of redox stress)
	CGD-like syndrome with recurrent bacterial infections
Laboratory evaluation	Neutrophil C6PD activity < 5% of normal
	Severely diminished respiratory burst and abnormal nitroblue tetrazolium test
	Associated CNSHA with elevated reticulocyte count and diminished erythrocyte G6PD activity
Differential diagnosis	CGD
	Glutathione reductase or synthetase deficiency
Therapy	Prophylactic trimethoprim-sulfamethoxazole
	Aggressive use of parenteral antibiotics
	Transfusion support for severe anemia
Prognosis	Not clear because too few patients have been reported
	May be as severe as CGD

CGD, chronic granulomatous disease; CNSHA, congenital nonspherocytic hemolytic anemia; G6PD, glucose-6-phosphate dehydrogenase; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

be expected that clinically significant neutrophil G6PD deficiency would occur more often than it does (fewer than 10 cases have been reported in the literature). One of the reasons that it does not is that neutrophils must have a severe deficiency (<5% of normal G6PD levels) before respiratory burst function is adversely affected. Even low levels of G6PD are apparently sufficient to recycle NADP$^+$ back to NADPH at a rate that permits reasonable levels of respiratory burst activity. Furthermore, studies on patients with variant CGD indicate that surprisingly low levels of respiratory burst activity (5% to 10% of normal) can still provide adequate protection against microbial infection (see earlier). Therefore, clinically significant decreases in levels of neutrophil G6PD are rarely encountered. In most types of G6PD deficiency, neutrophil levels are in the range of 20% to 75% of normal.[1167,1168] Because most G6PD mutations cause the enzyme to decay over a period of days and weeks, levels in the short-lived neutrophil do not usually become critically low, even in some of the more unstable G6PD variants. Hence, it appears that only a rare (and poorly understood) group of mutations cause extremely low levels of G6PD in neutrophils.

The diagnosis of G6PD deficiency should be considered in any patient with congenital nonspherocytic hemolytic anemia (CNSHA) in whom the erythrocyte G6PD level is unusually low or the frequency of infections is high. The diagnosis is established by measuring the level of G6PD activity in neutrophil homogenates. Though not necessary for the diagnosis, neutrophil function tests show a diminished respiratory burst (5% to 30% of normal).[1164,1169] Treatment of neutrophil G6PD deficiency is similar to that of CGD except that efficacy of rIFN-γ has not been demonstrated in the former. In general, G6PD deficiency appears to be somewhat milder than CGD, although recurrent pneumonia and a fatal infection with *C. violaceum* have been described.[1164,1169]

Myeloperoxidase Deficiency

MPO deficiency is the most common inherited disorder of phagocytes but is rarely associated with clinical symptoms. Although only 17 known cases had been collected up to 1979, the diagnosis is now easily made with the widespread use of automated flow cytochemistry in clinical hematology laboratories to enumerate peripheral blood neutrophils with peroxidase activity. In the United States and Europe, complete deficiency is seen in approximately 1 in 4000 individuals, and partial deficiencies occur in 1 in 2000 people, whereas MPO deficiency is uncommon in Japan.[1170-1172] MPO deficiency is seen in neutrophils and monocytes. Peroxidase levels in eosinophils, on the other hand, are normal because eosinophil peroxidase is encoded by a different gene.

MPO plays a pivotal role in amplifying the toxicity of hydrogen peroxide generated by the respiratory burst, and it catalyzes the formation of HOCl from chloride and hydrogen peroxide (see Fig. 21-7, reaction 4).[303,1171] HOCl, in turn, reacts with a variety of primary and sec-

ondary amines to form chloramines, some of which can be toxic.[233] Moreover, HOCl is capable of activating latent metalloproteinases. Based on these considerations, one would expect that severe MPO deficiency should attenuate important antimicrobial reactions catalyzed by HOCl. MPO-deficient mice have impaired host defense against *Candida* and *Klebsiella*.[1173,1174] Neutrophils from MPO-deficient patients show markedly abnormal in vitro killing of *C. albicans* and hyphal forms of *A. fumigatus*.[1171,1172] Curiously, however, these abnormalities are rarely reflected in an increased incidence of infection in patients, except for rare individuals who also suffer from diabetes mellitus.[1170,1172] In these individuals, disseminated candidiasis can be seen (Table 21-20). Several studies have suggested that MPO deficiency may also be associated with an increased susceptibility to malignancy.[1170,1175,1176]

Congenital MPO deficiency is inherited in an autosomal recessive manner,[1171,1172] and variable expression of the defect has been reported.[1176] The gene for MPO has been localized to the long arm of chromosome 17 at position q22-q23 near the breakpoint for the 15;17 translocation of promyelocytic leukemia.[1177,1178] The primary translation product is a 80-kd protein that undergoes cotranslational glycosylation and subsequent proteolytic cleavage to heavy and light chains, which oligomerize to form a tetramer composed of two heavy and two light chains.[1171] The molecular basis of congenital MPO deficiency reflects defects affecting MPO processing and heme incorporation. A variety of mutations have been reported.[1171] One common cause of complete absence of immunoreactive MPO is a point mutation that results in an arginine-to-tryptophan substitution at codon 569 (R569W).[1179,1180] The R569W mutation results in maturation arrest of the MPO apoprotein, which fails to incorporate heme.[1181]

In addition to inherited MPO deficiency, secondary or acquired MPO deficiency can occur. MPO-deficient cells can be seen in the M2, M3, and M4 forms of AML, as well as in approximately 25% of patients with MDS and CML.[1182,1183] Other clinical situations in which secondary MPO deficiency can occur include pregnancy, iron deficiency, lead poisoning, ceroid lipofuscinosis, and Hodgkin's disease.[1170]

There are several possible reasons for the surprisingly mild clinical phenotype of MPO deficiency. First, neutrophils contain such a large amount of MPO that appreciable levels may be left in the cell even in cases of severe deficiency. These residual stores, coupled with normal levels of eosinophil peroxidase, may provide at least some degree of peroxidative activity at sites of infection. Second, the respiratory burst in MPO-deficient neutrophils is substantially augmented in terms of velocity and duration.[1184,1185] This may be due to the enhanced stability of the respiratory burst oxidase made possible by the absence of HOCl, which normally inactivates the oxidase.[1186] Finally, other oxidants produced by the respiratory burst may work together with the various granule

TABLE 21-20	Summary of Myeloperoxidase Deficiency
Incidence	1 in 2000 (partial deficiency) 1 in 4000 (total deficiency)
Inheritance	Autosomal recessive with variable expression; myeloperoxidase gene on chromosome 17 at q22-q23
Molecular defect	Defective post-translational processing of an abnormal myeloperoxidase precursor polypeptide because of a variety of mutations; eosinophil peroxidase encoded by different gene, and levels normal
Pathogenesis	Partial or complete myeloperoxidase deficiency leads to diminished production of HOCl and HOCl-derived chloramines; myeloperoxidase products are necessary for rapid killing of microbes (especially *Candida*) but not absolutely required
Clinical manifestations	Usually clinically silent Rarely disseminated candidiasis/fungal disease (usually in conjunction with diabetes mellitus) May be increased risk of malignancy
Laboratory findings	Deficiency of neutrophil/monocyte peroxidase by histochemical analysis (eosinophil peroxidase normal) Delayed, but eventually normal killing of bacteria in vitro Failure to kill *Candida albicans* and hyphal forms of *Aspergillus fumigatus* in vitro
Differential diagnosis	Acquired partial myeloperoxidase deficiency seen in acute myelocytic leukemia (M2, M3, and M4), myelodysplastic syndromes, iron deficiency, or pregnancy
Therapy	None in asymptomatic patients Aggressive treatment of fungal infections when they occur Control of blood glucose levels in diabetes
Prognosis	Usually excellent

Modified from Curnutte JT. Disorders of phagocyte function. In Hoffman R, Benz EJ, Shattil S, et al (eds). Hematology: Basic Principles and Practice. New York, Churchill Livingstone, 1991, p 578.

antimicrobial proteins to provide sufficient protection against most microorganisms.

Given the mild clinical nature of MPO deficiency, no treatment is generally required. When they occur, infections are treated as in normal individuals. It is important for the clinician to be aware of the increased risk for *Candida* infections in MPO-deficient patients and to treat them aggressively when they do occur.

Disorders of Glutathione Metabolism

As shown in Figure 21-7 (reaction 6), glutathione peroxidase protects neutrophil proteins (including NADPH oxidase) from the harmful effects of the hydrogen peroxide generated in the course of the respiratory burst by degrading it to water. The reducing equivalents for this reaction are carried by the reduced form of glutathione (GSH), intracellular levels of which are maintained by recycling oxidized glutathione (GSSG) back to GSH by means of glutathione reductase (Fig. 21-7, reaction 7). Glutathione levels are also maintained through de novo synthesis catalyzed by glutathione synthetase (Fig. 21-7, reaction 9). Severe deficiencies of glutathione reductase and glutathione synthetase in neutrophils have been reported and found to cause moderately severe abnormalities in the respiratory burst.[1187-1191] The key features of each of these extremely rare disorders are summarized in Table 21-21.

Glutathione reductase deficiency has been reported in one family in which three siblings were found to have a marked deficiency of this enzyme in their neutrophils (10% to 15% of normal).[1187,1189] The inheritance appeared to be autosomal recessive inasmuch as the parents of the children were first cousins and their neutrophils contained 50% of the normal levels of glutathione reductase. The mutation responsible for the enzyme deficiency in this family has not been reported yet. It is known that the gene for glutathione reductase is located on chromosome 8 at position p21.1.[1192]

Clinically, none of the affected patients showed signs of increased infection. Their erythrocytes were also deficient in glutathione reductase and therefore were prone to hemolysis in the face of oxidant stress. Two siblings did suffer from juvenile cataracts and deafness. In vitro studies of neutrophil function were normal except for premature termination of the respiratory burst after about 5 minutes.[1187] The probable reason for this defect is that NADPH oxidase is inactivated by products of the MPO reaction.[1186] If glutathione reductase is deficient, the neutrophils cannot maintain a level of GSH sufficient to detoxify hydrogen peroxide. After several minutes of the respiratory burst, toxic levels of hydrogen peroxide accumulate and lead to deactivation of the oxidase. This explanation is supported by experiments showing that glutathione reductase–deficient neutrophils pre-exposed to exogenous hydrogen peroxide fail to undergo even an abbreviated respiratory burst. One important insight gained from the study of these patients is that only a brief respiratory burst appears to be necessary for adequate microbial killing.

The diagnosis of glutathione reductase deficiency is made by measuring levels of this enzyme in neutrophil homogenates. The finding of a truncated respiratory

TABLE 21-21	Disorders of Glutathione Metabolism	
Disease Aspect	**Glutathione Reductase Deficiency**	**Glutathione Synthetase Deficiency**
Incidence	One family, three siblings	Several reported cases
Inheritance	Autosomal recessive	Autosomal recessive
Molecular defect	Diminished glutathione reductase levels in neutrophils (10-15% of normal) and erythrocytes; mutation not known	Severe deficiency of glutathione synthetase activity (5-10% of normal); mutation(s) not know
Pathogenesis	Brief respiratory burst truncated by toxic accumulation of H_2O_2 by glutathione	Same as with glutathione reductase deficiency except that the respiratory burst is normal; elevated 5-oxoproline levels because of lack of feedback inhibition by glutathione
Clinical manifestations	No history of repeated infection Hemolysis with oxidant stress	Metabolic acidosis caused by elevated 5-oxoproline Otitis media Intermittent neutropenia Hemolysis with oxidant stress Severe decrease in glutathione synthetase level
Laboratory evaluation	Glutathione reductase level diminished	Normal respiratory burst
Differential diagnosis	Premature cessation of O_2^- production by neutrophils Chronic granulomatous disease Glucose-6-phosphate dehydrogenase deficiency	Glutathione reductase deficiency
Therapy	None required	Vitamin E for hemolysis and infections Treatment of metabolic acidosis
Prognosis	Benign disorder	Relatively benign disorder

burst provides supporting evidence, although a similar abnormality can be seen in G6PD deficiency. No therapy is required, but avoiding foods and drugs containing potent oxidants will decrease the chance of depleting intracellular glutathione.

Several forms of congenital glutathione synthetase deficiency have been described, all of which are inherited in an autosomal recessive fashion. Specific mutations have not been reported. Only in cases in which glutathione synthetase activity is severely deficient in neutrophils (5% to 10% of normal) is a phagocytic abnormality detected.[1188,1190,1191] In contrast to glutathione reductase deficiency, neutrophils deficient in glutathione synthetase have a normal respiratory burst.[1188,1191] For reasons that are uncertain, in vitro bacterial killing is decreased. Despite this in vitro microbicidal defect, patients with glutathione synthetase deficiency have only a relatively mild problem resolving infections. They do suffer from a severe metabolic acidosis resulting from elevated levels of 5-oxoproline, a metabolite formed in one of the early steps in the pathway of glutathione synthesis. This acidosis may be responsible for the intermittent neutropenia observed in glutathione synthetase–deficient patients.[1188] Because these patients' erythrocytes are also deficient in glutathione synthetase, a hemolytic anemia brought on by oxidant stress is seen. Therapy with vitamin E (400 IU/day) has been found to be beneficial in patients who suffer from hemolysis and infection.[1188]

Glutathione peroxidase (see Fig. 21-7, reaction 6) was found to be decreased to levels 25% of normal in three unrelated patients with a clinical syndrome resembling CGD.[1193,1194] Although this enzyme plays an important role in removing hydrogen peroxide, it has not been established whether the degree of deficiency seen in these patients is sufficient to cause functional abnormalities in neutrophils. Two of the affected kindreds have recently been restudied, and a severe deficiency of the respiratory burst oxidase flavocytochrome *b* has been identified in affected members of each.[1060] It thus appears that in at least two of these previously reported cases, CGD is the underlying problem, not glutathione peroxidase deficiency.

Disorders of Cytokines and Impaired Phagocyte Function

Inherited defects in the production and response to inflammatory cytokines by phagocytes or other cells of the immune system can be manifested as recurrent infections.[737] All of these disorders are rare. In addition to the disorders described later in this section, HIES is also due to defects in cytokine signaling. Sporadic and autosomal dominant cases of HIES result from mutations in STAT3, and autosomal aggressive HIES can result from defects in Tyk2, a JAK kinase family member.[818,825,826] HIES is discussed earlier in this chapter.

Defects in a group of genes regulating the production and macrophage response to IFN-γ are associated with recurrent and severe atypical mycobacterial infections, as well as *Salmonella* and viral infections in some subgroups.[737,1195-1197] The phenotype of this group of dis-

orders is also referred to as mendelian susceptibility to mycobacterial diseases (MSMD). The distinctive and limited spectrum of infections in affected patients results from defects in the IFN-γ pathway. IFN-γ is secreted by NK and T cells in response to IL-12 and IL-23 released by macrophages and dendritic cells. Some patients have autosomal recessive mutations in the p40 subunit of the IL-12 and IL-23 cytokines that lead to decreased expression of these cytokines, and another subgroup of patients have mutations in the β1 subunit of the receptor for IL-12 and IL-23; in both these groups, levels of IFN-γ are abnormally low. Other patients have autosomal recessive mutations affecting the IFN-γ receptor that lead to either loss of receptor expression or complete or partial loss of IFN-γ binding. Dominant IFN-γ receptor mutations resulting in partial IFN-γ receptor deficiency are also described. The phenotype is milder in patients with partial defects. Very rarely, patients have partial or complete deficiency of the STAT1 protein, which is critical for transduction of IFN-γ–mediated signals.

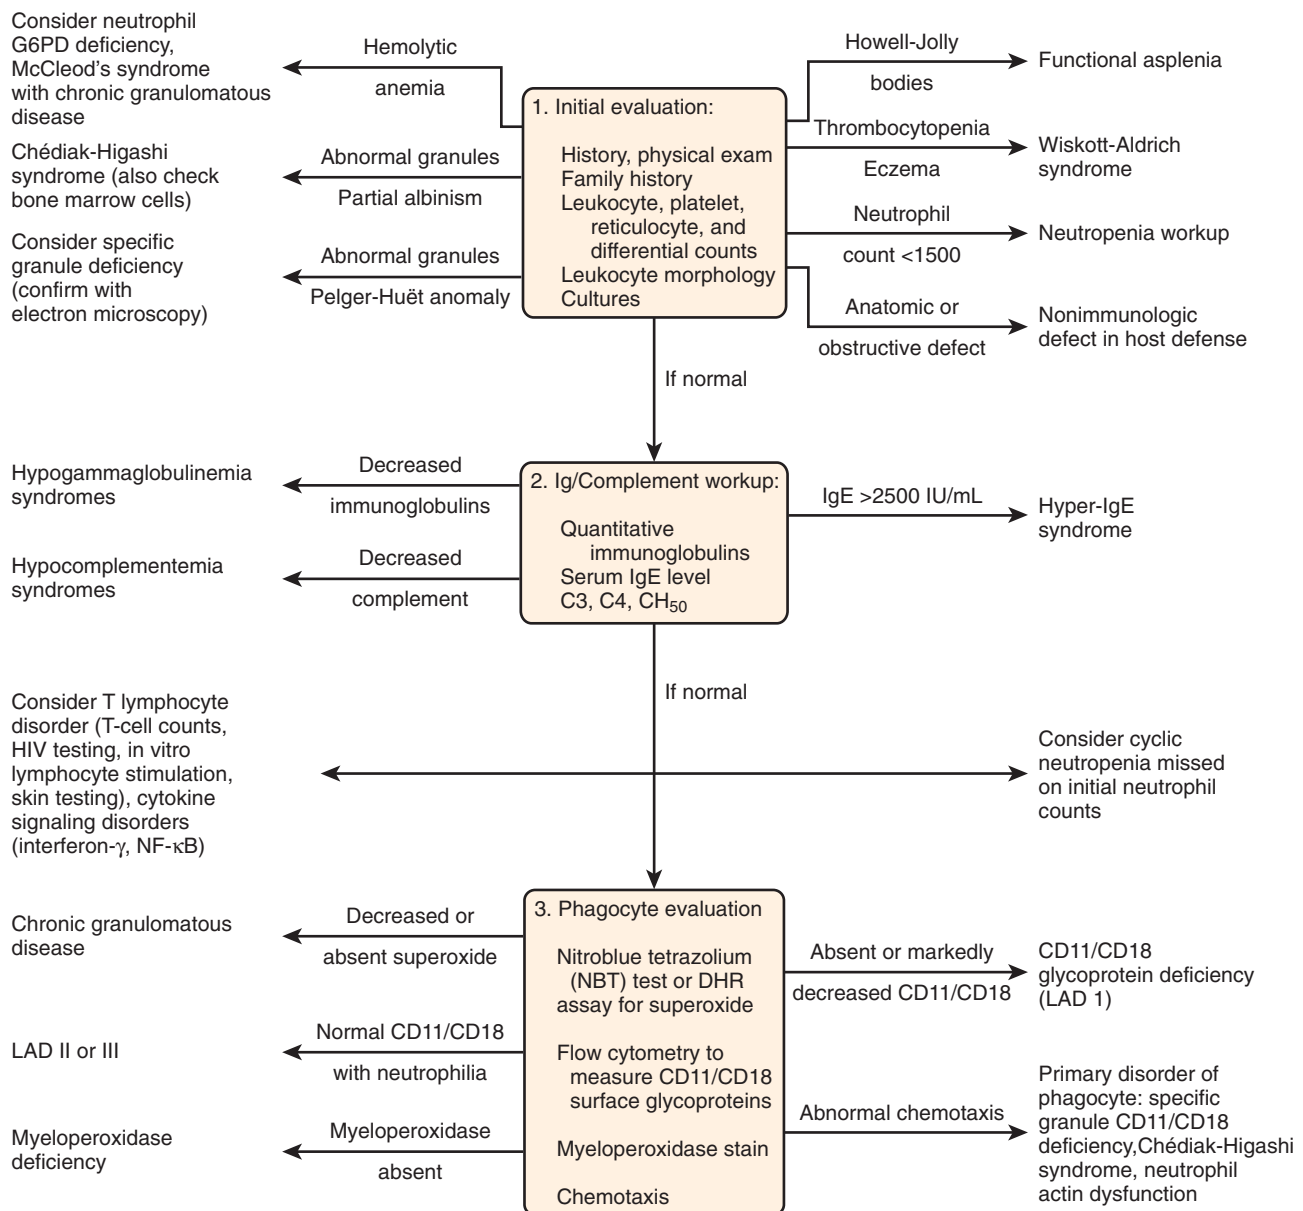
Recurrent pyogenic infections are characteristic of a group of genetic disorders involving the NF-κB signaling pathway. Included in this group are patients with autosomal recessive mutations in interleukin-1 receptor–associated kinase-4 (IRAK-4), a kinase in the Toll and IL-1 receptor signaling pathway.[737,1198,1199] Affected chil-


FIGURE 21-12. Algorithm for the workup of a patient with recurrent infections. The various tests are described in the appropriate sections of the chapter. G6PD, glucose-6-phosphate dehydrogenase; HIV, human immunodeficiency syndrome; Ig, immunoglobulin; LAD, leukocyte adhesion deficiency; NBT, nitroblue tetrazolium; O_2^-, superoxide. Units for the neutrophil count (box 1) are neutrophils/mm³. *(Adapted with permission from Lehrer RI, Ganz T, Selsted ME, et al. Neutrophils and host defense. Ann Intern Med. 1988;109:127-142.)*

dren have recurrent and sometimes fatal infections with *S. pneumoniae* and *S. aureus*, along with low or absent fever and inflammatory responses. Patients with the syndrome of anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID) have either X-linked recessive mutations in the gene encoding NEMO, a regulatory protein that activates NF-κB, or much less commonly, an autosomal dominant defect in IκBA, an NF-κB inhibitor. In addition to widely spaced abnormal teeth, hypohidrosis, and hypotrichosis, children with EDA-ID have recurrent pyogenic infections with a minimal systemic inflammatory response, and opportunistic infections with atypical mycobacteria, viruses, or *Pneumocystis carinii* can also develop.

Evaluation of Patients with Recurrent Infections

Patients with recurrent infections can be a diagnostic challenge. Many of the phagocyte disorders have similar clinical manifestations, which can overlap those seen in inherited or acquired disorders of lymphocyte function. Furthermore, the majority of patients with recurrent infections do not have an identifiable granulocyte or monocyte defect. Given this low yield and the lack of ability to characterize many aspects of phagocyte function in routine laboratory studies, physicians are faced with the difficult question of which patients merit a complete evaluation. Those who have at least one of the following clinical features are more likely to have a phagocyte defect: (1) an unusually high frequency of bacterial and fungal infections, (2) the presence of an infection at an unusual site (e.g., a hepatic or brain abscess), (3) infections with atypical pathogens (e.g., *Aspergillus* pneumonia, disseminated candidiasis, lymphadenitis secondary to *Serratia* or *Klebsiella*, disseminated mycobacterial infection), (4) infections of exceptional severity, and (5) childhood periodontal disease. Certain other clinical findings can also be helpful. For example, a child with nystagmus, fair skin, and recurrent staphylococcal infections should be evaluated for CHS, whereas an infant with neutrophilia, bacterial infections, and delayed separation of the umbilical cord should be tested for LAD. Once the physician has decided that a phagocyte evaluation is warranted, the algorithm presented in Figure 21-12 may be helpful in organizing the workup. When coupled with a thorough clinical history and physical examination, the laboratory tests outlined in Figure 21-12 should help the physician establish the diagnosis and formulate an appropriate therapeutic plan.

22 | The Immune Response

Sung-Yun Pai and Barbara Bierer

The immune system is a complex network of cells that serve to discriminate "self" from "nonself," that is, to recognize one cell as one's own and another cell as foreign or infected. This capacity helps protect the organism from infection by foreign pathogens (bacteria, viruses, and parasites) and from malignant degeneration. In addition, the cells involved in the immune response mediate rejection of foreign allografts. Although immune cells recognize and respond to all manner of foreign elements, at the same time they must not respond inappropriately to self-antigen. Education of immune cells results in a state of immunologic tolerance, that is, the absence of destructive antiself immune responses. Failure of self versus nonself discrimination, or failure of immunologic tolerance, may result in autoimmunity.

Whereas collectively a number of different kinds of cells are involved in the response to infection, the cells involved in mediating adaptive immunity are lymphocytes (Table 22-1). The adaptive immune response is broadly classified into two categories: (1) humoral immunity, mediated by antibodies produced by B lymphocytes and their progeny; and (2) cell-mediated immunity, dependent on cell-cell interactions and mediated by T lymphocytes. Both T and B lymphocytes are derived from early hematopoietic stem cells (HSCs) and are distinguished not by morphology but by rearrangement of their antigen-specific receptors, by function, and by the expression of different cell surface molecules. In addition to adaptive immunity, natural or innate immune mechanisms also work to defend an individual from pathogens (see Table 22-1). Natural killer (NK) cells, also derived from bone marrow progenitors, serve as principal components of innate immunity and are discussed briefly later in this chapter. In addition, polymorphonuclear leukocytes (neutrophils), eosinophils, macrophages, and other myeloid cells are important components of the body's early defense against microorganisms and are discussed in Chapter 21.

The acquired or adaptive immune response is mediated in large part by the recognition of a variety of cell surface proteins encoded by genes of the major histocompatibility complex (MHC). The MHC, located in the human genome on the short arm of chromosome 6, encodes two classes of proteins, MHC class I and MHC class II, that are highly polymorphic within the population and involved in the immune response. In humans, these genes are termed human leukocyte antigens (HLA

class I and HLA class II), as defined further later. In addition to HLA determinants, the MHC also encodes several secreted proteins of the complement system, selected immune modulators such as tumor necrosis factor (TNF), and specific proteins required for proper processing of antigen.

In addition to self-nonself discrimination, the adaptive immune response is further characterized by immunologic specificity and by memory. Acquired resistance to one antigen does not confer resistance to another unrelated (non–cross-reactive) antigen. The immune response must be capable of eliminating a foreign pathogen and developing mechanisms so that a second exposure to the same agent results not in worse disease but in more rapid elimination of the foreign agent. Cells previously exposed to and specific for one foreign protein or antigen respond more rapidly and more effectively to subsequent exposure to that same antigen, thereby leading to an anamnestic or secondary immune response. The immune response is highly regulated; cooperativity between different cellular elements and between cells and soluble mediators leads to modulation (i.e., amplification or suppression) of the immune response.

Technical advances, including single-cell cloning, monoclonal antibody production, generation of transgenic and knockout animals, and sequencing of the genome, have led to a veritable explosion in the number of cell surface proteins, cytokines, and chemokines discovered. The nomenclature has evolved and can be confusing. Cell surface proteins are generally named by a cluster of differentiation (CD) assignment; the website http://mpr.nci.nih.gov/prow/ is continuously updated with an annotated description of each CD and links to other relevant sites. Interleukins, the name given to soluble factors secreted by leukocytes or that act on leukocytes, or both, are named by the International Union of Immunologic Societies and can be found along with their receptors at http://www.genenames.org/genefamily/il.php. This chapter will focus on specific or acquired immunity and principally on the differentiation and function of B and T lymphocytes.

LYMPHOCYTE DEVELOPMENT

All B cells, T cells, and NK cells derive from pluripotent HSCs that arise first in fetal liver and then postnatally in

TABLE 22-1	Innate versus Acquired Immunity	
	Innate Immunity	**Acquired Immunity**
Specificity	Nonself	Random (in the context of self)
Effector cell type	Polymorphonuclear leukocytes (PMNs, neutrophils), natural killer cells, macrophages, eosinophils, etc.	Lymphocytes: B and T cells
Cell surface receptors	Germline	Rearranged
Distribution	Nonclonal	Clonal
Kinetics of the initial response	Rapid and immediate	Slow

the bone marrow. HSCs differentiate in the bone marrow and migrate to the appropriate lymphoid organs. These HSCs express cell surface CD34, a heavily glycosylated protein of 105 to 120 kd.[1] Although CD34 serves as a marker for hematopoietic progenitors, its expression is not limited to these cells alone. CD34 is also expressed on early lymphoid (but not pluripotent) progenitors, endothelial cells in small vessels, some embryonic fibroblasts, and some cells in the nervous system.[2] CD34 may be involved in cell-cell adhesion[3] and may be important for inhibition of hematopoietic differentiation.[4] CD34+ hematopoietic precursors give rise to both myeloid and lymphoid early progenitors. Early myeloid differentiation derives from common myeloid progenitors (CMPs), which can give rise to common granulocyte/monocyte precursors (GMPs) or megakaryocyte/erythroid precursors (MEPs). The common lymphoid progenitor (CLP) differentiates into cells of the T (and NK) and B lineage. Dendritic cells can be generated in vitro from CD34+ bone marrow cells exposed to certain cytokines, but the relevant in vivo precursor population remains controversial,[5] with the most recent data showing that CLP, CMP, and GMP all contain dendritic cell potential.[6-8] T-lymphocyte differentiation occurs largely in the thymus and is discussed in detail later. B-cell maturation occurs in the bone marrow and peripheral lymphoid organs.

Naïve B and T cells released into the peripheral blood have exquisite specificity. These resting B and T cells circulate in a quiescent state and function only after encountering cognate antigen (i.e., the specific substance that the lymphocyte recognizes). Recognition of antigen alone is generally insufficient to trigger lymphocyte activation; both B and T cells require other so-called costimulatory signals, in the form of cell surface receptor engagement or soluble factors, for effector function. Recognition of antigen by T cells and the costimulatory signals for both B and T cells are typically mediated by accessory cells of the innate immune system termed antigen-presenting cells (APCs). Lymphocytes activated by specific antigen in the appropriate costimulatory context proliferate and mature into effector cells, a portion of which eventually differentiate into long-lived memory cells. The specifics of peripheral maturation, costimulation, and function of B and T cells are detailed in later sections.

LYMPHOCYTE SPECIFICITY

Immunologic specificity is conferred by antigen-specific receptors expressed on the surface of B and T lymphocytes and by specific antibodies (immunoglobulins [Igs]) secreted by B cells and plasma cells (Fig. 22-1). Individual lymphocytes have only one specific antigen to which it can respond. Each T cell expresses a unique T-cell receptor (TCR) and each B cell a unique Ig that can either be displayed on the surface (B-cell receptor [BCR]) or be secreted. The membrane BCR and secreted Ig of the B cell interact with epitopes expressed by naïve antigens, largely protein and nonprotein antigens such as complex epitopes of glycoproteins, lipids, and nucleic acids. Unlike Ig, the TCR recognizes small (9 to 20 amino acids) processed oligopeptides bound within the cleft of an MHC molecule on the surface of an accessory cell termed an APC. Dendritic cells, B cells, monocytes/macrophages, epithelial Langerhans cells, and in humans, endothelial cells function efficiently as APCs. These APCs bear costimulatory molecules on their cell surface (see later), secrete cytokines, and process antigen; it is the complex formed between the processed peptide fragment of antigen and MHC proteins that interacts with the TCR. Exposure to antigen induces activation of only

FIGURE 22-1. Characteristics of B and T lymphocytes. Both B and T lymphocytes have rearranged immune system receptors. Immunoglobulin (Ig) molecules are expressed on the surface of cells, whereas T cells are characterized by expression of the clonotypic T-cell receptor complexed to CD3 chains. Other important differences are listed.

	B lymphocyte	**T lymphocyte**
	(image)	(image)
Antigen-specific receptor	Surface immunoglobulin (IgM, IgD)	T cell receptor (αβ or γδ)
Surface signaling molecules	Ig-α, Ig-β	CD3, ζ family
Surface molecules	CD19, CD22, FcR	CD4, CD8, CD2, CD28
Principal site of development	Bone marrow	Thymus
Effector function	Humoral immunity: antibody secretion	Cell-mediated immunity: cytokine production, cytolysis regulatory role
lymphocytes that bear Ig receptors or TCRs specific for that antigen. Any individual, however, has approximately 10^7 different T-cell and 10^7 to 10^9 different B-cell specificities. It is this clonal variability and diversity of the lymphocyte repertoire that maintain effective protection against foreign invasion.

B-CELL ONTOGENY

The first phase of B-cell maturation occurs in the bone marrow, where HSCs committed to B-lymphoid lineage develop into immature IgM$^+$ IgD$^-$ B cells. The immature B cells exit the bone marrow, circulate in peripheral tissues, and mature further (Fig. 22-2). The most critical steps in B-cell development at this stage involve the expression of Ig molecules on the surface as BCR, whose specificity is the same as the antibody that will ultimately be secreted by activated mature B-cell progeny. The diversity of the B-cell repertoire is due in large part to random rearrangement of multiple germline genes for Ig that are spliced to encode a unique Ig molecule for each cell. Highly regulated checkpoints ensure that only B cells that successfully rearrange Ig genes are selected for survival.[9-11] Elimination of B cells whose receptors have high affinity for self-antigens is important to prevent autoreactivity. Finally, immature B cells released from the bone marrow complete their development in the spleen and differentiate into at least two distinct lineages of mature naïve B cells: follicular B cells and marginal-zone B cells.

Immunoglobulin Structure

The structures of antibody molecules all share remarkable conservation of secondary conformation. The Ig-like fold is a domain shared among diverse proteins, each with signature hydrophobic common cores and common disulfide bridges. The antibody molecule is the prototype member of the Ig supergene family, a group that includes not only Ig but also TCR, the MHC, and a number of costimulatory molecules. Each Ig molecule is composed of two light chains of approximately 25 kd and two heavy chains of approximately 50 or 70 kd (Fig. 22-3); each chain is composed of multiple Ig domains. B-cell antibodies can be subdivided by heavy-chain isotype and further subdivided by subclass (Table 22-2).

There are five classes of antibodies—IgM, IgG, IgA, IgD, and IgE—defined by expression of the heavy chain: μ, γ, α, δ, and ε. The Ig heavy chains contain sites for binding of Fc receptor (FcR) and complement, and each subtype appears to have a particular role in immune defense. The first class of antibody to be produced during development is IgM, which is expressed on the surface as a monomer and secreted as a pentamer. B cells that have undergone class switching (see later) express IgG, IgA, IgD, or IgE on the surface as the BCR or secrete a splice form of the Ig with the same heavy-chain isotype and specificity but lacking a transmembrane region (or both). The function of IgD in humans is not clear, although its expression is a marker for later B-cell development. IgA is secreted as a dimer and is found at mucosal surfaces such as the intestine. The bulk
FIGURE 22-2. Overview of B-cell development. Pro-B cells develop from pluripotent hematopoietic stem cells (HSC) in bone marrow and acquire cell surface markers such as the pan-B-cell marker CD19, CD10, and terminal deoxynucleotidyl transferase (TdT). Serial rearrangement of the heavy and light chain loci drives expression of first the pre-B-cell receptor (pre-BCR) and later the B-cell receptor or surface IgM (sIgM). Downregulation of early markers at the pre-B stage gives way to expression of markers of immature and mature B cells, such as CD20, CD21, and CD22. Activation of the B cell with appropriate T-cell help leads to isotype switching and the expression of either IgA, IgG, or IgE. Switched B cells that form memory cells are characterized by expression of CD27 and downregulation of IgD, whereas activated B cells that proceed to the plasma cell stage lose most B-cell markers, upregulate CD38 and CD138, and secrete high levels of soluble specific antibody.

FIGURE 22-3. Diagrammatic representation of the immunoglobulin (Ig) molecule. The Ig molecule has two light chains of approximately 25 kd, each with two Ig domains (C_L and V_L), and two heavy chains of 50 to 70 kd, each composed of four Ig domains (C_H1, C_H2, C_H3, and V_H). The antigen binding region is defined by the variable regions of the heavy and light chains (V_H and V_L). There are five subclasses of the heavy chain: IgG, IgA, IgM, IgD, and IgE.
of circulating Ig is in the form of IgG, which is monomeric and further subdivided into four subclasses: IgG1, IgG2, IgG3, and IgG4. Persistently low serum levels of one or more IgG subclasses,[12,13] in the presence or absence of IgA deficiency,[14] may cause individuals to be susceptible to recurrent infections.[15] Though controversial, prophylactic use of intravenous Ig has been suggested.[16,17]

There are two subclasses of light chains: κ and λ (see Fig. 22-3). Both subclasses appear to serve similar functions. Monoclonal disorders of terminally differentiated mature B cells or plasma cells (e.g., multiple myeloma) express cells of a given light chain, that is, either κ or λ but not both.

The structure of each Ig molecule is determined by hydrophobic interactions and disulfide bridges between the two heavy chains and two light chains (see Fig. 22-3). For each chain the N-terminal domain has a variable or polymorphic amino acid structure (V_H for heavy chain, V_L for light chain), whereas the C-terminal portions are constant within each heavy-chain or light-chain class (termed C_H1, C_H2, C_H3 for heavy chain and C_L for light chain). These domains form pairs, V_H with V_L, C_H1 with C_L, and C_H3 with C_H3. Proteolytic digestion of Ig by papain results in two Fab fragments, each composed of the V_H/V_L, C_H1/C_L domains, and an Fc fragment composed of the two C_H2 and two C_H3 domains. The binding region of Ig that recognizes antigen is composed of portions of the V_H and V_L domains. Within each variable region there are three portions with increased amino acid variation, called hypervariable regions (HV1, HV2, HV3) or complementarity-determining regions (CDR1, CDR2, CDR3). The highest variability is found in CDR3, and all three CDRs from both chains participate in the

binding of antigen. Variability within each variable region and each CDR and pairing of a unique heavy chain with a unique light chain all contribute to the combinatorial diversity of Ig specificity.

Immunoglobulin Rearrangement and B-Cell Maturation in Bone Marrow

The genes encoding the heavy chains of Ig are located on human chromosome 14, whereas the genes encoding κ and λ light chains are located on chromosomes 2 and 22, respectively. The heavy- and light-chain loci are each composed of variable (V), diversity (D), and joining (J) gene segments that recombine to yield the V_H and V_L domains, which in turn form the antigen contact surface of the antibody molecule and confer specificity. In addition, the heavy-chain locus contains nine heavy-chain constant (C) region genes (μ, δ, γ1, γ2, γ3, γ4, α1, α2, and ε constant regions) that define the mature Ig isotype.

Ig rearrangement occurs serially, and cells failing to rearrange the Ig genes successfully are eliminated and do not develop further (Fig. 22-4). B-cell maturation also results in cell surface protein expression patterns that are used to define the pro-B-cell, pre-B-cell, and immature B-cell stages of development. $CD34^+$ $CD19^-$ $CD10^-$ progenitors that have not yet committed to the B lineage have Ig genes in the germline configuration. The earliest B-cell precursors express the pan-B-cell marker CD19 and the early marker CD10. They also express components of the rearrangement machinery such as recombination-activating genes (RAGs) and thus have early gene rearrangements detectable. Rearrangement begins with

TABLE 22-2   Immunoglobulin Subclass Definition

Class	Isotype	Heavy Chain	Molecular Formula	Molecular Mass (kd)	Plasma Concentration (mg/mL)*	Cross Placenta	Fix Complement	Biologic Functions
IgG								Complement activation, opsonization for Fc receptor
	IgG1	γ1	$\gamma 1_2 \kappa_2$ $\gamma 1_2 \lambda_2$	150	7-9	+	+	Antitoxins, antibody to most bacterial antigens
	IgG2	γ2	$\gamma 2_2 \kappa_2$ $\gamma 2_2 \lambda_2$	150	2-3	+	+	Antipolysaccharide antibodies to bacterial capsules
	IgG3	γ3	$\gamma 3_2 \kappa_2$ $\gamma 3_2 \lambda_2$	150	0.7-1	+	+	Cytophilic antibodies, e.g., to Rh antigens
	IgG4	γ4	$\gamma 4_2 \kappa 2$ $\gamma 4_2 \lambda_2$	150	0.3-0.5	+	–	Anticoagulants, such as anti–factor VIII in hemophiliacs
IgM		μ	$(\mu_2 \kappa_2)_5$ $(\mu_2 \lambda_2)_5$	950	1.5	–	+	Receptor in B-lymphocyte membrane, antibodies to lipopolysaccharides, complement activation, natural antibody
IgA				150 or 300				Present in external secretions, alternative complement activation (?)
	IgA1	α1	$\alpha 1_2 \kappa_2$ $\alpha 1_2 \lambda_2$		1-3	–	–	Virus-neutralizing antibody
	IgA2	α2	$(\alpha 2_2 \kappa_2)_2$		0.5-0.7	–	–	Principal secretory antibody
IgD		δ	$\delta_2 \lambda_2$ $\delta_2 \kappa_2$	180	0.3	–	–	Unknown, receptor in B lymphocyte membrane
IgE		ε	$\varepsilon_2 \lambda_2$ $\varepsilon_2 \kappa_2$	190	0.0005[†]	–	–	Anaphylactic antibodies or "reagins," binds to mast cells, mediator of release

*Plasma concentrations of the immunoglobulins vary significantly with age in pediatric populations. Adult norms are given here. IgG at birth reflects maternally transferred immunoglobulin and wanes over several months, with a nadir at approximately 4 months and rising thereafter as the infant's own production takes over. IgM and IgA levels rise with age during infancy and childhood.

[†]Usually expressed as international units; up to 200 IU is considered normal.

one heavy-chain allele; one of the 29 D_H exons is spliced to one of the 6 J_H exons, the intervening D and J sequences are eliminated, and a DJ segment is produced. The pro-B cell then splices one of the approximately 50 V_H exons to the DJ segment to form a V(D)J segment. Finally, the μ constant region of the heavy chain (C_μ) is spliced onto the V(D)J segments.

Differentiation to the pre-B stage is triggered by expression of intact μ heavy-chain protein or cytoplasmic μ, which occurs only in cells that bear in-frame productive V(D)J-C_μ rearrangements. If rearrangement of the first heavy-chain locus is unsuccessful, the second allele undergoes rearrangement. Because the light-chain genes have not yet been expressed, cytoplasmic μ complexes instead with the nonpolymorphic surrogate light-chain proteins λ5 and VpreB. Cytoplasmic μ, surrogate light

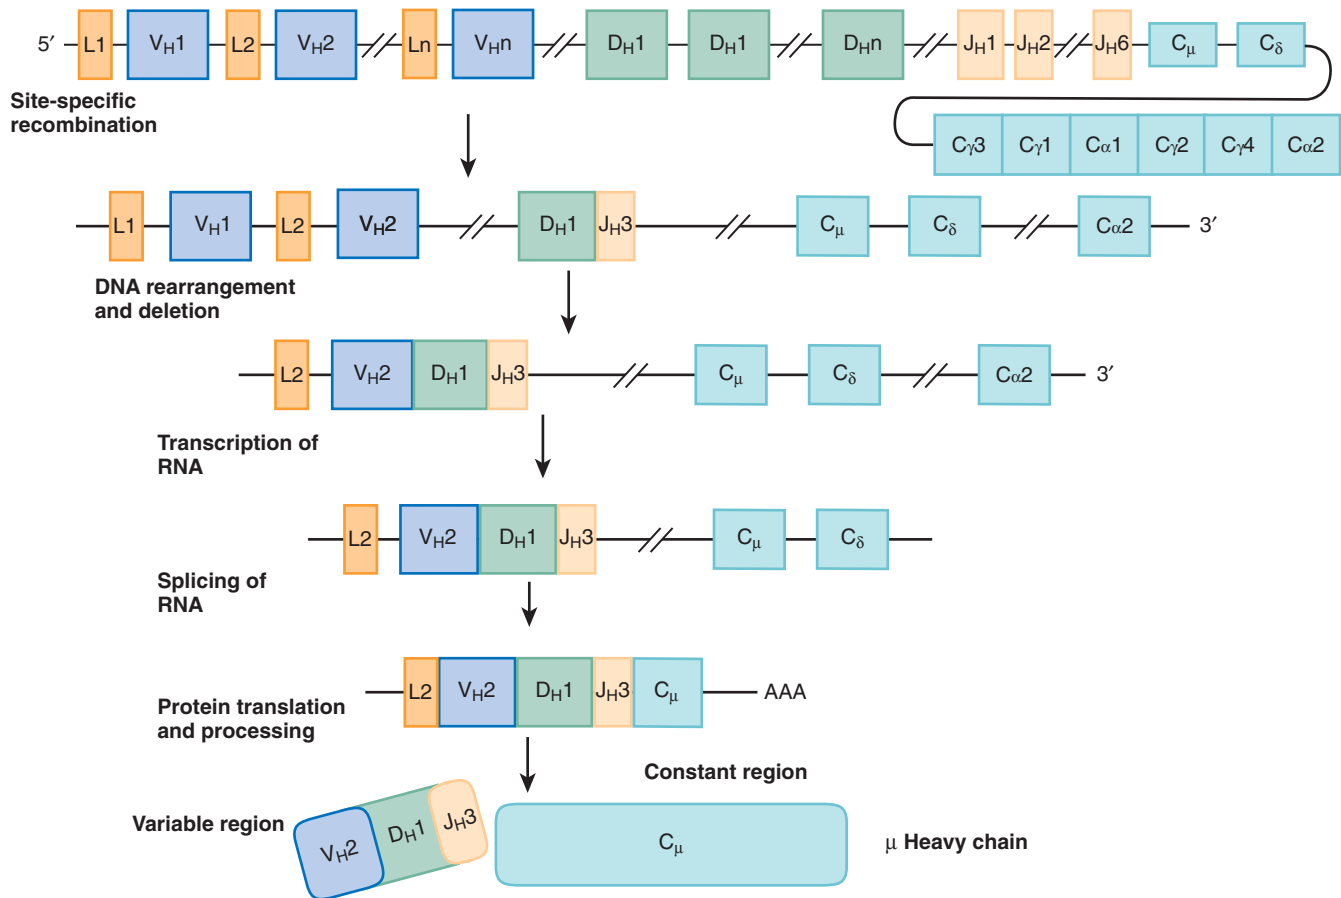
chain, and the accessory signaling molecules Ig-α (CD79a) and Ig-β (CD79b) together form the pre-B-cell receptor. Ensuing signals induce proliferation and instruct the cell to begin rearrangement of one of the κ light-chain loci. Pre-B cells lose CD34 expression, continue to express CD19 and CD10, and additionally upregulate CD20. The signaling cascade downstream of the pre-B-cell receptor is highly analogous to that of the mature BCR and activates a number of critical kinases, including Bruton's tyrosine kinase (Btk) (see later). Boys born with mutations in Btk, manifested as X-linked agammaglobulinemia, have normal numbers of pro-B cells but lack pre-B cells and their progeny.[18] Thus, formation of the pre-B-cell receptor along with activation of downstream signaling is a critical checkpoint in this stage of maturation.


FIGURE 22-4. Immunoglobulin rearrangement. Immunoglobulin genes are encoded on human chromosome 14. Approximately 100 variable (V) genes, 50 diversity (D) genes, and 4 to 6 joining (J) genes make up the heavy-chain variable locus. The constant region consists of nine constant (C) genes. During immunoglobulin gene rearrangement, gene segments are deleted so that specific regions are joined to form one of many individual and characteristic genes.

Light-chain genes rearrange by a process similar to the recombination of heavy-chain genes. The variable region of the κ gene, located on chromosome 2, is spliced to the J gene segment to produce a VJ region, which then splices to the one constant region (C_κ). If nonproductive, the second κ locus will rearrange. If both attempts to rearrange the κ locus are unsuccessful, the λ locus, located on chromosome 22, will begin to rearrange. Productive rearrangement of any light-chain locus prevents further B-cell rearrangement and also generates survival signals. Pre-B cells that successfully rearrange a light-chain gene will then express mature IgM protein, which appears as surface IgM (sIgM) complexed to Ig-α and Ig-β, thus forming the BCR. Immature B cells are sIgM[+], CD79[+], CD19[+], CD10[+], and CD20[+] but have not acquired IgD expression, which occurs after peripheral maturation.

Expression of the tissue-specific recombination-activating genes RAG-1 and RAG-2 is required for recombination.[19,20] In addition, diversity is enhanced by the fact that the junctions between the D and J regions and the V and DJ regions are not precise; not only can the nucleotides vary, but one or more nucleotides (termed N regions), not encoded in the genome, may also be randomly inserted (N-region diversification). The nuclear enzyme terminal deoxyribonucleotidyl transferase (TdT) is the polymerase that adds random nucleotides to recombination junctions[21] and may have other roles.[22] Recruitment of TdT to the junctions appears to depend on the Ku molecule (specifically Ku80), a heterodimer that binds DNA ends and is required for V(D)J recombination and DNA double-stranded break repair.[23,24] Other proteins critical for nonhomologous end rejoining include Ku70, DNA-dependent protein kinase, DNA ligase IV, XRCC4, and the recently cloned protein Artemis.[25] Defects in the recombination machinery in genes such as RAG1, RAG2, DNA ligase IV, and Artemis all result in severe combined immunodeficiency (see Chapter 23).[26-28]

Peripheral B-Cell Maturation and Differentiation

Immature B cells must undergo further maturation in the spleen before acquiring the phenotype and functions of a naïve mature B cell. Naïve mature B cells are resting cells in G_0 phase; express the pan-B-cell marker CD19, the marker CD20, and sIgM; and in contrast to immature bone marrow B cells, have lost CD10 expression and

gained IgD expression. A similar population in the mouse is believed to be the common precursor for both follicular and marginal-zone B cells, named for their location within the spleen.[29]

The spleen has a complex architecture divided grossly into red pulp and white pulp. The red pulp contains the sinusoids, which are lined by macrophages, and the cords of Billroth, which lie between the sinusoids and are composed of connective tissue, epithelial cells, monocytes, and macrophages. The white pulp is composed of primary follicles containing naïve mature B cells that co-express IgM and IgD, as well as secondary follicles containing activated B cells within its germinal center (GC), all termed follicular B cells. Naïve follicular B cells in the primary follicle are CD27⁻, in contrast to memory B cells, discussed later, which express CD27.[30,31]

In the mouse, T cells congregate around the central arteriole in the so-called periarteriolar lymphoid sheath (PALS) studded by follicles and GCs containing B cells; the marginal zone delineates the white pulp from the red and surrounds both the follicles and PALS. In humans, by contrast, T cells and B cells tend to interdigitate, and the follicles are encompassed within the PALS. The marginal zone in humans is positioned around the follicles, does not envelop the PALS, and is not in direct contact with red pulp.[32] Marginal zone B cells are IgM⁺ IgD⁻ CD1c⁺ CD23⁻ and thus are distinguished from follicular B cells (IgM⁻ IgD⁺ CD1c⁻ CD23⁺).[29] Additionally, marginal-zone B cells express high levels of CD21 and as a result are highly responsive to complement. Finally, in contrast to rodent marginal-zone B cells, which are sessile, marginal-zone B cells in humans can circulate in blood and have a memory phenotype, being IgM⁺ IgD⁺ CD27⁺.[33]

The development of early B precursors into immature B cells is a process that requires Ig rearrangement and expression of the pre-B-cell receptor and BCR, but it does not require recognition of antigen. Maturation to the naïve resting B cell involves selection of B cells that recognize antigen (positive selection) while eliminating B cells whose BCR recognize self-antigens with high affinity (negative selection). It has been proposed, based on murine data, that determination of mature B-cell fate relies on the relative signal strength and specificity of the BCR, with higher and lower signal strength driving to the follicular and marginal-zone lineages, respectively.[29] Negative selection in particular is important for the deletion of potentially autoreactive clones and induction of B-cell tolerance. Indeed, it is estimated that 55% to 75% of immature B cells in humans recognize self-antigens,[34] and thus a minority of developing B cells pass the negative-selection test.

B-CELL ACTIVATION AND FUNCTION

An appropriately diverse population of naïve B cells should collectively be capable of responding to any soluble antigen that the individual encounters, yet there are very few naïve B cells that are capable of recognizing any given antigen. B-cell activation that occurs in the appropriate costimulatory context is the trigger for clonal expansion of the responding B cell. A portion of these activated B cells differentiate into memory cells, which rapidly respond upon re-encounter with the same antigen, and another portion into plasma cells, which continuously secrete antibodies (see Fig. 22-2). In addition, activated B cells undergo isotype switching from low-affinity IgM to high-affinity IgG, IgA, or IgE and somatic hypermutation, also called affinity maturation, thus further ensuring that the humoral response is exquisitely specific, effective, and long lasting. Recognition of antigen by the BCR occurs with or without T-cell help, depending on the type of antigen, so-called thymus-dependent (TD) or thymus-independent (TI) antigens. BCR signals that occur during TD responses are modulated and enhanced by cell-cell contact with T cells via critical costimulatory molecules, discussed further in the section on T-cell costimulation.

Thymus-Dependent versus Thymus-Independent B-Cell Responses

Unlike T cells, which recognize either short peptides or small lipid molecules that must be presented in the cleft of an MHC or MHC-like molecule, the BCR is capable of binding a variety of antigens, including soluble proteins and polysaccharides. Recognition of protein antigen generally requires cooperation with T cells, or T-cell help, and thus such antigens are TD antigens. Naïve follicular B cells in lymph node follicles or the spleen recognize their cognate antigen while contacting a helper T cell specific for the same antigen; linked T-B interaction then fuels the formation of a key structure, the GC, where isotype switching, somatic hypermutation, memory cell generation, and plasma cell differentiation occur.

TI antigens are classified as type 1 or type 2 (TI-1 and TI-2).[35] TI-1 antigens are bacterial components that can trigger B-cell activation regardless of Ig specificity and thus lead to polyclonal activation. These components fall into the general category of pathogen-associated molecular pattern (PAMP) molecules, the canonic example being lipopolysaccharide (LPS). PAMP molecules activate B cells by binding to a distinct family of receptors, the Toll-like receptors (TLRs), thereby accounting for their independence from Ig. The Ig secreted in response to TI-1 antigens is typically low-affinity IgM because TI-1 antigen binding does not induce class switching.[36]

TI-2 antigens, in contrast, are molecules that have a repetitive structure and activate B cells by cross-linking of multiple BCRs on a single cell, hence leading to specific clonal antibody production. These antigens are typically bacterially derived polysaccharides, such as those found in the coating of encapsulated organisms. Mar-

ginal-zone B cells are important for responses to TI-2 antigens, and the fact that marginal-zone B cells typically take years to mature in children probably underlies the lack of response of children younger than 2 years to polysaccharides.[29] The spleen is the major site of TI-2 antigen recognition, and the antibody produced again is often IgM, although IgG responses also clearly occur. Class switching in this instance does not depend on cognate T-cell help but probably is enhanced by noncontact T-cell factors such as the cytokine interleukin-4 (IL-4).[35]

B-Cell Receptor Triggering and Signaling

B-cell activation involves a complex array of molecular signaling events. The signaling cascades that emanate from the BCR are highly analogous to those triggered in T cells by the TCR and involve a host of kinases, adaptor proteins, and other enzymes.

In brief, B-cell activation commences with engagement of surface Ig, which initiates receptor oligomerization, an event that depends on B-cell coreceptors such as the stimulatory CD19 and CD21 receptors and the inhibitory low-affinity FcR.[37-40] In addition, aggregation of Ig receptors takes place in specialized membrane microdomains, termed lipid rafts, that are characterized by their cholesterol- and sphingolipid-rich content.[41-44] In cellular systems, lipid rafts have been postulated to function in intracellular trafficking, apical sorting, and signal transduction.[45,46] In both T and B lymphocytes, lipid raft components may function as a potential signaling platform to foster the aggregation and colocalization of signaling proteins.[41,47-49]

Within the lipid raft, the Ig molecule transmits signals through the associated Ig-α and Ig-β molecules (Fig. 22-5), together termed the BCR; the BCR, like other members of the immune recognition receptors, has no intrinsic tyrosine kinase activity. Upon oligomerization, the cytoplasmic domains of Ig-α and Ig-β become tyrosine phosphorylated on so-called immunoreceptor tyrosine–based activation motifs (ITAMs) with the amino acid consensus sequence D/ExxYxxL/Ix7YxxL/I. Phosphorylation of ITAMs is mediated by Src kinase family members, notably Fyn, Blk, and Lyn (see Fig. 22-5),[49-51]
FIGURE 22-5. Schematic of B- and T-cell signaling pathways. Signaling cascades that emanate after engagement of antigen-specific receptors, the B-cell receptor (BCR) in B cells (*left*) and the T-cell receptor (TCR) in T cells (*right*), are depicted. Each receptor has short cytoplasmic tails that do not themselves signal; the receptors signal instead via a complex of associated transmembrane molecules (Ig-α, Ig-β for B cells and the CD3 γ, δ, ε, and ζ proteins for T cells) that have immunoreceptor tyrosine–based activation motifs (ITAMs, depicted as *blue boxes*). Phosphorylation of ITAMs by early protein tyrosine kinases such as Lyn and Lck is critical for recruitment of Syk in B cells and ZAP70 in T cells, which go on to trigger the rest of the cascade. Adaptor proteins such as SLP65 and SLP76 nucleate a host of signaling molecules to activate Ras and protein kinase C (PKC) and increase intracellular calcium (Ca). The final effects of proliferation, cytoskeletal reorganization, and transcriptional activation ensue. B and T cells share a number of intermediates such as phospholipase C γ (PLCγ), Grb2, Sos, Ras, and Vav. Related molecules specific to B or T cells are depicted with similar shapes (e.g., SLP65/SLP76, Btk/Itk). DAG, diacylglycerol; MAPK, mitogen-activated protein kinase; MEK, MAPK kinase; MEKK, MEK kinase.

which then recruit the critical tyrosine kinase Syk via its Src homology 2 (SH2) domains. Syk itself, when bound, requires activation either by autophosphorylation or phosphorylation by Src kinases, and thus clustering of multiple ITAM-bearing BCRs, Src kinases, and Syk is required to achieve a threshold of activation that initiates downstream cascades.[52]

Activation of Syk, similar to activation of ZAP70 in T cells (see later), is a crucial lynchpin in BCR signaling. Syk itself functions as a tyrosine kinase and is capable of phosphorylating key substrates, which then activate three main signals, the protein kinase C (PKC), intracellular calcium, and Ras pathways. Activation of these pathways occurs by assembly of a macromolecular complex of critical signaling molecules clustered on an adaptor protein known as the B-cell linker protein (BLNK) or SLP65.[51] Recruitment of a member of the Tec kinase family, Btk, to SLP65 via the SH2 and Src homology 3 (SH3) domains and to the membrane by the Pleckstrin homology (PH) domain activates Btk.[53] The critical nature of Btk activation in BCR signaling is underscored again by its role as the gene responsible for X-linked agammaglobulinemia. Btk in turn activates an isoform of phospholipase C (PLCγ2) that hydrolyzes inositol phosphates to generate diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP$_3$). DAG activates both an isoform of PKC (PKCβ) and Ras, whereas IP$_3$ induces an increase in intracellular calcium. Recruitment of Sos via the adaptor protein Grb2 also activates the Ras pathway, as does Vav, a guanine nucleotide exchange factor for Rac. Together, activation of these three pathways then triggers activation of mitogen-activated protein kinases (MAPKs), reorganization of the actin cytoskeleton, and nuclear translocation of critical transcriptional activators, including the NF-κB family, that promote survival and clonal expansion (Fig. 22-5).[50,52]

Coreceptors Involved in B-Cell Activation

Three important coreceptors for B-cell activation are CD21 (also called complement receptor 2 [CR2]), CD19, and CD81. Antigens derived from bacteria or other extracellular microorganisms are more efficiently cleared when opsonized or bound by complement components, a mechanism that links the early innate immune response elicited by activation of complement to the adaptive humoral B-cell response. Binding of C3b to CD21 coclusters CD21, CD19, and CD81 with the BCR within lipid rafts.[39,49,54] Phosphorylation of CD19 by proximity to the activated BCR complex in turn generates docking sites for phosphatidylinositol 3′-kinase (PI3K), for Vav, and for Lyn. PI3K generates phospholipid intermediates that recruit Btk as described earlier. Vav activates Rac, thereby activating MAPKs and inducing cytoskeletal reorganization. The response to opsonized antigens recognized by the BCR via its specific epitope is thus greatly enhanced by the binding of C3b to CD21.[55] CD81 appears to function primarily as an adaptor and is critically required for BCR and CD21/CD19 to associate with lipid rafts.[56,57]

Stimulation via the antigen receptor alone is insufficient to activate B or T cells, and in fact, binding of receptor-ligand pairs between B and T cells is critical for activation of both. Many costimulatory pathways are shared between B and T cells and are discussed further later; binding of CD40 to its ligand CD40L (CD154) is the most crucial of these pathways for B-cell activation. CD40 is a 48-kd member of the TNF receptor superfamily that is expressed on B cells and other APCs constitutively, whereas CD40L is a 33-kd transmembrane protein with homology to TNF upregulated on activated CD4$^+$ T cells. CD40/CD40L binding has been shown to be essential for B-cell growth and differentiation.[58] In vitro stimulation of B cells by cross-linking via monoclonal antibodies is sufficient to promote growth and class switching and is synergized by BCR stimulation or treatment with IL-4, or both. Engagement of CD40 with trimeric CD40L and clustering of the cytoplasmic tails lead to recruitment of a class of adaptor proteins, the TNF receptor–associated factors (TRAFs), which in turn activate a variety of kinases that ultimately culminates in activation of MAPK and NF-κB.[59] In addition to clonal expansion and survival, CD40 signaling also leads to upregulation of other costimulatory molecules such as CD80 (B7) and CD54 (intercellular adhesion molecule 1 [ICAM-1]).[59]

The relatively recently discovered TLR can trigger B-cell activation alone (see earlier) and also can serve a costimulatory function with BCR signals.[36,60] At least 11 TLRs in humans have been found, each recognizing different microbial components, such as LPS (via TLR4), peptidoglycan (TLR2), double-stranded RNA (TLR3), flagellin (TLR5), and CpG DNA (TLR9).[61] The response to intact microbes may involve recognition of microbial components simultaneously by the BCR and TLR, and interestingly, BCR-TLR corecognition may play a role in the generation of autoantibodies.[62,63]

Follicular B-Cell Differentiation: The Germinal Center

Activation of B cells and differentiation into memory and plasma cells have become increasingly well understood in the context of cellular trafficking and the complex architecture of the specialized anatomic site, the GC.[64,65] B cells, T cells, and specialized follicular dendritic cells (FDCs) must interact via costimulatory contact and soluble factors to generate a long-lasting humoral response.

In the early stages of infection, innate immune cells such as dendritic cells and macrophages capture antigen, migrate to lymph nodes, and present peptides in the cleft of class II MHC to CD4$^+$ T cells. Simultaneously, naïve B cells that recognize the same pathogen can internalize complex protein particles by receptor-mediated internal-

ization of Ig, with the protein fragments being broken down and displayed as peptides by class II MHC. Naïve B cells that encounter their cognate antigen and become activated then migrate through the T-cell zone and contact T cells stochastically during the journey.[66] When T and B cells that recognize the same antigen interact via TCR-MHC interactions, costimulatory signals, namely, CD40-CD40L interactions, enhance the interaction and result in clonal expansion of both T and B cells. These activated "helped" B cells then travel to the follicle and infiltrate a network of FDCs. FDCs are thought to have a specialized function consisting of capture of immune complexes and simultaneous binding of FcR to antibody and complement receptor 3 (CR3) to components of complement.[67] The antigen component of the immune complex can then be displayed to passing B cells via the BCR. Activated B cells that recognize antigen displayed on FDCs proliferate rapidly after further costimulation by $CD4^+$ T cells and become the centroblasts and centrocytes that form the GC.

Somatic hypermutation is thought to occur at the centroblast stage and further diversifies the overall antibody pool by introducing mutations in the V_H and V_L regions of Ig in B cells involved in a GC response.[68,69] Nucleotides are thought to be mutated in a somewhat random fashion, in both the rearranged and non-rearranged V regions, but ultimately, survival of B cells that have undergone hypermutation is dictated by positive and negative selection based on the affinity of the expressed Ig. In other words, mutations that disrupt affinity to the antigen to which the animal is responding will be selected against, whereas those that enhance affinity will be selected for, hence the term *affinity maturation*.

Isotype or class switching is thought to occur at the centrocyte stage. Because all naïve B cells express IgM, a low-affinity antibody, inducing activated B cells to produce high-affinity IgG or IgA significantly enhances the functional humoral immune response to specific antigen at the time of infection and requires splicing of the V(D)J regions to the C_γ or C_α region. CD40-CD40L interactions are critical for this process, and T-cell–derived cytokines enhance class switching while influencing the Ig class or subclass.[70-72] In the mouse, T-B interactions in the context of interferon-γ (IFN-γ) tend to promote switching to IgG2a and IgG3, whereas IL-4 directs switching to IgG1 and IgE (see Table 22-2).

GC B cells then differentiate into either plasma cells or switched memory B cells. How GC B cells "choose" between the plasma cell and memory B-cell fate remains unclear.[73] Plasma cells are terminally differentiated B cells found primarily in bone marrow and are specialized for high-level secretion of IgG, IgM, and IgA. They have a characteristic histologic appearance with so-called clockwork chromatin, eccentric nuclei, and markedly expanded endoplasmic reticulum and can be identified by expression of CD138 (also called syndecan-1). Class-switched memory B cells, which generally can be identi-

fied by virtue of the loss of IgD and gain of CD27 surface expression,[30] are able to circulate back to bone marrow and secondary lymphoid organs and, like memory T cells discussed later, are responsible for the rapid and effective anamnestic immune response characteristic of acquired immunity. A number of congenital deficiencies that affect T-cell–dependent B-cell maturation are characterized by a lack of GC formation and switched memory B cells; such conditions include CD40L deficiency (later), X-linked lymphoproliferative disease (caused by mutation in SH2D1A or SLAM-associated protein [SAP]), and two molecules recently shown when mutated in humans to cause common variable immunodeficiency, ICOS (inducible T-cell costimulator) and TACI (transmembrane activator and calcium modulator and cyclophilin ligand interactor).[74-78] More recently, both somatic hypermutation and class switch recombination have been found to require a newly discovered activation-induced deaminase (AID) that deaminates deoxycytidine to form deoxyuridine; subsequent repair of the deoxyuracil-deoxyguanosine mismatch triggers nucleotide substitution or excision, thereby generating diversity and also joining VDJ regions to a different constant region class.[69,79] Humans born with defects in the AID gene have failure of both processes that results in a hyper-IgM phenotype.[80-82]

B-Cell Tolerance

Like T-cell tolerance (discussed later), B-cell tolerance is essential to prevent autoimmune reactions. Immature B cells can be made tolerant in the bone marrow to antigens expressed by the host (i.e., self-antigens) through clonal deletion.[83] If the sIgM expressed on an immature B cell binds with high avidity to a self-antigen, the cell will be stimulated to undergo apoptosis, a form of cell death characterized by chromosomal fragmentation and membrane blebbing. The B cell may also undergo receptor editing, a process whereby that B cell's Ig gene will further rearrange to express a different, nonautoreactive Ig molecule.[84] The few B cells that escape central deletion may be rendered anergic in the periphery, a state in which the B cell expresses a gene that encodes a self-reactive antibody yet is unable to respond to antigen. The molecular mechanisms responsible for anergy are incompletely understood but may involve alternative signaling when the BCR is activated in the presence or absence of costimulation. For instance, BCR triggering in the context of concurrent TLR signaling (secondary to microbial products in addition to the BCR-specific antigen) leads to upregulation of CD86, which engages CD28 on T cells and recruits T-cell help. In the absence of TLR signals, the upregulation of CD86 is not sustained, and the BCR signals are attenuated.[85] A group of TNF and TNF receptor family members, including BAFF (TNFSF13B) and APRIL (TNFSF13A), whose receptors include TACI (TNFRSF13B, CD267), BCMA (TNFRSF17, CD269) and BAFF-R (TNFRSF13C, CD268), have been shown

to be important in B-cell homeostasis and autoimmunity. Interestingly, mice that overexpress BAFF exhibit auto-immunity,[86,87] and humans with a variety of rheumatologic diseases have been shown to have high BAFF serum levels.[88] The increasing use of rituximab, humanized anti-CD20 antibody, for the treatment of autoimmune disease and, recently, chronic graft-versus-host disease underscores the importance of dysregulated humoral immunity in human disease.

Function of Secreted Immunoglobulin

Secretion of a diverse repertoire of Ig is essential for protection of the host from infection and for neutralization of toxin. Once formed, binding of specific antibodies to microorganisms, virally infected cells, toxins, or other pathogens is essential for complement-mediated lysis, antibody-dependent cellular cytotoxicity (ADCC), opsonization, phagocytosis, and neutralization of toxins and viruses (see Table 22-2). Different heavy-chain isotypes perform different functions preferentially. IgM, IgG1, IgG2, and IgG3 activate the complement cascade, whereas only IgG1 and IgG3 bind effectively to phagocytic Fcγ receptors. IgE is able to bind to the Fcγ receptors expressed on mast cells and eosinophils. In addition, secreted IgA antibodies play a role in protection from invasion through mucosal surfaces.

Different classes of antibodies not only have different functions but also predominate in different compartments in the body. IgA is predominantly secreted, IgM is primarily intravascular, and IgG is generally the major antibody found in tissues and peripheral blood. IgG is able to cross the placenta to provide some protective immunity to the fetus; passive protection from long-lived IgG molecules confers postnatal immunity. However, although the function and location of the antibody classes differ, subpopulations of B cells are able to migrate and home to specific regions of antigen presentation. Therefore, generalized B-cell immunity may result from localized antigen presentation, as paradigmatically demonstrated by the efficacy of successful vaccination programs.

T-CELL ONTOGENY

T lymphocytes, like B lymphocytes and all other blood cells, are derived from self-renewing pluripotent HSCs. T cells are unique, however, in that their development also requires passage through a specific organ, the thymus. Indeed, the absolute requirement for the thymus is made clear by human congenital immunodeficiency states such as the DiGeorge syndrome, in which thymic organogenesis and therefore T-cell development are absent (see Chapter 23). Similar to B-cell ontogeny, the generation of millions of diverse T cells is accomplished by serial rearrangement of germline genes encoding the receptor for antigen recognition, the TCR. The bulk of peripheral T cells are either of the CD4+ helper or CD8+ cytolytic lineages.

T-Cell Receptor Subtypes and Specificity

The TCR is a cell surface receptor capable of recognizing discrete antigens bound to the MHC or to MHC-related molecules expressed on the surface of APCs. TCRs are disulfide-linked heterodimers of either αβ or γδ proteins.[89] TCR αβ–bearing T cells constitute the vast majority of circulating T cells, most of which recognize peptide antigens bound to polymorphic MHC class I or class II molecules. A subset of TCR αβ T cells, representing approximately 1% of all T cells in humans, in contrast recognize lipid antigens bound to the MHC class I–related nonpolymorphic molecule CD1 and are termed CD1-restricted or NKT cells, discussed in a later section. TCR γδ–bearing T cells account for a tiny fraction of the circulating T cells in humans but are very prevalent in intestinal tissue and are thought to recognize nonpeptide antigens (see later). The functions of CD1-restricted TCR αβ T cells and TCR γδ T cells are somewhat distinct from those of conventional TCR αβ T cells. The discussion of intrathymic T-cell development below will focus on the major conventional subset of T cells.

Early T-Cell Commitment and Seeding

The molecular events associated with and responsible for commitment to the T lineage have been increasingly elucidated in both mouse and human models over the last 10 years. The question of whether T-lineage commitment occurs within the thymus or the bone marrow has been actively investigated. In addition to pluripotent CD34+ HSCs, a number of other more committed progenitors in bone marrow with specific cell surface marker characteristics have been identified with T-lymphoid potential, primarily in the mouse, but these progenitors in general also retain the capacity to differentiate into other lymphoid lineages, including the B and NK lineages.[90] That various subsets identified in the human thymus similarly retain bilineage potential (i.e., NK/T potential or NK/dendritic cell potential) has led to the notion that the final steps in T-cell commitment occur in the thymus rather than the bone marrow.[91]

In addition to losing the capacity to differentiate into non–T-lineage cells in vitro, T-lineage commitment is characterized by the upregulation of certain cell surface markers (Fig. 22-6) and T-cell–specific genes important for the execution of downstream developmental programs. CD34+ cells in human thymus can be further subdivided by the expression of CD38 and the MHC-like molecule CD1a, with progression from the CD34+ CD38− CD1a− stage to the CD34+ CD38+ CD1a− stage to the CD34+ CD38+ CD1a+ stage. Acquisition of CD1a+ is largely associated with the loss of NK, dendritic cell, and plasmacytoid dendritic cell differentiation in vitro.[91] Likewise, CD1a+ cells express the recombinase-activating
FIGURE 22-6. Overview of T-cell development. Pluripotent hematopoietic stem cells (HSC) in bone marrow commit to the T lineage, seed the thymus as early triple-negative CD3$^-$ CD4$^-$ CD8$^-$ (TN) thymocytes, and express the T-cell markers CD7 and CD2. T-cell receptor genes rearrange serially (TCRβ then TCRα), which leads to expression of the first pre-T-cell receptor (pre-TCR) and then the mature TCR αβ complex. Double-negative CD4$^-$ CD8$^-$ (DN) thymocytes upregulate both CD4 and CD8 after passing through an intermediate single-positive (ISP) stage to become double-positive CD4$^+$ CD8$^+$ (DP) thymocytes, which undergo positive and negative selection. During lineage commitment, either CD4 or CD8 is downregulated, thereby resulting in the formation of single-positive (SP) thymocytes with CD4$^+$ thymocytes restricted to major histocompatibility (MHC) class II and CD8$^+$ thymocytes restricted to MHC class I. Mature T cells in the spleen and lymph node that have not encountered cognate antigen express markers associated with the naïve state such as CD45RA and CD62L, and the pattern of surface markers changes with activation, acquisition of effector function, and further differentiation into memory T cells.

gene products RAG1 and RAG2, and early TCR rearrangements are detectable after the acquisition of CD38 and CD1a. Transcription factors upregulated during these stages of early human T-cell commitment, whose requirement for T-cell development have also been demonstrated in gene-deficient mice, include GATA3 and NOTCH.[92-95]

Interactions between thymocytes and epithelial cells are critical for events in later thymic development, such as positive and negative selection, as detailed later, as well as for early commitment and development. The so-called nude mouse, which lacks expression of the epithelial transcription factor Foxn1, is born athymic, and humans lacking Foxn1 have severe T-cell deficiency, alopecia, and nail dystrophy.[96,97] Unlike B cells, which can be induced in vitro to mature from precursors by coculture on bone

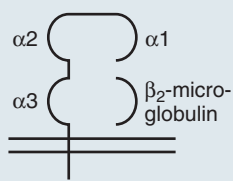
marrow stromal cells, T cells generally cannot be differentiated in vitro by this means, only when seeded into a three-dimensional source of primary thymic stroma, such as whole thymic organ culture. This distinction implies that specific soluble or cell-cell contact factors present only in the three-dimensional primary organ are required to engage developing thymocytes and induce their differentiation. The Notch signaling pathway, which is activated by the interaction of Notch ligands on epithelial cells and Notch family members on thymocytes, has emerged as one such factor.[98,99] Expression of activated Notch1 in human HSCs is sufficient to induce T-cell development in vitro and in immunodeficient mice,[100] and deletion of Notch1 from mouse thymocytes severely impairs early T-cell development.[101] Interestingly, primary three-dimensional thymic stroma expresses Notch ligands

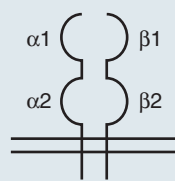
such as Delta-like 1, and this expression is lost when the architecture is disrupted.[102] Indeed, expression of Delta-like 1 in the OP9 bone marrow stromal cell line is capable of directing mouse and human uncommitted HSCs and even embryonic stem cells into the T lineage when cocultured in a two-dimensional format in vitro.[99,103,104] This powerful system raises the intriguing possibility of differentiating and expanding T cells in vitro for use in human therapeutics[105] and underscores the importance of thymocyte-epithelial interactions during intrathymic development.

Stages of Intrathymic TCR αβ T-Cell Development and Spatial Considerations

T-lymphoid precursors that enter the thymus from the blood mature through a series of ordered developmental stages characterized by changes in cell surface markers, sequential expression of the TCR genes, and predictable migration from the cortex to the medulla (see Fig. 22-6). The earliest thymocytes reside in the cortex, are CD34+, express pan-T-cell markers such as CD2 and CD7, but lack TCR, the TCR-associated CD3 complex, and the helper and cytotoxic mature T-cell coreceptors CD4 and CD8 and hence are CD3− CD4− CD8−, or triple negative. During αβ T-cell development, triple-negative thymocytes that succeed in rearranging a functional TCRβ chain express TCRβ complexed to the invariant pre-TCRα protein. TCR signaling in thymocytes, similar to what occurs upon engagement of the TCR in peripheral mature T cells, promotes rapid expansion and differentiation into double-positive (DP) thymocytes expressing both the CD4 and CD8 coreceptors and initiates rearrangement of the TCRα gene. In humans, in contrast to mice, there is an additional intermediate stage in which thymocytes express only CD4 and not CD8 (intermediate single positive [ISP]). DP thymocytes account for approximately 80% to 90% of the total thymocyte number and can be found at the corticomedullary junction. Although the majority of DP thymocytes die by apoptosis, those that successfully undergo positive and negative selection survive, commit to either the CD4/helper or CD8/cytotoxic lineage, and migrate to the thymic medulla before terminal maturation and export to the periphery.

T-Cell Recognition of Peptide-MHC Complexes

A hallmark of the cellular immune response is antigen specificity, which is conferred by the rearranged and selected TCR on the surface of T lymphocytes. The TCR recognizes processed fragments of foreign proteins embedded in MHC molecules. There are two forms of MHC molecules: MHC class I (the major determinants are HLA-A, HLA-B, and HLA-C in humans) and MHC class II (the major determinants are HLA-DR, HLA-DQ, and HLA-DP in humans) (Fig. 22-7).[106] MHC class I molecules are composed of a 42-kd transmembrane, polymorphic α chain encoded in the MHC and noncovalently associated with a 12-kd soluble, nonpolymorphic (non-MHC) β chain termed β2-microglobulin. X-ray crystallographic analysis of HLA molecules in which peptide was embedded[106] has demonstrated that the first two domains of the α chain both form α helices that together form a cleft (Fig. 22-8).[107] This cleft forms the binding domain for peptide antigen and accommodates a 9– to 11–amino acid fragment in an extended conformation; residues that interact with the MHC and those that interact with the TCR can be defined.[108,109] Polymor-




Structure	MHC class I	MHC class II
	α chain + β2-microglobulin	α + β chains
Molecular weight (Kd)	42 (α) + 12 (β2m)	33 (α) + 29 (β)
Expression	All nucleated cells	Antigen-presenting cells, mono/macrophages, B cells, dentritic cells
		Thymic epithelial cells
Major loci	A, B, C	DR, DQ, DP
Minor loci	E, F, G, H	DM, DN, DO
	>100	>20
Peptide presented to	CD8+ T cells	CD4+ T cells
Peptide bound	8–9 amino acids	12–20 amino acids
Source of peptide	Endogenous antigens	Exogenous antigens

FIGURE 22-7. Characteristics of major histocompatibility (MHC) class I and class II molecules. MHC class I molecules are single transmembrane molecules noncovalently associated with β2-microglobulin, whereas MHC class II molecules exist as heterodimers. CD8+ T cells recognize 8 to 9 amino acids, endogenous processed peptides embedded in the MHC class I groove, whereas CD4+ T cells recognize 12 to 20 amino acids, exogenous peptides embedded in the groove formed by MHC class II molecules. The major and minor loci are listed, as are important differences between the two classes.

phism within the MHC itself serves to ensure variation in the affinity of peptide binding; the extraordinary MHC polymorphism within the species further ensures that any single microbe is unlikely to mutate such that it is unable to bind all MHC molecules in the population and therefore escape T-cell recognition.[110-113]

MHC class II molecules are formed by the noncovalent association of two transmembrane glycoproteins, αβ, both of which are polymorphic and encoded in the MHC.[106,114] Solution of the structure of MHC class II molecules has shown that a peptide-binding cleft is formed by the first domains of each of the αβ chains; however, the ends of the cleft are open, unlike the situation in MHC class I molecules (see Fig. 22-8).[106] The peptide-binding cleft of MHC class II accommodates processed peptides that are 10 to 30 (mean of 14) amino acids in length.[115,116] As with MHC class I, the genetic polymorphism of MHC class II determines the affinity and specificity of peptide binding and T-cell recognition.[114-116] Although MHC class I molecules are expressed constitutively on all human nucleated cells, MHC class II molecules are constitutively expressed only on B cells, monocyte/macrophages, and dendritic cells. Expression of MHC class II proteins may be induced on the surface of monocyte/macrophages, fibroblasts, endothelial cells, and certain mesenchymal and epidermal cells by a variety of inflammatory mediators and cytokines such as IL-1. In humans but not in mice, MHC class II proteins can be inducibly expressed on T lymphocytes as well, thus rendering T cells capable of antigen presentation to other T cells. These two classes of MHC proteins generally interact with different classes of T lymphocytes: CD4+ T cells recognize peptide antigen in association with MHC

class II molecules, whereas CD8+ T cells recognize peptide antigen in association with MHC class I molecules, in part because CD8 binds to invariant portions of the α3 domain of MHC class I.

T-Cell Receptor Rearrangement and Selection in the Thymus

Effective adaptive immunity relies on the random generation of a diverse repertoire of antigen-specific T cells, along with appropriate quality control measures to ensure that nonfunctional T cells are not needlessly allowed to mature fully. To achieve this goal, the TCR genes undergo somatic rearrangement in a serial fashion, and the growth and proliferation of developing T cells are tightly linked to signaling and transcriptional events downstream of functional TCR or TCR intermediates.

The four TCR gene clusters, α, β, γ, δ, are each composed of germline genes encoding discontinuous variable regions ($V_\alpha, V_\beta, V_\gamma, V_\delta$), diversity regions ($D_\beta, D_\delta$), joining regions ($J_\alpha, J_\beta, J_\gamma, J_\delta$), and constant regions ($C_\alpha, C_\beta, C_\gamma, C_\delta$).[117] The TCRγ locus is situated on human chromosome 7, and the remaining three are located on human chromosome 14, with the TCRδ locus embedded between the V_α and J_α regions of the TCRα locus. The TCRβ germline genes consist of around 50 V_β, 2 D_β, 13 J_β, and 2 C_β genes, whereas the TCRα germline genes consists of at least 70 V_α, 60 J_α, and a single C_α gene. The TCRβ and TCRα loci have many more genes than the TCRδ or TCRγ loci do; however, the diversity of TCR γδ T cells is increased by the splicing of 2 D_δ regions to each other (VDDJ). Similar to the Ig genes in B cells, rear-
FIGURE 22-8. Peptide bound within the antigen-binding cleft of MHC class I molecules. **A,** Schematic representation of the structure of HLA-A2. **B,** Solution of the crystallographic structure of an influenza peptide bound within the peptide-binding groove of HLA-Aw68. The first α1 and α2 domains of the major histocompatibility (MHC) class I protein each form an a helix that together form a cleft. This cleft, or "groove," is the binding domain for the peptide antigen, here represented by amino acids 91 to 99 of influenza nucleoprotein. The T cell recognizes peptide plus MHC class I determinants. T cells become tolerant to self-peptides bound to MHC class I and class II proteins but retain the ability to respond to foreign or viral peptides bound to self-MHC class I or class II proteins. *(Reproduced From Bjorkman PJ. MHC restriction in three dimensions: a view of T cell receptor/ligand interactions. Cell. 1997;89:167-170.)*

rangement of the TCR genes is carried out by the RAG1 and RAG2 proteins, with serial somatic rearrangements between the V, D, J, and C regions. Although N-region diversification is found in both the TCRα and TCRβ genes, T cells do not undergo somatic mutation as readily as B cells do and instead undergo limited further rearrangements after emerging from the thymus.[84]

Several major checkpoints regulate the development of TCR αβ and TCR γδ thymocytes.[117-120] First, serial rearrangement of the TCR gene clusters in an ordered fashion ensures that the TCRβ and TCRα genes are not rearranged in developing TCR γδ T cells. Thus, in human thymocytes, TCRγ and TCRδ loci rearrange first, during the triple-negative stage.[95] That human TCR γδ T cells generally have unrearranged TCRβ genes and that TCR αβ T cells generally have nonproductively rearranged TCRδ genes imply that only thymocytes that do not generate a functional γδ TCR go on to rearrange the TCRβ gene.[121] The molecular mechanisms controlling this process are still being elucidated. The second or so-called beta selection checkpoint occurs after TCRβ rearrangement. Cells that undergo productive rearrangement of the TCRβ locus express functional TCRβ protein that complexes to the invariant pre-TCRα protein and CD3 signaling complex, thereby resulting in the expression of pre-TCR. In gene-deficient mice, where beta selection is known to occur during a precise phase of the triple-negative stage of development, loss of a number of signal-ing molecules or transcription factors downstream of pre-TCR results in defective beta selection, failure of differentiation into DP stage, and lack of proliferation or apoptosis (or both).[122] Beta selection in humans begins during the CD34$^+$ CD38$^+$ CD1a$^+$ stage and continues through the CD4 ISP and early DP stage of development (see Fig. 22-6).[95,121] Thus, only thymocytes that express functional TCRβ are allowed to proliferate and proceed to TCRα locus rearrangement.

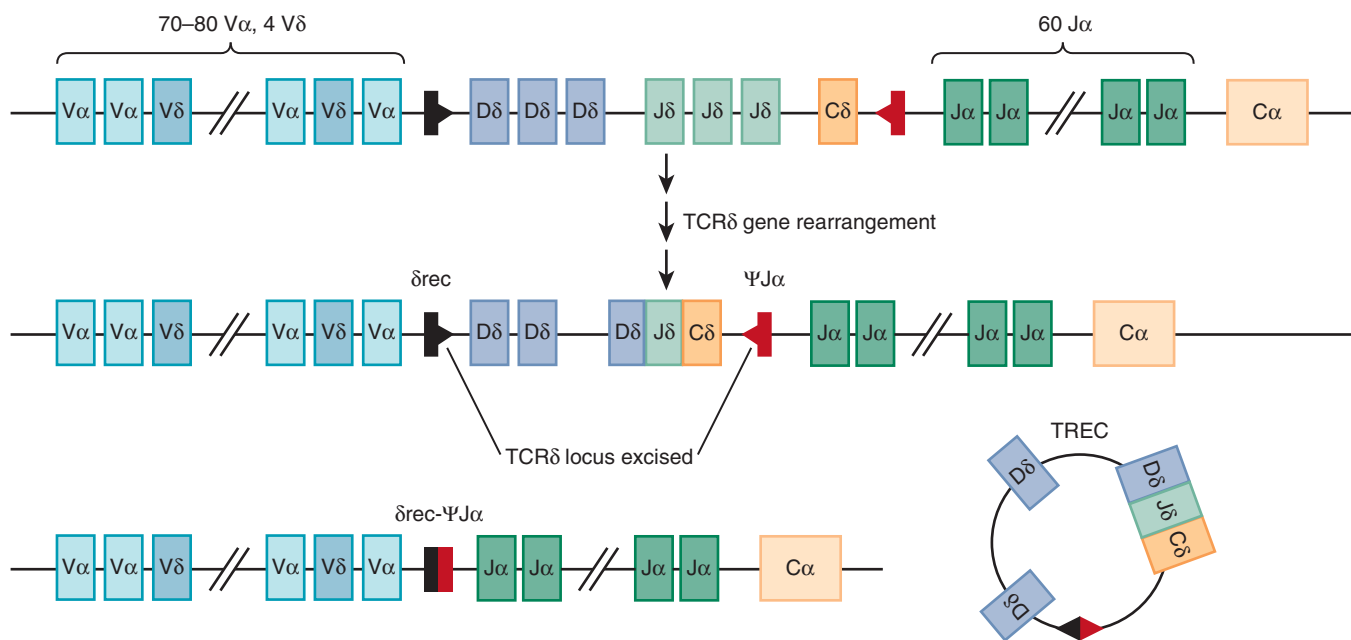
Before TCRα gene rearrangement, the TCRδ locus is excised by a nonproductive rearrangement between the δRec and ΨJα regions[123] that generates an episomal circle of DNA or T-cell receptor excision circle (TREC), which is increasingly being used on a research basis to quantify thymic activity (Fig. 22-9).[124,125] Unlike the TCRβ locus, rearrangement of the TCRα locus occurs processively; that is, Vα-Jα recombination of 5′ J segments that are nonproductive or out of frame is followed by further rearrangement on the same allele to more 3′ J segments.[126] This process increases the chances of generating a complete TCR αβ protein from any single developing DP thymocyte. Successful rearrangement of the TCRα gene results in expression of the mature TCR αβ and CD3 signaling complex during the late DP stage. These cells then undergo positive and negative selection (see the next section) and simultaneously commit to either the CD4 or the CD8 lineage to generate CD4 single-positive (SP) and CD8 SP thymocytes.


FIGURE 22-9. Formation of T-cell receptor excision circles (TRECs). The T-cell receptor α and δ (TCRα, TCRδ) loci are schematically depicted to show the basic rearrangement of variable (V), diversity (D), joining (J) and constant (C) regions. V$_δ$ regions are interspersed between V$_α$ regions, whereas the remainder of the TCRδ locus (D$_δ$, J$_δ$, C$_δ$) is embedded within the TCRα locus between the V$_α$ and J$_α$ regions. The *black box* and *red box* represent the δrec and ΨJα sequences, whereas the *black* and *white triangles* represent recombination signal sequences (RSSs) that recombination-activating gene (RAG) products recognize. The *first line* depicts the locus in the germline configuration. After TCRδ rearrangement, the D$_δ$, J$_δ$, and C$_δ$ segments are randomly recombined. Thereafter, if the cell undergoes TCRβ and TCRα rearrangement, joining of δrec to ΨJα excises the TCRδ locus and results in an episomal circle of DNA containing the fusion of RSS signals. Polymerase chain reaction primers specific for this joining region can thus be used to detect the presence of the excision circle, an indicator of active rearrangement and T-cell neogenesis.

Positive Selection, Negative Selection, and CD4/CD8 Lineage Commitment

The massive proliferation of DP thymocytes results in TCR αβ thymocytes with an immense range of specificities, including many that are incapable of binding host MHC, cannot recognize host MHC complexed to endogenous peptide ligands, or have inappropriately high affinity for MHC–self-peptide and hence are autoreactive. Selecting only thymocytes with intermediate MHC–self-peptide affinity (so-called Goldilocks or just-right conditions) is critical for maintaining diversity of the repertoire, conserving the energy of the animal, and promoting self-tolerance.[127]

Positive selection is the term used to describe the process of selecting thymocytes capable of recognizing host MHC complexed to self-peptides generated from the processing of endogenous proteins. DP thymocytes are exquisitely prone to cell death in response to γ-irradiation, corticosteroids, exposure to TCR or CD3 cross-linking antibodies, or simply removal of the thymus from the body, and thus a positive signal via TCR-MHC/peptide interactions is required to rescue the small number of DP thymocytes destined to become SP thymocytes from cell death. Gene-deficient mouse experiments have demonstrated that multiple elements of TCR signaling are required for optimal positive selection, including TCR components (TCRα, CD3δ), early signaling molecules (GADs, ZAP70), late signaling proteins (RasGRP, calcineurin, ERK), and transcription factors (nuclear factor of activated T cells [NF-AT], Egr family members).[126,128-130] Interestingly, humans deficient in CD3δ and ZAP70 have been described who have discrepant development when compared with the knockout mouse counterparts. Deficiency of CD3δ in humans causes an earlier block in development at the CD4⁻ CD8⁻ stage, well before the development of DP thymocytes.[131,132] ZAP70 deficiency results in selective deficiency of CD8 SP thymocytes and mature CD8⁺ T cells.[133-135] Likewise, although in the mouse interaction of DP thymocytes with MHC on radioresistant cortical thymic epithelium is probably the dominant requirement for positive selection, the source of MHC and the relative contributions of MHC from thymic epithelium, thymic dendritic cells, or other thymic APCs to positive selection in humans are less clear.

Negative selection is the term used to describe the process of removing thymocytes that are self-reactive, also termed "central tolerance," by clonal deletion.[136,137] This is the first and major mechanism for control of autoimmunity, although clones that escape deletion in the thymus are subject to peripheral tolerizing influences (discussed later). In mice, negative selection can be mediated by cortical epithelium, medullary epithelium, and medullary dendritic cells. However, it was never clear how thymocytes reactive against self-antigens expressed only in peripheral tissues, such as islet cells, were selected against in the thymus. In other words, how are these tissue-specific proteins expressed in the thymus? More recently, mouse and human studies have revealed that all three cell types, medullary thymic epithelial cells (mTECs) in particular, exhibit promiscuous gene expression and transcribe a broad range of tissue-specific, nonthymic antigens.[138] This insight helps explain how developing thymocytes reactive against nonthymic proteins can be centrally deleted during negative selection. A newly discovered gene, *AIRE* (autoimmune regulator), is a factor shown to control the transcription of tissue-specific antigen expression in murine mTECs.[139] Simultaneously, this gene was shown to be responsible for the autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome, characterized by chronic mucocutaneous candidiasis, hypoparathyroidism, adrenal insufficiency, and other organ-specific autoimmune manifestations.[140,141] Thus, this disease may be the first example of failure of negative selection underpinning a human monogenic autoimmune disorder.

Maturation of CD4 and CD8 SP thymocytes from DP thymocytes occurs concurrently with positive selection and results in "matching" of coreceptor to MHC restriction with downregulation of the opposite coreceptor. The mechanisms controlling the CD4/CD8 lineage decision are separable from those governing positive selection[142] and have been the subject of active investigation in murine models.[143-146] Expression of class I and class II MHC in the thymus is not surprisingly required for SP thymocyte development.[147-149] Indeed, patients with defects in a number of genes that control MHC class II expression, including *RFXANK*, *RFX5*, *RFXAP* and *CIITA*, all manifest the so-called bare lymphocyte syndrome, a rare autosomal recessive disorder characterized by decreased numbers of CD4⁺ T cells, deficient helper function, and absence of specific antibody production because of lack of CD4-mediated B-cell maturation.[150]

T-CELL ACTIVATION AND FUNCTION

CD4⁺ and CD8⁺ TCR αβ T cells exported from the thymus circulate in a naïve or resting state in the blood and lymphoid organs but are poised to be activated by cognate antigen presented by MHC on the surface of APCs. CD8⁺ cytolytic T cells induce the lysis of foreign cells, such as infected, malignant, or allogeneic cells. CD4⁺ helper T cells interact with B cells via cell-cell and soluble factors to induce class switching and the generation of antigen-specific antibodies. They also provide "help" to CD8⁺ cytolytic T cells. Activation of resting T cells not only relies on signaling cascades downstream of the TCR-MHC interaction (signal 1) but also requires or is enhanced by the binding of a variety of T-cell surface molecules to their ligands on APCs (signal 2). The lack of a second signal generally results in nonresponsiveness or anergy of the T cell and serves to ensure that activation of the naïve T cell is not only antigen specific but regulated as well. The affinity of the cognate antigen,

the engagement of specific costimulatory molecules, and the cytokine milieu collectively influence and modulate the outcome of T-cell activation and thereby result in the generation of distinct effector cell subsets. Although most effector T cells perform their function and expire, a subset of activated cells differentiate into long-lived memory cells capable of rapid anamnestic responses.

T-Cell Receptor Triggering and Activation

The accessibility of T cells from human blood, the development of transgenic and knockout murine models, the availability of agonistic and antagonistic antibodies to T-cell surface proteins, and live cell imaging with fluorescent confocal microscopy have made the study of T-cell signaling highly tractable.

In contrast to the highly polymorphic and critical extracellular domain of TCR, the intracellular domains of αβ and γδ TCR are short and do not have intrinsic signaling function. Rather, antigen recognition of sufficient density on the cell surface to cross-link and cluster the TCR triggers modification of the CD3 complex of proteins, which are noncovalently associated with the TCR's cytoplasmic domains. The CD3 family of proteins in humans consists of γ, δ, ε, and ζ subunits, all transmembrane proteins with conserved ITAMs, similar to those found in the accessory Ig-α and Ig-β proteins complexed to BCR (see earlier and Fig. 22-10).[151] The CD3 γδε subunits have similar structure with a single extracellular Ig domain and a single cytoplasmic ITAM and are encoded by closely linked genes on human chromosome 11q23. The CD3 ζ subunit, on the other hand, has a very short extracellular domain with a longer intracellular domain bearing three ITAMs and is encoded on human chromosome 1. In the mouse, an additional CD3 η subunit is generated by alternative splicing of the CD3 ζ gene; no CD3 η transcripts can be detected, however, in humans.[152] Complete assembly of TCR αβ, CD3 γ, δ, ε, and ζ in the endoplasmic reticulum is required for stability of the complex, which is then exported to the cell membrane in toto.[153] The CD3 ζ proteins exist as a homodimer linked by disulfides in the extracellular domain. The exact stoichiometry of the TCR-CD3 complex remains controversial.[154]

Our understanding of the signaling cascades downstream of the TCR has become increasingly complete and complex. Five major signal transduction pathways are triggered by TCR engagement: phosphotyrosine kinase (PTK) activation, plasma membrane phosphatidylinositol hydrolysis, changes in intracellular calcium concentration $[Ca^{2+}]_i$, RAS/MAPK, and PKC pathways (see Fig. 22-5). In recent years a variety of adaptor molecules and other families of proteins, including small Rho guanosine triphosphatases (GTPases), have been implicated in these pathways. Thus, there is much crosstalk between the main pathways, which then converge on the activation of nuclear transcription factors critical for the expression of T-cell effector molecules, namely, the cytokine genes,
FIGURE 22-10. The T-cell receptor (TCR)-CD3 complex. The TCR is a covalently linked heterodimer composed generally of an α and β subunit and more rarely of a γ and δ subunit. The TCR is noncovalently complexed on the cell surface to a family of invariant proteins known as CD3 and to the ζ family, which together are thought to transduce activating signals from the TCR to the cytoplasm of the cell. The ζ subunit exists primarily as a homodimer of ζ-ζ in the TCR-CD3 complex but can be complexed to η or the FcR γ chain as heterodimers. Each of the CD3 and ζ chains has one and three intracellular activation motifs (ITAMs), respectively, which are important for initiation of signaling pathways in the cell. The physical association of CD3 and ζ with the TCR is required for proper assembly of the TCR-CD3 complex, for cell surface expression, and for signal transduction.

particularly IL-2. Finally, the spatial organization of the TCR signaling complex in ordered lipid microdomains, in which an "immune synapse" is formed at the point of contact between the T cell and APC, is thought to enhance T cell–APC interaction and allow directed secretion of cytokines locally to the contacting APC.[155,156]

On a macromolecular level, TCR signaling begins when recognition of cognate antigen clusters the TCR molecules to the site of T cell–APC contact. The exact mechanism of how TCR occupancy induces the allosteric changes in CD3 necessary to transmit a signal is unclear, but within seconds to minutes of engagement, PTKs such as Lck and Fyn are activated and phosphorylate the ITAMs on CD3 subunits, particularly CD3 ζ (see Fig. 22-5). The physical association of Lck with the CD4 and CD8 coreceptor molecules, recruitment to the membrane by myristoylation and other modifications, and the multiplicity of Lck molecules in close proximity when the TCR-coreceptor complex is cross-linked are thought to promote and amplify its rapid activation.[157] Phosphorylated ITAM on CD3 ζ in turn recruits ZAP70, a 70-kd

protein kinase whose homologue in B cells is Syk, via the phosphotyrosine binding SH2 domain.[158] ZAP70 is phosphorylated by Lck, is activated, and then phosphorylates two key substrates, LAT (linker for activation of T cells) and SLP76 (SH2 domain–containing leukocyte protein of 76 kd). A host of downstream proteins, including Grb2, SOS, ITK, PLCγ, GADS, and VAV1, then converge on LAT and SLP76 to activate the phosphoinositol, calcium, and RAS/MAPK pathways.[51]

Recruitment of PLCγ to LAT and SLP76 catalyzes the hydrolysis of phosphatidylinositol 4,5-biphosphate to generate IP_3 and DAG, which in turn promote the increase in $[Ca^{2+}]_i$ and activation of the T-cell–specific isoform PKC θ, respectively (see Fig. 22-5).[159,160] The critical downstream effect of the rise in $[Ca^{2+}]_i$ is activation of the calcium- and calmodulin-dependent serine/threonine phosphatase calcineurin, whose key direct substrates in T cells are members of the NF-AT family.[161-163] Dephosphorylation of NF-AT allows translocation of it from the cytoplasm to the nucleus, where it binds, often in the presence of AP-1 elements, to the transcriptional regulatory sequences of IL-2 and other cytokine genes. The immunosuppressant agents cyclosporine and tacrolimus (FK506) function by forming macromolecular complexes with intracellular binding proteins (cyclophilins and FK-binding proteins [FKBPs], respectively), which in turn inhibit the phosphatase activity of calcineurin, thereby abrogating the early cytokine elaboration critical for T-cell expansion and function.[162,164,165]

Activation of the RAS pathway primarily occurs by the recruitment of the adaptor proteins Grb2 and Shc to phosphorylated LAT, which leads to recruitment of the guanine nucleotide exchange protein Sos (see Fig. 22-5). Sos catalyzes the conversion of inactive guanosine diphosphate (GDP)-bound RAS to active guanosine triphosphate (GTP)-bound RAS and activates a series of MAPKs.[166] Activation of PKCθ in response to PLCγ described earlier can crosstalk with this pathway and induce increases in RAS and MAPK activity, although the mechanisms and relative contributions are still unclear. Major downstream effects of PKCθ activation include stimulation of AP-1 nuclear activity, regulation of JNK (the upstream kinase of AP-1), and activation of NF-κB.[160] Induction of these and other transcription factors, which cooperate with NF-AT translocation in response to rises in $[Ca^{2+}]_i$, strongly stimulates production of IL-2.

The transcriptional program executed in response to TCR stimulation includes the major T-cell cytokine IL-2; other cytokines, including IFN-γ and IL-4, the canonic T-helper type 1 and type 2 cytokines (discussed later); proliferative factors, including c-myc and c-fos; a variety of activation markers such as CD69, CD45RO, CD44; and growth factor receptors, most prominently the high-affinity IL-2 receptor subunit IL2Rα, also called CD25.[167] Binding of IL-2 to its receptor, in both autocrine and paracrine fashion, results in a growth factor–induced signal to the cell and induces the transition from G_1 to S phase of the cell cycle. Interestingly, in recent years,

CD25 has been found not only to mark activated T cells but also to be expressed on naturally occurring T-regulatory cells, discussed later. The role of IL-2 in expanding activated effector cells and simultaneously its requirement for development and maintenance of the T-regulatory population result in pleiotropic effects of IL-2 in vivo and has complicated the potential use of IL-2 in the clinical setting.[168] The high-affinity IL-2 receptor is composed of IL-2Rα, IL-2Rβ (CD122), and IL2Rγ (γc, CD132), this last a common signaling component of the cytokine receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Mutations in the IL2Rγ gene and the downstream factor JAK3 (Janus kinase 3) result in X-linked and autosomal recessive forms of severe combined immunodeficiency (SCID), respectively. In contrast to the inhibition of early signals downstream of $[Ca^{2+}]_i$ by cyclosporine and tacrolimus, the late proliferative response of T cells to binding of IL-2 to its receptor are abrogated by the immunosuppressant sirolimus (rapamycin), which complexes with FKBP to inhibit mTOR (mammalian target of rapamycin). All three of these agents have been used in the prevention and treatment of graft-versus-host disease and solid organ graft rejection, and the actions of calcineurin inhibitors and rapamycin on serial events in T-cell activation have encouraged their use in combination therapy.

Coreceptors Involved in T-Cell Activation and the Immune Synapse

Because the affinity of the TCR for cognate antigen–MHC complexes and the density of TCRs on the naïve T cell are both relatively low, activation of the T cell depends on augmentation of the TCR signal by a complex combination of TCR-associated coreceptors, adhesion molecules, and other costimulatory molecules that transduce distinct signals (Fig. 22-11). Recent techniques that visualize the distribution of TCR and these affiliated molecules in relation to the site of T cell–APC contact have led to a model in which the immune synapse segregates into central and peripheral supramolecular activation clusters (c-SMAC and p-SMAC, respectively). The functional relevance of different synapse morphologies and the dynamics of formation and disassembly of the synapse are just being investigated.[155,156,169]

The CD4 and CD8 glycoprotein coreceptors bind to class II and class I MHC molecules, respectively, and are used to classify T cells into helper and cytolytic subtypes. The proximity of CD4 and CD8 coreceptors to the TCR-MHC complex and the association of both CD4 and CD8 intracellular domains with the Src family tyrosine kinase p56lck are thought to increase avidity of the T cell for the APC and bring p56lck into close association with its target CD3 ζ.[170,171] CD4 and CD8 coreceptors are generally found in the c-SMAC with TCR.

CD2 is a T-cell–specific glycoprotein receptor that binds to several ligands on the APC, including CD58
FIGURE 22-11. Receptor-ligand interactions important for T-cell adhesion and activation. The interaction of representative T-cell surface receptors with their ligands is shown. The T-cell receptor (TCR)-CD3 complex interacts with a specific antigen in association with major histocompatibility (MHC) class II (or class I) proteins. CD4 (or CD8) binds to monomorphic determinants on MHC class II (or MHC class I) proteins. The CD2 receptor binds to its principal ligand CD58 (shown). Two additional ligands, CD48 and CD59, have been identified. The ligands for CD28 and CD40L are CD80/CD86 and CD40, respectively, and are expressed on activated B cells. The ligands for CD26, CD43, and CD7 (not shown), among other molecules, are unknown. LFA-1 (CD11a/CD18, $\alpha_L\beta_2$) interacts with its ligands CD54, CD102, CD50, and perhaps others. Fibronectin (FN) and CD106 (vascular endothelial adhesion molecule 1[VCAM-1]) are two ligands for VLA-4 (CD49d/CD29, $\alpha_4\beta_1$). Two ligands for CD44 exist: hyaluronidate and osteopontin (Eta-1). The ligands for other lymphocyte homing receptors are shown in Table 22-3. APC, antigen-presenting cell; CO, collagen; Ln, laminin.

(LFA-3), CD59, and CD48 (see Fig. 22-11). Binding of CD2 to its ligand on the APC serves to improve adhesion and the strength of the TCR-MHC interaction, whereas the cytoplasmic region associates with p56lck and thus augments TCR-induced early signals. In turn, TCR signaling itself modifies the cytoplasmic tail via a critical asparagine residue and thereby induces conformational changes that improve CD2-ligand binding, an example of so-called inside-out signaling.[172] CD2 is generally found in the c-SMAC.

CD45, also known as leukocyte common antigen, is a phosphotyrosine phosphatase. It is generally excluded from the immune synapse in a manner that suggests that the size of the ectodomain of a given receptor determines its presence or absence in the synapse.[155] The major substrate of CD45 is thought to be p56lck, as well as possibly

JAK/STATs, CD3 ζ, and ZAP70[173]; it is suggested that the dynamic repositioning of CD45 during synapse formation and disruption alters its substrate specificity.[174] Deficiency of CD45 has been studied in mice and humans and results in defects in thymic T-cell development, T-cell function, and autoimmunity.[173,175,176] Alternative splicing of the CD45 message results in multiple isoforms, most notably CD45RA, expressed in naïve or resting T cells, and CD45RO, characteristic of activated or previously activated T cells.

Costimulation of T Cells

TCR ligation (signal 1), even in the presence of CD4 or CD8 engagement, is insufficient for activation of resting T cells. In the absence of appropriate costimulation, TCR occupancy alone can result in T-cell unresponsiveness (T-cell clonal anergy, ignorance, or tolerance) on subsequent exposure to antigen. Tolerance is characterized by the inability to proliferate or secrete cytokines in response to secondary stimulation by the same antigen. Anergy is classically defined as this same failure, but it can be rescued or reversed by exogenous IL-2 in vitro.[177] Costimulation (signal 2) typically is mediated by receptors on T cells recognizing ligands on activated APCs (see Fig. 22-11).

CD28, the first discovered costimulatory molecule that prevents the induction of anergy, is a member of a growing family of related molecules. Human CD28, a homodimer of two 44-kd glycoproteins, is expressed on essentially all CD4+ cells and approximately 50% of CD8+ cells. CD28 interacts with the B7 family members CD80 (B7-1) and CD86 (B7-2). Interaction of CD28 with CD80 or CD86 increases, quantitatively, the amount of IL-2 produced by both transcriptional and post-transcriptional mechanisms,[178] augments T-cell proliferative responses, and enhances T-cell survival by induction of the anti-apoptotic protein Bcl-X$_L$.[179] Notably, CD28-dependent costimulation appears to be resistant to inhibition by the immunosuppressants cyclosporine and tacrolimus (FK506), inhibitors of the serine/threonine phosphatase calcineurin, thus suggesting that this pathway uses a different cascade of biochemical signals than the calcineurin-sensitive TCR-CD3 complex.[180-182]

Structurally similar to CD28, CD152 (cytotoxic T-lymphocyte antigen 4, CTLA-4) is a second CD28 family member that also binds to CD80 and CD86. CD152 is expressed only minimally on resting T cells but is induced on recently activated T cells. Mice rendered genetically deficient in CD152 expression die postnatally with progressive lymphoproliferation[183,184]; it is now clear that the endogenous function of CD152 is to downregulate T-cell activation to terminate T-cell responses.[182,185]

CD278 (inducible costimulator [ICOS]) is another member of the CD28 family that was cloned by generating monoclonal antibodies directed against activated T cells.[186] Like CD152, ICOS is expressed on activated T cells. ICOS does not bind CD80 or CD86 but instead

TABLE 22-3	**CD28/B7 Superfamily Interactions**				
Receptor	**Mass (kd)**	**Molecular Chromosome**	**Human Ligands**	**Expression**	**Function**
CD28	44-90	2q33	CD80, CD86	CD4$^+$ T cells 50% CD8$^+$ T cells	Activation: costimulation of cytokine production, particularly IL-2; prevention of induction of anergy
CD152 (CTLA-4)	35-80	2q33	CD80, CD86	Activated T cells	Inhibition: negative regulator of T-cell activation and proliferation
ICOS	55-60	ND	B7h/ICOSL	Thymocytes, activated T cells	Activation: costimulation of IL-10 > IL-4, IL-5, IFN-β, TNF-α; enhancement of CD40L expression; regulation of T-cell hemostasis
PD-1	55	2q37	PD-L1 or B7-H1	Activated T and B cells, myeloid cells	Inhibition: decreases T-cell proliferation, decreases IFN-γ and IL-10 production
Unknown			B7-H3	Activated T cells	Activation: increases IFN-γ production

CTLA-4, cytotoxic T-lymphocyte antigen 4; ICOS, inducible T-cell costimulator; IFN, interferon; IL, interleukin; ND, not determined; PD-1, programmed death 1; TNF, tumor necrosis factor.

binds to a novel, TNF-α–inducible adhesion molecule, CD275 (inducible costimulator ligand [ICOSL], B7h, B7-H2, B7RP-1).[187] Importantly, engagement of ICOS appears to affect T-helper differentiation by favoring IL-10 and IFN-γ production (see later). ICOS appears to be a key regulatory molecule for T-cell help, essential for normal humoral responses and B-cell heavy-class switching.

The number of CD28/B7 family members that function as costimulatory molecules continues to grow (Table 22-3). Expressed on thymocytes and activated immune cells, programmed death 1 (PD-1) is a CD152-like molecule that also functions as an important negative regulator of immune responses.[188-190] An autoimmune disorder resembling systemic lupus erythematosus develops in PD-1–deficient mice. The molecular mechanism of negative regulation by PD-1, like that by CD152, appears to be recruitment of a phosphotyrosine phosphatase (SHP-2) to the signaling receptor.[191] Two PD-1 ligands have been isolated; both are posited to play a role in the induction and maintenance of peripheral tolerance.[188,192,193] Finally, B7-H3, a distinct B7 family member important for costimulation of IFN-γ production, has been isolated[194]; B7-H3 binds a counter-receptor on activated T cells distinct from any CD28 family member heretofore characterized.

In addition to CD28/B7 family members, members of the TNF family function as important costimulatory molecules involved in T-cell effector and T-cell–dependent B-cell responses. Interaction of CD154 (CD40L) with CD40 is essential for B-cell activation, Ig production, and heavy-chain isotype differentiation, as discussed earlier. The interaction of CD154 with CD40 also upregulates CD80 expression on APCs and is thus important for sustaining a T-helper precursor cell (T$_H$1) response.[195] X-linked hyper-IgM syndrome is an autoso-

mal recessive disorder characterized by a deficiency of CD4$^+$ T-cell function and T-cell–dependent antibody responses; it is caused by mutation in the CD154 gene located on human chromosome X.[196] Affected patients have normal or increased IgM levels and very low to undetectable IgG and IgA levels and are susceptible to opportunistic infections such as *Pneumocystis jiroveci* because of intrinsic CD4$^+$ T-helper dysfunction.[197,198] Allogeneic stem cell transplantation offers a curative therapy for patients with an appropriate donor.[199] Murine models of X-linked hyper-IgM syndrome have been developed by genetic disruption of either the CD40 or CD154 genes, which mimics the phenotype of the human disorder.[200-203]

Other TNF family molecules that are important for costimulation include CD70 (CD27L/TNFSF7) and CD252 (OX40L/TNFSF4). CD70, a ligand of approximately 50 kd that is transiently expressed on recently activated T and B lymphocytes, binds CD27, a homodimer expressed on the surface of naïve CD4$^+$ and CD8$^+$ T cells.[204,205] CD27/CD70 interactions promote TNF-α but not IL-2 production from T cells, as well as expression of CD154 on the T-cell surface. This receptor-ligand interaction also appears to induce B-cell terminal differentiation to plasma cells.[31] Expression of CD134 (OX40), a glycoprotein of approximately 48 kd, depends on TCR signaling on CD4$^+$ activated cells. CD134/CD252 costimulation enhances T-cell proliferation and cytokine production at limiting antigenic densities, enhances B-cell and dendritic cell function, and modulates T-cell migration to B-cell follicular areas.[206,207] Thus, CD134/CD252 interactions have been suggested to prolong and enhance clonal expansion and immune responses at sites of infection and inflammation.

Manipulation of costimulation by soluble receptors, ligands, or antibody-mediated blockade is of increasing

interest in the treatment of autoimmunity, cancer, and solid organ rejection.[208-210] More recently, the discovery that regulatory T cells (see later) are also exquisitely sensitive to costimulatory signals has complicated the potential outcome of such therapeutics. The pleiotropic effects in vivo of our current armamentarium are underscored by the sobering case of six patients in England who suffered life-threatening cytokine storm within hours of receiving an anti-CD28 antibody agonist intended to expand regulatory T cells.[211]

PERIPHERAL T-CELL MATURATION

A hallmark of adaptive immunity is the generation of an antigen-specific response that can be rapidly recalled upon re-exposure to the same antigen at a later time. Naïve T cells released from the thymus have a broad range of TCR specificities, with few clones that recognize any given antigen, and they generally do not proliferate in the absence of cognate antigen. Exposure to antigen results in differentiation and rapid proliferation of the specific naïve precursor population into effector T cells that either kill targets bearing cognate antigen in the case of CD8+ T cells or produce polarized sets of effector cytokines in the case of CD4+ T cells. The expansion of effector cells is rapid and brief, with the majority dying by activation-induced cell death. Long-lived memory T cells that survive after the effector response serve to increase the precursor frequency in the periphery and thus arm the organism for a more rapid and efficient response on subsequent exposure to the same antigen.

Naïve T-Cell Differentiation to Effector and Memory T Cells

Circulating naïve, effector (activated), and memory T cells can be differentiated by phenotypic differences, as well as by genetic changes (Fig. 22-12). With T-cell activation, a number of cell surface receptors, including CD2, CD58, LFA-1, CD29, and CD44, are upregulated and increase the avidity of the interaction between the T cell and the antigen-bearing APC. CD45RA, which is constitutively expressed on naïve T cells, is downregulated and replaced by the CD45RO isoform.[212]

More recently, human T-cell memory populations have been further characterized by the expression of CD62L (L-selectin) and the chemokine receptor CCR7 as either effector memory (CCR7−) or central memory (CCR7+) subsets. CCR7 is a lymph node–homing receptor that interacts with its ligand SLC on endothelial cells.[213] It is proposed that differential CCR7 expression serves to segregate effector memory cells to tissues, where they rapidly release cytokines and kill targets, and central memory cells to lymph nodes, where interactions with dendritic cells and B cells orchestrate effective T-cell help and secondary proliferation.[214,215] In addition to these cell

surface markers, tetramer-based technology now allows identification of antigen-specific CD8+ memory cells on a research basis.[216] Four MHC molecules are bound covalently and tagged with fluorescent marker and then loaded with specific cognate peptide.[217] T cells that recognize that MHC-peptide complex bind the tetramer and can be identified by flow cytometry. This technology is currently restricted by the number of MHC specificities and known peptides available and generally has been developed only for the more common HLA haplotypes in the white population.

Helper T-Cell Differentiation and Function

Effector helper T cells differentiate from naïve CD4+ T-helper precursors (T_Hp) into two main classes of T_H cells with distinct functional properties.[218,219] A panoply of factors in the microenvironment where antigen recognition occurs have been shown to influence the differentiation of T_H cells, including the nature and density of ligand, the strength of TCR ligation, the presence and kinds of costimulatory molecules, and the differentiation state of the APC.[220] The cytokines in the immediate milieu are thought to be critical and result in vitro and in vivo in the early upregulation of canonic transcription factors that drive the T_H cell to one lineage while suppressing the transcriptional program characteristic of the opposite lineage (Fig. 22-13).[221,222] For instance, under the influence of IL-12 and IFN-γ, the transcription factor T-bet is upregulated and drives the cell to the so-called T-helper type 1 (T_H1) lineage, which is characterized by production of the inflammatory cytokines IL-2, IFN-γ, and TNF-α.[223] These cytokines drive paracrine expansion of T cells and activation of macrophages and other innate cells, thus providing help to CD8+ T cells and promoting cell-based immune responses. IL-4 in the environment, in contrast, upregulates the transcription factor GATA-3, thereby directing the cell to a T-helper type 2 (T_H2) cell fate.[224,225] The elaboration of T_H2 cytokines such as IL-4 promotes class switching of B cells, important for T-cell–mediated help for humoral responses. IL-4 and other T_H2 cytokines such as IL-5 and IL-13 also promote eosinophil differentiation, IgE production, and the expulsion and control of parasites. Imbalance of T_H1 and T_H2 cell responses is thought to play a role in the development of autoimmunity, allergy, and asthma.

Cytotoxic T-Cell Differentiation and Function

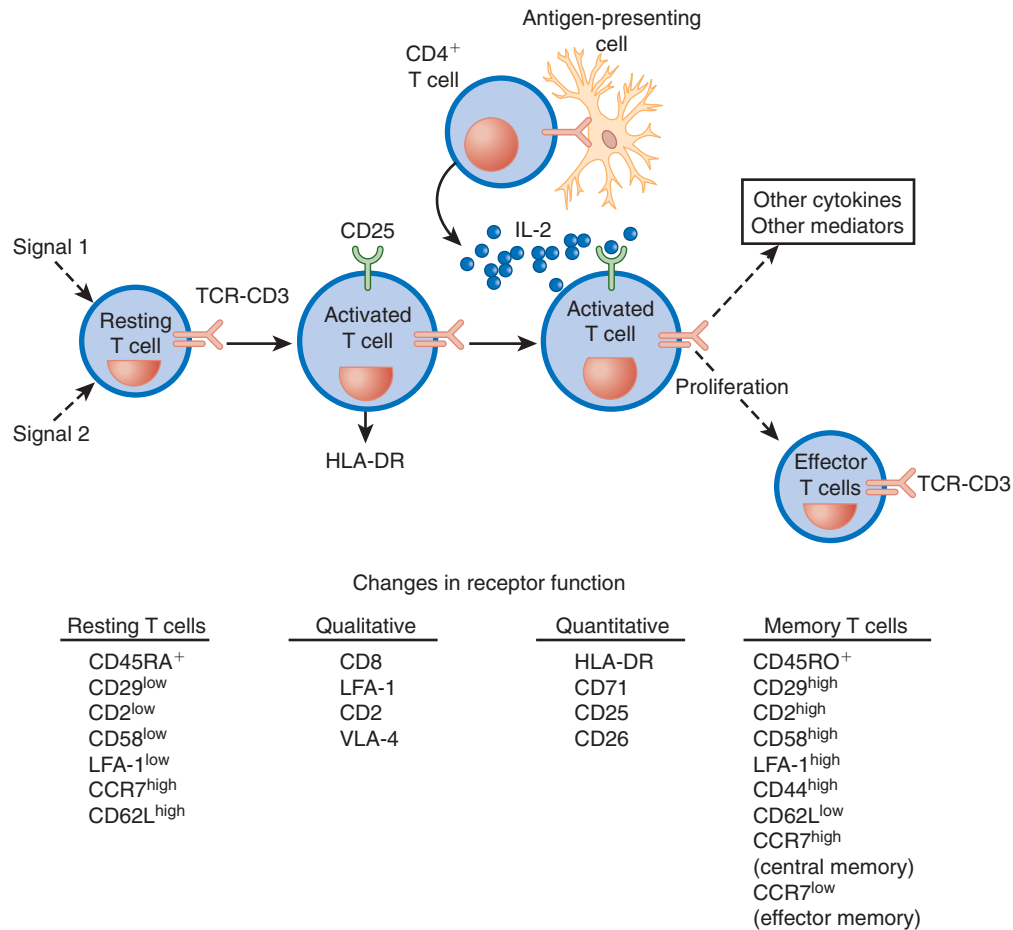
The primary function of effector CD8+ T cells is direct killing of APCs infected by virus or other intracellular organisms. Cytotoxicity is antigen dependent, is contact dependent, and does not result in destruction of the cytotoxic T cell itself, which can kill multiple targets serially. At least two mechanisms of cytolysis are now recog-


FIGURE 22-12. T-cell activation resulting in proliferation, acquisition of immunocompetence, and memory. Resting T cells are stimulated by antigen/major histocompatibility complex (MHC) molecules in the presence of a number of secondary signals. Appropriate activation results in an increase in both cell size and entry into the cell cycle. The high-affinity interleukin-2 (IL-2) receptor is expressed on the cell surface. Other activation antigens, such as transferrin receptor (CD71) and HLA-DR, are also expressed on the cell surface. The T cell is stimulated to produce cytokines (e.g., IL-2) that act in an autocrine and paracrine fashion on the T cell to promote cell replication and maturation to effector cells. $CD4^+$ T cells generally differentiate to become helper T cells that are able to secrete IL-2 and other cytokines in response to peptide antigen in the context of MHC class II proteins. Helper T cells secrete cytokines, which in turn help B cells and other T cells to proliferate and differentiate. T lymphocytes that express CD8 on their cell surface generally function as cytotoxic T lymphocytes (CTLs) and are able to kill target cells that express a foreign peptide antigen or viral product in the context of MHC class I proteins. In addition, a certain proportion of $CD8^+$ T cells function as suppressor T cells and inhibit the ability of B cells to secrete immunoglobulin, the generation of CTLs, or the production of cytokines by $CD4^+$ cells. A small proportion of circulating, stimulating T cells become immunocompetent memory T cells that are able to respond to antigen exposure in a secondary immune response. The phenotype of resting T cells changes upon T-cell activation, transcriptional activation, and acquisition of the memory phenotype. Certain cell surface receptors are upregulated quantitatively as shown, within days after activation. Although the level of expression of the TCR-CD3 complex remains constant, that of CD2, CD58, CD29, and CD44 increases. L-selectin expression decreases, and CD45RA expression fails. Expression of CD45RO is characteristic of the memory phenotype. In addition to early (e.g., CD2) and late (e.g., VLA-1) quantitative changes in receptor expression, the avidity of a number of T-cell surface receptors is changed quantitatively after T-cell triggering. The avidity of LFA-1 (CD11a/CD18) for its ligands is upregulated after T-cell stimulation, as is CD8 for MHC class I proteins, CD2 for CD58, and VLA-β_1 receptors for their ligands. The specific and dynamic regulation of T-cell avidity may impart sensitivity and plasticity to the immune response.

nized, cytotoxic granules and the Fas-Fas ligand pathway. Effector $CD8^+$ T cells release the contents of cytotoxic granules into the immune synapse after contact with an infected cell. The main components of these granules are perforin and the serine esterases granzyme A and granzyme B.[226] Perforin molecules form multimerized pores in the target cell and are classically thought to mediate delivery of granzymes into the cytoplasm. Targets then die by a combination of osmotic swelling and proteolytic damage. The importance of perforin in both responses to infection and immunoregulation is apparent by the study of patients with congenital mutations in both alleles of perforin, which results in congenital hemophagocytic lymphohistiocytosis.[227,228] Because perforin is also produced by NK cells (see later), this disease is characterized by deficiencies in both CD8 and NK cytotoxic function. The second mechanism is induction of caspase-mediated apoptosis by engagement of CD95 (Fas, Apo-1) on target cells with its ligand CD95L (Fas ligand, CD178) on effector $CD8^+$ T cells. CD95L is not constitutively expressed on naïve T cells and is upregulated on activation of T cells and NK cells. That this pathway also has
FIGURE 22-13. Differentiation of naïve CD4$^+$ cells to T-helper precursor cells (T$_H$1 and T$_H$2). Naïve CD4$^+$ cells, stimulated by ligation of the T-cell receptor and costimulatory molecules, differentiate into two classes of helper T cells. T$_H$1 cells produce inflammatory cytokines, characterized by interferon-γ (IFN-γ) and interleukin-2 (IL-2), that are capable of activating macrophages and promoting the further expansion of T cells; they appear to be the principal effectors of cell-mediated immunity. T$_H$2 cells produce IL-4, IL-10, and IL-5, among others, important for IgE production by B cells and differentiation of eosinophils, and thus are the principal effectors of humoral immunity. The cytokines produced by T$_H$1 cells (IL-2, IFN-γ, and IL-12) inhibit the induction of T$_H$2 differentiation, whereas the cytokines produced by T$_H$2 cells (IL-4 and IL-10) reciprocally inhibit the differentiation of T$_H$1 cells. TNF-α, tumor necrosis factor α.

important immunoregulatory function is implied by the fact that mutations in CD95 or CD95L typically cause not overwhelming infection but generalized lymphoproliferation and autoimmunity in humans.[229-231]

Control of the Immune Response: Regulation and Termination of T-Cell Activation

Maintaining a state of unresponsiveness to self-antigens, or self-tolerance, is as important for a healthy immune system as recognition of non-self, or foreign, antigens from infectious agents or tumors. Failure of self-tolerance can lead to autoimmunity. The main mechanisms of tolerance include central or clonal deletion (deletion by negative selection in the thymus, discussed earlier), anergy, activation-induced cell death (AICD; termination of T-cell activation), and cell-mediated suppression or regulation.

A productive T-cell response requires stimulation by antigen-MHC complexes via the T-cell receptor (signal 1) and appropriate costimulation (signal 2). T cells that encounter antigen in the absence of costimulation enter a state of anergy. Anergy is generally defined as the inability to proliferate when rechallenged with the same antigen while maintaining the ability to proliferate in response to cytokine (i.e., IL-2).[177,232] Anergy is also antigen specific, which means that an anergized cell can respond to other antigens if appropriately costimulated. Anergy ensures that autoreactive T cells that encounter peripherally expressed antigens in a noninflamed environment, where costimulatory molecules on APCs have not been upregulated, are not activated. AICD is important to ensure that the robust clonal expansion of antigen-specific T cells is short-lived. T cells exposed to foreign antigen or autoreactive T cells that escape thymic deletion and encounter self-antigen in the periphery can be killed by the CD95-CD95L pathway, which activates caspases and other

death signals. The importance of the CD95-CD95L pathway for control of lymphoproliferation in humans is demonstrated by the autoimmune lymphoproliferative syndrome (ALPS). Patients with ALPS have mutations in CD95 or more rarely CD95L or caspases, which leads to uncontrolled lymphoproliferation and autoimmunity.[231]

T cells that mediate suppression or regulation of other T cells have long been purported to exist. They were formerly thought to be a subset of CD8$^+$ T cells, so-called suppressor cells, but in recent years a distinct population of CD4$^+$ T cells with regulatory properties have emerged as important effectors of cell-based regulation. This population of so-called naturally occurring T-regulatory cells can be distinguished from other CD4$^+$ T cells by the expression of certain cell surface receptors, most commonly CD25,[233] and more recently by expression of a key transcription factor, FoxP3.[234-236] FoxP3$^+$ CD4$^+$ CD25$^+$ T cells develop in the thymus and in murine models require IL-2 for development and maintenance.[237] Humans deficient in FOXP3 have the immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome, which is characterized by autoimmune diabetes and thyroiditis, inflammatory bowel disease, allergy, and other organ-specific autoimmunity.[238-240] In vitro, suppressive activity of these cells is defined by the ability to depress proliferation by lymphocytes stimulated via the TCR.[241-243] In vivo depletion of these cells in mice leads to spontaneous autoimmunity, whereas cotransfer suppresses autoimmunity in various models.[237]

NONCONVENTIONAL T-CELL SUBTYPES

In addition to conventional TCR αβ–bearing T cells that recognize peptide antigens, other nonconventional smaller populations of T cells exist. The function of these cells is less well characterized, but their conservation through evolution implies nonredundant roles in the

immune system. Both populations share the ability to bind to the nonclassic MHC molecules and have restricted TCR diversity. They are generally believed to have functions during the innate immune response.

Development and Function of CD1-Restricted T Cells or Invariant Natural Killer T Cells

A subset of T cells that bear $\alpha\beta$ TCR but recognize lipid antigens rather than peptide antigens has been defined in several ways over the past couple of decades. These cells were first characterized in the mouse as TCR $\alpha\beta$ T cells that co-expressed cell surface markers also found on NK cells such as NK1.1 (CD161) and therefore were termed NK T cells.[244] When it was found that a subset of NK T cells recognize the CD1 family of nonclassic MHC molecules,[245] the term CD1-restricted T cells has been used as a more precise functional definition; conversely, not all CD1-restricted T cells express NK1.1. CD1 is a family of proteins with one isoform in the mouse, CD1d, and five isoforms in humans, CD1a, CD1b, CD1c, CD1d, CD1e, the last of which is not expressed on the cell surface.[246] These MHC class I–like proteins are generally expressed in a complex with β_2-microglobulin. The diversity of TCRα rearrangements used by CD1d-restricted T cells is limited, with many bearing $V_{\alpha}24$-$J_{\alpha}18$ rearranged TCRα protein, preferentially complexed to a $V_{\beta}11$ TCRβ protein. Thus, the term invariant NK T cells is also used to distinguish this main population from those with diverse $\alpha\beta$ TCR restricted by CD1 molecules, and most studies have focused on the invariant CD1d-restricted subset.

Invariant NK T cells develop in the thymus, arise from the DP stage of development, and in mouse models are selected by other DP thymocytes that express CD1d rather than by thymic stroma.[247] In contrast to conventional T cells, invariant NK T cells recognize lipid presented by CD1.[248] A number of foreign lipids and glycolipids have been identified that are recognized by invariant NK T cells, although the discovery of self-antigens has been more elusive.[249] In the laboratory, α-galactosylceramide, derived from marine sponge, is a highly potent agonist for invariant NK T cells[250] and can be loaded onto tetramers of CD1d molecules tagged to fluorescent molecules to identify human or mouse invariant NK T cells by flow cytometry, similar to MHC tetramer technology.[251,252] About half of these cells do not express either CD4 or CD8 and half express CD4 in humans.[253] Invariant NK T cells produce cytokines, such as IL-4 and IFN-γ, more rapidly than conventional TCR $\alpha\beta$ T cells do, within hours in mice after in vivo injection with antigen.[254] This early secretion has been proposed to function as bridge between innate and adaptive immunity in diverse processes, including the response to infection, antitumor immunity, autoimmune disease, and asthma.[255]

DEVELOPMENT AND FUNCTION OF TCR $\gamma\delta$ T CELLS

TCR $\gamma\delta$ T cells can be identified in mammals, chickens, and even cartilaginous fish, though not in jawless fish.[256] Although they develop in the thymus alongside TCR $\alpha\beta$ T cells, in contrast to conventional T cells, the variety of $\gamma\delta$ receptors is highly restricted, with 6 V_{γ} genes used (5 $V_{\gamma}1$ and 1 $V_{\gamma}2$) and 8 to 10 V_{δ} genes, 3 of which are commonly used in humans.[256,257] TCR $\gamma\delta$ T cells make up a very small percentage of cells in the thymus or lymph node, on the order of 1% to 2%, but are much more abundant in mucosal surfaces, particularly the human gastrointestinal tract. Interestingly, the distribution of human TCR $\gamma\delta$ T cells is skewed toward particular $\gamma\delta$ combinations: peripheral blood contains a preponderance of $V_{\gamma}9V_{\delta}2^+$ T cells, whereas TCR $\gamma\delta$ T cells found in intestinal epithelium often bear $V_{\delta}1^+$ or $V_{\delta}3^+$ TCR.[257] Most of these cells do not express either the CD4 or CD8 coreceptor. Although it is known that $\gamma\delta$ rearrangement precedes $\alpha\beta$ rearrangement and that $\gamma\delta$ development occurs early during embryonic life, whether $\gamma\delta$ development depends on ligand binding is unclear. Indeed, the natural ligands of TCR $\gamma\delta$ T cells remain poorly defined but can be nonpeptides, as shown for circulating human TCR $\gamma\delta$ T cells that recognize mycobacterial antigens.[258-260] $V_{\gamma}9V_{\delta}2^+$ T cells can generally recognize various types of phosphoantigens, whereas non-$V_{\delta}2^+$ T cells have more diverse ligands, including MHC class I–like molecules such as CD1. TCR $\gamma\delta$ T cells can be expanded during responses to a variety of infections and tumors.[257]

NATURAL KILLER CELL DEVELOPMENT AND FUNCTION

In the peripheral blood of all individuals are circulating lymphocytes that morphologically resemble large granular lymphocytes and have distinctive physical characteristics that allow separation of them on a Percoll density gradient *in vitro*. These cells are termed NK cells and consist of a distinct subset of lymphocytes that unlike T lymphocytes, do not rearrange the T-cell antigen receptor genes (see Table 22-1).[261] These cells have the capacity to mediate the spontaneous lysis of sensitive target cells, including certain tumor cells, virus-infected cells, and hematopoietic cells, and to mediate ADCC.[262,263] NK cells appear to lyse their targets by pathways similar to those used by cytotoxic T lymphocytes.[262-264] NK cells have been shown to have a role in allograft rejection and tumor surveillance. Despite the relative homogenicity of morphologic appearance and function, NK cells are clearly a heterogeneous population of cells. NK cells are derived from a common lymphoid precursor cell. Peripheral blood NK cells may be derived directly from precursors in the bone marrow or may transit through the thymus, although the thymus is not required for their development. Phenotypic and functional NK cells may

arise from immature CD7[+] CD1[−] TCR[−] CD3[−] CD4[−] CD8[−] prothymocyte precursors,[265,266] and they express CD2. Recent data indicate that Flt3L, IL-15, and IL-21, a cytokine closely related to IL-2 and IL-15, are all involved in NK hematopoietic development and expansion.[267] More recently, there is evidence that NK cells in humans can also mature in secondary lymphoid tissue.[268]

In addition to a role in immune surveillance, a role has been documented for NK cells in protection from viral infections, which is particularly important in the early phases of an immune response before T-cell recruitment. Indeed, NK cells are critical for protection against latent DNA viruses of the herpes family inasmuch as individuals with a deficiency in NK cell number or function typically have overwhelming herpesvirus infections.[264] Viral infection can trigger NK cell activity in several ways. First, elaboration of cytokines such as IFN-α, IFN-β, and IL-12 by infected cells, particularly monocytes, macrophages, and dendritic cells, induces NK cells to produce IFN-γ.[269] Second, cells expressing viral antigens that are then coated with specific Ig can bind to FcR on the surface of NK cells and trigger ADCC. Finally, NK cell surface receptors that usually recognize MHC class I and class I–like molecules mediate so-called missing self recognition.

NK cells interact with and are regulated by nonclassic MHC class I molecules. The killer cell Ig-like receptors (KIRs) recognize HLA class Ia and class Ib proteins, including HLA-G.[270] Members of a related family, termed Ig-like transcripts or leukocyte Ig-like receptors (LIRs), also recognize HLA class I proteins and are expressed not only by NK cells but also by cells of the myelomonocytic lineage.[271] These families of receptors act as inhibitory receptors that downregulate NK cell activity upon recognition of ligand by recruiting negative regulatory signaling proteins (e.g., tyrosine phosphatases) to the receptor complex.[272,273] Thus, NK cells can be activated or inhibited by HLA class I–like molecules; net activity depends on expression of these receptors and expression of MHC class I molecules on the target cells. Viruses may use the ability to downregulate MHC class I expression as a means of subverting the immune response; cells with low class I MHC expression are, however, targets of NK cytotoxicity. Importantly, human cytomegalovirus expresses an MHC class I homologue, UL18, that associates with β$_2$-microglobulin and endogenous host peptides. UL18 binds with high affinity to LIR-1 and related NK molecules, thereby effectively competing with host class I molecules, and escapes immune recognition.[274-276]

CONCLUSIONS

T and B cells play a central role in the acquired immune response, and NK cells are an early and critical effector of the innate immune response. The evolution of an adaptive immune response with the capacity for long-lived anamnestic responses affords exquisite specificity and adaptability to higher animals such that novel infections or arising malignancy can be both cleared initially and protected against upon re-exposure. Indeed, the requirement for T-cell function in normal homeostasis is exemplified by the consequences of its suppression. Deficiency of T-cell function associated with acquired immunodeficiency syndrome (AIDS), allogeneic stem cell transplantation, or T-cell–directed immunosuppressive therapy places patients at risk for herpes family viral reactivation (herpes simplex, herpes zoster, and cytomegalovirus) and lymphoproliferation (particularly Epstein-Barr virus–transformed B-cell lymphomas). As the mechanisms of immune control of nascent malignant degeneration become better understood, strategies to improve control of cancer by immunomodulatory therapy may become more tractable.

The same acquired immune response that gives higher animals an advantage in control of infection conversely predisposes these same species to the unique problems of autoimmunity. Failure of self-tolerance may result from the dysregulation of host T-cell responses after exposure to specific antigens in the setting of specific MHC molecules. Self-reactive B-cell clones may also mediate autoimmunity through inappropriate production of self-antigen–specific antibodies directed against a variety of tissue-specific targets. That enhancement of immune responses can precipitate autoimmunity is exemplified by the development of autoimmunity in melanoma patients who experienced tumor regression after peptide vaccination in the context of immunostimulatory anti–CTLA-4 antibody.[277] Greater understanding of antigen-specific activation and tolerance should open the way to the development of targeted immunomodulation and carry the field beyond global suppression of T-cell responses.

Immune compromise arises either as a heritable genetic defect (primary disease) or as a consequence of (secondary to) another pathologic process such as infection, malignancy, or iatrogenic immunosuppression. Immune system dysfunction is most often manifested as recurrent and chronic infections. Malignancy and autoimmunity also occur in certain syndromes. In most instances, symptoms and signs of immunodeficiency develop soon after birth. However, onset may be delayed into childhood, and milder variants may not be diagnosed until adulthood. Even though many patients with severe immunodeficiency suffer dramatic morbidity and mortality in infancy and early childhood, the majority of patients with immunodeficiency have milder forms that permit survival into adulthood, but often with reduced longevity because of infection, autoimmune disease, or constitutional debility. Health-related quality of life is significantly impaired in children with primary immunodeficiency.[1] The challenge to clinicians is to recognize and intervene aggressively in these "milder" forms to maximize quality of life for these patients.

Immunodeficiencies may be classified with respect to the specific immune effector mechanisms disrupted.[2,3] In broadest terms, one may distinguish cellular and humoral components of both specific immunity (T-cell cytotoxicity and B-cell antibody production) and nonspecific immunity (phagocytosis and the complement system). Discussed here are selected syndromes of immunodeficiency arising from aberrant development and function of T and B cells, as well as the complement system. Phagocytic disorders are the subject of Chapter 21. Table 23-1 lists several Internet sites with information relevant to primary immunodeficiencies.

COMBINED IMMUNODEFICIENCIES

Severe Combined Immunodeficiency

The term severe combined immunodeficiency (SCID) designates a genetically heterogeneous group of syndromes having in common a profound disturbance in the development and function of both T and B cells.[4] In Figure 23-1 the development of lymphocytes is outlined. In some instances, the molecular defect leading to SCID prevents only T-cell function, and B cells are normal. However, because T cells play a role in most B-cell responses, serious T-cell dysfunction precludes effective humoral immunity. Not surprisingly, complete absence of specific cellular and humoral immunity leads to an extreme infectious diathesis. Mucocutaneous candidiasis is a common early finding. Infections with common viral pathogens (e.g., varicella, herpes simplex, measles, adenoviruses, respiratory syncytial virus, influenza, and parainfluenza) are often fatal. Patients are also susceptible to opportunistic infections with commensal organisms that are normally nonpathogenic, such as *Pneumocystis jiroveci*. Even attenuated vaccine organisms such as oral polio vaccine virus and bacille Calmette-Guérin (BCG) can cause severe or fatal infection. Transfusion of blood products containing viable lymphocytes may lead to fatal graft-versus-host disease. The few patients who do not die of infection during childhood have an increased risk for malignancy.

Typical symptoms of SCID are recurrent severe infections, chronic diarrhea, and failure to thrive.[2,4] Symptoms are often seen in the newborn period but may be delayed by several months. Antibodies derived from the mother by transfer across the placenta provide some early protection. Physical examination may reveal foci of infection (e.g., thrush) and the absence of discernible lymphoid tissue. Hypogammaglobulinemia is often present but is not universal. Specific antibody responses are almost always severely impaired.

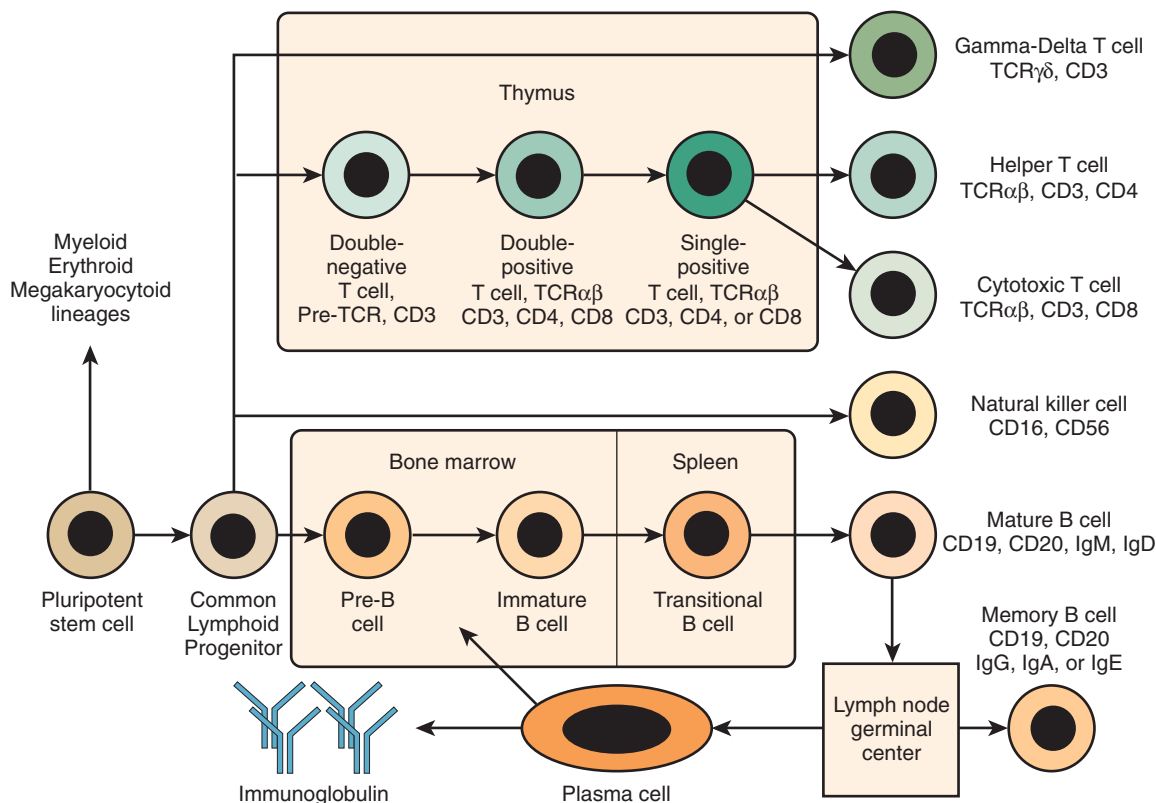
Abnormalities in lymphocyte populations vary, depending on the specific molecular defect. T cells are almost always absent or their numbers are very low, and they do not function. SCID is most often classified according to the peripheral blood lymphocyte phenotype, that is, absence or presence of the major lymphocyte types. T cells are absent (or very low) in all classic forms of SCID, a phenotype designated "T−." The presence or absence of B cells is indicated by adding "B+" or "B−," respectively. The same pattern applies for natural killer (NK) cells. Table 23-2 lists the various lymphocyte phenotypes of SCID and the molecular defects associated with them. Some syndromes classified as SCID have phenotypes that do not fall easily into any of these principal groups and are listed individually. Figure 23-2 shows the relative frequency of SCID secondary to some


FIGURE 23-1. Diagram of lymphocyte development. Pluripotent stem cells give rise to all cellular blood elements. The common lymphoid progenitor gives rise to the three principal lineages of lymphocytes: T cells, B cells, and natural killer cells. T cells develop in the thymus. Most peripheral T cells express the αβ form of the T-cell antigen receptor (TCR) and develop through distinct stages in the thymus. Mature helper T cells express the CD3 antigen coreceptor complex along with the major histocompatibility complex (MHC) class II receptor CD4, whereas cytotoxic cells express the MHC class I receptor CD8. A minority (1% to 5%) of peripheral T cells express the γδ form of the TCR along with CD3, but without CD4 or CD8; less is known about their development. B cells develop initially in the bone marrow and pass through several stages before exiting to complete development in the spleen. Mature B cells express distinct markers (CD19 and CD20) along with surface immunoglobulin M (IgM) and IgD. B cells are activated in germinal centers to undergo class switching and become either memory B cells expressing IgG, IgA, or IgE or Ig-secreting plasma cells. Most IgG-producing plasma cells reside in the bone marrow. Natural killer cells are a distinct lineage of cytotoxic cells; little is known regarding their development from lymphoid precursors.

of these defined genetic lesions. Approximately 10% of SCID cases result from unknown genetic lesions. In as many as 40% of patients with SCID, maternal T cells may have engrafted in the fetus during gestation, and this situation may occasionally confuse the diagnostic picture.[5]

Maternally derived T cells tend to be anergic, but they may also be associated with clinical manifestations similar to those of graft-versus-host disease, such as eczematous rash, eosinophilia, and splenomegaly. In rare circumstances, maternal engraftment may lead to even more unusual clinical findings, such as IgA monoclonal gammopathy in an infant.[6]

T⁻B⁻NK⁻ Severe Combined Immunodeficiency

Adenosine Deaminase and Purine Nucleoside Phosphorylase Deficiencies

Figure 23-3 shows the salvage pathway of purine nucleotide synthesis. The enzymes adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP) are the only known defects of nucleotide synthesis associated with immunodeficiency.[7,8] ADA deficiency (ADAD), which has an incidence of 1 in 200,000 live births, accounts for approximately 15% of all patients with SCID (see Fig. 23-2), or approximately a third of SCID cases with autosomal recessive inheritance. PNP deficiency (PNPD) is quite rare (30+ patients described). Absence of ADA or

PNP leads to intracellular accumulation of deoxyadenosine and deoxyguanosine, respectively. These molecules are not themselves toxic to lymphocytes. However, when they are converted to their 5′-triphosphates (deoxyadenosine triphosphatase [dATP] and deoxyguanosine triphosphatase [dGTP]), they inhibit ribonucleotide reductase and prevent de novo synthesis of deoxynucleotides. Without building blocks for the replication and repair of DNA, the cells cease to divide. Lymphocytes die to a much greater extent than other cell

FIGURE 23-2. Relative occurrence of severe combined immunodeficiency (SCID) syndromes. The category labeled "Other/unknown" contains a few patients with some of the less common genetic mutations associated with SCID, along with some whose causes have yet to be determined. (*Adapted from Buckley RH. A historical review of bone marrow transplantation for immunodeficiencies. J Allergy Clin Immunol. 2004;113:793-800.*)

types do. In ADAD and PNPD, T-cell precursors in the thymus appear to be especially sensitive to death by apoptosis (programmed cell death).[9-12] B cells are more often depleted in ADAD than in PNPD. In the latter, the B-cell phenotype is more variable.

Approximately 85% of individuals with ADAD will display a SCID phenotype with markedly reduced numbers of both T and B cells and low serum antibody levels. NK cells are only rarely found in patients with ADAD. Additional clinical manifestations may include radiographic alterations of the ribs, vertebral bodies, and iliac crests, as well as cognitive impairment later in life.[7,13] Without bone marrow transplantation (BMT), the majority of patients die of infection. Ten percent to 15% of patients with ADAD may have a delayed or late-onset form that may be manifested in late infancy or early childhood.[12] These patients may initially have variable numbers of circulating lymphocytes and some humoral immunity that quickly wanes. The severity of the phenotype appears to correlate to some degree with the amount of residual ADA activity. As little as 3% to 5% residual enzyme activity may be sufficient to maintain normal immune function even into adulthood, at which time infectious complications may arise.[14] ADAD has also been described in a few adult patients with "idiopathic" CD4 lymphocytopenia (see later).[15]

PNPD is mainly expressed as a somewhat selective defect in cellular immunity, although it is usually discussed together with ADAD because of similarities in their biochemical pathophysiology. Patients are extremely susceptible to viral and fungal infections. They have decreased numbers of circulating T cells, often initially with normal numbers of B cells and normal serum immunoglobulin (Ig) levels. With time, humoral immunity usually deteriorates. Analysis of a murine model of PNPD suggests that accumulation of dGTP inhibits mitochondrial DNA repair and leads to increased T-cell apoptosis.[11] Approximately 50% of children with PNPD have

FIGURE 23-3. Salvage pathway of purine nucleotide biosynthesis. d, deoxy; dATP, deoxyadenosine triphosphatase; dGTP, deoxyguanosine triphosphatase.

neurologic complications such as spasticity, diplegia, paresis, and other motor disorders, as well as cognitive impairment.[16]

After clinical suspicion is aroused, diagnosis of ADAD or PNPD is not difficult. Both ADA and PNP activity is readily measurable in red blood cell (RBC) or leukocyte lysates. In symptomatic patients, activity is usually 1% or less of that in normal subjects. These methods may be applied for screening of in utero cord blood samples or cultured amniotic or chorionic villus cells. PNP is required for the production of hypoxanthine, a precursor of uric acid (see Fig. 23-3). Thus, individuals with PNPD will have reduced serum and urine urate levels. Such is not the case for patients with ADAD.

ADAD is amenable to enzyme replacement therapy. RBCs contain high levels of ADA, and RBC transfusions can ameliorate the enzyme defect.[17] Such treatment is effective in approximately 50% of patients, mainly those with evidence of some residual immune function. However, these patients have a risk of complications after chronic RBC transfusions, such as iron overload and transfusion-associated infections. An alternative therapy is infusion of polyethylene glycol–conjugated bovine ADA (PEG-ADA or pegademase).[9,18] This treatment is generally well tolerated, but immune reconstitution is incomplete. Infectious complications may occur occasionally during therapy with PEG-ADA, and malignancies such as cerebral Epstein-Barr virus (EBV)-positive lymphoma have also been observed.[19] RBC transfusions have not benefited patients with PNPD. Other forms of enzyme replacement have not been explored.

BMT is curative of the immunodeficiency associated with ADAD and PNPD (see later). Other features, such as neurologic impairment, are not improved after BMT. ADAD has also been cured by gene therapy (see later).

T⁻B⁻NK⁺ Severe Combined Immunodeficiency

Defects of Recombinase-Activating Genes 1 and 2

Patients have very low numbers of T and B lymphocytes, and NK cells are found in about 75% of these patients. This form of SCID results from mutations in one of two DNA-binding proteins, the products of recombinase-activating genes 1 or 2 (*RAG1* or *RAG2*).[20] These proteins have critical roles in directing the somatic recombination of Ig and T-cell antigen receptor (TCR) genes. RAG1 and RAG2 proteins bind to specific recognition sequences flanking gene segments and participate in cutting and splicing of the DNA that assembles mature Ig or TCR genes (Fig. 23-4). B- and T-cell precursors are
FIGURE 23-4. Gene defects affecting lymphocyte antigen receptor gene rearrangement and causing T⁻B⁻NK⁺ severe combined immunodeficiency. The genes that encode immunoglobulin and T-cell antigen receptors are assembled from subunit segments that are separated in the germline and undergo assembly or somatic rearrangement during lymphocyte development. In the figure, a TCR or Ig heavy chain is shown. The heavy chains are composed of four distinct segments: V, variable; D, diversity; J, joining; C, constant. Some of the segments are flanked by recombination signal sequences (RSS). RAG1 and RAG2 initiate the process that leads to double-strand breaks (DSB) in DNA. The DNA in between coding segments is looped out and forms circles, with the coding sequences joining to one another. In the case of T cells, the larger DNA circle is referred to as a T-cell receptor excision circle. All these DNA joints are made by a group of molecules that together subserve the function of nonhomologous end joining (NHEJ).

present, but they are arrested at an early stage of development. Some patients with *RAG1* or *RAG2* mutations have variable degrees of immune deficiency and atypical lymphocyte phenotypes (limited development of small numbers of B or T lymphocytes, or both).[20] Mutations in these genes should be sought in individuals with partial combined immunodeficiency without other specific molecular diagnoses.

A distinct SCID phenotype known as Omenn's syndrome (OS) also results from *RAG1* or *RAG2* mutations.[21] OS has similar manifestations as acute graft-versus-host disease. Symptoms include recurrent severe infections, failure to thrive, chronic severe diarrhea, and erythroderma with exfoliation and exudation. Examination may reveal hepatosplenomegaly and lymphadenopathy. Laboratory studies show anemia, hypogammaglobulinemia with an elevated IgE level, a decrease in the number of peripheral B cells and poor antibody responses to antigen, appearance of immature CD4+CD8+ T cells ("double-positive" T cells) in the circulation, and absence of T-cell function in vitro. Patients exhibit infiltration of the skin, intestinal mucosa, liver, and spleen with histiocytes and oligoclonal populations of T cells and lymphocyte depletion in the thymus, spleen, and other peripheral lymphoid tissues. It has been proposed that mutations in *RAG1* or *RAG2* that permit partial function (so-called hypomorphic mutations) result in the OS phenotype rather than "classic" SCID. However, recent observations of similar mutations in patients with these two disorders suggest that other factors also play a role in determining the phenotype.[22] In at least one case, progression to OS was observed in a patient with a *RAG2* mutation after infection with parainfluenza virus type 3.[23] Occasionally, somatic mutations may become superimposed on null or "amorphic" mutations and yield mosaicism with revertant or hypomorphic populations of lymphocytes and resultant OS.[24] Additional genetic defects have also been associated with OS (*DCLRE1C*, or Artemis, and *IL7RA*, see later).

Mutations of DCLRE1C (Artemis)

A form of autosomal recessive SCID with the classic T−B−NK+ phenotype has an associated feature of general radiation sensitivity not seen with *RAG1* or *RAG2* mutations and is caused by mutations in the gene *DCLRE1C* (DNA cross-link repair enzyme 1C), whose protein product is called Artemis.[25] Artemis has a critical role in the function of nonhomologous end joining (NHEJ), or the repair of double-stranded DNA breaks (see Fig. 23-4).[26] Absence or impaired function of Artemis blocks lymphocyte development in the same manner as mutations in *RAG1* and *RAG2* do, by preventing proper assembly of mature Ig and TCR genes through somatic recombination. Artemis is ubiquitously expressed, and the generalized radiation sensitivity phenotype in these patients results from loss of its function in nonhematopoietic tissue. OS has been observed in some patients with Artemis defects.[27]

DNA Ligase IV Defects

Mutations in the DNA ligase IV gene (*LIG4*) lead to a form of T−B−NK+ SCID and radiosensitivity very similar to Artemis deficiency, with the added features of microcephaly and cognitive impairment.[28-30] Ligase IV is also required for NHEJ. Fewer than 10 patients have been described thus far. The severity of the immunologic and neurologic features is variable. Some patients have pancytopenia, and two patients have had leukemia.

Cernunnos Deficiency

Five patients have recently been described with another form of T−B−NK+ SCID, very similar to ligase IV deficiency, that is due to mutations in the *NHEJ1* (nonhomologous end joining 1) gene.[31] The protein product has been called Cernunnos. Clinical features include lymphopenia, radiation sensitivity, growth retardation, microcephaly, and developmental delay.

T−B+NK− Severe Combined Immunodeficiency

X-Linked Severe Combined Immunodeficiency, Mutations of the Cytokine Receptor Common γ Chain

Slightly less than half of all patients with SCID are males with an X-linked form of the disease, referred to simply as X-linked SCID (XSCID), that is due to mutations in the cytokine receptor common γ chain (γc).[32] This molecule is shared by no less than six different cytokine receptor complexes, including those for interleukin-2 (IL-2), IL-4, IL-7, IL-9, IL-15, and IL-21 (Fig. 23-5). Thus, a defect in a single molecule interrupts several cytokine pathways, thereby severely disrupting immune function. One patient with this disease received intense media attention ("the boy in the bubble").[33] These patients have a classic SCID phenotype: T cells are absent, and the thymus is empty of lymphocytes. The number of B cells is normal or increased; however, Ig is virtually nonexistent. This deficiency results largely from the absence of T-cell help for antibody production. However, B cells are not completely normal. Their function can be only partially complemented by normal T cells. NK cells are found in about 10% of patients. Some patients with XSCID may have variable numbers of their own T cells or B cells and partial immune function.[34] In addition, maternal T cells may enter the fetus's circulation during gestation and subsequently expand.[35] Thus, the diagnosis of γc deficiency should at least be considered in all males with SCID.

T lymphocytes of female carriers of XSCID show a highly skewed pattern of lyonization, or nonrandom X-chromosome inactivation.[36] This may be studied with DNA probes specific for highly polymorphic repetitive sequence regions, some of which may be associated with specific genetic loci, such as monoamine oxidase, or with the androgen receptor. Female carriers express a single allele at a polymorphic locus of the X chromosome in

FIGURE 23-5. Cytokine receptors and signaling via γc and Jak3. The γc chain participates in signaling via all of these cytokine receptors; it associates with the Jak3 kinase in every case. The α chains of each receptor are distinct; receptors for interleukin-2 (IL-2) and IL-15 also share a β chain. The α or β chains or both associate with Jak1. After cytokine binding, Jak kinases recruit STAT (signal transducer and activator of transcription) proteins. These molecules dimerize and then translocate to the nucleus, where they associate with other transcriptional regulators and alter gene expression. NK, natural killer.
more than 95% of T lymphocytes. This represents the preferential survival of cells retaining the functional gene on the active X chromosome. The expression of alleles in other tissues is less unequal. Similar analyses are useful with other X-linked immunodeficiency disorders, such as Wiskott-Aldrich syndrome (WAS) and X-linked agammaglobulinemia (XLA).

Urgent BMT is the standard therapy for all forms of SCID, including XSCID. In some patients, B cells may fail to engraft after BMT (see later), thus leaving patients with their own B cells and residual humoral immunodeficiency despite normal T-cell function. Gene therapy has also been successful in the treatment of XSCID (see later).

Jak3 Deficiency

A form of T⁻B⁺NK⁻ SCID phenotypically very similar to XSCID is associated with defects in the tyrosine kinase Jak3.[37,38] The similarity with XSCID is easily understood because Jak3 is a critical signal-transducing molecule associated with the γc chain (see Fig. 23-5). Oligoclonal and poorly functional T cells may develop in some of these patients, but NK cells are not generally found. Because of the variable immunologic phenotype, the diagnosis should be considered in patients with combined immunodeficiency and B cells. One patient displayed highly unusual functional maternal engraftment that provided partial immune protection, and the diagnosis was made at 8 years of age.[39]

CD25 Deficiency

A male infant was reported to have a form of SCID caused by mutation of the gene encoding the α chain of the IL-2 receptor (also called CD25, the signaling chain for this receptor is γc; see Fig. 23-5).[40] This child was seen at 6 months of age with oral and esophageal candidiasis, chronic diarrhea, failure to thrive, chronic lung disease, and autoimmunity with lymphadenopathy and splenomegaly. He had a reduced number of CD4⁺ T cells and NK cells and poor in vitro T-cell function that could not

be corrected with exogenous IL-2. B-cell number and function were normal. CD25 is important in T-cell development. The finding of reduced apoptosis of thymocytes in this patient suggested that they were resistant to negative selection and that this resistance permitted many autoreactive T-cell clones to reach the periphery and expand.

T⁻B⁺NK⁺ Severe Combined Immunodeficiency

Defects of the Interleukin-7 Receptor α Chain

Between 10 and 20 patients with a T⁻B⁺NK⁺ SCID phenotype have been found to have mutations in the gene encoding the α chain of the IL-7 receptor (IL-7Rα, also called CD127; the signaling chain for this receptor is γc; see Fig. 23-5).[41] This molecule is also a component of the receptor for thymic stromal lymphopoietin, a member of the IL-2 family of cytokines. In one review of 16 patients, BMT was successful in 13.[41] At least one patient with IL-7Rα defects was found to have OS at initial evaluation.[42]

Mutations Affecting Components of the T-Cell Antigen Receptor Complex

The TCR is made up of several different polypeptides (Fig. 23-6),[43] including the TCRα and TCRβ (or TCRγ and TCRδ) chains of the receptor making contact with major histocompatibility antigen-peptide complexes, as well as components of the CD3 signal-transducing complex: CD3γ, CD3δ, and CD3ε and a ζ₂ dimer or a ζ-η heterodimer.

Defects in CD3δ lead to a T⁻B⁺NK⁺ SCID phenotype.[44-47] Of the nine patients (four kindreds) described, all had varying degrees of panhypogammaglobulinemia and disseminated viral infections (except one in whom the defect was diagnosed at birth because of a family history). Three patients had thymus glands of normal size, in marked contrast to almost all other forms of SCID, in which the thymus is absent or extremely hypoplastic.[46] One other patient had a small thymus, thus
FIGURE 23-6. Components of the T-cell antigen receptor. The actual receptor making contact with a major histocompatibility complex (MHC)-peptide complex is a heterodimer of α and β (or γ and δ) chains. This heterodimer sits in the cell membrane in association with the signal-transducing CD3 complex. This complex contains two heterodimers, one γε and one δε, and one ζ dimer. Also shown is the MHC class II coreceptor molecule CD4. Tyrosine kinases Lck, Fyn, and ZAP-70 associate with components of the receptor complex via immunoreceptor tyrosine-based activating motifs (ITAMs) and transduce signals after interaction of the receptor with peptide/MHC.

suggesting that a normal-size thymus may not be a consistent feature of this form of SCID.[44] Three patients (one kindred) with deficiency of CD3ε leading to a similar phenotype have been described.[45,47] Finally, one patient with a similar phenotype and germline and mosaic partial revertant mutations of the gene encoding the CD3γ chain has also been described.[48]

One family has been identified in which two sibling boys had mutations in the genes encoding the γ chain of the CD3 complex.[49] One sibling had a SCID phenotype with a normal number of lymphocytes and a selective deficiency of IgG2. He died of parainfluenza 3 pneumonia at 31 months of age. His brother had a similar laboratory profile; however, he was healthy and did not have recurrent infections. The reason for the differential phenotypic expression of the same defect in these brothers is not known.

CD45 Deficiency

A few patients have been found to have a form of SCID resulting from mutations in the gene encoding the protein tyrosine phosphatase CD45.[50-52] This molecule plays an important role in T-cell activation. These patients have a SCID phenotype with diminished numbers of poorly functional T cells and normal numbers of B cells and NK cells.

Severe Combined Immunodeficiency with Selective Deficiency of CD4+ T Cells

Mutations Affecting the HLA Class II Gene Transcription Complex

The major histocompatibility complex (MHC) in humans is called the human leukocyte antigen (HLA) complex. The class I and class II HLA molecules expressed on cell surfaces are critical for practically all mechanisms of specific immune activation. Class I molecules are present on most cells of the body. They present antigenic peptides derived principally from intracellular sources to the antigen receptors of T cells expressing CD8. Class II HLA molecules are generally restricted to specialized antigen-presenting cells (APCs), including monocytes and macrophages, dendritic cells, and B cells. HLA class II molecules mainly present peptides imported from outside the cell to antigen receptors of T cells bearing CD4. Defects in the synthesis, expression, or function of HLA molecules may be expected to have profound consequences on immune competence.

More than 50 patients with HLA class II deficiency have been described to date.[53] Most children who have this disorder are seen within the first weeks of life with a classic SCID phenotype. Lymphocyte numbers tend to be normal, but all forms of MHC class II (DP, DQ, and DR) are not expressed. Most patients have profound hypogammaglobulinemia, no delayed hypersensitivity responses, and decreased numbers of circulating CD4+ T cells. Some patients have normal serum Ig levels; however, specific antibody responses are not elicited. Alloreactivity in mixed lymphocyte culture is preserved to a large extent. As a rule, these children do not survive without BMT. For reasons that are not clear, however, BMT in these patients has not been consistently successful.[54]

MHC class II deficiency results from defective regulation of gene transcription.[53] Four complementation groups (A through D) are recognized, each corresponding to a component of the HLA class II transcription complex (Fig. 23-7). Mutations in *CIITA* (class II transactivator) correspond to group A, mutations in *RFXANK* (the B subunit of the regulatory factor X complex) to group B, mutations in *RFX5* (encoding another subunit of RFX) to group C, and mutations in *RFXAP* to group D. Without a complete transcription complex, no mRNA is produced, and class II proteins cannot be synthesized. The same complex activates transcription at all HLA class II gene promoters.

CIITA*

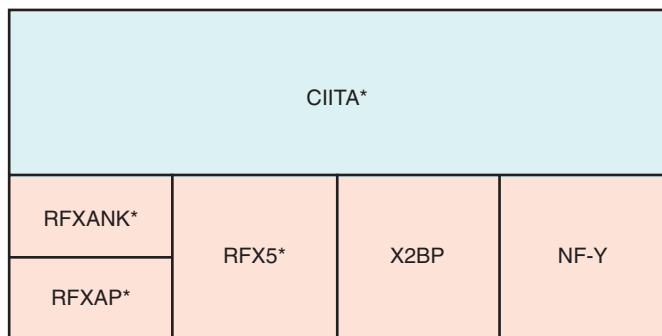

FIGURE 23-7. Transcription complex for major histocompatibility complex (MHC) class II genes. Shown are the known components of the complex of proteins that regulates transcription of MHC class II genes. Mutations of the genes encoding the components indicated by asterisks lead to MHC class II–deficient severe combined immunodeficiency (see text).

Partial MHC class II deficiency has also been reported in male twins.[55] These children had trace amounts of HLA-DR α and β protein detected by immunoblotting techniques. Interestingly, one twin was hypogammaglobulinemic and suffered from recurrent infections; he showed a good response to replacement therapy with intravenous immunoglobulin (IVIG). The other twin was completely asymptomatic and had normal serum antibody levels and immune responses, although he had no more DR expression than his brother did. The molecular defect in these children is not known.

Selective Deficiency of CD8+ T Cells

ZAP-70 Deficiency

Several patients with mutations in the gene encoding the ZAP-70 (TCRζ-associated protein of 70 kd) tyrosine kinase (see Fig. 23-6) have been described.[56] The ZAP-70 tyrosine kinase has a critical role in signals transmitted via the TCR. Individuals with ZAP-70 deficiency have a classic SCID phenotype. They may exhibit somewhat elevated total lymphocyte counts with a high number of CD4+ T cells and almost complete absence of CD8+ T cells. Although circulating CD4+ cells appear normal, they fail to respond to signals delivered via the TCR. These characteristics suggest that ZAP-70 kinase is critical for normal thymic development of CD8+ cells and not for the CD4+ subset. However, mature CD4+ T cells depend on ZAP-70 for activation.

Defective Expression of HLA Class I

Several patients with defective expression of HLA class I molecules have been described.[57,58] These patients have mutations in one of two genes encoding either TAP1 or TAP2 (transporter associated with antigen processing 1 or 2). The TAP1/TAP2 heterodimer is required for shuttling of cytosolic peptides across the endoplasmic reticulum to load onto nascent HLA class I molecules for eventual expression at the cell surface and presentation

to TCRs (Fig. 23-8). HLA class I molecules are highly unstable without a peptide in their binding cleft, and they are not transported to the cell surface. Another patient has been described with reduced MHC class I expression because of a mutation affecting the molecular chaperone TAP-binding protein, also called tapasin.[59] These entities are frequently categorized as forms of SCID, although patients with defective expression of HLA class I appear to suffer mainly upper and lower respiratory tract bacterial infections and bronchiectasis. A few patients may exhibit granulomatous skin inflammation. Occasional asymptomatic individuals have also been described. The main immunologic abnormality is low peripheral blood CD8+ T cells; antibody responses may be normal.

Severe Combined Immunodeficiency with Normal Lymphocyte Populations

Defect in Orai1

After lymphocyte receptor engagement and costimulation by cytokines and other intercellular contacts, mobilization of calcium from both intracellular and extracellular sources is absolutely necessary for downstream signaling, activation, and proliferation. Two patients from a single kindred have been found to have a form of SCID caused by an impairment in this critical calcium flux.[60] The defective protein has been called Orai1, and its function is required for operation of the calcium release–activated calcium (CRAC) channel. These two males had essentially normal peripheral blood lymphocyte phenotypes with normal or elevated Ig levels.[61] However, T cells did not respond to stimulation in vitro, and no specific antibody was produced. One patient died of disseminated BCG infection. The other survived BMT but has persistent anhidrotic ectodermal dysplasia and myopathy.[60]

Griscelli's Syndrome

Griscelli's syndrome (GS) is one of a group of diseases of "pigmentary dilution" whereby abnormalities in melanosome trafficking within cells lead to characteristic pale skin and silvery-gray or ashen hair. In GS, this may be associated with a profound cellular immunodeficiency and neurologic abnormalities (seizures, ataxia, oculomotor and reflex abnormalities).[62,63] Screening studies of immune function may be normal. Patients may have lymphadenopathy and hepatosplenomegaly at initial evaluation. Infections consist principally of bacterial infections of the respiratory tract, skin, and other organs. Without BMT, fulminant and fatal lymphoproliferation with hemophagocytosis ultimately develops.

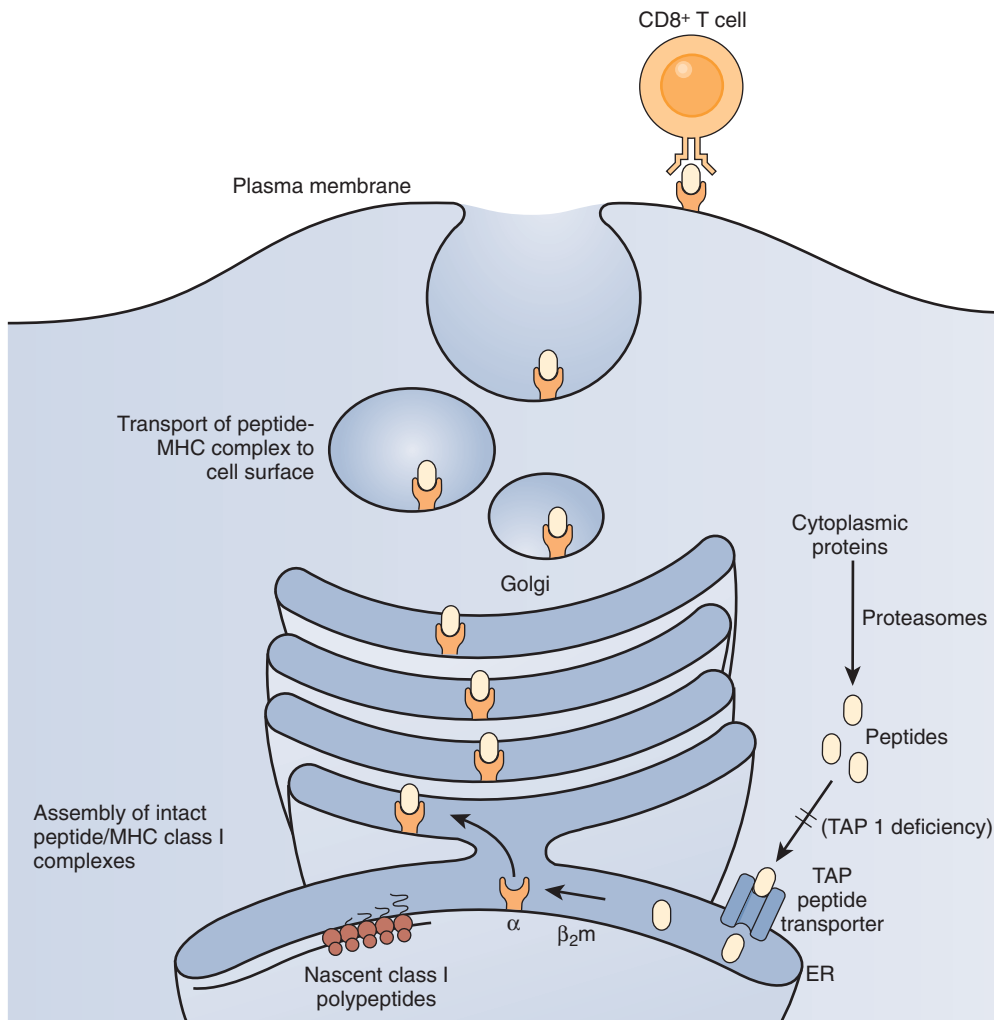
The full spectrum of symptoms in GS is referred to as GS type 2, and it results from mutations in *RAB27A*.[62,63] The *RAB27A* gene product plays an important role in transporting cytotoxic T-cell granules to the site of contact with a target cell. Lack of Rab27a protein impedes this process and diminishes the ability of cytotoxic T cells to kill their targets. Patients with GS type 1 exhibit


FIGURE 23-8. Synthesis and assembly of major histocompatibility complex (MHC) class I molecules. ER, endoplasmic reticulum; β_2m, β_2-microglobulin; TAP, transporter associated with antigen processing.

pigmentary changes and neurologic symptoms without immunodeficiency and have mutations in the *MYO5A* gene that encodes the myosin Va protein. Myosin Va binds to actin and hydrolyzes adenosine triphosphate. It also has a role in vesicle transport within cells. GS type 3 consists of only pigmentary change and is associated with defects in the melanin chaperone melanophilin.

Therapy for Severe Combined Immunodeficiency

Bone Marrow Transplantation

Identification of a patient with SCID is an immunologic "emergency."[64] Children with this disorder are so prone to infections that extreme measures must be taken to protect them from microbial invasion. Most patients are already infected when initially evaluated and require aggressive interventions to keep their clinical course from running inexorably downhill. After full immunologic evaluation has been performed (as expeditiously as possible), these patients should begin receiving IVIG infusions. Prophylaxis for *P. jiroveci* pneumonia is indicated for all patients.

Although alternative therapies may work for some patients (e.g., PEG-ADA for ADAD), the definitive treatment for the great majority of patients with SCID is BMT. A variety of sources have been used for stem cells, including HLA-identical sibling donors, haploidentical related donors (usually parents), HLA-matched unrelated donors, and partially matched umbilical cord blood.[65-70] Pretransplant conditioning with chemotherapy, radiation therapy, or both may be indicated, depending on the particular form of SCID and the relatedness of the donor. After BMT, patients have variable patterns of leukocyte chimerism. Almost universal reconstitution with donor T cells is seen. B-cell engraftment is less reliable, but its likelihood may be increased in some forms of SCID with prior myeloablation. Humoral immunity is generally intact if engraftment of donor B cells takes place. However, if it does not, lifelong replacement therapy with IVIG is required. The origins of NK and myeloid populations are unpredictable.

The best outcomes are obtained with BMT from HLA-identical related donors in the first 1 to 3 months of life in the absence of any infections. After BMT, thymic output of T cells may be measured by determining the

number of T cells that bear T-cell receptor gene excision circles (TRECs).[71-73] TRECs are episomal DNA circles composed of the DNA segment between TCR variable region and D region gene segments that are excised in the process of somatic recombination during thymic T-cell development (see Fig. 23-4). The largest and earliest increases in TRECs predict the most robust T-cell reconstitution after BMT. However, more than 10 years after BMT, levels of TRECs fall more rapidly than in normal individuals, and the diversity of the T-cell repertoire is diminished.

TRECs can be measured in dried blood spots, such as those obtained in the course of newborn screening for a variety of inherited disorders.[74,75] In the vast majority of forms of SCID, TRECs are very low in number as a result of the absence of significant thymic T-cell output. Methods for detecting TRECs will probably soon be applied in pilot studies of newborn screening for SCID.

Gene Therapy

Gene therapy for the treatment of human disease was first attempted in patients with ADAD.[76] A functional copy of the ADA gene in a retroviral vector was transduced into populations of hematopoietic cells or mature T cells. Transduced cells expressed normal levels of ADA and showed normal function in vitro. However, clinical efficacy was difficult to assess in these early attempts because adjunctive therapy with PEG-ADA was considered to be mandated on ethical grounds, even after the reintroduction of transduced cells into patients. As the therapy developed, eventual complete immune reconstitution was achieved, even after discontinuation of PEG-ADA.[77,78] In some cases, myeloablative therapy was also administered.

The earliest "complete" success of gene therapy is considered to have occurred with XSCID.[79,80] Hematopoietic stem cells were transduced ex vivo with a retroviral vector carrying a functional copy of the γ_c gene and then infused into patients. Between 10 and 15 patients have been treated in this manner thus far in several trials in different locations. Most patients have exhibited rapid reconstitution of T cells. B-cell numbers are low, but Ig levels and antibody responses are adequate to permit cessation of IVIG replacement therapy. The therapy appears to work only early in development (within the first year of life) because of deterioration of the thymic rudiment over time.[81] Attempts at transduction in older patients after failed BMT have not succeeded.

Unfortunately, at least three late (>2 years after therapy) occurrences of T-cell leukemia in recipients of transduced cells have tempered the early enthusiasm.[82,83] The leukemias appear to have arisen after insertion of the vector into a leukemogenic site, the *LMO2* gene locus.[84] The *LMO2* gene product appears to modify the activities of several transcription factors; it is itself inappropriately transcribed in certain leukemogenic chromosomal translocations. Insertion of the γ_c vector had the same leukemogenic effect in these patients. It is likely that alterations in the vector and transduction methods will be required to avoid similar complications in the future.

Combined Immunodeficiency Associated with Other Syndromes

Wiskott-Aldrich Syndrome

These disorders and the selective cellular deficiencies, together with their associated gene defects, are listed in Table 23-3. Wiskott-Aldrich syndrome (WAS) is an X-linked disease, the classic manifestations of which include eczema, immunodeficiency, and thrombocytopenia.[85,86] Bloody diarrhea is often seen and may be the initial feature. Eczema may be mild or exuberant; staphylococcal superinfection is common. Recurrent otitides and sinopulmonary infections occur frequently, and opportunistic infections are also seen. In addition, autoimmune vasculitis and glomerulonephritis, as well as other autoimmune processes, have been observed in WAS. Patients most often die of overwhelming infection or massive hemorrhage. Those who avoid these complications have a greatly increased risk for lymphoma, many of which are

EBV positive. Atypical nonmalignant lymphoproliferation may also occur.[87]

Platelets are small, do not function normally, and are also cleared more rapidly and produced more slowly than normal (although the number of bone marrow megakaryocytes is normal or even increased).[85,86] In the appropriate clinical context, measurement of platelet size confirms the diagnosis. In normal individuals, platelet volume is 7.1 to 10.5 fL, with a diameter of 2.3 ± 0.12 μm, whereas platelets from patients with WAS have volumes ranging from 3.8 to 5.0 fL with diameters of 1.82 ± 0.12 μm. Small platelet size is occasionally seen in immune thrombocytopenias, but WAS can be distinguished by its other manifestations. However, immune thrombocytopenia may develop in as many as 20% of patients with WAS, either before or after splenectomy.

The only available cure for WAS is BMT.[88,89] Without BMT, survival beyond early childhood is uncommon. In general, BMT from a matched sibling donor is highly successful and considered the treatment of choice for WAS. To date, the results of BMT from an unmatched donor have been disappointing. Pretransplant morbidity and mortality may be reduced with regular infusions of IVIG, antibiotic prophylaxis, and blood component replacement.[85,86] Splenectomy often lessens the requirement for platelet transfusions, although immune thrombocytopenia may later supervene. Splenectomy alone increases the median survival in patients with WAS from 5 to 25 years.

The immune defects in WAS are variable.[85,86] Immune function may be normal in early infancy but gradually wanes. T-cell numbers may be decreased, and there may be inversion of the CD4/CD8 ratio. Cutaneous delayed hypersensitivity responses are often absent. T cells have diminished, but not absent responses to mitogens and antigens in vitro. T cells in WAS will also proliferate in response to nonspecific activating stimuli such as phorbol esters and calcium ionophores but show a striking absence of reactivity to antibodies directed against the CD3 complex of the TCR. The diversity of the T-cell repertoire appears normal throughout childhood, but it may become more restricted with consequent worsening immunodeficiency in adulthood.[90]

The level of IgM is diminished early in the course of the disease, whereas levels of IgG, IgA, and IgE may be elevated initially and then gradually decline. Isohemagglutinins and specific antibody responses are also elicited in young patients with WAS. This responsiveness likewise diminishes with time. Although the frequency of class-switched B cells (i.e., those not expressing IgM) appears to be normal, there are fewer memory B cells expressing CD27, thus indicating some alteration in B-cell activation in germinal centers that could underlie or contribute to the humoral immunodeficiency.[91]

The gene defective in WAS has been identified; its official name is *WAS* and its product is designated the WAS protein (WASP). One group recently studied descendants of the original patients reported by Dr. Wiskott to demonstrate the *WAS* mutation in this kindred.[92] The same gene is defective in the syndrome known as X-linked thrombocytopenia, as well as in X-linked congenital severe neutropenia.[85,86] WASP interacts with several intracellular partners, including the WASP-interacting protein (WIP), Rho family guanosine triphosphatases, and the Arp2/3 complex, which leads to reorganization of the actin cytoskeleton.[93] These processes recruit the additional internal and external membrane-associated molecules needed for full execution of the signaling programs after ligation of the TCR (and other receptors, such as NK receptors for HLA class I). Even though it is clear that WASP has direct and indirect relationships with various components of the cytoskeletal machinery, it also appears to have roles in activating nuclear factor of activated T cells (NF-AT) and nuclear factor κB (NF-κB) transcription factors after receptor engagement, independently of actin polymerization.[94] Although biochemical and cytoskeletal abnormalities have been observed in platelets, no clear defects in structure (other than size) or in function (e.g., aggregation) have been demonstrated.

The best clinical correlations with WASP mutation have come from careful analysis of WASP expression in lymphocytes with various *WAS* mutations.[95] This study has raised important challenges to assumptions regarding the consequences of genetic lesions for protein expression. In particular, missense mutations may lead to absence of protein rather than expression of mutant protein because of a failed stabilizing interaction with another partner. On the other hand, supposed null nonsense or frameshift *WAS* mutations may permit the expression of partially functional truncated forms of WASP. Splice site mutations may also lead to small amounts of normal protein or absence of protein. In general, the more severe phenotypes are associated with complete absence of protein and milder types with the presence of at least partially functioning protein. However, it is necessary to correlate the functional consequences of particular genetic lesions at the protein level directly rather than attempting to predict them.

WAS may be diagnosed in many patients by demonstration of the absence of WASP in Western blots of cytoplasmic lysates probed with specific antisera.[85,86] Intracellular flow cytometric analysis may yield the same finding. DNA-based methods may be used as well. Determination of maternal carrier status may also aid in diagnosis. Female carriers of WAS are generally asymptomatic and have normal platelet counts but show nonrandom X-chromosome inactivation in lymphocytes and granulocytes. One female with WAS has been reported; she is a carrier and her disease is expressed because of extreme nonrandom X-chromosome inactivation.[96] In a different consanguineous kindred, a female exhibited X-linked thrombocytopenia as a result of homozygous *WAS* mutations. Apparent spontaneous reversion of the WASP mutation has been observed in some populations of T cells in at least one patient.[97]

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is an autosomal recessive disorder with an estimated incidence of 1 in 20,000 U.S. white births (95% confidence interval, 1 in 2,500 to 700,000).[98] AT is characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, and immunodeficiency.[99] Associated features are an increased incidence of lymphoma and sensitivity to radiation. Impairment in motor development may be noted early in the disease course and is progressive. Walking may be delayed until 16 to 18 months of age or later. Telangiectases of conjunctival and cutaneous vessels do not appear until children are 3 to 5 years of age. The cutaneous lesions are found mainly on the pinnae and in skin creases. Immunodeficiency will occur in approximately 70% of patients. Manifestation of the immunodeficiency is quite varied, but it is often seen as recurrent sinopulmonary bacterial infections. Growth retardation is a prominent feature in many patients and has been associated with decreases in insulin-like growth factor I and its binding protein; the mechanism is unknown.[100]

The median age at death in patients with AT is approximately 19 to 25 years.[101] Many patients die of progressive pulmonary disease caused by repeated infection. Possibly, noninfectious and ultimately fatal interstitial lung disease may also occur in approximately 25% of patients.[102] Beyond 10 years of age, the incidence of cancer in patients with AT is 1% per year; 85% of the cancers are acute leukemias or lymphomas.[103] Serum levels of oncofetoproteins such as α-fetoprotein and carcinoembryonic antigen are markedly elevated in about 95% of patients with AT.[99] In the appropriate clinical context, an elevated serum level of α-fetoprotein is diagnostic.

Numbers of circulating T and B cells are often normal. T cells bearing the γ-δ form of the TCR constitute up to 50% or more of the total number of T cells in patients with AT.[104] These cells make up only 1% to 5% of peripheral T cells in normal individuals. Cutaneous delayed hypersensitivity responses, as well as results of in vitro assays of T-cell function, are often depressed. Some suggest that T-cell dysfunction may not be as impaired as is often thought in this disease.[105] However, it is difficult to generalize from the small number (four) of patients studied in this report. Varying degrees of deficiency of particular antibody isotypes are common. IgA deficiency occurs in two thirds of patients. Decreased levels of IgG2, IgG4, and IgE are also common. Hypergammaglobulinemia occurs in about 40% of patients with AT.[106] It is usually of the IgM isotype, although elevated levels of IgG and IgA have also been observed. In about a fifth of these cases, the elevated Igs are oligoclonal or monoclonal. Impaired specific antibody responses, particularly to pneumococcal polysaccharide antigens, have also been noted in AT patients.[107]

The gene that is defective in AT is designated *ATM* (AT mutated).[99] ATM has critical roles in regulation of the cell cycle: it is involved in the detection of DNA damage and in the initiation of repair. There is a marked delay in induction of the tumor suppressors p53 and BRCA1 after exposure of AT cells to radiation. Even low-dose radiation leads to significantly greater DNA damage in AT fibroblasts and lymphoblasts than in normal individuals.[108]

Lymphocyte activation is linked to proliferation (i.e., induction of cell division), which also proceeds abnormally without functional ATM.[99] For example, defective activation of protein kinase C has been observed in T cells in AT, although the role of ATM here is not yet known. Lymphocytes of patients with AT also show a remarkable number of chromosomal translocations and inversions. These changes predominantly involve the loci that rearrange to generate mature Ig (2p12, 22q12, and 14q32) and TCR (7p15, 7q35, and 14q11) genes and reflect defective repair of the double-stranded breaks produced as part of the physiologic gene rearrangement process during lymphocyte development.

Whether pathologic changes result from the heterozygous carrier state of AT remains a subject of controversy. Carriers heterozygous for AT have none of the classic clinical manifestations of AT; however, the sensitivity of their DNA to radiation is increased, and they may have a higher incidence of malignancy. Several reports suggest that AT heterozygotes have an increased rate of a variety of malignancies, such as breast cancer.[109,110] Polymorphisms of AT may also affect the expression of malignancies such as lung cancer.[111]

The Nijmegen breakage syndrome is a disorder of chromosome fragility with autosomal recessive inheritance.[112] The phenotype is similar to that of AT and consists of growth retardation, microcephaly, immunodeficiency, sensitivity to radiation, and a high rate of lymphoma. The affected gene is called *NBS1*. Nibrin, its protein product, is another substrate of ATM in the cellular response to ionizing radiation. Absence of nibrin function leads to disruption of mechanisms of DNA repair, but it does not appear to result in abnormal function of cell cycle check points. Another similar syndrome called "AT-like disorder" results from mutations of the gene *MRE11*, which encodes another ATM substrate.[113] Polymorphisms of *MRE11* may be associated with the development of non-Hodgkin's lymphoma; however, this was not found for *NBS1*.[113]

DiGeorge's Syndrome

DiGeorge's syndrome (DGS) arises as a result of a failure of migration of neural crest cells into the third and fourth pharyngeal pouches. Patients display a characteristic facies, cardiac defects, parathyroid hormone deficiency, and varied immune defects.[114,115] The facies consists of hypertelorism, micrognathia, short philtrum, and low-set, posteriorly rotated ears with small pinnae. Cardiac defects are varied. Type B interrupted aortic arch is the most common and is associated with DGS in 50% of patients with this defect. Truncus arteriosus and other

conotruncal anomalies are also common. Structural anomalies of the airways have likewise been found in some patients, as well as dysphagia secondary to laryngoesophageal dysmotility. The bilateral paired parathyroid glands are normally adherent to the thymus. Thus, these organs are affected together in this disease. The parathyroid deficiency is often more pronounced than the thymic defect; hypocalcemic tetany is one of the more common initial symptoms of DGS. Even small islands of ectopic thymus tissue permit the development of sufficient T cells for immune competence. Some degree of cognitive impairment is seen in many patients.

Partial and complete forms of DGS have been distinguished on the basis of clinical and immunologic characteristics.[114,115] In the complete form, the thymus is absent or weighs less than 1 g.[116] These patients have no or markedly decreased numbers of oligoclonal T cells that function poorly. B cells are present and their number may even be increased, but little if any antibody is produced. Complete DGS is usually fatal in early childhood; patients die of hypocalcemia, cardiac complications, infection, or a combination of these causes. However, rare patients may not exhibit hypocalcemia and dysmorphism, and their condition may be manifested as T⁻B⁺NK⁺ SCID.[117] Though not seen as commonly as in SCID, engraftment of maternal T cells with a graft-versus-host reaction has also been reported.[118] In addition, patients may have features similar to those of OS.[116] In the largest series of patients with complete DGS reported (54 individuals), only half had a 22q11 deletion or structural heart disease, thus suggesting that there may be significant differences in the genetic makeup of the complete and partial forms.[116] An OS-like picture developed in a third of patients.

The occurrence of partial forms of DGS outnumbers that of the complete form by about 10:1. T-cell number and function in most patients are varied and presumably correlate with the amount of ectopic thymus tissue present. Immune function in patients with complete DGS does not improve; patients with partial DGS may have less immunodeficiency as they get older. In some cases the diagnosis has been made in adults being evaluated for hypoparathyroidism and hypocalcemia.[119] Most patients, despite having reduced numbers of T cells, have a normal or perhaps slightly diminished repertoire of expressed TCR V$_\beta$ genes and in vitro response to T-cell mitogens.[120,121] T-cell numbers are lowest in infancy and rise through the first years of life.[122] A relatively high prevalence (5% to 15%) of IgA deficiency has been reported.[123,124] Patients may also exhibit impaired responses to vaccine antigens (although this is not a consistent finding), as well as decreased peripheral memory (CD27⁺) B cells.[123] Atopy, manifested as atopic dermatitis and asthma, may be increased in individuals with 22q11 deletion.[125]

Approximately 80% to 90% of patients with DGS have 2- to 3-megabase (Mb) deletions involving chromosome 22q11.2.[126] Deletions in the same region are found in patients with velocardiofacial syndrome and conotruncal anomaly–face syndrome and in some patients with isolated cardiac defects. There is heterogeneity in expression of the DGS phenotype, even in monozygotic twins. Approximately 40 genes are present in the deleted regions in DGS, and the contributions of each to the phenotype are only beginning to be understood.[127] *TBX1* encodes a member of a family (T-box) of transcription factors. Mice that are heterozygous for deletion of this gene have a phenotype very similar to that of humans with DGS, including thymic and parathyroid hypoplasia, cardiac outflow tract abnormalities, and abnormal facial structure.[127] Point mutations in *TBX1* have been found in six Japanese patients (four kindreds) with DGS or velocardiofacial syndrome.[128] Some patients with DGS have deletions on chromosome 10p.[129] Further genetic information relevant to DGS regarding this region does not yet exist. Additional genetic loci may also be responsible for the DGS phenotype. Thus far, major clinical distinctions between patients with and without 22q11 deletions have not been seen.

Most patients with partial DGS do not have significant difficulty with infections, and even live viral vaccines may be administered safely.[130-132] IVIG replacement or antibiotic prophylaxis may be helpful in patients with the more immunodeficient partial forms of DGS. Complete DGS has been treated very successfully by thymus transplantation, with 75% of the 44 most recent transplant recipients surviving up to 13 years.[116]

X-Linked Immunodeficiency with Normal or Elevated IgM

As its name implies, X-linked immunodeficiency with normal or elevated IgM (XHIM, also HIM1) denotes a form of selective hypogammaglobulinemia G and A, together with normal or elevated amounts of IgM. Approximately 200 patients have been described.[133] These patients are seen in the first 1 or 2 years of life with the recurrent bacterial infections often found in those with hypogammaglobulinemia, together with opportunistic infections by organisms such as *P. jiroveci*, *Cryptosporidium*, and *Histoplasma*. Affected patients are also prone to the development of neutropenia, anemia secondary to parvovirus, stomatitis, sclerosing cholangitis, and liver and hematologic malignancies. The number of circulating B cells is normal, but they express IgM exclusively (in association with IgD) on their surface. Immune responses are varied. Isohemagglutinins are often present, and vaccination may elicit specific IgM responses. No other isotypes are produced; there is no B-cell memory. Secondary lymphoid tissues are sparsely populated and do not contain germinal centers. Patients should be maintained on gamma globulin replacement therapy, as well as prophylaxis for *P. jiroveci* pneumonia. The disease is curable by BMT. Successful use of sequential liver transplantation and BMT has also been reported.[133,134]

The genetic lesion in XHIM is in *TNFSF5* (tumor necrosis factor superfamily member 5), also known as

T-B Cell Interactions

FIGURE 23-9. Signals required for T-cell activation by antigen-presenting cells, B-cell activation by the T cell, and B-cell immunoglobulin class switching. CD40L, CD40 ligand; IL-4R, interleukin-4 receptor; TCR, T-cell antigen receptor.
CD40 ligand (CD40L) and CD154.[133] This is an integral membrane protein that is mainly expressed on T cells after an activating stimulus, such as interaction of the TCR with an MHC-peptide complex on the surface of a B cell or APC (Fig. 23-9). The signal delivered via T-cell CD40L to CD40 is critical for Ig class switching (the production of isotypes other than IgM or IgD), the development of B-cell memory, affinity maturation of the antibody response (somatic hypermutation of Ig V regions), and the expression of important costimulatory molecules such as those of the B7 family by B cells and APCs (see Fig. 23-9).[135]

The CD40 system has additional roles in the interaction of T cells with monocytes. Several T-cell–derived cytokines (granulocyte-macrophage colony-stimulating factor, IL-3, and interferon-γ [IFN-γ]) induce the expression of CD40 on monocytes. Furthermore, engagement of monocyte CD40 induces cytokine synthesis and activates tumoricidal mechanisms.[136] These phenomena suggest an important interaction, the lack of which may underlie the predisposition to opportunistic infection and malignancy seen in patients with XHIM. One male patient has been described with a form of HIM associated with growth hormone deficiency.[137] Although the gene defect was not determined, it is most likely to have been the X-linked form because the association with growth hormone deficiency has been seen with other immunodeficiencies such as X-linked lymphoproliferative disease (XLPD) and XLA (see later).

Perhaps not too surprisingly, a clinically and immunologically identical immunodeficiency syndrome arises from mutations in the gene *TNFRSF5*, which encodes CD40.[138,139] Only a few patients with this defect have been found so far.

Other Forms of Hyperimmunoglobulin M Syndrome

Mutations in Activation-Induced Cytidine Deaminase and Uracil Nucleoside Glycosylase

Strictly speaking, activation-induced cytidine deaminase (AID) and uracil nucleoside glycosylase (UNG) deficiencies are best considered as humoral immunodeficiencies because these defects exclusively affect B-cell function and T-cell number and function are completely normal. They are included here because they have originally been defined in the medical literature as forms of hyper-IgM syndrome. They may be abbreviated as HIM2 (AID)[140-146] and HIM5 (UNG; see Table 23-3).[144,147,148] The AID and UNG enzymes are RNA modifiers expressed in B cells that act during class-switch recombination. In the absence of their activity, B cells cannot switch from production of IgM and IgD to production of downstream Ig isotypes (see Fig. 23-11). Somatic hypermutation is also affected. These processes occur normally during B-cell activation in germinal centers.

Another form of hyper-IgM syndrome with an unknown gene defect leads to impaired Ig class–switching recombination.[142,144,149] This has been called HIM4. All these disorders are very similar clinically and immunologically. Patients suffer mainly from respiratory tract bacterial infections and lymphadenopathy, and cellular immunodeficiency is not seen. IgG, IgA, and IgE are all low or absent; IgM levels tend to be higher than in the X-linked HIM syndrome. Patients tend to do well with IVIG replacement.

Mutations of the Nuclear Factor κB Pathway

NF-κB is a transcription factor that is critical for the activation of numerous genes upon leukocyte

stimulation.[150] Activity of this factor is regulated by an inhibitor known as IκB. Phosphorylation of IκB by IκB kinase (IKK) liberates active NF-κB. IKK is composed of three subunits, α, β, and γ; the latter is also known as the NF-κB essential modulator (NEMO). The gene encoding NEMO is on the X chromosome. Null mutations are incompatible with life for males and lead to the X-linked dominant disease incontinentia pigmenti in females. Certain mutations that allow partial NEMO function are associated with an immunologic phenotype that may have some similarities to hyper-IgM. The earliest reports of these patients actually used the abbreviation hyper-IgM type 4, although this designation is now reserved for a syndrome associated with an unknown defect of Ig class switching (see earlier). Along with a combined immunodeficiency, these patients may exhibit hypohidrotic ectodermal dysplasia and lymphedema with osteopetrosis.[150-157]

Patients may suffer opportunistic-type disseminated viral infections and *P. jiroveci* pneumonia and are also highly susceptible to atypical mycobacterial infections. Most are hypogammaglobulinemic and have impaired vaccine responses (especially to polysaccharide antigens). In many patients, either elevated serum IgA or IgM may develop, but not both. Peripheral blood lymphocyte subsets and in vitro measures of lymphocyte function may be unremarkable or variably diminished; NK cell cytotoxicity may be impaired. Signaling via toll-like receptors (TLRs) is also affected. Therapy with gamma globulin and antibiotic prophylaxis is essential. Despite these measures, infections may still occur. A few patients have been successfully reconstituted by BMT,[158] but experience is limited.

A few patients have been found to have a similar phenotype as a result of a so-called hypermorphic (gain of function) function mutation of the IKK α chain.[150,152,159] In this situation, the IKK kinase is resistant to phosphorylation and cannot be dissociated, degraded, and induced to release NF-κB so that it may translocate to the nucleus to activate transcription.

Defects in Toll-Like Receptor Signaling

TLRs are a family of transmembrane molecules with a characteristic structure that bind to so-called pathogen-associated molecular patterns (PAMPs).[160,161] PAMPs are pathogenic microbial macromolecules consisting of repeating units such as lipoproteins, lipopolysaccharide, RNA, DNA, flagellin, and other constituents. TLRs are expressed variably by hematopoietic and other cell types; their ligation may promote the production of inflammatory cytokines such as tumor necrosis factor, IL-1β, IL-6, IL-8, and IL-12. Some TLRs also activate the production of type 1 (α and β) interferons by inducing the transcription factors interferon regulatory factors 3 and 7. TLRs influence many aspects of innate nonspecific inflammation, as well as the initiation and execution of adaptive immune responses. TLRs activate several signaling path-

ways, chief among them being the NF-κB pathway described earlier.

Recently, patients have been described with mutations of the interleukin-1 receptor–associated kinase 4 (IRAK-4).[150,162-166] Deficiency of this kinase impedes signaling by many of the TLRs and the IL-1 receptor. These patients are susceptible to severe infections (cellulitis, arthritis, meningitis, osteomyelitis, organ abscesses, and sepsis) caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, and other bacteria. Antibody responses to pneumococcal polysaccharides may be impaired, but screening tests of humoral and cellular immune function may also be normal.

The Syndrome of Warts, Hypogammaglobulinemia, Infections, and Myelokathexis

The WHIM (warts, hypogammaglobulinemia, infections, myelokathexis) syndrome is named for its major clinical manifestations.[167-172] This disorder is caused by defects in the chemokine receptor CXCR4. The chemokines are a large cytokine family that share a structural motif of conserved cysteine residues.[173,174] Many chemokines have important roles in activating leukocytes and directing homing or migration of cells in blood and lymph and in tissues in inflammation or immune responses. The infections usually seen in these patients are those most characteristic of hypogammaglobulinemia, generally respiratory tract bacterial infections. As the name suggests, verrucosis is also common and is indicative of an important component of impaired cellular immunity. One of the more common features of this disorder is myelokathexis, or retention of mature neutrophils in the bone marrow with resultant peripheral neutropenia. Although Ig levels are low, specific antibody formation may be normal. Gamma globulin replacement therapy generally reduces the rate of infection. There are no characteristic alterations in lymphocyte subsets, but in vitro (mitogen and antigen stimulation) and in vivo (cutaneous anergy) T-cell function may be impaired. Neutrophil counts are generally lower than 0.5×10^9 cells/L. Both granulocyte and granulocyte-macrophage colony-stimulating factors have been used to raise neutrophil counts.[175]

X-Linked Lymphoproliferative Disease

The "classic" manifestation of XLPD is fulminant, often fatal acute infectious mononucleosis secondary to EBV infection.[176] Additional clinical findings may include lymphoid necrosis, lymphoma, aplastic anemia, and pulmonary lymphoid granulomatosis with vasculitis. The diagnosis of XLPD is made in most patients before 10 years of age, but rare cases occur in adults.[177] Patients often have completely normal measures of humoral and cellular immune function; some may have impaired NK cell cytotoxicity.[178] Interestingly, NK T cells (NKT cells, or T cells that also express certain NK cell surface markers such as CD56) are absent in individuals with XLPD.[179]

NKT cells have important roles in regulating the immune response to infection, and their absence is likely to have a prominent role in the pathophysiology of the clinical manifestations of XLPD. Some patients show dysgammaglobulinemia with high levels of IgA or IgM and low levels of IgG1, IgG3, or both. A number of patients also have recurrent viral and bacterial infections. Some patients may have a clinical and laboratory phenotype consistent with common variable immunodeficiency (CVID).[180,181] One patient has been described with XLPD and growth hormone deficiency.[182] This association has previously been reported only with XLA (see later).

XLPD results from mutations in the gene encoding the SLAM (signaling lymphocyte activation molecule)-associated protein (SAP).[176] This molecule is also known as SH2D1A (SH2 [Src homology domain 2]-containing protein 1A).[183] SLAM is a member of the CD2 family of adhesion molecules that have roles in leukocyte-membrane interactions. SAP is also a member of a family of adapter proteins that link CD2 family members to downstream cytoplasmic signaling pathways. Another CD2 family member that signals through SAP is 2B4, a molecule important in triggering NK cell cytotoxicity. EBV-infected B cells express high levels of the 2B4 ligand CD48. Normal NK cells are activated by this interaction, whereas NK cells from patients with SAP mutations are strongly inhibited. The absence of the SAP interaction appears to lead to the constitutive association of 2B4 with the inhibitory tyrosine phosphatase SHP2.

Mononucleosis in XLPD can be treated with anti-inflammatory and chemotherapeutic regimens; BMT may be curative. Recently, several patients with XLPD-associated hemophagocytic syndrome have been successfully treated with the monoclonal anti–B-cell antibody rituximab.[184] This therapy may be effective through the elimination of a large reservoir of EBV antigenic stimulus.

Autoimmune Polyglandular Syndrome Type 1

A heterogeneous group of disorders characterized by recurrent and severe skin and mucous membrane infections with *Candida albicans* are referred to as syndromes of chronic mucocutaneous candidiasis (CMC). In these individuals, cellular immunity to *Candida* is selectively impaired, whereas other aspects of cellular and humoral immunity are usually normal. Occasional patients exhibit more profound suppression of cellular immunity, variable defects such as a relative decrease in NK cells, or abnormalities in Igs, IgG subclasses, or specific antibody production.[185-187] The genetic defects in these patients have yet to be identified.

One particular form of CMC is autoimmune polyglandular syndrome type 1 (APS-1), also called autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED).[188-192]

In addition to *Candida* infection, patients with APS-1 have high levels of a variety of organ-specific autoantibodies (e.g., thyroid, ovary, testis, and adrenal gland), as well as non–organ-specific autoantibodies. The gene responsible for this disorder has been named autoimmune regulator (*AIRE*).[193] AIRE is a transcription factor expressed in thymic epithelium that directs the expression of an array of endocrine-related genes. When developing thymocytes that are specific for these antigens encounter them, they are deleted by a process of negative selection. In this way, the mature T-cell pool that leaves the thymus is depleted of cells with these self-reactivities. In the absence of functional AIRE, these clones are not deleted; they exit the thymus and are then activated when they encounter these antigens in endocrine tissues and cause autoimmune responses.

Hyperimmunoglobulin E Syndromes

The first or "classic" form of hyper-IgE syndrome (HIES) described, which has also been known by the eponym "Job's syndrome," consists of severe sinopulmonary bacterial infections, severe skin superinfections with *S. aureus* on a chronic eczematous eruption, and susceptibility to *Aspergillus fumigatus* pneumonitis with pneumatocele formation.[194-196] Inheritance is autosomal dominant; the defective gene has not yet been identified. Additional manifestations include asymmetric or coarse facial features, delayed shedding of primary teeth, bone fragility and fractures, scoliosis, and keratoconjunctivitis. *P. jiroveci* infection may complicate some cases,[197] and malignancies such as Hodgkin's lymphoma and T-cell lymphoma have been reported as well.[198,199] A few patients have also recently been reported to have associated cardiovascular anomalies such as patent ductus venosus,[200] thoracic aortic aneurysm,[201] and coronary artery aneurysms.[202] The major immunologic findings are elevated serum levels of IgE (3000 to >50,000 IU/mL) and, occasionally, impaired neutrophil chemotaxis (some classify HIES among the neutrophil disorders). Additional features include eosinophilia and the presence of *Staphylococcus*-binding IgE in serum. Note that these two findings are often likewise seen in patients with severe atopic dermatitis. Some patients with HIES also show evidence of reduced T-cell function in vitro. In particular, the lymphocyte response to IL-12 is abnormal, and IFN-γ production is reduced. The diagnosis is established on clinical and laboratory grounds; a scoring system has been developed that may be helpful.[203] Management of autosomal dominant HIES is mainly by prevention and treatment of infectious complications. One patient was treated with BMT and exhibited successful donor engraftment with resolution of disease, only to later suffer a relapse.[204] Other patients have been treated with interferon gamma or intravenous gamma globulin infusions. Neither of these therapies has been shown to have consistent benefit for patients.[205-208] Chronic molluscum contagiosum in one patient was successfully treated with systemic interferon alfa.[209]

At least one autosomal recessive form of HIES has also been characterized clinically; the gene defect is

unknown, however.[194,210] This form of HIES has many similarities with the autosomal dominant form described earlier. Patients with the recessive type do not have skeletal or dental abnormalities, and pneumatoceles do not develop. This group of patients has the additional feature of autoimmune vasculopathy with central nervous system involvement.

A single patient with an autosomal recessive deficiency of the Tyk2 kinase and a phenotype similar to HIES has been reported.[211,212] It may be distinct from that just described, but this is not yet known. The patient with Tyk2 deficiency had recurrent respiratory tract and skin bacterial infections, molluscum contagiosum, oral thrush, cutaneous herpes simplex, and BCG infection. He had severe eczematous dermatitis and an IgE level of 2100 U/mL. Lymphocyte populations were normal. The Tyk2 kinase is required for signaling of receptors for IFN-α/β, IL-6, IL-10, IL-12, and IL-23.

CELLULAR IMMUNODEFICIENCY

Defects of the Interferon-γ/Interleukin-12/23 Pathway

IL-12 is a monocyte/macrophage product that is the principal stimulus for IFN-γ production by NK cells. Mononuclear cells rely on IFN-γ for activation of full microbicidal capacity for intracellular killing. Patients with defective response to IFN-γ have exquisite susceptibility to mycobacterial infection, especially atypical species.[213-216] Other types of infections may also occur, such as disseminated histoplasmosis.[217] The genetic lesions described include both chains of the IFN-γ receptor (*IFNGR1*, *IFNGR2*) and the gene encoding the STAT1 (signal transducer and activator of transcription 1) signaling molecule. Defects of *IFNGR1* include a "complete" (absent function) autosomal recessive form, as well as "partial" (partial function) autosomal dominant and recessive forms.[215,218] In at least one patient with a partial recessive form, disseminated *Mycobacterium avium-intracellulare* infection was diagnosed in adulthood after previously being healthy.[218] Patients with defects in the IL-12/23 pathway appear to have greater susceptibility to severe infections with *Salmonella* species.[213,214,219-222] These defects include the gene encoding the IL-12 receptor β_1 chain (*IL12RB1*), which is shared by the receptors for IL-12 and IL-23, as well as the gene encoding the IL-12 p40 subunit, which is also shared by IL-23. A similar patient with an IL-12 signaling defect and unknown genetic lesion has also been reported.[223] Most patients with these defects in IFN-γ and IL-12/23 signaling have normal lymphocyte subsets and in vitro T-cell responses to mitogens and antigens, together with normal Ig levels and antibody responses. These disorders are curable by BMT.[224] The phenotypes of patients with these genetic defects underscore the importance of these pathways for the control of infections with microbes that replicate intracellularly.

SYNDROMIC IMMUNODEFICIENCY

The term syndromic immunodeficiency has been coined to describe the occurrence of a component of immune compromise and susceptibility to infection or malignancy (or both) in the setting of a genetically determined disorder with characteristic features of altered development or function of other organ systems or the body as a whole. Included are syndromes of large-scale chromosomal anomalies (monosomies, trisomies, translocations, etc.), as well as monogenic disorders of metabolism or other maldevelopment, in addition to "acquired" congenital diseases secondary to teratogen exposure. Space does not permit even a cursory description of the tremendous variety of syndromes that have been consistently or occasionally associated with immunodeficiency. Interested readers are referred to an excellent recent review.[225]

HUMORAL IMMUNODEFICIENCY

The humoral immunodeficiencies and their associated gene defects are listed in Table 23-4. These disorders are characterized by relative deficiency of antibody responses to various forms of antigenic challenge.[2,3] Cellular immunity is generally intact. Humoral immunodeficiency is most commonly manifested as recurrent bacterial infections of the upper and lower respiratory tract. Pyogenic skin infections, as well as meningitis, osteomyelitis, and other foci of infection, are also seen frequently. These infections are generally caused by the same organisms

TABLE 23-4	Humoral Immunodeficiencies and Associated Gene Defects
Syndrome	**Gene**
The agammaglobulinemias	
X-linked (Bruton's)	*BTK*
IgM heavy-chain deficiency	*IGHM*
Surrogate light-chain deficiency	*IGLL1*
Ig-α deficiency	*IGA*★
B-cell linker protein deficiency	*BLNK*
Leucine-rich repeat–containing 8 defect (hemizygous)	*LRRC8*
Common variable immunodeficiency	*ICOS*, *TACI*,[†] *CD19*
Selective IgA deficiency	Undefined
IgG subclass deficiency	Undefined
Specific antibody deficiency	Undefined
Transient hypogammaglobulinemia of infancy	Undefined

★Note that this is the gene designation for the Ig-α signal-transducing component of the B-cell antigen receptor. The designation for the gene encoding the immunoglobulin A (IgA) heavy chain is *IGHA*.
[†]A role for *TACI* mutation in common variable immunodeficiency has not yet been conclusively established.

that are virulent in immunocompetent hosts—predominantly encapsulated bacteria such as *S. pneumoniae*, *Haemophilus influenzae*, *S. aureus*, and *Neisseria meningitidis*. Viral infections usually resolve normally in these patients, although a higher rate of recurrence with the same agent may be seen because there is no production of neutralizing antibodies or B-cell memory. The results of physical examination are not specific and show only the presence or sequelae of microbial infections. A relative paucity of peripheral lymphoid tissue may be noted in some patients, especially areas rich in B cells (e.g., tonsils). Studies of peripheral blood lymphocyte subsets are often normal; the number of B cells may be reduced in certain syndromes.

The amounts of one or more antibody isotypes are reduced in many of these diseases.[2,3] The severity of the phenotype often correlates with the degree of hypogammaglobulinemia. The predisposition that patients have to particular types of infections may also depend on the affected isotypes (see later). Antibody titers to specific antigens may be measured before or after immunization. The specific antibodies most commonly assayed for protein antigens are tetanus toxoid and the capsular polysaccharide (polyribosylribitol phosphate) of *H. influenzae* type B (HiB). With respect to polysaccharide antigens, measurement of antibodies to pneumococcal serotypes is frequently undertaken. If a child has had a particular illness (e.g., varicella), a specific viral antibody titer may be useful. Note that the HiB vaccines and newer pneumococcal vaccines (e.g., Prevnar) currently in use for primary immunization in children are protein conjugates. Thus, measuring a polyribosylribitol phosphate or pneumococcal titer in children who have received these vaccines does not necessarily reflect a polysaccharide antibody response. The adequacy of carbohydrate responses may be tested by challenge with 23-valent pneumococcal polysaccharide vaccines (e.g., Pneumovax or Pnu-Imune) or meningococcal vaccines. In children who are not fully immunized, isohemagglutinins may be measured.

A high index of suspicion for antibody deficiency should be maintained in patients with recurrent, refractory, or severe infections.[2,3] One study in the United Kingdom of the delay in diagnosis of primary antibody deficiency found that the median delay was 2 years (mean, 4.4 years) after the onset of symptoms, even after the introduction of a set of national guidelines intended to reduce this delay.[226]

The mainstay of therapy for significantly impaired ability to produce antibody is gamma globulin replacement.[2,227] As has already been mentioned several times earlier, this therapy is also important for the treatment of any combined immunodeficiency in which defective antibody production may occur. In most countries, gamma globulin replacement is administered predominantly via the intravenous route every 3 to 4 weeks. However, IgG can also be administered by subcutaneous infusion.[228-231] Smaller doses are given weekly or twice weekly. Intrave-

nous infusion is generally well tolerated but requires intravenous access and is associated with frequent mild (10% to 20% of patients) or moderate (5%) side effects. Subcutaneous infusions may be administered by patients themselves at their own convenience with a much lower rate of systemic effects at the cost of generally mild and transient (24-hour) local irritation. The general efficacy of intravenous versus subcutaneous administration appears to be equivalent. It is likely that subcutaneous infusions will become increasingly popular.

The Agammaglobulinemias

X-Linked Agammaglobulinemia

XLA is also known as "Bruton's agammaglobulinemia" because Bruton provided the classic description of the disease in 1952.[232] Affected males are often asymptomatic during the first months of life while they are protected by transplacentally acquired maternal antibodies. These antibodies fall to low levels by 6 to 9 months of age, and patients begin to experience recurrent bacterial infections.[233,234] Physical examination at any age often reveals a striking absence of tonsils and palpable lymphoid tissue. Serum Ig is absent or the level is extremely low; in addition, no B cells are found or their numbers are extremely low. Cellular immunity is completely intact. However, these patients are prone to the development of chronic enteroviral meningoencephalitis and vaccine-associated paralytic poliomyelitis, which suggests an important role for humoral immunity in the control of these infections. Moreover, patients may have arthropathy resembling rheumatic disease, which may be due to infection with *Mycoplasma* or *Ureaplasma* organisms. Other opportunistic infections such as *P. jiroveci* pneumonia are seen only rarely.[235]

XLA is another example of an immunodeficiency caused by a defect in a signal transduction molecule. In fact, this protein tyrosine kinase is now known as Bruton's tyrosine kinase (Btk, Fig. 23-10).[233,236] It is expressed in B cells at all stages of development, as well as in cell lines derived from monocytes, macrophages, mast cells, and erythroid cells. A variety of *BTK* gene defects such as point mutations, deletions, and insertions have been described in patients with XLA.[236-239] In most patients, B-cell development is impeded at an early stage (the pro-B-cell–pre-B-cell transition).

BTK mutations account for approximately 85% of all cases of agammaglobulinemia.[233] *BTK* mutations have also been described in patients with "atypical" XLA who have low numbers of B cells and low-level antibody production.[240,241] In some patients with atypical XLA, CVID was misdiagnosed (see later) before discovery of the Btk defect.[242] In general, *BTK* mutations that permit the expression of small amounts of functional or partially functional Btk protein are associated with milder clinical phenotypes and slightly higher numbers of B cells in the circulation.[233,236-239] However, even siblings with identical
FIGURE 23-10. Signaling via the pre–B-cell receptor (Pre-BCR). The Pre-BCR is composed of an IgM heavy chain with a surrogate light-chain heterodimer (VpreB + λ5), along with a signaling heterodimer of Igα + Igβ. The immunoreceptor tyrosine-based activating motifs (ITAMs) (see Fig. 23-6) recruit tyrosine kinases (Lyn, Syk, Btk) that initiate downstream signaling. The adapter proteins BLNK and Vav recruit additional signaling intermediates. DAG, diacylglycerol; IP3, inositol triphosphate; PKC, protein kinase C; PLC, phospholipase C; MAPK, mitogen-activated protein kinase. Defects in components shown in blue lead to agammaglobulinemia by blocking pre-BCR signaling and interrupting B-cell development.

mutations may show quite divergent phenotypes. Female carriers of XLA show nonrandom X-chromosome inactivation in their B cells.[243]

Patients with XLA were the first to receive human gamma globulin therapy. The effect of intramuscular injections of gamma globulin was prompt and dramatic, with a reduction in the occurrence of infections. A retrospective study of bacterial infections in patients with XLA showed a reduction in incidence from 0.4 to 0.06 per patient per year with IVIG therapy.[244] Some viral infections, including enteroviral meningoencephalitis, occurred in patients while they were receiving IVIG. At present, administration of IVIG provides these patients with an almost normal lifestyle.[245]

A very small number of patients have been described with a distinct syndrome of XLA and growth hormone deficiency.[246-248] The clinical manifestation is similar to that of XLA described earlier, with the added feature of low growth hormone levels. In one patient a possible mutation in the transcription factor myeloid Elf-like 1 has been suggested but not clearly established.[246]

Autosomal Recessive Agammaglobulinemias

Female patients with agammaglobulinemia and no B cells and males with a similar phenotype lacking *BTK* mutations have been described. These patients have forms of agammaglobulinemia with autosomal recessive inheritance that result from several distinct molecular defects,[233] including mutations of the Ig μ heavy-chain

locus, which prevents formation of the IgM heavy chain required for formation of the Ig receptors on pre-B cells and mature B cells (see Fig. 23-10). Defects of λ5 (surrogate light chain) prevent formation of the pre-B-cell Ig receptor required for B-cell development. Igα (CD79a) is a transmembrane molecule required for signal transduction via the pre-B-cell and mature B-cell Ig receptors. Lesions in this gene prevent Ig receptor signaling and B-cell development. Defects in the signal transduction adapter protein BLNK (B-cell linker protein) have also been found; absence of BLNK function prevents signaling after ligation of the B-cell receptor. All these mutations arrest B-cell development at early stages in bone marrow.

One patient has been described with an apparent dominantly expressed translocation abrogating the function of the *LRRC8* (leucine-rich repeat–containing 8) gene.[249-251] The function of the LRRC8 protein is not yet known; it is a member of a growing family of proteins of unknown function called the LRRC8 family, within the much larger and very diverse superfamily of leucine-rich repeat proteins. The female patient has agammaglobulinemia with arrest of B-cell development in bone marrow.

Other Predominantly Antibody Deficiency Syndromes

Common Variable Immunodeficiency

The diagnostic label of CVID encompasses an unknown number of conditions that are genetically and etiologically distinct but have in common late-onset humoral immunodeficiency, most often in the first or third decades of life.[252,253] Hypogammaglobulinemia and impaired specific antibody production are universal by definition. Patients with CVID resemble individuals with XLA (and other humoral immunodeficiencies) because they also have recurrent sinopulmonary bacterial infections. Chronic enteroviral infections, including meningoencephalitis, may also be seen in CVID. A form of granulocytic/lymphocytic interstitial lung disease occurs in a subset of patients and has been linked to human herpesvirus 8 infection.[254] Additional manifestations include asthma, chronic rhinitis, chronic giardiasis, and recurrent or chronic arthropathy. The apparent "atopic" symptoms occur in the absence of allergen-specific IgE. Malabsorptive inflammatory bowel disease may occur. A broad spectrum of autoimmune diseases may be associated, including a variety of cytopenias, arthritides, and vasculitides.[255,256] Noncaseating granulomatous disease resembling sarcoidosis may be encountered in the skin or viscera. It often responds well to steroid therapy.[257,258] Widespread lymphoproliferation may cause splenomegaly, adenopathy, and intestinal lymphonodular hyperplasia. Patients with CVID also have a higher incidence of gastrointestinal and lymphoid malignancies. The relative risk for lymphoma has been estimated to be as much as 30- to 400-fold greater than that in the general population.[259]

Deficiency of IgA is very common in CVID.[253] IgM is also frequently affected; the pattern varies from one individual to another. The levels of particular isotypes in any patient are often static over time, but fluctuations may occur. B cells appear to be normal in many patients and produce antibody on stimulation in vitro, whereas others may have low numbers of poorly functional B cells. A reduction of the ratio of CD4[+] to CD8[+] T cells is common. A plethora of additional immunologic abnormalities have been reported in at least a fraction of patients with CVID. There are no single unifying immunologic features beyond those that are used to build the clinical definition. It is not useful to discuss most of these in detail here because their relationship to the pathogenesis of the disorder is not known. "Abnormalities" reported include altered thymic development,[260] cytokine production,[261-265] surface marker expression,[265-269] signal transduction,[270] and apoptosis[271] of T cells; altered surface marker expression on B cells[269,272]; altered development of plasma cells[273]; altered cytokine production by monocytes[264]; defective maturation,[274] altered distribution,[275] and altered cytokine production[276,277] of dendritic cells; and impaired signaling via TLR9.[278] Some authors have suggested that nutritional or biochemical imbalances such as vitamin A deficiency[279] or hypoleptinemia and insulin resistance[280,281] may even contribute to the immunodeficiency of CVID.

Memory B-cell subpopulations may be useful diagnostic and potentially prognostic markers in CVID.[282-285] Memory B cells express the CD27 (TNFRSF7) molecule. Naïve B cells express IgM and IgD. So-called unswitched memory B cells express IgM, some IgD, and CD27. After class switching in germinal centers, B cells cease expressing IgM and IgD, as well as "downstream" Ig isotypes such as IgG, IgA, and IgE (Fig. 23-11). Memory B cells after class switching ("switched" memory B cells) are CD27[+] and IgM[-]IgD[-]. Some authors have devised classification schemes for CVID patients based on these markers (low switched memory B cells, in particular) that correlate at least partially with clinical characteristics (Table 23-5).[284-286] At least one study suggests that the number of memory B cells correlates better with infection, lymphoproliferation, and autoimmunity than serum Ig levels or specific antibody responses do.[287] Other authors have reported that low levels of unswitched (IgM) memory B cells correlate with impaired pneumococcal polysaccharide antibody responses and with chronic lung disease and bronchiectasis in CVID.[288] Classifications of CVID based on memory B-cell phenotypes are summarized in Table 23-5.

Most patients with CVID should be treated with IVIG infusions.[289] Antibiotic prophylaxis may also be required. Therapy for autoimmune or inflammatory complications in CVID generally follows regimens

```
– M – – D – – G3 – – G1 – – psE – – A1 – – psG – – G2 – – G4 – – E – – A2

		Group Ib (NL CD21)		↑	+	↓↓	↓↓
NL Mem.	MB2	Group II			+	↓	↓

AI, autoimmunity; GR, granulomas; Ig, serum immunoglobulin level; Mem, memory; SM/LPD, splenomegaly/lymphoproliferative disease; NL, normal; Sw Mem, switched memory; Vac. Ab, vaccine-specific antibody responses; ↑, increased; ↓, decreased; +, present.

applied in similar situations in the absence of the immunodeficiency.[255,256,290-294] However, patients with CVID are even more at risk for infectious complications from such immunomodulation or immunosuppression.

The genetic heterogeneity of CVID is beginning to yield to molecular biologic analysis. Several single-gene defects have been found in varying (small) proportions of patients with CVID and are described in more detail later. It may also occur that individuals classified as having CVID (or a phenotype consistent with CVID) on clinical and laboratory grounds may be found to have mutations in genes characteristically associated with other primary immunodeficiencies. Such has been the case with some individuals with mutations in *BTK* (XLA),[242,295] *SH2D1A* (XLPD),[181] and *TNFSF5* (XHIM).[296]

Among the majority of CVID patients and in IgA deficiency, where immunologically relevant point mutations are still generally unknown, there is evidence for linkage to loci within the HLA complex on chromosome 6.[297-299] Both syndromes tend to occur in families, and it is possible for IgA deficiency to sometimes evolve into CVID. Some families have pedigrees that suggest an autosomal dominant pattern of inheritance. Study of one large kindred indicated linkage to a region of chromosome 4q.[300] Candidate genes in these regions are yet to be identified.

Deficiency of Inducible T-Cell Costimulator

The inducible T-cell costimulator (ICOS) is expressed on T cells after stimulation. It interacts with a member of the B7 family of molecules known as ICOS ligand. A total of nine patients have been found to have CVID associated with ICOS deficiency.[301] All these individuals have the same founder mutation and have ancestral origins in the Black Forest region of Germany. These patients may manifest recurrent respiratory and gastrointestinal infections in adulthood, panhypogammaglobulinemia and impaired vaccine responses, autoimmune disease (neutropenia), lymphoproliferation, and cancer (carcinoma of the vulva). Lymphoid tissues exhibit poorly formed germinal centers, and circulating switched memory B cells are markedly reduced.[302] To date, mutations of ICOS ligand have not been found in CVID patients.

Deficiency of Transmembrane Activator and Calcium Modulator and Cyclophilin Ligand Interactor

Defects of the transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI; official designation, TNFRSF13B) have been associated with CVID in approximately 10% of patients studied to date.[303-306] However, its pathogenic role is not yet clear. Some patients are homozygous or compound heterozygous for *TACI* mutations, whereas other patients are hemizygous. Furthermore, "deleterious" *TACI* mutations occur at a rate of 1% in the general population. It is possible that other genes modify expression of *TACI* mutations or that *TACI* mutations predispose to pathology triggered by other infectious or environmental exposure (or both). To date, mutations in either of the TACI ligands α-proliferation–inducing ligand (APRIL; TNFSF13) and B-cell–activating factor (BAFF; TNFSF13B) have not been found in any CVID patients.[305-307]

TACI is expressed on B cells and interacts with the ligands BAFF and APRIL expressed on macrophages and dendritic cells. These interactions have important roles in B-cell activation and Ig class switching. CVID patients with *TACI* mutations have recurrent infections, autoimmunity (cytopenia, positive antinuclear antibody), lymphoproliferation and lymphoma, low IgG with or without low IgA, poor responses to vaccines (particularly pneumococcal polysaccharides), low B-cell number, and low switched memory B cells.

CD19 Deficiency

CD19 is expressed on B cells and is a component of a receptor complex that contains CD21, a receptor for the complement fragment C3dg (it is also called complement receptor 2, and it is the receptor for EBV). Simultaneous cross-linking of CD21 and the B-cell Ig receptor lowers the threshold for B-cell activation. Four patients in two kindreds have been found to have mutations in CD19.[308] They exhibit recurrent infections, hypogammaglobulinemia, and low levels of switched memory B cells.

The occurrence of thymoma in the context of a clinical and immunologic picture very similar to that of CVID with low numbers of B cells and generally more severely impaired T-cell function has been designated Good's syndrome. It is not clear whether these patients exhibit as yet undiscovered specific genetic or immunologic abnormalities that distinguish them from the larger group of patients with CVID.

Immunoglobulin A Deficiency

There are two subclasses of human IgA: IgA1 and IgA2. They are encoded by separate genes on the heavy-chain C region locus on chromosome 14 (see Fig. 23-11). IgA1 predominates in serum (80% to 90%), whereas IgA1 and IgA2 are equally prevalent in secretions. Both subclasses are equally affected in IgA deficiency (IGAD). Selective IGAD is defined as a serum IgA level of less than 0.07 g/L with normal serum IgG and IgM in a child older than 4 years of age in whom other causes of hypogammaglobulinemia have been excluded.[2] Note that this definition is restricted to the absence of serum IgA. There is no known clinical association with IgA levels between the lower limit of detection and the lower limit of the normal range. It is not appropriate to refer to patients with these nonzero low IgA values as being IgA deficient.

Failure to produce normal levels of IgA is seen in about 1 in 700 white individuals.[309] In contrast, its incidence among Japanese is only 1 in 18,500.[310] This presumably reflects population genetic differences, possibly

related to the HLA complex. IGAD has been associated with extended HLA haplotypes similar to those observed in CVID.[298,299] The majority of individuals with IGAD are completely asymptomatic. Some may have a clinical course similar to that seen in CVID or in IgG subclass deficiency (see later). The proportion of patients with IGAD is increased in a population of people with chronic lung disease, and 20 years of observation of blood donors with IGAD has documented an increased incidence of respiratory infections and autoimmune disease.[311]

IGAD is also associated with an increased incidence of autoimmune syndromes, as with CVID.[312] In addition, atopic diseases appear to be more prevalent among those with IGAD, and some have noted an increased incidence of the type of malignancies encountered in CVID. In rare patients IGAD has evolved into CVID or levels of IgA have increased over time.[313,314] Treatment of IGAD has generally focused on management of complications as they occur. In some instances, gamma globulin infusions may be helpful, especially if an associated IgG subclass or specific antibody deficiency is present (see later). However, one study did not find an association between a history of infections and lower antibody responses to pneumococcal polysaccharides.[315] Some studies do show an association of increased infections if there is an IgG subclass deficiency or mannose-binding lectin (MBL) deficiency together with IGAD.[316]

Molecular genetic defects have not been described in IGAD. Lesions in IgA C region genes are not found, except in rare instances associated with other deletions (see later). IGAD and CVID have been associated with the HLA haplotype A1, B8, DR3 in whites.[299,317] An IGAD susceptibility locus (IGAD1) has been mapped to the boundary region between HLA class II and class III.[318-320] A more detailed analysis identified a positive association of IGAD with HLA-DRB1*0301, DQB1*02 and a negative association with DRB1*1501, DQB1*0602. Another study identified an association of IGAD with DRB1*0102, DQB1*0501.[321] The significance of these associations requires clarification.

IGAD may occur as a drug side effect, as has been reported with phenytoin, carbamazepine, valproic acid, zonisamide, sulfasalazine, gold, penicillamine, hydroxychloroquine, and nonsteroidal anti-inflammatory drugs.[322] The IgA level may normalize after cessation of use of the drug.

Immunoglobulin G Subclass Deficiency

Four subclasses of IgG exist in humans: IgG1, IgG2, IgG3, and IgG4. Their designations order their prevalence in serum, with each constituting roughly 67%, 23%, 7%, and 3% of the total, respectively. A different gene encodes the heavy-chain constant region of each subclass (see Fig. 23-11). Each subclass has unique structural properties and probably plays a different role in immune responses as a result of different interactions with the complement system and with receptors for IgG on phagocytic cells and lymphocytes. In addition, IgG

subclasses are produced in different relative amounts depending on the antigenic stimulus.[323] Mainly IgG1 is produced in response to soluble protein antigens. Viral antigens also elicit predominantly IgG1 responses and often significant amounts of IgG3 as well. Particular viruses (e.g., hepatitis, herpes simplex, and varicella) also elicit IgG4. The pneumococcal capsular polysaccharide response is almost exclusively of the IgG2 subclass, whereas HIB polysaccharide elicits mainly IgG2, with some IgG1 (the latter is found in younger children particularly). Note that the current HIB and new pneumococcal (Prevnar) vaccines are protein conjugates and elicit responses characteristic of protein antigens.

IgG subclass deficiency is defined as the relative lack of one or more IgG subclasses with a normal total level of IgG. If the level of total IgG is low, the diagnosis should usually be CVID.[2] Precise criteria for diagnosis are difficult to establish because of variability in Ig measurements by various techniques (e.g., nephelometry and radial immunodiffusion) and the wide variability in normal ranges with respect to age and ethnicity. The significance of decreased levels of IgG subclasses in patients with recurrent infections is further clouded by the fact that the majority of individuals with isolated subclass deficiencies are asymptomatic (see later). Assessing the response to antigen challenge is the most important element in evaluation of these patients. Most children have been immunized with tetanus toxoid and HIB, and antibody titers may be determined at the first visit. If titers are low, response to booster immunization may be assessed. Patients may also be immunized with 23-valent pneumococcal or meningococcal vaccines for rigorous assessment of polysaccharide responses. However, the latter vaccines produce unreliable results in normal children younger than 2 years, and negative responses in these patients should be interpreted with caution. Assessment of memory B-cell subsets may become a useful diagnostic tool; one study suggests that reduced switched memory B cells have better a correlation with risk for infection than antibody responses do.[287]

Patients with IgG subclass deficiency are commonly seen with recurrent sinopulmonary infections of varying severity caused by common respiratory bacterial pathogens.[324] Some may also have recurrent diarrhea, often of infectious origin. Furthermore, atopic diseases such as asthma and allergic rhinitis are more prevalent in patients with IgG subclass deficiency. Deficiency of the IgG2 subclass is detected most commonly in symptomatic patients. It may occur in isolation but is also usually associated with deficiency of IgG4, IgA, or both.[315,325,326] Selective deficiency of IgG3 alone is likewise observed (most often in adult females) and is associated with the same clinical picture described earlier.[325,327] The lowest IgG4 levels are usually associated with IgG2 deficiency. Recurrent infections have been described in some patients with only IgG4 deficiency.[328]

The C region genes determining antibody classes and subclasses are arranged in the same transcriptional

orientation on chromosome 14 (see Fig. 23-11). As with IGAD, only rarely is clinically significant IgG subclass deficiency associated with genetic lesions of IgG C region genes. This has been observed in a single reported patient with IgG2 deficiency, in whom mutation prevented expression of cell surface IgG2.[329] In fact, large deletions of Ig C region genes are surprisingly common; six multigene deletion haplotypes have been identified (see Fig. 23-11).[330] In one population with a high degree of consanguinity, individuals were found to be homozygous for one haplotype or heterozygous for two different haplotypes. Fifteen of 16 people with deletions on both chromosomes were entirely healthy despite a complete lack of one or more IgG subclasses or IgA1; one person had recurrent infections. Similarly, two healthy siblings have been described, each having homozygous deletions of IgA1, IgG2, IgG4, and IgE.[331] Furthermore, an analysis of the Ig heavy-chain loci of 33 patients with CVID revealed only 2 patients who were heterozygous for C gene deletions.[332]

Specific Antibody Deficiency with Normal Immunoglobulins

A population of patients with recurrent infections and poor antibody responses (mainly to polysaccharide antigens) have completely normal levels of antibody classes and subclasses. This condition has been called "specific antibody deficiency with normal immunoglobulins" or "functional antibody deficiency."[333-336] In one recent retrospective compilation of 90 patients in a tertiary care institution in whom immunodeficiency was diagnosed, specific antibody deficiency with normal Igs was the most common diagnosis, made in 23% of patients.[333] Several studies have shown an increased proportion of individuals with subclass deficiencies among patients with recurrent infections. Not all of these patients have demonstrably impaired responses to vaccines, however. Thus, the relationship between lack of an antibody isotype and susceptibility to infection is far from straightforward. Measurement of memory B-cell populations may correlate better with infection risk in these patients, although further study is required.[287] IGAD, IgG subclass deficiency, and a subset of CVID may be entities in a spectrum with similar pathophysiologic characteristics.

Patients with recurrent infections, regardless of antibody class or subclass levels, should receive prophylactic antibiotic therapy initially and undergo thorough evaluation to rule out other potential predisposing factors (e.g., anatomic defects or environmental allergies).[2] Repeated immunization may lead to measurable antibody responses, although even protein conjugate pneumococcal polysaccharide vaccines may not be as effective as in healthy individuals.[337] If infections are recurrent and unacceptably severe and antibody responses to immunization are poor, gamma globulin replacement is indicated. Most children have a good response and a decreased incidence of infections.[2,334,335,338] The natural history of IgG subclass deficiency and specific antibody deficiency is usually slow spontaneous resolution. Most children have a greatly reduced incidence of infections by late childhood.

Transient Hypogammaglobulinemia of Infancy

Transient hypogammaglobulinemia of infancy (THI) is, as its name suggests, an antibody deficiency beginning in infancy that resolves spontaneously, usually by 4 to 5 years of age.[339-343] It is defined as the occurrence of an IgG level more than 2 SD below the mean for age. Many patients also have low IgA, and some also have low IgM. Vaccine antibody responses are usually intact, but this is not always the case. Peripheral lymphoid tissue is sparsely populated with small or no germinal centers and markedly reduced plasma cell contents. Numbers of circulating B and T cells are generally normal, as are in vitro assays of lymphocyte function (e.g., mitogen response). One recent study documented higher B-cell counts than in an age-matched group.[340]

Ig levels in THI gradually increase over time, and the majority of patients have normal levels by the age of 4 or 5. Thus, the diagnosis can be confirmed only after Ig levels normalize. Recent prospective studies show a preponderance of the diagnosis in males and normalization of Ig levels at a median of around 2 years with an upper limit of approximately 5 years.[339-341] Patients with lower IgG levels tend to take longer to normalize. One study showed a significantly longer time until normalization in females.[339]

The chain of recurrent infections in THI may often be broken with antibiotic prophylaxis. Particularly severe or recurrent infections may warrant a period of gamma globulin replacement.[2] After 6 to 12 months, infusions should be stopped and antibody production evaluated. For children in whom antibody levels increase sluggishly, the clinical course is particularly difficult, or a response to gamma globulin therapy is not seen, immune function should be thoroughly evaluated.

COMPLEMENT DEFICIENCIES

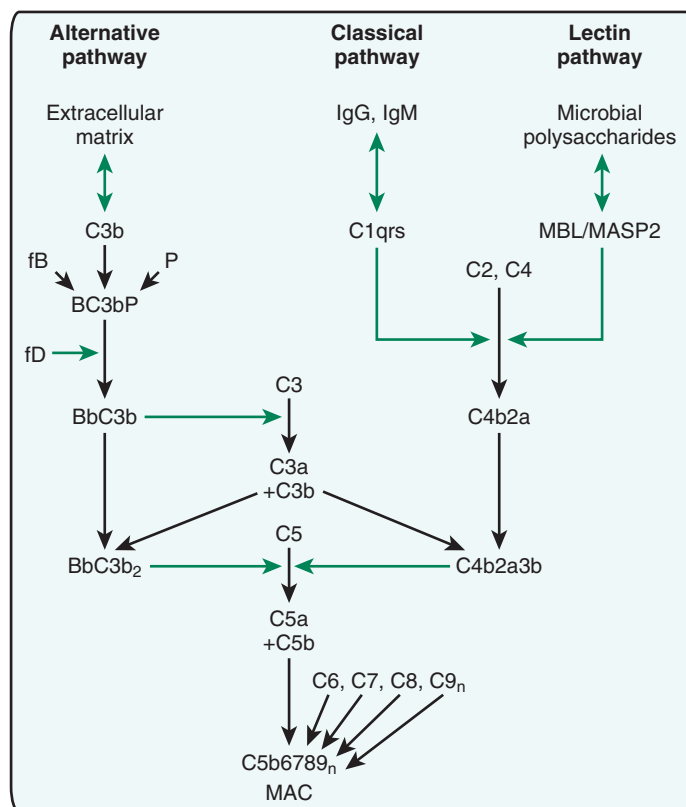
The complement system is composed of some 20 serum proteins, 5 complement receptors with varied distribution among leukocytes, and several integral membrane regulators found on most cells of the body.[344,345] The latter group of molecules limit cell damage as a result of a low constitutive level of complement activation. There are three distinct modes of complement activation: the classical pathway, the alternative pathway, and the lectin pathway. These pathways are shown in Figure 23-12. Soluble or surface-bound antigen-antibody complexes initiate the classical pathway; the alternative pathway is activated when complexes of properdin, factor B, and C3b are deposited on bacterial surfaces or extracellular matrix components. The lectin pathway is initiated by binding of MBL to mannose-containing microbial


FIGURE 23-12. Complement activation pathways. The alternative pathway is initiated when the C3b fragment with factor B (fB) and properdin (P) bind to the extracellular matrix or some microbial polysaccharides. Factor D (fD) cleaves fB to yield the C3 convertase BbC3b. Addition of C3b creates the C5 convertase BbC3b$_2$. The classical pathway begins when IgG or IgM bound to a surface forms a complex with C1qrs. The lectin pathway is initiated when mannose-binding lectin (MBL) and MBL-associated serine protease 2 (MASP2) bind to microbial polysaccharides. Activated C1qrs and MBL/MASP2 are both capable of cleaving C2 and C4 to yield the C3 convertase C4b2a. Addition of C3b to this complex yields the C5 convertase C4b2a3b. The C5 convertases generate C5b, the nucleus for the membrane attack complex (MAC), which is formed by the addition of one each of C6, C7, and C8 and several molecules of C9.

TABLE 23-6	Clinical Associations with Complement Deficiencies
Component	**Symptoms/Syndrome Associated with Deficiency**
C1q, C1r	Systemic lupus erythematosus–like syndrome
C2	Systemic lupus erythematosus–like syndrome, vasculitis, polymyositis
C4	Systemic lupus erythematosus–like syndrome
C3	Recurrent pyogenic infections
C5, C6, C7, C8, C9	Neisserial infection, systemic lupus erythematosus–like syndrome
C1-INH	Hereditary angioedema
Factor I, factor H	Recurrent pyogenic infections
Factor D, properdin	Neisserial infections
MBL, MASP-2	Recurrent pyogenic infections

C1-INH, C1 esterase inhibitor; MASP, MBL-associated serine proteases; MBL, mannose-binding lectin.

polysaccharides. All pathways consist of sequential proteolytic interactions having a common outcome: cleavage (activation) of the C3 complement component to yield the anaphylatoxin C3a and the C3b fragment. C3b attaches to cell membranes (e.g., bacteria) and is the principal opsonin for phagocytosis. After cleavage of the C5 component, additional reactions are nonenzymatic aggregation of C6, C7, C8, and C9 to form the macromolecular membrane attack complex. The membrane attack complex is an amphiphilic cylinder; its hydrophobic end inserts into target cell membranes and permits free flow of ions and other solutes, which leads to metabolic derangement or lysis. Genetic defects of almost all complement components are known.[346] The clinical manifestations of these defects are categorized in Table 23-6. Complement deficiencies are among the rarest of primary immunodeficiencies. Altogether, they account for less than 1% of all patients diagnosed.

Deficiency of Classical Complement Pathway Components

C1 Deficiency

C1 is a large complex multimer consisting of three major subunits: C1q, C1r, and C1s. C1q is itself a complex of 18 separate polypeptides, 6 molecules each of C1qA, C1qB, and C1qC. The C1 complex is completed by the addition of two molecules each of C1r and C1s, which brings the total to 22 polypeptides. Patients with defects in any of the major subunits of C1 have a syndrome resembling systemic lupus erythematosus (SLE) and susceptibility to recurrent infections.[347] Deficiency of C1q may be due to antigenically normal nonfunctional protein or complete absence of C1q.[348] The C1qA, C1qB, and C1qC genes are closely linked on chromosome 1; defects in the C1qB and C1qC genes have been described. The genes encoding C1r and C1s are closely linked on chromosome 12, and mutations of both C1r and C1s have also been described.[349-351]

C2 Deficiency

The monomeric C2 component of complement is the substrate for the activated C1s component of the C1q complex. Two fragments are generated in this reaction: the C2a fragment associates with C4b on a cell surface and becomes an activator for C3 ("C3 convertase"). The C2b fragment is a substrate for plasmin and releases a vasoactive peptide that may play a role in hereditary angioedema (HAE, see later). Approximately 50% of individuals with C2 deficiency are asymptomatic. The rest have one or more of the following: various forms of vasculitis such as discoid or systemic lupus erythematosus, chronic Henoch-Schönlein purpura, polymyositis, or recurrent pyogenic infections.[352-355] Only approximately

25% of C2-deficient patients are prone to infections.[352] C2 deficiency is associated with low levels of IgG subclasses, and low levels of IgG4 and IgA may play a role in determining susceptibility to infection.

The gene encoding C2 resides in the class III region of the HLA complex on chromosome 6. Between 1% and 1.5% of whites are heterozygous for a null C2 allele (*C2Q0*). Thus, about 1 in 10,000 will be homozygous for *C2Q0* and have a complete deficiency of C2. Two forms of C2 deficiency independent of *C2Q0* have been identified. In type I, a mutation results in loss of a mRNA splice site and C2 cannot be translated. In type 2 deficiency, C2 is not secreted, but the basis for this is unknown.

C4 Deficiency

The C4 component is another substrate for activated C1s. The C4a fragment is a very weak anaphylatoxin, and the C4b fragment associates with C2a on a cell membrane to constitute C3 convertase. Complete deficiency of C4 is rare. Virtually all such individuals with C4 deficiency have SLE and severe glomerulonephritis.[356-358] Renal failure and infection are the leading causes of death. The genes encoding C4 are also located in the class III region of the HLA complex. There are two copies on each chromosome, *C4A* and *C4B*. Each encodes proteins that differ in structure only minimally, although their biologic activities are distinct. Null alleles at these loci occur frequently; 35% of people have one copy of either *C4AQ0* or *C4BQ0*. Ten percent of the population have two null alleles, and 1% have three.[359] The presence of four null alleles (complete C4 deficiency) is rare. All of these partial deficiency states are often asymptomatic. However, HLA haplotypes containing null alleles are frequently found in patients with SLE, CVID, or IGAD.[360,361] One study has found an association of *C4B* null alleles with Henoch-Schönlein purpura.[362] The relatively high rate of occurrence of C2 and C4 null alleles leads to combined heterozygous partial deficiencies of both in about 1 in 1000 whites. Around a third of these patients have SLE and other autoimmune diseases.[347,363,364]

C3 Deficiency

The C3 component sits at the confluence of the classical and alternative pathways of complement activation. The various fragments of C3 generated through the action of C3 convertases (C4b2a and C3b2Bb), as well as other serum proteases, have diverse influences within the immune system. C3a is a potent anaphylatoxin, whereas C3b is the principal opsonin for phagocytosis and is a component of enzyme complexes in the alternative pathway of complement activation. Additional C3 fragments influence lymphocyte function. For example, C3d is an important regulator of B-cell activation.[365] Patients with C3 deficiency are susceptible to recurrent pyogenic infections, and this condition is often clinically indistinguishable from hypogammaglobulinemia. These patients may also exhibit skin, kidney, and joint inflammation caused by immune complex deposition.[366-369]

Deficiency of Alternative Complement Pathway Components

Properdin Deficiency

Properdin stabilizes the alternative pathway C3 convertase. The properdin gene is located on the X chromosome. Lack of properdin does not cause any changes in serum levels of complement components; activation through the alternative pathway is inefficient. Susceptibility to meningococcal infection and discoid lupus erythematosus has been associated with properdin deficiency.[347,364,370,371] One patient found to have coincidental deficiency of both properdin and C2 suffered recurrent *S. pneumoniae* bacteremia.[372] Concomitant deficiency of properdin and MBL may also lead to increased susceptibility to infection (meningitis).[373]

Factor D Deficiency

Factor D cleaves factor B after it associates with C3b. Only a handful of patients with factor D deficiency have been described. Three with complete deficiency had recurrent neisserial infections.[374,375] Another with partial deficiency had recurrent respiratory tract infections.[376] An additional patient was seen with neonatal pneumococcal sepsis.[377]

Deficiency of Lectin Pathway Complement Components

Mannose-Binding Lectin Deficiency

MBL is a member of the collectin protein family, which also includes lung surfactant proteins A and D.[378] MBL has a structure similar to C1q and interacts with polysaccharides containing mannose, glucose, and fucose, as well as acetylated derivatives of these sugars. Thus, MBL may interact with members of virtually all classes of infectious microbes. Three proteins called MBL-associated serine proteases (MASP) 1 to 3 are similar to C1r and C1s.[379] MASP-2 may have the most important role in catalyzing cleavage of C2 and C4 in a manner analogous to C1s. Once this is accomplished, the classical pathway C3 convertase has been created and further reactions are identical to the classical pathway. There are polymorphisms of the gene encoding MBL that affect both structure and expression.[380,381] Structural polymorphisms may impair the ability of MBL to form functional oligomers that bind effectively to carbohydrates and may also impair the association with MASP-2 and subsequent activation of the remainder of the classical pathway.[382] Promoter polymorphisms lead to variation in blood MBL levels of greater than 1000-fold from 5 ng up to 10 g/mL. The "cutoff" for clinical deficiency is not well established. Many studies use values of approximately 100 to 200 ng/mL, although slightly different values are occasionally used. Low MBL levels vary among ethnic groups. The genotype or functional tests may be more informative than the serum level alone because it is

possible to have normal serum levels of a nonfunctional protein.[381]

Low blood MBL level or function does not by itself predispose to disease, except possibly during infancy, when it may be associated with a higher rate of bacterial respiratory tract infections.[380,381,383] In the setting of other disease processes or "stresses" on the immune system, MBL deficiency may predispose to a higher rate of a variety of infectious complications. Examples include the administration of chemotherapy and the development of systemic inflammatory response syndrome, sepsis, or adult respiratory distress syndrome after admission to an intensive care unit.[381,384] Low blood MBL levels may also increase the severity of the immunodeficiency occurring via other principal mechanisms, such as in CVID or with IgA/IgG subclass deficiencies or properdin deficiency.[316,373,385,386] In addition, MBL deficiency may predispose to or worsen autoimmune or inflammatory diseases such as rheumatoid arthritis, SLE, and celiac disease.[381] Recombinant human MBL is under development as a therapeutic agent; one phase I trial has shown no adverse effects of administration to healthy MBL-deficient individuals.[387]

MASP-2 Deficiency

The gene frequency of mutant *MASP2* is 3.6% among white individuals.[388] Abrogation of MASP-2 function is expected to have the same consequence as the absence of MBL function: failure to activate complement via the lectin pathway.[388,389] Patients homozygous for *MASP2* mutations who have recurrent respiratory bacterial infections and autoimmune disease have been described.[388,390]

Deficiency of Terminal Complement Components

Recurrent neisserial and pneumococcal infections and rheumatic disease have been reported in patients with C5,[391,392] C6,[393,394] and C7[395-398] deficiencies. In two families, patients with deficiency of both C6 and C7 have been identified.[399] C6 deficiency has been found in approximately 1 in 1600 African Americans in the southeastern United States in association with a higher incidence of meningococcal meningitis.[400] Molecular lesions have been defined in several patients.[401] A 1.1% incidence of a mutant C7 allele has been found in a large cohort of healthy people of Moroccan Jewish descent.[402] The C8 molecule is a heterotrimer of chains designated α, β, and γ. The α and β genes are on chromosome 1, whereas the γ gene resides on chromosome 9. C8 deficiency is also associated with recurrent neisserial infection; patients have been identified with lack of α and γ together or β alone.[403,404] Patients with lesions in C8 α genes also lack C8 γ protein, even though the latter genes are normal, because C8 α and γ are normally covalently linked. C9 deficiency is usually asymptomatic; a few patients with recurrent neisserial infections have been described.[405-407] One patient with IgA nephropathy associated with C9 deficiency has been reported.[408] C9 deficiency has also been found in one patient with dermatomyositis.[409] Allotypy at IgG Fc receptor gene loci may have an impact on the susceptibility to infection in patients with deficiencies of terminal complement components.[410]

Deficiency of Complement Regulatory Factors

C1 Inhibitor Deficiency (Hereditary Angioedema)

HAE exhibits autosomal dominant inheritance. The symptoms of this disease are unpredictable recurrences of acute and profound subepithelial edema in a variety of locations.[411] Physical trauma may be a precipitating factor. The distal ends of the extremities, face, intestines, and pharynx are often affected. Extremity edema is painless but impedes function. Intestinal edema causes excruciating pain and is associated with abdominal distention, vomiting, and diarrhea. Pharyngeal edema may lead to fatal airway obstruction. Attacks evolve over a period of about 12 hours and resolve in 24 to 48 hours. Attacks in childhood are not uncommon but occur less frequently than in adulthood. An increase in incidence and severity often occurs during puberty and is sustained thereafter. Attacks may be associated with menses in females. Patients may become symptomatic or may have more frequent symptoms when receiving estrogen replacement or contraceptive therapy.[412]

C1 esterase inhibitor (C1-INH) is a serum serine protease inhibitor (serpin) that limits activities of the complement proteases C1r and C1s, as well as those of kallikrein, coagulation factors XIa and XIIa, and plasmin.[413,414] In type I HAE (about 85% of patients), levels of C1-INH are less than 30% of normal. In type II HAE, patients have normal levels of a mutated (nonfunctional) protein. There is at least one additional form of HAE with autosomal dominant inheritance and completely normal C1-INH function. It is designated HAE type III. In HAE I and II, the unopposed activities of C1r, C1s, and kallikrein lead to consumption of C2, C4, and bradykinin.[415] Diminished levels of these proteins are highly characteristic of HAE. Peptides derived from C2 and bradykinin cause an increase in vascular permeability and edema.

The C1-INH gene is located on chromosome 11. A variety of genetic lesions have been identified in patients with HAE.[416] Despite having one normal copy of the gene, patients have inadequate levels of C1-INH, well below the 50% one would expect to be due to a simple gene dosage effect. This may be attributable to a *trans*-inhibitory effect of the mutant allele, which leads to inhibition of transcription of the normal gene. Although inheritance is autosomal dominant, as many as 10% to

25% of patients may express new mutations. Only one patient with homozygous HAE has been reported.[417]

In managing acute attacks in patients with HAE, medications such as epinephrine, antihistamines, and corticosteroids, used to treat angioedema subsequent to hypersensitivity reactions, are entirely useless because the mechanism of swelling in HAE is unrelated.[418-421] Analgesia is indicated for painful abdominal crises. Airway protection is vital and may require a tracheostomy. Fresh frozen plasma has been used in attempts to replace C1-INH, but this is dangerous because fresh frozen plasma also contains C2 and bradykinin and may add fuel to the reaction. Intravenous infusion of purified human C1-INH from human plasma can immediately halt the progression of an HAE attack. This therapy may even be administered at home.[422] Unfortunately, despite more than a decade of experience worldwide indicating its safety and efficacy, a human C1-INH product has not yet been approved in the United States. In addition to replacement therapy for HAE, purified C1-INH may be useful in limiting the complement activation associated with sepsis, cytokine-induced vascular leak syndrome, acute myocardial infarction, or other diseases. Impeded androgens such as danazol, stanozolol, and oxandrolone are useful for reducing the rate of occurrence of attacks. These hormones act to increase expression of the normal C1-INH gene. Their use in children is limited by their tendency to promote epiphyseal closure; use in females is limited by their undesirable virilizing effects. Note that these drugs would not be effective in the very rare individuals with two mutant alleles. New small-molecule therapeutics are in development,[423] including a kallikrein inhibitor and a bradykinin receptor antagonist.

Acquired forms of HAE have also been described. In acquired angioedema (AAE) type 1, C1-INH levels decrease by an unknown mechanism, usually as a paraneoplastic process associated with lymphoma and lymphoproliferative disorders.[424] In AAE type 2, autoantibodies against C1-INH deplete it from serum.[425,426] These antibodies may arise sporadically or in association with lymphoproliferation.

Factor I Deficiency

Also known as C3 inactivator, the disulfide-linked heterodimeric complement regulatory molecule factor I cleaves C3b. Deficiency of factor I leads to increased degradation of C3 (and factor B), principally because of the inability to control constitutive low-level activity of the alternative pathway of activation. These patients have manifestations of C3 deficiency such as recurrent infections, urticaria, and immune complex disease.[427-431]

Factor H Deficiency

Factor H cooperates with factor I in the inactivation of C3b; its absence leads to reduced C3 and factor B and a syndrome of recurrent infections with *Neisseria meningitidis* and membranoproliferative glomerulonephritis.[432,433] Both familial and sporadic relapsing hemolytic-uremic syndromes have been associated with mutations in factor H.[434-436]

THE FUTURE

The diagnosis of disease, in general, may undergo significant transformation in the years ahead. This is no less true of primary immunodeficiency than it is of any other subspecialty in medicine. The refinement of a host of molecular methods that permit high-throughput analysis of gene structure and expression at all levels (RNA, protein, biochemistry, cell, and tissue/organ function) may bring definitive diagnosis into clear focus much more easily than is now possible.[437] Of course, much work is still needed to bring such techniques to fruition.

Study of patients who have the syndromes described in this chapter has provided a wealth of information about the physiology of the immune system. Each patient with one of these conditions—or with immune defects yet to be defined—presents a unique opportunity to gain further insight. As we continue to refine our understanding of the pathophysiology of these disorders, our therapies are increasingly able to compensate for these defects and help these patients lead productive lives.

24 Storage Diseases of the Reticuloendothelial System

Alessandra d'Azzo, Edwin H. Kolodny, Erik Bonten, and Ida Annunziata

Lysosomal storage disease (LSDs) comprise a large group of congenital disorders of metabolism caused by impaired lysosomal function. These diseases are heterogeneous in nature and have a broad range of clinical manifestations that affect systemic organs and the nervous system to a different extent. At the cellular level, dramatic morphologic changes can be readily identified in circulating blood and the reticuloendothelial system. Such changes include pancytopenia, vacuolization of mononuclear cells, storage of foam cells, and enlargement of the liver, spleen, and lymph nodes.

The majority of the LSDs are caused by deficiency of a single lysosomal hydrolase, which underscores the lack of redundancy for these enzymes and their importance in maintaining cell homeostasis. Consequently, products of cellular metabolism that are ordinarily degraded by these enzymes remain undigested, overload the lysosomes, and cause severe disruption of cellular architecture.

LSDs have been the object of intensive study by clinician, biochemists, geneticists, and molecular biologists. Their investigations have established the following for each disease: mode of inheritance, histologic and ultrastructural features, chemical structure of the stored materials, and properties of the missing enzyme and its molecular genetics. In recent years, the generation of small laboratory animal models that closely recapitulate the corresponding human conditions has facilitated studies of disease pathogenesis and the implementation of various therapeutic modalities. Simple definitive laboratory methods have been developed that permit accurate prenatal and postnatal diagnosis of these diseases. As a result, many of them are now being diagnosed in many more patients, including individuals with perplexing clinical manifestations representing variant forms of LSDs.

A hematologic perspective is particularly pertinent to the diagnosis of inherited storage diseases. Circulating leukocytes have not only a rapid metabolic rate but also the capacity to phagocytize nondegradable materials. Therefore, these cells are doubly vulnerable, and thus it is not surprising that various morphologic changes are observed in leukocytes from patients with storage diseases and used as diagnostic tools. The same holds true for the bone marrow–derived monocytes and macrophages that become engorged with lysosomes full of undegraded metabolites. Consequently, bone marrow and other tissues of the hematopoietic system reflect the storage phenomenon, and examination of such tissues is often diagnostic of the disease.

Biochemical studies are usually required for a definitive diagnosis, and there too, peripheral blood may serve an important function. Serum, plasma, and mixed leukocyte fractions provide a rich and readily available source of material for substrate analysis and enzymatic assays. Enzyme testing in blood samples is also helpful for screening relatives who are heterozygous for the mutated allele. The incidence of some LSDs, such as the Tay-Sachs variant of G_{M2}-gangliosidosis, has actually been reduced by large-scale screening programs for testing serum and leukocytes in at-risk populations. If both members of a couple are discovered to be carriers of a disease allele and therefore at risk for bearing affected children, they can elect to have amniocentesis performed for prenatal diagnosis and, if the fetus is affected, can choose termination of the pregnancy. Through the use of more efficient and economical testing methods, this prototype program for prevention of genetic disease may become applicable to other storage diseases that are fatal in early childhood. In some clinical centers, neonatal screening for LSDs has recently been established. However, for now, we can still reduce the burden of these diseases by properly testing and counseling family members of individuals known to have these disorders. Such counseling should include full disclosure of the option for prenatal diagnosis as soon as possible after an LSD has been diagnosed.

Considerable phenotypic heterogeneity characterizes each of the storage diseases. The development of DNA-based methods for molecular diagnosis now makes possible improved genotype-phenotype correlations. Different mutations within the same gene appear to account for clinical variations within superficially similar diseases. Therefore, physicians faced with a perplexing occurrence of a suspected storage disease should not exclude otherwise similar conditions because of a few phenotypic dissimilarities. Although blood enzyme assays will remain a cornerstone in the classification of these diseases, greater diagnostic specificity is now possible by direct analysis of individual mutations in genomic DNA.

Therapies for LSDs pose a great challenge, given the systemic nature of most of these disorders and the involvement of the nervous system, which is invariably present, especially in patients with an early onset of symptoms. However, during the last decades, new or improved therapeutic approaches have been and continue to be tested for the treatment of LSDs, including enzyme replacement therapy (ERT) with genetically engineered recombinant enzymes, substrate reduction therapy (SRT) with specific inhibitors of the synthesis of target natural substrates, chaperone-mediated enzyme enhancement with synthetic sugar nucleotides, hematopoietic stem cell (HSC) transplantation, and ex vivo and in vivo gene therapy. Some of these therapeutic modalities are currently available to patients or are in clinical trials, whereas others have been tested only in animal models.

The emphasis here is on LSDs with manifestations in the reticuloendothelial system. One of the purposes of this chapter is to guide the reader through some of the complex chemical pathways involved in these diseases. The references provided at the end of the chapter reflect the most recent findings in this rapidly developing field of medicine, and they should be consulted for further clinical and biochemical information on the storage diseases.

GENERAL CONCEPTS

Lysosomes and Lysosomal Enzymes

Morphology and Physiology. Lysosomes are membrane-bound, specialized organelles that constitute up to 5% of the intracellular volume and are heterogeneous in size, morphology, and content. Lysosomes are found in basically all cells, with the exclusion of mature erythrocytes. Among hematopoietic cells, they account for the characteristic azurophilic-staining granules in polymorphonuclear leukocytes and eosinophils and are numerous in reticulocytes, especially after splenectomy.[1] Electron microscopic studies reveal that lysosomes are delineated by a single membrane that may fuse with pinocytic or phagocytic vesicles containing ingested foreign material (heterophagy) or with vacuoles containing cellular constituents or metabolites destined for further catabolism (autophagy).[2] The secondary lysosomes formed during the processes of heterophagy and autophagy are polymorphic in size. The undigested material remaining in secondary lysosomes after digestion coalesces into a residual body that can be extruded from the cell via an excretory pathway, for example, in bile from the liver and in urine from the kidney.

Biosynthesis. The lysosomal system represents the major site of intracellular compartmentalized degradation. With their complement of more than 70 hydrolytic enzymes, lysosomes regulate the turnover of many cellular constituents; proteins, glycoproteins, nucleic acids, polysaccharides, glycolipids, phospholipids, and neutral lipids are the enzymes' natural substrates.[3,4] Most of the lysosomal enzymes are soluble, whereas a few are membrane associated. Soluble enzyme precursors are specialized forms of secretory proteins. As the latter, they are synthesized on membrane-bound polysomes and gain access to the lumen of the endoplasmic reticulum (ER) via a conventional signal sequence; once in the ER, they are cotranslationally glycosylated on specific asparagine residues[5] and fold in their native tertiary structure with the aid of folding catalysts or assemble into multiprotein complexes. Partial modification of their sugar chains in the ER allows transfer of the enzyme precursors to the Golgi and trans-Golgi network. At this site they undergo further processing of their glycans and acquire a key determinant, the mannose 6-phosphate (M6P) recognition marker, that ensures segregation of the enzyme precursors from the bulk of secretory proteins by interaction with the M6P receptor and finally correct compartmentalization of them in endosomes/lysosomes.[6-8] In some instances, soluble enzyme precursors can reach the lysosomes in an M6P-independent manner.[9] Membrane-bound lysosomal enzymes use different receptors for reaching their final destination; such is the case for the enzyme glucocerebrosidase or β-glucosidase (see later), which is transported to lysosomes via interaction with the lysosomal integral membrane protein Limp-2.[10] Once in

the acidic endosomal/lysosomal environment, most lysosomal enzyme precursors undergo partial proteolysis, which renders them fully mature and catalytically active. By default, a small percentage of the precursor proteins may escape to the exterior of the cell, but these secreted forms retain the capacity to be reinternalized via M6P receptor–mediated endocytosis and to be efficiently targeted to the lysosome, where they function normally.[11,12] This secretion and recapture mechanism of lysosomal enzymes may occur between cells[13] or between cells and the extracellular environment. Such exchange is readily demonstrable in skin fibroblast cultures. Release of enzyme from the cell can be demonstrated in culture media that do not initially contain any activity of the relevant enzyme. Cellular uptake of enzyme from nutrient media has been shown to restore enzyme activity in genetically deficient cells. This mode of cross-correction has served as the paradigm for the treatment of LSDs (see later). Release of lysosomal enzyme activity may also occur during phagocytosis or exocytosis, on exposure to membrane-disruptive agents or immune complexes,[14] or during treatment with acetylcholine and cyclic guanosine monophosphate in the presence of calcium.[15] In many hematopoietic cells, such as platelets, neutrophils, eosinophils, mast cells, macrophages, and cytotoxic T cells, a cohort of organelles with the characteristics of lysosomes have been shown to release their secretory products via calcium-dependent fusion of the lysosomal membrane with the plasma membrane, a process termed *lysosomal exocytosis*.[16] These observations gave rise to the concept of "secretory lysosomes,"[3,17] which was thought to be confined to specialized secretory cells. It is now apparent that the process of lysosomal exocytosis also plays the general role of membrane repair in nonsecretory cells such as fibroblasts.[18,19] Drugs such as epinephrine, isoproterenol, cyclic adenosine monophosphate,[15] and anti-inflammatory drugs[20] inhibit the release of lysosomal enzymes. Some of these factors could be involved in regulating levels of lysosomal enzyme activity in body fluids such as plasma, urine, and tears.

Enzyme Activity. Lysosomal enzymes are hydrolases that have maximal activity in an acidic pH environment and are specific with respect to the chemical linkage and structure of the monomeric unit that they hydrolyze. Small synthetic substrates can often substitute for more complex natural products in assays of lysosomal enzyme activity in vitro. Complex isozyme systems exist in which two or more enzymes act on a single substrate. The β-*N*-acetylhexosaminidases, arylsulfatases, α-galactosidases, α-mannosidases, and neuraminidases are examples. The specificity of lysosomal enzymes is reflected in the wide range of glycosidases and proteases, which represent the largest classes of these enzymes. Glycosidases bring about the catabolism of specific sugar chains on glycoconjugates in a stepwise and concerted fashion. If any of these enzymes is deficient or functionally defective, the process of degradation is halted at the level of the missing enzyme.

Such blockage leads first to the progressive intralysosomal accumulation of partially degraded metabolites and, subsequently, to the cellular and organ dysfunction associated with LSDs.[12,21] Not surprisingly, genetic lesions that result in faulty enzyme function are heterogeneous, given the numerous modifications that must occur with some precision between the site of synthesis of a lysosomal protein and its final sequestration and full activation within the lysosome. The genotype and familial history of the disease may eventually have an impact on the response to treatment.

Pathogenesis

Based on his studies of type II glycogen storage disease (Pompe's disease), Hers[22] proposed the concept of inborn lysosomal disease in 1965. He concluded that deficiency of a single lysosomal enzyme (α-glucosidase) results in the accumulation of its substrate (glycogen) within membrane-bound vesicles of lysosomal origin. According to this concept, progressive lysosomal accumulation of nonmetabolized material leads to abnormal expansion of the number of lysosomes within cells, disruption of normal cell functions, and possibly cell death.

The signs and symptoms produced by each of the storage diseases primarily reflect the pattern of distribution of the nondegradable natural products. In Gaucher's disease and Niemann-Pick disease, turnover of erythrocyte and leukocyte membranes leads to the formation of lipids that become trapped within the visceral organs principally involved in their metabolism. However, in disorders of ganglioside metabolism, the principal pathologic changes occur in the central nervous system (CNS) because ganglioside concentrations in this tissue under normal circumstances are much greater than those in extraneural tissues. Glycoproteins are abundant in nearly all tissues, both inside and outside the CNS. Therefore, diseases caused by the storage of mucopolysaccharides and other complex carbohydrates derived from glycoproteins affect a variety of different organ systems.

Natural materials with apparently intact pathways for their metabolism sometimes accumulate as secondary products in some of the LSDs. For example, cholesterol is closely associated with sphingomyelin in membranes and apparently for this reason also accumulates in Niemann-Pick disease (sphingomyelin lipidosis). High concentrations of mucopolysaccharide can inhibit β-galactosidase, so patients with mucopolysaccharidoses may secondarily accumulate not only mucopolysaccharide but also gangliosides in their brain tissue.

Genetics

Nearly all the LSDs are transmitted as autosomal recessive traits. Two exceptions, Fabry's disease (α-galactosidase deficiency) and Hunter's disease (iduronate sulfatase deficiency), follow an X-linked pattern of inheritance. During the seventies, interspecies somatic cell hybrids were widely used in gene-mapping experiments to make specific chromosome assignments for genes that code for lysosomal hydrolases. In situ hybridization of the cloned genes later provided additional information on their subchromosomal localization. With advent of the human genome project, lysosomal genes have been accurately mapped and their genomic organization established.[23] Knowledge of the gene and its genomic structure has enabled identification of disease-causing mutations in each of the LSDs and correlation between genotype and phenotype in patients with different clinical phenotypes (Table 24-1). Recombinant DNA technology has facilitated studies of the molecular basis of these diseases and has provided tools for more precise diagnosis, as well as the potential for definitive therapy through gene transfer.

Two or more enzyme activities can be affected by a single mutation in a particular gene locus. One explanation is that under ordinary circumstances, the gene involved in such situations regulates the synthesis of a subunit that is shared by more than one enzyme. For example, in Sandhoff's disease, failure to properly code for the β subunit shared by both the hexosaminidase A (Hex-A) and B (Hex-B) isozymes accounts for deficiencies in both these enzymes. Alternatively, the mutation could affect a post-translational event, such as attachment or removal of carbohydrate residues during conversion of the enzyme to its final glycoprotein form, which could result in an enzyme molecule that is catalytically active but can be neither retained nor selectively taken up by the cell. This type of defect occurs in mucolipidoses II and III and probably accounts for the altered electrophoretic properties of lysosomal enzymes in these diseases. In several LSDs, catalytically inactive enzyme protein can be detected by using antibodies to normal purified enzyme. Although the substrate binding or catalytic sites of this cross-reacting material may be altered, its antigenic sites are intact. Immunoassays for cross-reacting material are therefore an additional means of classifying variants of individual LSDs.

A number of heat-stable activator proteins, including the G_{M2} activator protein ($G_{M2}A$) and the saposins (SAP-A to SAP-D), have been shown to function either as natural detergents to stimulate the enzymatic hydrolysis of individual hydrophobic substrates or as cofactors of the enzyme.[24-26] Saposins are derived from proteolytic cleavage of a single, one-chain precursor, prosaposin.[27] Defects in these activator proteins are associated with variant forms of LSDs (see later). For example, in patients with a deficiency of SAP-C, a clinical condition resembling non-neuropathic Gaucher's disease develops.[28] Deficiency of $G_{M2}A$ has been implicated in the pathogenesis of the AB variant of G_{M2}-gangliosidosis.[29] In Morquio's disease type B, SAP-A works as cofactor of the mutant β-galactosidase in the degradation of G_{M1}-ganglioside (G_{M1}).[29] These various mechanisms allow enormous genetic heterogeneity and are, in fact, reflected

Enzyme	Disease	OMIM	Gene Map Locus
β-Mannosidase	β-Mannosidosis	248510	4q22-q25
α-L-Fucosidose	Fucosidosis	230000	1p34
Glucocerebrosidase	Gaucher's disease types 1, 2, and 3	230800, 230900, 231000	1q21
β-Galactosidase	G$_{M1}$-gangliodidosis	230500	3p21.33
α-L-Iduronidase	Hurler's disease type I, Scheie's disease	252800	4p16.3

OMIM, Online Mendelian Inheritance in Man.

in the marked phenotypic variations that distinguish many of the storage diseases.

Clinical Diagnosis

The undigested products found in the lysosomes of patients with LSDs are not uniformly distributed in all organs. Instead, they accumulate preferentially in certain tissues or cell types where under normal conditions, they are actively metabolized or recycled. The distribution of the storage material reflects the pattern of expression of the involved lysosomal enzyme and the specific function or metabolic need of any given cell. The involvement of specific tissues and organs thus determines the manner of clinical expression of each of the storage diseases (Table 24-2).

Dysmorphic facial features and hepatomegaly are two common features. The former occurs in type 1 G$_{M1}$-gangliosidosis, the mucopolysaccharidoses, mucolipidoses II and III, α-mannosidosis, galactosialidosis, and fucosidosis. Many of these diseases also display evidence of connective tissue infiltration, such as joint contractures, skeletal dysplasia, and corneal clouding. Some degree of liver enlargement also occurs in most of these disorders, including Gaucher's disease, Niemann-Pick disease, galactosialidosis, sialidosis type II, and Wolman's disease. Splenomegaly is also a common initial sign in Gaucher's disease, Niemann-Pick disease, galactosialidosis, sialidosis type II, and Wolman's disease. Lymphadenopathy and granulomatous joint deposits are characteristic of Farber's disease.

Signs of CNS dysfunction occur in most patients, particularly those with an early onset of signs of the disease. Slowed development, hypotonia, and excessive startle response in an infant may suggest a gangliosidosis. Actual regression in neurologic functioning with loss of previously acquired developmental milestones eventually occurs not only in the gangliosidoses but also in Niemann-Pick disease type A and several of the mucopolysaccharidoses. Seizures, megalencephaly, and blindness result

TABLE 24-2 Storage Diseases of the Reticuloendothelial System	
Age at Onset	**Initial Signs**
FIRST YEAR	
Niemann-Pick disease, type A	Slow development, hepatosplenomegaly
Gaucher's disease, type 2	Failure to thrive, hepatosplenomegaly, brainstem signs
Farber's disease	Hoarseness, vomiting, swollen joints, lymphadenopathy
G_{M1}-gangliosidosis, type 1	Slow development, increased startle, hepatosplenomegaly
G_{M2}-gangliosidosis, Sandhoff variant	Slow development, increased startle, cherry-red macula
Hurler's disease	Coarse facies, stiff joints
Hunter's disease	Coarse facies, stiff joints
Sanfilippo's disease	Coarse facies, stiff joints, severe mental retardation
Mucosulfatidosis	Slow development, coarse facies
Sialidosis, type II (infantile/congenital)	Fetal hydrops, coarse facies, hepatosplenomegaly, mental retardation
Galactosialidosis, early infantile	Fetal hydrops, coarse facies, hepatosplenomegaly, mental retardation
Mucolipidosis II	Wizened face at birth, gingival hyperplasia, stiff joints
Mucolipidosis IV	Slow development, corneal clouding
Sialic acid storage disease	Slow development, coarse facies, hepatosplenomegaly
Fucosidosis, type 1	Slow development, coarse facies
α-Mannosidosis	Slow development, coarse facies, hepatosplenomegaly
Wolman's disease	Vomiting, diarrhea, hepatosplenomegaly, calcified adrenals
Neuronal ceroid lipofuscinosis, infantile type	Slow development, poor vision
SECOND YEAR	
Niemann-Pick disease, type B	Hepatosplenomegaly
G_{M1}-gangliosidosis, type 2	Slow development, increased startle
Galactosialidosis, late infantile	Coarse facies, hepatospenomegaly, cherry-red macula, cardiac abnormalities
Morquio's syndrome	Dwarfism, skeletal abnormalities, loose joints
Maroteaux-Lamy syndrome	Coarse facies, stiff joints, corneal clouding
Mucolipidosis III	Stiff hands and shoulders
Fucosidosis, type 2	Slow neurologic deterioration
Aspartylglucosaminuria	Slow development, coarse facies, aggressive behavior
Neuronal ceroid lipofuscinosis, late infantile type	Seizures, myoclonus, decreased vision, decreased intellect
CHILDHOOD	
Niemann-Pick disease, chronic neuropathic form	Tetraparesis, hepatomegaly, decreased intellect
Gaucher's disease, type 1	Splenomegaly, anemia, thrombocytopenia
Scheie's disease	Clawhands
Cholesteryl ester storage disease	Hepatomegaly, increased plasma cholesterol and triglycerides
Neuronal ceroid lipofuscinosis, juvenile type	Blindness, seizures, decreased intellect
ADOLESCENCE	
Gaucher's disease, type 3	Splenomegaly, seizures, myoclonus
Sialidosis, type I	Unexpected falls, myoclonus, seizures, cherry-red macula
Galactosialidosis, juvenile/adult	Corneal clouding, coarse facies, seizures, cherry-red macula, mental retardation

later in the course of the ganglioside storage diseases. Vomiting may be an initial sign in Niemann-Pick disease type A and Wolman's disease.

Generally, the later clinical signs appear, the slower the progression of the disease and the less severe the disease process. In contrast to the severely retarded epileptic infant with a gangliosidosis and life expectancy measured in months, a patient who is seen in late childhood or early adolescence with seizures as a result of juvenile Gaucher's disease (type 3) or the cherry-red macula/myoclonus forms of sialidosis (type I) may survive 10 or more years without loss of intellect. Although mental retardation does occur in aspartylglucosaminuria, fucosidosis, the mannosidoses, and the less severe form of Hunter's disease, these diseases progress slowly, and patients survive into adulthood. In the adult form of

Gaucher's disease (type 1) and Niemann-Pick disease type B, splenic lipid storage may build up very slowly, no mental deficiency occurs, and a normal life span is possible.

Knowledge of the patient's family history is often helpful in determining a diagnosis. Patients with adult Gaucher's disease and type A Niemann-Pick disease are very often of northeastern European Jewish ancestry. A Scandinavian background is common in patients with aspartylglucosaminuria, and many patients with fucosidosis are of Italian extraction. Therefore, in the clinical evaluation of patients suspected of having a storage disease, particular attention should be devoted to review of the chronology of the disease and the family background, and careful assessment should be made of the neurologic, visceral, and skeletal manifestations. However,

because of considerable genetic heterogeneity, the physical signs and severity of the LSDs vary considerably. For this reason, laboratory studies play an important role in the diagnosis of these conditions.

Laboratory Diagnosis

Morphologic Findings

The histologic changes observed in the storage diseases are especially pronounced in organs with a significant reticuloendothelial component, such as the liver, spleen, lymph nodes, and bone marrow. The accumulations of natural products form inclusions that display specific staining characteristics and a defined ultrastructure. They may be readily observed in easily accessible tissues such as peripheral blood, bone marrow, liver, and skin (Table 24-3).

Peripheral Blood. Vacuolated lymphocytes are a common finding in the storage diseases (Fig. 24-1A through D).[30-37] They can be readily recognized in blood smears because they contain vacuoles that stain positively with periodic acid–Schiff (PAS). At the electron microscopic level, these vacuoles generally appear as dense cytoplasmic bodies or lamellar arrays surrounded by a single limiting membrane. In Wolman's disease, both intracytoplasmic and intranuclear lymphocytic vacuoles may occur. Other types of circulating monocytes, in addition to lymphocytes, may also form vacuoles. This change occurs, for example, in sialidosis, galactosialidosis, and mucolipidosis II. Excessive granulation of circulating neutrophils helps distinguish several of the storage diseases. In the mucopolysaccharidoses and mucosulfatidosis, metachromatic granules known as Alder-Reilly bodies are present (see Fig. 24-1B).[38] Azurophilic hypergranulation of neutrophils is a characteristic feature in many

TABLE 24-3   Laboratory Findings in the Storage Diseases: Presence of Inclusions in Readily Accessible Tissues

| Disease | PERIPHERAL BLOOD | | BONE MARROW | LIVER | | SKIN | |
	Vacuolated Lymphocytes	Granulated Neutrophils*	Foam Cells	Kupffer Cells	Hepatocytes	Biopsy	Culture
Gaucher's			Gaucher cell	Gaucher cell	Gaucher cell		+

patients with the neuronal ceroid lipofuscinoses. Ultrastructural studies of buffy coat preparations from the peripheral blood of these patients can be used to detect the abnormal intracytoplasmic inclusions typical of these diseases.[39,40]

Bone Marrow. The foam cell, a lipid-laden macrophage often called a histiocyte, provides perhaps the most dramatic and convincing histologic evidence of a storage disease. It may be easily recognized in unstained preparations of bone marrow aspirate as a round or oval cell measuring 20 to 90 μm in diameter. It generally has a single eccentric nucleus with a prominent nucleolus. Under darkfield microscopy, these cells appear as large, white spheres on a dark background (see Fig. 24-1E). They may be distinguished on phase-contrast micros-

copy as large, glittering cells with numerous cytoplasmic droplets or particles. These droplets are fairly uniform in size and, when viewed under polarization microscopy, are often birefringent (see Fig. 24-1F). They impart a mulberry- or honeycomb-like appearance to the cell and have a finely reticulated cytoplasmic web that is better seen in stained preparations (see Fig. 24-1G). Under the electron microscope, the droplets appear as polymorphic lipid vacuoles ranging from less than 1 μm to greater than 5 μm in diameter and consisting of both concentrically laminated myelin-like membranous arrays and dense homogeneous residual bodies.

The staining properties of foam cells in each of the storage diseases may differ. They often stain red with oil red O and black with Sudan black B, thus indicating that sudanophilic material is present. The PAS reaction may be weakly positive. The presence of lipofuscin is indicated by the appearance of autofluorescence under ultraviolet light. These histochemical reactions may be lost if alcohol or other lipid solvents are used to fix the bone marrow smears or tissue sections before staining. Therefore, for examining the staining properties of biopsy specimens from patients with storage diseases, formalin-fixed frozen sections are preferable to alcohol-treated paraffin-embedded material.

Occasionally, sea-blue histiocytes[41] are noted in the bone marrow preparations of patients with Niemann-Pick disease[42] and other systemic lipidoses.[43] These large cells measure up to 60 μm in diameter and contain several large, homogeneous granules that display a blue or blue-green color with Giemsa or Wright stains. Their major chemical constituent was believed to be ceroid, but increased levels of phospholipids and glycolipids are likely to occur. The Gaucher cell is sometimes mistakenly identified as a foam cell. It is also a large histiocyte that measures 20 to 100 μm in diameter, but instead of lipid droplets, its cytoplasm contains striated rod-shaped inclusion bodies that give it a wrinkled tissue paper or crumpled silk appearance (see Fig. 24-1H). The Gaucher cell stains pale pink with hematoxylin-eosin and stains only slightly with oil red O and Sudan black B. The inclusions are autofluorescent and PAS positive.

Electron microscopic studies indicate that these deposits consist of hollow tubules contained within a limiting membrane. Analysis of purified preparations of these deposits by freeze-fracture and x-ray diffraction techniques suggests that they exist as a series of gradually twisting membranous bilayers 3 to 6 nm thick.[44] They are composed of glucocerebroside (66%), phospholipid (17%), cholesterol (6%), and protein and glycoprotein (11%).[45] Strong acid phosphatase activity[46] and iron deposition[47] have also been demonstrated in Gaucher cells with the use of histochemical staining methods. Unlike the foam cell, which is found in many lipid storage diseases, the Gaucher cell is unique to the Gaucher form of inherited lipidosis. However, it cannot be regarded as being entirely specific for Gaucher's disease because it has also been observed in the bone marrow of some patients with certain blood disorders, including chronic myelogenous leukemia[48] and thalassemia[49] and in one patient who had both Gaucher's disease and coexistent Philadelphia chromosome–positive chronic granulocytic leukemia.[50] Presumably, Gaucher cells can form when the breakdown of blood cells exceeds the capacity of macrophages to metabolize the effete lipids.

Careful examination of the bone marrow smear is therefore an essential part of the diagnosis of a storage disease. In addition to the foam cell, sea-blue histiocyte, and Gaucher cell, other abnormal structures can be detected in the bone marrow, such as the Alder-Reilly bodies characteristic of Hurler's disease and multiple sulfatase deficiency and the vacuolated plasma cells associated with mucolipidoses III and IV.

Liver. In many storage diseases, an enlarged liver provides a tempting target for diagnostic biopsy despite the fact that many of the cellular changes occurring in the liver are similar to those present in the bone marrow. A liver biopsy has the added advantage of allowing access to a solid tissue for biochemical analysis. Needle biopsy can yield 10 to 25 mg of fresh tissue that could be divided equally between the biochemistry and pathology laboratories. The specimen for biochemical studies must be preserved frozen in a sealed container, preferably one flushed with nitrogen gas before sealing to displace oxygen and prevent oxidation and dehydration during storage. One segment of the tissue destined for the pathology laboratory is immediately immersed in buffered glutaraldehyde for electron microscopic studies. The remainder is fixed in formalin and further subdivided into two specimens. Half of the specimen is routinely processed and embedded in paraffin. The other half of the formalin-fixed material is used to prepare frozen sections, with care taken to avoid exposure to alcohol or other lipid solvents.

Liver involvement may be reflected in changes in tissue macrophages (Kupffer cells), hepatocytes, and endothelial cells. Kupffer cells are enlarged and contain membrane-limited vacuoles of various size. Electron microscopic studies of their ultrastructure demonstrate cytoplasmic bodies ranging from membranous and granuloreticular lamellar structures to more polymorphous and homogeneous dense bodies. Vacuolated histiocytes may infiltrate the sinuses, where they appear as discrete islands of light-staining cells in routinely stained sections. Hepatic parenchymal cell involvement is variable. A mild vacuolar change may be noticed, or more extensive infiltration can occur in these cells, as indicated by obvious enlargement and foamy metamorphosis. On electron microscopic examination, dense bodies and osmophilic bodies are present. Vascular endothelial cells in the liver may also contain inclusions, and in some specimens the lobular architecture of the liver itself is disturbed. The typical appearance of the Gaucher cell in liver specimens from patients with Gaucher's disease and the presence of both intralysosomal and cytoplasmic glycogen in Pompe's

disease distinguish these conditions from other forms of storage disease. In all other instances, the histologic changes in the liver are not distinctive enough to permit the diagnosis of a specific storage disease.

Skin. Many different types of cells are present in skin, including epithelial cells, hair follicles, fibroblasts, eccrine sweat glands, smooth muscle cells, sebaceous glands, vascular cells, and nerve bundles, thus making skin biopsy an extremely useful technique for the histologic diagnosis of storage diseases.[51] Vacuoles may be found in the secretory coils of eccrine sweat glands, the bulbs of hair follicles, fibroblasts, and Schwann cells in a number of diseases. Biopsy specimens from patients with the ganglioside storage diseases contain complex osmophilic lipid deposits in axons, Schwann cells, and nerve fascicles, whereas similar deposits in both neural and extraneural dermal elements characterize mucolipidosis IV. Study of skin ultrastructure is particularly helpful for diagnosis of the neuronal ceroid lipofuscinoses because the same distinctive pattern of inclusions present in the nervous system may be evident in skin[34,51-54] and enzymatic diagnosis of all forms of these diseases is not yet possible.

Cultured skin fibroblasts are less informative, but ultrastructural changes have also been noted in these cells.[55] The membrane-bound, electron-dense inclusions of mucolipidosis II[56] and IV[57] and the curvilinear profiles of neuronal ceroid lipofuscinoses[58] are examples of this phenomenon. However, not all storage diseases produce histologic changes in the skin; for example, none has been found in Gaucher's disease.[34] Nevertheless, as electron microscopists have become more proficient in examining this type of tissue and cell culture and specialists and biochemists have recognized the usefulness of cultured skin fibroblasts for metabolic studies, the popularity of diagnostic skin biopsy has increased. Other extracerebral tissues, including conjunctiva, skeletal muscle, and rectal tissue, may also provide useful samples for biopsy.[51]

Biochemical and Molecular Studies

Storage Substances. The results of morphologic studies suggest the presumptive diagnosis of a storage disease, but biochemical studies are required for a specific diagnosis (Table 24-4). For the majority of the storage diseases, structural identification of the major substances that accumulate preceded elucidation of the enzyme defects. Characterization of these compounds is generally more difficult than assaying the relevant enzyme, so for diagnostic purposes, determination of enzyme activity is preferred. However, a number of laboratory techniques have been developed that facilitate screening for storage products in readily available tissue and fluid specimens.

The urine of patients with sphingolipidoses, mucopolysaccharidoses, mucolipidoses, and other oligosaccharidoses is a rich source of storage material.[59] The sphingolipids present in a filtered 24-hour urine specimen can be extracted from the filter paper, separated from other lipids on a silicic acid column, and quantitated by a combination of thin-layer and gas-liquid chromatography.[60] An excess of mucopolysaccharides is recognized in urine by positive results on the Berry spot test,[61] and these substances can be isolated by precipitation with quaternary ammonium salts and fractionated into separated species by electrophoresis.[62] Complexing of urinary mucopolysaccharides with 1,9-dimethylmethylene blue simplifies their quantification.[63] Simple thin-layer chromatographic methods using microliter quantities of whole desalted urine have been described as a means of separating the oligosaccharides excreted in fucosidosis,[59,64] mannosidosis,[65] G_{M1}-gangliosidosis,[64] and the sialidoses[66,67] into patterns distinctive for each disease. The presence of aspartylglucosamine on a urinary amino acid chromatogram aids in the diagnosis of aspartylglucosaminuria. More recently, new detection methods have been applied to the diagnosis of LSDs, including a filter paper method for mass and high-risk urinary screening for Fabry's disease[68] and mass spectrometry.[69]

Sphingoglycolipids present in plasma can be quantitated by high-performance liquid chromatography.[70,71] The procedure requires less than 1 mL of plasma and permits detection of elevated ceramide, cerebroside, and globoside levels in Farber's disease,[70] Gaucher's disease,[71] and the Sandhoff variant of G_{M2}-gangliosidosis, respectively. The high-performance liquid chromatographic technique has also been used to demonstrate elevated sphingomyelin levels in cultured skin fibroblasts from patients with Niemann-Pick disease type A.[72]

In other storage diseases as well, cultured skin fibroblasts provide an opportunity for biochemical analysis of storage material. The kinetics of $^{35}SO_4$ accumulation has been used as an indicator of defective degradation of polysaccharides in the mucopolysaccharidoses[73] and mucolipidoses.[74,75] In Gaucher disease cells, metabolic utilization of radioactively labeled glucocerebroside is reduced,[76] and in vivo studies of Farber disease cells reveal a defect in their ability to metabolize the ceramide portion of a fatty acid–labeled precursor.[77] Fucosidosis fibroblasts store abnormal quantities of tritiated fucose,[78] and Wolman disease cell lines incorporate increased amounts of ^{14}C-mevalonate into cholesterol.[79] In certain instances, solid tissues may need to be analyzed. This step is required when a strong clinical presumption of storage disease exists, but studies of body fluids and more readily accessible tissues such as leukocytes and cultured fibroblasts disclose neither the nature of the stored substance nor the presence of a deficient enzyme. Biopsy of cerebral tissue is no longer warranted except in very rare instances of neurodegenerative disease without extraneural morphologic or biochemical stigmata.

Deficient Enzyme Activity. Specific enzyme defects have been established for all the LSDs, and in the majority of cases, enzymatic assays are an especially convincing means for confirming the diagnosis. These assays can be

TABLE 24-4 Laboratory Findings in the Storage Diseases: Biochemistry

Disease	Stored Material	Enzyme Deficiency	SUBSTRATES USED IN ENZYME ASSAYS	
			Natural	Artificial
SPHINGOLIPIDOSES				
Gaucher's	Glucocerebroside	Glucocerebrosidase	Glucocerebroside	4-MU-β-glucoside
Niemann-Pick	Sphingomyelin	Sphingomyelinase	Sphingomyelin	2-*N*-Hexodecanoyl-amino-4-nitrophenyl-phosphorylcholine monohydrate
Farber's	Ceramide	Ceramidase	Ceramide	
G_{M1}-gangliosidosis	G_{M1}-ganglioside, glycoprotein	G_{M1}-ganglioside, β-galactosidase	G_{M1}-ganglioside, asialo-G_{M2}-ganglioside, globoside	pNP-β-galactoside, 4-MU-β-galactoside
G_{M2}-gangliosidosis, Sandhoff variant	G_{M2}-ganglioside, globoside	Hexosaminidase A + B		pNP-β-*N*-acetylglucosamine, 4-MU-β-*N*-acetylglucosamine
MUCOPOLYSACCHARIDOSES				
Hurler's and Scheie's	Dermatan sulfate, heparan sulfate	α-Iduronidase		4-MU-α-L-iduronide
Hunter's	Dermatan sulfate, heparan sulfate	Iduronate sulfatase	^{35}S-heparin	Disulfated ^{3}H-disaccharide
Sanfilippo's				
Type A	Heparan sulfate	Heparan-*N*-sulfatase	Unacetylated trisaccharide isolated from heparin	4-MU-α-D-*N*-sulfoglucosamide
Type B	Heparan sulfate	*N*-Acetyl-α-glucosaminidase	[u-^{14}C]Glucosamine + acetyl CoA	pNP-α-*N*-acetylglucosaminide, 4-MU-α-*N*-acetylglucosaminide
Type C	Heparan sulfate	Acetyl CoA:α-glucosaminide acetyltransferase		4-MU-β-D- glucosaminide + acetyl CoA
Type D	Heparan sulfate	*N*-Acetyl-α-glucosamine-6-sulfatase	*N*-Acetylglucosamine 6-sulfate	4-MU-α-*N*-acetylglucosamine 6-sulfate
Morquio's syndrome				
Type A	Keratan sulfate	Galactosamine 6-sulfatase	Disulfated ^{3}H-trisaccharide	
Type B	Keratan sulfate	β-Galactosidase		4-MU-β-galactoside

TABLE 24-4   Laboratory Findings in the Storage Diseases: Biochemistry—cont'd

| Disease | Stored Material | Enzyme Deficiency | SUBSTRATES USED IN ENZYME ASSAYS | |
			Natural	Artificial
Maroteaux-Lamy syndrome	Dermatan sulfate	Galactosamine-4-sulfatase (arylsulfatase B)	Chondroitin 4-sulfate	*p*-Nitrocatechol sulfate, 4-MU-sulfate
β-Glucuronidase deficiency	Dermatan sulfate, heparan sulfate	β-Glucuronidase		pNP-glucuronide, 4-MU-glucuronide
Mucosulfatidosis	Sulfatides, mucopolysaccharides	Arysulfatase A, B, and C; other sulfatases	Disulfated disaccharide, heparan, sulfatide	*p*-Nitrocatechol sulfate, 4-MU-sulfate
MUCOLIPIDOSES/GLYCOPROTEINOSES				
Sialidosis (mucolipidosis I)	Sialyloligosaccharides, glycopeptides	NEU1		4-MU-α-D-*N*-acetylneuraminide
Galactosialidosis	Sialyloligosaccharides, glycopeptides	PPCA	Bioactive peptides	
Mucolipidosis II	Sialyloligosaccharides, glycoproteins, glycolipids	High serum, low fibroblast enzymes; *N*-acetylglucosamine-1-phosphate transferase		4-MU-glycosides, UDP-*N*-acetylglucosamine, α-methylmannoside
Mucolipidosis III	Glycoproteins, glycolipids	Same as above		
Mucolipidosis IV	Glycolipids, glycoproteins	Mucolipin I		Same as above
OTHER DISEASES OF COMPLEX CARBOHYDRATE METABOLISM				
Sialic acid storage disease	Free sialic acid	Sialin		
Fucosidosis	Fucoglycolipids, fucosyloligosaccharides	α-Fucosidase		pNP-α-L-fucoside, 4-MU-α-fucoside
Mannosidosis	Mannosyloligosaccharides	α-Mannosidase		pNP-α-mannoside, 4-MU-α-mannoside
Aspartylglucosaminuria	Aspartylglucosamine	Aspartylglucosamine amidase		1-Aspartamido-β-*N*-acetylglucosamine
Wolman's	Cholesteryl esters, triglycerides	Acid lipase	Glyceryl tripalmitate	pNP-palmitate, 4-MU-oleate
Neuronal ceroid lipofuscinoses	Ceroid lipofuscin pigments	CLN-1: palmitoyl-protein thioesterase CLN-2 to CLN-5: unknown		

CoA, coenzyme A; 4-MU, 4-methylumbelliferyll; pNP, nitrophenol.

performed in vitro on readily accessible patient material such as serum, plasma, leukocytes, lymphocytes, cultured skin fibroblasts, and tears.

As mentioned earlier, artificial substrates can substitute for natural substrates for measuring enzyme activity. The chromogenic *p*-nitrophenyl and fluorogenic 4-methylumbelliferyl derivatives are commonly used for this purpose because they are more easily cleaved in vitro than the natural substrates are and the aglycone product of their hydrolysis can readily be quantitated by colorimetry or fluorometry. When natural substrates are used, they generally carry a radioactive label. Assays with these compounds are processed by separating the reaction products and quantitating the labeled component in a liquid scintillation spectrometer. Reviews are available that describe the methodology used in assaying most of the enzymes shown in Table 24-4.[80,81] These techniques are usually beyond the scope of a routine clinical chemistry laboratory and are most competently performed in a research laboratory setting, preferably one devoted to lysosomal enzymology. It is fortunate that most lysosomal enzymes are quite stable on freezing (α-neuraminidase is an exception); so if necessary, enzyme preparations can be shipped to distant localities for assay.

A leukocyte pellet sufficient for multiple assays can be isolated from 10 mL of fresh, whole heparinized blood by the dextran sedimentation procedure.[82] A repeat sedimentation step can double the yield of leukocytes, an especially valuable consideration when the amount of blood is limited because of the size, age, or medical condition of the patient (usually a child). If molecular DNA analyses are to be performed, ethylenediaminetetraacetic acid is the preferred anticoagulant because heparin can inhibit the polymerase chain reaction (PCR) assay. Specimens of blood should also be obtained from the child's parents to be used for confirmation of any enzyme defect discovered in the child's blood. When tested for activity of the relevant enzyme, the parents' specimens should demonstrate intermediate levels of enzyme activity, indicative of their heterozygous status.

Molecular Analysis. Detection of heterozygotes in X-linked conditions, such as Hunter's disease, by enzyme assay is more difficult because of the overlap with normal values that can occur as a result of mosaicism in expression of the X chromosome in females,[83] and therefore DNA techniques[84] have proved to be more reliable for detection of carriers in this disease.[85,86] For each lysosomal enzyme gene that has been cloned, a multiplicity of mutant alleles have been discovered. Although a number of these mutations may be common in patients with the same LSDs, many are sporadic and specific to individual families. Therefore, it is not practical to use mutation analysis only as a marker for a particular disease or to screen for carriers of the gene for this disease.

However, within a research laboratory setting, genomic DNA or total mRNA can be isolated from peripheral lymphocytes or cultured fibroblasts and processed further for nucleotide base sequencing. For genomic DNA, single-strand conformational polymorphism is used to locate fragments with an anomalous migration pattern on a gel, possibly indicative of an abnormal sequence. With the use of primers specific to this fragment, it can be amplified by PCR and sequenced to find the error. Alternatively, PCR of sequences encompassing the exon/intron boundaries may help identify splicing variants. Such molecular analysis is especially useful when the clinical phenotype is severe and residual enzyme activity is very low or absent and thus suggests the possibility of no transcription to mRNA.

In later-onset forms of disease with a less severe phenotype, mRNA may be detectable. It can be reverse-transcribed to complementary DNA (cDNA) and the specific disease-related cDNA amplified by PCR and cloned so that its nucleotide base sequence can be determined. This method is likely to reveal point mutations causing primarily amino acid substitutions but may also reveal splicing errors, as well as small insertions and duplications. To distinguish polymorphic changes from true disease-causing mutations, transient enzyme expression studies can be done with a culture system such as the COS cell, a strain of monkey cells. For more accurate detection of mutant enzymes that have only low residual enzyme activity, transient expression studies should be performed on patient fibroblasts that have no endogenous enzyme activity.[87] Only alterations resulting in partial or complete loss of enzyme activity can be relied on as markers for the carrier state in relatives of an affected patient and for prenatal diagnosis.

In families in which specific molecular defects in DNA have been detected, enzyme analysis can be supplemented by mutation analysis. This approach is not only useful for carrier testing and prenatal diagnosis but can also be extended to retrospective diagnosis for an affected family member who died without a specific biochemical diagnosis. This option is available through PCR amplification of genomic DNA extracted from paraffin-embedded biopsy or autopsy material originally prepared for histologic study.

Animal Models

Although the common macroscopic evidence of LSD in tissues is the presence of vacuolated cells, the cellular and molecular consequences of the intralysosomal accumulation of various metabolites are still largely unknown. Given the complexity of these disorders, this information will prove crucial for addressing the feasibility and limitations of therapy for neurodegenerative LSDs, analysis of which is often impossible in affected children. Studies are currently beginning to emerge that will help relate storage of potentially toxic metabolites to cell dysfunction and cell death.[88,89] Many LSDs have now been genetically engineered in small laboratory animals or have been diagnosed in spontaneously occurring animal models. In most instances, these models closely recapitulate the corresponding human diseases and are therefore important

tools for studies of disease pathogenesis and treatment of these disorders.[90,91]

Treatment

Symptomatic Treatment

After the diagnosis of a storage disease is made, the physician often believes that the family must be given a prognosis. Because none of the storage diseases can be cured and their progressive course cannot usually be halted, a bleak outlook is presented and the distraught family leaves without a clear understanding of how to manage their child's illness. Actually, the clinical state is quite stable in a number of the storage diseases (e.g., adult Gaucher's disease; type B Niemann-Pick disease, α-mannosidosis, aspartylglucosaminuria, and the cherry-red spot/myoclonus variant of sialidosis). Moreover, the same storage disease does not follow the same timetable of clinical signs in any two patients. Instead of prognostication, attention should be focused on alleviating or ameliorating existing signs and symptoms.

Feeding problems may arise because of bulbar paralysis, and hence changes in the consistency of the child's food and in feeding techniques might be required. Consultation with a nutritionist may be needed to ensure that the child continues to receive adequate fluid and caloric intake. Chronic constipation must be managed, the skin surface must be protected from ulcerations, and dental hygiene must be maintained to prevent caries. Seizures occurring in the course of gray matter storage disease of the brain generally respond to combinations of certain drugs, including diazepam (Valium), carbamazepine (Tegretol), valproic acid (Depakene), clonazepam (Klonopin), and lamotrigine (Lamictal). To prevent joint contractures, a regular program of physical therapy should be established. Orthopedic corrective procedures, otorhinolaryngologic surgery, and other types of operative intervention should not be withheld if they will make nursing care easier or bring relief to a child who has a clinically vexing problem.

The child's education is also important. Infant stimulation programs in daycare centers and special nursery school and kindergarten programs are available for handicapped children through the Easter Seals Society, United Cerebral Palsy, and similar organizations. By taking advantage of these resources, the family and child can feel that they are not missing out on opportunities for self-expression and achievement available to other children.

Enzyme Replacement Therapy

The lysosomal enzyme precursors secreted into the extracellular milieu are usually completely poised to be reinternalized by the same cell or neighboring cells via receptor-mediated endocytosis. Most cell types express the M6P receptor, which accommodates efficient uptake of mannose-6-phosphorylated lysosomal enzymes.[6]

However, Kupffer cells in the liver, microglia in the brain, and resident macrophages in other tissues express mannose receptors that allow uptake of mannosylated enzymes. Specific overexpression systems are currently used to achieve the desired modification of the overexpressed enzyme, such as CHO cells for M6P and yeast, plant, or insect cells for mannosylated enzymes.[92-95] Alternatively, the complex carbohydrates on CHO-expressed enzymes are enzymatically remodeled to the mannose core type to facilitate uptake by the mannose receptor.[96]

The unique capacity of most lysosomal enzyme to be released and recaptured by different cell types has formed the basis of ERT.[97] This therapeutic approach has been shown to be extraordinarily effective for patients with the non-neuropathic form of Gaucher's disease, the most prevalent metabolic storage disorder in humans and the first to be treated by this approach. Demonstration of the benefit of ERT in this disorder led eventually to extension of this therapeutic modality to the treatment of other LSDs.[98] The results of ERT in clinical trials of Pompe's disease,[99] Fabry's disease[100,101] and mucopolysaccharidosis I and VI (MPS I and VI),[102] as well as in numerous animal models,[102-105] have demonstrated that this procedure could be effective against some non-neuropathic LSDs. However, ERT alone is unlikely to ameliorate the more severe neuropathic forms of LSDs unless it is combined with other treatments.[106] The presence of the blood-brain barrier, which effectively prevents most soluble molecules from entering the CNS, hampers the applicability of this approach for the cure of neuropathic patients, so different therapies should be sought.

Substrate Reduction Therapy

Glycosphingolipids (GSLs) are components of the outer leaflet of plasma membranes in most eukaryotic cells. They are present in cell-specific patterns and are composed of a hydrophobic ceramide moiety that is linked to a hydrophilic glycan chain of variable length and structure. GSLs have been implicated in a variety of functions ranging from cellular differentiation to intracellular signaling. They are synthesized de novo, beginning with the rate-limiting step of ceramide formation by glycosyltransferase and the subsequent addition of glycan chains to this glycosylceramide core. Upon exerting their metabolic actions, they are eventually degraded in lysosomes via an endocytic process.[107]

Imino sugars such as *N*-butyldeoxygalactonojirimycin (NB-DGJ), one of the early GSL synthesis inhibitors to be studied, was initially investigated as an antiviral agent for patients with acquired immunodeficiency syndrome, but its use was abandoned when other antiviral agents became available.[108] However, further research into the biology of GSLs showed that inhibition of their synthesis may play a role in the treatment of some LSDs. The rationale behind this principle is that by reducing the amount of available substrate, a decrease in the degree of their deposition in affected cells should be expected.

It is also hypothesized that in certain LSD variants, the presence of residual enzymatic activity may be enough to control the signs and symptoms of disease if synthesis of GSLs is concomitantly decreased. This would therefore lead to a certain degree of "metabolic balance." One of the potential additional advantages of this approach is that these compounds cross the blood-brain barrier, in contrast to ERT, which is restricted to act outside the CNS and thus cannot aid in clearing lysosomal storage from neurons.

The first published suggestion for using this approach to treating the LSDs came from Radin.[109] Since then, several studies have been performed in vitro and in various animal models for these conditions and in at least one clinical trial.[110] In the latter, several patients with the non-neuronopathic variant of Gaucher's disease (type 1 β-glucocerebrosidase deficiency) were treated with *N*-butyldeoxynojirimycin (miglustat), a potent inhibitor of glucosylceramide synthase, which is a glucosyltransferase enzyme responsible for the first step in the synthesis of most GSLs; such treatment resulted in decreased visceral volumes and improved hematologic parameters after 1 year. Further studies in other animal models for LSDs, such as Fabry's disease[111] and G_{M2}-gangliosidosis,[112,113] have shown additional promising effects. Side effects often encountered include diarrhea, weight loss, a reversible peripheral neuropathy, and at least in mice, lymphoid organ acellularity.[114-117] In 2003, miglustat was approved by the Food and Drug Administration for the treatment of symptoms in Gaucher type 1 patients who were not treated with Cerezyme (see later). Miglustat is now commercially available as Zavesca (Actelion Pharmaceuticals) and may be administered in combination with Cerezyme. In addition, the therapeutic effects of miglustat in patients with type C Niemann-Pick disease have been evaluated in a clinical trial (see later). The therapeutic benefits were consistent with previous trials in type 1 Gaucher patients, and miglustat improved or stabilized multiple clinically relevant markers of Niemann-Pick disease type C.[118]

Chaperone-Mediated Enzyme Enhancement

Chaperone-mediated therapy is a new therapeutic approach that is being developed for the treatment of selected patients with LSDs.[117] This method is based on the use of small sugar nucleotides that function as pharmacologic chaperones by specifically binding to and stabilizing misfolded mutant proteins in the ER. Binding of the chaperone molecule to the nascent mutant enzyme helps it fold into its correct three-dimensional shape and to be transported out of the ER and routed to the lysosome. The end result is an increase in residual enzyme activity of the mutant protein, an increase that can be sufficient to clear storage products in lysosomes and to correct the disease phenotype. This therapeutic approach has proved beneficial for some of the disease-causing mutations in patients with Gaucher's disease.[119] Though very promising, the caveats of this strategy are that (1)

only patients with single point mutations and residual enzyme activity will be potentially responsive to treatment and (2) not all the amino acid substitutions on a given enzyme may be corrected by the chaperones.

Hematopoietic Stem Cell Transplantation

More than 25 years has passed since the first report of bone marrow transplantation (BMT) being used to treat an LSD, namely, Hurler's disease.[120] Subsequent studies have proved its efficacy for some, but not all of the LSDs (Table 24-5). However, many questions remain, including proper selection of candidates, expected final outcome, and the appropriate time to perform BMT. Furthermore, great advances have been made in understanding the cellular and biochemical mechanisms that underlie engraftment or rejection processes, yet the overall mortality rate associated with this procedure remains relatively high, between 5% and 15%, depending on the institution and type of underlying disease. Nevertheless, BMT is increasingly being used for a wider range of disorders, both genetic and acquired, and with fewer associated complications than before. Finally, ethical issues (including exposure of asymptomatic children to the morbidity associated with BMT) and the futile prolongation of a life without consciousness of existence are beginning to emerge, and it is likely that they will become more urgent with the use of stem cells in the near future.

Because autologous BMT is not yet a therapeutic option for patients with LSDs, allogeneic (either related or unrelated) donors are the usual source of hematopoietic progenitors for these patients.[133,148] Donors who were identical human leukocyte antigen (HLA) matches have been used, preferably not those who are heterozygous carriers for the condition, with good results; however, this situation is not a common one. Therefore, either distant relatives (partial HLA matches) or unrelated donors are still the most common sources of HSCs. This fact increases the likelihood of not only rejection but also graft-versus-host disease, a significant source of both morbidity and mortality in recipients of bone marrow transplants.

Besides BMT, umbilical cord blood from unrelated donors who are not HLA identical with the recipient has been applied to the treatment of pediatric LSDs and been shown to restore hematopoiesis after myeloablative therapy.[149] Although immunologic rejection can be avoided with this therapeutic approach, the amount of these cells that is commonly obtained is rate limiting, and therefore only infants are likely to benefit from this procedure.[150] Nonetheless, use of these immunologically privileged cells as an alternative to BMT has given promising results in eliminating graft-versus-host disease in the majority of treated patients.[149] Survival rates associated with this procedure can be expected to be at least similar to those seen when transplants from HLA-identical donors are used. Rates have been as high as 73% at 1 year after umbilical cord blood stem cell

TABLE 24-5	Bone Marrow Transplantation for Lysosomal Storage Diseases		
	CLINICAL RESPONSE		
Disease	**Effective***	**Not Effective**	**References**
Aspartylglucosaminuria		+	121, 122

transplantation.[149,150] However, it is not yet clear to what extent stem cells from umbilical cord blood can provide an adequate source of enzyme to correct the respective deficiency in the long term because many of these precursor cells may not be fully differentiated and able to degrade excess intracellular macromolecules.

Although data on the actual percentage of successful engraftment are quite encouraging, with values of up to 90% attained in patients with adrenoleukodystrophy (for both related and unrelated donors as a whole),* there is no evidence that enzymes circulating in blood can reach the brain parenchyma. Instead, the efficacy of this procedure is due to the entry of marrow-derived cells that can cross the blood-brain barrier. In several of the inherited leukodystrophies, neurologic progression has been halted by BMT,[133] possibly through the appearance of a new population of macrophage-derived microglia and perhaps even astrocytes.[151,152] In animal models, BMT has been particularly successful in improving or delaying the advent of CNS disease.[91,153] However, patients with diseases in which neuronal storage occurs (such as G_{M1}-gangliosidosis, Pompe's disease, acute neuronopathic Gaucher's disease, and Niemann-Pick disease type A) have not benefitted from BMT.

In summary, HSC transplantation is most likely to succeed when an HLA-identical donor is available, when the disease to be treated is not associated with gross nerve cell storage, and when the disease is treated before severe structural damage has occurred.[129,154] It seems very likely that with recent advances in understanding the molecular biology of the immune mechanisms underlying donor cell rejection and other associated complications, use of this procedure will become an acceptable means of treating patients with LSDs for which no additional therapy is yet available. Finally, the possibility of using minimal myeloablation in small infants to obtain initial engraftment with less associated morbidity is slowly becoming an additional option. However, it is important to keep in mind that response to HSC transplantation may also be influenced by the following variables that could have a different impact on the therapeutic outcome in different LSDs: (1) the type and number of engrafted donor cells; (2) the biochemical and physical properties of the secreted, correcting enzyme; (3) the efficiency of secretion and extracellular stability of the correcting enzyme; (4) the extent of uptake by target cells; and (5) the characteristics of the affected cells, as well as the level of cell degeneration.

Gene Therapy

Ex Vivo. Somatic gene therapy could be the treatment of choice for LSDs if the patient's own cells could

---

*Peters C: Personal communication.

be genetically modified in vitro or in vivo to constitutively express and secrete the correcting enzyme and thus become the source of the correcting enzyme in the patient. Both ex vivo and in vivo gene transfer methods have been tested for somatic gene therapy for LSDs. Delivery systems include gated vectors containing partial sequences from retroviruses, adenoviruses, adeno-associated viruses (AAVs), herpes simplex viruses, lentiviruses, and others, as well as nonviral systems. Although these methods have proved efficient for the transfer of genetic material into deficient cells in culture and for correction of the deficient enzyme activity,[155-150] the same gene transfer systems applied to humans or animal models have shown inconsistent results, the bases for which are not yet fully understood.

Retroviral vectors have thus far been the most exploited gene transfer vehicles[160] for the treatment of LSDs because they have the advantage of stably integrating at random sites into the host genome, thereby potentially affording long-term expression. However, their use is limited by the fact that they target only dividing cells, they are difficult to produce at high titer for in vivo application, and depending on their integration site, they can permanently alter the expression of neighboring genes. Nevertheless, numerous studies describing the use of retroviral-mediated gene therapy in animal models of LSDs are reported in the literature.[161-166]

The overall outcome of these studies points to the potential of retroviral-mediated gene transfer to HSCs for improving systemic disease in small laboratory animals, but again, use of this procedure for the treatment of CNS pathology has yielded inconsistent results in different animal models. Once more, the time of treatment seems to be the rate-limiting step in these therapeutic procedures, especially if we attempt to prevent or delay progression or even reverse CNS pathology. Despite the limitations encountered so far, ex vivo studies in animal models have helped set the stage for trials of human stem cell gene therapy in patients with Gaucher's disease.[167-169] HSCs from patients' peripheral blood or bone marrow were transduced with a retrovirus expressing human glucocerebrosidase cDNA and infused into nonablated recipients. Although transduction efficiency was low, gene-marked cells persisted for about 3 months, but the number of corrected cells was too low to afford any increase in enzyme activity and therapeutic benefit. To circumvent the problems of low transduction efficiency and expression, alternative gene therapy approaches are being developed that make use of vectors based on lentiviruses, including human immunodeficiency virus type 1 (HIV-1).[170] These vectors have a broader host range than retroviral vectors do because they transduce both dividing and nondividing cells and have been shown to effectively target human CD34+ cells.[171] In addition, treatment of the CNS pathology in LSDs remains a challenging issue that is specifically being addressed in many of the gene transfer studies currently pursued.

In Vivo. In vivo gene therapy refers to the injection of a gene transfer vector directly into a tissue or into the circulation. There are a number of preclinical studies in small and large animal models of LSD in which this procedure has been tested, with variable outcome. Although these have been useful, proof-of-principle experiments, expression of the gene of interest was often transient because of the severe immune reactions directed against the vector.[172]

Intravenous delivery of AAV-based vectors has resulted in biochemical, histologic, and clinical improvement in several murine models of LSD. Robust expression plus a reduction in lysosomal storage was observed in many tissues after AAV injection in young adult animals with MPS VII or Fabry's disease.[173,174] Even more convincing results, such as improved bone or skeletal development, retinal function, and auditory function, were observed in MPS VII and MPS I mice injected during the neonatal period.[175-177] Studies in neonates demonstrate the utility of early (disease prevention) rather than delayed (disease reversal) intervention for these progressive disorders. Lentiviral gene transfer vectors have also been tested for direct in vivo gene therapy applications. Intravenous injections of either a feline immunodeficiency viral vector in the MPS VII mouse or an HIV-based vector in MPS I and MPS IIIB mice resulted in persistent high-level expression of the respective enzymes and reduction of lysosomal storage in multiple tissues.[178-180]

Partial biochemical and histologic correction has been achieved in the mouse model of Fabry's disease after either hydrodynamic delivery of naked plasmid DNA or plasmid DNA complexed to cationic lipids.[181] Although these approaches reduce some of the concerns surrounding the use of viral vectors, expression is transient and repeated administration will be required.

Regardless of the delivery system, some diseases may be more resilient to treatment than others. In such instances, we might approach therapy from the standpoint of the accumulated products rather the enzyme deficiency. As discussed earlier, inhibition of substrate synthesis, as opposed to supplementation of the missing enzyme, has already been investigated for the treatment of glycolipid storage diseases with promising results.[110,115] Combining substrate inhibitors and BMT was found to be synergistic in correcting pathologic signs in the Sandhoff mouse model.[182] Last but not least, early treatment may be the only approach for early-onset patients, who are often devoid of residual enzyme. Ultimately, a combination of different therapies may be the method of choice for neurologic LSDs that require both systemic and CNS correction. Behind the relatively simple concept of cross-correction that makes LSDs particularly amenable models for gene therapy trials lies the complexity and diversity of these diseases, which must be addressed and carefully evaluated because they are likely to influence the response to treatment. It is clear that many limitations and pitfalls still need to be overcome to make

the transition of gene therapy from animal models to the clinic an educated and judicious approach.

Prevention

In most instances, the amount of lysosomal enzyme activity correlates with the level of the wild-type gene present. For example, enzyme levels in carriers of an abnormal allele (heterozygotes) are approximately half those in normal individuals. Thus, heterozygotes for specific recessive disease traits can in principle be identified by enzyme assay, provided that there is no overlap between enzyme levels in heterozygotes and those in normal or diseased individuals. In actual practice, this is rarely, if ever achieved.

Detection of heterozygotes by enzyme assay serves several functions. The finding of heterozygosity in the parents of an individual with a storage disease helps confirm the diagnosis in that individual. This method of testing is particularly valuable when the propositus has died without enzymatic confirmation of a diagnosis. Siblings, cousins, and other close relatives of a patient with a storage disease can be told specifically whether there is a chance that they can pass the abnormal gene to their offspring. Relatives who have the abnormal gene and who are married will probably also want their spouses tested to assess their joint risk of having an affected child.

In families in which specific molecular defects in genomic DNA have been detected, enzyme analysis can be complemented by mutation analysis. This approach not only is useful for carrier testing and prenatal diagnosis but can also be extended to retrospective diagnosis for an affected family member who has died without a specific biochemical diagnosis. This option is available through PCR amplification of genomic DNA extracted from paraffin-embedded biopsy or autopsy material originally prepared for histologic study.

In the rare instances in which both spouses are heterozygotes, the risk with each pregnancy of producing an affected offspring is 25%. In these circumstances, chorionic villus biopsy performed at about the 8th to 9th week or amniocentesis at the 14th to 16th week of gestation permits biochemical determinations to be made on cells of fetal origin. In this way, a prenatal diagnosis can be made early enough so that a pregnancy can be terminated if the fetus is affected. Families previously affected by the tragedy of an infant with a fatal form of a storage disease may thus be spared the burden of additional progeny having the same disease and can anticipate having healthy children without fear. Happily, the outcome for the majority (75%) of prenatal diagnoses in these high-risk families is a clinically unaffected child. This reduces the incidence of abortion in families who are determined to avoid having an affected child because without this assurance, such families may otherwise elect to terminate all pregnancies.

Prenatal diagnosis has been accomplished or is theoretically possible for each of the storage diseases.[183] An abnormality often reported in these conditions is the presence of hydrops fetalis or unexplained fetal death. In these instances, examination of tissue morphology should be performed carefully.[184] Parents of a child with a sphingolipidosis, mucopolysaccharidosis, or oligosaccharidosis are advised to consult a genetic counselor as soon as possible after the diagnosis is made in their child to be judiciously informed about the availability of prenatal diagnosis for future pregnancies. Otherwise, one or both parents may choose to undergo a sterilization procedure in the mistaken belief that all their subsequent offspring will be similarly affected. In addition, the mother might already be pregnant or might become pregnant and be unaware of the prenatal diagnostic option until after the optimal time for conducting such studies has passed. Frequently, one of the factors motivating parents to obtain a specific diagnosis in their young child with a storage disease is a current pregnancy. This circumstance may place a severe time constraint on the laboratory by requiring diagnosis of the affected child before the pregnancy passes the midtrimester point, after which prenatal diagnostic amniocentesis is no longer practical.

Screening of large populations for heterozygotes has been accomplished most successfully for Tay-Sachs disease. The circumstances that have made this practicable are a high incidence of the gene in a small subgroup of the population (Ashkenazic Jews) and the availability of a simple, dependable, and economical test for heterozygotes. These conditions have not been met for massive screening of other storage diseases, either because the disease trait is very rare and distributed equally throughout the general population or because the enzyme assay for heterozygotes is complicated and cannot be automated or in some other way performed inexpensively. In addition, without knowledge of an index case in the family, interpretation of enzyme tests for heterozygotes may be difficult because carriers of two diseases with a different clinical prognosis, such as Hurler's disease and Scheie's disease, may be indistinguishable. Molecular probes should help clarify the exact genotype in such circumstances. Finally, because trace amounts of fetal DNA can be detected in the maternal circulation,[185] it is entirely possible that affected pregnancies will be identified at early stages of gestation and could then be analyzed for known or suspected mutations.

Preimplantation genetic diagnosis represents an alternative to prenatal diagnosis in couples in whom in vitro fertilization is an acceptable option. It involves the molecular analysis of embryonic cells that are removed at very early stages of development, usually polar bodies from the oocyte/zygote state or blastomeres.[186,187] After a diagnosis is made, the healthy embryos are then implanted, thereby avoiding the ethical and medical dilemmas that are commonly associated with termination of pregnancy.[188] However, at present, prevention of the storage diseases relies on the concepts of early case identification, screening of close relatives for heterozygosity, and prena-

tal diagnosis during pregnancies in which both spouses carry the same recessive trait.

GLYCOSPHINGOLIPIDOSES

The glycosphingolipidoses account for 10 categories of storage disease, each characterized by the accumulation of a particular sphingolipid in either neural or extraneural tissues, or both. The basic unit of the stored material, ceramide, is composed of the long-chain amino alcohol sphingosine joined to a fatty acid of 16 to 26 carbon atoms by an amide linkage at the nitrogen atom on carbon 2 of sphingosine (Fig. 24-2).

Individual sphingolipids belong to one of four subgroups, depending on the types of substituents joined to the primary alcohol on carbon 1 of sphingosine (i.e., sphingomyelin, neutral GSLs, sulfatoglycosphingolipids, and gangliosides). Sphingomyelin is a phospholipid component of cell membranes. The neutral GSLs are found in many body tissues, with normally high concentrations of globoside in red blood cell membranes and ceramide trihexoside in the kidney. The sulfolipids and galactolipids are important in the formation of myelin. Gangliosides are abundant in the nervous system.

Catabolism of the sphingolipids occurs by the stepwise hydrolysis of linkages joining the various components of the molecule. The sequence of cleavage is from the terminal nonreducing hydrophilic end of the molecule toward the hydrophobic sphingosine portion. The structure of the individual sphingolipids, their degradative pathway, and the reactions blocked in each of the sphingolipidoses are shown in Figure 24-3.

Not all the glycosphingolipidoses cause lipid storage in cells of the reticuloendothelial system. The pathologic findings in metachromatic leukodystrophy and Krabbe's disease are confined to the nervous system and consist of severe myelin destruction and a segmental peripheral neuropathy. Clinically, blindness, long-tract signs, and loss of reflexes occur. Elevated spinal fluid protein concentrations and delayed nerve conduction velocities are early diagnostic findings.

Tay-Sachs disease, the most common form of G_{M2}-gangliosidosis, results in ballooning of nerve cells throughout the neuraxis. Psychomotor retardation and a cherry-red spot in the macula are early signs. Eventually, seizures, megacephaly, blindness, and flaccid quadripare-

sis develop before the affected child dies, usually between 3 and 5 years of age. Before heterozygote testing for the Tay-Sachs trait became widely available, the majority of cases were found in the offspring of Ashkenazic Jews. As a result of carrier testing and prenatal diagnosis in this population, the number of patients with Tay-Sachs disease has since declined, with a much greater proportion now being observed in children of non-Jewish parentage.

The lesions in Fabry's disease are predominantly extraneural, located primarily in the vascular endothelium and kidneys. It is an X-linked disease that is usually recognized in early adolescent boys by the onset of intermittent pain in the hands and feet and the appearance of clusters of purple punctate angiokeratomas. The presence of feathery corneal opacities on slit-lamp examination helps establish the diagnosis in hemizygotes and confirm heterozygosity in their mothers and sisters.

Another of the sphingolipidoses, fucosidosis, is discussed with the oligosaccharidoses.

Gaucher's Disease (Glucosylceramide Lipidosis)

Gaucher's disease is the oldest known and most often encountered type of inherited lipidosis. Large lipid-filled macrophages, known as Gaucher cells, accumulate within the bone marrow, spleen, liver, and other components of the reticuloendothelial system. It was first reported in 1882 by Philippe C. E. Gaucher, who described it as an epithelioma of the spleen without leukemia.[189] The degree of clinical involvement differs greatly in individual patients, even those harboring the same genotype and those affected within the same family. The major storage product is glucocerebroside, catabolism of which is blocked by a deficiency of the lysosomal enzyme glucocerebroside β-glucosidase (glucocerebrosidase). The glucocerebroside is derived from three compounds commonly present in senescent blood cells: (1) lactosylceramide, the major glycolipid of leukocytes; (2) globoside, the principal red blood cell glycolipid; and (3) the blood group GSLs. Gaucher's disease is also important from a historical perspective in the study of LSDs in that it was the first of such conditions in which identification of the accumulated product led to isolation and purification of the enzyme and eventual therapy for patients with these disorders. The success was such that it has become the prototype for research and therapeutic efforts in this field.

Gaucher's disease is a relatively common disorder. The three clinical forms of this condition (see later) are pan-ethnic. However, the incidence of type 1 is increased in Ashkenazic Jews to approximately 1 in 350 to 450 live births. In the general population the incidence of type 1 is 1 in 40,000 to 60,000 live births. The respective incidence of carriers is 1 in 8 to 10 for Ashkenazic Jews and 1 in 100 for non-Jews. Types 2 and 3 are much rarer, with an estimated incidence of about 1 in 500,000 and 1 in

Sphingosine

50,000 live births, respectively, although an isolate of type 3 is present in the population of northern Sweden (Norbottnian). The comparable incidence of carriers is 1 in 150 and 1 in 100.

Gaucher's disease has been classified on the basis of CNS involvement into three types. Type 1, the most common form, has no primary CNS involvement. Types 2 and 3 both affect the CNS, but they do so at different rates. Type 2 is the so-called acute neuronopathic type, whereas type 3 has a more protracted course. However,

some investigators have recently challenged this classification[190] and believe that the distinction between type 2 and type 3 is probably artificial. They propose only two variants: the non-neuronopathic and the neuronopathic forms. Further discussion on this issue is likely to occur in the coming years because this distinction may have important implications for treatment and prognosis.

In addition, four other rare neuronopathic variants have been reported in infancy: one in which calcification of the aortic arch and valves is the prominent feature[191];

one in which nonimmune hydrops fetalis dominates the clinical picture[192]; one in which the neuronopathic findings are associated with hydrocephalus, corneal opacities, and deformed toes[193]; and one in which acute neuronopathic features are associated with congenital ichthyosis.[194,195] Interestingly, this fulminant form of the disease was identified after similar dermatologic findings were reported in the knockout mouse model for Gaucher's disease.[196] In this latter model death occurs within a few hours of birth.

Type 1: Chronic Non-neuronopathic (Adult) Gaucher's Disease

The great majority of occurrences of Gaucher's disease are type 1, the chronic non-neuronopathic form of the disease. Hematologic findings dominate the clinical picture of patients with this form of the disease, although osseous complications may on occasion be the initial feature. The spleen is usually enlarged from an early age and, in some patients, can become so large that it causes abdominal distention and pain. Anemia is generally present because of decreased red blood cell survival, although bone marrow infiltration may also be a contributing factor. The anemia may be either normocytic or microcytic and hypochromic and is probably due to hypersplenism rather than crowding out of erythropoietic activity in the bone marrow by Gaucher's cells. Although iron therapy may temporarily help the anemia, it is not recommended because Gaucher cells avidly take up iron, thereby reducing its availability for erythropoiesis and leading to secondary hemochromatosis.

A tendency toward bleeding as a result of thrombocytopenia and coagulation factor abnormalities is a more serious consequence of the hypersplenism and liver involvement that occurs in this form of Gaucher's disease. Easy bruising and epistaxis are also common complaints in childhood. Trauma to the enlarged spleen is a special danger because of the possibility of rupture and hemorrhage. This hazard also exists when a patient with Gaucher's disease and hypersplenism contracts an infection in which splenic involvement is common, such as acute mononucleosis. Bleeding into other organs and metrorrhagia may also occur. In one patient with portal hypertension, hematemesis occurred as a result of rupture of esophageal varices.[197] As mentioned earlier, various coagulation defects, including deficiencies of factors VIII, IX, and XI and von Willebrand factor antigen, probably contribute to the tendency for bleeding in this condition. These deficiencies are variable and not consistently demonstrable in all patients,[198-200] but they can become a source for concern in patients who will be subjected to either surgical or extensive dental procedures. In the past, splenectomy was performed because of thrombocytopenia with recurrent bleeding or because of marked abdominal pain and discomfort produced by the large spleen. Although platelet counts increase after splenectomy and episodes of bleeding no longer occur, this radical surgical approach is rarely recommended now because of its

inherent complications, including high susceptibility to infections. Fluctuations in spleen size can occur in Gaucher's disease as a result of intercurrent infection or pregnancy.[201] Additional hematologic complications include mild megaloblastic anemia secondary to vitamin B_{12} deficiency and monoclonal gammopathies. A few individuals with coexistent multiple myeloma have been reported.[202-204] As mentioned earlier, there is also a slightly increased incidence of malignancies, especially of the hematopoietic system,[204] such as leukemia[205] and Hodgkin's disease.[206] This increase in lymphoid neoplasia could result from the reduction in natural killer cells reported to occur in Gaucher's disease.[207] Finally, there is a general increase in activity of the immune system as manifested by hypergammaglobulinemia and a significant increase in the incidence of autoantibodies.[208] These most likely result from increased levels of cytokines. Commonly used serum inflammatory markers such as transferrin and angiotensin-converting enzyme are often elevated.

Bone complications are common. As Gaucher cells infiltrate the medullary cavity, there is loss of bone density, thinning of the cortex, loss of the normal trabeculations, patchy myelosclerosis, and bone infarcts and the resulting osteonecrosis. At least half of all patients show an "Erlenmeyer flask" deformity, in which the midshaft of the femur has a tapered appearance and the distal end is widened because of failure of trabeculation. This same change may also be seen in the proximal ends of the tibia and fibula. In addition, aseptic necrosis of the head and neck of the femur can occur and cause disability and pain that may require surgical arthroplasty. Other forms of pathologic fractures are also seen, as well as bone infarcts that cause episodes of severe incapacitating bone and joint pain.[209] In children with this condition, growth failure is commonly found. Such failure could be related to the anemia or to the reported increase in resting energy expenditure in patients with this condition.[210] Furthermore, although they may eventually reach their final predicted height late in life, there are serious concerns about the final quality of the bone and the possibility of early osteoporosis.

Most patients have some degree of hepatosplenomegaly, and portal hypertension sometimes occurs, but liver failure is rare, although mild abnormalities in liver function test results are commonly encountered. Rare patients in whom liver failure or cirrhosis has developed have a concomitant history of infection with hepatitis C virus, probably caused by previous transfusion of contaminated blood.

The onset of puberty may be delayed and heavy menstrual bleeding can occur. During pregnancy, anemia and thrombocytopenia may worsen and bone crises can develop. However, most women with Gaucher's disease successfully complete their pregnancies without complications from the disease.[211]

Diffuse pulmonary infiltration develops in a few patients, although this serious complication seems to occur more often in children with severe disease. Pulmo-

nary hypertension is another rarely reported complication.[212] Renal disease is unusual. Finally, indirect neurologic involvement can also occur, such as spinal cord compression secondary to vertebral fractures or peripheral nerve injuries associated with long bone fractures or bleeding into a nerve sheath.

As mentioned earlier, approximately 60% of patients with type 1 Gaucher's disease are of Ashkenazic Jewish ancestry. In this particular population, the rate of occurrence of the gene may be as high as 8% or greater.[209] However, the actual incidence of disease is much less than expected because the clinical spectrum includes many mildly affected individuals in whom the condition remains undiagnosed until late in life[213] or who may never become symptomatic. This latter category has been grossly estimated to include up to 25% of all patients. The variability in clinical expression is evident in families in which several members are affected; one family member may have severe incapacitating bone disease, whereas another has only mild hypersplenism and occasional joint pain. A particularly malignant form of the disease is seen primarily in non-Jewish children, in whom substantial splenomegaly develops by age 3 and portal hypertension by age 10. These patients have massive abdominal swelling and stunted linear growth and tend to have severe bone involvement as well. In this group of patients there is always the question of whether their disease may actually represent an early form of the chronic neuronopathic variant usually associated with lower levels of enzyme activity.

Laboratory diagnosis depends on the presence of Gaucher cells in bone marrow and the demonstration of a deficiency in lysosomal β-glucosidase activity measured in leukocytes or cultured skin fibroblasts. Conventional radiographs are used to determine the extent and pattern of bone involvement but are not helpful for determination of disease activity.[214] Dual-energy radiographic and quantitative computed tomographic methods permit evaluation of osteoporosis. The use of abdominal magnetic resonance imaging allows volumetric determinations to be made of the spleen and liver. It can disclose the presence of splenic nodules and infarcts and zones of ischemia within the liver. Magnetic resonance imaging is also used for quantitative imaging of bone to measure the marrow fat fraction. Nuclear bone scanning with ^{99m}Tc-methylenediphosphonate is a sensitive tool for examining active bone disease.[215] Ancillary findings in serum include elevations in activities of non–tartrate-inhibitable acid phosphatase (isoenzyme 5B), angiotensin 1–converting enzyme,[216] and transcobalamin II.[217] Plasma chitotriosidase may be elevated more than several hundred–fold above normal and can serve as a useful parameter for monitoring the treatment of patients.[218]

Type 2: Acute Neuronopathic (Infantile) Gaucher's Disease

A child with the acute neuronopathic variety of Gaucher's disease (type 2) is seen between birth and 6 months of age with failure to thrive, hepatosplenomegaly, muscular hypertonicity, and signs of brainstem dysfunction, including strabismus and retroflexion of the head. Other nervous system signs include dysphagia, laryngospasm, dyspnea, vomiting, and generalized spasticity. In addition, there are feeding difficulties, inanition, and weight loss. Death is inevitable before 2 years of age. A later-onset form has also been recognized in which strabismus develops during the first year but the child is otherwise normal until the second or third year of age.

Perivascular accumulations of Gaucher cells are found in the brains of these children, and their nerve cells are swollen by a PAS-positive, weakly sudanophilic material.[219] Brain specimens from patients with type 2 Gaucher's disease contain the highest concentrations of glucocerebroside and psychosine (sphingosine glucose)[220] and the most pronounced deficiency of acid β-glucosidase activity.[221] Psychosine (lysosphingosine) is believed to be neurotoxic. Interestingly, the degree of substrate accumulation in the brain is not as extensive as suspected from the biochemical findings alone, and the presence of neuronal death (which can be extensive at the cerebellar level) is probably more of a contributing factor than the accumulation of glycolipid by itself. Clearly, other factors, which may include increased apoptosis or dysregulated cell growth, may contribute to the pathophysiologic course of this condition and somehow explain the lack of definitive clinical response to ERT in these patients. Because of the early onset and fatal outcome of type 2 Gaucher's disease, prenatal diagnosis provides a feasible alternative to families at risk for having additional children with this disorder. Unfortunately, no therapeutic modality has proved to be effective in patients with this type of Gaucher's disease.

Type 3: Subacute Neuronopathic (Juvenile) Gaucher's Disease

In rare instances, nervous system involvement has occurred in older children and adults with Gaucher's disease. Neurologic findings have included decreased mental ability, seizures, oculomotor apraxia, poor coordination, and an increase in muscle tone. In some patients the condition most closely resembles the acute neuronopathic variety of Gaucher's disease,[222] whereas in others the clinical course is similar in many respects to the more common adult non-neuronopathic variety of the disease.[223] In a subset of these patients, a relatively stable clinical course is suddenly altered by the appearance of myoclonic epilepsy; the prognosis for these patients is poor. Electrophysiologic studies, which include measurement of brainstem auditory evoked responses, are a monitoring tool for the development of neurologic disease.[224]

Genetically, this particular condition is distinct from type 1 adult Gaucher's disease. It has been identified in several related patients from the Norbottnian region of northern Sweden but has not been reported in Ashkenazic Jews because genotype/phenotype correlations have

demonstrated that the presence of only one N370S allele protects against the neuronopathic forms of the disease. This type 3 variant is also more commonly seen in patients exhibiting the L444P homozygous allele.[225] After splenectomy, the neurologic symptoms and mental retardation worsen, possibly as a result of increased levels of glucocerebroside in blood and perivascular Gaucher cells in the brain.[226] Because of the relentlessly progressive neurologic deterioration, these patients have been prime candidates for therapeutic experimentation such as enzyme replacement,[227] organ transplantation,[228] and bone marrow replacement.[229-232] Fortunately, in at least a subset of these patients, a response or stabilization of their condition has been seen after the administration of high doses of ERT (see later).

Molecular and Genetic Aspects

The mature enzyme, glucocerebroside β-glucosidase, is a glycosylated polypeptide of 497 amino acids. Binding studies with conduritol-β-epoxide have identified Asp443 as the active amino acid residue site.[233] Its structural gene, which contains 11 exons and 10 introns, maps to the human chromosome locus 1q21[234] and consists of 7604 nucleotides.[235,236] Interestingly, a pseudogene has also been identified within a single 32-kilobase (kb) fragment of genomic DNA. This pseudogene is 96% homologous with the active gene, but it contains four large deletions and numerous point substitutions. Both structures map to the same chromosomal locus; thus, great care must be exercised when mutation analysis is performed for these patients because the pseudogene normally contains sequences that are pathologic if present in the functional gene. This duplicate mapping could potentially lead to substantial diagnostic errors. It has also been hypothesized that the proximity between these two structures somehow increases the chance of abnormal recombination events during DNA replication.

In close proximity to these two genes reside several other genes that could, at least theoretically, influence the phenotype of the disease: the metaxin (*MTX*) gene (which also has a nearby pseudogene) and the thrombospondin 3 gene.[237,238] Metaxin is a mitochondrial import protein[239] that seems to be required for embryonic development in the mouse.[237] The second closely located gene (thrombospondin 3) codes for a protein that is probably involved in a variety of cellular regulatory processes and has been linked to large cell lymphoma.[240] Tissue-specific expression of glucocerebroside β-glucosidase is suggested by the presence of high steady-state levels of acid β-glucosidase mRNA in epithelial cells, intermediate levels in skin fibroblasts and promyelocytes, low levels in macrophages, and barely detectable levels in B cells. In Gaucher's disease these levels are increased, indicative of possible feedback regulation of acid β-glucosidase expression.[241]

More than 200 mutations in the glucocerebrosidase gene are now known to cause Gaucher's disease.[242,243] The majority are missense mutations resulting in substi-

tution of one amino acid for another. There are also insertions and deletions, as well as recombination events caused by crossing over with the pseudogene. Four are "public" mutations in that they account for more than 96% of type 1 alleles in Ashkenazic Jews and 61% of type 1 alleles in non-Jews. The remainder are "private" mutations in that they are uncommon or rare and occur in only a single family or a few individuals.

The most common mutation, present in 6% of Ashkenazic Jews, results in an Asn370Ser amino acid substitution and is associated with about 7% to 12% residual enzyme activity and a generally milder phenotype. It is not present in either of the neuronopathic forms of Gaucher's disease. The second most common allele, found in 0.6% of the Jewish population, is the 84GG nucleotide insertion, which results in a frameshift that causes loss of all enzyme activity.[244]

Much rarer are the Leu444Pro and His409Asp amino acid substitutions and IVS2(+1) nucleotide insertion. The Leu444Pro change is close to the active site of the enzyme and results in severe loss of enzyme activity. Homozygotes for this mutation generally have neuronopathic disease, either type 2 or type 3.[243] Rarely, this mutation may also be found in patients with type 1 disease, who are usually compound heterozygotes and have more severe and earlier involvement than do type 1 patients with the Asn370Ser mutation. Eye movement abnormalities and calcifications of the aortic or mitral valves, or both, develop in patients with the His409Asp substitution.[191,245] Interestingly, this is the only genotypic variant in which close correlation with phenotype can be made. The IVS2(+1) mutation results in aberrant splicing of the mRNA.[246,247]

Finally, the activator protein SAP-C is required by β-glucosidase to exert its activity.[26] Two patients with deficiency of SAP-C have been described, both with the clinical course of type 3 Gaucher's disease.[28]

Treatment

The advent of ERT with macrophage-targeted α-mannosyl–terminated placental glucocerebrosidase has dramatically altered the approach to therapy for Gaucher's disease. In patients with type 1 and type 3 Gaucher's disease, ERT is efficacious,[190,224] whereas in patients with type 2 disease, it may slow but does not prevent the occurrence of lethal CNS disease.[248] Pulmonary disease also appears to be resistant to imiglucerase (Cerezyme) treatment, although some researchers have reported good results.[249] Various schedules of dosing ranging from 1 to 120 U/kg body weight infused intravenously every other day to once a month have been tried.[250,251] Currently, the usual starting dose ranges from 30 to 60 U/kg given by the intravenous route every 2 weeks. Within a few months there is an increase in hemoglobin concentration, and by 1 year, 60% to 70% of patients have a normal hemoglobin concentration and improved sense of well-being. Platelet counts rise, but the response is not as rapid as that for the anemia. A decrease in spleen and liver size

correlates with the improvement in hemoglobin concentration. Skeletal responses to ERT occur more slowly, and usually a high-dose regimen (30 to 60 U/kg) is required for major improvements to be noted in cortical and trabecular bone mass.[252] However, a reduction in bone pain and a growth spurt in children who have short stature may be observed early during treatment. Allergic reactions occur in less than 0.1% of patients. The lack of reaction could be related to the presence of minimal amounts of residual enzymatic activity in these patients, which probably makes their immune systems more tolerant. Although IgG antibodies are commonly seen in up to 13% of patients undergoing ERT, they are generally of the non-neutralizing variant and are therefore not clinically relevant.[253,254]

ERT for Gaucher's disease has given patients with this condition the option of a nearly normal life if therapy is started at the appropriate time. Although questions remain about whether some of the CNS signs and symptoms respond to this therapy, the vast majority of patients (i.e., those with type 1 disease) experience a substantial improvement in hematologic parameters, bone quality, and overall quality of life. Splenectomy is now rarely necessary, and recurrent episodes of bone crisis have become a rarity. However, management of the complications that could already be present is mandatory because they still contribute to morbidity in these patients.

Alternative therapeutic strategies for patients with Gaucher's disease are also being studied. Gene therapy approaches have been applied to restore β-glucosidase activity in cultured human hematopoietic cells. Promising results were obtained, albeit in vitro, with enriched populations of these cells transduced with retroviral or AAV vectors containing normal β-glucosidase cDNA to promote long-term expression of enzyme activity.[255-257] An ex vivo gene therapy trial was performed in four human subjects[258]; however, gene expression was transient and lasted for only a few months but was accompanied by a modest degree of clinical improvement. The ultimate goal of these studies is to reintroduce into patients with Gaucher's disease autologous HSCs that have been transduced with the β-glucosidase gene and are capable of high levels of enzyme expression.

Another therapeutic modality, which involves the administration of miglustat, has shown promise in clinical trials in patients with Gaucher's disease.[259] This substance is a potent inhibitor of the enzyme glycosyltransferase and apparently also functions as a chemical chaperone by improving the activity of mutated β-glucosidase.[260] Side effects associated with the administration of miglustat to patients with Gaucher's disease have included persistent diarrhea, weight loss, and peripheral neuropathy, but they may be obviated in the future by the use of other pharmacologic chaperones (see earlier) that have recently been shown to increase the enzyme activity of some β-glucosidase mutant proteins in vitro.[261]

Symptomatic care is an important aspect of the management of patients with Gaucher's disease.[262] To counteract the diffuse osteopenia, administration of vitamin D, calcium supplements, and aminohydroxypropylidene biphosphonate has been tried. Biphosphonate appears to diminish the incidence of traumatic bone fractures, normalize bone density, and encourage positive calcium balance.[263] Organ transplantation has been effective in a small number of patients. However, the inherent morbidity and mortality associated with this method make this option obsolete. The beneficial results achieved by successful allogeneic BMT in patients with Gaucher's disease[148,264] augurs well for the future of gene therapy trials. For patients with severe liver failure, liver transplantation has been a lifesaving procedure.

Finally, significant advances have been made in the field of prenatal diagnosis, and the choice of early detection of affected fetuses is now available for couples with a history of a previously affected child. Presumably, this option would be considered primarily in families who have members with type 2 or type 3 (i.e., CNS) variants. Preimplantation genetic diagnosis is also possible.[265]

Niemann-Pick Disease (Sphingomyelin Lipidosis)

Niemann-Pick disease (NPD) comprises a group of disorders in which the reticuloendothelial system is infiltrated by foam cells containing either sphingomyelin or unesterified cholesterol and other cell membrane lipids. The eponym refers to Albert Niemann, the German pediatrician who published the first clinical description in 1914,[266] and Ludwig Pick, whose histologic studies published in 1922 and 1927 differentiated this condition from Gaucher's disease.[267,268] The proposed division of NPD into four clinical subtypes by Crocker in 1961[269] and the later addition of a fifth (adult non-neuronopathic) form was based mainly on clinical and preliminary biochemical data. However, additional studies carried out since then suggest that this classification should be modified. Currently, two major patient groups are distinguished. Patients in whom the underlying metabolic defect is a deficiency of acid sphingomyelinase (ASM) activity with subsequent sphingomyelin accumulation in lysosomes have type A (NPD-A) and type B (NPD-B). The clinical spectrum of this disorder ranges from the early-onset, neurologic form, which results in death by 3 years of age (type A), to the non-neurologic form (type B), which is associated with survival into adulthood.[270] Patients with defective intracellular processing and transport of low-density lipoprotein–derived cholesterol have NPD-C and NPD-D.[271] It is now believed that the modest decrease in ASM activity levels in patients with the latter types is probably related more to a secondary disturbance in intracellular lipid metabolism than to a primary defect in the degradation of sphingomyelin.[272] All types of the disease share clinical involvement of the reticuloendothelial system and the presence of lipid-filled macrophages in pathologic studies.

Sphingomyelin is both a phospholipid and a sphingolipid. Its two major components are ceramide and phosphorylcholine, which are linked by a phosphodiester bond to the first carbon atom of sphingosine. The ASM gene has been mapped to an imprinted region on chromosome 11 (11p15.1-15.4).[273,274] More than 100 mutations have been identified in patients with type A and type B disease.[275-277] Of these, three (L302P, fsP330, and R496L) account for 92% of the mutant alleles in Ashkenazic Jewish patients with NPD-A,[278] and one, ΔR608, has a high prevalence in patients with type B disease who originate from northern Africa.[279]

Mouse models of NPD-A/B have also been created by gene targeting.[280,281] These ASM-deficient mice have been used to study disease pathogenesis and investigate different therapeutic modalities.[272,282,283] Based on these studies, an ERT clinical trial has recently begun in adult patients with non-neurologic sphingomyelinase-deficient NPD.

Though clinically similar, the underlying metabolic defect in NPD-C is quite different from that for classic NPD and primarily involves abnormal intracellular trafficking of cholesterol. It is caused by mutations in at least two unrelated genes named *NPC1* and *HE1* (see later). NPD-D is mostly a geographic variant of type C and occurs mainly in persons residing in Nova Scotia. However, it differs from the latter in that it tends to have a prominent degree of dystonia. Thus far it has been found to cosegregate with a mutation found in NPD-C, probably the result of a founder effect.[284] Therefore, the different forms of NPD are grouped together because of similarities in clinical features, including hepatosplenomegaly and foam cell infiltration of the bone marrow, rather than because each variant shares the same enzyme deficiency.

Acute Neuronopathic Form (Type A)

Patients with the classic infantile form of NPD are seen at 2 to 4 months of age with feeding difficulties, liver and spleen enlargement, and developmental delay. Periorbital puffiness, pulmonary infiltration, and lymphadenopathy may occur, and in most patients a cherry-red macula is noted on funduscopic examination. During the succeeding months, neurodevelopmental arrest occurs and is followed by regression, the abdomen becomes protuberant, intermittent jaundice may be noted, and general inanition is seen with wasting of the extremities and recurrent infections. Death occurs by 2 to 3 years of age. On postmortem examination, ascitic fluid is found in the abdomen; the liver, spleen, and lymph nodes are enlarged, yellow, and fatty; and foam cells are present in many different tissues. The brain is atrophic with widespread nerve cell loss and gliosis, and a profound lack of myelin lipids can be observed in the white matter.[285,286] Accumulation of the compound sphingosylphosphorylcholine has been seen in the brains of patients with this variant of NPD but not in the brains of those with the non-neuronopathic variants,[285] thus suggesting that this lyso-somal substance could play a role in the pathophysiologic process of brain dysfunction. Because sphingomyelin contents are normal in the brains of newborns affected with NPD-A, an alternative degradation pathway probably exists for this lipid, possibly through neutral sphingomyelinase, which is not defective in this disease.[286]

Many of these patients are of Ashkenazic Jewish heritage, but this disease is considerably less common than Tay-Sachs or adult (type 1) Gaucher's disease, two other sphingolipidoses that occur more often among Ashkenazim.

Chronic Form without Central Nervous System Involvement (Type B)

Patients with NPD-B are usually seen in early childhood with abdominal distention secondary to liver and spleen enlargement. Foam cell infiltration of the lungs may occur,[287] but survival with preservation of intellect for many years is common. The massive enlargement of the spleen in these patients may necessitate splenectomy, but curiously, plasma sphingomyelin levels are not elevated. Bone pathologic changes of the type seen in Gaucher's disease do not occur; however, osteoporosis, widening of the medullary cavities, and modeling defects can be demonstrated radiologically. There is periorbital fullness and a macular halo may be found in the fundus,[288] but vision is not disturbed. Growth retardation as a result of polyglandular involvement has also been reported.[289] Caution has been recommended by some researchers because increased levels of glycogen may be found in hepatic biopsy specimens and lead to the incorrect diagnosis of a glycogen storage disease.[290] Sea-blue histiocytes are present in the bone marrow of some patients. The bluish cast revealed by the Giemsa stain results from the accumulation of ceroid within these cells. The presence of residual sphingomyelinase activity in the brains of patients with type B probably protects their CNS from accumulation of sphingomyelin.[291] Life expectancy is still affected, and patients usually survive into their 30s.

Chronic Neuronopathic Form (Types C and D)

This category probably includes the largest group of patients with sphingomyelin-related lipidoses. In some patients, developmental delay and psychomotor retardation are present in the first year, whereas other children experience a period of normal early development followed by mild, but progressive intellectual impairment at a later age.[292] Those in the first group usually die at 5 to 6 years of age, whereas those in the second group survive into adulthood. Ataxia, progressive tetraparesis, loss of speech, and deterioration of mental function develop in affected children. Vertical gaze paresis, dysarthria, dysphagia, seizures, and dystonic posturing are also common.[293] Pyramidal tract signs and abnormal brainstem auditory evoked responses occur at a later stage, and finally the patient becomes nonambulatory and enters a vegetative state.[294] The initial manifestation in a patient with adult onset of the disease may be an atypical

progressive dementia or a psychosis.[295,296] Rarely, a peripheral neuropathy may occur in patients with this clinically heterogeneous form of NPD.[297] Brain magnetic resonance imaging may show symmetrical cerebral and cerebellar atrophy, hypoplasia of the corpus callosum, and high signal intensity in the central white matter.[298] Approximately half of the patients with type C disease are seen in the newborn period with clinical features suggesting neonatal cholestatic hepatitis, including jaundice, hepatosplenomegaly, and the liver biopsy appearance of chronic hepatitis with giant cells. The cholestasis and hepatomegaly subside in most of these infants, but the splenomegaly can persist and serial liver biopsy specimens show hepatic fibrosis with progression to cirrhosis in some.[299] Patients with the Crocker-type C and D disease and some patients with the sea-blue histiocyte syndrome are included in this category. An in utero manifestation consisting of fetal ascites also occurs.[300] Interestingly, faster neurologic deterioration can be noticed in these patients as soon as puberty begins, a finding that has prompted therapeutic approaches in which onset of puberty is delayed.

Recent advances in the elucidation of intracellular cholesterol trafficking and metabolism have shed further light on the pathogenesis of this disorder. It is now known that in patients with NPD-C, incorporation of cholesterol into the lysosome is normal; however, proper processing and trafficking to the ER are abnormal.[301] This has led to the current concept of NPD-C as a disorder in which "exogenous cholesterol is trapped in traffic."[302] The fact that only exogenously derived cholesterol but no endogenously synthesized cholesterol accumulates in lysosomes is also part of the mystery surrounding the pathophysiologic features of NPD-C.[303]

Accumulation of low-density lipoprotein cholesterol has been demonstrated in all patients,[304] and in more than 90% a defect in intracellular cholesterol esterification is found when tests with a nonlipoprotein source of cholesterol are performed.[305] Cholesterol ester synthesis is partially reduced in cultured cells from heterozygotes. Positive filipin staining of the large amount of free cholesterol within cultured cells provides a useful diagnostic marker for NPD-C.

As mentioned earlier, this variant of NPD is caused by mutations in at least two genes, *NPC1*[306,307] and *HE1*.[308] *NPC1* maps to chromosome 18q11, and its product is a protein of the permease family with five transmembrane domains.[309] Genotype-to-phenotype correlations are now possible because mutations involving the coding sequence for the sterol-sensing domain seem to be present in patients with more severe and early-onset neurologic disease. The NPC1 protein shares structural homology with sterol-sensing domains and other enzymes involved in cellular cholesterol homeostasis, and mutations in this gene result in severe disruption of intracellular trafficking of cholesterol and trapping of low-density lipoprotein cholesterol and other lipids in lysosomes. The second gene, *HE1*, maps to chromosome 14q24.3,[308] and

mutations in this gene have been found in patients with NPD-C whose genetic defect did not involve the former gene. By subcellular fractionation methods, the protein product HE1 was localized to lysosomes.

Neurofibrillary tangles consisting of paired helical filaments strongly reactive to antibody to τ protein are present in many regions of the brain. They are ultrastructurally identical to those of Alzheimer's disease and are not associated with β-amyloid deposits. Their distribution corresponds fairly closely to that of the abnormal storage material, thus suggesting that they may be a reaction to the accumulating cytoplasmic material.[310-312]

Cholesterol-lowering agents will decrease hepatic and plasma cholesterol levels, but there is little evidence that this treatment can ameliorate the CNS complications of the disease.[313] One infant with NPD-C and an abnormal lipid signal on magnetic resonance spectroscopy at 9 months of age showed normal spectra 4 and 10 months after treatment with cholestyramine and lovastatin was begun.[314] Several reports have mentioned the need to avoid neuroleptic medications, mostly those of the hydrophobic amine type such as thioridazine, when one attempts to control behavioral disturbances in these patients. Although few other drugs are available (i.e., clozapine), experimental evidence suggests that such medications may worsen intracellular cholesterol accumulation, at least in vitro.[315]

Prenatal diagnosis of NPD-C has been successfully done numerous times.[316-318] The existence of various naturally occurring animal models for type C disease[319-321] should assist researchers in developing a better understanding of the molecular cause and pathogenesis of this disease. BMT has been attempted with promising results on liver enlargement, but the neurologic deterioration was not halted.[322]

Adult Non-neuronopathic Form

These patients have normal sphingomyelinase activity but store sphingomyelin in organs of the reticuloendothelial system. They usually have no neurologic involvement, and several have survived to old age. NPD must be suspected in infants and children with hepatosplenomegaly and bone marrow findings of enlarged foamy or sea-blue histiocytes. The diagnosis may be confirmed by the use of leukocytes or cultured skin fibroblasts to assay sphingomyelinase activity and cholesterol ester synthesis. Another useful finding is the presence of lymphocytic vacuolization in peripheral blood smears.

Heterozygotes for the A and B types can be identified by the reduced levels of sphingomyelinase activity present in their leukocytes or cultured skin fibroblasts, with [14]C-sphingomyelin used as substrate.

Treatment

BMT in one presymptomatic infant with NPD-A normalized his leukocyte sphingomyelinase activity. However, visceral storage increased and neurologic impairment progressed, though less rapidly than in his untreated

sibling, and he died at 30 months of age.[143] Currently, there is no therapy available for this severe condition.

Preclinical studies involving the administration of recombinant ASM to knockout mice have shown promise in that treated animals exhibited striking improvements in histologic and biochemical parameters in their reticuloendothelial systems.[161] Unfortunately, neither prolonged life expectancy nor improvement in the neurologic compromise was seen. Phase I clinical trials are expected to begin soon.

More recently, implantation of neural stem cells in NPD-C mice was shown to extend the life span of these animals.[323] However, this procedure was found to be only partially therapeutic inasmuch as the overall clinical condition of the treated mutant animals was not significantly different from that of the untreated controls.[323] Because of their secondary ganglioside accumulation, NPD-C mice were treated with miglustat, which resulted in a reduction in ganglioside accumulation, delayed onset of neurologic symptoms, and increased survival.[324] Based on these positive effects, a randomized, controlled clinical trial was performed in NPD-C patients.[118] Twelve months after treatment, positive neurologic effects were observed only in the miglustat-treated group, thus suggesting that ganglioside accumulation rather than cholesterol storage is responsible for the neurologic symptoms of these patients.[325] These results encourage the use of SRT to treat the neurologic signs in patients with NPD-C.

Farber's Disease (Lipogranulomatosis)

To date, more than 70 cases of this autosomal recessive disease have been reported since Farber and colleagues' original description in 1957.[326] Death generally occurs before 2 years of age, but some patients with onset in the second year survive until the second decade.

In its most typical variant, the clinical manifestations of this rare disorder consist of painful swelling in the hands and feet, hoarseness, and recurrent vomiting. These difficulties may be present as early as a few weeks after birth. As the disease progresses, subcutaneous and periarticular nodules develop, especially near the interphalangeal, ankle, wrist, and elbow joints, and lead to flexion contractures. Swelling and granuloma formation in the epiglottis and larynx cause hoarseness or swallowing and respiratory disturbances. Foam cell infiltration and granulomatous deposits in the lungs further complicate the pulmonary problems. The tongue, heart, and liver may become enlarged, and granulomatous lesions of the heart valves also develop. Seven subtypes have been described, each with differing severity and sites of tissue involvement. A neonatal form has been observed that is characterized by massive hepatosplenomegaly but no subcutaneous nodules,[327] and in at least one patient the disease was manifested as nonimmune hydrops fetalis.[328]

Despite involvement of the degradative pathways of ceramide, there are few CNS signs in the clinical course of some of the variants of Farber's disease, a finding that is somehow surprising because of the pivotal role that this compound plays in the biochemistry of the mammalian CNS. Ceramide and its intermediate breakdown product sphingosine have been shown to mediate many cellular events, including growth arrest, stress responses, and apoptosis.[329] In addition to CNS involvement, a peripheral neuropathy consisting of a decrease in response of the deep tendon reflexes and electromyographic signs of denervation occurs in some patients. Seizures have been reported in two patients.

The principal finding in pathologic studies is the presence of granulomatous infiltrates composed of foam cells containing a PAS-positive material that is extractable with lipid solvents. Comma-shaped curvilinear tubular structures (Farber bodies) are a characteristic feature of this disease. Analysis of this material by electron microscopy suggests a heterogeneous ultrastructure consisting principally of membrane-bound inclusions. Despite the absence of gross neurologic involvement, neuronal cytoplasm is also filled with PAS-positive storage material.

Chemical studies of the subcutaneous nodules indicate that ceramides account for 10% to 20% of the total lipids present. Increased ceramide concentrations in the urine, brain, and other organs have also been demonstrated.

Two enzymes, one with acid and another one with alkaline pH optima, have been described that are capable of catalyzing ceramide hydrolysis. Leukocytes, cultured skin fibroblasts, and solid tissue specimens from patients with Farber's disease are deficient in acid ceramidase. The first human alkaline ceramidase has recently been characterized and cloned[330] but to date has not been linked to any particular metabolic disorder. In addition, a novel ceramidase enzyme that is limited only to mitochondrial membranes has been described,[331] thus suggesting a topologically restricted pathway in sphingolipid metabolism.

Because acid ceramidase (together with glucosylceramidase and galactosylceramidase) also needs activation by the saposin family of proteins, it is not surprising that a patient with type 7 Farber's disease was found to have a mutation in the prosaposin gene.[332] The clinical features were very similar to those for Gaucher's disease type 2 (i.e., the acute neuronopathic form). That child had neonatal seizures, hepatosplenomegaly, and foamy macrophages. However, there were no joint deformities, subcutaneous nodules, or hoarseness. The child died at 16 weeks of age. Autopsy demonstrated an abnormal accumulation of ceramide, glucosylceramide, and lactosylceramide. Biochemical studies demonstrated diminished ceramidase activity.

Little is known about the pathophysiologic features of this condition, but clearly, recent advances in understanding the biologic roles of ceramide will shed light on the pathophysiology of Farber's disease.[333] In the meantime, the possible role of ceramide in the intracellular

signaling cascade as a second messenger[334] and as a mediator in cellular apoptosis[329] may eventually give further insight on the molecular mechanisms of toxicity in this disease.

Human acid ceramidase has been characterized and purified,[335] and its gene has been cloned.[336] It maps to chromosome 8p22-21.2 and consists of 14 exons and 13 introns spanning approximately 26.5 kb of genomic DNA. To date, at least 10 different mutations have been reported.[337,338] Acid ceramidase activity can be measured in both cultured chorionic villus and amniotic fluid cells, thus allowing prenatal diagnosis of affected pregnancies.

No therapy is available for this condition, except for palliative management of its complications. Tracheostomy may be useful in managing upper airway obstruction, and some relief of joint pain may be obtained with the administration of corticosteroids. Resection of granulomas in the oral cavity was reported to improve upper airway obstruction.[339] Allogenic BMT was attempted in a presymptomatic infant at 9.5 months of age.[340] It resulted in reversal of the peripheral abnormalities (lipogranulomas, pain on joint motion, and hoarseness), but her neurologic deterioration progressed relentlessly. She died of pulmonary complications at 37 months of age. Correction of the metabolic defect in cultured Farber disease cells was achieved by retroviral vector–mediated transfection,[341] but no clinical reports on gene therapy are available to date. Current management of these patients has therefore focused on pain therapy, physical therapy, surgical correction of severe contractures, and anti-inflammatory medication.

G_{M1}-Gangliosidosis

G_{M1}-gangliosidosis was first defined clinically and pathologically by Landing and associates[342] as a familial neurovisceral lipidosis. Biochemical analysis demonstrated generalized accumulation of G_{M1}-ganglioside (G_{M1}) in the brain and visceral organs and led to designation of this disease as generalized gangliosidosis.[343] Shortly thereafter, deficient activity of the lysosomal acid β-D-galactosidase (β-gal) was found to be the primary defect in this disease.[344] G_{M1}-gangliosidosis is currently the third most frequently diagnosed LSD, and the incidence of specific allelic mutations is particularly high in certain geographic regions, such as Cyprus and southern Brazil.[345,346] The disease is transmitted as an autosomal recessive trait. The causative gene (*GLB1*), located on chromosome 3 (3p21-33),[347] codes for two distinct proteins derived from two alternatively spliced β-gal mRNA molecules.[348,349] The first is the canonic lysosomal β-gal enzyme; the second is an enzymatically inactive, functionally distinct product named the elastin-binding protein (EBP).[349,350] The latter protein controls early stages of elastogenesis and also contains a galactolectin domain that binds galactosugar-bearing molecules.[351] The EBP functions as a molecular chaperone that pro-

tects tropoelastin from premature intracellular degradation and hence facilitates assembly of the appropriately folded elastic fibers after deposition in the extracellular matrix.[352] A total of 99 mutations have been reported thus far in the *GLB1* gene that alter lysosomal β-gal, EBP, or both, to a different extent.[353]

Gangliosides are acidic, sialic acid–containing GSLs that are found on the surface of essentially all mammalian cells but are particularly abundant on neuronal membranes. G_{M1} accounts for 5% to 10% of the lipid mass of the plasma membrane of neurons.[354] Gangliosides are synthesized in the ER, Golgi, and trans-Golgi network by adding carbohydrate residues in a stepwise manner to the lipid membrane anchor ceramide.[355] De novo synthesized gangliosides are then transferred via vesicular transport mostly to the outer leaflet of the plasma membrane, where they distribute asymmetrically or segregate into unique membrane microdomains (e.g., caveolae and lipid rafts).[356] They are degraded in the endosomal/lysosomal compartment via the sequential removal of individual sugars; exoglycosidases or membrane sialidases work in concert with activator proteins to hydrolyze these compounds, and the products are either recycled or degraded.[26]

β-Gal is the primary enzyme involved in the degradation of GM1, for which it has the highest affinity. However, the enzyme can also remove β-linked galactosyl moieties from keratan sulfate, a mucopolysaccharide that belongs to an important group of extracellular proteins in bone and connective tissue. Although G_{M1}-gangliosidosis is clinically distinct from the mucopolysaccharidosis type B Morquio's disease, or MPS IVB (see later), they both result from deficiency of the same enzyme and are therefore allelic variants of the same gene defect.[357] The fact that G_{M1}-gangliosidosis is primarily a CNS condition whereas Morquio type B disease is primarily a disease of connective tissues reflects the relative tissue distribution of the main storage products G_{M1} and keratan sulfate. This also explains why patients with these disorders may share some of their clinical manifestations; for instance, skeletal and connective tissue abnormalities and urinary excretion of keratan sulfate have been observed in some patients with G_{M1}-gangliosidosis.[358] Functional analysis of the different mutations affecting the *GLB1* gene has explained at least in part why loss of activity of the same enzyme could lead to such different clinical outcome. It is now apparent that the diverse amino acid substitutions in β-gal found in either G_{M1}-gangliosidosis or Morquio B patients alter in a different way the enzyme's catalytic site and in turn its kinetic properties toward one or the other of the substrates.[359] In addition, because β-gal is part of a lysosomal multienzyme complex composed of at least two other enzymes—the protective protein/cathepsin A and neuraminidase (see galactosialidosis)—required for compartmentalization of β-gal and lysosomal stability, different β-gal mutations may impair the way that the enzyme is post-translationally regulated by the other two interacting proteins.[360] Finally, patients

carrying mutations that affect both β-gal and EBP have impaired assembly and deposition of the elastic fibers.[351,352,361,362] Thus, impaired elastogenesis could contribute to the development of connective tissue abnormalities in patients with type B Morquio's disease and G_{M1}-gangliosidosis.

G_{M1}-gangliosidosis has a broad range of clinical manifestations that suggests a continuum of disease severity. Based on the age at onset and severity of symptoms, patients have been classified as having the early infantile (type 1), the late infantile (type 2), and the adult (type 3) form of the disease. The gray matter in the brain accumulates approximately 10 times the normal amount of G_{M1} because of a deficiency in G_{M1} β-gal. Therefore, the CNS is the primary affected site, which accounts for the severe neurologic signs characteristic of this disease. However, as discussed earlier, β-gal deficiency in extraneural tissues may also lead to accumulation of keratan sulfate in the liver, spleen, and bone and cause the typical subcutaneous and osseous features of this disease.[358] In general, higher residual enzyme activity is found in patients with type 2 and the adult form of G_{M1}-gangliosidosis than in patients with type 1 disease. In Morquio's disease, the residual β-gal is more active toward G_{M1} than toward keratan sulfate or oligosaccharide, and therefore patients are neurologically normal but display connective tissue and skeletal abnormalities. However, a more severe form of the disease may also occur (see MPS IVB).

Early Infantile G_{M1}-Gangliosidosis (Type 1)

Symptoms of early infantile G_{M1} (the most severe subtype, with onset shortly after birth) may include neurodegeneration, seizures, liver and spleen enlargement, coarsening of facial features, skeletal irregularities, joint stiffness, distended abdomen, muscle weakness, exaggerated startle response to sound, and problems with gait. A case of fetal hydrops has also been reported.[363] Cherry-red spots in the eye develop in about half of affected patients. Children may be deaf and blind by 1 year of age and often die by age 3 of cardiac complications or pneumonia.[359]

G_{M1}-gangliosidosis type 1 is the most common and severe subtype. The age at onset varies from birth to 6 to 7 months. Infants with early severe disease may be edematous at birth (nonimmune hydrops fetalis) with weak sucking, poor feeding, and slow weight gain. Developmental arrest typically occurs between 3 and 6 months of age. Hypotonia and an increased startle response may be the initial findings. CNS involvement is progressive, and spastic quadriplegia, decerebrate rigidity, clonic-tonic seizures, deafness, nystagmus, esotropia, and blindness ultimately develop. These children are born with or in their first few months exhibit coarse facial features with frontal bossing and a depressed nasal bridge. Bony deformities include stubby hands, broad wrists, anterior beaking of the lumbar vertebrae, thickening of the midshaft of the humerus, and spatulate ribs. A cherry-red macula occurs in half the infants with type 1 disease. In at least one infant, bilateral calcification of the basal ganglia was noted as well.[364] Isolated cardiomyopathy has also been described in an infantile form of the disease.[361,365] Death usually results from bronchopneumonia between 1 and 2 years of age.

Late Infantile/Juvenile G_{M1}-Gangliosidosis (Type 2)

The early development of a patient with type 2 G_{M1}-gangliosidosis may be normal, but careful review of the history usually discloses an exaggerated startle response and hypotonia from an early age. The onset of symptoms, including locomotor ataxia, which ultimately leads to a state of decerebration with epileptic seizures, varies from 7 months to 3 years of age. The viscera are only slightly affected. Toward the end of the first year, the child may lose the ability to crawl, sit, and stand, and language development ceases. The plantar responses become extensor, and seizures develop. Some pallor of the optic discs may be noted, but a cherry-red spot is not usually present. Corneal clouding and rotatory nystagmus may occur. In most patients the liver is not enlarged and there are no skeletal abnormalities. These children may survive for 3 to 10 years after onset of the disease.[334]

Adult/Chronic Form (Type 3)

In the adult form (type 3), or chronic G_{M1}-gangliosidosis, the age at onset may be as early as 3 years to as late as 30 years; sometimes symptoms have already occurred in adolescence but the diagnosis is not made until adulthood. Clinical signs are variable and often resemble those found in juvenile forms of Parkinson's disease. Some patients have only focal neurologic signs, such as atypical spinocerebellar degeneration or dystonia, whereas others have a chronic and progressive disease with pyramidal and extrapyramidal signs and mental retardation. The degree of CNS involvement is not as extensive as in the other types. Skeletal changes are minimal, and visceromegaly and cherry-red spots do not occur.[358]

Pathologic and Molecular Aspects

Gross morphologic changes consisting of atrophy of the gray matter and cerebellum are evident in the type 1 and type 2 forms of G_{M1}-gangliosidosis. Autopsy and radiographic examination of the brain reveal delay[366,367] or even arrest[368] of myelination. The cortical architecture is severely altered by substantial neuronal cell loss.[358] Neurons appear distended with an expanded number of lysosomes often containing membranous material. The reticuloendothelial system contains foamy histiocytes filled with strongly PAS-positive granular material. Vacuolated lymphocytes can readily be recognized in peripheral blood and bone marrow smears, where sea-blue histiocytes may also be distinguished.[369] Tissue macrophages (histiocytes) with grossly distended cytoplasm filled with storage lysosomes can be identified in most of the organs, such as the liver, kidney, spleen, lymph nodes, thymus, lung, intestine, pancreas, and skeletal muscle.[370] Marked hepatosplenomegaly is usually detected in the

early-onset cases, but it is less prominent or absent in late-onset patients. Storage of G_{M1} may occur in the liver of patients with type 1 but not type 2 G_{M1}-gangliosidosis. Accumulations of other galactose-containing oligosaccharides have been found to various degrees in the viscera and urine of individuals with all forms of the disease.[371] Several of these oligosaccharides appear to be derived from the incomplete degradation of certain erythrocyte glycoproteins and plasma immunoglobulins.[372]

The diagnosis of G_{M1}-gangliosidosis may be confirmed by assay of β-gal activity in plasma, leukocytes, or cultured fibroblasts.[373] Molecular analysis has demonstrated a wide variety of mutations associated with this disorder.[353,374] Common mutations that segregate with different forms of the disease have also been identified. For example, the mutations R201C and I51T have been found in Japanese patients with late infantile/juvenile G_{M1}-gangliosidosis and in white patients with adult/chronic G_M-gangliosidosis, respectively,[375] whereas the W273L mutation is found in patients with type B Morquio's syndrome.[376] A polymorphism has been shown to have a modulating effect on a mutation present in a patient with type 2 G_{M1}-gangliosidosis.[377]

Further studies on the molecular biology of β-gal have also led to important clues about post-translational processing and distribution of this lysosomal enzyme.[360] Zhang and associates[359] described patients with either G_{M1}-gangliosidosis or type B Morquio's disease who share the same two mutations. They suggested that although the missense mutations described in G_{M1}-gangliosidosis have little effect on catalytic activity, they nevertheless do affect protein conformation in such a way that the resulting protein cannot be transported out of the ER and fails to reach the lysosome. Stimulation of β-gal by SAP-A results in the hydrolysis of sulfatide and globotriaosylceramide.[25,378] Sulfatide but not G_{M1} accumulates in patients with SAP-A deficiency.[378]

The precise mechanism by which accumulation of ganglioside induces cellular dysfunction is not yet fully elucidated, but recent studies on the G_{M1}-gangliosidosis mouse model[379-381] have identified molecular pathways that are altered or activated as a consequence of the accumulation of G_{M1}. The G_{M1}-gangliosidosis mouse model closely recapitulates the clinical features of the human disease. A generalized nervous system condition characterized by tremors, ataxia, and abnormal gait develops in these mice and culminates in rigidity and paralysis of the hind limbs.[380] This phenotype is accompanied by gradual deterioration of motor function, progressive neurodegeneration, and neuroinflammation.[382]

Cell-specific morphologic and biochemical changes have been mapped in the CNS and the visceral organs of β-gal$^{-/-}$ mice with the use of light and electron microscopic and immunohistochemical methods. Both neurons and astroglia show extensive and progressive vacuolization of their cytosol as the animal ages. Lysosomes appear to be filled with heterogeneous membranous material, and neuronal cell death is a consistent feature that accounts for the extensive neurodegenerative characteristic of the disease.[89] Neuronal apoptosis is accompanied by activation and upregulation of an inflammatory response consisting of increased levels of cytokines and chemokines in various regions of the brain and spinal cord.[165,382] Recent studies on the pathophysiology underlying the CNS phenotype in this model have begun to identify the molecular pathways that are deregulated by abnormal buildup of G_{M1} in lysosomes and other subcellular sites. Although the precise mechanism by which G_{M1} induces cellular dysfunction is not yet fully elucidated, it has been shown that impaired lysosomal degradation of this ganglioside leads to its accumulation at the ER membrane. Given the important role of gangliosides in calcium homeostasis and signaling,[383] increases in the local concentration of G_{M1} at the ER membrane have indeed been shown to provoke calcium imbalance through depletion of ER calcium stores.[89] Disruption of intracellular calcium levels induces the activation of an ER stress response or unfolded protein response (UPR).[384] Upregulation of folding catalysts and transcription factors and activation of specific kinases and caspases were found to occur in the brain and spinal cord of mice with G_{M1}-gangliosidosis and culminated in neuronal apoptosis. Remarkably, activation of the UPR pathway does not occur in mice doubly deficient in β-gal and ganglioside synthase, one of the enzymes responsible for the synthesis of G_{M1}; such mice do not accumulate G_{M1}. These observations directly implicate G_{M1} in causing ER stress and present a novel mechanism of neuronal apoptosis in an LSD.[89] In addition, they give new prospective on the role of GSLs, specifically gangliosides, in normal cell metabolism and disease pathogenesis. Investigation of the cellular events underlying these complex disorders will provide more insight into lysosomal function in normal cell physiology and prove crucial to the development of tailored or alternative therapies for neurodegenerative LSDs.

Treatment

No effective therapy is currently available for G_{M1}-gangliosidosis, but several therapeutic modalities have been tested both in vitro and in vivo. Retroviral vector–mediated gene transfer has corrected β-gal deficiency in human fibroblasts.[155] More recently, use of an amplicon hybrid vector containing sequences of herpes simplex virus type 1 and AAV for expression of the entire human *GLB1* gene has led to temporary expression and functional activity of β-gal in human deficient cells.[385] BMT in a presymptomatic juvenile-onset patient resulted in complete normalization of β-gal enzyme levels in white blood cells but did not improve the long-term clinical outcome.[386]

Encouraging results have recently been obtained in mouse models of G_{M1}-gangliosidosis. Knockout mice transplanted with bone marrow progenitor cells transduced ex vivo with a retroviral vector expressing murine β-gal cDNA have shown a remarkable increase in β-gal activity in different brain regions and reduction of lyso-

somal storage of G_{M1}. These surprising results were explained by the increased levels of chemokines in specific brain nuclei of the β-gal$^{-/-}$ mice that probably create a microenvironment within the CNS favoring the response to bone marrow–mediated therapy.[165] Indeed, these authors demonstrated that that β-gal–expressing bone marrow–derived monocytes selectively migrate to the CNS under a gradient of chemokines and become a source of enzyme for correction of deficient neurons, thereby resulting in reversion of the enzyme defect and restoration of neurologic function. These findings suggest that a condition such G_{M1}-gangliosidosis, which is characterized by neurodegeneration and neuroinflammation, may influence the response of the CNS to ex vivo gene therapy.[165]

Administration of low-molecular-weight substrate analogues, or chemical chaperones, has also been investigated for the treatment of murine G_{M1}-gangliosidosis.[387] These chemical chaperones act as both in vitro competitive inhibitors and intracellular enhancers by stabilizing the mutant enzyme. The compound *N*-octyl-4-epi-β-valienamine was administered orally to deficient mice expressing the R201C mutant human β-gal and shown to be delivered rapidly to the brain with no adverse effect. Treatment resulted in increased brain activity of β-gal, decreased G_{M1} storage, and prevention of neurologic deterioration during a treatment period of a few months.[387] These studies are supportive of the use of chemical chaperone therapy for G_{M1}-gangliosidosis. SRT has been tested in knockout mice and shown to result in reduced accumulation of GSLs in the cerebrum, brainstem, and cerebellum.[388]

G_{M2}-Gangliosidosis, Sandhoff Variant

The G_{M2}-gangliosidoses consist of a group of six GSL storage diseases that are of interest to the pediatric hematologist because of a mild to moderate degree of visceral involvement seen in one of its variants, Sandhoff's disease. These conditions are caused by impaired degradation of G_{M2}-ganglioside (G_{M2}), a minor brain acidic GSL,[26] as a result of deficiency of one of the isozymes Hex-A or Hex-B or their activator protein G_{M2}A.[389]

The hexosaminidases are two related dimeric enzymes that catalyze the removal of hexoses (both glucose and galactose) from complex molecules in the body, including gangliosides. Hex-A results from the dimerization of one α and one β subunit, whereas Hex-B is made up of two β subunits.[390,391] The Hex-S isozyme consists of an α-subunit homodimer and is thought to catabolize glycosaminoglycans (GAGs). These subunits are coded for by genes located on chromosomes 15 (α subunit) and 5 (β subunit).[390] Both hexosaminidases need the activator protein G_{M2}A to make their liposoluble substrates more accessible.

In the classic and most common form, Tay-Sachs disease, Hex-A is deficient. Hex-A activity is also reduced or absent in the juvenile and adult variants of G_{M2}-

gangliosidosis, the so-called late-onset Tay-Sachs disease. In each of these variants, mutations have been found within the gene encoding the α subunit of this enzyme.[392] A fourth form of the disease known as the B1 variant also results from mutations within the α-subunit gene.[390] However, the Hex-A deficiency in this disorder becomes evident only when the enzyme assay is performed with a sulfated derivative of the artificial compound generally used for determination of Hex-A activity. Patients with the much rarer AB variant lack the G_{M2}A activator. G_{M2} and smaller amounts of its asialo derivative G_{A2} accumulate in the brain and, to a considerably lesser extent, in the visceral organs of patients with each of these diseases. Consequently, the clinical signs in these diseases are confined to the CNS, and obvious infiltration of the reticuloendothelial system has not been noted.

Considerable involvement of extraneural tissues does, however, occur in the Sandhoff variant of G_{M2}-gangliosidosis.[393] Sandhoff provided the first description of this neurodegenerative disorder that bears his name. This variant is due to mutations in the gene encoding the β subunit of hexosaminidase. Both Hex-A and Hex-B contain β subunits, so the activity of both enzymes is lacking in Sandhoff's disease. It is associated with more marked accumulation of G_{A2}-ganglioside in both the brain and viscera than in any of the other variants. In addition, levels of globoside, the major red blood cell glycolipid, are markedly elevated, particularly in the liver, spleen, and kidney.[391] Consequently, signs of involvement of the reticuloendothelial system emerge, including foam cells in the bone marrow and other organs. In all other respects, Sandhoff's disease in an infant is clinically indistinguishable from Tay-Sachs disease.

An infant with Tay-Sachs or Sandhoff's disease may appear normal at birth, but an alert parent or an experienced professional can detect hypotonia and an exaggerated startle response within the first 2 months. Between 3 and 6 months of age, motor weakness and then listlessness become evident. The child may roll from side to side but cannot turn over completely, slumps forward when placed in a sitting position, and cannot crawl or stand. There is poor visual fixation with roving eye movements. Quite early in the course of the disease and definitely by 4 months, a cherry-red spot with a white perimacular halo can be observed in both fundi. Weakness, spasticity, and increased deep tendon reflexes develop, and feeding difficulties with associated gagging become a concern.

At approximately 1 year of age, seizures are first noted, excessive drooling begins, and bouts of unmotivated laughter occur. During the second year, the head begins enlarging disproportionately. The optic discs become pale and atrophic, and cortical blindness ensues. After 2 years of age, there are episodes of autonomic dysfunction with unexplained temperature elevations; spells of rubor, pallor, or cyanosis; and irregular breathing. Although visceral lipid storage occurs in Sandhoff's disease, the liver and spleen are not clinically enlarged, and there are no obvious skeletal changes. Great effort

must be expended to maintain hydration and nutrition, control constipation and seizures, and prevent infection. These children rarely survive beyond 3 or 4 years of age.

Sandhoff's disease can be distinguished from other forms of G_{M2}-gangliosidosis by the presence of foam cells in bone marrow and the total absence of β-N-acetylhexosaminidase in serum, leukocytes, cultured fibroblasts, tears, and urine.[391]

Individuals heterozygous for the gene for Sandhoff's disease can usually be identified by a reduced level of total serum hexosaminidase (A and B forms) and a higher than normal percentage (>70%) of the Hex-S isoform. The same test used to screen for carriers of the Tay-Sachs trait can be used to detect carriers of Sandhoff's disease. No instances of Sandhoff's disease have been recorded in children of Jewish parents, in contrast to Tay-Sachs disease, which until population screening became popular, was seen much more often in the offspring of Ashkenazic Jews.

Molecular Aspects

Recent advances in determining the neuropathophysiologic mechanisms in Sandhoff's disease have been made on the mouse model of this disease.[394-396] Genetically engineered mice with disruption of both Hex-A and Hex-B genes lack both the α and β subunits of hexosaminidase and display a total deficiency of all forms of lysosomal hexosaminidase, including the small amount of Hex-S (α-α homodimer). These mice exhibit the phenotypic, pathologic, and biochemical features of the mucopolysaccharidoses (see later), LSDs caused by the accumulation of GAGs (mucopolysaccharides). The mucopolysaccharidosis phenotype is not seen in the Tay-Sachs or Sandhoff mice disease model or in the corresponding human patients.[391,394,397] These findings demonstrate that GAGs are crucial substrates for β-hexosaminidase and that functional redundancy appears to exist, at least in mice, in the hexosaminidase enzyme system.

As is the case for G_{M1}-gagliosidosis, the pathogenesis of G_{M2}-gangliosidosis relates at least in part to massive accumulation of G_{M2} in the brain and other tissues. In the Sandhoff disease mouse model, abnormal buildup of G_{M2} alters the Vmax of the ER calcium pump, sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase (SERCA), thereby inhibiting calcium uptake into the ER and increasing cytosolic calcium levels.[398,399] Investigators have recently shown a mechanistic link between G_{M2} accumulation, neuronal cell death, reduced activity, and axonal outgrowth in the Sandhoff mice and could demonstrate reversal of these phenotypes in embryonic hippocampal neurons transduced with a bicistronic lentiviral vector (SIV.ASB) encoding both the α and β chains of hexosaminidase. This transfer vector has previously been shown to correct the hexosaminidase deficiency and to reduce G_{M2} levels in both transduced and cross-corrected human Sandhoff fibroblasts. Normal axonal growth

rates were restored, as were the rate of Ca^{2+} uptake via the SERCA and the sensitivity of the neurons to thapsigargin-induced cell death, concomitant with a decrease in G_{M2} and G_{A2} levels. These data demonstrated that the bicistronic vector can reverse the biochemical defects and downstream consequences in Sandhoff neurons, thus reinforcing its potential for in vivo gene treatment of Sandhoff's disease.[399]

Treatment

Currently, no treatment is available for the G_{M2}-gangliosidoses, although recent animal studies involving inhibition of GSL synthesis seem promising.[115] Administration of miglustat to Sandhoff mice has delayed the onset of symptoms and disease progression and significantly increased life expectancy.[400] Combined treatment with miglustat and BMT was found to have a synergistic effect.[182] Based on these preclinical findings, clinical trials of miglustat are currently in progress for patients with late-onset G_{M2}-gangliosidosis. Although BMT has been shown to prolong life and ameliorate neurologic manifestations in animal models,[401] we are not aware of any reports involving human subjects.

Another approach based on the use of cationic liposome-mediated plasmid gene therapy has been evaluated in the Sandhoff mouse model.[402] The mice received a single intravenous injection of two plasmids encoding the human α and β subunits of hexosaminidase. As a result, 10% to 35% of normal levels of hexosaminidase expression, theoretically therapeutic levels, were achieved in most visceral organs, but not in the brain, 3 days after injection, with decreased levels evident by day 7. Histochemical staining confirmed widespread enzyme activity in visceral organs. Both G_{M2} and G_{A2} were reduced by almost 10% and 50%, respectively, on day 3 and by 60% and 70% on day 7 in comparison to untreated age-matched mice. Consistent with the biochemical results, a reduction in G_{M2} was observed in liver cells as well.[378]

Adenovirus-mediated transfer of the β subunit of β-hexosaminidase was shown to restore Hex-A and Hex-B activity after infection of Sandhoff fibroblasts. After direct intracerebral injection of this recombinant adenoviral vector into Sandhoff mice, nearly normal levels of enzymatic activity were demonstrated in the entire brain at the different doses tested. The addition of hyperosmotic concentrations of mannitol to the adenoviral vector resulted in enhanced diffusion of the vector in the injected hemisphere. Although adenoviral-induced lesions were found in brains injected with a high dose of the vector, they were not detected in brains injected with 100-fold lower doses, even in the presence of mannitol, thus suggesting the potential of this approach in achieving efficient vector transduction without viral cytotoxicity.[403] In another recent study, Sandhoff mice were treated by stereotactic intracranial inoculation of recombinant AAV vectors encoding the complementing human β-hexosaminidase α- and β-subunit genes and elements,

including an HIV tat sequence, to enhance protein expression and distribution. The animals survived longer than 1 year with sustained, widespread, and abundant delivery of enzyme to the nervous system. Onset of the disease was delayed with preservation of motor function; inflammation and storage of G_{M2}-ganglioside in the brain and spinal cord were reduced. This study demonstrates that gene delivery of β-Hex-A via AAV vectors has realistic potential for treating the human Tay-Sachs–related diseases.[404]

MUCOPOLYSACCHARIDOSES

The mucopolysaccharidoses are a group of inherited disorders that result from deficiency of one or more of the lysosomal enzymes required for GAG or mucopolysaccharide catabolism. GAGs, which are a major constituent of connective tissue such as cartilage and bone, are long-chain complex carbohydrates that are usually linked to proteins to form proteoglycans, including chondroitin 4-sulfate, chondroitin 6-sulfate, heparan sulfate, dermatan sulfate, keratan sulfate, and hyaluronic acid. Patients with mucopolysaccharidosis typically display coarse facial features, skeletal dysplasia, and limitation of joint motion. These features, which dominate the clinical picture of the mucopolysaccharidoses, set this group of LSDs apart from the glycosphingolipidoses, although overlapping phenotypes are present. The urine of

these patients contains excessive amounts of mucopolysaccharides.[405]

The occurrence of this group of disorders is relatively rare. Nelson[406] in Northern Ireland found an overall incidence of approximately 1 in 25,000 live births, with MPS I occurring in approximately 1 in 76,000 live births. Some of these disorders occur even more rarely. For instance, the incidence of MPS I of the Hurler/Scheie variant is 1 in 280,000. MPS III may be as rare as 1 in 280,000 live births, although the incidence may be underreported. A total of seven variants have been described.

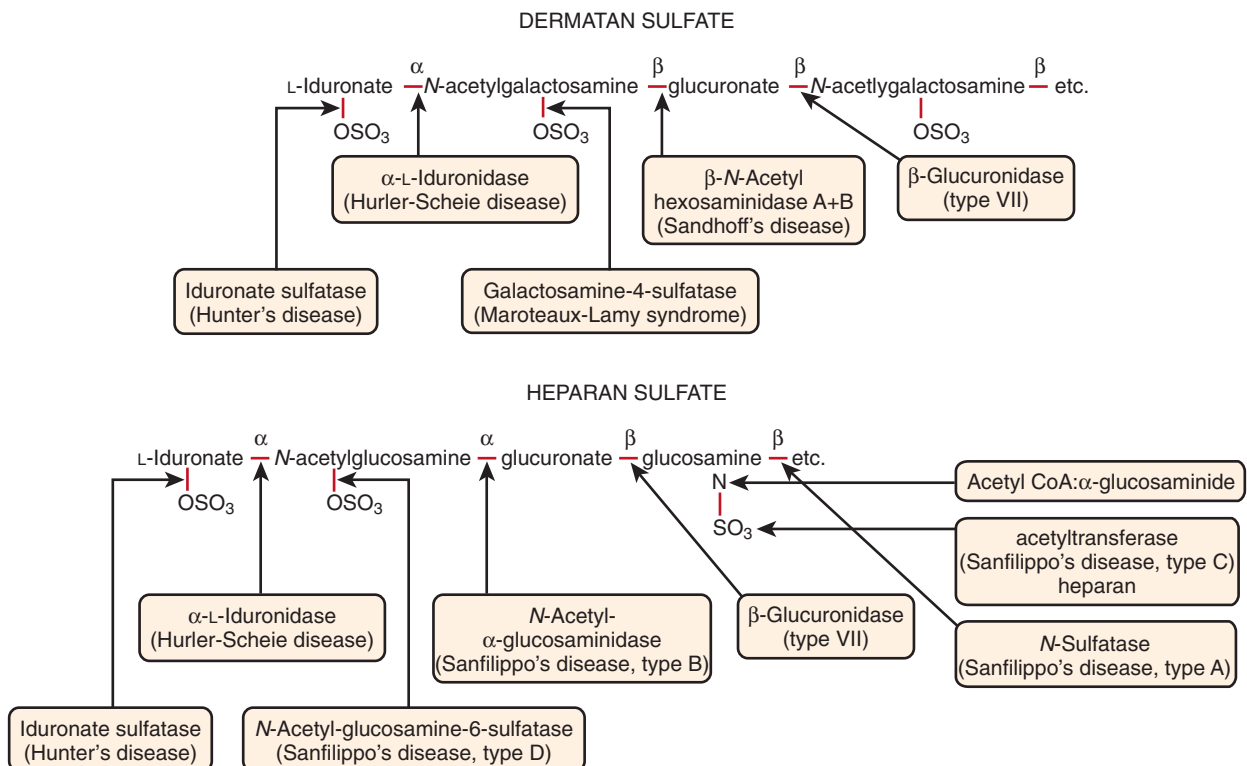
The typical mucopolysaccharide contains a core polypeptide to which a number of polysaccharide chains are attached by a xylose link. Each polysaccharide chain may contain 100 or more sugar residues joined together in repeating disaccharide units consisting of a uronic acid (glucuronic or L-iduronic acid) alternating with a sulfated hexosamine (glucosamine or galactosamine) (Fig. 24-4). The hexosamine in dermatan sulfate is N-acetyl-α-D-galactosamine; in heparan sulfate, it is N-acetyl-α-D-glucosamine. Iduronic acid is occasionally sulfated, but glucuronic acid is not. Fragments from one or both of these mucopolysaccharides accumulate in each of the mucopolysaccharidoses (Table 24-6) because of a block in their sequential hydrolysis as a result of a lysosomal enzyme deficiency (see Fig. 24-4). An exception is Morquio's syndrome, which is characterized by the accumulation of two other mucopolysaccharides, chondroitin 6-sulfate and keratan sulfate, with galactose substituting for the uronic acid moiety (Fig. 24-5).


FIGURE 24-4. Pathways for the enzymatic degradation of dermatan sulfate and heparan sulfate. Deficiencies of each of the enzyme activities shown are correlated with specific mucopolysaccharidoses.

TABLE 24-6   The Mucopolysaccharidoses

Class	Eponym	Enzyme Defect	Urinary Mucopolysaccharides	Mental Retardation	Corneal Clouding	Skeletal Dysplasia	Life Expectancy (yr)
I H	Hurler's disease	α-L-Iduronidase	DS, HS	++	+	+++	<10
I S	Scheie's disease	α-L-Iduronidase	DS, HS	−	+	+	Normal
I H/S	Hurler-Scheie compound	α-L-Iduronidase	DS, HS	+	+	++	20s
II severe	Hunter's disease	Iduronate sulfatase	DS, HS	++	−	++	<15
II mild	Hunter's disease	Iduronate sulfatase	DS, HS	+/−	−	+	Adulthood
IIIA	Sanfilippo's disease	Heparan-N-sulfatase	HS	+++	−	+	<20
IIIB	Sanfilippo's disease	N-Acetyl-α-glucosaminidase	HS	+++	−	+	<20
IIIC	Sanfilippo's disease	Acetyl CoA:α-glucosaminide transferase	HS	++	−	+	Adulthood
IIID	Sanfilippo's disease	N-Acetylglucosamine-6-sulfatase	HS	++	−	+	<20
IVA	Morquio's syndrome	Galactosamine-6-sulfatase	KS, CS	−	+	+++	20-40
IVB	Morquio's syndrome	β-Galactosidase	KS	−	+	+++	20-40
VI	Maroteaux-Lamy syndrome	Galactosamine-4-sulfatase (arylsulfatase B)	DS	−	+	++	20s
VII	Sly's disease	β-Glucuronidase	DS, HS	+	+/−	+	<1-40
Mucosulfatidosis		Multiple sulfatases	DS, HS, Cholesterol S sulfatide	++	−	+	3-12

Cholesterol S, cholesterol sulfate; CS, chondroitin 6-sulfate; DS, dermatan sulfate; HS, heparan sulfate; KS, keratan sulfate.

KERATAN SULFATE

Mucopolysaccharide storage leads to several alterations in cell morphology in blood and bone marrow. Azurophilic granulations are present in polymorphonuclear leukocytes and lymphocytes (Alder-Reilly bodies) (see Fig. 24-1B).[38] Vacuoles with basophilic granulations are also found in circulating lymphocytes, bone marrow reticulocytes (Gasser cells), and bone marrow plasma cells (Buhot cells). Circulating lymphocytes may also contain metachromatic vacuoles without granulation (Mittwoch cells).

Other cells also manifest changes associated with excessive tissue mucopolysaccharide content. Coarse hair and skin, clouding of the cornea, thickening of the leptomeninges with hydrocephalus, alterations in bone architecture, thickening of heart valves, hepatic fibrosis, ballooning of neurons, and infiltration of the reticuloendothelial system by foam cells are some of the changes observed. Progressive narrowing of the trachea in these patients creates difficulty maintaining an adequate airway during and after surgical anesthesia. Operations for median nerve compression related to carpal tunnel syndrome and for compressive myelopathy have been especially useful in patients with normal intelligence. Abnormal binding of elastin to fibroblasts has been reported in MPS I, which could be related to inactivation of molecular chaperons and may somehow be related to the clinical involvement of connective tissue that is so prominent in these diseases.[407,408] In addition, an excess of intracellular amyloid-β peptide (Aβ [1-40]) has been reported in brains from patients with mucopolysaccharidosis, a finding that might help explain part of the CNS involvement that is commonly seen in some of these conditions.[408] The salient clinical and biochemical features of each type of mucopolysaccharidosis are presented in Table 24-6.

Mucopolysaccharidosis Type I (Hurler, Scheie, and Hurler-Scheie Syndromes)

MPS I is one of the most rare of these disorders. There are three variants that differ widely in severity, with Hurler's syndrome being the most severe, Scheie's syndrome the mildest, and Hurler-Scheie syndrome generating an intermediate phenotype.

These three autosomal recessive syndromes result from deficiency of the acid hydrolase α-L-iduronidase (IDUA). The clinical phenotype of type I is a continuum between the severe form, as found in Hurler's syndrome, and a mild form, as seen with Scheie's syndrome.

Infants with the Hurler phenotype usually appear to be normal at birth, although some have inguinal or umbilical hernias. These infants may seem to be unusually large, but by 6 to 18 months of age there is a deceleration in growth and they ultimately become dwarfed. Seven infants with type I were described who initially were seen with acute cardiomyopathy associated with endocardial fibroelastosis.[409,410] The diagnosis is usually made by the age of 6 to 24 months when coarse facial features, corneal opacities, chronic hearing loss, an enlarged tongue, a prominent forehead, hepatosplenomegaly, skeletal deformities, and joint stiffness become evident. Some may have glaucoma,[411] and communicating hydrocephalus with increased intracranial pressure develops. These children are severely developmentally delayed with limited language skills. They often have recurring upper respiratory tract and ear infections, stertorous breathing, and persistent rhinorrhea.

Skull radiographs may demonstrate a large thickened calvaria, premature closure of the sutures, poorly developed sinuses, shallow orbits, and a J-shaped sella turcica. Other radiologic signs include oar-shaped ribs, rounding

and anterior beaking of the vertebrae, anterior hypoplasia of the lumbar vertebrae with kyphosis, and shortening of the metacarpals and phalanges. These skeletal abnormalities are known as dysostosis multiplex. Death usually occurs by 10 years of age. Cardiac disease with valvular involvement and cardiomegaly develops and contributes to the premature death of these patients. Other causes of death are obstructive airway disease and respiratory infections.

Patients with Hurler-Scheie syndrome are usually seen between the ages of 3 and 8 years with progressive corneal clouding, deafness, hepatosplenomegaly, joint stiffness, valvular heart disease, and dysostosis multiplex. They are less retarded, and some have nearly normal intellect. A receding chin and arachnoid cyst formation in the region of the sella turcica have been reported in several of these patients. GAGs may be deposited on the cervical dura (pachymeningitis cervicalis) and result in myelopathy. These patients may live well into their 20s; however, cardiac involvement and upper airway obstruction can result in early death.[405]

Scheie's syndrome is less common than Hurler's syndrome. Patients are generally seen after 5 years of age with joint stiffness and clawhand and clawfoot deformities. Intelligence and height are normal. These patients survive well into adulthood. They eventually suffer from visual disturbances such as glaucoma and retinal degeneration, in addition to the corneal opacities. Some patients have hearing loss. Aortic valvular disease may develop, and their facial features eventually become coarse. Sleep apnea can occur and is usually relieved with a tracheostomy. Classification in some patients may be rather difficult because there can be overlapping symptoms among the three phenotypes.[405]

Distinction among these three clinical phenotypes cannot be made by routine biochemical analysis. Most patients are subclassified solely on a clinical basis. Large amounts of partially degraded heparan sulfate and dermatan sulfate are stored and excreted in all three conditions. However, heparan sulfate is excreted in greater amounts in patients with Hurler's syndrome than in those with the Scheie and Hurler-Scheie syndromes.[412] Diagnosis of these syndromes plus detection of carriers is ultimately achieved by the demonstration of markedly reduced IDUA activity in cultured fibroblasts, leukocytes, plasma, or serum. Chromogenic (*p*-nitrophenyl) or fluorogenic (4-methylumbelliferyl) derivatives are commonly used as substrates in these assays. However, with desulfated heparan as the sulfate, enzymatic differences can be demonstrated in the different clinical phenotypes. Fibroblasts of patients with Hurler's disease cannot degrade this substrate, whereas this same substrate is effectively hydrolyzed by cells from patients with Hurler-Scheie and Scheie's disease.

The gene for IDUA has been localized to chromosome 4p16.3. Of the more than 30 mutations thus far described, most have been associated with the Hurler phenotype.[413,414] The two most common mutations,

Q70X and W402X, result in chain termination of the α-iduronidase protein and are therefore associated with a severe form of Hurler's disease. A recently described mutation (P533R) seems to be common in northern Africa.[415] Although most occurrences of the Hurler-Scheie phenotype are due to compound heterozygosity for two different mutant alleles, some patients have been reported with homozygosity for a single mutation.[414] Prenatal diagnosis has been successfully performed.[416] The biochemical diagnosis can also be confirmed by measuring deficient IDUA levels on filter paper obtained at birth during routine neonatal screening.[417]

Treatment

Successful engraftment after BMT has resulted in overall improvement of the facial features typically seen in patients with Hurler's syndrome. Urinary GAG excretion has returned to normal, metachromatic inclusions have disappeared, and clearing of lysosomal inclusions in the liver and improvement in corneal clouding have also been noted.[121] The skeletal anomalies are not reversed, except perhaps odontoid dysplasia.[418] Hydrocephalus does not appear to resolve, nor does it develop after BMT. Factors affecting the outcome include the child's age at the time of transplantation, the clinical phenotype, the defined genotype,[419] and the donor type.

Based on promising results of trials of ERT in animal models of MPS I,[420,421] clinical trials were performed in selected patients. Phase III clinical trials of recombinant IDUA therapy have been performed in patients with the Hurler/Scheie variant of MPS I.[102] Marked reductions in liver and spleen size were reported, together with improved joint range of motion and exercise tolerance. Moreover, there was a clear decrease in the amount of GAGs in the urine of these patients. Phase I/II and phase III clinical trials have recently been conducted and have demonstrated that this therapy is effective in treating patients with the attenuated forms of MPS I (i.e., little or no neuronal involvement).[422] A mild degree of humoral hypersensitivity reaction developed in about 50% of the patients, but almost all were managed conservatively, and the reactions eventually disappeared despite continuous exposure to the enzyme.

Gene therapy by means of AAV vectors containing human cDNA for IDUA has resulted in enzymatic correction and cellular cross-correction of affected cells.[423] In contrast to intravenous administration,[424] intrathecal injection of AAV vectors carrying the IDUA sequence into cerebrospinal fluid was reported.[425] This procedure was successful in restoring enzyme activity in the brain. In general, IDUA activity correlated with vector dose. High doses of vector resulted in enzyme levels close to normal in the brain. Histopathologic analysis revealed that the number of cells with storage vacuoles was reduced. Thus far, no human trials have been reported with this approach in MPS I.

Finally, the finding that treatment of human cells carrying stop codon mutations in the IDUA gene with

gentamicin increases protein production has led to the proposal of a novel therapeutic approach. This antibiotic suppresses stop mutations within certain genes, and therefore it would be expected that protein production could be restored to a certain extent. At least in morphologic studies of such cells, lysosomal accumulation of mucopolysaccharides was quickly reduced after treatment with this substance.[426] Enhanced stop codon readthrough will be a potential treatment strategy for a large subgroup of MPS I patients.

Mucopolysaccharidosis Type II (Hunter's Syndrome)

Hunter's syndrome is an X-linked recessive disorder that has a broad spectrum of clinical phenotypes ranging from a mild to a severe form. All forms of the syndrome result from a deficiency of the lysosomal enzyme iduronate-2-sulfatase (IDS). The severe type has many features similar to those of Hurler's syndrome. These patients are characteristically seen between 2 and 4 years of age with coarse facial features, progressive mental retardation, progressive deafness, short stature, dysostosis multiplex, stiff joints, and hepatosplenomegaly. Atypical retinitis pigmentosa or retinal degeneration may occur, but unlike patients with Hurler's syndrome, the corneas remain clear. These patients are hirsute and may have white nodular skin lesions on the posterior of the thorax and upper part of the arms. Cardiac involvement is also common and may be manifested as aortic valve stenosis or mitral insufficiency, which could be severe and life threatening. Isolated mitral valve prolapse has also been reported.[427] The presence or absence of these lesions does not necessarily correlate with the severity of the disease. Survival beyond adolescence is rare.

In the mild form of Hunter's syndrome, minimal to no CNS involvement is characteristically seen, and patients survive into adult life. Some of the somatic features described in the severe form of Hunter's syndrome also develop in these patients, but at a slower rate of progression. Hearing impairment, carpal tunnel syndrome, joint stiffness, degenerative arthritis of the hips, heart disease, and hepatosplenomegaly may occur. Older adult patients have rosy cheeks and a hoarse voice.

The human *IDS* gene has been isolated, cloned, and sequenced.[428] It is a large gene that spans about 24 kb and contains nine exons. It is located on the Xq27-28 boundary.[429] Because IDS is deficient in all forms of Hunter's disease, it has been difficult to distinguish the clinical phenotypes biochemically. The clinical heterogeneity is believed to be a result of the different mutations found on the *IDS* gene. Thus far, 319 mutations have been described, including deletions, major rearrangements, and missense and nonsense point mutations (Human Gene Mutation Database).[86,430] In some very severe cases with unusual features, complete deficiency of the gene may be associated with loss of adjacent loci, suggestive of a contiguous gene syndrome. Mutation analysis may help identify the various forms of Hunter's disease. A 140-kb pseudogene-like structure (*IDS2* gene) has been identified that is 20 kb distal to the active *IDS* gene.[431] The protein that it codes is identical to IDS except for absence of the 207–amino acid carboxyl-terminal domain.[432] Further studies will probably clarify its contribution to the clinical heterogeneity seen in Hunter's syndrome.

The diagnosis of Hunter's syndrome is occasionally considered in females with deficiency of IDS. However, on further study, some of these patients have been determined to have mucosulfatidosis (multiple sulfatase deficiency). One female patient with Hunter's disease was found to have a mutation on the paternal IDS locus that resulted in both a deficiency of IDS and inactivation of the maternal, structurally normal X chromosome.[433] Determination of heterozygosity is valid only when enzyme activity is reduced to levels less than 50% of normal. Normal levels of IDS activity in females with relatives who have Hunter's syndrome do not rule out heterozygosity. One method for carrier diagnosis uses [35]S-labeled sulfate incorporated into fibroblasts in the presence of fructose 1-phosphate. In the cell population, uptake of IDS produced by the normal cells in culture is prevented, and [35]S-labeled acid mucopolysaccharide therefore accumulates.[434]

Prenatal diagnosis has been accomplished with specimens from a variety of sources, including chorionic villi[435] and fetal plasma.[436]

Treatment

At present, the therapeutic approaches for MPS II are ERT and BMT, although these therapies have some limitations. Successful transfection of affected human cells has been achieved with specially designed retroviral vectors, which led to an increase in enzymatic activity of up to 49%.[437] A phase II/III clinical study of ERT was reported.[438] Although recombinant human IDS (idursulfase) was generally well tolerated, antibodies against the recombinant enzyme were found in almost 50% of patients during the study. Recently, an approach to gene therapy involving the use of AAV vectors for the treatment of MPS II in mice has been described. Viral particles were administrated to adult mice with MPS II.[439] IDS activity was completely restored in the plasma and tissue of all the treated mice and resulted in complete clearance of the accumulated GAGs in all tissues analyzed, normalization of GAG levels in urine, and correction of the skeletal abnormalities. These results suggest that this approach could be promising for the systemic treatment of patients with Hunter's syndrome.

Mucopolysaccharidosis Type III (Sanfilippo's Syndrome Types A, B, C, and D)

Patients with Sanfilippo's syndrome characteristically have progressive CNS disease but only mild physical

stigmata typically associated with the mucopolysaccharidoses. This feature makes Sanfilippo's disease a very difficult entity to diagnose unless a high level of suspicion exists. In fact, it has been suggested that MPS III is probably more common than expected in institutions for the mentally handicapped. The mental retardation is usually extreme, although survival to adulthood is possible. Affected children are typically seen between 2 and 6 years of age with delayed development, marked hyperactivity with aggressive behavior, sleep disorders, and hirsutism. Joint stiffness and, in some patients, mild hepatosplenomegaly and hearing loss may be present. There is minimal skeletal involvement with mild dysostosis multiplex and usually normal stature for age. Radiologic signs include thickening of the calvaria and a biconvex configuration of the dorsolumbar vertebral bodies. The diagnosis may be delayed in these patients because of the mild somatic and radiographic features and a high incidence of false-negative results in the urinary screening test for mucopolysaccharides. Corneal opacities are absent.[405]

It is not clear why the selective CNS degeneration occurs in this variant of mucopolysaccharidosis. Recent studies have suggested that in addition to abnormal accumulation of mucopolysaccharide, excessive GSL deposits are also present.[440,441] G_{M3}, G_{D3}, and lactosyl ceramide were the principal GSLs accumulated in MPS IIID caprine brain specimens. These changes were attributed, in part, to the reduction in sialidase and UDP-N-acetylgalactosamine: G_{M3} N-acetylgalactosaminyltransferase (GalNAc-T) activities in MPS IIID caprine brain. Pathologic accumulation of subunit c of mitochondrial ATP synthase has been identified in the neuronal lysosomes of the MPS IIIB mouse model.[442]

All patients with Sanfilippo's syndrome seem to conform to a single phenotype, yet four forms can be distinguished enzymatically; all of them are transmitted in an autosomal recessive fashion. In the type A variant, an N-sulfatase also known as sulfamidase (heparan-N-sulfatase) is deficient. Its gene localizes to chromosome 17q25.3,[443] and about 62 different mutations have been described.[444]

The other variants are caused by deficiencies in O-sulfatases. In the type B variant, an α-N-acetylglucosaminidase is absent. This variant is particularly important in Sanfilippo's disease because a murine model is available and trials of ERT have been attempted with promising results.[445] Recently, the gene for the type C variant has been discovered, an acetyl coenzyme A (CoA)/acetyltransferase. It is a transmembrane protein 76 gene (*TMEM76*) that encodes a 73-kd protein with predicted multiple transmembrane domains and glycosylation sites.[446] In the type D variant, the deficient enzyme is N-acetylglucosaminide-6-sulfatase.

Although the type A variant can cause the most severe effects of the four variants, with an earlier onset, rapid progression of symptoms, and shorter survival, patients with mild disease have been reported.[447] Type B

is believed to have milder features, whereas type C may be intermediate between types A and B. Overall, the ultimate factor differentiating among the variants is biochemical analysis. Carriers of these diseases can be distinguished by enzyme assay, and prevention of each type is possible through prenatal diagnosis.

Treatment

Different therapeutic approaches have been tested in the animal models available for MPS III. MPS IIIA mice treated at birth with recombinant sulfamidase demonstrated a reduction in storage material in cells of the CNS and general improvement in body weight, behavior, and ability to learn.[448] In another trial, injection of recombinant human sulfamidase into cerebrospinal fluid via the cisterna magna in the CNS was shown to reduce lysosomal storage in different neural cells. An immune response to the recombinant protein was observed.[449] A substrate inhibitor, rhodamine B, has been shown to suppress GAG chain synthesis by inhibiting the formation of sugar precursors or the activity of glycosyltransferases, or both. Use of rhodamine B has been shown to diminish visceral symptoms and improve the behavioral aspects of murine MPS IIIA without causing any apparent side effects.[450] A gene therapy approach involving intraventricular injection of recombinant AAV in a mouse model of MPS IIIA was recently reported. Treatment with a recombinant AAV vector resulted in a visible reduction in lysosomal storage and inflammatory markers in transduced brain regions in the treated animals and general improvement in both motor and cognitive function. These results suggest that early treatment of CNS lesions by AAV-mediated intraventricular injection may be a feasible therapy for MPS IIIA.[451]

Gene therapy with genetically modified bone marrow transduced with human NAGLU cDNA in a mouse knockout model for MPS IIIB showed that genetically modified cells of hematopoietic origin can reduce the pathologic manifestations of MPS IIIB.[452] Transplanted human umbilical cord blood was used in another therapeutic approach and demonstrated that umbilical cord blood cells are able to survive long-term, migrate into the CNS and peripheral organs, and reduce GAGs in the livers of treated mutant mice.[453] A combined approach involving intravenous and intracisternal injection was used to achieve CNS delivery of an AAV vector for treating MPS IIIB in young adult mice. This treatment resulted in a significantly prolonged life span of the treated mice and variable correction of lysosomal storage pathology in the CNS and different visceral organs.[453]

Lentiviral-mediated gene transfer via systemic injections has been tested on an MPS IIIB mouse model. Long-term analysis has demonstrated that integration of the viral genome persists in target tissues and is accompanied by a decrease in GAG levels in several visceral tissues.[180]

Finally, a spontaneous caprine model for MPS IIID was used to evaluate the potential efficacy of ERT.

Recombinant caprine enzyme was administered systemically to one MPS IIID goat kid at different weeks of age. A significant reduction in lysosomal storage material in the hepatic cells of the treated animal was detected, but ERT had no effect on the CNS lesions.[455]

Mucopolysaccharidosis Type IV (Morquio's Syndrome [Types IVA and IVB])

Children with Morquio's syndrome usually have normal intelligence and a generalized skeletal dysplasia. MPS IVA and IVB result from two different enzyme deficiencies. MPS IVA is associated with a deficiency of the lysosomal enzyme *N*-acetylgalactosamine-6-sulfatase (GALNS, galactosamine-6-sulfatase), whereas MPS IVB is caused by a deficiency of lysosomal β-gal (see "G_{M1}-Gangliosidosis" earlier). Both variants result in a defect in the degradation of keratan sulfate. Therefore, excessive keratan sulfate is excreted in the urine of the patients.

Based on age at onset and severity of the bone dysplasia, type A is subdivided into three clinical subtypes (severe, intermediate, and mild forms). In the severe form, skeletal deformities begin to appear between 1 and 2 years of age. These children have a short neck and trunk, a prominent sternum, kyphosis, a waddling gait, bowed knees, and excessive excretion of keratan sulfate and chondroitin 6-sulfate. Absence or severe hypoplasia of the odontoid process of the second cervical vertebra results in atlantoaxial subluxation and subsequent cervical myelopathy. The maxilla is broad, and the dental enamel is abnormally thin. The joints are loose and hypermobile. The facial features become coarse, and deafness and mild corneal clouding develop. The major medical problem in adult life is cardiorespiratory insufficiency secondary to valvular heart disease and restrictions in size and motion of the thoracic cage.

In the mild phenotypic form, the disease progresses slowly, and patients are less severely affected. The broad spectrum of clinical phenotypes seen in MPS IVA correlates with different mutations of the *GALNS* gene, localized to chromosome 16q24.[456-458] Specific DNA analysis and polymorphic markers for carrier detection and prenatal diagnosis are available for families at risk for the disease.[459]

MPS IVB was initially thought to be a mild form of Morquio's syndrome because the symptoms were less pronounced than those in MPS IVA. However, ensuing reports have described patients with MPS IVB whose clinical symptoms were as severe as those seen in the severe form of MPS IVA.[460,461] Children with MPS IVB demonstrate a variety of bone and connective tissue abnormalities without major neurologic impairment. A variety of mutations of the *GLB1* gene have been found to cause different phenotypic expressions. Some mutations may affect the catabolism of both G_{M1} and keratan sulfate and cause a phenotype overlapping between that of G_{M1}-gangliosidosis and Morquio IVB, with both neurologic and skeletal manifestations.[462,463] Other amino acid changes only impair the activity of β-gal toward keratan sulfate. However, as discussed earlier, the β-gal precursor mRNA can give rise to an alternative spliced transcript that encodes EBP.[349] Mutations that affect both β-gal and EBP are believed to cause abnormal elastin fiber assembly and deposition in the extracellular matrix and to worsen the connective tissue and bone abnormalities characteristic of this disease.

Treatment

Except for management of its skeletal and spinal complications, no therapy is available for this condition.

Mucopolysaccharidosis Type VI (Maroteaux-Lamy Syndrome)

MPS VI is a clinically heterogeneous syndrome with severe, intermediate, and mild forms. Many of the signs and symptoms of Hurler's syndrome are also present in children with Maroteaux-Lamy syndrome, including short stature, clawhand deformities, coarse facies, umbilical or inguinal hernias, marked corneal clouding, and deafness. Sleep apnea may occur. These children may require shunting for progressive hydrocephalus. Contractions of the knees, hips, and elbows cause the children to assume a crouched stance. Involvement of the heart valves with associated murmurs and heart disease is common. Acute infantile cardiomyopathy has been reported as an initial symptom in Maroteaux-Lamy syndrome.[464] The preservation of intellect in this syndrome clearly differentiates it from Hurler's syndrome. Like Morquio's syndrome, there is hypoplasia of the odontoid process with subluxation of the C1 vertebra onto C2. Diffuse thickening of the dura and ligaments covering the spinal cord can cause chronic nerve root entrapment and myelopathy and necessitate laminectomy and opening of the dural sac.[465] Female patients with the mild variant require cesarean section to deliver a child because of involvement of their pelvic ligaments in the disease process.

Leukocytes from patients with Maroteaux-Lamy syndrome present a more striking picture of metachromatic inclusions than do leukocytes in most other mucopolysaccharidoses.

The lysosomal enzyme arylsulfatase B (ARSB, galactosamine-4-sulfatase) is deficient in this syndrome. Deficiency of the enzyme results in the accumulation of dermatan sulfate in tissues, primarily connective tissue, and in reticuloendothelial lysosomes and urine. The *ARSB* gene has been sequenced and cloned, and many mutations have been identified, with some exhibiting genotype/phenotype correlation.[466] Mutation analysis has demonstrated broad molecular heterogeneity in this syndrome, which should be expected because of the associated clinical heterogeneity.[467]

Treatment

BMT in several patients resulted in restitution of ARSB levels in both circulating leukocytes and the liver. At 1 to 9 years of follow-up, clinical improvement with regression of hepatosplenomegaly and improved joint mobility was noted. This treatment has been shown to prolong survival and improve quality of life.[139]

ERT with the recombinant product has been successfully attempted in the feline model of this condition,[103] and phase I and II human clinical trials are currently under study.* On the basis of the phase I/II results, a phase II study in patients with severe disease was initiated primarily to evaluate efficacy. ERT was shown to improve mobility and joint function and reduce urinary excretion of GAGs.[468] Cultured fibroblast ARSB mutant protein and residual activity were determined for each patient and, together with genotype information, used to predict the expected clinical severity of each patient.[469]

Gene therapy has also been attempted in the same feline animal model.[470] After gene transfer, muscle or liver can theoretically be converted into factories for systemic secretion of ARSB, thereby leading to uptake by nontransduced cells. In a recent study, newborn MPS VI rats and cats were injected with AAV vectors expressing ARSB under the control of liver-specific, muscle-specific, or universally active promoters. Systemic or intramuscular injection of AAV resulted in curative levels of ARSB that improved the skeletal abnormalities and significantly reduced GAG storage, inflammation, and apoptosis. This study suggests that AAV-mediated expression of ARSB from the liver could represent a potential therapeutic approach for MPS VI.[471]

Mucopolysaccharidosis Type VII (Sly's Syndrome)

More than 30 cases of mucopolysaccharidosis with β-glucuronidase deficiency have been observed since the publication of Sly and colleagues' original case report in 1973.[472] The clinical manifestation, however, has been quite varied. The original patient exhibited slowing of development at 2 to 3 years of age, coarse facial features, anterior chest deformity, hepatosplenomegaly, bilateral inguinal hernias, and clear corneas. He died at 19 years of age. At the time of his death he had dysostosis multiplex and extensive cardiovascular lesions, including arterial stenosis and marked fibrous thickening of the atrioventricular and aortic valves. There were only trace amounts of β-glucuronidase in multiple tissues postmortem. Various tissues demonstrated accumulation of chondroitin 4- and 6-sulfate.[473]

Other patients have had onset in infancy, clouding of the corneas, and dysostosis multiplex. Hydrops fetalis

was described in two infants; one died less than an hour after delivery and the other died at 6 months of age.[474] Patients with onset after 4 or 5 years of age are less likely to have cloudy corneas, pectus carinatum, hernia, short stature, or developmental delay.[475] Characteristics common to all patients with this syndrome are recurrent bouts of pneumonia during infancy and the abundant coarse granulations characteristic of Alder-Reilly bodies in their granulocytes. The excessive excretion of mucopolysaccharides may not be present in some patients.[476]

The gene encoding β-glucuronidase (*GUSB*)[477] has been localized to chromosome 7q21.1-q22.[478] Mutational analysis of the original patient with Sly's syndrome demonstrated a compound heterozygote with a missense mutation in exon 12 and a nonsense mutation in exon 7. Several other mutations have been described, among them the A354V and R611W substitutions identified in the first reported occurrence of nonimmune hydropic MPS VII.[479] These mutations correlate with the severe form of the syndrome. Prenatal diagnosis is available with chorionic villus and amniotic fluid sampling.[480]

Treatment

Naturally occurring dog and mouse models of β-glucuronidase deficiency were identified in the eighties.[481,482] Because the clinical manifestations are quite similar to the corresponding human conditions, these animals, in particular the mouse model, have been extensively exploited for testing numerous therapeutic protocols, including BMT, ERT, and ex vivo and in vivo gene therapy.[405] Neural progenitor cells have been transplanted into the CNS of newborn mice with the enzyme deficiency. β-Glucuronidase activity was found to be expressed along the entire neuraxis, which resulted in correction of the storage disease in the neurons and glia of the affected mice.[483] BMT has also been attempted in the mouse with some success.[484] ERT studies in the mouse model suggested that therapeutic enzyme can be delivered across the blood-brain barrier in adult mice if administered at higher doses than conventionally used in ERT trials.[485] A gene therapy study involving a murine model of MPS VII has been reported. Injection of AAV vectors containing β-glucuronidase into different regions of the brain was able to correct LSDs. The treated MPS VII mice showed improvement in spatial learning and memory, thus suggesting that this therapy could be effective in curing the CNS pathology.[486]

Mucosulfatidosis (Multiple Sulfatase Deficiency)

The clinical phenotype of patients with mucosulfatidosis (multiple sulfatase deficiency) combines the features of late infantile metachromatic leukodystrophy with those of a mucopolysaccharidosis.[487] Metachromatic leukodystrophy alone does not affect the reticuloendothelial system. It results from failure to degrade cerebroside

---

*Kakkis E: Personal communication, BioMarin Corp.

sulfate because of deficiency of arylsulfatase A. Metachromatic leukodystrophy leads to widespread degeneration of both central and peripheral myelin and subsequent spastic tetraparesis, blindness, peripheral neuropathy, and an elevation in cerebrospinal fluid protein content.

Neonatal, late infantile, and juvenile forms of multiple sulfatase deficiency have been described. In the early-onset form, facial dysmorphism, a short neck, hepatomegaly, vertebral hypoplasia, and epiphyseal dysplasia are present from birth. The early development of children with the late infantile form is usually less advanced than that of children with late infantile metachromatic leukodystrophy. The child may learn to sit and stand but does not develop speech and regresses after the second year, with previously acquired skills being lost. The forehead is prominent and the nasal bridge flattened. There may be an excessive startle reaction, spasticity, and extensor plantar responses. Seizures eventually appear. Hepatosplenomegaly has been reported in some patients. Many have had ichthyosis. The corneas are clear, and the maculae are abnormally gray. The skeletal changes are similar to those found in the mucopolysaccharidoses and include lumbar kyphosis, a prominent sternum, broad phalanges, and a J-shaped sella turcica. A less severe form beginning after 5 years of age with survival into the third decade has also been described.

A child with multiple sulfatase deficiency accumulates not only cerebroside sulfate but also cholesterol sulfate and sulfated mucopolysaccharides because of deficiencies of 17 different sulfatases, including arylsulfatases A and B, steroid sulfatase, heparan-*N*-sulfatase, iduronate sulfatase, and galactosamine-6-sulfatase. In tissue culture, these deficiencies can be partially corrected by maintaining the cells in a medium at high pH (pH 7.4) or by the addition of sodium thiosulfate. Laboratory tests for this disease should include a search for Alder-Reilly bodies in circulating granulocytes and bone marrow, a Berry spot test for mucopolysacchariduria, and determination of arylsulfatase A and B activity in leukocytes. Prenatal diagnosis may be achieved by chorionic villus sampling and detection of specific mutant alleles.[488]

In two of the sulfatases, structural analysis has indicated that in place of a cysteine residue normally expected on the basis of their cDNA sequence, a 2-amino-3-oxopropionic acid residue appears. However, in the sulfatases derived from cells with multiple sulfatase deficiency, the cysteine residue is retained. This suggests that the defect in multiple sulfatase deficiency is failure of the cotranslational or post-translational conversion of a cysteine to 2-amino-3-oxopropionic acid or α-formylglycine.[489] The gene mutated in multiple sulfatase deficiency has been identified by different approachs[490,491] and has been named sulfatase-modifying factor 1 (*SUMF1*). SUMF1 is responsible for conversion of the cysteine residue located in the active site of all the sulfatases to α-formylglycine. Recently, a mouse line carrying a mouse model for multiple sulfatase deficiency has been generated. Similar to patients with multiple sulfatase deficiency, the mouse model deficient in Sumf1 displays frequent early mortality, congenital growth retardation, skeletal abnormalities, and neurologic defects.[492]

GLYCOPROTEINOSES AND MUCOLIPIDOSES

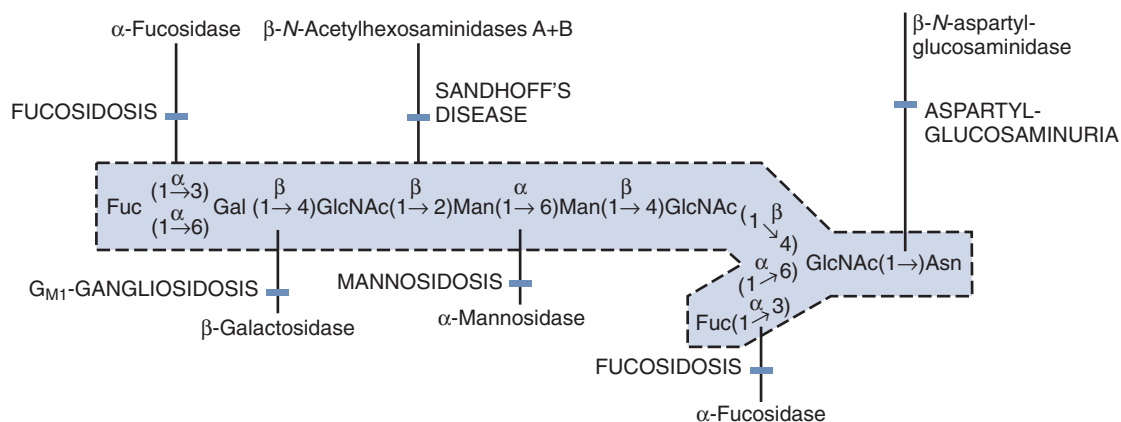
In 1970, Spranger and Wiedemann[493] established a new category of storage diseases for patients who exhibited the clinical features of Hurler's disease (the so-called "mucopolysaccharidosis phenotype") without an excess of urinary mucopolysaccharides. The term *mucolipidosis* was selected to indicate the coexistence in these patients of signs and symptoms typical of both the mucopolysaccharidoses and the sphingolipidoses. Although excretion of mucopolysaccharides is not seen, the urine of these patients contains large quantities of oligosaccharides identical in structure to the carbohydrate side chains in glycoproteins. Therefore, the name glycoproteinoses more appropriately refers to this group of LSDs, whose common hallmark is the genetic defect of a lysosomal protein involved in the catabolic pathway of glycoproteins (Fig. 24-6; also see Table 24-4). The deficient protein may be a glycosidase, a protease, or a lysosomal mem-


FIGURE 24-6. Fucosyloligosaccharide unit of a hypothetical glycoprotein indicating the sites of catabolic block in fucosidosis, G_{M1}-gangliosidosis, Sandhoff's disease, mannosidosis, and aspartylglucosaminuria. Asn, asparagine; Fuc, fucose; Gal, galactose; GlcNAc, *N*-acetylglucosamine; Man, mannose.

brane carrier that expels catabolic products into the cytosol. Degradation of glycoproteins begins with the action of exoglycosidases, which degrade the glycan portion of these substrates in a stepwise manner starting at their nonreducing end. The lack of a single enzyme leads to complete blockage of the catabolic chain and results in the accumulation of undegraded oligosaccharides and glycopeptides in lysosomes. Elevated urinary excretion of oligosaccharides is also diagnostic of these diseases.[494] The oligosaccharides are of two types: sialyloligosaccharides and neutral oligosaccharides.

High sialyloligosaccharide concentrations correlate with a primary or secondary deficiency of the acid lysosomal neuraminidase 1 (NEU1, sialidase), which is associated with sialidosis and galactosialidosis, two autosomal recessive LSDs primarily affecting the reticuloendothelial system.[495,496] The early infantile variant of sialidosis was known as mucolipidosis I in the past. Similar findings occur secondarily in mucolipidosis II and III. In these LSDs, which are two phenotypic variants of the same enzyme deficiency, the primary defect is in posttranslational modification of the carbohydrate unit that is common to most lysosomal enzymes (i.e., the M6P recognition marker). This is required for uptake of these enzymes from the cell surface. The latter is not formed because of a deficiency of *N*-acetylglucosamine phosphotransferase, and consequently the intracellular content of several soluble lysosomal enzymes (including neuraminidase) is reduced.

Laboratory screening for these diseases is accomplished by thin-layer chromatographic analysis of urine for oligosaccharides and sialyloligosaccharides and by quantitation of free sialic acid in urine.[67] In these conditions, mucopolysaccharides are not present in excess in the urine. On the basis of these tests, the activities of the relevant lysosomal enzymes are then examined in leukocytes or fibroblasts.

Sialidosis

Sialidosis (formerly mucolipidosis I) is caused by deficiency of NEU1 (sialidase).[496] The enzyme is encoded by the NEU1 gene on chromosome 6p21.3 and is genomically positioned inside the major histocompatibility complex.[497] In mammalian tissues, three additional neuraminidases—NEU2, NEU3, and NEU4—have been identified that differ in their subcellular distributions, pH optimum, kinetic properties, response to ions and detergents, and substrate specificity.[498,499] Of the four, only NEU1 is expressed in all tissues, albeit at different levels,[500,501] and is the only mammalian sialidase that is clinically relevant. The importance of these enzymes in normal cellular physiology is illustrated by the numerous metabolic processes that they control, including cellular proliferation and differentiation, cell adhesion, membrane fusion and fluidity, immunocyte function, and receptor modification.[499]

NEU1 initiates the intralysosomal hydrolysis of sialo-oligosaccharides and sialoglycoproteins by removing their terminal sialic acid residues. In both human and murine tissue, lysosomal neuraminidase forms a complex with at least two other proteins, β-gal and the protective protein/cathepsin A (PPCA).[495,502] By virtue of their association with PPCA, NEU1 and β-gal acquire their active and stable conformation in lysosomes. However, NEU1 strictly depends on PPCA for correct compartmentalization in lysosomes, which makes it unique among other mammalian sialidases. This is because the protein is poorly mannose-6-phosphorylated and requires PPCA for transport through the biosynthetic pathway and to remain catalytically active once in lysosomes.[503] Thus, PPCA appears to function as a chaperone/transport protein that is crucial to NEU1 both in route to and within the lysosome. Only a small amount of PPCA and β-gal activity is consistently found in the NEU1/PPCA/β-gal complex, which contains all of the neuraminidase activity. This finding further supports the notion that NEU1 is not active outside the protein complex.

Genetic evidence of the dependence of NEU1 on its interaction with PPCA to remain catalytically active is illustrated by the LSD galactosialidosis (discussed later). The latter condition is caused by a primary defect in the PPCA gene, but the clinical manifestations in patients are mostly attributed to the secondary deficiencies of NEU1 and β-gal. Therefore, sialidosis and galactosialidosis patients share many of their clinical and biochemical features. However, differences in onset, severity, and range of symptoms are associated with both diseases.

In addition to its known lysosomal activity, NEU1 may be involved in releasing sialic acids from cell surface glycoconjugates of neutrophils and monocytes during inflammatory or immune responses, as indicated by increasing evidence.[504,505] NEU1 may also regulate sialylation at the surface of immature thymocytes and, in turn, control T-cell response during development and differentiation.[506] Thus, NEU1 has a potential role in processes that influence the functional capacity of cells in the hematopoietic and immune systems.

Correct diagnosis of either sialidosis or galactosialidosis can be achieved by measuring the catalytic activity of cathepsin A, NEU1, and β-gal. To date, more than 20 unique mutations have been identified, most of which are missense mutations that result in single amino acid substitutions and involve conserved amino acids or are located within conserved regions of the enzyme.[497,507-512]

Sialidosis Type I (Normomorphic Sialidosis, Cherry-Red Spot/Myoclonus Syndrome)

Type I sialidosis is also referred to as "cherry-red spot–myoclonus" syndrome and is the attenuated form of this disease. Generally, patients have no obvious physical features, and their intelligence is normal or only slightly impaired. The disease is recognized in the second or third decade of life with the onset of gait abnormalities, decreased visual acuity, or both.[513-517] The visual loss is

progressive and associated with bilateral macular cherry-red spots that may fade later in the course of the disease. In some patients, small punctate opacities occur in the lens.

The most striking clinical feature is myoclonus, which may be precipitated by voluntary movements, the thought of movement, passive joint movements, or light touch or sound stimuli. Initially there are intention tremors and difficulty with fine motor movements, but eventually the myoclonus becomes so disabling that despite continued normal muscle strength, patients cannot speak, feed themselves, walk, or even roll over in bed. The deep tendon reflexes are increased. Leg tremors and generalized seizures may occur in the early morning before awakening. Myoclonic jerking is more severe in the premenstrual phase of the monthly cycle. As the disease progresses, the patient is confined to a wheelchair and is helped by passive restraints on the limbs. Anticonvulsants suppress the convulsions but do not decrease the myoclonus dramatically. A significant reduction in action myoclonus has occurred in a few patients with the use of 5-hydroxytryptophan, with the best response noted in combination with carbidopa.[518] However, the disease has an inexorable and relentlessly progressive course.

Though disabled, patients have continued to be intellectually active. Sensation is normal, and there are no Hurler disease–like features such as corneal cloudiness, hepatomegaly, or bone or joint abnormalities. In a few patients, scoliosis has developed late in the course of the disease. Some patients have complained of severe pain in the hands and feet during hot weather of the type observed in Fabry's disease.

A few vacuolated lymphocytes may be seen in the peripheral blood smear, and foamy histiocytes have been described in the bone marrow. Nerve cells contain PAS-positive material that can be removed with alcohol fixation. Electron microscopic examination discloses vacuoles in the abnormal bone marrow cells and in Kupffer cells. Most of these vacuoles are empty, but some contain fine fibrillar material or electron-dense bodies. The sialic acid content of cultured fibroblasts may be normal or elevated,[517] but there is an increase in sialic acid–containing compounds in the urine.

Sialidosis Type II (Dysmorphic Sialidosis)

The type II form of sialidosis can be subdivided into congenital, infantile, and juvenile types, all of which feature dysmorphic facies and complete absence of NEU1 activity.[496,508,519] More than 10 patients with congenital sialidosis type II have been reported; 2 were stillborn infants with hydrops fetalis, ascites, hepatosplenomegaly, stippling of the epiphyses, and periosteal cloaking of the long bones.[520] Patients in this group were reported to also have severely reduced β-gal activity (5% to 10%), which may mean that many of the patients in this subgroup may actually suffer from early infantile galactosialidosis.

When the disease is manifested at birth, the infants have coarse puffy facies, a depressed nasal bridge, and a broad maxilla. Development is slow, but by 2 years of age the child can walk and speak single words. Many skeletal abnormalities are found, and radiologic examination reveals findings typical of dysostosis multiplex. The trunk is short and the extremities are relatively long. There may be a thoracic deformity of either the pectus excavatum or carinatum type, and thoracic kyphosis is present. Joint mobility is mildly restricted. Radiographic signs include stippled epiphyses, ovoid vertebral bodies, and thickened calvaria. Eye examination discloses punctate lens opacities and a macular cherry-red spot. Other signs include inner ear hearing loss, mild gingival hyperplasia, widely spaced teeth, and hepatomegaly.

Mental retardation is evident from an early age, and progressive neurologic deterioration occurs during childhood. Initially, the gait is broad based and waddling, but as muscle wasting and weakness develop, the patient exhibits further unsteadiness and then is unable to walk. Slowing of nerve conduction velocity suggests that these neurologic difficulties may be due to a degenerative neuropathy. Gross myoclonus and a tonic-clonic seizure disorder may develop, and death occurs later in childhood or adolescence.

In peripheral blood smears, a small number of lymphocytes and monocytes may contain large cytoplasmic vacuoles. Fine abnormal granulations may also be present in these cell types and granulocytes. Foam cells are found in the bone marrow. These cells contain vacuoles of different size that appear under the electron microscope as single membrane-bound clear inclusions. Similar cytoplasmic inclusions have also been found in liver, cartilage, and cultured fibroblasts. Neuronal storage has been demonstrated, and sural nerve biopsy has revealed myelin and axonal degeneration.

The quantity of bound sialic acid in the leukocytes and fibroblasts of these patients is increased severalfold, whereas the sialyloligosaccharide content of their urine is several hundred times greater than normal.[521,533] Thin-layer chromatographic analysis of urine is therefore a very useful diagnostic test. There is a marked deficiency of NEU1 activity in fibroblasts and a partial deficiency of this enzyme in obligate heterozygotes. The juvenile form of sialidosis type II is manifested as mild developmental delay and disproportionate stature with relatively long legs. Coarse facies are evident by 10 years of age, and radiographs reveal dysostosis multiplex. Intellect declines in adolescence. The patient becomes severely disabled, with death occurring in the second decade of life.

Galactosialidosis

Galactosialidosis is a neurosomatic disorder caused by mutation of the PPCA gene[495,523,524] and is the only LSD that is associated with deficiency of one of the lysosomal cathepsins. The physiologic consequences of total deficiency of cathepsin A are still unclear, given that most phenotypic abnormalities characteristic of the disease

have been attributed to the secondary, profound loss of NEU1 activity. The PPCA gene maps to chromosome 20q13.1 and overlaps with two other genes: with the phospholipid transfer protein (PLTP) gene at the 3′ end[525] and with the gene encoding the neutralized-like protein OZZ at the 5′ end.[526,527] The PPCA gene is transcribed in the opposite orientation with respect to the OZZ gene, and the two genes share a minimal promoter; this rather unique genomic organization is conserved in the mouse and human. However, whereas PPCA is differentially but ubiquitously expressed in all tissues and cell types, OZZ expression is restricted to skeletal muscle and the heart. The OZZ protein is a component of a RING-type ubiquitin ligase complex that is involved in muscle development, differentiation, and regeneration.[527] It is therefore conceivable that mutations affecting the PPCA gene may influence expression of OZZ and account for some of the phenotypes observed in galactosialidosis patients.

The PPCA transcript encodes a 480–amino acid serine carboxypeptidase that is structurally similar to yeast and plant serine carboxypeptidases.[528] However, its protective function toward NEU1 and β-gal is unique to higher eukaryotic species, including fish, birds, and mammals. The 54-kd PPCA zymogen carries two *N*-glycans and is conventionally routed to the endosomal/lysosomal compartment via the M6P receptor. There is evidence in support of the view that both NEU1 and β-gal are poorly mannose-6-phosphorylated and depend at least in part on interaction with PPCA for correct lysosomal routing. Once in the lysosome, the PPCA precursor is activated by partial trypsin-like proteolysis of a short internal peptide that covers the catalytic pocket.[529] In lysosomes, the mature and active two-chain enzyme remains in complex with the other two glycosidases, which is essential for activation of NEU1 and stabilization of β-gal. In the absence of functional PPCA, the enzyme complex is not formed and NEU1 looses its catalytic activity. In vitro mutagenesis experiments have demonstrated that the cathepsin A activity of PPCA is apparently not needed for formation of the multienzyme complex and the activities of NEU1 and β-gal.[87,503,530,531]

Besides its acidic carboxypeptidase activity, at neutral pH PPCA functions as a deamidase and esterase toward a selected number of neuropeptides, such as substance P and neurokinin, and can hydrolyze the C-terminal amino acid from oxytocin-free acid, bradykinin, and endothelin I. In addition, catalytically active cathepsin A was shown to be released from thrombin-stimulated platelets and from ionophore B–stimulated natural killer cells and was also detected in granules of human interleukin-2–activated killer cells. All PPCA's catalytic properties were severely reduced in lymphoblastoid cells and fibroblasts from galactosialidosis patients. Together, these findings show that PPCA may be important in metabolic processes such as inactivation of bioactive peptides or granzyme-mediated cellular cytotoxicity.[532,533]

Eleven amino acid substitutions identified in mutant PPCAs from clinically different galactosialidosis patients have been modeled in a three-dimensional structure of the wild-type precursor form of PPCA.[531,534-536] Nine of the mutations were located in positions that appeared to drastically influence folding and stability of the mutant protein. Two other mutations had a less disruptive effect on the protein structure. None of the mutations involved the active site or were located at the surface, where they could have disrupted the protective functions toward NEU1 and β-gal. Close correlation was noted between the clinical severity of the patient and the effect of the corresponding mutation on the structure of PPCA. The most plausible reason for the many mutations that affect the overall folding of the protein is that no single mutation is likely to disrupt PPCA's protective properties toward both NEU1 and β-gal.

The secondary severe loss of NEU1 activity probably accounts for most of the overt clinical manifestations in galactosialidosis patients and for the pathogenesis of the disease, which in many respects is similar to that of sialidosis. Light microscopy revealed the presence of foam cells in bone marrow and vacuolated lymphocytes in the peripheral blood of patients with galactosialidosis. Sialyloligosacchariduria is also diagnostic of the disease, although it is indistinguishable from that measured in sialidosis patients. More than 20 different sialyloligosaccharides have been isolated from the urine of patients with galactosialidosis.[537] Autopsy studies have shown the presence of fibroblasts and macrophages containing cytoplasmic vacuoles limited by a unit membrane in the lymph nodes, liver, and spleen. The brainstem nuclei and anterior horn cells were swollen with Sudan black B–positive granular material. Ultrastructurally, these inclusions consisted of membranous lamellar structures and multilamellar arrangements mixed with vacuole-like granules of low electron density.[538]

Early Infantile Galactosialidosis

The most severe form of the disease has been reported in 19 patients and is manifested between birth and 3 months of age as fetal hydrops, neonatal edema, coarse facies, proteinuria, inguinal hernias, and telangiectases.[495,539-541] Other common features may include enlargement of the spleen and liver, kidney involvement, skeletal dysplasia most prominently in the spine, psychomotor delay, and severe neurodegeneration. Eye abnormalities such as corneal clouding and a cherry-red macula have been described in several infant patients. Cardiomegaly, a thickened septum, and cardiac failure have also been reported in several patients. Patients die on average at the early age of 7 months, probably as a result of renal or cardiac failure (or both).

Late Infantile Galactosialidosis

Thirteen patients have been reported with the late infantile form of galactosialidosis.[495,536,542,543] They are generally seen in the first months of life with coarse facies, hepato-

splenomegaly, and dysostosis multiplex, again affecting the spine in particular. Ocular abnormalities such as cherry-red spots and corneal clouding were observed in several patients, whereas others had no ocular symptoms toward the end of their second decade of life. In addition, hearing loss has also been reported in several patients. Severe neurologic manifestations such as myoclonus and ataxia are absent in most patients, but very mild mental retardation has been reported in about 50% of cases. Progressive valvular heart disease characterized by thickened mitral and aortic valves develops in most patients. One of the reported patients died at the age of 15; all others are alive, some into their second decade of life.

Juvenile/Adult Galactosialidosis

The juvenile/adult form of galactosialidosis comprises the largest group of patients.[495,544,545] It owes its dual designation to the broad spectrum of clinical severity, symptoms, and age at onset, which varies from 1 to 40 years with an average of 16 years. Patients in this group are predominantly of Japanese descent, and parental consanguinity has been reported frequently. Patients have coarse facies but less pronounced than in most of the other LSDs. General myoclonus is rare, but some patients have spinal abnormalities. The most common symptoms include a cherry-red macula and corneal clouding with loss of visual acuity, cerebellar ataxia, and angiokeratoma. Neurologic symptoms include myoclonus, cerebellar ataxia, seizures, and progressive mental retardation. Remarkably, unlike the other two galactosialidosis groups, nearly all patients with the juvenile/adult form have no visceromegaly.

Molecular Aspects

In-depth understanding of the mechanisms of pathogenesis in sialidosis and galactosialidosis is likely to come from analysis of the corresponding animal models of these two LSDs. There are currently three mouse models with either primary or secondary neu1 deficiency and the clinical manifestation of sialidosis and galactosialidosis. Neu1- and ppca-deficient mice were generated by targeted disruption of the neu1 and ppca genes.[546,547]

Though viable and fertile, ppca$^{-/-}$ mice have clinical, biochemical, and pathologic manifestations reminiscent of early-onset galactosialidosis early in life.[548] As in affected children, massive oligosacchariduria is diagnostic of the disease. In knockout mice, cells of the reticuloendothelial system are primarily affected. Extensive lysosomal storage is present in these cells of most organs, particularly the kidney, spleen, bone marrow, liver, intestine, heart, and brain. Affected mice progressively deteriorate, with severe nephropathy and ataxia developing, and they succumb to the disease at around 10 months of age. The distribution of lysosomal ppca mRNA and ppca protein in normal adult mouse tissues coincides with the occurrence of lysosomal storage in ppca$^{-/-}$ mice.[501] The distribution of affected cells is particularly complex in the brain, where only selected neurons become affected, most notably those of the limbic system and cerebellum. The most overt morphologic changes are seen in the cerebellum, where loss of Purkinje cells starts to occur at approximately 2.5 months of age and progresses throughout the life of the animal.

Neu1$^{-/-}$ mice display clinical abnormalities reminiscent of early-onset sialidosis in children. These homozygous mice are infertile and die between the age of 6 and 9 months. As is the case for galactosialidosis, the primary target of the disease is the reticuloendothelial system. Severe nephropathy, progressive edema, splenomegaly, kyphosis, and urinary excretion of sialylated oligosaccharides are the main pathologic features. Although the sialidosis mouse model shares clinical and histopathologic features with galactosialidosis mice, some phenotypic abnormalities seem to be specific for sialidosis mice, including progressive deformity of the spine, a high incidence of premature death, age-related extramedullary hematopoiesis, and lack of early degeneration of cerebellar Purkinje cells. The differences and similarities identified in these mouse models have helped investigators better understand the pathophysiology of these diseases in children and identify more targeted therapies for each of these diseases.

SM/J mice exhibit partial deficiency of neu1 activity. This naturally occurring strain is homozygous for a point mutation that alters the affinity of neu1 for its natural substrates and results in a mild sialidosis phenotype.[501] SM/J mice cannot elicit a T_H2-mediated immune response because they cannot stimulate naïve T cells to become T_H2 lymphocytes.[548] These immunologic aberrations reiterate a potential role of Neu1 in the processing of sialoglycoconjugates at the plasma membrane.

Treatment

BMT in ppca$^{-/-}$ mice was performed with transgenic bone marrow overexpressing the corrective enzyme in either erythroid cells or monocytes/macrophages.[546,549] This strategy effectively improved the phenotype and encouraged the use of genetically modified bone marrow cells for ex vivo gene therapy for galactosialidosis. Knockout mice that received hematopoietic progenitors transduced with a murine stem cell virus (MSCV)-based, bicistronic retroviral vector overexpressing ppca afforded stable donor hematopoiesis. Complete correction of the disease phenotype in systemic organs was achieved up to 10 months after transplantation.[163] ppca$^+$ hematopoietic and nonhematopoietic cells were detected in all tissues, with the highest expression in the liver, spleen, bone marrow, thymus, and lung, thus indicating efficient uptake of the corrective protein and cross-correction. ppca expression in the brain occurred throughout the parenchyma but was localized mainly in perivascular areas; however, expression was apparently sufficient to delay the onset of Purkinje cell degeneration and correct the ataxia.

Short-term ERT with mannosylated insect cell–produced enzymes has been investigated in both ppca-

and neu1-deficient mice.[95,550] This therapeutic strategy resulted in successful clearance of lysosomal storage in systemic organs. However, neu1 null mice died as a result of a rapid and severe immunologic response to the recombinant protein.

Mucolipidoses

Mucolipidosis Type II (I-Cell Disease)

Mucolipidosis II (or I-cell disease) is a rare autosomal recessive LSD caused by UDP-*N*-acetylglucosamine: lysosomal-enzyme *N*-acetylglucosamine-1-phosphotransferase (GNPT) deficiency. This enzyme catalyzes the initial step in synthesis of the M6P determinant required for intracellular lysosomal targeting of newly synthesized lysosomal hydrolases. GNPT catalyzes the formation of M6P markers on high-mannose–type oligosaccharides in the Golgi apparatus. M6P residues are required to bind to the M6P receptors (MPRs), which mediate the vesicular transport of lysosomal enzymes to the endosomal/prelysosomal compartment. Because of the low pH in these organelles, the lysosomal enzyme–MPR complex dissociates, upon which the enzyme is delivered to the lysosome.[551] GNPT is an $\alpha_2\beta_2\gamma_2$ hexameric complex[552] encoded by two separate genes.[9] It has been proposed that the α or the β subunit (or both) contains the catalytic portion of the enzyme and that the γ subunit is involved in recognition of the lysosomal enzymes.[553] The α and β subunits are encoded by the *GNPTAB* gene on chromosome 12q23.2, and the γ subunit is encoded by the *GNPTG* gene on chromosome 16p.[553] Both I-cell disease and pseudo-Hurler polydystrophy (mucolipidosis III) are caused by mutations in the *GNPTAB* gene, which leads to defective lysosomal targeting of many lysosomal enzymes. The clinical and radiologic signs are similar to those in Hurler's disease, albeit with earlier onset during the first months of life and sometimes before birth.

Although there are reports of patients surviving into their teens, death usually occurs between 5 and 8 years of age. Other distinguishing features of this disorder are striking gingival hyperplasia, less apparent corneal clouding, and hearing impairment in some. As in other mucolipidoses, these patients lack mucopolysaccharides in their urine. Birth weight and length are often less than normal, and the clinical features may be evident from birth. Neonates may be seen with coarse facial features, tight hip muscles with dislocation of the hip, joint stiffness, hernias, severe skeletal dysplasia, downy hirsutism, and a tight, thickened skin. Psychomotor delay is usually obvious by 6 months of age. Linear growth decelerates and stops by the second year of life.

Children with I-cell disease are often recognized after 6 months of age by an abnormal low-pitched cry, small triangular head, hypertrophied maxillary alveolar ridge, enlarged tongue, kyphoscoliosis, protuberant abdomen, hepatomegaly, and hypotonia with poor head control. Patients are able to sit but cannot walk. They often have systolic murmurs and recurrent respiratory tract infections. Death usually results from cardiopulmonary complications.

In a study of nine patients from eight families, both interfamilial and intrafamilial variability was described. Marked variability in age at onset, organ manifestation, and radiologic findings was noted, even among siblings.[554]

I-cell disease has been found in association with non-immune hydrops fetalis and elevated amniotic fluid optical density (ΔOD450), thus indicating the possibility of fetal blood hemolysis in this disease.[555] Fetal ultrasonographic studies have shown abnormally short femurs and intrauterine growth retardation.[556] Radiographs of an affected fetus demonstrate deficient endosteal bone formation, small epiphyses, and poorly developed intervertebral discs. Skeletal lesions in infants with the disease are characterized by delayed conversion of cartilage to bone; diffuse periosteal new bone formation in the long bones and ribs; marked osteopenia; resorption of the scapula, clavicle, and mandible; and irregular demineralization of the metaphyses of long tubular bones.[557]

Among the many radiographic signs of skeletal dysplasia in this disease are thickening of the calvaria, cone-shaped phalanges, proximal pointing of metacarpals, V-shaped deformity of the wrist joint, short rounded vertebral bodies with anteroinferior beaking of T12 or L1, broad ribs, flaring of the iliac wing, dysplasia of the acetabulum, and cortical thickening in the diaphyses of long bones. Bone encroachment in the region of the foramen magnum causes significant brainstem and upper cervical cord compression. Neurologic consequences include respiratory impairment and obstruction of cerebrospinal fluid outflow from the fourth ventricle. The internal hydrocephalus produced may require a shunting procedure, and cervical laminectomy may be needed to prevent cord paralysis.

Vacuolated lymphocytes are abundant in circulating blood,[33] but no foam cells are seen in the bone marrow. The dense cytoplasmic inclusions in cultured fibroblasts stain positively with PAS and Sudan black but negatively with Alcian blue, which indicates that glycolipids but not mucopolysaccharides are stored in these cells. These inclusions are characteristic of this disease, hence the name inclusion cell (I-cell) disease. Foam cells staining positively with PAS are found in various tissues, including the spleen and portal spaces of the liver, but storage in Kupffer cells and neurons is variable.

M6P is a recognition marker needed for internalization of acid hydrolases into lysosomes[5] and acts as a "ZIP code" during intracellular trafficking. Patients with I-cell disease have a defect in synthesis of this marker. Under normal conditions, the enzyme GNPT phosphorylates the oligosaccharide portion of lysosomal enzymes to produce M6P. Patients with I-cell disease have a phosphotransferase deficiency that results in a defect in incorporation of M6P. Because M6P is the marker ultimately responsible for transfer of the various acid hydrolases into

lysosomes, the deficiency explains the discrepancy in acid hydrolase activity between sera and fibroblasts. The gene for the phosphotransferase has been mapped to chromosome 4q21-q23.[558]

As a result of the primary underlying metabolic defect, a variety of acid hydrolases are deficient in the fibroblasts of these patients, including α-neuraminidase, β-hexosaminidase, iduronate sulfatase, and arylsulfatase A. However, β-glucosidase and acid phosphatase activities are not affected. The various acid hydrolase activities in serum, on the other hand, are far above normal levels. Leukocyte enzyme activity is generally normal.

The diagnosis of I-cell disease can be confirmed by measuring and comparing the activity of various lysosomal enzymes in serum and cultured fibroblasts. It can also be ascertained by measuring phosphotransferase activity within fibroblasts or leukocytes.[559]

Carrier detection is possible with the use of cultured fibroblasts and artificial substrates (α-methylmannoside). Prenatal diagnosis has been successfully achieved by assaying amniotic fluid cells for multiple deficiencies of lysosomal enzymes and for deficiency of phosphotransferase.[560] It has been reported that phosphotransferase assays may be performed on chorionic villi obtained at 9 weeks of gestation.[561]

Successful engraftment of bone marrow from a heterozygous sibling into an 8-month-old patient has resulted in a 50% to 80% reduction in plasma lysosomal enzyme activity and increases in lymphocytic and hepatic phosphotransferase activity. In addition, pulmonary function has improved, hepatomegaly has subsided, and no further progression of corneal clouding has been seen. However, mental and growth retardation, dysostosis multiplex, and gingival hyperplasia have persisted to age 4.[562]

Mucolipidosis Type III (Pseudo-Hurler Polydystrophy)

Mucolipidosis III is an attenuated form of I-cell disease that is caused by mutations in the α subunit of the *GNTPAB* gene. However, unlike I-cell disease, the age at onset is later and the course is slowly progressive. These patients can survive well into adulthood. Many clinical features of this autosomal recessive disease are reminiscent of those of MPS I (Hurler) and VI (Maroteaux-Lamy). However, patients with mucolipidosis III lack mucopolysaccharides in their urine. They are seen between 2 and 4 years of age with stiffness of the hands and shoulders, which initially may suggest a diagnosis of rheumatoid arthritis.[563] Coarsening of facial features, short stature, and scoliosis become noticeable by 6 years of age. The joint stiffness is progressive and ultimately results in restriction of joint mobility. Destruction of the hip joints produces a waddling gait. As the disease progresses, a clawhand deformity and carpal tunnel syndrome usually appear before 12 years of age. Other clinical features may include mild mental retardation, mild corneal clouding, retinal and optic nerve abnormalities,[564] cardiac murmurs of aortic or mitral

valvular disease, short stature, and progressive skeletal dysplasia, particularly of the spine and pelvis. Patients surviving into the 30s and as late as the 60s have been described.

Peripheral leukocytes in this disease are normal, but vacuolated plasma cells are found in bone marrow specimens. Cultured skin fibroblasts manifest the same phase-dense inclusions as seen in I-cell disease, although the findings are not always as prominent.

As in mucolipidosis II, these patients also have multiple acid hydrolase deficiencies in cultured fibroblasts and markedly elevated lysosomal enzyme activity in serum. They also have a deficiency of phosphotransferase in fibroblasts and leukocytes, although there is some residual activity in patients with mucolipidosis III.[565] Carrier detection has been described.[566]

Complementation studies of cultured mucolipidosis III fibroblasts have demonstrated genetic heterogeneity. Two different functions of *N*-acetylglucosamine-1-phosphotransferase have been identified. One is associated with its catalytic activity and the other with the specific site of recognition of the lysosomal enzymes. A less common variant of mucolipidosis III (group C of the complementation groups) has a mutation at the recognition site but normal enzymatic activity toward artificial substrates. Patients with this uncommon variant and heterozygotes will show normal phosphotransferase activity when α-methylmannoside is used as the acceptor substrate in the assay mixture.

Mucolipidosis Type IV

In 1974, this autosomal recessive disorder was first described in children of Ashkenazic Jewish parentage whose ancestry was traced to southern Poland.[567] Since then, a few more cases have been described in other ethnic groups.[568] Mucolipidosis type IV is characterized by a variety of neurologic and ophthalmologic abnormalities, including motor and language delay, and patients with this disease do not usually progress beyond the 12- to 15-month level developmentally. These children do not have coarse facial features, skeletal deformities, or hepatosplenomegaly, and mucopolysaccharides and oligosaccharides are not evident in urine. Other possible signs include short stature; normal tone or hypotonia; hyperreflexia; a small head, often below the third percentile; and a full face. More recently, constitutive achlorhydria and hypergastrinemia have been reported as almost pathognomonic findings for this condition.[569] Although most of these patients are described as being profoundly retarded, patients have been reported with minimal retardation.[570,571] These patients can survive well into adulthood.

Corneal clouding develops in nearly all patients, but the age at onset varies. It may remain static or lessen with time. The use of contact lenses has been associated with clearing of the cornea. In one patient who received a corneal transplant, the clouding subsequently returned. Other ophthalmologic manifestations include a pigmen-

tary retinopathy, cataract formation, and optic atrophy. Bouts of tearing and conjunctival injection with photophobia have been troublesome in a few patients.

The original report of this disease described numerous large histiocyte-like cells in the bone marrow that contained small sudanophilic, weakly PAS-positive vacuoles. These cells also showed weak metachromasia after staining with toluidine blue.[567] However, bone marrow studies in another patient did not reveal storage cells. Blood smears from this patient were also normal when examined by light microscopy, but under the electron microscope, dense lamellar inclusion bodies were observed in lymphocytes of the buffy coat.[572] Ultrastructural changes have also been observed in various other tissues, including the brain, conjunctiva, and cultured fibroblasts.[573,574] These changes consist of concentric laminated lipid-like bodies and vacuoles containing amorphous, sparse fibrillogranular material. In the liver, multilamellar cytosomes are present in hepatocytes, whereas clear vacuoles are seen in Kupffer cells. Both types of inclusions appear in the epithelial and stromal cells of the conjunctiva, which may be sampled to aid in the diagnosis.[575]

The gene for mucolipidosis type IV (named *MCOLN1*) maps to chromosome 19p13.3-p13.2, and several mutations have been identified.[576] A founder effect was discovered in approximately 95% of affected Ashkenazic patients. The *MCOLN1* gene encodes a transmembrane protein called mucolipin that appears to regulate calcium influx in excitable and nonexcitable cells.[576] The protein belongs to the "transient receptor potential" family of proteins and functions as a nonselective cation channel whose activity is modulated by pH. Two defects have been described in patient fibroblasts: hyperacidification of lysosomes and a delay in the exit of lipids from lysosomes. It is plausible that the protein is involved in the endocytic process during lysosomal function because patients' cells display abnormal incorporation of lipids and abnormally large vesicles.[577]

A complete autopsy study was performed on a patient with mucolipidosis type IV. The results demonstrated that the storage material in neurons differed from that in non-neural cells. Neuronal inclusions stained with Sudan black but not with Luxol fast blue, thus suggesting that the stored material was a nonpolar lipid. In contrast, the storage material in hepatocytes, kidneys, and myocytes stained intensely with Luxol fast blue, thus suggesting that the accumulations were polar lipids. Inclusion material in all cells stained positively with PAS because of the accumulation of carbohydrates.[578,579]

Prenatal diagnosis has been accomplished by demonstration of abnormal storage bodies in cultured amniotic fluid cells[580] and cultured chorionic cells.[581] It is hoped that with elucidation of the underlying genetic defect in this condition, more accurate prenatal diagnosis will now be possible. Other than symptomatic treatment of its complications, no therapy is available for this condition.

Fucosidosis

Fucosidosis is a rare autosomal recessive disorder caused by deficient activity of the enzyme α-L-fucosidase. This disorder is due to faulty degradation of both sphingolipids and oligosaccharides. Fucose-containing oligosaccharides, glycopeptides, and glycolipids accumulate in both tissues and urine. The main storage material in the brain is oligosaccharides.[582,583] Glycolipids accumulate predominantly in the liver but are only a minor storage component in the brain.[584]

The clinical picture consists of progressive mental and motor deterioration. Three types of fucosidosis have been described on the basis of the initial findings and severity of the disease. Willems and associates[585] suggested that the disease exhibits a wide and continuous clinical spectrum with a rapidly progressive type 1 at one extreme and a slowly progressive type 2 at the other. At the DNA level, several mutations in the α-fucosidosis gene have been identified, but such genotypic differences do not explain the observed phenotypic differences.

Type 1 is recognized by a delay in psychomotor development between 6 and 18 months of age. Hypotonia rapidly progresses to hypertonia, then to severe spasticity, and finally to decerebrate rigidity. Thick skin, coarse facial features, skeletal abnormalities, and growth retardation develop. Other signs are a nonfunctioning ("strawberry") gallbladder and hyperhidrosis with a marked increase in the sodium chloride content of sweat. Patients have also had seizures, cardiomegaly, hepatomegaly, and corneal opacities. Respiratory tract infections are common, with most patients surviving only to 4 or 5 years of age.

Most patients with fucosidosis, however, experience a slower course of degeneration. Type 2 is a milder variant manifested at 2 or 3 years of age by slow neurologic deterioration. There are no corneal opacities, and the optic fundi are normal. Patients have coarse facies, growth retardation, dysostosis multiplex, and neurologic signs similar to those seen in type 1, except that they are slightly milder. Type 3 develops in the first few years of life and progresses slowly to a state of severe mental and motor deterioration by adolescence or adulthood. The major distinguishing features of type 2 are the presence of angiokeratoma corporis diffusum, more normal sodium chloride values in sweat, and longer survival. Telangiectatic lesions are seen in the mouth. Tortuosity of conjunctival vessels and pigmentary degeneration of the retina have been reported. Different forms of the disease may exist in the same family.[586]

Vacuoles are present in the cells of most tissues, including neurons, hepatocytes, Kupffer cells, and cells of the spleen, lung, kidney, heart, and skin. Electron microscopic studies demonstrate vacuoles with a heterogeneous content; some appear empty, some have a reticular pattern,[587,588] and others display a lamellar structure. There is vacuolization of the epithelial cells of the sweat glands and conjunctiva.[589] Peripheral lymphocytes

contain vacuoles and granular inclusions. Histiocytes with inclusions surrounded by vacuoles have been reported in bone marrow smears.

The diagnosis is ultimately determined by the demonstration of low α-fucosidase activity in either leukocytes or fibroblasts. Because the residual activity of this enzyme may be relatively high, it is always necessary to carry out thin-layer chromatographic analysis for oligosaccharides. Quantitative differences in urinary excretion patterns were described between a patient with type 1 and a patient with type 2 disease.[590] Lewis blood group activity is increased in fucosidosis tissues, and elevated levels of Le[a] and Le[b] activity have been found in the sera, erythrocytes, and saliva of patients with fucosidosis.[591]

The gene encoding lysosomal α-fucosidase (*FUCA1*) has been mapped to the short arm of chromosome 1p34.1-p36.1. Both *FUCA1* and a pseudogene (*FUCA1P*) have been sequenced. The gene consists of eight exons spanning 23 kb. At least 22 different mutations have been identified among the different exons.[592-597] The pseudogene is 80% identical to that of fucosidase cDNA but does not contain an open reading frame.[598] *FUCA1P* has been mapped to chromosome 2q31-q32 by in situ hybridization.[599] A second gene (*FUCA2*) has been mapped to chromosome 6q25. This gene is not involved in α-fucosidosis but influences the activity of plasma α-fucosidase. It may be a regulatory gene rather than a structural gene. This is important to note because *FUCA2* is associated with low α-fucosidase activity in plasma, which is found in 6% to 11% of the normal population.[600] Plasma is not an appropriate source for testing the activity of this enzyme. Carrier testing is now possible, and prenatal diagnosis has been successfully performed.

Prospects for the use of BMT in this disease have received mild encouragement from studies performed in dogs with fucosidosis; these dogs exhibited improvements in visceral lesions and a more gradual improvement in CNS pathologic changes.[601] At least three patients with human α-fucosidosis have also received transplants, with some success in two of these patients.[125] In addition, both human and canine fibroblasts in α-L-fucosidase can be corrected by retroviral vector–mediated gene transfer.[602-604] The authors are not aware of an attempt to use ERT in patients with fucosidosis.

α-Mannosidosis

This autosomal recessive disease results from a deficiency of α-D-mannosidase activity. It was first described in 1967 by Ockerman.[605] Clinically and biochemically, α-mannosidosis conforms to the stereotype of an oligosaccharide storage disease. There is an accumulation of mannose-rich glycoconjugates in tissues and body fluids. Excessive amounts of mannose-rich oligosaccharides are also excreted in urine. As in fucosidosis and aspartylglucosaminuria, patients exhibit skeletal changes, a dysmorphic facial appearance, moderate to severe mental retardation, hepatomegaly, hernias, recurrent bacterial infections, lenticular or corneal opacities, lymphocytic vacuoles, foam cell infiltration of the bone marrow, and an absence of mucopolysacchariduria.[606-608]

Two distinct clinical phenotypes are described in the literature. Type I is the severe infantile phenotype, whereas type II is a milder juvenile-adult form. As for fucosidosis, it is more likely that there is a continuum of clinical expression rather than clear separation into two phenotypes. The type I variant is characterized by rapid mental deterioration, coarse facial features, hepatosplenomegaly, severe dysostosis multiplex, and frequently, death between 3 and 10 years of age. In patients with type II disease, early development may be normal or slightly delayed. The mental retardation may be varied and may not be apparent until childhood or adolescence. Hearing loss is a particularly prominent feature. The skeletal abnormalities may be mild, but more severe manifestations (including deforming arthropathy) have been reported in this latter variant.[609] Destructive synovitis,[610-612] gingival hyperplasia, hydrocephalus, spastic paraplegia, and pancytopenia have been reported.[613-616] Radiographic studies of the brain show thickened diploic spaces and enlargement of the Virchow-Robin spaces.[617] In one 3-year-old boy with α-mannosidase deficiency, macrocephaly and intracranial hypertension developed in conjunction with synostosis of multiple sutures.[618] Patients with this form of the disease may survive into adulthood.

Between 20% and 90% of the lymphocytes in the peripheral blood contain translucent vacuoles, and a proportion of the polymorphonuclear leukocytes are coarsely granulated. The vacuoles remain PAS positive after fixation with alcohol. They have also been found in hepatocytes and Kupffer cells, and in the nervous system they are associated with widespread ballooning of nerve cell cytoplasm in the cerebral cortex, brainstem, spinal medulla, and pituitary gland.[608,619] Abnormalities in the chemotactic function of neutrophils may account for the increased susceptibility of these patients to infection. Hypogammaglobulinemia has been described as well.

Thin-layer chromatographic analysis of urine easily discloses a pattern of glycoconjugates that is distinctive for this particular type of oligosacchariduria. The major oligosaccharide excreted is a trisaccharide. A defect in hydrolysis of this compound has been demonstrated in an enzyme preparation from the liver of a patient with α-mannosidosis. The deficient enzyme, lysosomal acid α-mannosidase, may be assayed with leukocytes or cultured fibroblasts as the enzyme source. Although this enzyme is not a major component of serum or plasma, careful adjustment of reaction conditions will allow detection of α-mannosidase deficiency in patient sera.[620] Heterozygote detection is available,[621] and prenatal diagnosis has been performed successfully.[622]

The gene for α-mannosidase (also named *LAMAN*) has been isolated and sequenced,[623] and it maps to 19cen-q12. More than 20 mutations, most of them private, have been reported.[624] In these studies no correlation between

specific mutations and the clinical spectrum of the disease was found.

The residual α-mannosidase activity in mannosidosis can be stimulated and stabilized by zinc ions,[612,625] but long-term therapy with oral zinc sulfate has failed in several patients inasmuch as it caused no change in clinical status or biochemical findings.[626-629] In one patient who died 18 weeks after successful engraftment following BMT, the somatic effects of the disease were reversed, but lysosomal storage within the brain did not appear to be altered.[630]

Human recombinant α-mannosidase has been successfully synthesized and purified by expressing its cloned gene in Chinese hamster ovary cells.[631] Correction of affected human fibroblasts has been achieved by transfection with human cDNA via a retroviral vector.[632] This, together with the availability of animal models for this condition,[633,634] establishes the grounds for trials with either ERT or gene therapy. A guinea pig model of α-mannosidosis is available. Disease in this model resembles the clinical, histopathologic, biochemical, and molecular features of the human disease. In a recent study, the efficacy of ERT for α-mannosidosis was investigated in this model. Intravenous administration of human recombinant enzyme resulted in a significant increase in α-mannosidase activity (1.4 times normal levels) that was detected in the circulation 1 week after injection. By monitoring clearance of storage products with tandem mass spectrometry, this therapeutic approach was found to be effective in reducing accumulated metabolites in peripheral tissues and in brain in comparison to untreated controls. Reductions of up to 60% of urinary mannose containing oligosaccharides were also observed. No histologic improvement was observed in the brain, but a decrease in lysosomal vacuolation was seen in the liver, kidney, spleen, endocrine pancreas, and trigeminal ganglion neurons.[635]

BMT may be effective in controlling some manifestations of the disease if performed early in its course. Thus far, no clinical trials have been reported in the literature.

β-Mannosidosis

Since first described in humans in 1986, 11 cases of β-mannosidosis deficiency have been reported. All patients with this rare autosomal recessive disease are mentally retarded, but their other clinical findings have differed. The most severe phenotype described involved status epilepticus at 12 months of age, severe quadriplegia, and death by 15 months of age. The mildest phenotype described involved two adult brothers, one of whom was 50 years old with mental retardation, angiokeratomas, and few other phenotypic features.[636] Most patients were normal in the first few months of life, but mental retardation eventually developed in all. Other findings described included mild facial dysmorphism, hearing loss, speech impairment, seizures, angiokeratomas, aggressive behav-

ior, hypotonia, spastic quadriplegia, peripheral neuropathy, and rarely, skeletal abnormalities.[637] Interpretation of the clinical features has been complicated in some patients because one patient was coincidentally affected with type A Sanfilippo's disease[638] and another with ethanolaminuria.[639] A 14-year-old black African boy with severely deficient β-mannosidase activity was described who had bilateral thenar and hypothenar amyotrophy, electrophysiologically demonstrable demyelinating peripheral neuropathy, and cytoplasmic vacuolation of skin fibroblasts and lymphoid cells.[640] Hepatomegaly has not been described.

The enzymatic defect in this condition involves deficient removal of the innermost mannosyl residue in the N-linked oligosaccharide side chain, which is a β-linkage. As a result, there is excessive urinary excretion and tissue accumulation of oligosaccharides, particularly mannosyl-β-1,4-glucosamine. The specific deficiency of β-mannosidase can be demonstrated in leukocytes, cultured fibroblasts, and plasma. Parents are clinically unaffected but have reduced levels of β-mannosidase activity.

The gene for human β-mannosidase is located on chromosome 4q22-25.[641] Mutations in this gene have been identified in a pair of affected siblings, and prenatal diagnosis has been accomplished.[642]

A β-mannosidase knockout mouse was produced. Homozygous mutant mice have undetectable β-mannosidase activity. The general appearance and growth of the knockout mice are similar to that of their wild-type littermates. When older than 1 year, these mice exhibited no dysmorphology or overt neurologic problems. The mutant animals have consistent cytoplasmic vacuolation in the CNS and minimal vacuolation in most visceral organs. Thin-layer chromatography demonstrated an accumulation of disaccharide in the epididymis and brain. Because this mouse model closely resembles human β-mannosidosis, and it will provide a useful tool for studying the phenotypic variation in different species and facilitate the study of potential therapies for LSDs.[643]

Aspartylglucosaminuria

Aspartylglycosaminuria is a recessively inherited oligosaccharide storage disease that occurs primarily in the Finnish population. The carrier incidence of this disease was determined to be 1 in 36 in a sample of control individuals from the capital area of Finland.[644] Rare isolated instances have been reported in other countries, including Canada, Europe, Japan, Puerto Rico, Turkey, and the United States.[645-650] It is caused by a deficiency of the lysosomal enzyme aspartylglucosaminidase (N-aspartyl-β-glucosaminidase), which cleaves the bond between asparagine and N-acetylglucosamine during the lysosomal degradation of N-linked glycoproteins. Aspartylglucosamine accumulates in tissues, particularly the liver, spleen, and thyroid gland, with moderate increases in the kidney and brain.[651] Large amounts of aspartylglucosamine are excreted in urine.

The clinical features of the Finnish type appear to be consistent[652,653] in that the children are healthy for the first few months of life and then begin to have recurrent infections, diarrhea, and hernias during the rest of the first year of life. Some children have a history of muscular hypotonia and weak sucking as babies.[654] Short stature, microcephaly, and rarely, hepatomegaly develop in some. By the age of 10 there is coarsening of the facies and sagging skinfolds. Some of the other features noted are an increased incidence of acne, large nevi, sun sensitivity, angiokeratoma (seen in one patient), crystal-like lens opacification, macroglossia, hoarse voice, brachycephaly, and joint laxity. Macro-orchidism and subnormal excretion of 17-ketosteroids occur in some men, and menstrual abnormalities have been noted in some of the affected women. Reactive overgrowth of the oral mucosa and facial skin has recently been reported.[655] Cardiac valvular insufficiency is not common, but cardiac murmurs may be heard.

Progressive mental retardation is the main clinical symptom in aspartylglucosaminuria. Gradual loss of skills occurs after 13 to 16 years of age, and a rapid decline is noted after 25 to 28 years of age.[654] Intelligence quotient values are usually less than 40 in adults. Speech is delayed and remains poor or is never acquired. Behavioral abnormalities, such as excitability, hyperactivity, and at times, periods of apathy, are seen. The behavioral problems appear to become worse with age and could be related to the delayed myelination reported in patients with this condition, which is commonly seen in neuroradiologic studies.

Vacuolated lymphocytes and neutropenia are observed frequently. Many patients have a decrease in the prothrombin time. The radiographic findings may demonstrate very mild dysostosis multiplex with wedge-shaped vertebral bodies, spondylolisthesis, or spondylolysis. There is thickening of the calvaria with underdeveloped cranial sinuses. The non-Finnish children with aspartylglucosaminuria have all demonstrated mental retardation and skeletal dysplasia. The disease follows an insidious course, and many patients may live well into adulthood.

Aspartylglucosylamine may be detected in urine by chromatography. Because this compound serves as a link between the carbohydrate group and the peptide chain in glycoproteins and keratan sulfate, lesser amounts of other glycoasparagines containing galactose, N-acetyl-neuraminic acid, and additional *N*-acetylglucosamine residues have also been isolated from urine. Ultimately, the diagnosis is made by measuring aspartylglucosaminidase activity in an easily obtained tissue source, such as sonicates of white blood cells, fibroblasts, or amniotic fluid cells.[656,657] Serum, fibroblasts, and leukocytes of affected patients show less than 10% enzyme activity. The condition is best diagnosed in heterozygotes by using fibroblasts or lymphocytes.[658] Prenatal diagnosis is possible within the first trimester of pregnancy by enzyme analysis of direct chorionic villus biopsy material.[659,660]

The gene has been mapped to chromosome 4q32-q33 and has been cloned and sequenced. Currently, more than 20 different mutations have been reported.[661] In the most common form (the Finnish population), a double point mutation has been identified. Each results in an amino acid substitution: Arg161→Gln and Cys163→Ser. The first of these base changes is a polymorphism; the second is the disease-causing mutation. They occur together in 98% of Finnish patients with aspartylglucosaminuria. These mutations affect a critical region of the protein that triggers its autocatalytic processing before entering the ER. To screen for aspartylglucosaminuria carriers among the Finnish, a DNA-based test that can detect both mutations has been developed.[662] An improved screening method involving a PCR/oligonucleotide ligation assay is now available for the Finnish population; it is rapid, reliable, and nonisotopic.[663]

Two reports have described treatment of this condition with BMT.[664,665] In both, correction was seen only in the liver and not in the CNS.

The three-dimensional structure of *N*-aspartyl-β-glucosaminidase was used to predict the structural consequences of several mutations on intracellular stability, maturation, transport, and enzyme activity. Most mutations were amino acid substitutions that replaced the original amino acid with a bulkier residue. Mutations at the dimer interface prevented dimerization of the enzyme in the ER, whereas active-site mutations destroyed its catalytic activity and affected maturation of the precursor. Depending on their effects on stability of the enzyme, the authors categorized mutations as mild, moderate, or severe.[661]

An aspartylglycosaminuria mouse model was generated by targeted disruption of the mouse *N*-aspartyl-β-glucosaminidase gene. Homozygous mice had massive accumulation of aspartylglucosamine, extensive lysosomal vacuolization, and axonal swelling in the gracile nucleus and displayed impaired neuromotor coordination at 5 to 10 months of age. Older null mice (>10 months) showed progressive motor impairment and had impaired bladder function. The oldest surviving mice (20 months old) showed a dramatic loss of Purkinje cells, intensive astrogliosis, and vacuolation of neurons in the deep cerebellar nuclei leading to a severe ataxic gait. These findings are consistent with the pathogenesis of aspartylglycosaminuria in patients, and the knockout mice may be a suitable animal model for testing therapeutic modalities.[666,667]

ACID LIPASE DEFICIENCY

Wolman's disease and cholesteryl ester storage disease are autosomal recessive disorders that result in the massive accumulation of both cholesteryl ester and triglycerides in cells and tissues throughout the body. Both

diseases are characterized by a defective lysosomal acid lipase, also known as acid esterase. Lysosomal acid lipase is found in fibroblasts, macrophages, lymphocytes, and hepatocytes. The full-length cDNA encoding acid lipase has been isolated and sequenced[668] and may provide tools for DNA diagnosis and possibly enzyme therapy in the future. The gene has been mapped to chromosome 10q23.2-q23.[669] It consists of 10 exons dispersed over 36 kb.[670] Several mutations have been reported.[671] One mutation in the last nucleotide of exon 8 has been found in 11 of 17 patients with cholesteryl ester storage disease.

Extracts of normal cultured fibroblasts contain at least three electrophoretically dissimilar acid lipase components: A, B, and C. The least anodal band, A, is most prominent but is reduced in heterozygotes with Wolman's disease and is undetectable in both Wolman's disease and cholesteryl ester storage disease cells. This isoenzyme pattern is also seen in amniotic fluid cells, chorionic villus cells, lymphocytes, and several other tissues.[672] Diagnosis of both disorders is determined by the clinical picture and demonstration of decreased acid lipase activity and band A in cultured skin fibroblasts, lymphocytes, or other tissues. Prenatal diagnosis is now possible by identifying a deficiency of both acid lipase and band A in amniotic and chorionic villus cells.[673]

A diet low in cholesterol and triglycerides and the use of both cholestyramine (0.22 g/kg twice daily) and simvastatin (0.28 mg/kg each evening), which is a 3-hydroxy-3-methylglutaryl CoA reductase inhibitor, with lipophilic vitamins (A, D, E, and K) has resulted in clinical improvement[674,675] in some patients with cholesteryl ester storage disease. Although these diseases share a common enzyme defect, they differ considerably in their clinical expression.

BMT has been attempted in a child with Wolman's disease with apparently good results.[676] The neurologic performance of this patient, who received a transplant at 5 months of age, has been good, and no deterioration has been seen. The procedure had been attempted previously in four other patients who died of complications of the BMT procedure. It seems that when the disease appears so early in life and tends to occur with such severity, BMT should be performed as soon as possible, probably in the first 2 weeks of life, even before signs or symptoms develop. It should be done with minimal myeloablation and a goal of partial but not full engraftment, which may minimize the incidence of complications at this early age.

More recently, trials of ERT in animal models of this condition[677] and gene transfer in affected cells[678] have been performed with good results.

Wolman's Disease

Wolman's disease is the more severe of the two conditions. Symptoms can begin as early as during the first few weeks of life.[679] The major clinical signs and symptoms are severe vomiting, failure to thrive, abdominal distention, massive hepatosplenomegaly, which has been reported in patients as young as 4 days of age,[680] and foul-smelling, watery stools. Jaundice or persistent low-grade fever develops in a few infants. A prominent feature, though not necessarily pathognomonic, is grossly symmetrically enlarged, calcified adrenal glands.[681] Radiographic examination demonstrates extensive, stippled, or punctuate calcific deposits.

By the sixth week of life, anemia usually develops and becomes progressively worse. Lymphocytes contain both intracytoplasmic and intranuclear lipid vacuoles. In contrast to other diseases characterized by vacuolated cells, the vacuoles in Wolman's disease are strongly sudanophilic. They also stain positively with oil red O, Nile red, and stains for cholesterol. Their lysosomal origin is indicated by a strong reaction to staining for acid phosphatase activity. Lipid droplets are also present in neutrophils and monocytes. Foam cells (lipid-laden histiocytes) are seen in the bone marrow, in the peripheral blood, and in all organs.[680] Thrombocytopenia has not been reported.

The vomiting, diarrhea, and inanition result from severe damage to the microvilli and the accumulation of foam cells in the intestinal mucosa. Abdominal ultrasonography may demonstrate the thickened bowel walls.[682] Enteral nutrition is not possible, and therefore nutritional care must be given by intravenous hyperalimentation, even if it is only palliative.[683] The disease progresses rapidly, and death usually occurs before 1 year of age.

The diagnosis is determined by the clinical findings and deficient activity of acid lipase in cultured fibroblasts or circulating leukocytes. Routine laboratory observations often demonstrate abnormal liver function test results and plasma lipid levels in the low end of the normal range. Calcifications of the adrenal glands may be seen in Addison's disease, adrenal teratomas, neuroblastoma, and other conditions, but the presence of bilateral adrenal calcification associated with hepatosplenomegaly and gastrointestinal symptoms strongly suggests the diagnosis of Wolman's disease. Atypical forms without adrenal calcifications have been described.[684]

Cholesteryl Ester Storage Disease

Cholesteryl ester storage disease has a variable phenotype. It can be benign and may be undetected until adulthood.[685] Hepatomegaly, a prominent sign, may be evident at birth, during early childhood, or occasionally in the second decade of life. It results from the fatty infiltration of foam cells and ultimately progresses to hepatic fibrosis. Alcohol has been known to accelerate the process and therefore should be avoided. Other possible signs and symptoms include splenomegaly, esophageal varices, a decreased concentration of blood clotting factor V,[686] recurrent abdominal pain, delayed puberty, recurrent epistaxis, and jaundice. Calcified adrenal glands are rarely

present. Unlike the case in Wolman's disease, malabsorption and malnutrition have not been described in patients with cholesteryl ester storage disease.

Plasma levels of cholesterol, triglyceride, and low-density lipoproteins are elevated, and the plasma high-density lipoprotein concentration is reduced. No other abnormal results are noted on routine laboratory tests. Lymphocytes and monocytes are the only blood cells affected in cholesteryl ester storage disease. Bone marrow aspirates may demonstrate large macrophages filled with birefringent droplets. Cultured skin fibroblasts of patients with cholesteryl ester storage disease demonstrate birefringence in plain polarized light and absence of lysosomal acid lipase, thereby establishing the diagnosis. Hepatic acid esterase activity is reduced but detectable and is substantially greater than such activity in the liver of patients with Wolman's disease.[687]

In some patients, treatment with the 3-hydroxy-3-methylglutaryl CoA reductase inhibitor lovastatin has resulted in significant reductions in plasma cholesterol, triglyceride, and low-density lipoprotein cholesterol levels.[688] Two patients with cholesteryl ester storage disease received liver transplants and are reported to be doing well.[675,689]

A null-mutant mouse model of lysosomal acid lipase appeared normal at birth and developed normally into adulthood. However, massive accumulation of triglycerides and cholesteryl esters (30-fold increase in comparison to normal) occurred in several organs, and at 3 weeks of age the liver appeared yellow-orange and up to two times larger than normal. This mouse model is a phenocopy of cholesteryl ester storage disease and a biochemical and histopathologic mimic of human Wolman's disease.[690] ERT with recombinant acid lipase resulted in nearly complete resolution of the hepatic yellow color and a decrease in hepatic weight. Histologic analysis of tissues from ERT-treated mice showed a reduction in macrophage lipid storage and a 50% to 70% decrease in triglyceride and cholesterol levels in the liver, spleen, and small intestine. ERT with recombinant enzyme for human Wolman disease patients and patients with cholesteryl ester storage disease may be feasible.[677,678]

NEURONAL CEROID LIPOFUSCINOSES

Lysosomal accumulation of lipopigments is characteristic of the neuronal ceroid lipofuscinoses, a group of neurodegenerative conditions whose biochemical bases have only recently begun to be understood. The stored material consists of autofluorescent lipopigments resembling lipofuscin, the material that accumulates in neurons in normal aging. However, the storage material related to neuronal ceroid lipofuscinoses is less sharply outlined and more faintly stained by aldehyde fuchsin than the normal lipofuscin deposits.[691]

The accumulations present in brain lysosomes include glycoconjugates consisting primarily of dolichol pyrophosphate-linked oligosaccharides and proteins, the major component being subunit c (unit 9) of mitochondrial adenosine triphosphate (ATP) synthase. By immunohistochemistry, this excess of subunit c can be identified in skin fibroblasts[692] and in urine.[693] In infantile-onset disease, the major storage protein is not subunit c but the sphingolipid activator proteins A and D. Furthermore, two GSLs have also been identified in the stored lipids of infants with neuronal ceroid lipofuscinosis.[694]

On electron microscopy, the residual bodies have a heterogeneous ultrastructural appearance. They are present in all tissues but are particularly abundant in the neuronal perikaryon and axon hillock, where they continue to accumulate until the nerve cell degenerates. The various types of deposits found include curvilinear bodies, zebra bodies, fingerprint profiles, homogeneous osmiophilic bodies, and osmiophilic granular deposits.

Clinically, the neuronal ceroid lipofuscinoses represent a broad spectrum of diseases with an overall incidence of 1 in 12,500 to 25,000 births.[695] The age at onset; visual, mental, and motor signs; and types of inclusions present vary in the different forms of the disease. At least eight major forms of the disease have been identified (Table 24-7). These forms show a consistent clinical, pathologic, and genetic picture. The classic forms are infantile (CLN-1), late infantile (CLN-2), and juvenile (CLN-3) neuronal ceroid lipofuscinosis. These forms are inherited in an autosomal recessive pattern and have different genetic bases. An adult-onset variant without vision loss (CLN-4) also occurs. Most patients demonstrate autosomal recessive inheritance, but an autosomal dominant pattern has also been found in a few patients. Three additional variants (Gypsy/Indian or type 6, Turkish or type 7, and northern epilepsy with mental retardation or type 8) have thus far been restricted to specific ethnic groups. Their phenotypes resemble that for type 2, and only one of their genes has been identified (in type 8), in which a missense mutation has been found in all affected patients.

With only rare exceptions, patients who show symptoms before adulthood become blind, and for this reason older texts usually grouped these diseases among the familial amaurotic idiocies. However, the absence of ganglioside storage and the marked brain atrophy that occur in the neuronal ceroid lipofuscinoses clearly set these diseases apart from the classic forms of gangliosidoses, that is, Tay-Sachs disease, Sandhoff's disease, and the G_{M1}-gangliosidoses. Seizures, another common sign in neuronal ceroid lipofuscinoses, may be related to selective loss of inhibitory synapses within the axon hillock and initial segment of pyramidal cells. Their presence could lead to confusion with other causes of progressive myoclonic epilepsy, such as Unverricht-Lundborg disease, the myoclonus-epilepsy–ragged red fiber syndrome, Lafora body disease, and the sialidoses. Each variant of the neuronal ceroid lipofuscinoses, in contrast to these other disorders, is associated with the accumulation of autofluorescent material.

TABLE 24-7 **Phenotypic/Genotypic Correlations of Neuronal Ceroid Lipofuscinoses**

From Wisniewski KE. Pheno/genotypic correlations of neuronal ceroid lipofuscinoses. Neurology. 2001;57:576.

Retinal degeneration can be monitored with electroretinography. With complete degeneration of the outer retinal layer, the electroretinographic response is totally abolished. Another useful test is electroencephalography, the results of which may be abnormal even before the development of dementia. Subtle electro-ophthalmologic findings have been reported in heterozygotes. Radiographic studies such as computed tomography and magnetic resonance imaging have been useful in the early diagnosis of infantile neuronal ceroid lipofuscinosis.[696] Measurements of mitochondrial ATP synthase subunit c may help in diagnosis of the late infantile and juvenile variants, but quantitative analysis of urinary dolichols is no longer considered a reliable biochemical marker for the disease because elevated urinary dolichol levels can also be detected in other degenerative neurologic diseases. It is not clear why these conditions involve the CNS almost exclusively because the proteins affected are also found in many extraneural tissues.[697]

Diagnosis of these relatively common disorders depends primarily on the clinical features, but examination of a skin biopsy specimen by electron microscopy also helps greatly. Lymphocyte vacuolization and azurophilic hypergranulation of neutrophils are often found in the peripheral blood smear, except in the infantile form of the disease. Electron microscopic studies of these blood elements and urinary sediment, conjunctiva, liver, skeletal muscle, and sural nerve have also aided in the diagnosis. In juvenile neuronal ceroid lipofuscinosis, fingerprint lipopigments may appear on electron micrographs of lymphocytes in the absence of vacuoles. More recently, molecular diagnosis has become available for some of the most common forms of neuronal ceroid lipofuscinosis.

Prenatal diagnosis of the infantile and juvenile forms has been accomplished through ultrastructural studies of chorionic villus biopsy specimens, and late infantile neuronal ceroid lipofuscinosis has been diagnosed by similar examination of uncultured amniotic fluid cells.[698] With prior knowledge of the individual mutations involved in a family, rapid and specific diagnosis can now be accomplished for the majority of these disorders.

Clinical, pathologic, and biochemical changes similar to those seen in humans with neuronal ceroid lipofuscinosis have been detected in several animal species.[699-702] These naturally occurring animal models provide important clues to the pathogenesis of neuronal ceroid lipofuscinoses and offer investigators the opportunity to study potential treatments of these disorders. Bone marrow and liver transplantation in English setter dogs did not succeed, nor have treatments with vitamin E, selenium, levodopa, or glutathione or peroxidase enzyme. Addition of 20% Maizena oil to their diet did improve their quality of life[700] but did not alter the natural history of the condition.

The only treatment currently available is symptomatic. Baclofen (15 to 25 mg/day, increasing to as much as 200 mg/day) and tizanidine (1 to 9 mg/day, later 20 to 60 mg/day) have been helpful for the irritability, choreoathetotic behavior, and sleep disturbances. Levomepromazine (5 to 20 mg/day) or benzodiazepines may also be beneficial.[703]

Infantile Type (Haltia-Santavuori Syndrome, CLN-1)

This is the most common progressive encephalopathy in Finnish children younger than 2 years, with an incidence of 1 in 20,000.[704] Early psychomotor development is normal until 6 to 12 months of age (stage 1), although some children have microcephaly at that time. Subsequently, development is slowed, with hypotonia, motor clumsiness, slight irritability, and sleeping problems (stage 2). Between 12 and 20 months there is rapid deterioration of the child's condition, with truncal ataxia, hyperkinesis of the upper extremities, dystonia, myoclonic jerks, and loss of vision (stage 3). The optic discs are pale, the retinal vessels are narrowed, and the retina itself is hypopigmented. By 24 to 36 months of age affected children are no longer able to sit (stage 4). A prolonged stationary burnt-out phase precedes death, which may not occur until 9 or 10 years of age.

The early stages of CLN-1 resemble those of Rett's syndrome, but sphingolipidoses and even less common disorders have to be considered. Severe neuronal destruction occurs, with almost total loss of cortical and subcortical neurons and cerebellar Purkinje cells resulting in severe brain atrophy and subsequent microcephaly. Magnetic resonance imaging can facilitate early diagnosis even before the appearance of clinical symptoms, with signal loss found in the thalami in children by 1 year of age. By 17 months of age, the basal ganglia look hypointense in comparison to the hyperintense white matter. Hyperintensity around the lateral ventricles is marked. Electroencephalographic findings consist of missing or abnormally slow sleep spindles during sleep, which begin to disappear by the age of 13 months, are absent by 2 years of age, and become isoelectric by 2.7 years.[705] Abnormal visual evoked potentials and electroretinograms are late manifestations and are clearly evident by stage 4. The diagnosis is ultimately confirmed by electron microscopic examination. The electron micrograph demonstrates membrane-bound irregular granular bodies, with the major storage material consisting of sphingolipid activator proteins A and D.

The gene for CLN-1 has been mapped to chromosome 1p32 and codes for palmitoyl-protein thioesterase (PPT1), a small glycoprotein that removes palmitate groups from cysteine residues in lipid-modified proteins.[706] The two most common mutations are 223A→G and 451C→T. The normal protein is transported to synaptosomes and is likely to be involved in early neuronal development.[707,708] Mutations in this gene can produce several phenotypes, including congenital, infantile, late

infantile, juvenile, or even adult-onset variants.[709] These different phenotypes could be related to different degrees of disruption in intracellular trafficking of the mutant protein.[708] More than 39 mutations in this gene have been delineated, and a website has been developed for updating the mutations database in this group of conditions: http://www.ucl.ac.uk/ncl/.

Homologous cDNA to PPT1 was identified in the expressed sequence tags (EST) database.[710] The cDNA was derived from another gene that localizes to chromosome 6p21 and encodes a protein (PPT2) that shares 18% amino acid identity with PPT1. Recombinant PPT2, like PPT1, had thioesterase activity and localized to the lysosome. However, PPT2 could not substitute for PPT1 in correcting the metabolic defect in PPT1-deficient cells and was unable to remove palmitate groups from the palmitoylated proteins routinely used as substrates for PPT1.[710]

The three-dimensional structure of PPT1 was solved, with and without bound palmitate, by multiwavelength anomalous diffraction phasing. The structure showed an α/β-hydrolase fold with a catalytic triad consisting of Ser115-His289-Asp233. This has given insight into the structural basis for the phenotypes associated with PPT1 mutations.[711]

Ppt1 and Ppt2 null mice were generated that were deficient in either enzyme.[712] Mice from both knockout lines were viable and fertile, but spasticity developed at a median age of 21 weeks and 29 weeks, respectively. Myoclonic jerking and seizures were prominent in the Ppt1 mice, and motor abnormalities were progressive and caused death by 10 months of age. In contrast, Ppt2 homozygous mice were less affected and survived longer (>12 months). Neuronal loss and apoptosis were most prominent in the brains of Ppt1-deficient mice; however, autofluorescent storage material was prominent throughout the brains of both knockout mouse strains. These studies provided a mouse model for infantile neuronal ceroid lipofuscinosis and further suggested that PPT2 serves a role in the brain that is not carried out by PPT1.

Late Infantile Type (Jansky-Bielschowsky Syndrome, CLN-2)

This type is the second most common variant encountered in the United States. Onset occurs between 2 and 4 years of age. The earliest and most prominent symptoms are motor seizures of various types (myoclonic jerks, absence attacks, and atonic seizures) and truncal ataxia. The children are often described as being awkward, clumsy, tremulous, and dysarthric. The initial hypotonia progresses to spasticity with hyperactive reflexes, painful flexor spasms, and severe flexion contractures. By 5 years of age there is loss of intellect, inability to walk and talk, loss of vision, difficulty swallowing and clearing secretions, and incontinence. Death usually occurs between 10 and 15 years of age.

Eye examination reveals optic atrophy and granular or pigmentary degeneration of the macula. Initially, the visual evoked potentials are enlarged, but over the course of the disease both the visual evoked potentials and the electroretinogram signal become small and then absent. The electroencephalogram may show positive spikes during low-frequency photic stimulation.[713] The earliest radiographic findings demonstrate a large fourth ventricle and cerebellar atrophy,[714] with eventual progression to severe cortical atrophy.

Electron microscopic studies demonstrate the presence of curvilinear bodies. Large spheroidal lysosomal inclusion bodies, called protein-type myoclonus bodies, have also been identified. Their incidence, significance, and biochemical composition have not been determined. Unlike the curvilinear bodies, the majority of these inclusions were nonreactive to antibodies for subunit c.[715] Autopsy studies have disclosed storage material involving both neural cells and visceral cells such as the bone marrow parenchyma, spleen, Kupffer cells of the liver, lymph nodes, and renal parenchyma.

The CLN-2 gene encodes tripeptidyl peptidase 1, a lysosomal enzyme acting as an aminopeptidase that removes tripeptides from the free amino-terminals of proteins, and it maps to chromosome 11p15.[716] As in CLN-1, mutations in the same gene can also produce juvenile-onset disease.[709] At least 43 mutations have been identified. The diagnosis is confirmed by measuring tripeptidyl peptidase 1 activity in cells, most commonly fibroblasts. Because similar phenotypes can be produced in other variants of neuronal ceroid lipofuscinosis, enzymatic confirmation is recommended to corroborate the diagnosis.[709]

Early Juvenile Type (Variant Jansky-Bielschowsky Disease, Finnish Variant CLN-5)

Manifestations of this subtype begin at about the same age as those of the juvenile variant, but the course and neurophysiologic pattern are similar to those of the late infantile variant. Early psychomotor development is essentially normal up until 4 to 6 years of age, when motor clumsiness, epilepsy, and some visual difficulties begin to appear. The disease progresses in a subacute fashion, and by 9 to 10.5 years of age there is marked cognitive decline, ataxia with difficulty walking, dysarthria, and athetosis. Death occurs between 10 and 30 years of age. The characteristic electroencephalographic abnormalities seen in the late infantile type are also present in this variant. Visual evoked potentials and electroretinogram signals are abolished by 4 to 5 years of age. The characteristic abnormal early radiographic findings seen in the late infantile type are also seen in this variant. Unlike the juvenile variant, vacuolated lymphocytes have not been observed. Skin and rectal biopsy specimens are the preferred tissues for diagnosis. Electron microscopy

demonstrates both the curvilinear and fingerprint patterns.

The CLN-5 gene localizes to chromosome 13q21-32[717] and encodes a putative 407–amino acid transmembrane protein.[718] The 60-kd glycoprotein is expressed in lysosomes in all human tissues, with up to a fivefold variation in levels of expression.[718,719] Glycosylated polypeptides were also present in the media of cultured cells, thus suggesting that the CLN5 protein may be a soluble lysosomal protein rather than an integral transmembrane protein as predicted previously.

To date, four mutations have been identified in the CLN-5 gene, including "Fin-major," a 2-bp deletion in exon 4, being the most common and two other isolated mutations that were found in non-Finnish patients (Dutch and Columbian).[720,721]

A knockout mouse model of CLN-5 was generated by targeted deletion of exon 3 of the mouse Cln5 gene.[722] Homozygous knockout mice had loss of vision and accumulation of autofluorescent storage material in the CNS and peripheral tissues, but no prominent brain atrophy. Profiling of brain transcripts in Cln5-deficient mice showed altered expression of several genes that are known to be involved in neurodegeneration, as well as genes involved in defense and immune response, findings typical of age-associated changes in the CNS. In addition, downregulation of structural components of myelin was detected, which was consistent with hypomyelination occurring in human CLN-5 patients. It was proposed that this mouse model may serve as a model for studying molecular processes associated with advanced aging.

Juvenile Type (Spielmeyer-Sjögren Syndrome, Batten's Disease, CLN-3)

This form is the most common variant seen in the United States. It has a chronic course, with the initial manifestations beginning between the ages of 4 and 6. The earliest symptoms are a decline in central visual acuity and retinitis pigmentosa. The disease course is insidious; it is slowly progressive and eventually leads to blindness, which is seldom detected before 7 or 8 years of age.[723] Formed and unformed visual hallucinations unrelated to seizures have been described.[724] By 10 to 12 years of age, only light perception remains, and low-frequency nystagmus is present. At about this same age, convulsions first appear and mental capacity declines. Thereafter, memory, school performance, and behavior steadily deteriorate. The behavioral problems may range from angry outbursts to depression. By the midteens these patients are moderately mentally retarded, and bouts of uncontrollable positional myoclonic jerking develop in some. Their speech is slurred and monotonous, with stammering, perseveration, and echolalia, and their thoughts become incoherent. An extrapyramidal syndrome consisting of a dull facial expression, peculiar postures, paratonic rigidity, and a parkinsonian-like gait can develop. Cerebellar disturbances are also noticed, including clumsiness in all movements, progressive ataxia, and compulsive, monotonous, dysarthric speech. Patients become mute by their mid to late 20s and become bedridden in a semiflexed posture with recurrent seizures. These seizures are difficult to control and may be accompanied by opisthotonic posturing and prolonged spells of apnea. The early radiologic picture can be completely normal in 25% of patients, but by the late teens there is severe diffuse cerebral cortical, subcortical, and cerebellar atrophy. The visual evoked potentials and electroretinogram signal are initially abnormal but eventually are absent. The electroencephalogram is abnormal, and motor nerve conduction velocities are often decreased.

Twenty percent of the circulating lymphocytes in CLN-3 patients contain vacuoles. Microscopic examination has shown intracytoplasmic autofluorescent lipopigments in the nerve cells throughout the CNS and viscera. The reactive astrocytes are enlarged mainly in the superficial layers of the cerebral cortex. Calcifications have also been noted along the outer and inner brain surfaces.[725] The ultrastructural appearance of the lipopigments is predominantly a fingerprint-like profile. Treatment with polyunsaturated fatty acids may be of some benefit.[726]

The defective gene in CLN-3 is localized to chromosome 16p12.1 and encodes a deduced 438–amino acid hydrophobic transmembrane protein (battenin), which may be involved in the endocytosis/exocytosis pathway of vesicle-secreting cells.[727,728] In addition, battenin appears to contain a putative mitochondrial targeting site and has four predicted *N*-glycosylation sites. A yeast homologue of battenin was identified with 36% amino acid identity,[729] and it was reported that all known point mutations of *CLN3* concerned residues identical between the human and yeast protein. Of the more than 30 mutations that have been identified, one is especially common, a 1.02-kb deletion that involves exons 7 and 8.

Adult Type (Kufs' Disease, CLN-4)

The adult-type variant may represent up to 10% of all cases of neuronal ceroid lipofuscinosis.[730] Inheritance of CLN-4 is autosomal recessive or sporadic and occasionally dominant. The clinical course is chronic, insidious, and highly varied, beginning at between 20 and 60 years of age. Unlike the childhood forms, these patients do not have loss of vision or retinal degeneration. They may be seen with either myoclonic seizures (type A) or behavioral abnormalities (type B). Dementia, ataxia, and pyramidal and extrapyramidal signs are also present in both types. As with the progressive myoclonic epilepsies, the electroretinogram may show an intense photoparoxysmal response to low-frequency photic stimulation. Lafora's disease, myoclonus-epilepsy–ragged red fiber syndrome, G_{M2}-gangliosidosis, galactosialidosis, and other storage disorders should be considered, but enzymatic assays and ultrastructural findings in skin and muscle biopsy speci-

mens help differentiate these diseases from CLN-4. Skin, muscle, rectal, or even brain biopsy may be necessary to confirm the diagnosis. Electron microscopic studies may show various types of abnormal profiles, for example, a combination of distorted curvilinear profiles and fingerprint and rectilin ear profiles in membrane-bound vacuoles. Lipofuscin pigments may be seen with normal aging, but not the characteristic profile of neuronal ceroid lipofuscinoses. Immunostaining with antibodies against β-amyloid protein and subunit c of mitochondrial ATP synthetase may also be useful in distinguishing these variants from Alzheimer's disease. Autofluorescent lipopigments have been demonstrated in the neuronal perikaryon and axonal hillocks of the isocortex, allocortex, basal ganglia, thalamus, brainstem nuclei, cerebellum, and neurons of the anterior horns in the spinal cord. Cerebellar atrophy is present. CLN-4 has not been mapped to any genetic locus, and the cause of the disease remains unknown.

Platelets and the Vessel Wall

Peter J. Newman and Debra K. Newman

In a 1881 communication to the Turin Royal Academy of Medicine, the Italian physician Giulio Bizzozero disclosed the presence in circulating human blood of discrete elements that he termed "*piastrine*" ("*blutplättchen*" in a 1882 publication in a German journal and "*petites plaques*" in a communication in French).[1] Previously speculated to be merely nonphysiologic "*granular aggregates*," blood platelets have since become central to our understanding of thrombosis and hemostasis, and detailed understanding of their participation in cardiovascular disease, stroke, and even cancer has led to remarkable progress in the rational treatment of these disorders.

Although platelets are most often studied in the context of their ability to form a hemostatically effective plug, it is now widely recognized that their influence extends far beyond this process to all aspects of hemostasis, as well as to wound healing and vascular remodeling. For example, platelets generate or secrete biologically active mediators such as thromboxane A_2 (TXA_2) and serotonin, which not only amplify platelet activation responses but also modulate vascular tone. In addition, platelets secrete a broad array of granule constituents that stimulate vessel repair, induce megakaryocytopoiesis, promote coagulation, and limit fibrinolysis.

The same pathways that lead to platelet plug formation can also produce pathologic thrombosis, a process that has been described as hemostasis occurring at the wrong time or in the wrong place. Platelets are particularly important for hemostasis on the arterial side of the circulation, where blood flows under higher pressure and experiences greater shear force. As a result, platelet function is generally considered to be critical to the pathogenesis of arterial thrombosis and less so for venous thrombosis, and antiplatelet drugs are most widely used in the former setting. However, this distinction between the mechanisms underlying arterial and venous thrombosis is not absolute, and the spectrum of thrombotic disorders should be considered a continuum.

Arterial thrombosis is a particularly common problem in middle-aged and older adults and is a major cause of morbidity and mortality in developed countries. The thrombi that arise in atherosclerotic vessels are predominantly platelet in origin and are the proximate cause of myocardial infarction and most cerebrovascular accidents. Although arterial thrombosis is considerably less common in children than adults, it may contribute to major morbidity in patients with sickle cell disease, as well as complications of some childhood infections, Kawasaki's syndrome, and various forms of arteritis, autoimmune disorders, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura (see Chapter 33).

In this chapter we review platelet structure and function, with special emphasis on the cell surface glycoproteins that function as sentries for areas of vascular damage and the signal transduction events that both amplify and limit platelet responsiveness. The information provided here should be helpful in understanding subsequent chapters that describe inherited and acquired platelet disorders (see Chapters 29 and 33) and the role of the adhesive protein von Willebrand factor (VWF) (see Chapter 30) in hemostasis. Finally, there is growing appreciation of the role that platelets play in inflammation and the pathogenesis of atherothrombosis, which is briefly discussed at the end of the chapter.

PLATELET MORPHOLOGY AND SUBCELLULAR ORGANIZATION

Platelets are adhesion and signaling machines that circulate as small, disc-shaped cellular fragments in the whole blood of healthy individuals at a concentration of approximately 150,000 to 300,000/µL. Early studies suggested that platelets might be produced via cytoplasmic fragmentation along a network of internal demarcation membranes that were observed in large, polyploid megakaryocytes.[2,3] More recent studies,[4-6] however, support the notion that proplatelets are assembled and packaged with their various constituents at the ends of long cytoplasmic extensions of differentiated megakaryocytes that have migrated from the proliferative osteoblastic niche to the capillary-rich vascular niche of the bone marrow microenvironment,[7] with the invaginated demarcation membrane system serving simply as a reservoir of internal membrane used for proplatelet extension.[8,9] Once adjacent to the adluminal face of the endothelium, proplatelets are released into the bloodstream, where they circulate as mature platelets for approximately 7 to 10 days before being cleared by the liver and spleen[10]—their life span being controlled, at least in part, by an antagonistic balance between the apoptotic proteins Bcl-xL and Bak.[11]

The size of resting platelets is somewhat variable, averaging approximately 1.5 µm in diameter and 0.5 to 1 µm in thickness. Platelet size is undoubtedly regulated by numerous factors during their biogenesis, but both the 224-kd nonmuscle myosin heavy chain IIA (MYHIIA) and the cell surface glycoprotein Ib (GPIb) complex appear to play critical roles. Thus, mutations in the *MYH9* gene predominantly interfere with contractile events important for platelet formation,[12] whereas failure to express GPIb—the molecular basis for the platelet disorder known as Bernard-Soulier syndrome[13,14]—disrupts critical associations with the cytoskeletal protein filamin[15,16] that play an essential role in both platelet formation and platelet compliance.[17] In both these inherited platelet disorders, platelets can appear as large as lymphocytes (see Chapter 29). Correction of GPIb expression in GPIb-deficient (Bernard-Soulier) mice has been shown to restore platelets to their normal size.[18]

The volume of a platelet (mean platelet volume) normally ranges from 6 to 10 fL (1 fL = 10^{-15} L). Platelet density is also variable,[19] and the issue of whether young platelets are more[20,21] or less[22] dense as they gain versus lose content during their circulating lifetime has never

been satisfactorily resolved. Because platelets retain most species of messenger RNA (mRNA) for a short period after their release from bone marrow megakaryocytes,[23] young platelets can be distinguished from older ones by their RNA content.[24]

As shown in Figure 25-1A and C, resting platelets are discoid in shape, largely because of the presence of a circumferential coil of microtubules,[25,26] and they are packed with numerous electron-opaque alpha granules, a few dense granules (granule contents and their functions are discussed later), several mitochondria, and lysosomes.[27] Platelets also retain a few Golgi remnants, as well as occasional vestiges of rough endoplasmic reticulum—the exception being platelets from patients with rapid platelet turnover, in whom very young platelets containing more abundant protein synthesis machinery are readily observed in the circulation. Platelets also contain two highly specialized membrane systems not found in other cells of the body: the surface-connected open canalicular system (OCS) (see Fig. 25-1B and C) and the dense tubular system (DTS). The OCS is a series of tortuous invaginations of the plasma membrane that appear to tunnel throughout the cytoplasm of the cell[28] and serve as an internal reservoir of plasma membrane that is called upon when platelets round up, extend lamellipods and filopods (see Fig. 25-1B and D), and spread during platelet activation—a process that can increase the surface area of exposed plasma membrane by more than 400%.[29] Because

OCS channels are proximal to internal granules, they also probably function as a conduit for the rapid expulsion of alpha and dense granule contents during platelet activation.[30] The DTS, on the other hand, is a remnant of the smooth endoplasmic reticulum[31] and is found randomly dispersed throughout the cytoplasm. The DTS appears to be one of several organelles within the platelet known to harbor high concentrations of calcium,[32,33] and it is thought to contain a 100-kd calcium adenosine triphosphatase (ATPase) known as SERCA2b[34] that functions to sequester and store cytosolic calcium in resting cells. Recent evidence suggests that adenosine diphosphate (ADP) is able to induce selective release of calcium from the DTS[35] whereas activation of the GPIb/V/IX receptor for VWF releases calcium primarily from a poorly defined acidic compartment[36] within the cell.[35] Thrombin, a strong platelet agonist, appears to elicit release of calcium from both stores on binding to the platelet thrombin receptor PAR1.[35]

The platelet cytoskeleton is composed of a single rigid, but dynamic microtubule approximately 100 μm in length that is coiled about 8 to 12 times around the equatorial plane of the cell.[37-39] This marginal band of microtubules is largely responsible for maintaining the discoid shape of the resting cell, as illustrated by the observations that (1) incubation of platelets with colchicine—an agent that dissolves microtubules—results in their rounding,[40] (2) platelets from mice lacking
FIGURE 25-1. Platelet morphology. Resting platelets (shown in thin section in **A** and from a scanning electron micrograph of a flash-frozen, freeze-dried platelet in **C**) are shaped like a disc and contain numerous electron-opaque alpha granules, a few dense granules, and several mitochondria and lysosomes. A circumferential coil of microtubules (mc—highlighted with an *oval*) is responsible for maintaining their discoid shape. Platelets also contain a number of cytoplasmic membrane systems that subserve specialized functions, including vestiges of the smooth endoplasmic reticulum that sequester calcium and tortuous invaginations of the plasma membrane that form a surface-connected open canalicular system (OCS). When platelets become activated (**B** and **D**), they rapidly round up, extend lamellipodia (lam) and filopodia (fil), and release the contents of their granules, often into the nearby OCS. *(Photographs generously provided by John H. Hartwig and used with permission.)*

β_1-tubulin remain largely spherical,[41] and (3) "*platelet spherocytosis*" in humans results when tubulin fails to polymerize normally into microtubules.[42] Directly underneath the plasma membrane lies an intricate, two-dimensional, tightly woven membrane skeleton[43] composed of nonerythroid spectrin,[44,45] a network of actin filaments,[43,45] vinculin,[46] and the actin-binding protein filamin,[47] which itself is tethered to the inner face of the plasma membrane via linkages with the cytoplasmic domain of GPIb.[15,47] The membrane skeleton, because of its location, serves as a scaffold that links elements of the plasma membrane with contractile elements of the cytoskeleton and cytosolic signaling proteins and thereby regulates such diverse functions as receptor mobility,[48,49] receptor clustering,[50-52] and signal transduction.[53] Finally, the platelet is filled with an extensive cytoplasmic network of actin filaments[45,54] organized by the actin-binding proteins filamin[55,56] and α-actinin[57] that constitute its cytoskeleton.

When platelets become exposed to components of the extracellular matrix[58] or to soluble agonists such as ADP[59] or thrombin,[60,61] they undergo dramatic changes in their morphology.[62,63] The marginal band of microtubules disappears,[54] which allows the platelet to transform from a disc to an irregular sphere. At nearly the same time, the actin filament–capping protein α-adducin becomes phosphorylated and dissociates from existing F-actin filaments,[64] thereby exposing the barbed end of the filament to cytosolic actin monomers and driving rapid polymerization of actin into microfilaments.[62] This has the dual effect of driving the extension of lamellipodia and filopodia and forcing granules toward the center of the platelet, where they can fuse with membranes of the OCS and release their contents to the exterior of the cell. Phosphorylation of myosin additionally induces contractile events that facilitate centralization of the granules.[65]

PLATELET GENOMICS AND PROTEOMICS

Though anucleate, platelets contain measurable and manipulable levels of megakaryocyte-derived mRNA,[23] at least some of which is capable of being synthesized into small, but detectable amounts of protein.[66,67] Both serial analysis of gene expression (SAGE) and gene microarray analysis have been used to estimate the size and composition of the platelet transcriptome.[68-70] A consistent finding of all genomic analyses performed to date is that mitochondrially derived transcripts dominate the platelet transcriptome—presumably because of persistent transcription of the mitochondrial genome after platelet release from the bone marrow. This problem has recently been addressed by analyzing the transcriptome of cultured megakaryocytes derived from cord blood stem cells.[71] Of the 20,488 genes present in the human genome, 2000 to 3000 distinct transcripts have been identified in unstimulated platelets—considerably fewer

than normally found in a nucleated cell, but perhaps more than one might have expected from an anucleate circulating cellular fragment. One of the more surprising findings in recent years has been the identification of heterogeneous nuclear RNA (hnRNA) in the platelet cytosol, as well as all of the spliceosome components necessary to splice the hnRNA into mature message that can thereafter be translated into protein.[72] Enlisted during the activation process, signal-dependent protein translation has thus far been demonstrated for mRNA molecules encoding interleukin-1β (IL-1β),[72] tissue factor,[73] and Bcl-3,[74] the protein products of which have the potential to influence inflammation, thrombosis, and wound repair.

The platelet proteome appears to be equally complex and diverse and, unlike the transcriptome, reports both the breadth and relative amounts of protein products actually present in the cell. Obtained by refined two-dimensional gel electrophoretic techniques that were originally developed in the 1970s[75,76] or by liquid chromatographic separation, proteins are fragmented and separated via a combination of proteolytic and ionization techniques and then analyzed by mass spectrometry. Such analysis has allowed the identification of dozens of proteins present in complex cellular lysates or subcellular fractions (see elsewhere[77,78] for recent reviews of this topic). In addition to yielding the expected menu of major plasma membrane glycoprotein receptors, one of the more complete global profiling analyses to date[79] identified a core platelet proteome composed of 641 proteins, including an abundance of molecules involved in signal transduction, cytoskeletal change, and metabolism—understandable given the importance of cellular activation and its control in platelet function. By combining prefractionation methods with suitable separation techniques, proteomic analysis has also been used to compile an inventory of proteins that are either (1) post-translationally modified (normally by phosphorylation) during the platelet activation process[80-82] or (2) present at low abundance in the total platelet proteome but enriched within various subcellular compartments, including the platelet cytoskeleton,[83] alpha granules,[81,84,85] membrane fraction,[86] membrane rafts,[87] and microparticles.[88]

ANTITHROMBOTIC COMPONENTS OF THE VESSEL WALL

Although hundreds of thousands of platelets per microliter circulate in blood, under normal conditions very few, if any, interact with the intact vessel wall because the endothelial lining of the blood vessel presents an excellent nonthrombogenic surface. In fact, this property of the vessel wall has not yet been duplicated in any prosthetic or extracorporeal device. Healthy endothelium not only provides an effective barrier between blood components and the highly thrombogenic components of the

subendothelium (see later) but also actively produces both membrane-bound and secretory products that limit fibrin generation and promote clot dissolution. For example, heparin-like glycosaminoglycans present on the luminal side of the endothelial cell surface recruit plasma antithrombin, which effects a conformational change that promotes binding and neutralization of thrombin and other serine proteases.[89] Thrombin, when bound to the endothelial cell surface receptor thrombomodulin, takes on anticoagulant properties via its cleavage and activation of protein C, which in turn cleaves coagulation factors V and VIII, thereby further suppressing thrombin generation.[90] Endothelial cells also express a specific receptor for activated protein C that serves to concentrate the protein on the endothelial surface (see Chapter 26).[91] Finally, endothelial cells synthesize, secrete, and rebind tissue plasminogen activator,[92,93] which activates plasminogen to facilitate fibrin dissolution (see Chapter 27). These activities are summarized in schematic form in Figure 25-2.

The endothelial cell also produces two important inhibitors of platelet activation: prostacyclin (PGI$_2$)[94-96] and nitric oxide (NO).[97-99] A labile oxygenated metabolite of arachidonic acid generated by endothelial cell cyclooxygenase-2 (COX-2), PGI$_2$ diffuses out of the cell and binds to a platelet G$_s$ protein–coupled receptor (GPCR)

known as the isoprostenoid (IP) receptor.[100,101] Such binding stimulates adenylate cyclase to increase cytosolic cyclic adenosine monophosphate (cAMP) levels, which (1) activates a pump in the DTS that decreases cytosolic Ca^{2+}, thereby helping keep platelets quiescent, and (2) activates protein kinase A (PKA), the actions of which will be discussed later. PGI$_2$ also has potent vasodilatory effects by binding to IP on arterial smooth muscles cells to effect vessel relaxation.[94] The PGI$_2$ produced by vascular endothelium thus serves to counterbalance the proaggregatory and vasoconstrictor activities of the platelet-derived prostanoid TXA$_2$, the biology of which is discussed later. In fact, upsetting the delicate balance between COX-1–derived TXA$_2$ and COX-2–derived PGI$_2$ has been shown to increase the risk for adverse cardiovascular events.[102]

Whereas PGI$_2$ stimulates adenylate cyclase to produce cAMP, NO, a product of L-arginine generated by endothelial nitric oxide synthase (eNOS),[103] directly activates platelet guanylate cyclase, which results in increased cytosolic levels of cyclic guanosine monophosphate (cGMP). Although platelet responses to low levels of this cyclic nucleotide can at first be mildly stimulatory,[104] cGMP, largely via its activation of protein kinase G (PKG), has the overall effect of dampening platelet responses, inhibiting platelet adhesion[105,106] and aggregation,[107-110] and

FIGURE 25-2. Anticoagulant and antithrombotic components of the vascular endothelium. Endothelial cells produce a number of substances, including nitric oxide (NO) and prostacyclin (PGI$_2$), that act on platelet surface receptors to dampen platelet responsiveness. They also scavenge the platelet agonist adenosine diphosphate (ADP), inactivate thrombin, and activate the fibrinolytic enzyme plasmin. APC, activated protein C; AMP, adenosine monophosphate; ATIII, antithrombin III; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; COX-2, cyclooxygenase-2; eNOS, endothelial nitric oxide synthase; EPCR, endothelial cell protein C receptor; FV, factor V; GAGs, glycosaminoglycans; TM, thrombomodulin; IP, isoprostenoid; PC, protein C; PKA, protein kinase A; PKG, protein kinase G; TPA, tissue plasminogen activator.
impeding platelet-mediated recruitment of leukocytes during the inflammatory response.[111] Its mechanism of action is discussed in more detail later.

In addition to the soluble metabolites PGI_2 and NO, endothelial cells also express on their surface a potent adenosine diphosphatase (ADPase) known as CD39 that scavenges plasma ADP to prevent platelet aggregation.[112,113] Finally, it is important to note that inflammatory cytokines, oxidized lipids, and immune complexes can, under pathologic conditions, inhibit these protective biochemical pathways and impair the antithrombotic state of the endothelial cell. The latter changes permit unrestrained formation of platelet- and fibrin-containing thrombi, as well as thrombus formation beyond sites of vascular injury, and can thus contribute to atherothrombosis—a topic that is discussed more extensively at the end of this chapter.

REACTING TO THE BREACH—CELL SURFACE RECEPTORS THAT MEDIATE TETHERING AND ADHESION AND TRANSMIT EARLY ACTIVATION SIGNALS

As antithrombotic as the endothelial lining is, the underlying extracellular matrix consists of a rich mixture of glycosaminoglycans into which are embedded an abundance of highly concentrated prothrombotic proteins, including structural components such as collagen and elastin (which constitute ≈30% of body weight) and adhesive proteins such as laminin, fibronectin, and VWF. Not surprisingly, platelets have evolved receptors for most of these proteins and initiate a series of rapid biochemical events both on the surface and inside the cell when exposed to them. As a result, adhesion is an activating event!

The large number of circulating red blood cells serve to marginate platelets, and when the vessel wall is breached, either by mechanical injury or after rupture of atherosclerotic plaque, the first layer of platelets to encounter exposed matrix undergoes a series of sequential events similar to what leukocytes experience during the inflammatory response—namely, tethering, initial signaling to the cell interior, integrin-mediated adhesion, and cytoskeletally directed cell spreading. Whereas leukocyte tethering is mediated by members of the selectin family, the first layer of platelets become tethered on VWF,[114] which is sprinkled on exposed collagen fibers. VWF interacts with a high-affinity, platelet-specific multisubunit receptor known as the GPIb/V/IX complex.[115] This latter complex, which is expressed at approximately 25,000 copies per cell,[116] binds to the A1 domain of VWF[117] with high-enough affinity to tether platelets even under conditions of arterial shear.[118] Loss of the GPIB/V/IX receptor in both humans and mice results in a clinical condition known as Bernard-Soulier syndrome,[13,14] which is characterized not only by an increase in platelet size but also by prolonged bleeding caused, in large part,

by the inability of platelets to adhere to the vessel wall. After engagement with its ligand, GPIb acts through membrane-proximal Src family kinases,[119] through adapter molecules,[120] and to a lesser extent, via its association with immunoreceptor tyrosine–based activation motif (ITAM)-bearing subunits[121,122] to transmit early activation signals[123,124] that together result in the recruitment and activation by tyrosine phosphorylation of phospholipase Cγ2 (PLCγ2),[125,126] a key enzymatic component of platelet amplification that is required to achieve thrombus growth and stability (Fig. 25-3).[127]

Once tethered, two different platelet integrins—each of which exists in a low-affinity state on the platelet surface—begin to engage specific extracellular matrix components and, together with the small calcium transients and kinase-generated signals emanating from the GPIb complex and from the mechanical shear force generated by the flowing blood,[128] initiate the reciprocal processes of platelet adhesion and activation. Thus, the $\alpha_2\beta_1$ integrin binds to exposed collagen fibrils,[129] whereas the integrin receptor $\alpha_6\beta_1$ engages laminin.[130] Both these integrins "hand off" to a member of the immunoglobulin superfamily, GPVI,[131,132] which via its noncovalent association in the plane of the plasma membrane with the ITAM-bearing Fc receptor γ chain dimer[131,133] elicits strong PLCγ2-dependent events that (1) begin the process of cytoskeletally directed shape change and cell spreading (discussed earlier); (2) initiate signal transduction pathways (illustrated in Fig. 25-3) that cause dramatic structural changes in platelet integrins and thereby result in their adopting a high-affinity, ligand-binding–competent conformation[134]—a process known as "*inside-out*" signal transduction (to be described in more detail later); and (3) facilitate fusion of alpha and dense granules with the OCS and underlying plasma membrane.

PLATELET GRANULES AND THEIR ROLE IN HEMOSTASIS

Platelet-specific granules are synthesized, assembled, and packaged during megakaryocyte biogenesis, and at later stages of maturation they appear to come into contact with microtubules, which then transport them, via the microtubule motor protein kinesin, along the shafts of proplatelets until they reach the proplatelet tips.[135] Once inside a mature platelet, platelet granules remain relatively evenly dispersed throughout the cytoplasm, their contents awaiting threshold signals for cellular activation, at which time their membranes fuse with the plasma membrane or, more likely, the invaginated subdomains of the plasma membrane known as the OCS[136] (see earlier). The regulated secretion of granule contents ensures that hemostasis remains highly localized—an event that has recently been exploited to deliver non–platelet-derived procoagulant proteins such as factor VIII to sites of vascular injury.[137,138]
FIGURE 25-3. Platelet adhesion receptors that signal through phospholipase Cγ2 (PLCγ2). Each of the cell surface receptors shown recognizes different component of the extracellular matrix and thus works in coordinated fashion to send early activation signals into the cell. Binding of platelets to von Willebrand factor (VWF) slows platelets down so that integrins can associate productively with matrix collagen and laminin. Signals emanating from each of these events are transmitted into the cell interior, in part via the action of receptor-associated Src family kinases (Src, Fyn, Lyn), which phosphorylate tyrosine residues within nearby immunoreceptor tyrosine–based activation motifs (ITAMs), thus forming a nucleation point for the assembly of miniature organelles sometime referred to as signalosomes. Signalosomes are themselves composed of the adaptor proteins LAT, SLP-76, and Gads and the receptor tyrosine kinase Btk and function to localize, phosphorylate, and then activate PLCγ2, which coordinates all these responses by generating the classic signaling molecules 1,4,5-inositol triphosphate (IP_3) and diacylglycerol (DAG). Details regarding the molecular events that take place after the generation of IP_3 and DAG are shown in Figures 25-4 and 25-6. Btk, Bruton's tyrosine kinase; CRP, C-reactive protein; DTS, dense tubular system; GP1b, glycoprotein Ib; GSK3β, glycogen synthase kinase 3β; PI3K, posphatidylinositol-3′-kinase; PKC, protein kinase C; RIAM, $Rap1_{GTP}$-interacting adaptor molecule; SH2, Src homology domain 2.

Platelets harbor three distinct types of granules (Box 25-1). Two—alpha and dense granules—are found only in platelets, whereas lysosomes are present in nearly all cell types. Alpha granules are by far the most numerous, with as many as 40 to 80 per cell, and they contain a wide array of proteins and bioactive peptides. For ease of discussion, Box 25-1 classifies alpha granule proteins as those that reside within the alpha granule membrane (P-selectin being the most diagnostic), those pinocytosed from plasma and packaged (IgG, fibrinogen, albumin),[139] and those synthesized by megakaryocytes and stored (VWF,

platelet factor 4, thrombospondin). mRNA molecules encoding the latter group have all been identified in the platelet cytoplasm. Upon platelet activation, granules become redistributed toward the center of the cell,[136] at which time SNARE (soluble N-ethylmaleimide–sensitive attachment protein receptor) proteins within the alpha granule membrane facilitate fusion,[140] with members of the Rab family of low-molecular-weight guanosine triphosphatases (GTPases) playing a prominent role in vesicle docking and exocytosis.[141,142] After membrane fusion, P-selectin[143-145] and alpha granule membrane–

   Willebrand factor.

specific proteins such as TLT-1[146] become expressed on
the platelet surface, and the contents of the granule are
released into the plasma milieu. Exposed P-selectin, diag-
nostic of an activated platelet,[147,148] serves to recruit leu-
kocytes to the site of injury,[149] one of a number of impor-
tant links between thrombosis and inflammation[150]
(discussed at the end of this chapter). Proteins secreted
from platelets include the adhesive ligands VWF and
fibrinogen, which serve to support platelet-platelet inter-
actions; growth factors and cytokines, which promote cell
migration[151] and wound healing[152] and maintain vascular
integrity[153]; and autocrine factors such as growth arrest–
specific gene 6 (*Gas6*)[154] and CD40L,[155] which are released
and rebind platelet receptors to help amplify platelet
responsiveness. Finally, alpha granules and their contents
are a source of procoagulant proteins, with release of
factor V[156] and exposure of tissue factor[73,157] promoting
localized fibrin deposition at sites of vascular injury. Plate-
let alpha granules, or at least their contents,[158] are severely
reduced in an inherited bleeding disorder known as gray
platelet syndrome (GPS) (see Chapter 29).[159]

   Dense granules (four to eight per platelet) are mor-
phologically distinct, electron-opaque storage organelles

that contain the vasoconstrictive substance seroto-
nin,[160-162] adenine and guanine nucleotides such as ADP
and ATP, inorganic pyrophosphates[163] and polyphos-
phates,[164] and the divalent cation calcium.[165] Complexes
of the latter two are probably responsible for the dark
appearance of these bodies on thin-section electron
microscopy.[166] Dense granule membranes contain a few
components in common with lysosomal membranes, such
as granulophysin (CD63, lysosome-associated membrane
protein-3 [LAMP-3])[167] and LAMP-2,[168] as well as mem-
brane proteins also present in alpha granule membranes,
such as P-selectin,[167] thus suggesting a common origin
during biogenesis. Like their alpha granule counterparts,
these dense granule membrane proteins become expressed
on the platelet cell surface after granule fusion and secre-
tion and can be used as platelet activation markers. Curi-
ously, a number of plasma membrane glycoproteins,
including GPIb and GPIIb-IIIa, have also been reported
in dense granule membranes.[169] Dense granule contents,
especially ADP,[170] play a physiologically important role in
hemostasis, as evidenced by characteristic platelet func-
tion defects in patients whose platelets lack dense gran-
ules or their contents,[171] collectively known as storage
pool disorders.[172-174] Chédiak-Higashi and Hermansky-
Pudlak[175] syndromes are two such examples of autosomal
recessive dense granule defects that lead to platelet dys-
function and bleeding, the former being associated with
immunodeficiency and the latter with albinism (see
Chapter 29).

   Primary lysosomes are the third organelle whose
contents are secreted upon platelet activation, but only
three or fewer per cell are normally identifiable.[176]
Although a clear role for lysosomes in platelet function
has not been identified, they do contain more than a
dozen different acid hydrolases, cathepsins D and E, and
other degradative enzymes that can be secreted if plate-
lets are subjected to strong agonist stimulation. Their
contents have been shown to be mildly reduced in the
platelets of individuals with GPS,[177] in keeping with the
notion that the latter disorder is caused by a defect in
packaging. The membrane proteins on platelet lysosomes
are typical of lysosomes in other cells and include LAMP-
1,[178] LAMP-2,[168] and LAMP-3.[167]

FEED-FORWARD AMPLIFICATION PATHWAYS INVOLVED IN PLATELET RECRUITMENT AND THROMBUS STABILITY

Although platelet adhesion, early activation signals, and
granule release are prerequisites for thrombus formation,
efficient recruitment of additional platelets to the site of
the vascular lesion to yield a stable platelet plug requires
a host of additional receptor/ligand interactions—each of
which results in signal transmission and subsequent bio-
chemical and cell biologic changes that help sustain
platelet activation. Among the most important of these is
the binding of released ADP to one of its two platelet G

protein–coupled receptors, P_2Y_{12}.[179,180] Like the α_2 receptor for epinephrine, P_2Y_{12} is coupled to an inhibitory G protein that slows down the activity of adenylate cyclase, thus lowering cytosolic levels of cAMP (Fig. 25-4). This greatly potentiates platelet responses by other agonists because it allows calcium ions—released from the DTS
FIGURE 25-4. $G_{\alpha}i$ protein–coupled receptors on platelets inhibit adenylate cyclase and lower cyclic adenosine monophosphate (cAMP) levels. Shown are the two major receptors responsible for dampening the activity of adenylate cyclase. As cAMP levels drop, the ability of the SERCA2b calcium pump to sequester cytosolic calcium ions is impaired, thereby allowing calcium-mediated activation events to occur more readily.

as a result of the action of phospholipase-generated 1,4,5-inositol triphosphate (IP_3, discussed in more detail later)—to remain cytosolic. "Bioavailable" calcium ions, in turn, support a host of additional cellular events, including more robust granule secretion, activation of metal ion–dependent proteases, and activation of cell surface integrins. The importance of ADP in amplifying platelet responses is illustrated by the clinical effectiveness of ticlopidine and clopidogrel—widely used pharmacologic agents that antagonize the activity of P_2Y_{12}—in pacifying platelet reactivity and inhibiting platelet aggregation.[181]

In addition to ADP-induced, P_2Y_{12}-mediated signaling, nearly a dozen other soluble ligands are either generated or released at sites of vascular injury and function in signal amplification and platelet activation. These ligands can, for the sake of simplicity, be broken into three classes according to the type of platelet receptor to which they bind (Fig. 25-5). The first class of ligands is composed of ADP, thrombin, TXA_2, and serotonin (5′-hydroxytryptamine [5-HT]), each of which binds to a specific GPCR that is coupled to the heterotrimeric α subunit, G_q. Thus, ADP binds to P_2Y_1,[182-185] thrombin to the protease-activated receptors PAR1 and PAR4,[186,187] TXA_2 to the thromboxane receptor,[188,189] and serotonin to 5-HT_{2A}.[190] When released as a consequence of ligand binding to any of these GPCRs, the G_q subunit binds to the β isoform of phospholipase C (PLC). PLCs are lipid hydrolases that act on membrane-associated phosphatidylinositol 4,5-diphosphate (PIP_2) to produce the second messengers IP_3 and diacylglycerol (DAG). IP_3 binds and opens calcium channels, whereas DAG activates the most abundant forms of protein kinase C (PKC), thereby

FIGURE 25-5. Agonist receptors that initiate or amplify platelet activation responses (or both). Three different families of receptors are involved in signal amplification pathways: G_q-coupled GPCRs, integrins, and receptor tyrosine kinases (RTKs). Note how each activates either the γ or β isoform of phospholipase C (PLC). The sum total of PLC-generated products serves to determine the activation state of the platelet, its ability to respond to vascular injury, and its participation in thrombus growth. ADP, adenosine triphosphate; Btk, Bruton's tyrosine kinase; DAG, diacylglycerol; DTS, dense tubular system; GPCR, G_s protein–coupled receptor; 5-HT, 5′-hydroxytryptamine; IP_3, 1,4,5-inositol triphosphate; ITAM, immunoreceptor tyrosine–based activation motif; PKC, protein kinase C; RIAM, $Rap1_{GTP}$-interacting adaptor molecule; SH2, Src homology domain 2; TXA_2, thromboxane A_2; VWF, von Willebrand factor.
initiating additional signaling cascades downstream of this serine/threonine kinase. As shown in Figure 25-5, it is the sum of these products—generated by the γ2 isoform of PLC in response to adhesion and by the β isoform of PLC in response to ligand-GPCR interactions—that the platelet integrates when deciding whether to become fully activated. This concept is important in the context of designing pharmacologic strategies to inhibit platelet function because blocking adhesion and its consequent activation of PLCγ2 leaves PLCβ-mediated platelet activation largely intact, and vice versa.

The second class of signal amplifiers consists of the cell surface integrins themselves.[191] As illustrated in the middle section of Figure 25-5, when ligands bind to integrins, the Src family kinases associated with integrin cytoplasmic tails[192] trigger a series of incompletely understood amplification events[193] that have been collectively termed "*outside-in*" signaling.[194-196] Although this has best been demonstrated after interaction of the major platelet integrin $\alpha_{IIb}\beta_3$ with its ligand fibrinogen, signals also probably emanate from $\alpha_2\beta_1$[134,197,198] and $\alpha_6\beta_1$[132] upon engaging collagen and laminin, respectively. Activation signals from the latter two may be relatively weak by comparison because of the fact that only a few thousand of each are expressed on each platelet as compared with 50,000 to 80,000 $\alpha_{IIb}\beta_3$ receptors per cell.[199,200] The protein kinases Syk and FAK have been shown to become activated downstream of $\alpha_{IIb}\beta_3$ engagement, as has activation of PLCγ2.[201] However, the details of these events remain to be worked out. Finally, there is at least one autocrine loop that uses integrin-mediated outside-in signal amplification—that being cleavage and rebinding of soluble CD40L after alpha granule fusion and secretion.[155]

The third class of feed-forward amplification reactions is mediated by ligand-activated plasma membrane receptor tyrosine kinases. The first of these to be described were receptors for Gas6, a vitamin K–dependent protein related to the anticoagulant protein S. Gas6 is thought to reside in platelet alpha granules[202,203] and, like other alpha granule proteins, becomes secreted upon platelet activation. Interestingly, platelets have three different receptors for Gas6—Axl, Sky, and Mer—all of which have active cytoplasmic tyrosine kinase activity (see Fig. 25-5). Upon engagement, Gas6 receptors appear to be able to trigger tyrosine phosphorylation of the β_3 integrin cytoplasmic domain and thereby support outside-in integrin signaling, as well as activate phosphatidylinositol-3′-kinase (PI3K) to further sustain granule secretion.[154] Platelets also express two members of the Eph receptor tyrosine kinase family, EphA4 and EphB1, which when in contact with their membrane-bound counter-receptor Ephrin B1, stimulate tyrosine phosphorylation of the integrin β_3 tail and activate the integrin activator Rap1b.[204] Like Gas6 signaling,[154,205,206] genetic loss or pharmacologic blockade of Ephrin/Eph kinase interactions results in decreased ability to form a stable thrombus or retract a fibrin clot.[207]

ACTIVATION OF THE MAJOR PLATELET INTEGRIN $\alpha_{IIb}\beta_3$ (GPIIB-IIIA COMPLEX)—THE FINAL COMMON END POINT OF PLATELET ACTIVATION

Human platelets express at least five different members of the 24-member integrin family,[196,208] including three β_1 integrins ($\alpha_2\beta_1$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$—specific for collagen, fibronectin, and laminin, respectively) and two β_3 integrins—$\alpha_v\beta_3$ and its close relative $\alpha_{IIb}\beta_3$ (also known as the GPIIb-IIIa complex). $\alpha_{IIb}\beta_3$ is by far the most abundant and well studied. This section focuses on our current understanding of how $\alpha_{IIb}\beta_3$ becomes transformed from a resting to an active ligand-binding–competent conformation, with the understanding that the biochemical and cell biologic principles described for this integrin may well apply to the others.

As shown in schematic form on the left side of Figure 25-6, $\alpha_{IIb}\beta_3$ exists on the platelet surface in a bent-over conformation that is unable to associate effectively with its major soluble ligands fibrinogen, VWF, and fibronectin.[209,210] Though relatively short, the cytoplasmic domains of α_{IIb} and β_3 are thought to play a key role in maintaining the "off" state of this integrin complex as a result of weak charge interactions between them[211,212] that allow the hydrophobic transmembrane domain helices of each subunit to interact and maintain the integrin in a low-affinity state.[213,214] When platelets become activated—either by adhesion- or soluble agonist-mediated events—calcium and DAG, generated as a result of the actions of PLCγ2 and PLCβ (see Figs. 25-3 and 25-5), bind to and activate PKC and the guanine exchange factor CalDAG-GEF1. As illustrated in Figure 25-6, each of these can independently activate Rap1[215-219]—a low-molecular-weight GTPase that has been implicated in integrin activation.[220-222] Rap1 appears to activate integrins via an effector molecule known as RIAM (Rap1$_{GTP}$-interacting adaptor molecule), which recruits the highly abundant cytosolic protein talin to the inner face of the plasma membrane to form an integrin activation complex. Binding of RIAM-associated talin to the β_3 integrin subunit represents the final common step in integrin activation[223-225] because it disrupts the weak ionic clasp between the $\alpha_{IIb}\beta_3$ tails and thereby allows tail separation and a dramatic, rapid unfolding of the extracellular domain.[210] Simultaneous conformational changes in the integrin head[226,227] result in the formation of an integrin receptor with high affinity for its soluble adhesive ligands. Finally, clustering of integrins occurs[228] and ensures that bound ligands effectively broker with high avidity the platelet-platelet interactions that permit thrombus growth and stabilization.

CELL SURFACE AND CYTOSOLIC PROTEINS THAT LIMIT PLATELET RESPONSES

As anyone who has suffered a myocardial infarction or thrombotic stroke can attest to, unrestrained thrombus
FIGURE 25-6. Integrin activation. As shown in the schematic at the *bottom*, calcium and diacylglycerol (DAG), generated as a result of the combined actions of phospholipase γ (PLCγ) and PLCβ, activate two proteins: (1) protein kinase C (PKC) and (2) the Rap guanine exchange factor CalDAG-GEF1. Each of these is able to independently activate the small guanosine triphosphates (GTPase) Rap1. In its GTP-bound form, Rap1 binds to and activates one of its effector molecules, $Rap1_{GTP}$-interacting adaptor molecule (RIAM), which then binds talin to form an integrin activation complex (IAC). When the IAC binds specific sites within the β_3 cytoplasmic domain, the clasp breaks, thereby destabilizing transmembrane domain helix associations that are thought to maintain the integrin in its low-affinity state (shown on the *left*). Breaking the hinge causes extensive conformational changes in the extracellular domain and produces a high-affinity, ligand-binding–competent integrin (shown on the *right*). EGF, epidermal growth factor; PSI, plexin-semiphorin-integrin; β-TD, beta terminal domain. *(Portions adapted from Wegener KL, Partridge AW, Han J, et al: Structural basis of integrin activation by talin. Cell 2007;128:171, with permission.)*

growth at inappropriate sites can be as harmful as excessive bleeding because it can result in vessel occlusion, ischemia, and tissue damage. Numerous active processes are therefore in place to limit platelet responsiveness in healthy vessels so that thrombus growth is kept localized to specific sites of vascular injury and dissolution of the platelet plug during recovery is facilitated.

As discussed earlier, healthy endothelium contributes to platelet passivation via rather continuous generation of PGI_2 and NO, which act on platelets by activating adenylate and guanylate cyclases to increase intracellular levels of cAMP and cGMP. These messengers activate PKA and PKG, respectively (illustrated in Fig. 25-2). PKG controls the threshold for platelet activation primarily by phosphorylating the IP_3 receptor–associated cGMP kinase substrate IRAG,[229] a protein that associates with PKG and IP_3 receptor type I to inhibit IP_3-induced calcium release from intracellular stores.[230,231] Both PKA and PKG interfere with platelet activation by phosphorylating and inactivating VASP (vasodilator-stimulated phosphoprotein),[232] a molecule with anticapping activity that is important for the processes of actin polymerization and filopod formation.[233-237] PKCδ can also bind VASP and interfere with its ability to promote filopodia formation, although this pathway is unique to collagen-stimulated platelets and does not involve regulation of PKA- or PKG-mediated VASP phosphorylation.[238]

One of the better characterized inhibitory receptors in platelets is platelet endothelial cell adhesion molecule-1 (PECAM-1)—a cell surface molecule composed of six extracellular immunoglobulin domains, the most amino-terminal of which engages in homophilic interactions with PECAM-1 molecules on other cells, and two cytoplasmic immunoreceptor tyrosine–based inhibitory motifs (ITIMs) that upon phosphorylation, recruit and activate the cytosolic SH2 domain–containing protein tyrosine phosphatase-2 (SHP-2).[239,240] PECAM-1 has been shown to negatively regulate both GPVI- and GPIb/V/IX-mediated platelet activation[241-243]—perhaps by controlling the phosphorylation state of these two ITAM-bearing signaling receptors—and appears to be one of several inhibitory receptors that control the rate and extent of platelet thrombus formation in vivo.[244] Platelets have also recently been found to express two other immunoglobulin/ITIM-containing molecules: triggering receptor expressed on myeloid (TREM) cells–like transcript-1 (TLT-1) and products of the *G6b* gene. TLT-1 is contained within platelet alpha granules and is expressed on the platelet surface in an activation-dependent manner.[146,245] Although the two cytoplasmic ITIMs of TLT-1 are capable of becoming phosphorylated and recruiting SHP-2,[146] the extent to which TLT-1/SHP-2 complexes regulate platelet function is not yet known. The *G6b* gene, which is located within the class III region of the human major histocompatibility complex,[246] gives rise to multiple alternatively spliced transcripts (G6b-A through G6b-G).[247] Platelets contain at least two (G6b-A and G6b-B)[71,86,248] and possibly four (G6b-A, G6b-B, G6b-D, and G6b-E)[249] of these transcripts, and the G6b-B isoform contains cytoplasmic ITIMs that are capable of becoming tyrosine-phosphorylated and recruiting SHP-1 and SHP-2.[247] In platelets, the G6b-B isoform has been shown to be tyrosine-phosphorylated in resting and activated platelets, but to associate with SHP-1 only upon platelet activation.[248] Cross-linking of antibodies specific for *G6b* gene products has been shown to inhibit platelet aggregation in response to multiple stimuli[249]; however, whether these effects are due to the inhibitory function of G6b-B remains to be determined.

Several inhibitory pathways have been identified in platelets that either regulate or are regulated by PI3K—a lipid kinase that phosphorylates the 3′ position of PIP_2 to generate phosphatidylinositol 3,4,5-triphoshate (PIP_3), thereby creating docking sites on the inner face of the

plasma membrane for Pleckstrin homology (PH) domain–containing molecules.[250] The actions of PI3K are opposed by the lipid phosphatase SHIP1 (SH2 domain–containing inositol 5′-phosphatase 1, which hydrolyzes the 5′-phosphate of PIP_3).[251,252] In platelets, SHIP1 has been shown to downregulate PIP_3 generation after $\alpha_{IIb}\beta_3$-mediated outside-in signaling[253] and thus may interfere with the feed-forward amplification pathways that increase the efficiency with which platelets are recruited to growing thrombi. Interestingly, the 5′-inositol phosphatase activity of SHIP1 appears to be enhanced, at least in part, by the actions of the Src family tyrosine kinase Lyn,[254-256] which itself has been shown to limit platelet aggregation in response to GPVI-specific stimuli[257] and after platelet spreading on immobilized fibrinogen.[253]

Akt (also known as protein kinase B) is a PH domain–containing serine/threonine kinase that is a well-characterized effector of PI3K.[258,259] Akt contributes positively to platelet activation in multiple ways, one of which appears to be by inactivating the serine/threonine kinase glycogen synthase kinase 3 (GSK3). The GSK3 family is composed of three isoforms (α, β, β_2) that are constitutively active in resting cells but become inactivated in activated cells by Akt-mediated phosphorylation.[260] Platelets express two isoforms of GSK3 (α and β), both of which become phosphorylated and inactivated after exposure of the platelet to multiple agonists that activate PI3K and Akt.[261] Whereas initial studies reported that specific inhibitors of GSK3 activity block rather than enhance platelet responses to agonist stimulation,[261] a recent report suggest that as in other cells, the β isoform of GSK3 acts as a negative regulator of platelet function both in vitro and in vivo.[262]

ADDITIONAL ROLES FOR PLATELETS IN VASCULAR PHYSIOLOGY: VESSEL REPAIR (ANGIOGENESIS), INFLAMMATION, AND ATHEROTHROMBOSIS

In addition to being essential for primary hemostasis, activated platelets and their secreted products have the ability to influence a broad array of pathophysiologic processes, including leukocyte trafficking and inflammation, tissue regeneration and angiogenesis, and both the beginning and end stages of atherosclerosis.

Activated platelets that become spread on components of the extracellular matrix, or on each other, display an altered surface phenotype—the most prominent of which is exposure of several thousand copies of the alpha granule–derived membrane protein P-selectin. P-selectin is also expressed on cytokine-activated endothelial cells. Thus, after either a thrombotic or inflammatory event, P-selectin appears on the luminal face of the vessel wall, where it serves to recruit monocytes and neutrophils into the underlying tissue by binding PSGL-1—a constitutively expressed counter-receptor for P-selectin that is present on most leukocytes. In vivo, mice lacking P-selectin exhibit greatly diminished leukocyte rolling, delayed recruitment into sites of inflammation, and increased susceptibility to infection.[263,264] Although endothelial P-selectin no doubt has a major role in leukocyte capture, platelet P-selectin probably plays a prominent role in "secondary capture."[265,266] As in platelets, tethering also initiates activation of leukocyte integrins, which are then able to mediate cell spreading and transendothelial migration. P-selectin/PSGL-1 interactions therefore constitute an important link between thrombosis and inflammation.[150,267] Other platelet/leukocyte receptor/counter-receptor pairs have also been shown to facilitate the inflammatory response, including binding of platelet-associated fibrinogen to the leukocyte integrin MAC-1[268] and platelet JAM-3 binding to MAC-1 on monocytes[269] and dendritic cells.[270]

In addition to forming a platform for leukocyte recruitment during acute inflammation, platelets also deliver to the vessel wall proinflammatory chemokines that are thought to play a role in the development of atherosclerosis by promoting further chemoattraction of leukocytes and stimulating proliferation of vessel wall smooth muscle cells and fibroblasts. Such secreted factors include the C-X-C chemokine platelet factor 4, macrophage inflammatory protein 1a (MIP-1a), the C-C chemokine RANTES (regulated on activation, T cell expressed and secreted), CD40 ligand, platelet-derived growth factor (PDGF), and transforming growth factor β (TGF-β).[150,267,271,272] Activated platelets also synthesize de novo IL-1β,[273,274] a potent stimulator of endothelial cells and monocytes that upregulates adhesion molecule expression. Thus, platelets appear to contribute in a number of ways to the development and progression of atherosclerotic lesions.

Finally, so that one is not left with the impression that platelets only exacerbate chronic human disease, it should be noted that platelets and their secreted products were shown as early as 1969[153] to be able to "nurture" the vascular endothelium, and they have recently been proposed as a source of biologic response modifiers for a plethora of uses, including organ preservation, gum restoration after dental procedures, and tissue repair after surgery.[152] Their ability to adhere at sites of vascular injury and secrete both degradative enzymes and at the same time growth-promoting factors such as vascular endothelial growth factor (VEGF), PDGF, fibroblast growth factor (FGF), epidermal growth factor (EGF), and angiopoietin 1 allows them to play a uniquely supportive role in endothelial cell migration and survival during the process of wound healing and angiogenesis.[151]

26 Blood Coagulation

Kenneth G. Mann and Kathleen Brummel-Ziedins

OVERVIEW OF COAGULATION

Generation of the enzyme thrombin from its precursor prothrombin is the central event in the blood coagulation process, essential for hemostasis and the culprit in thrombosis. Blood loss through lack of hemorrhage control has captured the attention of individuals from many walks of life throughout history. At the end of the 19th century, the role of thrombin in the clotting of fibrinogen was accurately described by Schmitt.[1] Since that time hemostasis has been synonymous with blood clotting. Congenital diseases associated with absence or reduced production of thrombin (the hemophilias) represent important clinical problems (see Chapters 30 and 31). In contrast, the unregulated production of thrombin in an inappropriate location leads to another series of diseases associated with thrombotic occlusion (see Chapter 32).

The development of plasma clot–based assays in vitro has played a central role in establishing the logical relationships between the reactants and reactions of hemostasis (Fig. 26-1). The prothrombin time (PT) and the activated partial thromboplastin time (APTT) both rely on the end point of fibrin formation (clotting), which occurs with the generation of less than 5% of the thrombin ultimately produced. The primary pathway leading to hemostatic and thrombotic pathology appears to be associated with the tissue factor (TF)-initiated, "extrinsic" coagulation pathway. In contrast, components unique to the "intrinsic" or contact pathway (factor XII, prekallikrein, high-molecular-weight kininogen [HMWK]) do not appear to be essential to hemostasis.

The observation that tissue extracts added to plasma initiated clotting led Quick to develop the PT assay.[2] This assay is still used extensively in the management of warfarin anticoagulant therapy and establishes the continuity of components in the *extrinsic pathway*. The tissue preparations (thromboplastin) contain the protein TF and phospholipids, with plasma contributing factor VIIa and calcium to form the *extrinsic factor Xase*, which converts plasma factor X to factor Xa (see Fig. 26-1). Factor Xa subsequently combines with plasma factor Va, phospholipids, and calcium to activate prothrombin to thrombin, the latter serving as the catalyst that cleaves fibrinogen to produce fibrin, the clotting end point.

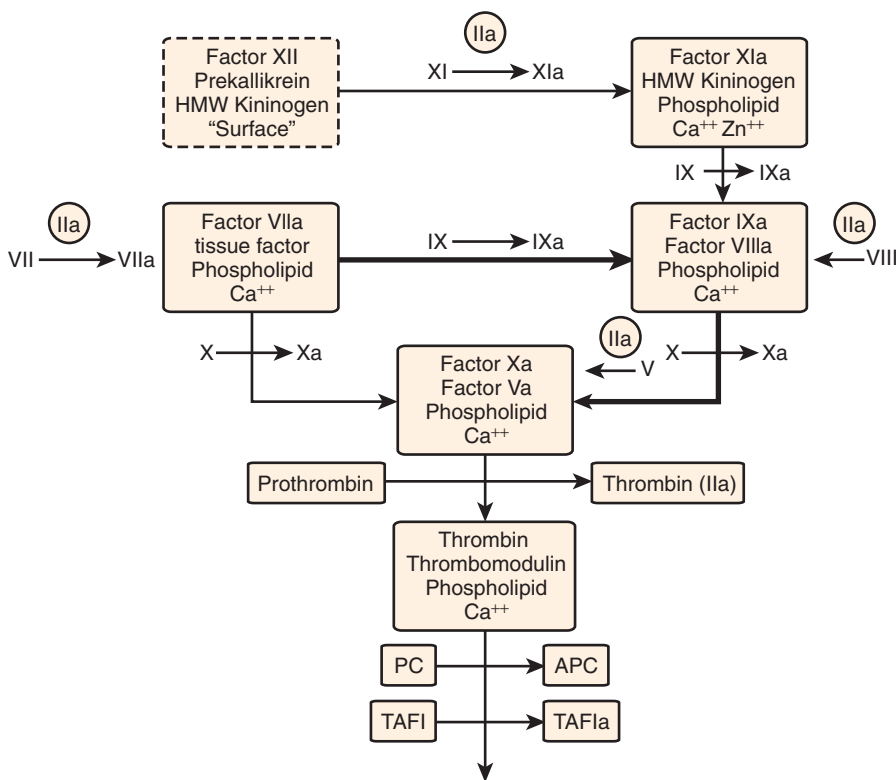
Langdell and colleagues[3] subsequently explored the spontaneous clotting of recalcified citrate plasma and developed the APTT, thus providing the tool that defined the *intrinsic pathway* of coagulation (see Fig. 26-1). This pathway, dependent only on the protein components present in blood plasma, was formalized by the cascade/waterfall hypotheses of MacFarlane[4] and Davie and Ratnoff.[5] The APTT assay involves the addition of an artificial surface, phospholipids, and calcium chloride to blood plasma. Initiation of this contact pathway begins with the surface-dependent activation of factor XII to factor XIIa; this leads to activation of prekallikrein to kallikrein, which, together with HMWK, provides a self-amplifying catalytic system that results in rapid activation of factor XI to factor XIa. Factor XIa, together with HMWK, phospholipid, and metal ions, catalyzes the activation of factor IX to factor IXa. Factor IXa, with factor VIIIa and a membrane surface, form the *intrinsic factor*


FIGURE 26-1. Schematic of the catalysts of the hemostatic system. The outline of the "contact catalyst" of the intrinsic pathway is *dashed* because of its uncertain contributions to hemostasis. The contribution of the contact catalyst to thrombosis is unresolved. The various points at which thrombin catalyzes its own generation by the conversion of zymogens and procofactors to the active species required for catalyst formation are illustrated by *circles* (IIa). APC, activated protein C; HMW, high molecular weight; PC, protein C; TAFI, thrombin-activatable fibrinolysis inhibitor.

Xase, which activates factor X to factor Xa as illustrated in Figure 26-1.

By the mid-1980s, the conclusion that TF was probably the principal initiator of the hemostatic process[6] and the absence of bleeding associated with deficiencies of the contact pathway initiators (factor XII, prekallikrein, and HMWK) presented a significant conundrum for the scientific community. This was accentuated by the absence of linkage between hemophilia A and B and the extrinsic pathway as evaluated by the PT assay. Subsequently, the intersections between intrinsic and extrinsic and the reactions linking these two "classical" pathways were identified.[7-9]

Of equal importance to the procoagulant process is its regulation by stoichiometric and dynamic inhibitory systems. Antithrombin (AT)[10] and tissue factor pathway inhibitor (TFPI)[11] are the primary stoichiometric inhibitors, whereas the thrombin-thrombomodulin–protein C system is dynamic in its inhibitory function. The latter catalyst activates protein C to activated protein C (APC), which proteolytically destroys the cofactors factor Va and factor VIIIa, thereby eliminating the intrinsic factor Xase and prothrombinase. TFPI blocks the factor VIIa–TF–factor Xa product complex,[12] thus effectively neutralizing the extrinsic factor Xase (Fig. 26-2). However, TFPI is present in low abundance ($\approx$2.5 nM) in blood and can only delay the hemostatic reaction.[13] AT, normally present in plasma at twice the concentration (~3.2 μM) of any potential coagulation enzyme, neutralizes all the procoagulant serine proteases, primarily in the uncomplexed state.[10]

The dynamic protein C system is activated by binding of thrombin to vascular thrombomodulin, with this complex (Fig. 26-3) converting protein C to its activated species APC.[14] APC proteolytically inactivates factors Va and VIIIa.[15] The protein C system, TFPI, and AT cooperate to produce steep TF concentration thresholds that act like a digital "switch" to allow or block thrombin formation.

Thus, there are three membrane-associated procoagulant complexes[16] (corresponding to the proteases factor IXa, factor Xa, and factor VIIa), each interacting with a cofactor protein (factor VIIIa, factor Va, TF). An analogous anticoagulant complex is composed of thrombin-thrombomodulin (see Fig. 26-3). Each complex involves a vitamin K–dependent serine protease, phospholipid, and an associated cofactor protein assembled on a membrane surface provided by an exposed, activated or damaged cell.

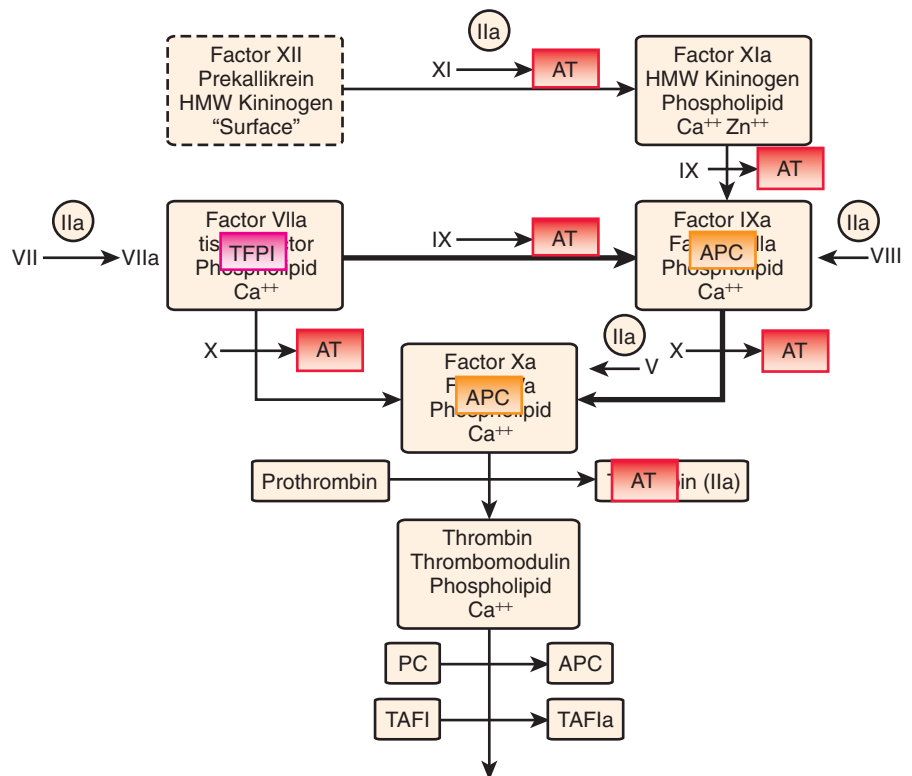
The membrane-binding properties of the vitamin K–dependent proteins (VKDPs) are the consequence of post-translational γ-carboxylation of these macromolecules. The cofactor proteins are either membrane-binding proteins (factor Va, factor VIIIa) recruited from plasma as procofactors or intrinsic membrane proteins (TF, thrombomodulin) regulated by presentation. Each complex catalyst is orders of magnitude (10^3- to 10^6-fold) more efficient than the individual serine protease acting on its substrate in solution.[17-19] When considered on a temporal scale, the amount of thrombin produced by prothrombinase in 1 minute would be produced by factor Xa acting alone in 6 months. As a consequence, factor Xa is ineffective in hemostasis without the presentation of both factor Va and the platelet membrane binding sites on which prothrombinase is formed. The blood coagulation reaction can be described as occurring in three overlapped phases: initiation, propagation, and termination.


FIGURE 26-2. Points of regulation of the catalyst of Figure 26-1 by tissue factor pathway inhibitor (TFPI), antithrombin (AT), and activated protein C (APC) are illustrated. HMW, high molecular weight; PC, protein C; TAFI, thrombin-activatable fibrinolysis inhibitor.
FIGURE 26-3. Vitamin K–dependent complexes. Three procoagulant complexes (extrinsic factor Xase, intrinsic factor Xase, and prothrombinase) and one anticoagulant complex (protein Case) are illustrated. Each membrane complex consists of a vitamin K–dependent serine protease (factor VIIa, factor IXa, prothrombin [II], or protein C [C]) and a soluble or cell surface–associated cofactor (factor VIIIa [heavy and light chain factor $VIII_H$ and factor $VIII_L$], factor Va [heavy- and light-chain factor V_H and factor V_L], tissue factor [TF], or thrombomodulin [TM]). Each serine protease is shown in association with the appropriate cofactor protein and zymogen substrate or substrates (factors X, IX, and II and protein C) on the membrane surface. The membrane serves as a scaffold for the coagulation reactants and enhances reaction rates by 10^5- to 10^6-fold. (*Redrawn with permission from Mann KG. Dynamics of Hemostasis. Essex Junction, VT, Haematologic Technologies, 2002.*)

Initiation

The factor VIIa–TF–membrane complex (extrinsic factor Xase) (Fig. 26-4A; also see Fig. 26-3) catalyzes the activation of both factor IX and factor X, the latter being the more efficient substrate.[7] Thus, the initial product formed is factor Xa. Feedback cleavage of factor IX by membrane-bound factor Xa enhances the rate of generation of factor IXa in a cooperative process with the factor VIIa–TF complex.[9]

The initially formed, membrane-bound factor Xa activates small amounts of prothrombin to thrombin.[20] This initial activation of prothrombin provides the thrombin essential for acceleration of the hemostatic process by serving as the activator for platelets and the procofactors factor V[15] and factor VIII (see Fig. 26-1). Once factor VIIIa is formed, the factor IXa generated by the factor VIIa–TF complex combines with factor VIIIa on the activated platelet membrane to form the intrinsic factor Xase (Figs. 26-3 and 26-4A), which becomes the major activator of factor X. The factor IXa–factor VIIIa complex is 10^6-fold more active as a factor X activator and 50 times more efficient than the factor VIIa–TF complex in
FIGURE 26-4. A, The factor Xa generated by the factor VIIa–tissue factor (TF) complex catalyzes the formation of a small amount of thrombin, which activates factors V and VIII and leads to the presentation of the intrinsic factor Xase (factor IXa-VIIIa) and prothrombinase (factor Xa-Va). At this point in the reaction, generation of factor IXa is cooperatively catalyzed by membrane-bound factor Xa and by factor VIIa–TF. The *thick arrow* representing generation of factor Xa by the intrinsic factor Xase illustrates the more efficient generation of factor Xa by this catalyst. **B,** The tissue factor pathway inhibitor (TFPI) interacts with the factor VIIa–TF–factor Xa product complex to block TF-initiated activation of both factor IX and X, thus leaving the factor IXaβ-VIIIa complex as the only viable catalyst for activation of factor X. (*Redrawn with permission from Mann KG. Dynamics of Hemostasis. Essex Junction, VT, Haematologic Technologies, 2002.*)

catalyzing activation of factor X (thus, the bulk of factor Xa is ultimately produced by the factor IXa–factor VIIIa complex).

Propagation

As the reaction progresses, generation of factor Xa by the more active intrinsic factor Xase exceeds that of the extrinsic factor Xase complex.[21] In addition, the extrinsic factor Xase complex is subject to inhibition by TFPI[11] (Fig. 26-4B). As a consequence, most (>90%) of factor Xa is ultimately produced by the factor VIIIa–factor IXa complex. In hemophilia A and hemophilia B, this amplification of factor Xa generation does not occur.[22] Factor Xa combines with factor Va on the activated platelet membrane receptors, and this factor Va–factor Xa prothrombinase catalyst (see Figs. 26-3 and 26-4) converts most prothrombin to thrombin. Prothrombinase is 300,000-fold more active than factor Xa alone in catalyzing activation of prothrombin.[17]

Termination

The same hemostatic process required for preventing leaks from the vasculature may also be life threatening when responsible for intravascular occlusion. Thus, equally important to the hemostatic process are the stoichiometric and dynamic inhibitory systems, which block the presentation of thrombin. The sum of inhibitory functions is far in excess of the potential coagulant response. These inhibitory processes governed by TFPI, AT, and the protein C pathway act in synergy to provide activation thresholds, for which a minimum level of TF stimulation must be achieved before significant thrombin generation can occur.[23] The termination phase thus occurs throughout the reaction process.

Flow Regulation

Current data are consistent with the concept of a two-compartment model for regulation of the procoagulant response to a breach in a blood vessel (Fig. 26-5). Regulation of clotting in the extravascular space, apart from providing the initiating TF, is primarily passive and controlled by the availability of fresh blood, whereas regulation in the intravascular compartment is dynamic. Mechanical disruption of a blood vessel results in the movement of blood to an environment where TF is exposed and platelets bind and are activated (see Fig. 26-5, stage 1). These events localize the initiating procoagulant reactions to blood now outside the vasculature, with adhesion and activation of platelets in this extravascular blood providing sufficient receptors and surfaces to support the propagation phase of thrombin generation (see Fig. 26-5, stage 2). This extravascular process rapidly becomes independent of TF as generation of thrombin becomes supplied by the intrinsic factor Xase and prothrombinase complexes. As long as new blood flows into

this space, and fibrin formation and platelet aggregation have not achieved a sufficient barrier to stop flow, the system is open and the propagation phase of thrombin generation will continue. If blood ceases to move into the extravascular compartment, the system becomes closed, available prothrombin is consumed, and the complex enzymes are ultimately destroyed or sequestered into inactive complexes (see Fig. 26-5, stage 3). However, the stability of the prothrombin activating potential incorporated into the platelet-rich thrombus and its localization in the extravascular space ensure that if the barrier springs a leak, robust generation of thrombin will begin immediately on contact and continue until consequent platelet activation and fibrin deposition re-establish a secure barrier.

Three mechanisms act to limit clot growth into the intravascular space (see Fig. 26-5, stage 4): thrombomodulin-dependent activation of protein C,[14] the presence of abundant AT, and the actively nonthrombogenic and nonadhesive surface of the vascular endothelium. Thus, thrombin generation with consequent ongoing fibrin deposition and platelet activation is suppressed at the extravascular-intravascular boundary by these processes. In contrast, complexes at the extravascular side will remain relatively protected from APC and AT by the forming barrier and are therefore ready to respond to any leakage of blood.

The general properties of proteins of the blood coagulation proteome are summarized in Table 26-1 and discussed in the following text.

THE VITAMIN K–DEPENDENT PROTEIN FAMILY

The Nobel Prize was awarded to Dam and Doisy in 1941 for their discovery of the fat-soluble vitamin K. Nearly simultaneously with the discovery of vitamin K, a naturally occurring antagonist, bishydroxycoumarin (dicumarol), was described. This antagonist was identified as a toxic agent in spoiled sweet clover that caused hemorrhage in cattle because of decreased thrombin formation. This agent was introduced as an anticoagulant in humans in 1941.[24]

Vitamin K, essential for the biosynthesis of clotting factors, contributes to the conversion of 10 to 13 glutamate residues to γ-carboxyglutamate residues (Gla). This post-translational modification endows the VKDP with Ca^{2+}- and membrane-binding qualities.[25] Gla formation is decreased or absent after treatment with coumarin derivatives.

The VKDPs (Fig. 26-6) can be divided into two classes: procoagulant (factors II, VII, IX, X) and anticoagulant (protein C, protein S, and protein Z). The homology among these proteins is probably due to a common ancestral gene.[26] Each VKDP is composed of discreet domains characterized by highly conserved regions. The NH_2-terminal "Gla" domains (see Fig. 26-6) are fol-

FIGURE 26-5. Schema of a two-compartment model of the regulation of tissue factor (TF)-initiated blood coagulation. A cross section of a blood vessel showing the luminal space, endothelial cell layer, and extravascular region is presented at the site of a perforation. The blood coagulation process in response is depicted in four stages. TF–factor VIIa complex, TF-VIIa; prothrombinase complex, Xa-Va; intrinsic factor Xase, VIIIa-IXa; antithrombin III (ATIII)–endothelial cell heparan sulfate (HS) proteoglycan complex bound to thrombin or factor Xa, HS-ATIII-(IIa or Xa); protein C (PC) bound to thrombomodulin-thrombin, TM-IIa-PC. **Stage 1.** Perforation results in delivery of blood and, with it, circulating factor VIIa and platelets to an extravascular space rich in membrane-bound TF. Platelets adhere to collagen and von Willebrand factor associated with the extravascular tissue, and TF binds factor VIIa , thereby initiating the process of activation of factor IX and X. Factor Xa activates small amounts of prothrombin to thrombin, which in turn activates more platelets and converts factors V and VIII to factors Va and VIIIa. **Stage 2.** The reaction is propagated by platelet-bound intrinsic factor Xase and prothrombinase, with the former being the principal generator of factor Xa. Initial clotting occurs and fibrin begins to fill in the void in cooperation with activated platelets. **Stage 3.** A barrier composed of activated platelets laden with procoagulant complexes and enmeshed in fibrin scaffolding is formed. The reaction in the now-filled perforation is terminated by consumption of reagent, which attenuates further generation of thrombin, but functional procoagulant enzyme complexes persist because they are protected from the dynamic inhibitory processes found on the intravascular face. **Stage 4.** View downstream of the perforation. Enzymes escaping from the plugged perforation are captured by antithrombin-heparan complexes, and the protein C system is activated by binding of residual thrombin to endothelial cell thrombomodulin, thereby initiating the dynamic anticoagulant system. These intravascular processes work against occlusion of the vessel despite continuous resupply of reactants across the intravascular face of the thrombus. (*From Orfeo T, Butenas S, Brummel-Ziedens KE, Mann KG. The tissue factor requirement in blood coagulation. J Biol Chem. 2005;280:42887-42896.*)

lowed by either kringle domains in prothrombin or epidermal growth factor (EGF)-like domains in factor VII, factor IX, factor X, protein C, protein S, and protein Z. Protein S contains four EGF domains followed by a sex hormone–binding domain (SHD). The serine protease domain for prothrombin, factor VII, factor IX, factor X, and protein C becomes functional after cleavage of specific peptide bonds. Protein S is not a serine protease precursor but is sensitive to thrombin cleavage. Protein

Z contains a "pseudocatalytic domain" in the COOH-terminal but cannot function as a serine protease.

Synthesis of these proteins occurs primarily in the liver, although synthesis in other tissue has been reported. The plasma concentration of circulating VKDP varies 200-fold from approximately 100 µg/mL for prothrombin to 0.5 µg/mL for factor VII (see Table 26-1). Clearance rates of the VKDPs vary with their half-lives, from 6 hours (factor VII) to 2.5 days (prothrombin; see Table 26-1).

TABLE 26-1   General Properties of Blood Coagulation Proteins

Protein	Molecular Weight	PLASMA CONCENTRATION		Plasma $t_{1/2}$ (Days)	Chromosome* (Gene Location)	Functional Classification
		nmol/L	µg/mL			
INTRINSIC PATHWAY PROTEINS						
Factor XII	80,000	500 (265)	40 (21)	2-3	Chr 5 (176 Mb)	Zymogen

The VKDPs are synthesized as preproproteins and are modified post-translationally at specific glutamates (γ-carboxylation) to form γ-carboxyglutamic acid (Gla).[25] Other modifications include β-hydroxylation at select aspartate and asparagine residues, tyrosine sulfation, and glycosylation. After synthesis of the single-chain precursors, the hydrophobic signal peptide directs each polypeptide to the endoplasmic reticulum. The propeptides, which play a role in docking vitamin K–dependent carboxylase,[27] are removed by an endoproteinase. For factor X and protein C, removal of an internal dipeptide or tripeptide converts them to their mature plasma two-chain zymogen forms.

The Gla domains constitute the first approximately 50 residues of the VKDPs (Fig. 26-6). The negative charge elicited from the string of Gla residues (9 to 13) contributes to the binding of Ca^{2+} and generation of the conformation required for binding to anionic phospholipid membranes. In vivo, this surface is supplied

by activated platelets or other blood cells in response to vascular damage through exposure of the phosphatidylserine-rich internal face of their cell membranes. Without vitamin K, or in the presence of vitamin K antagonists, the coagulation protein precursors are synthesized but not γ-carboxylated. In this form they are still secreted into plasma but display diminished function. The γ-carboxylation reaction is catalyzed by the enzyme γ-glutamyl carboxylase. This enzyme is located in the rough endoplasmic reticulum and requires the reduced form of vitamin K, oxygen, and carbon dioxide[25] to convert glutamic acid residues to γ-carboxyglutamic acid.

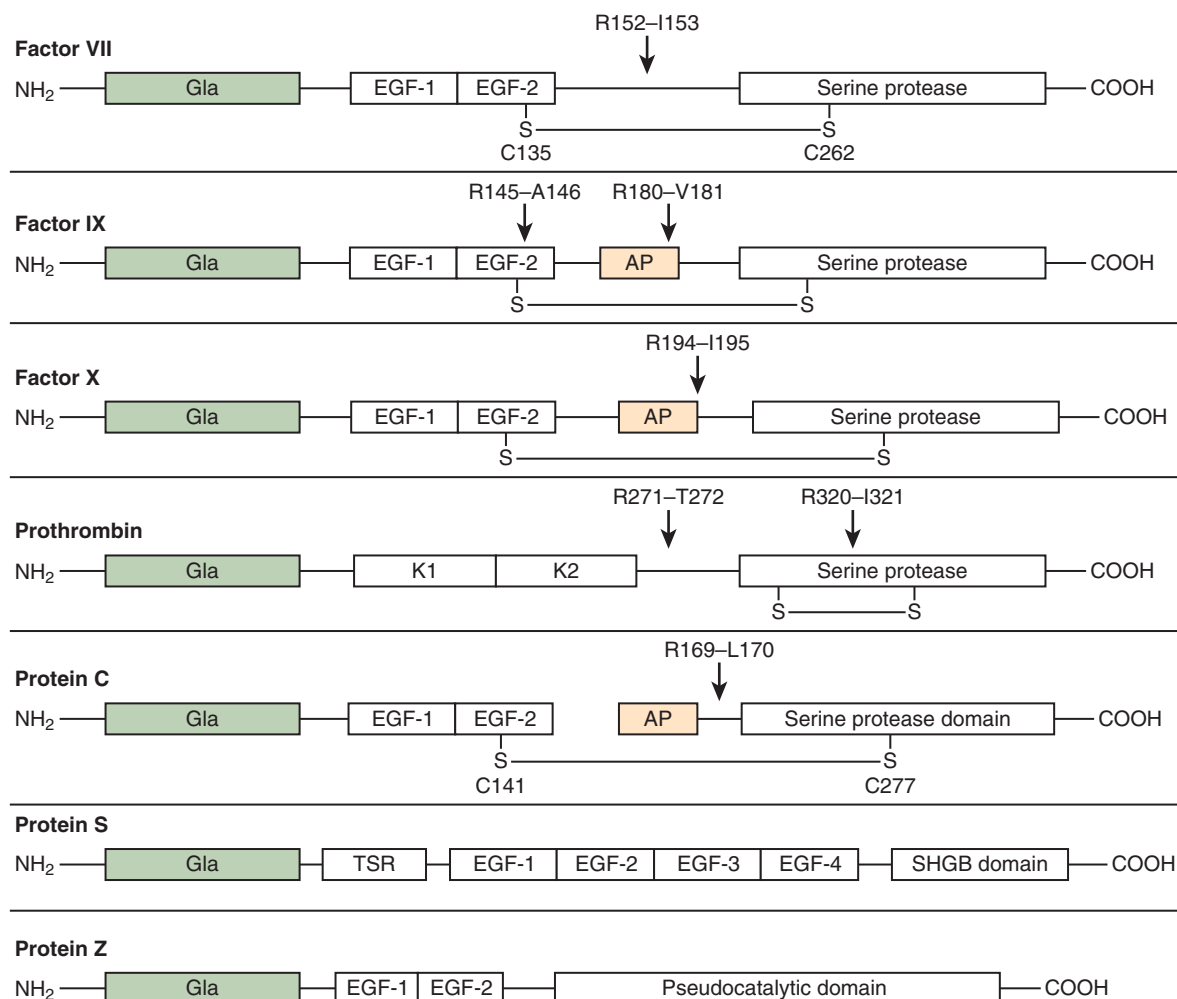
Vitamin K_1 (phylloquinone) is primarily found in leafy green vegetables and vegetable oil. Additional K activity may be provided by vitamin K_2 (menaquinones) synthesized by intestinal gram-negative bacteria. Synthetic vitamin K_3 (menadione) has no intrinsic activity until it undergoes in vivo modification to the active


FIGURE 26-6. Schematic representation of the vitamin–K dependent proteins. The building blocks for these proteins are composed of Gla domains (9 to 13 Gla residues), followed by either kringle domains (K) in prothrombin or epidermal growth factor–like domains (EGF) in factors VII, IX, and X, protein C, protein S, and protein Z. Protein S contains a thrombin-sensitive region (TSR) before the EGF domain. The active site is contained within the serine protease domain for prothrombin, factors VII, IX, and X, and protein C and is functional upon cleavage at the activation site. Protein S is not a serine protease precursor and instead contains a sex hormone globulin binding–like domain (SHGB) in the COOH-terminal. Protein Z contains a "pseudocatalytic domain" in the COOH-terminal and does not function as a serine protease enzyme. For reference, the molecular weight for each protein is listed under its name, and disulfide bonds are illustrated as (-S-S-).

menaquinone form. In vivo, vitamin K is recycled in a microsomal oxidation-reduction system for continued use in the γ-carboxylation reaction.[28,29] In order to perform the γ-carboxylation reaction, vitamin K has to be present in its reduced hydroquinone form. As the precursor proteins are carboxylated, vitamin K is oxidized to the epoxide. The epoxide in the presence of 2,3-epoxide reductase, with thiols being used as the reducing agent, yields the quinone form of vitamin K.[30] A subsequent reduced nicotinamide adenine dinucleotide phosphate (NADPH) or NADH-dependent quinone reductase reaction resynthesizes the hydroquinone form. The cycle can thus continue. Warfarin anticoagulant therapy blocks the process required for the regeneration of reduced hydroquinone vitamin K.[28,29] Because warfarin and other coumarin derivative drugs indirectly affect carboxylation, they can be overcome with excess vitamin K.

The Gla domain is followed by two tandem EGF domains (EGF-1 and EGF-2) in factor VII, factor IX, factor X, and protein C and four EGF domains (EGF-1 to EGF-4) in protein S[31] (see Fig. 26-6). Each EGF-like domain consists of 40 to 50 amino acids, including six cysteine residues involved in disulfide bond formation. These domains are found widely distributed in extracellular and membrane proteins. Proteins containing these EGF-like domains are involved in blood coagulation, fibrinolysis, complement activation, connective tissue microfibril formation, and signal transduction.[32] The function of the EGF domain is still unclear. One hypothesis is that it serves as a spacer. There is a consistent elongation of the molecules of factors VII, IX, and X, protein C, and protein S. The distance between the membrane-binding Gla domain and the serine protease domain is crucial to placement of the active site in an appropriate position relative to the target peptide bond in its substrate.[33]

The serine protease domains (see Fig. 26-6) account for approximately half the mass of each protein. Peptide bond cleavage at specific sites converts the vitamin K–dependent zymogens to their active, chymotrypsin-like, serine protease forms. The mechanism of proteolysis by chymotrypsin involves a catalytic triad composed of Asp102, His57, and Ser195 (chymotrypsin numbering). The serine protease domains of all the Gla-containing factors are homologous members of the chymotrypsin family but cleave almost specifically at arginyl residues. However, unlike trypsin, which shows little specificity beyond the requirement for arginyl or lysyl residues at the cleavage site, the activated coagulation factors have extended substrate specificity pockets whereby only selected amino acid sequences are recognized by each protease. Thus, despite the high degree of homology between the protease domains of protein C and factors II, VII, IX, and X, each of these factors has a highly specific function in coagulation. Some of this discrimination is mediated by surface loops, along with other domains distant from the substrate binding pocket termed exosites.

Factor VII (Proconvertin, Convertin)

The single-chain factor VII zymogen is activated to its two-chain protease form by cleavage of a single peptide bond between Arg152 and Ile153 (see Fig. 26-6). The mechanism for the initial activation of this zymogen is unclear. The resulting protease consists of an NH2-terminal light chain linked by a single disulfide bond to a COOH-terminal heavy chain containing the catalytic domain. Factor VIIa has very poor catalytic efficiency without the presence of its cofactor TF.[34,35] Cleavage of factor VII to factor VIIa can be catalyzed by several proteases, including α-thrombin,[36] factor IXa,[37] factor Xa,[36] factor XIIa,[38] and factor VII–activating protease,[39] as well as by autoactivation by factor VIIa.[40] The active factor VIIa serine protease bound to TF forms the extrinsic factor Xase complex (see Fig. 26-3).

Factor VIIa, unlike other serine proteases of the coagulation cascade,[35] is not readily inhibited by circulating protease inhibitors, including the AT-heparin complex, unless bound to TF.[41,42] Thus, regulation of TF expression is the primary means of controlling factor VIIa activity. Paradoxically, the zymogen factor VII (10 nM) is an effective competitor of factor VIIa (0.1 nM) for binding to TF. This competition downregulates the level of enzymatically active complex (factor VIIa–TF), thereby suppressing initiation of the clotting cascade. Once the extrinsic tenase complex activates factor X to factor Xa, TFPI can form a quaternary complex (factor VIIa–TF–factor Xa–TFPI) with no enzymatic activity[43] (see Fig. 26-4). Thus, once assembled and functioning, the extrinsic tenase, along with its substrate factor Xa, is a target for inactivation through the action of TFPI.

Factor IX (Plasma Thromboplastin Component, Christmas Factor, Hemophilia B Factor)

Factor IX is a single-chain zymogen consisting of 415 amino acids organized with a Gla domain (12 Gla residues), two tandem EGF domains, an activation peptide region, and a serine protease domain (see Fig. 26-6). Glycosylation in the form of O-linked and N-linked oligosaccharides makes up 17% of the factor IX protein by weight.[44] Activation of factor IX is a two-stage process that requires cleavage at Arg145 and Arg180 and results in the release of a 35-residue activation peptide[45] (see Fig. 26-6). The physiologic activators of factor IX are either TF–factor VIIa (extrinsic tenase complex)[7] or factor XIa. The first cleavage at Arg145-Ala146 results in factor IXα. This cleavage has been shown to be important in its affinity for its cofactor factor VIIIa.[46] The second cleavage occurs at Arg180-Val181 and results in factor IXαβ, the active form, also referred to as factor IXa. Both cleavages are required for the biologic activity of factor IXa.[45] Plasma factor IXa is primarily inhibited by AT[47] (see Fig. 26-2). In vitro experiments conducted on phospholipid

vesicles and cell membranes showed that protease nexin-2/amyloid β-protein precursor (PN2/APP) can also inhibit factor IXa.[48]

Factor X (Stuart Factor)

Factor X is synthesized in the liver and circulates as a two-chain molecule linked by a disulfide bond. The NH_2-terminal light chain consists of a Gla domain and two EGF-like domains (Fig. 26-6). The COOH-terminal heavy chain consists of an activation peptide region and a catalytic (serine protease) domain. Factor X is activated by both the intrinsic and extrinsic factor Xases (see Figs. 26-1 and 26-3) by cleavage at Arg194-Ile195 (see Fig. 26-6). A 52–amino acid activation peptide is released. The resulting catalytic serine protease, factor Xa, is composed of a light chain and a disulfide-linked heavy chain. Factor X has to be bound to the membrane before activation.[19] Factor Xa participates in forming the prothrombinase complex (see Fig. 26-4).[17] The propagation phase of thrombin generation is catalyzed principally by factor Xa generated via the intrinsic tenase complex (see Fig. 26-3), which activates factor X at a 50- to 100-fold higher rate than the extrinsic tenase complex does.[9] The factor Xa active site associates with the COOH-terminal of TFPI.[49] The factor Xa–TFPI complex rapidly inactivates TF–factor VIIa to form a stable quaternary complex, TF–factor VIIa–TFPI–factor Xa.[49] Factor Xa is inhibited by AT[50] but only poorly when in the prothrombinase complex.[51]

Factor II (Prothrombin)

Prothrombin is the single-chain precursor of factor IIa (thrombin), the key enzyme in blood coagulation. The zymogen prothrombin is the most abundant of the plasma VKDPs and circulates in plasma at a mean concentration of 1.4 μM, or 100 μg/mL[52] (see Table 26-1). Prothrombin is synthesized primarily in the liver. Low levels of prothrombin expression have also been identified in other tissues, including the brain, diaphragm, stomach, kidney, spleen, intestine, uterus, placenta, and adrenal gland. Removal of the 43–amino acid propeptide generates the mature protein of 579 amino acids. An NH_2-terminal Gla domain is followed by two kringle domains and the serine protease precursor domain (see Fig. 26-6). Kringles have been identified as common motifs in many plasma proteins, including prothrombin, plasminogen, tissue plasminogen activator, urokinase, factor XII, and apolipoprotein(a).[53] The kringle 1 domain may interact with factor Va,[54] although kringle 2 appears to be the primary region mediating interaction with factor Va to form the prothrombinase complex.[55] This latter interaction may initiate conformational changes that make reaction sites accessible for enzymatic cleavage of prothrombin.[56] The NH_2-terminal Gla domain and the first kringle domain together are referred to as prothrombin fragment 1, with the kringle 2 domain being located in

prothrombin fragment 2. The sequence of the enzyme α-thrombin is contained within prethrombin 2.

Activation of prothrombin by prothrombinase proceeds through an initial cleavage of prothrombin at Arg320-Ile321, which gives rise to meizothrombin, a two-chain disulfide-linked molecule (see Fig. 26-6). Meizothrombin expresses some of the activities of α-thrombin. However, the fibrinogen clotting ability of meizothrombin is impaired in comparison to that of α-thrombin.[57] Meizothrombin is subsequently cleaved at Arg271-Thr272 to yield the NH_2-terminal half of the molecule (prothrombin fragment 1.2) and α-thrombin. α-Thrombin consists of an NH_2-terminal 49-residue A-chain disulfide linked to a COOH-terminal 259-residue B chain containing the catalytic triad.

An alternative cleavage pathway occurs when factor Xa independently acts on prothrombin. In the presence of factor Xa and Ca^{2+}, the initial cleavage occurs at Arg271-Thr272 and gives rise to prothrombin fragment 1.2 and prethrombin 2. Subsequent cleavage at Arg320 in prethrombin 2 yields α-thrombin. Prothrombin fragment 1.2 remains noncovalently associated with α-thrombin.[58] In contrast to other VKDPs, the phospholipid-binding Gla region is not covalently attached to the serine protease domain after cleavage of prothrombin to thrombin.

α-Thrombin is the central enzyme in blood coagulation in that it contributes to reactions at all levels, thereby allowing overall maintenance of vascular integrity. Its premier role in hemostasis results in platelet-fibrin clot formation.[59] However, the events that lead up to and beyond fibrin formation also involve protein cleavage by α-thrombin, as well as activating platelets,[60,61] factor VII,[36] factor V,[15] factor VIII,[62] factor XI,[8] and factor XIII. The contributions of α-thrombin also extend to anticoagulant and fibrinolytic reactions, including activation of protein C and thrombin-activatable fibrinolysis inhibitor (TAFI).[63]

The stable form of human α-thrombin possesses at least five distinct binding sites for substrates, inhibitors, cofactors, apolar molecules, and sodium ions (Na^+).[64] Exosite I, the fibrinogen binding site, is an electropositive anion binding site distinct from, but acting in concert with, the active site of the α-thrombin molecule. In addition to fibrinogen, exosite I also recognizes the COOH-terminal domain of hirudin, the hirudin-like region of PAR-1, and the fifth and sixth EGF-like domains of thrombomodulin.[64]

Many of the effects of α-thrombin on platelets and cells are elicited through the interaction of α-thrombin with receptor molecules, with α-thrombin binding to a receptor and initiating a signal transduction mechanism. The interaction between α-thrombin and the human platelet thrombin receptor PAR-1, however, is characterized by a more unusual mechanism in which the receptor is also a substrate for α-thrombin.[65] α-Thrombin cleaves the extracellular region of the receptor and produces a "tethered ligand." The new NH_2-terminal binds back to

and activates the receptor.[65,66] Two additional α-thrombin receptors homologous to PAR-1, PAR-3 and PAR-4, have been identified. α-Thrombin's role continues beyond hemostasis into the realm of tissue repair and the remodeling phase necessary to regenerate damaged vascular tissue. α-Thrombin is a potent mitogen[67] and stimulates cell division in macrophages,[68] smooth muscle cells,[69] and endothelial cells.[70]

Protein C (Autoprothrombin II-A)

Protein C circulates as a heterodimer consisting of disulfide-linked heavy and light chains[71] (see Fig. 26-6). However, approximately 5% to 10% of circulating protein C is in the single-chain form. The NH_2-terminal light chain contains the Gla domain and a hydrophobic region that connects the Gla domain to two EGF domains. The COOH-terminal heavy chain contains the serine protease domain.[72] Cleavage at Arg169-Leu170 releases the activation peptide from the heavy chain to generate the enzyme. Although the α-thrombin–thrombomodulin complex is probably the major physiologic activator of protein C,[73] other potential activators include plasmin and factor Xa.[72] The half-life of protein C (8 to 10 hours; see Table 26-1) is markedly shorter than the half-life of other members of the VKDP family, which is probably the basis of the transient hypercoagulable state that may occur subsequent to the administration of coumarin-based anticoagulants.

The anticoagulant role of the dynamic protein C inhibitory pathway is proteolytic inactivation of factor Va. APC inactivates factor Va via a sequential series of proteolytic cleavages and thus inhibits the generation of α-thrombin.[74] APC also cleaves and inactivates factor VIIIa, although the spontaneous dissociation/inactivation of factor VIIIa is probably the physiologic regulator of factor Xa generation.[75] Complete inactivation of factor Va by APC requires an anionic phospholipid surface, and rates of inactivation of factors Va and VIIIa by APC have been reported to be enhanced by protein S.[76,77] APC also has profibrinolytic effects associated with decreased activation of TAFI. TAFI is activated by the α-thrombin–thrombomodulin complex and acts to prolong clot lysis. Cleavage of factor Va by APC inhibits α-thrombin generation, thus reducing α-thrombin–thrombomodulin–mediated TAFI activation.[78]

Protein C activation and APC activity are controlled on several levels. The endothelial cell protein C receptor (EPCR) provides cell-specific binding sites for both protein C and APC.[79] Inflammatory agents such as endotoxin, interleukin-1β (IL-1β), tumor necrosis factor-β (TNF-β), and TNF-α upregulate protein C activation on endothelial cells.[80-82] TNF-α downregulates thrombomodulin on the endothelial cell surface.[82] There are multiple other factors that downregulate thrombomodulin as well. APC activity is further regulated by the protein C inhibitor plasminogen activator inhibitor 3 (PAI-3).[83]

Protein S

Protein S is a VDKP that is not a serine protease precursor. Approximately 40% of protein S circulates in the free form, and the remaining 60% circulates as a 1:1 complex with C4b-binding protein (C4bBP), a regulatory protein of the complement system.[84] The precise function of protein S in the protein C inhibitory pathway is controversial. Protein S is thought to function as a cofactor for APC in the inactivation of factors Va and VIIIa.[85-87] Protein S has also been reported to bind to factor Xa,[88] factor VIII,[89] and factor Va[90] and compete for prothrombinase binding sites on the membrane surface.[91] The C4bBP–protein S complex may inhibit factor X activation as well.[92] Protein S may have other roles apart from anticoagulation.[93] α-Thrombin cleavage of protein S inhibits the ability of protein S to act as a cofactor for APC.[94] The anticoagulant activity of protein S is also neutralized when bound to C4bBP.[84,92]

Protein Z

Protein Z is an enzymatically inactive homologue of factors VII, IX, and X and protein C.[95,96] Protein Z circulates in plasma in a complex with protein Z–dependent protease inhibitor (ZPI). ZPI is a 72-kd member of the serpin superfamily. However, like protein S, protein Z does not function as a protease. Although the COOH-terminal contains a homologue to the catalytic domains present in serine protease zymogens, the catalytic triad is not present.[96] The function of protein Z in vivo is unclear. Even though protein Z–deficient mice appear normal, severe thrombosis is observed when combined in mice with factor V Leiden.[97]

FACTOR XI, THE CONTACT PATHWAY CROSSOVER (PLASMA THROMBOPLASTIN ANTECEDENT)

Factor XI is a substrate for thrombin (see Fig. 26-1) and, when cleaved to factor XIa, activates factor IX.[8] Factor XI circulates as a homodimer in complex with HMWK[98] (see Table 26-1) and is also found in platelets.[99] Unlike other members of the accessory or contact pathway, factor XIa has a role in coagulation as part of a positive feedback loop that enhances the generation of α-thrombin.[8] Plasma factor XI accounts for most of the factor XI activity in humans and is a disulfide-linked homodimer (see Table 26-1). The NH_2-terminal contains four tandem sequences termed Apple domains (Apple 1 to Apple 4), followed by the COOH-terminal catalytic domain. The Apple domains are homologous to the Apple domains in human plasma prekallikrein.[100] The Apple domains mediate factor XI dimerization, as well as binding to its various cofactors and substrates.[98,101]

Plasma factor XI is cleaved at an internal Arg369-Ile370 bond to yield a disulfide-linked two-chain acti-

vated serine protease. The factor XI homodimer yields two disulfide-linked heavy chains containing the Apple domains and two light chains containing the active sites.[102,103] Activation of factor XI can be accomplished by factor XIIa and α-thrombin and by autoactivation by factor XIa itself. Activation of factor XI by factor XIIa requires HMWK and an anionic surface. However, deficiencies of factor XII and HMWK do not result in bleeding diatheses, whereas factor XI deficiency is associated with hemorrhage. This suggests that factor XIIa–dependent activation of factor XI as part of the contact pathway is not likely to be the primary route of factor XIa generation in hemostasis. The physiologically relevant pathway for activation of factor XI in coagulation is believed to involve α-thrombin.[8,104] Subsequent to activation, factor XIa remains bound to the surface. Factor XIa is a trypsin-like serine protease that cleaves and activates factor IX in a Ca^{2+}-dependent fashion.[105,106] Factor IXa is the enzyme component of the intrinsic tenase complex that provides the burst of factor Xa needed for normal coagulation. As part of a positive feedback loop, α-thrombin activates factor XI. In turn, factor XIa generates factor IXa, which leads to the high levels of factor Xa that ensure efficient generation of α-thrombin.[8]

Factor XIa is regulated by four serine protease inhibitors: AT, α_1-protease inhibitor, C1 inhibitor, and α_2-antiplasmin.[107-109] Factor XIa is also reported to be inhibited by PAI-1 and protein C inhibitor.[110] In addition, platelets secrete several factor XIa inhibitors,[111] including PN2.[112]

COFACTOR PROTEINS

There are two categories of procoagulant cofactor proteins: the plasma-derived soluble procofactors factor V and factor VIII (the latter in complex with its circulating carrier von Willebrand factor [VWF]) and the cell-associated cofactors TF and thrombomodulin. Factors V and VIII are highly homologous (40% identity). The cell-associated cofactors are single-chain transmembrane proteins, each composed of extracellular, transmembrane, and cytoplasmic domains, but they do not share homology in primary structure.

Factor V (Labile Factor)

The procofactors factors VIII and V are organized into discrete structural domains (Fig. 26-7). Factor V was initially recognized as an unstable plasma component necessary for the generation of α-thrombin.[113] Most factor V circulates in plasma (see Table 26-1), but 18% to 25% of the total factor V is present in platelet alpha granules.[114]

The intron-exon structure of the factor V and factor VIII genes are quite similar, and the genes probably evolved from a common ancestor. The liver appears to be the primary site of factor V biosynthesis. Although human megakaryocytes have also been reported to express factor V,[115] platelet factor V appears to be primarily derived from plasma factor V.[116] Human factor V is composed of A1-A2 domains, a central B domain, and a COOH-terminal light-chain precursor (A3-C1-C2 domains). The A domains are homologous to those found in factor VIII and ceruloplasmin; the C domains are homologous to the slime mold protein discoidin. Like factor VIII and ceruloplasmin, factor V is a copper-binding protein.[117]

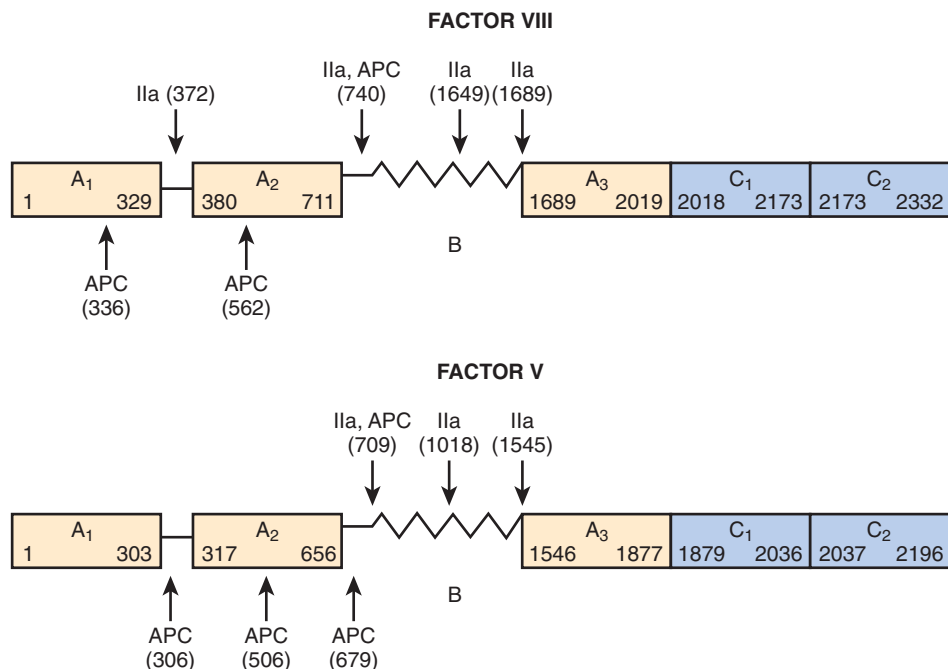
Factor V undergoes extensive post-translational modification, including phosphorylation, sulfation, and glycosylation. Phosphorylation at Ser692 affects the rate of inactivation of factor Va by APC.[118] The tyrosine sulfation status of factor V has also been related to its function.[119]


FIGURE 26-7. Soluble cofactor domain structures (factors VIII and V). The domain structures (A1-A2-A3-B-C1-C2) are bracketed by the beginning and ending amino acid residue. α-Thrombin (IIa) and activated protein C (APC)/factor Xa cleavage sites are shown with *vertical arrows*.

Carbohydrate accounts for 13% to 25% of the mass of factor V and about 50% of the mass of the B region.[120] Differential glycosylation of Asn2182 in the C2 domain is reported to be responsible for the factor V1 and factor V2 variants observed in plasma.[121] Factors Va1 and Va2 appear to also be distinguished by functional differences.

The procofactor factor V does not bind factor Xa and is essentially completely inactive.[17] Limited proteolysis of the factor V molecule yields the active cofactor. α-Thrombin cleaves factor V at Arg709, Arg1018, and Arg1545 (see Fig. 26-7). The α-thrombin–generated form of factor Va is a heterodimer consisting of an NH_2-terminal heavy chain (A1-A2 domains) linked noncovalently to a COOH-terminal light chain (A3-C1-C2 domains).[122-125] The B domain is excised during proteolytic activation.[126] Factor Xa also cleaves factor V to produce a molecule similar to the factor Va produced by α-thrombin cleavage.[127] In addition, other enzymes may fully or partially activate factor V.[128] Factor Va functions both as a receptor for factor Xa and as a positive modulator of the catalytic potential of factor Xa in the prothrombinase complex. The cofactor forms at least part of the receptor for factor Xa on platelets and serves to anchor factor Xa to the membrane surface.[15,16,62]

Factor Va is downregulated via proteolytic inactivation by APC. APC cleaves factor Va at three sites: Arg506, Arg306, and Arg679. Initial factor Va cleavage occurs at Arg506. Subsequently, the membrane-dependent cleavage at Arg306 results in dissociation of the A2 domain as two fragments and complete loss of factor Va cofactor activity. An additional APC-mediated cleavage of factor Va fragments occurs at Arg679. The importance of this regulatory mechanism is demonstrated by the "APC resistance" syndrome associated with factor V Leiden.[129,130] The factor V Leiden Arg506→Gln mutation eliminates the first and most rapid of the sequential inactivating cleavages by APC. Factor Va Leiden thus retains cofactor activity and continues to promote α-thrombin generation for an extended period. Ultimately, inactivation of factor Va Leiden by cleavage of the Arg306 bond does occur, but at a markedly slower rate.[131]

Factor VIII (Antihemophilic Factor, Factor VIII:C)

Factor VIII circulates in plasma in complex with the large multimeric protein VWF. The ratio of factor VIII to VWF is in the range of 1 molecule of factor VIII to 50 to 100 molecules of VWF monomeric units. VWF acts to transport and stabilize plasma factor VIII. Factor VIII in complex with VWF has a plasma half-life of approximately 12 hours, whereas factor VIII alone undergoes rapid clearance and has a half-life of approximately 2 hours.[132,133] The liver and spleen are thought to be the primary sites of factor VIII biosynthesis.[134]

Though synthesized as a 2351–amino acid single-chain protein, human plasma factor VIII undergoes significant proteolytic processing that results in a heterogenous collection of forms. The heterogeneity in molecular weight is due to proteolysis of the protein in circulation or processing before secretion (or both). The initial synthesized product is composed of three A domains, two C domains, and a connecting B domain (see Fig. 26-7). The secreted factor VIII molecule is a two-chain heterodimer as a result of intracellular proteolysis at the B-A3 junction. Additional cleavages within the B chain yield a heavy chain of A1-A2 domains linked to B fragments of variable length.[135] The B domain is highly glycosylated and contains 18 of the 25 potential N-linked glycosylation sites in factor VIII. Activation by α-thrombin involves cleavage at Arg372 (the A1-A2 junction), Arg740 (the A2-B junction), and Arg1689 in the light chain (the B-A3 junction) and excision of the remnant of the B domain. The resulting molecule contains three separate polypeptide chains: a light chain (A3-C1-C2) bound to the NH_2-derived heavy chain and the noncovalently associated A2 region of the heavy chain. Factor VIIIa is an unstable molecule, with dissociation of the A2 domain leading to spontaneous inactivation.[136] Factor VIII shares homology with the copper ion–binding protein ceruloplasmin and contains a reduced copper ion (Cu^+) binding site in the A1 domain that is important for function.[137] A specific VWF binding site has been identified between residues 1673 and 1684 of the factor VIII light chain.[138] The VWF binding site is removed from factor VIII during activation by α-thrombin cleavage at Arg1689. High-affinity factor IXa binding is observed for the factor VIIIa light-chain A3 domain.[139] Sulfation of several tyrosine residues in factor VIII is also important for function.[140]

The cofactor factor VIIIa binds factor IXa with Ca^{2+} (and membrane) to form the intrinsic factor Xase complex (see Fig. 26-3). The intrinsic factor Xase complex catalyzes the activation of factor X at a rate orders of magnitude greater than the enzyme factor IXa alone[18] (see Fig. 26-4). Factor Xa generated via the intrinsic factor Xase complex is the primary contributor of the factor Xa required for the propagation phase of thrombin generation.[21] In hemophilia A or B the intrinsic factor Xase complex cannot be formed, and the factor Xa levels required to induce the propagation phase of thrombin generation are not produced,[22] thereby resulting in lethargic thrombin formation and poor clot formation (see Fig. 26-5).

The spontaneous loss of factor VIIIa function is primarily a consequence of dissociation of the A2 subunit from the heterotrimer. Once the A2 subunit is displaced, factor VIIIa loses cofactor function. Dissociation occurs rapidly under physiologic conditions. The factor IXa–membrane complex interactions stabilize factor VIIIa and thus delay dissociation of the heterotrimer and prolong the transient activity of factor VIIIa.[141] Factor VIIIa is also regulated by limited proteolysis. Factor IXa cleaves the A1 subunit of factor VIIIa at Arg336 and eliminates factor VIIIa function.[142] APC is a key anticoagulant

enzyme that likewise cleaves the A1 subunit at Arg336. APC also cleaves the A2 subunit of factor VIIIa at Arg562.[143] These APC cleavages occur sequentially, with the A1 cleavage occurring first and the A2 cleavage second.[144] Factor IXa protects factor VIIIa from APC cleavage at Arg562; however, protein S blocks the protective effect.[145] Although factor VIIIa is proteolytically inactivated by a number of enzymes, spontaneous dissociation appears to be the key regulator of cofactor function.

von Willebrand Factor (Ristocetin Cofactor)

VWF is a multifunctional protein with several key roles in coagulation. VWF circulates in plasma and is also contained in the alpha granules of human platelets.[146] In addition, it is known for its role in ristocetin-induced platelet aggregation (see Chapters 25 and 30). VWF is expressed by endothelial cells and megakaryocytes and is stored in Weibel-Palade bodies in endothelial cells and in alpha granules in platelets.[147,148] VWF is a large adhesive glycoprotein that circulates in plasma as a heterogeneous mixture of disulfide-linked multimers (Chapter 30). The disulfide-linked multimers range in size from dimers, M_r = 600,000, to extremely large multimers consisting of greater than 20 million Daltons. VWF has binding sites for factor VIII, heparin, collagen, platelet glycoprotein Ib and platelet glycoprotein IIb-IIIa.[149] Plasma VWF transports and stabilizes factor VIII and protects it from

inactivation by APC,[87] thus significantly prolonging the half-life of factor VIII in circulation.[133] VWF also acts as a bridge between platelets and promotes platelet aggregation. The primary platelet binding site for VWF is the glycoprotein Ib-IX-V receptor complex (Chapters 25 and 30). Endothelial cells secrete VWF multimers that are larger than those found circulating in plasma. The function of these large multimeric forms of VWF is to bind to and agglutinate blood platelets under high shear rates. These large multimers of VWF are degraded by a specific metalloproteinase, ADAMTS-13.[150]

Tissue Factor (Tissue Thromboplastin CD142 and Coagulation Factor III)

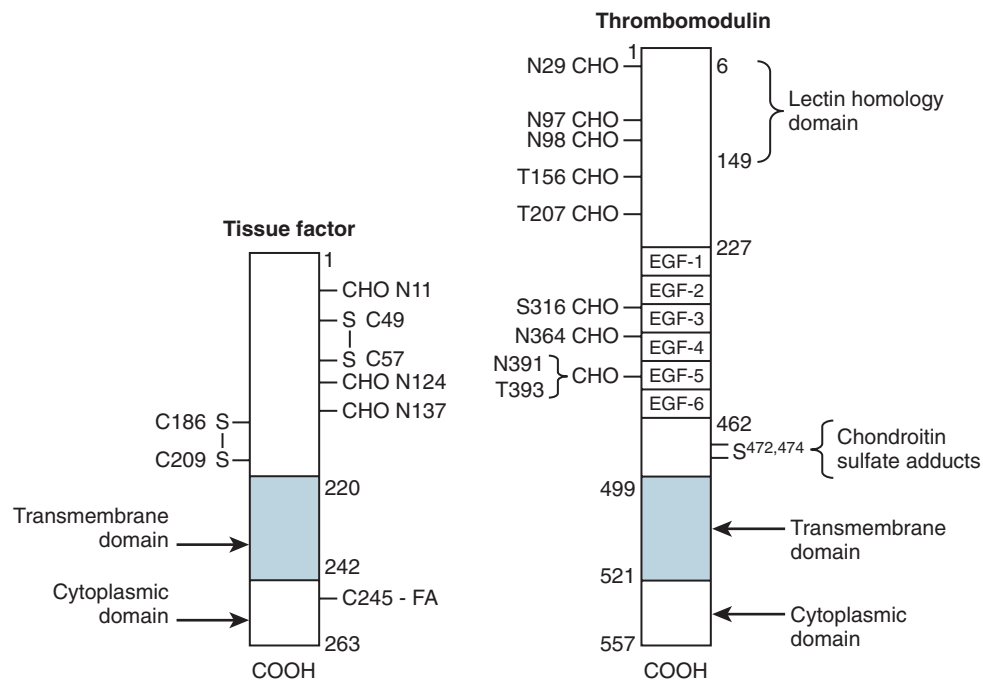
TF and thrombomodulin (Fig. 26-8) are intrinsic membrane proteins that are essential cofactors for factor VIIa and thrombin, respectively. They share no homology at the molecular level. TF is a transmembrane protein that functions as a cofactor for factor VIIa in the extrinsic factor Xase complex. In the absence of injury or stimulation, active TF is not ordinarily expressed on cellular surfaces in direct contact with circulating blood. Presentation of TF to the circulation is the event that triggers the primary procoagulant pathway of coagulation (see Fig. 26-1). Expression of TF can be induced in a number of cultured cell types. Monocytic cells and monocytes


FIGURE 26-8. Transmembrane cofactors. Tissue factor is composed of an extracellular domain (residues 1 to 219), a transmembrane domain (residues 220 to 242), and a cytoplasmic domain (residues 243 to 263). Two disulfide bonds (S-S) and the sites of the three carbohydrate moieties (CHO) are identified by amino acid residue. One cysteine (C245) contains a thiol ester linkage to a fatty acid. Thrombomodulin is composed of five distinct domains. The domain structures are a lectin-like domain (residues 6 to 149), a domain containing six epidermal growth factor (EGF)-like (EGF) regions (residues 227 to 462), a small extracellular domain rich in threonine and serine residues (two have been identified as sites of chondroitin sulfate adducts: S472 and S474), a membrane-spanning region (residues 499 to 521), and a cytoplasmic tail (residues 522 to 557). There are nine known glycosylation sites (CHO) on the thrombomodulin molecule.

isolated from peripheral blood also express TF when stimulated by bacterial endotoxin or other proinflammatory agents. There is little or no detectable TF expression on unstimulated endothelial cells in vivo, although certain conditions such as sepsis, placental villitis, and graft rejection induce endothelial TF expression.[151] The mechanism governing TF expression under nonpathologic conditions is unknown.

TF is a member of the class 2 cytokine receptor superfamily and a type I integral membrane protein. The NH$_2$-terminal of TF (residues 1 to 219) is extracellular, whereas the COOH-terminal of the protein is intracellular (residues 243 to 263). TF also contains a hydrophobic membrane-spanning domain (see Fig. 26-8). This domain appears to function as an anchor for TF in the membrane.[152] The NH$_2$-terminal domain of TF is composed of two fibronectin type III domains and is glycosylated. The COOH-terminal cytoplasmic domain is quite short, and its function is unclear because deletion of this domain has no significant effect on TF procoagulant activity.[152]

TF can bind either factor VII or factor VIIa to form a high-affinity 1:1 complex. Once bound to TF, the zymogen factor VII may be converted to factor VIIa via limited proteolysis.[153,154] The TF–factor VIIa or extrinsic tenase complex activates both factor IX and factor X. When TF is exposed or expressed subsequent to vascular perturbation, the low levels of circulating factor VIIa bind to TF, and the extrinsic factor Xase complex triggers the procoagulant cascade (see Fig. 26-4A).[9,155]

In the absence of TF, factor VIIa is relatively inert. TF alters the active site of factor VIIa, thus functioning as an allosteric activator of the enzyme.[40,155] Although the cofactor is necessary for enzymatic activity, formation of the TF–factor VIIa complex does not require an anionic phospholipid membrane surface as do the other procoagulant complexes. The membrane dependency of the extrinsic factor Xase complex function in factor X and factor IX activation arises from membrane-mediated substrate delivery. Both factors X and IX bind to the membrane surface for efficient two-dimensional transfer to the extrinsic factor Xase complex.

TF is primarily regulated through availability. In normal hemostasis, the commonly accepted source of functional TF is through exposure of the subendothelium after vascular perforation. However, controversy has arisen regarding the sources and presentation of active TF and whether functional TF circulates in blood.[156,157] Once the TF–factor VIIa complex is formed in the vicinity of an injury, the extrinsic tenase activity is then modulated by TFPI and AT.

Thrombomodulin

Thrombomodulin is a type 1 transmembrane protein that is constitutively expressed on the surface of vascular endothelial cells (see Fig. 26-8). Thrombomodulin is a high-affinity receptor for α-thrombin and acts as a cofactor for the α-thrombin–dependent activation of protein C and TAFI. Thrombomodulin expression has been reported in a variety of cell types, including vascular endothelial cells.[158] The activity of thrombomodulin on the surface of endothelial cells is decreased by inflammatory cytokines, which may contribute to the hypercoagulation characteristic of inflammatory states. Homozygous thrombomodulin-deficient mice die in utero before formation of the cardiovascular system, thus suggesting a potential role for thrombomodulin in mammalian development.[159]

The domain structure of thrombomodulin is depicted in Figure 26-8. The fifth and sixth EGF domains support α-thrombin association.[160] The presence of chondroitin sulfate increases the affinity for α-thrombin 10-fold.[161] The chondroitin sulfate moiety also enhances inactivation of α-thrombin by AT[162] and modulates protein C activation.[161,162] The O-linked sugar domain of thrombomodulin is required for generation of APC on cellular surfaces. This domain is extended and rigid and probably functions to elevate α-thrombin from the membrane surface.

Production of APC by the α-thrombin–thrombomodulin complex is approximately 1000 times faster than equivalent concentrations of protein C and α-thrombin. Once bound to thrombomodulin, α-thrombin's procoagulant activities are neutralized. The high-affinity α-thrombin–thrombomodulin interaction is mediated mainly by exosite I on the α-thrombin molecule. Exosite I also binds fibrinogen, and interaction of α-thrombin with thrombomodulin therefore blocks fibrinogen binding and cleavage. In addition, thrombomodulin induces conformational changes in α-thrombin.[163,164] The changes that occur upon interaction of α-thrombin with thrombomodulin reduce the ability of α-thrombin to generate fibrin, activate factor V, or activate platelets[165] and increase the inactivation of α-thrombin by AT.[165] Thus, the α-thrombin–thrombomodulin complex, or protein Case (see Fig. 26-3), functions in an anticoagulant and antifibrinolytic capacity.

THE INTRINSIC (ACCESSORY) PATHWAY FACTORS

The procoagulant proteins that make up the intrinsic or accessory pathway consist of factor XII, plasma prekallikrein, HMWK, and factor XI. These proteins are responsible for the contact (intrinsic) activation of blood coagulation (see Fig. 26-1).

Factor XII (Hageman Factor, Contact Factor)

Factor XII plays a primary role in initiation of the contact or intrinsic pathway of coagulation upon binding with substances such as glass or kaolin. The contact pathway is the basis for the APTT clotting assay. Deficiency of factor XII is not associated with bleeding abnormalities, and therefore the precise role of factor XII in hemostasis

is unclear, although the components of the contact pathway may provide a link between coagulation and inflammation.

The factor XII molecule is composed of two domains: a NH$_2$-terminal heavy chain and a COOH-terminal light chain. The heavy chain contains fibronectin type I and type II domains, two EGF-like domains, a kringle domain, and a proline-rich region. The light chain contains the serine protease catalytic domain, a region homologous to the B chain of the enzyme plasmin.

Factor XII undergoes autoactivation upon interaction with negatively charged surfaces such as glass, kaolin, dextran sulfate, ellagic acid, celite, or bismuth subgallate.[166] These are probably artifactual triggers and the physiologic activator is unknown. Although factor XII associates with many physiologically relevant anionic surfaces, including negatively charged phospholipids, the autoactivation of factor XII induced by these surfaces in vitro does not appear to represent the mechanism of factor XII activation in vivo.[167]

Factor XIIa, prekallikrein, and HMWK form a complex on anionic phospholipids of the cell membrane, and prekallikrein is cleaved to kallikrein. Kallikrein activates factor XII by cleavage at Arg353-Val354 to generate an 80-kD two-chain enzyme, α-factor XIIa (factor XIIa). This cleavage is essential for exposure of the active site in factor XIIa.[168]

Factor XIIa activates factor XI and prekallikrein by mechanisms dependent on anionic surfaces and the cofactor HMWK. Factor XIIa also activates the C1 component of the complement system,[169] downregulates the Fc receptor on monocytes and macrophages,[170] and stimulates neutrophils.[171] Although these roles have no apparent impact on normal coagulation, factor XII/XIIa may be an important link between coagulation and inflammation. Factor XIIa also activates plasminogen to plasmin, thereby linking the contact pathway to fibrinolysis.[172]

Plasma Prekallikrein (Fletcher Factor)

Plasma prekallikrein deficiency is rare and not associated with a hemostatic defect. Approximately 75% of plasma prekallikrein circulates in a noncovalent complex with HMWK,[173] and the remaining 25% circulates as free prekallikrein. Prekallikrein contains four tandemly repeated Apple domains in the NH$_2$-terminal portion of the molecule that are highly homologous to the Apple domains of factor XI. Prekallikrein is activated by factor XIIa in complex with the cofactor HMWK on an anionic surface (see Fig. 26-1). The enzyme kallikrein is a two-chain molecule composed of an NH$_2$-terminal heavy chain containing the four Apple domains and a COOH-terminal light chain containing the active site.[174]

Kallikrein is a member of the trypsin family of serine proteases. In the presence of an appropriate anionic surface and the cofactor HMWK, kallikrein activates factor XII to factor XIIa and proteolyses factor XIIa to β-factor XIIa. Kallikrein also undergoes autoproteolysis

to yield β-kallikrein.[175] Enzyme activity is significantly reduced upon conversion of kallikrein to β-kallikrein. Kallikrein cleaves HMWK at two sites to generate the vasoactive nonapeptide bradykinin, a potent vasodilator. Kallikrein is also an activator of fibrinolytic zymogens and converts both plasminogen to plasmin and pro–urokinase plasminogen activator (pro-uPA) to uPA.[176] In addition, kallikrein has been reported to activate neutrophils and stimulate release of elastase as part of the hemostatic and inflammatory responses.[177] C1 inhibitor and α$_2$-macroglobulin are the major inhibitors of kallikrein.[178]

High-Molecular-Weight Kininogen (Fitzgerald Factor, Williams Factor)

HMWK acts as a cofactor for the activation of factor XII and prekallikrein and is the precursor of the vasoactive peptide bradykinin. A second form of kininogen, low-molecular-weight (LMWK), is also found in plasma. LMWK can be cleaved to yield bradykinin but has no procoagulant activity. Deficiencies of HMWK and LMWK are rare and not associated with bleeding diatheses.[179] The major established function of the kininogens is to serve as a source of bradykinin and thereby contribute to a number of vascular events regulated by bradykinin.

The two forms of kininogen, HMWK and LMWK, are the products of a single gene and are produced by alternative splicing.[180] The NH$_2$-terminal heavy chains of the two forms are identical and contain potent inhibitors of cysteine proteases such as calpain.[181] The central domain of both kininogens is the bradykinin region. The two forms of kininogen have different COOH-terminal light-chain regions. The light chain of HMWK contains binding sites for prekallikrein and factor XI.[182] Kallikrein, factor XIIa, and factor XIa cleave HMWK to release bradykinin. Kallikrein will also cleave LMWK to release bradykinin.

As noted earlier, the biologic significance of the contact pathway of coagulation is not established. In hemostasis, generation of factor XIa most likely proceeds via an α-thrombin–dependent pathway, and any factor XIa generated by the contact pathway would not have a measurable impact on coagulation. Release of bradykinin as a consequence of these activation events, however, does provide a key vasoactive agent with a variety of roles and directly links the contact pathway to vascular repair processes.

STOICHIOMETRIC INHIBITORS

In vivo, the hemostatic reaction is tightly regulated to ensure that adequate but limited levels of α-thrombin are generated. Two systems, one stoichiometric and one proteolytic, regulate the generation of thrombin. In the

proteolytic system (described earlier), α-thrombin participates in its downregulation by binding to thrombomodulin on the vascular cell surface and converting protein C to APC. This anticoagulant serine protease cleaves factors Va and VIIIa, thereby eliminating thrombin generation. The stoichiometric inhibitors consist of the AT-heparin complex, which inhibits virtually all the procoagulant serine proteases, and TFPI, which targets the factor VIIa–TF–factor Xa complex and principally regulates the initiation phase of the blood coagulation process (see Fig. 26-2).

Tissue Factor Pathway Inhibitor (Extrinsic Pathway Inhibitor, Lipoprotein-Associated Coagulation Inhibitor)

TFPI is a multivalent protein that modulates TF-dependent coagulation by inhibiting the extrinsic tenase complex.[183] TFPI is expressed constitutively by cultured endothelial cells and consists of an acidic NH_2-terminal region, three tandem Kunitz-like serine protease inhibitor domains (K1 to K3), and a positively charged COOH-terminal region. The tandem Kunitz domains are essential for function.[184] Two variants of TFPI (isoforms α and β) are generated by alternative splicing. A significant proportion of TFPI molecules in blood are truncated to a variable extent at the COOH-terminal end, with resultant compromised inhibitory activity. The inhibitory activity of TFPI is enhanced by heparin. Upon heparin administration, TFPI is released from endothelial cells, with a 2- to 10-fold increase in circulating levels being achieved. Release of TFPI with heparin therapy is responsible for a portion of the observed elevation in PT and raises the possibility that part of the antithrombotic effect of heparin may be mediated by release of TFPI. A minor pool of TFPI (approximately 10% of the total TFPI in blood) is located within platelets.[185] Transgenic mice with complete TFPI deficiency do not survive.[186] There are no known human TFPI-deficient individuals.

TFPI is the principal stoichiometric inhibitor of the extrinsic pathway (see Figs. 26-2 and 26-4B). The TFPI mechanism allows the factor VIIa–TF complex to initiate factor Xa formation, but it suppresses the generation of high levels of factor Xa product formation by binding the enzyme-product complex (see Fig. 26-4B). The inhibitor mechanism involves rapid interaction between the second Kunitz domain of TFPI with the active site of factor Xa; localization of the complex to the membrane surface is mediated by the Gla domain of factor Xa.[49] Once surface bound, the factor Xa–TFPI complex rapidly inactivates TF–factor VIIa. This complex formation depends on binding of the first Kunitz domain of TFPI to the active site of factor VIIa. These interactions together form a stable quaternary complex, TF–factor VIIa–TFPI–factor Xa. The factor IXa–TFPI complex can also inhibit factor VIIa–TF, although the physiologic relevance of this route of inhibition is unclear because high plasma concentrations of TFPI are required. At normal plasma concentrations, this multicomponent interaction of TFPI allows basal function of the factor VIIa–TF complex but inhibits it after more extensive activation takes place.

When combined with the stoichiometric inhibitor AT, a synergistic regulatory effect of blood coagulation occurs by inducing kinetic "thresholds" such that the initiating TF stimulus must achieve a significant magnitude to propel thrombin generation.[187] TF concentrations below the threshold concentration are ineffective in promoting robust generation of thrombin because of the cooperative influence of the inhibitors; concentrations in excess of the threshold yield robust and almost equivalent thrombin generation. TFPI and the dynamic protein C–thrombomodulin-thrombin system also cooperate to provide threshold-limited, synergistic inhibition of thrombin production. In this instance, TFPI slows the initiation phase while the APC system reduces the availability of the cofactors factors Va and VIIIa, thereby shutting down the propagation phase of thrombin generation.

Antithrombin

AT is a member of the serpin proteinase inhibitor family and circulates in blood as a single-chain glycoprotein. Despite its name, AT inhibits not only thrombin but also most of the proteases in the coagulation pathway. Human AT circulates as two glycoforms, the α and β variants, that contain identical polypeptide backbones but differ in both carbohydrate content and heparin affinity. AT-β binds heparin more tightly than AT-α and is observed to preferentially accumulate on the vessel wall where heparan sulfate proteoglycans are exposed.[188]

AT has a broad spectrum of inhibitory activity, with most of its target proteases participating in the coagulation cascade. It is primarily an inhibitor of thrombin, factor Xa, factor IXa, factor VIIa–TF, factor XIa, factor XIIa, and plasma kallikrein[10,189] (see Fig. 26-2). AT also displays antiproliferative and anti-inflammatory properties that may derive from its ability to inhibit thrombin. Heparin and heparan sulfate potentiate these reactions and are used in the treatment of thrombosis. When AT is complexed with heparin, its rate of binding to thrombin increases 1000-fold. The general mechanism of inhibition involves reaction of the active site of the enzyme with a peptide loop structure of the serpin to form a tight, equimolar (1:1) complex, followed by inactivating structural rearrangements of both AT and the protease.

Heparin Cofactor II (Leuserpin 2)

Heparin cofactor II is another member of the serpin family and is uniquely stimulated by the proteoglycan dermatan sulfate. The only coagulation enzyme inhibited by heparin cofactor II appears to be thrombin.[190] However, the rate of thrombin inhibition by heparin cofactor II in the absence or presence of glycosaminoglycans is significantly slower than inhibition by AT under

similar conditions. In view of the fact that the plasma concentration of heparin cofactor II is 25% to 50% that of AT and that low levels of heparin cofactor II are not strongly associated with thrombosis, the physiologic role of heparin cofactor II as a systemic thrombin inhibitor has been questioned.

Protein C Inhibitor (Plasminogen Activator Inhibitor 3)

Protein C inhibitor is a member of the serine proteinase inhibitor family. Its targets range from the procoagulant, anticoagulant, and fibrinolytic enzymes to plasma and tissue kallikreins, the sperm protease acrosin, and prostate-specific antigen. Hereditary or acquired protein C inhibitor deficiency has not been documented. Protein C inhibitor–deficient mice show impaired spermatogenesis and male infertility.[191] The importance of the regulation of APC by protein C inhibitor in humans is suggested by the use of this complex as a marker for detection of deep vein thrombosis by immunofluorometric assay measurements.[192]

PROTEINS OF CLOT FORMATION

The central event in blood coagulation is the conversion of soluble fibrinogen (factor I) to insoluble cross-linked fibrin. This conversion is accomplished when thrombin removes small polar peptides (termed fibrinopeptides A and B) from the fibrinogen molecule forming fibrin. These fibrin molecules noncovalently interact with each other to form a fibrin web. Fibrin stabilization is accomplished by the action of a second coagulation enzyme (factor XIIIa) that introduces numerous covalent cross-links between these fibrin molecules. The resulting fibrin web is able to capture platelets and red blood cells, thus effectively sealing the wound and stemming plasma loss.

Factor XIII (Fibrin-Stabilizing Factor)

Factor XIII is a protransglutaminase that when proteolytically activated, can form cross-linked amide bonds between glutamyl and lysinyl residues. The zymogen circulates in plasma as a tetramer composed of two A and two B subunits. It plays an important role in hemostasis and thrombosis, as well as participates in the physiologic processes of cell proliferation and cell migration. The product enzyme factor XIII(a) has multiple substrates, including fibrin/fibrinogen, fibronectin, α_2-plasmin inhibitor, collagen, vitronectin, VWF, actin, myosin, factor V, and thrombospondin.[193-196]

Factor XIII is distributed into plasma and platelet pools. Plasma factor XIII circulates as a 320-kD A_2B_2 heterotetramer composed of two identical A chains and two B chains associated noncovalently.[197] The A subunit is the procatalyst and contains three important functional sites: the catalytic site, a calcium binding site, and the activation peptide.[198,199] The activation peptide of one A subunit limits access to the active site cysteine of the other A subunit of the dimer. The B chain has no enzymatic activity and has been thought to function as a carrier of the A subunit.[200]

Bone marrow is the prime site of synthesis of the A chain of plasma factor XIII,[201] which is also present intracellularly as a 160-kd A_2 homodimer in platelets, megakaryocytes, and monocytes.[202,203] How the A_2 dimer is transferred out of the cell and which cell types are the primary sources of plasma A_2 are not understood. Approximately 50% of the total potential factor XIII A chain activity in human blood is found in platelets.[202] The B subunit is synthesized in hepatocytes and secreted as a monomer.[204] After being secreted, the A and B subunits associate and become an A_2B_2 tetrameric molecule in plasma.

Plasma factor XIII is activated by cleavage of thrombin at the NH_2-terminal of the A chains, with release of a 36–amino acid activation peptide. Catalytic activity is expressed only after the A chain dimer is dissociated from the B chain. Fibrin/fibrinogen plays an important role as a cofactor in dissociation of the B chains from thrombin-cleaved factor XIII.[201] The intracellular form of factor XIII contains only the A chain and thus does not require dissociation of the B chain.

Activation of factor XIII during blood clotting is tightly correlated with fibrin formation.[205] This creates a regulated system in which cross-linked polymers occur coincident with fibrin being formed. The rate of thrombin cleavage of plasma factor XIII has been shown to be greatly accelerated by the presence of fibrin polymers.[206] This positive feedback network between thrombin, fibrin/fibrinogen, and factor XIIIa ensures that a stable clot can form rapidly to maintain hemostasis. To date, no known endogenous inhibitor has been described that regulates this important enzyme.[193-196] Fibrin is the main physiologic substrate for factor XIIIa.

Fibrinogen (Factor I) and Fibrin

Fibrinogen is composed of six polypeptide chains (two Aα chains, two Bβ chains, and two γ chains); after posttranslational modification, the mature protein circulates in blood with an average molecular weight of 340,000 D (see Table 26-1).[207,208] The polypeptide chains are distributed into two symmetrical half molecules, each containing one Aα, one Bβ, and one γ chain, with the NH_2-terminals oriented toward each other (Fig. 26-9). The half molecules are linked by noncovalent and disulfide bonds near their NH_2-terminals to yield a linear arrangement of three nodular structures. The outside two domains, formed by the carboxyl-terminal regions of the Bβ and γ chains of fibrinogen, are designated "D," whereas the central domain, which contains the amino-terminals of all the chains, is designated "E." Between 1.7 and 5.0 g
FIGURE 26-9. Schematic representation of fibrinogen to illustrate thrombin and plasmin cleavage sites in the intact molecule. The six polypeptide chains, $A\alpha_2B\beta_2\gamma_2$ are folded into three globular structures, two "D" and one "E," which are connected by "coiled-coil" segments. The NH$_2$-terminal regions of the $A\alpha$, $B\beta$ chains extend from the central "E" domain and, when cleaved by thrombin, yield fibrinopeptide A and fibrinopeptide B. The macromolecular product fibrin is then referred to as $\alpha_2\beta_2\gamma_2$. A small fraction of fibrinogen contains a COOH-terminal extension of the γ chain that is referred to as γ'.

of fibrinogen is synthesized per day by the liver, with approximately 75% of this fibrinogen being secreted into plasma and the remainder being distributed between the lymph and interstitial fluids.[209] Fibrinogen is an acute phase reactant and is upregulated 2- to 10-fold in response to a variety of physiologic stresses, including trauma, pregnancy, and tissue inflammation.

The fibrinogen locus is composed of three closely linked genes (specifying the polypeptides $A\alpha$, $B\beta$, and γ) found as single copies in a region of approximately 50 kilobases. The three fibrinogen genes most likely evolved from a common ancestor through a series of duplications that began approximately 1 billion years ago.[210] Expression of the three chains is coordinately controlled and, at least for the hepatocyte, results in almost equal levels of mRNA for each chain in the cell.[211] Although most γ chains end at γ-Val411 (human numbering), approximately 10% of the time during splicing the last intron is retained, which resulting in a new chain, γ', that ends at γ-Leu427.[212] A less common variant of the α chain adds a 236–amino acid extension at the C-terminal.[213] After synthesis but before secretion, a number of post-translational modifications occur, including glycosylation and phosphorylation. Factor XIIIa cross-linking occurs between sites on the $A\alpha$ and γ but not on the $B\beta$ chain.

Thrombin catalyzes the hydrolysis of Arg-Gly bonds, with small, polar amino-terminal pieces (fibrinopeptides) being removed from the α and β chains[207,208,214] (see Fig. 26-9). Cleavage of $A\alpha$-Arg16 by thrombin releases fibrinopeptide A (FPA) and forms fibrin I. The release of two FPA peptides exposes a site in the E domain that aligns with a complementary site in the D domain to form overlapping fibrils. Subsequent cleavage by thrombin at $B\beta$-Arg14 releases fibrinopeptide B (FPB) and leads to the formation of fibrin II, which presumably increases lateral aggregation of the protofibrils. FPA and FPB vary in length, between 13 and 21 amino acids in various mammals, and constitute less than 2% of the total mass.

Release of fibrinopeptides from fibrinogen results in the formation of an intermediate termed the fibrin monomer, which is all but indistinguishable from fibrinogen. In purified systems, removal of either FPA or FPB leads to formation of the fibrin dimer through noncovalent (i.e., charge-charge [salt links]) and hydrogen bond interactions. As fibrin monomers continue to be generated, the dimer elongates from both ends as a two-stranded molecule until it reaches approximately 30 monomers, at which point it becomes a protofibril. The second step in fibrin assembly is lateral association of the protofibrils into thicker fibrin fibers. These fibers are formed from the association of between 14 and 22 protofibrils. Because protofibrils, not dimers, are required for this step, it is believed that the forces involved in lateral association are weak and therefore become "strong" only in large numbers. Clots are known to branch, although how branching is accomplished is not clear.

The description of fibrinogen activation and fibrin assembly has been based on studies involving the use of citrated plasma or purified proteins, or both. To understand the in vivo process of fibrin formation, a system with nonanticoagulated blood has been used; in this experimental model the pattern of fibrin formation based on release of fibrinopeptide is different from systems using citrated plasma or purified fibrinogen.[205] In this study, most cleavage of FPA and subsequent clot formation take place just before the propagation phase of thrombin generation (Fig. 26-10). At the point of visual clot formation, virtually all fibrinogen (and some product already cross-linked) disappears from the fluid phase of the reaction. Thus, the "clot" appears to be a mixture composed of fibrin I and fibrinogen. The insoluble material present in the fibrin clot is virtually all cross-linked by factor XIIIa, whose activation occurs nearly simultaneously with removal of FPA[205] (see Fig. 26-10). It has been proposed that as many as six cross-links can form between a fibrin monomer and its neighbors and that the presence of these
FIGURE 26-10. Schematic representation of whole blood fibrin formation. Thrombin at the beginning of clot formation simultaneously acts on fibrinogen (D-E-D) and factor XIII (fXIII). A portion (≈40%) of fibrinopeptide A (FPA) is released from fibrinogen, and an initial clot is formed from the complementary overlap of the exposed sites between the E and D domains of adjacent molecules. Activated factor XIII (fXIIIa) simultaneously cross-links adjacent D domains (D = D). Thus, the initial soluble fibrin clot is composed of fibrinogen, fibrin, and γ-γ dimers with fibrinopeptide B (FPB) still attached. The initial clot is continuously acted on by thrombin, which releases the remaining FPA and some of the FPB to yield a final clot with the majority of FPB still attached. The FPB released is selectively acted on by a carboxypeptidase B–like enzyme (CPB) to cleave the carboxyl-terminal arginine and produce des-Arg FPB. The significance of this cleavage is still unclear. *(Redrawn with permission from Brummel KE, Butenas S, Mann KG. An integrated study of fibrinogen during blood coagulation. cross-links increases the strength, chemical resistance to urea, and lysis by plasmin.[207,208,215]

CONCLUSION

As the result of molecular investigation of blood coagulation for more than 100 years, the components of the blood coagulation system and their connections are well understood. Critical insights into this process and its regulation have often come from the study of patients with mutations in the genes encoding the relevant coagulation factors. It is only fitting that this knowledge has formed the basis for the development of reliable diagnostic tools and effective therapies for patients with both inherited and acquired disorders of hemostasis, as detailed in the ensuing chapters.

27 | The Molecular Basis of Fibrinolysis

Katherine Amberson Hajjar

Fibrinolysis is the process by which the insoluble protein fibrin is converted to a defined set of soluble degradation products. It occurs in both intravascular and extravascular locations and is essential to human health and survival. Modern molecular biologic techniques have identified the major fibrinolytic genes, the mechanisms regulating their expression, and the consequences of their deficiency or overexpression in genetically engineered mice. In many cases these experiments have yielded surprising and instructive data that have revealed physiologic and pathophysiologic roles for the fibrinolytic system that are much more extensive than originally thought. Furthermore, with the dawn of the genomic age, molecular analysis of human syndromes has identified specific mutations that result in either thrombosis secondary to fibrinolytic deficiency or hemorrhage secondary to fibrinolytic excess. In this chapter the molecular basis of fibrinolysis, as well as its physiologic role in human health and disease, is reviewed.

BASIC CONCEPTS OF FIBRINOLYSIS

In response to vascular injury and activation of the coagulation cascade, thrombin induces polymerization of the soluble plasma protein fibrinogen, thereby producing an insoluble, cross-linked end product called fibrin (see Chapter 26). Once the flow of blood has been stemmed and vascular integrity restored, fibrin, which is found in both intravascular and extravascular sites, is cleared by a process known as fibrinolysis (Fig. 27-1A). Normally, the fibrinolytic process is tightly regulated by a series of activators, inhibitors, cofactors, and receptors.[1] In the presence of fibrin, which serves as a cofactor for its own destruction, tissue plasminogen activator (tPA) is released from endothelial cells and possibly other cell types and interacts with the circulating zymogen plasminogen. tPA, plasminogen, and fibrin form a ternary complex that accelerates the catalytic efficiency of plasmin generation by approximately 500-fold. Urokinase is also an efficient plasminogen activator (uPA), but its action is only minimally enhanced by fibrin. The action of plasmin on fibrin generates soluble fibrin degradation products, which have their own unique biologic properties.

The dynamic regulation of plasmin generation is complex. On the surface of a fibrin-containing thrombus, tPA and plasmin are protected from their major circulating inhibitors plasminogen activator inhibitor 1 (PAI-1) and α_2-antiplasmin (α_2-AP), respectively. On release into the circulation, however, plasmin and tPA are rapidly neutralized by these inhibitors and cleared by the liver. Because uPA and the nonenzymatic plasminogen activator streptokinase do not use fibrin as a cofactor, they function well in the fluid phase. Plasminogen may also be activated, albeit rather inefficiently, by proteases of the contact system such as kallikrein, factor XIa, and factor XIIa (Chapter 26).

Cell surfaces represent protected environments in which plasmin can be generated without the risk of neutralization by fluid-phase inhibitors (Fig. 27-1B).[2] Endothelial cells, platelets, monocytes, macrophages, and some tumor cells all express protein receptor sites for plasminogen, tPA, or uPA.[3] The broad substrate specificity of plasmin observed in vitro may relate to its generation in nonvascular sites through fibrin-independent mechanisms. Plasmin may thus play an important role in extravascular events such as the modification of growth and differentiation factors, processing of matrix proteins, and activation of procoagulant molecules.

COMPONENTS OF THE FIBRINOLYTIC SYSTEM

Plasminogen

Synthesized primarily in the liver,[4,5] plasminogen is a single-chain proenzyme with a molecular weight (M_r) of approximately 92,000 that circulates in plasma at a concentration of approximately 1.5 μmol/L (Table 27-1).[6] The plasma half-life of plasminogen in humans is approximately 2 days.[7] Its 791 amino acids are cross-linked by 24 disulfide bridges, 16 of which yield five homologous triple-loop structures called *kringles*[8] (Fig. 27-2). The first (K1) and fourth (K4) of these 80–amino acid structures with an M_r of 10,000 impart high- and low-affinity lysine binding, respectively.[9] The lysine-binding domains of plasminogen appear to mediate its specific interactions with fibrin, cell surface receptors, and other proteins, including its circulating inhibitor α_2-AP.[10-14]

Post-translational modification of plasminogen results in two glycosylation variants (forms 1 and 2)[15-17] (see Table 27-1). An *O*-linked oligosaccharide on Thr345 is common to both forms. Only form 2, however, contains an *N*-linked oligosaccharide on Asn288. The carbohydrate portion of plasminogen appears to regulate its affinity for cellular receptors and may also specify its physiologic degradation pathway.

Activation of plasminogen results from cleavage of a single Arg-Val peptide bond at position 560 to 561,[18] which produces the active protease plasmin (see Table 27-1). Plasmin contains a typical serine protease catalytic triad[6] but exhibits broad substrate specificity in comparison to other proteases of this class.[19] The circulating form of plasminogen, amino-terminal glutamic acid plasminogen (Glu-Plg), is readily converted by limited proteolysis to several modified forms known collectively as lysine plasminogen (Lys-Plg).[20,21] Hydrolysis of the Lys77-Lys78 peptide bond results in an altered conformation that more readily binds fibrin, displays twofold to threefold higher avidity for cellular receptors, and is activated 10 to 20 times more rapidly than Glu-Plg is.[12,18,22] Lys-Plg does not normally circulate in plasma[18] but has been identified on cell surfaces.[23]
FIGURE 27-1. Overview of the fibrinolytic system. **A,** Fibrin-based plasminogen activation. The zymogen plasminogen (Plg) is converted to the active serine protease plasmin (PN) through the action of tissue plasminogen activator (tPA) or urokinase (uPA). The activity of tPA is greatly enhanced by its assembly with Plg through lysine residues (K) on a fibrin-containing thrombus. uPA acts independently of fibrin. Both tPA and uPA can be inhibited by plasminogen activator inhibitor 1 (PAI-1), which is released by endothelial cells and activated platelets. PAI-2, on the other hand, neutralizes uPA more efficiently than it does tPA. By binding to fibrin, plasmin is protected from its major inhibitor α_2-antiplasmin (α_2-AP). Bound plasmin degrades cross-linked fibrin, which gives rise to soluble fibrin degradation products (FDPs). **B,** Some cell surface fibrinolytic receptors. **a,** Endothelial cells, monocytes, and macrophages express the uPA receptor (uPAR), which can interact with both uPA, thereby preserving its activity, and adhesive glycoproteins, such as fibrinogen (FGN) and vitronectin (VN). uPAR association with Mac-1 appears to facilitate adhesive interactions, whereas its interaction with uPA has a negative impact on adhesion. **b,** Endothelial cells, monocytes, and macrophages also express annexin A2 (A2), a coreceptor for tPA and Plg that augments the efficiency of plasmin generation. A2 forms a heterotetramer with protein p11, a member of the S100 family, which accentuates the efficiency of plasmin generation. **c,** Low-density lipoprotein receptor–related protein (LRP) is expressed by macrophages and smooth muscle cells. It binds a wide variety of ligands, including α_2-macroglobulin (α_2-MG) and uPA or tPA in complex with PAI-1. Originally thought to function as a clearance receptor, LRP appears to signal to activate NF-κB and augment expression of downstream effectors such as metalloproteinase 9 (MMP-9). *(Adapted from Ragno P. The urokinase receptor: a ligand or a receptor? Cell Mol Life Sci. 2006;63:1028-1037.)*

Spanning 52.5 kilobases (kb) of DNA on chromosome 6q26-27, the plasminogen gene consists of 19 exons[24,25] and directs expression of a 2.7-kb messenger RNA (mRNA)[8] (see Fig. 27-2). Plasminogen gene activity is stimulated by the acute phase mediator interleukin-6, both in vitro and in vivo.[26] The gene is closely linked and structurally related to that of apolipoprotein(a), an apoprotein associated with the highly atherogenic low-density lipoprotein–like particle lipoprotein(a)[27] and more distantly related to other kringle-containing proteins such as tPA, uPA, hepatocyte growth factor, and macrophage-stimulating protein.[28-32] The significance of the latter two proteins to the fibrinolytic system remains to be determined.

Plasminogen Activators

Tissue Plasminogen Activator

One of the two major endogenous plasminogen activators, tPA is a 527–amino acid glycoprotein with an M_r of approximately 72,000[33] (see Table 27-1). tPA contains five structural domains, including a fibronectin-like "finger," an epidermal growth factor–like domain, two kringle structures homologous to those of plasminogen, and a serine protease domain (see Fig. 27-2). Cleavage of the Arg275-Ile276 peptide bond by plasmin converts tPA to a disulfide-linked, two-chain form.[33] Although single-chain tPA is less active than two-chain tPA in the

Structure-function relationships of plasminogen, tissue plasminogen activator (tPA), and urokinase (uPA) and alignment of the intron-exon structure of the plasminogen, tPA, and uPA genes with functional protein domains. Protein domains are labeled signal peptide (SP), preactivation peptide (PAP), kringle domains (K), fibronectin-like "finger" (F), epidermal growth factor–like domain (EGF), and protease. The position of the catalytic triad of amino acids histidine (H), aspartic acid (D), and serine (S) are shown within individual protease domains. The positions of individual introns relative to amino acid–encoding exons are indicated with *inverted triangles*.

fluid phase, both forms demonstrate equivalent activity when bound to fibrin.[34]

The two glycosylation forms of tPA are distinguishable by the presence (type 1) or absence (type 2) of a complex *N*-linked oligosaccharide moiety on Asn184 (see Table 27-1).[35,36] Both types, however, contain a high-mannose carbohydrate on Asn117, a complex oligosaccharide on Asn448, and an *O*-linked α-fucose residue on Thr61.[37] The carbohydrate moieties of tPA may modulate its functional activity, regulate its binding to cell surface receptors, and specify degradation pathways.

Located on chromosome 8p12-q11.2, the gene for human tPA is encoded by 14 exons spanning a total of 36.6 kb (see Fig. 27-2).[38-40] Most of the structural domains of tPA are encoded by one or two exons, and the organization of these exons is similar across related domains of tPA and the other fibrinolytic proteases (see Fig. 27-2). This observation suggests that the tPA gene arose by an evolutionary process called "exon shuffling," whereby functionally related genes are generated through rearrangement of exons encoding autonomous domains. Consistent with this hypothesis, various functions of tPA

can be localized to specific domains. For example, deletion of the fibronectin-like finger or kringle 2, but not kringle 1, results in a tPA resistant to the cofactor activity of fibrin, whereas catalytic activity in the absence of fibrin remains intact.[41]

The proximal promoter of the human tPA gene contains binding sequences for potentially important transcriptional factors, including AP1, NF1, SP1, and AP2,[42,43] as well as a potential cyclic adenosine monophosphate (cAMP)-responsive element.[44] In vitro, many agents have been shown to exert small effects on the expression of tPA mRNA, but relatively few enhance tPA synthesis without augmenting PAI-1 synthesis as well. Agents that regulate tPA gene expression independently of PAI-1 include arterial shear stress, thrombin, endotoxin, histamine, butyrate, retinoids, and dexamethasone.[45-50] Forskolin, which increases intracellular cAMP levels, has been reported to decrease the synthesis of both tPA and PAI-1.[43,51]

tPA is synthesized and secreted primarily by endothelial cells, and its release is governed by a variety of stimuli such as shear stress, butyrate, thrombin, histamine, bradykinin, epinephrine, acetylcholine, arginine vasopressin, gonadotropins, exercise, and venous occlusion.[45,47,52,53] Its circulating half-life is exceedingly short ($\approx$5 minutes). By itself, tPA is a poor activator of plasminogen. However, in the presence of fibrin, the catalytic efficiency of tPA-dependent plasmin generation (k_{cat}/K_m) increases by at least 2 orders of magnitude[22] because of a dramatic increase in affinity (decreased Michaelis constant [K_m]) between tPA and its substrate plasminogen in the presence of fibrin. Although it is expressed by extravascular cells, tPA appears to represent the major intravascular activator of plasminogen.[19]

Urokinase

The second endogenous plasminogen activator, single-chain uPA or prourokinase, is a glycoprotein with an M_r of approximately 54,000 and consists of 411 amino acids (see Table 27-1). uPA contains an epidermal growth factor–like domain and a single plasminogen-like kringle and possesses a classic catalytic triad within its serine protease domain[54] (see Fig. 27-2). Cleavage of the Lys158-Ile159 peptide bond by plasmin or kallikrein converts single-chain uPA to a disulfide-linked two-chain derivative.[55] Located on chromosome 10, the human uPA gene is encoded by 11 exons spanning 6.4 kb and expressed by endothelial cells, macrophages, renal epithelial cells, and some tumor cells.[56,57] As noted earlier, its intron-exon structure is closely related to that of the tPA gene.

There is circumstantial evidence that uPA may be induced during neoplastic transformation, possibly through a mechanism involving the transcription factors AP1 and AP2.[58] Other agents that appear to induce expression of uPA in vitro include hormones, growth factors, and cAMP.[49] Inflammatory cytokines such as interleukin-1 and lipopolysaccharide induce only small increments in uPA expression, whereas tumor necrosis

factor and transforming growth factor β (TGF-β) have a more dramatic (5- to 30-fold) effect.[59-61]

Two-chain uPA occurs in both high-molecular-weight (M_r of 54,000) and low-molecular-weight (M_r of 33,000) forms that differ by the presence or absence, respectively, of a 135-residue amino-terminal fragment released by plasmin cleavage between Lys135 and Lys136.[62,63] Although both forms are capable of activating plasminogen, only the high-molecular-weight form binds to the uPA receptor (uPAR). uPA has much lower affinity for fibrin than tPA does and is an effective plasminogen activator both in the presence and in the absence of fibrin.[64,65] The extent to which prourokinase possesses intrinsic plasminogen-activating capacity is an area of controversy.[66,67]

Accessory Plasminogen Activators

Under certain conditions, proteases traditionally classified within the intrinsic arm of the coagulation cascade (see Chapter 26) have been shown to be capable of activating plasminogen directly. Such proteases include kallikrein, factor XIa, and factor XIIa.[68-70] Normally, however, they account for no more than 15% of the total plasmin-generating activity in plasma.

Inhibitors of Fibrinolysis

Plasmin Inhibitors

The action of plasmin is negatively modulated by a family of serine protease inhibitors called serpins[71] (see Table 27-1). All serpins share a common mechanism of action by forming an irreversible complex with the active-site serine of the target protease after proteolytic cleavage of the inhibitor by the target protease. Within such a complex, both protease and inhibitor lose their activity.

A single-chain glycoprotein with an M_r of approximately 70,000, α_2-AP circulates in plasma at relatively high concentrations ($\approx$0.9 µmol/L) and has a plasma half-life of 2.4 days[72] (see Table 27-1). This serpin contains about 13% carbohydrate by mass and consists of 452 amino acids with two disulfide bridges.[73] In humans, the gene is located on chromosome 18 and contains 10 exons distributed over 16 kb of DNA.[74] The promoter region of the α_2-AP gene contains a hepatitis B–like enhancer element that directs tissue-specific expression in the liver.[74] α_2-AP is also a constituent of platelet alpha granules.[75] Plasmin released into flowing blood or in the vicinity of a platelet-rich thrombus is immediately neutralized on forming an irreversible 1:1 stoichiometric, lysine binding site–dependent complex with α_2-AP. Interaction with plasmin is accompanied by cleavage of the Arg364-Met365 peptide bond, and the resulting covalent complexes are cleared in the liver.

Several other proteins appear to inhibit the activity of fibrinolytic serine proteases (see Table 27-1). α_2-Macroglobulin (α_2-MG) is a tetrameric protein with an M_r of

725,000 that is synthesized by the liver, endothelial cells, macrophages, and fibroblasts and is found in platelet alpha granules. The gene for α_2-MG, which consists of 36 exons distributed over 48 kb of DNA on chromosome 12, directs the expression of a 1451–amino acid polypeptide.[76-78] As a generic inhibitor of all four classes of proteases (serine, cysteine, aspartyl, and metallo), α_2-MG is a nonserpin that inhibits plasmin with approximately 10% of the efficiency exhibited by α_2-AP by forming a noncovalent complex.[79] C1 esterase inhibitor can also serve as an inhibitor of tPA in plasma.[80] The protease nexin may function as a noncirculating cell surface inhibitor[81] of trypsin, thrombin, factor Xa, urokinase, or plasmin and result in protease-inhibitor complexes that are endocytosed via a specific nexin receptor.[82]

Thrombin-activatable fibrinolysis inhibitor (TAFI) is a plasma carboxypeptidase that acts as a potent inhibitor of fibrinolysis.[83] Identical to the previously cloned carboxypeptidase B[84] and the previously isolated carboxypeptidase U,[85] this single-chain polypeptide with an M_r of 45,000 circulates in plasma at concentrations of about 75 nmol/L and undergoes limited proteolysis in the presence of plasmin or thrombin, which leads to its activation.[86] Carboxypeptidase B–like molecules remove carboxyl-terminal lysine or arginine residues from fibrin and other proteins, thereby reducing binding of plasminogen to fibrin and cell surfaces and limiting plasmin generation.[87] The potentially antifibrinolytic effect of thrombin appears to be mediated through its ability to activate TAFI in the presence of thrombomodulin.[83,88] Anticoagulation by inhibition of factor XI also appears to have an antifibrinolytic effect in vivo by downregulation of thrombin-mediated activation of TAFI.[89] In a system of purified components, TAFI has been shown to reduce tPA-induced fibrinolysis half-maximally at approximately 1 nmol/L, which is well below its concentration in plasma.[90]

Plasminogen Activator Inhibitors

Plasminogen Activator Inhibitor 1

Of the two major plasminogen activator inhibitors[91] (see Table 27-1), PAI-1 is the most ubiquitous. This single-chain cysteine-less glycoprotein with an M_r of approximately 52,000 is released by endothelial cells, monocytes, macrophages, hepatocytes, adipocytes, and platelets.[92-94] Release of PAI-1 is stimulated by many cytokines, growth factors, and lipoproteins common to the global inflammatory response.[60,95-97] The PAI-1 gene consists of nine exons spanning 12.2 kb on chromosome 7q21.3-q22.[98] The serpin reactive site is located at Arg346-Met347, and activity of this labile serpin is stabilized upon complex formation with vitronectin, a component of plasma and the pericellular matrix.[99,100]

Regulation of PAI-1 gene expression is complex.[101-104] Agents that have been shown to enhance expression of PAI-1 at the message level, the protein level,

or both without affecting the synthesis of tPA include the inflammatory cytokines lipopolysaccharide, interleukin-1, tumor necrosis factor α,[60,61,95,97,105-107] TGF-β and basic fibroblast growth factor,[59,95,102,104] very-low-density lipoprotein and lipoprotein(a),[108,109] angiotensin II,[110] thrombin,[106,111] and phorbol esters.[112] In addition, endothelial cell PAI-1 is downregulated by forskolin[42,51] and by endothelial cell growth factor in the presence of heparin.[113]

Plasminogen Activator Inhibitor 2

Originally purified from human placenta,[91,114] PAI-2 is a 393–amino acid member of the serpin family whose reactive site is the Arg358-Thr359 peptide bond[114] (see Table 27-1). The gene encoding PAI-2 is located on chromosome 18q21-23, spans 16.5 kb, and contains eight exons.[115] PAI-2 exists as both a nonglycosylated intracellular form with an M_r of 47,000 and a glycosylated form with an M_r of 60,000 secreted primarily by macrophages and keratinocytes. Functionally, PAI-2 inhibits both two-chain tPA and two-chain uPA with comparable efficiency (second-order rate constants of 10^5 mmol/L/sec). However, it is less effective in inhibiting single-chain tPA (second-order rate constant of 10^3 mol/L/sec) and does not inhibit prourokinase.

Significant levels of PAI-2 are found in human plasma only during pregnancy but can be markedly enhanced in vitro by the inflammatory mediator tumor necrosis factor.[116] Regulation of PAI-2 gene expression is modulated by a variety of factors, including a number of inflammatory mediators.[117-120] In macrophages in vitro, secretion of PAI-2 is enhanced by endotoxin and phorbol esters.[120,121]

Cellular Receptors in Fibrinolysis

Though structurally diverse, cell surface fibrinolytic receptors can be classified into two groups whose integrated actions are likely to be essential for homeostatic control of plasmin activity[3] (see Table 27-1). Activation receptors localize and potentiate plasminogen activation, whereas clearance receptors eliminate plasmin and plasminogen activators from the blood or focal microenvironments.

Activation Receptors

Plasminogen Receptors

Plasminogen receptors are a diverse group of proteins expressed on a wide array of cell types.[3] Receptors reported include α-enolase, glycoprotein IIb-IIIa complex, the Heymann nephritis antigen, amphoterin, and annexin A2 (A2)/p11 and have been found to be expressed primarily on monocytoid cells,[122] platelets,[123] renal epithelial cells,[124] neuroblastoma cells,[125] and endothelial cells,[126-128] respectively. These binding proteins commonly interact with the kringle structures of plasminogen through carboxyl-terminal lysine residues.

The Urokinase Receptor

uPAR is expressed on monocytes, macrophages, fibroblasts, endothelial cells, and a variety of tumor cells[3] (see Table 27-1). uPAR complementary DNA (cDNA) was cloned and sequenced from a human fibroblast cDNA library[129] and encodes a protein of 313 amino acids with a 21-residue signal peptide. The gene structure consists of seven exons distributed over 23 kb of genomic DNA, which places this glycoprotein within the Ly-1/elapid venom toxin superfamily of cysteine-rich proteins.[130-132] uPAR is anchored to the plasma membrane through glycosylphosphatidylinositol linkages.[133] uPA bound to its receptor maintains its activity and susceptibility to PAI-1.[134] Formation of uPA–PAI-1 complexes appears to hasten clearance of uPA by hepatic or monocytoid cells.[135-137]

High-resolution (1.9 to 2.7 Å) analysis of the crystal structure of a complex formed by various amino-terminal uPA peptides and a soluble form of uPAR reveals that uPA engages a central cone-shaped cavity in uPAR formed by its three-finger motif. This arrangement leaves surface residues of uPAR available for binding of other proteins such as integrins and vitronectin. It is therefore postulated that these interactions may be regulated by binding of uPA itself.[138-140]

Aside from a potential role in fibrinolysis, uPAR appears to play a novel role in cellular signaling and adhesion events.[141] uPAR binds to the adhesive glycoprotein vitronectin at a site distinct from the uPA-binding domain,[142,143] and uPAR-transfected renal epithelial cells acquire enhanced adhesion to vitronectin and lose their adhesion to fibronectin.[144] Furthermore, uPAR colocalizes with integrins in focal contacts and at the leading edge of migrating cells[145] and also associates with caveolin, a major component of caveolae, structures abundant in endothelial cells and thought to participate in signaling events.[146-148] Thus, integrin function may be regulated by uPAR, an association signifying an integrated relationship between cellular adhesion and proteolysis.

These findings have important implications for the behavior of malignant cells, in which uPAR is frequently overexpressed.[149] High-level uPAR expression also appears to be an indicator of a poor prognosis in breast, lung, colon, esophageal, and gastric cancer.[149] uPA has been identified by protease activity profiling as being important in intravasation of fibrosarcoma,[150] and RNA interference–mediated "knockdown" of uPA and uPAR seems to block the in vivo invasiveness of highly malignant cells.[150,151]

Annexin A2

A2 is a widely distributed, highly conserved, peripheral membrane protein with an M_r of 36,000 that is expressed abundantly on endothelial cells,[128,146,148,152-154] monocyte/macrophages,[155,156] myeloid cells,[157] and some tumor cells.[158-160] It belongs to a more than 60-member superfamily of calcium-dependent, phospholipid-binding proteins[161,162] that have in common a conserved carboxyl-terminal "core" region preceded by a more variable amino-terminal "tail."[163] The human A2 gene consists of 13 exons distributed over 40 kb of genomic DNA on chromosome 15 (15q21).[164]

In vitro, A2 possesses the unique property of binding both plasminogen (K_d of 114 nmol/L)[127] and tPA (K_d of 30 nmol/L),[165] but not uPA.[126] Purified native human A2 stimulates the catalytic efficiency of tPA-dependent plasminogen activation by 60-fold in the fluid phase.[166] This effect is completely inhibited in the presence of lysine analogues or upon treatment of A2 with carboxypeptidase B, an agent that removes basic carboxyl-terminal amino acids. Although it lacks a classic signal peptide, A2 is constitutively translocated to the endothelial cell surface within 16 hours of its biosynthesis, where it binds phospholipid via core repeat 2.[167] Translocation of A2 requires association with protein p11, tyrosine phosphorylation by an src-like kinase, and a stimulus such as heat stress or thrombin stimulation.[168,169] The A2 heterotetramer, composed of two annexin monomers and two p11 subunits, may have even greater stimulatory effects on tPA-dependent plasmin generation.[170]

Lipoprotein(a), an atherogenic low-density lipoprotein–like particle, competes with plasminogen for binding to A2[171,172] and reduces cell surface plasmin generation. Lipoprotein(a) contains an apoprotein called apoprotein(a) that contains kringle structures highly homologous to those of plasminogen.[27] This mechanism may contribute to atherogenesis by reducing fibrinolytic surveillance at the blood vessel wall.

Binding of tPA to A2 requires residues 8 to 13 (LCKLSL) within the amino-terminal "tail" domain of the receptor.[173] This sequence is a target for homocysteine (HC), a thiol-containing amino acid that accumulates in association with nutritional deficiencies of vitamin B_6, vitamin B_{12}, or folic acid or in inherited abnormalities of cystathionine β-synthase, methylenetetrahydrofolate reductase, or methionine synthase; it is associated with atherothrombotic disease.[174-176] In vitro, HC impairs the intrinsic fibrinolytic system of the endothelial cell by approximately 50%[177] by forming a covalent derivative with Cys9 of A2, thereby preventing its interaction with tPA.[173] The half-maximal dose of HC for inhibition of binding of tPA to A2 is approximately 11 μmol/L HC, a value close to the upper limit of normal for HC in plasma (14 μmol/L).

There is now clear evidence that A2 contributes to intravascular fibrin balance in vivo. Homozygous A2-null mice display microvascular fibrin deposition, reduced clearance of arterial thrombi, and markedly deficient microvascular endothelial cell surface plasmin generation.[178] In addition, pretreatment of the rat carotid artery with A2 prevents vessel thrombosis in response to injury.[179] Furthermore, overexpression of A2 by acute promyelocytic leukemia cells appears to correlate with the severity of the hemorrhagic state seen at initial evaluation.[157] In addition, patients with antiphospholipid syndrome and

anti-A2 antibodies have a significantly higher risk for clinical thrombosis than do those who lack this antibody.[180] There is also evidence that polymorphisms in A2 may correlate with a higher incidence of vaso-occlusive stroke in patients with sickle cell disease.[181]

Clearance Receptors

Both uPA and tPA are cleared from the circulation via the liver.[182] In vitro, clearance of tPA–PAI-1 complexes also appears to be mediated by a large two-chain receptor called the low-density lipoprotein receptor–related protein (LRP).[183-185] This complex interaction requires both the growth factor and finger domains of tPA. An additional "receptor-associated protein" with an M_r of 39,000 copurifies with LRP and may regulate the binding and uptake of LRP ligands.[186] Interestingly, LRP-knockout embryos undergo developmental arrest by 13.5 days after conception, thus suggesting that regulation of serine protease activity may be crucial for early embryogenesis.[187,188] Although several PAI-1–independent clearance pathways for tPA involving the large LRP subunit,[189] the mannose receptor,[190] or an α-fucose–specific receptor[191] have been proposed, in vivo studies in mice suggest that

LRP and the mannose receptor play a dominant role in clearance of tPA.[187]

THE FIBRINOLYTIC ACTIONS OF PLASMIN

Fibrinogen

Fibrinogen possesses distinct proteolytic cleavage sites for plasmin and thrombin (Fig. 27-3). Whereas plasmin cleaves carboxyl-terminal Aα and amino-terminal fibrinopeptide B moieties, thrombin primarily releases fibrinopeptide A, which exposes the Gly-Pro-Arg tripeptide sequence and allows fibrinogen to polymerize and form insoluble fibrin[192] (see Chapter 26). Cleavage of fibrinogen (M_r of 340,000) by plasmin initially produces carboxyl-terminal fragments from the α chain within the D domain of fibrinogen (Aα fragment).[193-196] Simultaneously but more slowly, the amino-terminal segments of the β chains are cleaved, with release of a peptide containing fibrinopeptide B. The resulting molecule with an M_r of approximately 250,000 is termed fragment X and represents a clottable form of fibrinogen.
FIGURE 27-3. Degradation of fibrinogen and cross-linked fibrin by plasmin. **Top panel,** Plasmin initially cleaves the carboxyl-terminal regions of the α and β chains within the D domain of fibrinogen, thereby releasing the Aα and Bβ fragments. In addition, a fragment containing fibrinopeptide B (FPB) from the amino-terminal region of the β chain is released, with the intermediate fragment known as fragment X being produced. Subsequently, plasmin cleaves the three polypeptide chains connecting the D and E domains, which produces fragments D, E, and Y. **Bottom panel,** Fibrinogen can also be polymerized by thrombin to form fibrin. When degrading cross-linked fibrin, plasmin initially cleaves the carboxyl-terminal region of the α and β chains within the D domain. Subsequently, some of the connecting regions between the D and E domains are severed. Fibrin is ultimately solubilized upon hydrolysis of additional peptide bonds within the central portions of the coiled-coil connectors and gives rise to fibrin degradation products such as D-dimer.

Additional cleavage events may release the Bβ fragment from the carboxyl-terminal of the β chain, and in a series of subsequent reactions, plasmin cleaves the three polypeptide chains that connect the D and E domains to produce a free D domain (M_r of ≈100,000) plus the binodular D-E fragment known as fragment Y (M_r of ≈150,000). Finally, domains D and E are separated from each other, and some of the amino-terminal fibrinopeptide A sites on domain E are also modified. Although fragment X can be converted to fibrin by thrombin, the fragments Y, D, and E are all nonclottable and may in fact inhibit the spontaneous polymerization of fibrinogen.[197]

Fibrin

Degradation of fibrin by plasmin leads to a distinct set of molecular products.[198] Species similar to fragments Y, D, and E but lacking fibrinopeptide sites are released from non–cross-linked fibrin. If fibrin has been extensively cross-linked by factor XIII, however, the resulting D fragments are cross-linked to an E domain fragment. An assay of cross-linked D-dimer fragments is used clinically to identify disseminated intravascular coagulation–like states associated with excessive plasmin-mediated fibrinolysis. Several biologic activities, including inhibition of platelet function,[199] potentiation of the hypotensive effects of bradykinin,[200] chemotaxis,[201] and immune modulation, have been ascribed to fibrin breakdown products.[202]

Tissue Plasminogen Activator–Mediated Plasminogen Activation

With or without fibrin, tPA-mediated activation of plasminogen follows Michaelis-Menten kinetics.[22] In the absence of fibrin, tPA is a weak activator of plasminogen. However, in the presence of fibrin, the catalytic efficiency (k_{cat}/K_m) of tPA-dependent plasminogen activation is enhanced by at least 2 orders of magnitude. This is the basis for its specificity as a lytic agent in the treatment of thrombosis. The affinity between tPA and plasminogen in the absence of fibrin is low (K_m of 65 μmol/L) but increases significantly in its presence (K_m of 0.16 μmol/L), even though the catalytic rate constant remains essentially unchanged (k_{cat} of ≈0.05 sec^{-1}). When plasmin forms on the fibrin surface, both its lysine binding sites and its active site are occupied. Thus, it is relatively protected from its physiologic inhibitor $α_2$-AP.[203] The interaction of tPA with fibrin is probably initiated by its finger domain. However, once fibrin is modified by plasmin, carboxyl-terminal lysine residues are generated, and these residues become binding sites for kringle 2 of tPA and kringles 1 and 4 of plasminogen.[204] Therefore, fibrin accelerates its own destruction by (1) enhancing the catalytic efficiency of plasmin formation by tPA, (2) protecting plasmin from its physiologic inhibitor $α_2$-AP, and (3)

providing new binding sites for plasminogen and tPA once its degradation has begun.

Urokinase-Mediated Plasmin Generation

For activation of Glu-Plg by uPA in a fibrin-free system, reported K_m values vary from 1.4 to 200 μmol/L, whereas k_{cat} values range from 0.26 to 1.48 sec^{-1}. Interestingly, activation of Glu-Plg by two-chain uPA is increased in the presence of fibrin by about 10-fold even though uPA does not bind to fibrin.[205] In contrast, single-chain uPA has considerable fibrin specificity. This may reflect neutralization by fibrin of components in plasma that impair plasminogen activation.[206] It may also reflect a conformational change in plasminogen upon binding to fibrin.[207] It is important to recognize, however, that the intrinsic plasminogen-activating potential of single-chain uPA is less than 1% that of two-chain uPA. Two-chain uPA has been used effectively as a thrombolytic agent for many years.[208]

PHYSIOLOGIC FUNCTIONS OF THE FIBRINOLYTIC SYSTEM

Thrombosis and Thrombolysis

Congenital plasminogen deficiency was first reported in a 31-year-old man with recurrent thrombosis.[209] In groups of patients with plasminogen deficiency, however, whether type I, in which both immunologically detectable protein and enzymatic function are decreased, or type II, in which just plasminogen function is impaired, only about 25% of patients report a history of thrombosis.[210-212] Indeed, the most common clinical manifestations of plasminogen deficiency, occurring in 80% and 34% of patients, respectively, are ligneous conjunctivitis and ligneous gingivitis, disorders characterized by the deposition of fibrin-rich pseudomembranes on mucosal surfaces.[213] These findings strongly suggest that plasminogen acts in extravascular as well as intravascular locations.[214-216]

The relative infrequency of thrombosis in patients with plasminogen deficiency may, in part, reflect the fact that in only a small fraction of patients with sonographic evidence of thrombosis does symptomatic vascular occlusion eventually develop.[217] Furthermore, although a recent study showed that impaired plasma-based fibrinolysis conferred an approximately twofold increase in the risk for deep venous thrombosis,[218] the prevalence of plasminogen deficiency in consecutive patients with thrombophilia was only 1.9%.[219] Together, these data suggest that measurement of plasma plasminogen, tPA, or PAI-1 in patients with thrombophilia is likely to be a low-yield procedure[220,221] and that the physiologic roles of plasmin and plasminogen may be much broader than originally thought.

Although congenital deficiencies of plasminogen activators (tPA and uPA) have not been linked specifically to thrombophilia in humans,[220] elevated levels of fibrinolytic inhibitors appear to increase the risk for thrombosis. Increased levels of PAI-1 were prevalent in young survivors of myocardial infarction,[222] and TAFI levels above the 90th percentile in a case-control study approximately doubled the risk for venous thrombosis.[223] As one might expect, congenital deficiency of either α_2-AP or PAI-1 is generally associated with delayed rebleeding at sites of trauma or wound healing.[224,225] To date, no human disorders reflecting primary deficiencies of fibrinolytic receptors have been reported.

In general, analyses of genetically engineered mice support the hypothesis that the fibrinolytic system functions to regulate fibrin balance in both the intravascular and extravascular compartments (Table 27-2). That fibrinogen is central to hemostasis is underscored by findings of postnatal bleeding at multiple sites in fibrinogen-null mice,[226] similar to that seen in human patients with afibrinogenemia. Similarly, although mice deficient in plasminogen have normal embryogenesis, survive to adulthood, and can sire offspring, they display significant runting, spontaneous thrombi develop in multiple tissues, and extravascular fibrin accumulates in the liver (see Table 27-2).[227,228] Ulcerative lesions are observed in the gastrointestinal tract, particularly the rectum, where prolapse is also seen. Plg$^{-/-}$ mice also clear induced thrombi much less readily than wild-type mice do,[229] and this defect is reversed by bolus injection of exogenous plasminogen.[230] Because the spontaneous thrombosis observed in plasminogen-deficient mice is completely reversed when fibrinogen is also deleted, it is clear that the thrombosis observed in plasminogen deficiency is related to failure of intravascular fibrin clearance.[231] Plasminogen-deficient mice also display ligneous conjunctivitis, a disorder similar to that observed in humans with plasminogen deficiency.[232]

Because no examples of complete deficiency of tPA or uPA have been documented in humans, the most compelling evidence for their role in fibrin balance derives from gene-knockout experiments in the mouse (see Table 27-2).[233] Both uPA- and tPA-null mice exhibit normal fertility and embryonic development. Although little spontaneous thrombosis is seen in either genotype, uPA$^{-/-}$ mice exhibit occasional fibrin deposition and tPA-deficient mice display impaired lysis of artificially induced pulmonary thrombi. In contrast, doubly deficient (tPA$^{-/-}$, uPA$^{-/-}$) mice exhibit extensive spontaneous fibrin accumulation in multiple organs, rectal prolapse, runting, and cachexia, all reminiscent of the phenotype seen in Plg$^{-/-}$ mice. These findings demonstrate that tPA and uPA are not essential for normal embryologic development, but they do play crucial roles in the activation of plasminogen, in the lysis of spontaneous and induced thrombi, and in fibrinolytic surveillance.

Although complete PAI-1 deficiency in humans is associated with a moderately severe bleeding tendency,[224]

mice deficient in PAI-1 exhibit normal development, survival, and fertility, with no evidence of spontaneous hemorrhage[234] (see Table 27-2). PAI-1–deficient mice do, however, exhibit resistance to thrombosis after injury[235] and enhanced sensitivity to thrombolytic therapy.[236] On the other hand, in transgenic mice that overexpress human PAI-1, a dramatic vascular occlusive process develops in the tail and hind limbs.[237] This finding may be due to unique effects of human PAI-1 in the mouse in that mice overexpressing murine PAI-1 do not exhibit this abnormality.[238]

Deficiency of α_2-AP, the major serpin directly blocking plasmin activity, is a rare cause of bleeding disorder in humans.[239] Although no overt bleeding is seen in α_2-AP–deficient mice, increased lysis of artificially induced thrombi has been reported.[240] PAI-2–deficient mice exhibit no obvious phenotype even when PAI-1 is also absent in doubly deficient animals.[241] Complete TAFI deficiency in mice is fully compatible with life and does not appear to alter the response to vascular injury, artificially induced thrombosis, or endotoxin-induced disseminated intravascular coagulation.[242]

Mice transgenic for the catalytically inactive plasminogen analogue apolipoprotein(a) are subject to atherosclerosis and resistant to tPA-induced lysis of experimental pulmonary emboli.[243] The accelerated atherosclerosis observed in these mice is blunted under conditions of concomitant fibrinogen deficiency.[244] These data suggest that apolipoprotein(a)-associated atherosclerosis may be rooted in functional plasminogen deficiency and accumulation of intravascular fibrin.

Whereas complete deficiency of uPAR is associated with normal lysis of intravenously injected plasma clots in mice,[245] A2-deficient mice have impaired lysis of experimentally induced thrombi, and fibrin accumulates in both intravascular and extravascular locations.[178] In addition, A2-deficient microvascular endothelial cells lack tPA cofactor activity and migrate slowly through fibrin and collagen matrices. Interestingly, A2-deficient mice also display significant impairment of postnatal angiogenesis in a variety of experimental models.

Wound Healing and Tissue Fibrosis

As discussed earlier, extravascular fibrin deposition is a hallmark of plasminogen deficiency in both mice and humans.[227,228] Plasminogen-deficient mice, as well as uPA$^{-/-}$/tPA$^{-/-}$ but not uPAR$^{-/-}$/tPA$^{-/-}$ mice, also exhibit defective wound healing characterized by impaired keratinocyte migration despite abundant neovascularization and granulation tissue within experimental wounds.[246,247] Although fibrinogen-deficient mice exhibit subtle histologic defects in wound repair,[248] the impaired healing in plasminogen-deficient mice disappears when fibrinogen is also absent.[231] Consistent with the hypothesis that plasmin is necessary for clearance of extravascular fibrin, deficiency of either PAI-1 or α_2-AP in mice is associated with accelerated cutaneous wound healing.[249,250] In

addition, sciatic nerve regeneration after crush injury also appears to require tPA/plasmin-mediated clearance of fibrin to protect against axonal degeneration and demyelination.[251] Surprisingly, TAFI deficiency seems to be associated with impaired, rather than accelerated healing of cutaneous wounds.[252]

Although extravascular fibrin commonly forms in response to injury, its exact role in tissue fibrosis is unclear. In a well-established model of bleomycin-induced pulmonary fibrosis, plasminogen$^{-/-}$, tPA$^{-/-}$, and uPA$^{-/-}$ mice but neither uPAR$^{-/-}$ nor fibrinogen$^{-/-}$ mice have increased deposition of both fibrin and collagen after injury.[253-255] Similarly, PAI-1–deficient mice exhibit less bleomycin-induced pulmonary fibrosis than wild-type animals do.[256] Surprisingly, however, fibrin does not seem to be a prerequisite for the induction of pulmonary fibrosis in this model because mice deficient in fibrinogen were susceptible to fibrosis to the same degree as wild-type animals.[256] Thus, the mechanism by which fibrinolytic proteins regulate fibrosis may relate to modulation of adhesive interactions that promote leukocyte adherence rather than plasmin catalytic activity.

Atherosclerosis and Cardiovascular Remodeling

Atherosclerosis is thought to represent a response to vascular injury that leads to atheromatous plaque formation and vascular remodeling.[257] In the setting of apolipoprotein E deficiency, simultaneous plasminogen deficiency accelerates vessel wall disease.[258] In this model, fibrin is not strictly required for the development of atherosclerotic lesions, thus suggesting that the role of plasmin may relate to its ability to remove one or more nonfibrin substrates.[259] Interestingly, although plasminogen deficiency accelerates hyperlipidemic atherosclerosis, the same mice are relatively resistant to transplant-associated atherosclerosis.[260]

Plasmin appears to promote the pathologic response to vascular and myocardial injury.[261] After induction of myocardial infarction in plasminogen-null mice, myocardial healing was markedly inhibited inasmuch as inflammatory cells failed to appear at the wound site, necrotic cardiomyocytes failed to disappear, and granulation and fibrous tissue failed to develop.[262] Similarly, healing of electrically injured femoral arteries, arteries treated with a flexible cuff, or arteries undergoing guidewire endothelial denudation was impaired in plasminogen-null mice, with reduced infiltration of inflammatory and smooth muscle cells and decreased neointima formation.[229,263,264] All these processes require cellular migration, which may entail plasmin-dependent matrix remodeling through activation of downstream matrix metalloproteinase 1 (MMP-1) and MMP-3.[265-267]

Plasmin may play a role in the activation of growth factors and in the proliferative response to blood vessel injury. Macrophages cultured on labeled matrices release both basic fibroblast growth factor and TGF-β into the medium in a plasminogen-dependent fashion.[268] TGF-β, a homodimeric polypeptide with an M_r of 25,000 whose effects on vascular cell growth and differentiation are pleiomorphic,[269] also appears to be converted from a latent to an active form by cell-associated plasmin. The latter process can be blocked by the presence of plasmin inhibitors such as aprotinin or α$_2$-AP and appears to involve alteration of its tertiary structure upon cleavage of an amino-terminal glycopeptide.[270]

uPA but neither tPA nor uPAR appears to be required for vascular cell migration and pericellular plasmin formation in some injured vessels.[271,272] uPA appears to mediate the activation of MMPs in both atherosclerotic aortic aneurysm[273] and postinfarction cardiac rupture,[274] presumably through its activation of plasmin rather than direct cleavage of pro-MMPs. Together, these data suggest a unique role for uPA in postinjury vascular remodeling.

Tumor Biology

Tumor cells may use the fibrinolytic system for local invasion and metastasis. Although plasminogen-deficient mice display normal growth of both primary and metastatic tumors in the Lewis lung carcinoma model,[275] pulmonary metastases from a polyoma middle T antigen–induced mammary cancer were significantly reduced in plasminogen-null animals.[276] Fibrinogen-null mice exhibited normal growth of implanted Lewis lung carcinoma, whereas lymph node and hematogenous lung metastases were markedly reduced in both Lewis lung carcinoma and melanoma.[277,278] These data suggest that plasmin-mediated fibrin clearance is required for tumor cell invasion and metastasis in these specific settings.

Analysis of tumor behavior in mice with genetic alterations in other components of the fibrinolytic system has produced a spectrum of results. uPA-deficient mice displayed markedly diminished murine sarcoma cell proliferation and tumor-associated angiogenesis when compared with wild-type animals.[279] These mice also failed to support local progression of cutaneous melanoma,[280] as well as polyoma middle T antigen–induced vascular tumors.[281] The absence of TAFI, on the other hand, does not appear to alter the progression of primary Lewis lung carcinoma, B16 melanoma, or T241 sarcoma tumors or their metastases.[282]

PAI-1 has a surprising stimulatory effect on the growth and invasiveness of murine tumors derived from malignant keratinocytes. In PAI-1–deficient mice, these tumors are subject to loss of local invasion and tumor vascularity,[283] thus suggesting that PAI-1 may play an adhesive rather than an anticatalytic role in this system. Similarly, murine fibrosarcoma cells implanted in PAI-1$^{-/-}$ mice display reduced tumor cell proliferation and neovascularization.[279] On the other hand, neither tumor cell burden nor overall host survival were affected by the absence of PAI-1 in a murine model of metastatic

melanoma.[238] Thus, the precise role of PAI-1 in tumor biology may depend critically on the specific context.

Microbial Virulence and Host Defense Mechanisms

There is increasing evidence that pathogenic bacteria can usurp elements of the host fibrinolytic system to enhance their own virulence.[284,285] In Lyme disease, for example, dissemination of *Borrelia burgdorferi* in both the tick vector and the mammalian host requires that the spirochete bind host plasminogen and use host plasminogen activator.[286] Similarly, *Borrelia* species use host plasminogen for heart and brain invasion in relapsing fever.[287] Plasminogen-deficient mice also appear to be remarkably resistant to *Yersinia pestis*, whose own plasminogen activator (Pla) is required for the rapid progression of primary pneumonic plague.[287-289] Expression of human plasminogen in mice overrides their natural resistance to invasive infection with group A β-hemolytic streptococci.[290]

Components of the fibrinolytic system are required for the recruitment of host cells to sites of inflammation. In plasminogen-null mice, for example, the influx of neutrophils to the peritoneum in response to thioglycolate is normal, whereas recruitment of lymphocytes and monocytes is significantly impaired.[291] In the murine lung, similarly, recruitment of phagocytes and lymphocytes in response to *Cryptococcus neoformans*[292] and *Pneumocystis carinii*[293] requires uPA. Recruitment of neutrophils in response to *Pseudomonas aeruginosa*, on the other hand, depends on uPAR but not on uPA, thus suggesting a nonfibrinolytic, possibly adhesive role for this receptor.[294]

Neurologic Plasticity

tPA appears to play a relatively unique role in modulating plasticity and cell death within the central nervous system. tPA, which is stored within neuronal cells, is released upon calcium-mediated membrane depolarization[295] and participates in the immediate early response after electrical or pharmacologic stimulation of hippocampal neurons.[295,296] tPA expression is induced in Purkinje neurons after cerebellar motor learning,[297] and excessive tPA-related proteolytic activity in granule neurons may contribute to neuronal death in the weaver mouse cerebellum.[298] tPA-deficient mice do not display discernible motor or sensory deficiencies but do exhibit a mild defect in long-term potentiation.[299,300] These animals are resistant to excitotoxic neuronal degeneration in the hippocampus, in which plasmin-catalyzed degradation of laminin is blocked both by tPA deficiency and by infusion of a plasmin inhibitor.[301]

Neuronal migration within the cerebellum of the developing mouse brain is reduced by approximately 50% in tPA-deficient mice,[302] and these animals exhibit increased sensitivity to the locomotor effects of cocaine.[303]

During the remodeling of neuronal connections that occurs in response to seizure activity in the hippocampus, mice lacking either tPA or plasminogen show decreased mossy fiber outgrowth in this region and accumulate an extracellular matrix component known as DSD-1-PG/phosphacan. These data suggest both plasmin-dependent and plasmin-independent roles for tPA in neuronal plasticity.[304]

In both ischemic and hemorrhagic stroke, infusion of tPA can have a major effect on clinical outcome. After ischemic stroke in mice, tPA increases infarct size in both wild-type and tPA-null animals,[305] and smaller infarcts are observed in untreated tPA-deficient animals than in uPA-deficient or wild-type mice. Interestingly, the largest infarcts in the latter study were found in PAI-1$^{-/-}$ mice.[306] In a thrombotic stroke model, on the other hand, deficiency of tPA leads to more extensive vascular fibrin deposition and cerebrovascular thrombosis and consequently a sixfold to eightfold increase in infarct volume.[307]

Engagement of LRP by the tPA–PAI-1 complex may regulate the vascular response to injury by triggering NF-κB–mediated release and activation of MMP-9, which may lead to weakening of the blood-brain barrier and catastrophic hemorrhage. In a mouse model, this process was inhibited by concomitant infusion of activated protein C, which by interacting with endothelial protein C receptor or protease activated receptor 1, or both, blocked the activation of NF-κB and hence release of metalloproteinase.[308] Together, these data suggest that the actions of tPA in the central nervous system extend beyond the activation of plasmin.

NON–PLASMIN-MEDIATED FIBRINOLYSIS

There is accumulating evidence that proteases other than the traditional members of the fibrinolytic family may participate in fibrinolysis. Fibrin appears to be subject to degradation by activated monocytoid cells that express cathepsins.[309] In addition, MMP-3, MMP-7, and membrane type 1 MMP may cleave fibrinogen and cross-linked fibrin into fragments similar to those produced by plasmin.[310] Matrix MMPs have been shown to act as pericellular fibrinolysins, thereby providing an alternative pathway for fibrin-based angiogenesis in a plasminogen-free milieu.[311] In particular, membrane-type matrix MMPs appear to function in this way within a three-dimensional fibrin meshwork.[312]

Clinical and Laboratory Approach to the Patient with Bleeding

Madhvi Rajpurkar and Jeanne M. Lusher

HISTORY AND CLINICAL EVALUATION

Hemostasis involves a complex interplay between the vessel wall, platelets, coagulation factors, and fibrinolysis (see Chapters 25 to 27). A hematologist is often consulted to evaluate patients who have unusual, spontaneous, prolonged, or delayed bleeding. Occasionally, patients are referred because of abnormal coagulation test results obtained as a part of preoperative evaluation. As in any other field of medicine, when a clinician is confronted with a child who has a possible bleeding disorder, a detailed assessment of the patient's bleeding history and a physical examination should be performed before ordering a battery of laboratory studies. The art of history taking comes with experience and should guide the extent to which one investigates bleeding and requests laboratory tests. In view of the variability of patients' perception of bleeding, as well as the lack of a uniform clinical measure of bleeding severity, the history is most discriminatory when a standardized and validated questionnaire is used and a "bleeding score" is incorporated into the diagnosis.[1,2] Several such instruments currently exist, but there is no consensus on a single questionnaire that can quantitate bleeding optimally.[3-5]

Site of Bleeding

The observed pattern of bleeding is an important factor in establishing a differential diagnosis. The severity of bleeding may also aid the physician in differentiating between bruising after normal child play and pathologic bleeding. Persistent bleeding from a single site is generally suggestive of a local cause (e.g., unilateral epistaxis is often due to excoriation of a superficial vessel in the Kiesselbach triangle). Mucous membrane bleeding (epistaxis, excessive menorrhagia, bleeding from gums) is often the consequence of a problem with primary hemostasis, namely, a platelet disorder or von Willebrand disease (VWD).[6] Hereditary hemorrhagic telangiectasia may also be manifested as mucosal bleeding. Profuse bleeding into soft tissues or joints is suggestive of deficiency of a coagulation factor (such as factors VIII or IX). Umbilical stump bleeding is typically seen with factor XIII deficiency, but it may also occur with deficiencies of prothrombin, factor X, and fibrinogen.[7]

Clinical Manifestations

The immediate history often provides useful clues to the diagnosis (Table 28-1). A sick child with fever, shock, and mucocutaneous purpura frequently has disseminated intravascular coagulation (DIC) associated with bacteremia. A male toddler who has just started crawling and exhibits subcutaneous or joint bleeding frequently has hemophilia. A girl who has had severe menorrhagia since menarche may have VWD. A well-looking child covered with petechiae often has immune thrombocytopenia, or if the bruising is localized to the buttocks, ankles, and feet, Henoch-Schönlein purpura should be considered.

Age at Onset

Generally, early age at onset correlates with the severity of the bleeding disorder and also indicates its congenital nature. The development of bleeding later in childhood may indicate an acquired problem or be suggestive of a milder congenital disease. For example, mild hemophilia may be missed in early childhood and first be noted in an older adolescent at a time of increased hemostatic challenge from increased sports activities.[8,9] Diagnostic considerations in neonates with bleeding are quite different and often unique.

Past Medical History

Response to trauma is an excellent screening test. In eliciting the child's past history, it is important to inquire about past surgical procedures, serious injuries, and fractures that provide hemostatic challenges. Additional details that are often helpful include the bleeding outcome after invasive dentistry, transfusion requirement, or iron-responsive anemia. A history of surgical procedures or tooth extractions without any abnormal bleeding is good evidence against the presence of a congenital hemorrhagic disorder. A detailed menstrual history should be obtained when applicable. The prevalence of bleeding disorders in women with menorrhagia is as high as 20%. Conversely, menorrhagia is a common initial symptom in women with VWD and has been reported to occur in more than 90% of patients.[10-14]

TABLE 28-1	Differences in Clinical Manifestations of Primary Hemostatic Defects and Clotting Factor Deficiencies (Individual Patients May Vary)	
Clinical Characteristic	**Primary Hemostatic Defect**	**Clotting Factor Deficiency**
Site of bleeding	Skin, mucous membranes	Soft tissues, muscles, joints
Bleeding after minor cuts	Yes	Not usually
Petechiae	Present	Absent
Ecchymosis	Small, superficial	Larger, deeper, palpable
Hemarthrosis	Rare	Common
Bleeding after trauma/surgery	Immediate	Delayed

It is also important to note whether the patient has an underlying medical disorder that may affect hemostasis, such as hepatic or renal disease, malabsorption syndrome, or Ehlers-Danlos syndrome (Table 28-2).[15,16] Most of the coagulation proteins are synthesized in hepatocytes.[17,18] Certain metabolites that accumulate in individuals with uremia can interfere with platelet function,[19,20] whereas low-molecular-weight coagulation proteins (factors IX and XI) are lost through the kidney in children with nephrotic syndrome.[21] In malabsorption syndrome, levels of the vitamin K–dependent coagulation factors (II, VII, IX, and X) (see Chapter 26) may be depleted and lead to excessive bleeding.[22,23] A child with cyanotic congenital heart disease and polycythemia may have petechiae and excessive bleeding with surgery, in part as a result of thrombocytopenia and hypofibrinogenemia.[24] Reducing the red cell mass (by phlebotomy and replacement with normal saline solution) to lower the child's hematocrit will often lessen the hemostatic abnormalities associated with these conditions.

Family History

The child's family history may be very helpful in formulating a differential diagnosis. One should inquire about any known bleeding problems in other family members and whether a specific diagnosis has been made. If the family history is positive for bleeding, one should note the type and severity of bleeding (e.g., joint bleeding, epistaxis, or menorrhagia), age at onset, and the relationship of the affected family member or members to the patient. An X-linked recessive inheritance pattern suggests a diagnosis of hemophilia A or B,[25] whereas an autosomal dominant pattern would be more consistent with VWD or hereditary hemorrhagic telangiectasia. Most of the other clotting factor deficiencies are inherited in an autosomal recessive manner. In the latter group of disorders, the family history is frequently negative for bleeding, although consanguinity may be noted.

Approximately a third of infants and young children with newly diagnosed hemophilia have a negative family history, consistent with the Haldane hypothesis for the fraction of new mutations in all lethal X-linked recessive disorders.[26,27] For VWD, considerable variation in symptoms may be noted among affected family members. Bleeding manifestations may be very mild in some and give the impression of a "negative" family history. Factor XI deficiency, an autosomal trait most often (but not exclusively) seen in persons of Ashkenazi Jewish descent, may be associated with a very mild or a moderate tendency for bleeding. The degree of bleeding manifestations does not correlate well with the level of factor XI or the partial thromboplastin time, although the patient's specific mutation may be predictive.[28,29]

TABLE 28-2	Acquired Bleeding Disorders	
Underlying Bleeding Disorder	**Hemostatic Defect**	**Cause**
Overwhelming sepsis	Acute disseminated intravascular coagulation	Initiation of coagulation, damage to the endothelium; decrease in clotting and anticlotting factors
Liver disease	Multiple coagulation factor deficiency	Decreased hepatic synthesis
	Increased fibrinolysis	Decreased clearance of plasminogen activators
	Hypercoagulable state	Decreased production of natural anticoagulants
	Thrombocytopenia	Hypersplenism
Malabsorption syndrome	Decreased production of factors II, VII, IX, and X and proteins C and S	Vitamin K deficiency
Cyanotic congenital heart disease	Mild to moderate thrombocytopenia	Shortened platelet survival
	Abnormal platelet function	Acquired defects in platelet aggregation
Acyanotic congenital heart disease (e.g., ASD, PDA)	Decreased high-molecular-weight VWF multimers	Consumption
ECMO and CPB	Platelet dysfunction	Platelet activation in the oxygenator and physical damage to the platelet membrane
	Coagulation factor deficiency	Consumption of coagulation factors in the circuit
	Hyperfibrinolysis	Increase in tPA and decrease in α_2-antiplasmin
Acute promyelocytic leukemia	Thrombocytopenia	Decreased production in bone marrow and increased consumption
	Disseminated intravascular coagulation	Release of procoagulant material from the leukemic cells
	Hyperfibrinolysis	Increased synthesis of plasminogen activators

ASD, atrial septal defect; CPB, cardiopulmonary bypass; ECMO, extracorporeal membrane oxygenation; PDA, patent ductus arteriosus; tPA, tissue plasminogen activator; VWF, von Willebrand factor.

Medications

A careful history of medication use should be obtained, including prescribed medications, over-the-counter drugs, and herbal products.[30] A number of drugs are associated with bleeding diatheses, with mechanisms including induction of thrombocytopenia and platelet dysfunction.[31,32] Drug use may also exacerbate the bleeding symptoms of an underlying coagulation disorder. In addition, prolonged antibiotic use may lead to lower vitamin K levels and induce bleeding secondary to acquired deficiency of vitamin K–dependent factors.

PHYSICAL EXAMINATION

When examining a child with bleeding, the bleeding pattern should be noted. Petechiae are small capillary hemorrhages and characteristically develop in crops in areas of increased venous pressure, as in dependent parts of the body. Petechiae are nonpainful, nonpalpable, and nonblanching and need to be distinguished from small telangiectases and angiomas. In general, petechiae are indicative of problems with primary hemostasis (platelet number or function or vascular integrity). Ecchymotic lesions are palpable purplish lesions induced by subcutaneous bleeding and are usually indicative of deficiency of a coagulation factor. Additional note should be made of joint size, swelling, and limitation of motion, findings indicative of hemarthrosis. Identification of hepatomegaly and splenic enlargement may point toward coagulopathy associated with systemic disorders such as leukemia or hepatocellular disease.

APPROACH TO BLEEDING IN NEONATES

In the pediatric age group, the neonatal period, despite being a short 4 weeks, is quite unique. The neonate has physiologically decreased levels of most procoagulant and anticoagulant proteins (although factor VIII levels are normal), and thus the hemostatic system can be easily overwhelmed (see Chapter 5). Moreover, a neonate undergoes significant trauma to the head during labor and delivery. A recent study reported intracranial hemorrhage (ICH) after spontaneous vaginal delivery at a rate of 1 per 1900, whereas the rate of ICH in babies delivered by vacuum-assisted delivery was 1 in 860.[33] In addition, 15% to 30% of patients with inherited bleeding disorders have bleeding manifestations in the neonatal period.[34] Certain disorders, such as neonatal alloimmune thrombocytopenia (NAIT), are unique to the neonatal period. Furthermore, the neonate is significantly affected by the state of maternal health and medications used during labor. Blood volume in a neonate is small, and a relatively small degree of blood loss can have major consequences.

When evaluating bleeding in a neonate, the first step is to assess whether the baby is well or has medical conditions that may have precipitated hemorrhage. It is important to inquire about prolonged rupture of membranes, chorioamnionitis, and fetal distress during labor. Additional details about the maternal state of health, including infections, autoimmune disease, and maternal platelet count, should be obtained. Vitamin K administration to the baby should be confirmed. The neonate should be examined with particular attention directed to the presence of birth trauma, bruises and petechiae, and evidence of flank masses (renal vein thrombosis). The presence of hepatosplenomegaly may suggest disseminated intrauterine infection. When obtaining blood for various coagulation tests, particular attention should be paid to the hematocrit of the patient and the volume of the sample. Additionally, all laboratory results should be compared with normal values for different gestational ages (see Chapter 5).[35,36]

Isolated thrombocytopenia in a well infant may be seen in NAIT, in maternal autoimmune thrombocytopenia, or in cases of decreased platelet production such as amegakaryocytic thrombocytopenia or the syndrome of thrombocytopenia with absent radii (TAR). Rarely, type 2B VWD may be manifested as thrombocytopenia in a well infant. Thrombocytopenia in sick neonates is often due to the underlying cause, such as infection or DIC. Isolated prolongation of the prothrombin time (PT) or activated partial thromboplastin time (APTT) in a well baby may be due to a clotting factor deficiency, and prolongation of both the PT and APTT is suggestive of a clotting factor deficiency (in the common pathway) or vitamin K deficiency (hemorrhagic disease of the newborn). In sick babies, prolongation of clotting studies along with thrombocytopenia is suggestive of DIC.

LABORATORY ASSESSMENT

Sample Collection and Technique

A properly drawn blood sample is crucial for proper interpretation of the results of coagulation tests.[37] Blood for coagulation assays should be obtained by clean venipuncture without air bubbles and without contamination by tissue fluids. Drawing of samples from an indwelling catheter often results in sample contamination with heparin or intravenous fluids and spuriously abnormal values. Improper sample collection is one of the most common reasons for falsely elevated clotting times.[38]

Whole blood is collected into citrated anticoagulant in an evacuated sample tube containing a fixed amount of citrate (3.2% or 3.8%) as anticoagulant in the ratio of one part citrate to nine parts whole blood. If the patient is polycythemic (hematocrit >55%), the amount of plasma in the tube would be reduced in proportion to the citrate, thereby leading to falsely abnormal coagulation test results. In such circumstances, the amount of citrated anticoagulant should be reduced proportionate to the high hematocrit (Box 28-1).[39,40] Conversely, anemia

(hematocrit < 25%) does not seem to significantly affect the accuracy of coagulation tests, and adjustment of citrate need not be done.[41] For infants and children, small 3.0-mL tubes (2.7 mL blood to 0.3 mL citrate) are available. The tubes need to be filled to the appropriate mark on the tubes. It is recommended that the tubes be filled to at least 90% of the expected fill volume. Incompletely filled tubes often lead to falsely elevated clotting times.[38]

Once the tube is filled, the anticoagulated blood should be gently mixed by inversion three to four times and sent to the coagulation laboratory in an expeditious manner. Samples with visible hemolysis or clots should be discarded. Samples should be tested within 2 hours of collection if maintained at room temperature or within 4 hours if kept cold. Plasma samples must be frozen if not tested within this time frame. When they are to be analyzed, frozen samples should be rapidly thawed at 37° C and tested immediately. It is helpful to the laboratory to know whether the patient is taking a medication that may affect one or more coagulation tests. Normal values differ from one laboratory to another and between instruments and reagents. Thus, the values obtained should be compared with the normal range for that laboratory. It should also be kept in mind that normal values for coagulation and anticoagulant proteins in children differ with age (Chapter 5).[35,36]

Screening Tests

Often the child's history and physical examination will lead the physician to obtain certain assays immediately. However, if the initial evaluation is not suggestive of a specific disorder, a panel of screening tests should be ordered, including a complete blood count with evaluation of platelet number, morphology, PT, APTT, and thrombin time (TT) (Fig. 28-1).

Prothrombin Time

The PT is performed by adding a thromboplastin reagent that contains calcium chloride to the citrated plasma sample. The time required for clot formation is recorded with an automated instrument that signals the end point, as defined by optical or electromechanical change. The normal (reference) range varies depending on the laboratory (its instrumentation and the lot of thromboplastin), but it is generally 10 to 11 seconds. The PT measures the activities of factors I (fibrinogen), II (prothrombin), V, VII, and X. Prolongation of the PT beyond the reference range is not generally seen until the functional level of one of these factors is less than 30% or until fibrinogen is less than 100 mg/dL. Isolated prolongation of the PT may reflect factor VII deficiency. Though rare, the PT can also be prolonged by a circulating inhibitor or by the presence of abnormal fibrinogen molecules or fragments in the circulation.

The PT is also quite useful for monitoring the effect of coumarin-type anticoagulants. When the PT is used to monitor a patient taking warfarin, differences in the sensitivities of different thromboplastin preparations need to be taken into account. This consideration has led to the development of a standardized method of expressing the prolongation as an international normalized ratio (INR). The INR is calculated as INR = (patient's PT/control PT)$^{\text{International Sensitivity Index (ISI)}}$. The ISI should be determined for each thromboplastin reagent and instrument.

Activated Partial Thromboplastin Time

The APTT is performed by adding a "partial thromboplastin" reagent, which is a source of phospholipids without tissue factor, to the patient's citrated plasma sample, plus introducing controlled activation of the contact factors (factors XI and XII, prekallikrein, and high-molecular-weight kininogen) (Chapter 26) by preincubation with a surface-activating reagent (such as celite, kaolin, silica, or ellagic acid).[42] This mixture is incubated for 2 to 5 minutes before calcium chloride is added, and the time required for clot formation is recorded. As for the PT, automated instruments are generally used. The APTT measures factors I (fibrinogen), II (prothrombin), V, VIII, IX, X, XI, and XII; prekallikrein; and high-molecular-weight kininogen. Deficiency of any of the latter three factors can result in a markedly prolonged APTT in the absence of clinically significant bleeding. Isolated prolongation of the APTT in a patient with clinical bleeding is likely to result from a deficiency of factor VIII, IX, or XI. It should be noted that the sensitivity and reproducibility of the APTT are highly dependent on the specific reagents used (particularly the activator in the partial thromboplastin reagent).[43] With most APTT reagents, the APTT will not be prolonged until the amount of factor VIII is less than 35% (0.35 U/mL). The laboratory should establish a reference range for each new lot of reagent and each new method of clot detection. The reference range will generally be approximately 26 to 35 seconds for children and adults but longer (30 to 54 seconds) in term infants (and often even longer in premature infants).

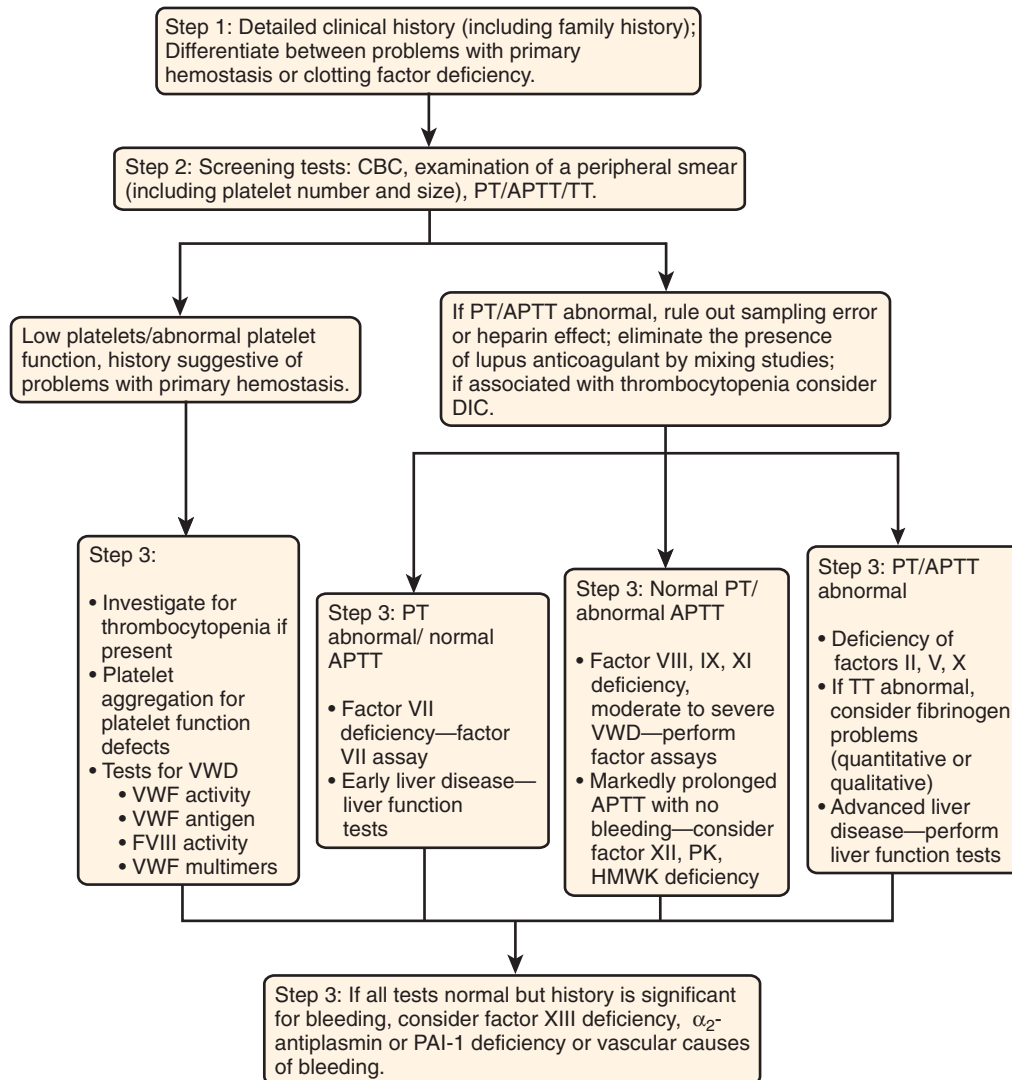
The APTT is somewhat less sensitive than the PT to deficiency of the vitamin K–dependent factors, but it is more sensitive to the presence of circulating anticoagulants and heparin. The APTT can detect circulating


FIGURE 28-1. Stepwise approach to bleeding. APTT, activated partial thromboplastin time; CBC, complete blood count; DIC, disseminated intravascular coagulation; FVIII, factor VIII; HMWK, high-molecular-weight kininogen; PAI-1, plasminogen activator inhibitor 1; PK, prekallikrein; PT, prothrombin time; TT, thrombin time; VWD, von Willebrand's disease; VWF, von Willebrand factor.

anticoagulants (such as lupus anticoagulants [LAs]) and is routinely used to monitor standard heparin therapy.[44] Among hospitalized infants or children, unintentional contamination of patient samples with heparin is a common cause of an unexpected prolongation of the APTT that does not correct on mixing.

Thrombin Time

The TT measures the thrombin-induced conversion of fibrinogen to fibrin and is performed by adding bovine thrombin to the patient's citrated plasma and recording the clotting time. The TT measures the amount and the clotting function of fibrinogen and is also prolonged in the presence of heparin or circulating fibrin degradation products (FDPs). An extremely prolonged TT usually indicates a heparin effect. Reptilase, a snake venom protease, clots fibrinogen in the presence of

heparin and thus can be used to identify heparin as the cause of a prolonged TT. Thus, in the presence of heparin the TT is prolonged, whereas the reptilase time is normal. Alternatively, one can test for heparin activity by its anti–factor Xa activity or with the use of commercial heparinase. The sensitivity of the TT can be increased by dilution of the thrombin to give a control TT of 16 to 18 seconds.

Platelet Count

The normal platelet count (for all ages) ranges from 150,000 to 450,000/μL. Platelets are counted with an electronic particle counter or (less often) by direct-phase microscopy. Review of the platelets on a well-prepared, stained blood smear should give a visual estimate that matches the laboratory's printed value. A spuriously low automated platelet count (pseudothrombocytopenia)

may result from ethylenediaminetetraacetic acid (EDTA) anticoagulant plus an IgG or IgM platelet antibody, platelet cold agglutinins, or platelet clumping from a partially clotted sample. In the setting of thrombocytopenia, increased or decreased platelet size may suggest increased platelet turnover or decreased production, respectively. Large platelets are also seen in the hereditary giant platelet syndromes, and small platelets are characteristic of Wiskott-Aldrich syndrome. Electric particle counters also often provide a mean platelet volume and platelet volume (size) distribution.

Bleeding Time

The bleeding time (BT) is a measure of the interaction of platelets with the blood vessel wall. Although the BT can provide useful information, it does have significant limitations. It is no doubt the most difficult of the tests of hemostasis to standardize, and thus results may not be reliable. The most widely used method is the modified Ivy BT performed with a template. Although commercially available devices incorporate a spring-loaded blade that is designed to make a skin incision of standard depth and width, arm wiggling in young children, the amount of pressure applied to the arm, and operator experience are a few examples of details that can influence test results.

The BT is performed with a tourniquet maintained at 40 mm Hg and placement of the template device on an area of the forearm (just below the elbow) that is devoid of obvious superficial veins. By breaking off the small tab, the spring is activated and the blade or blades make a linear cut 1 to 2 mm deep (if done correctly, this superficial cut is above the pain fibers). With a stop watch and a piece of filter paper, the blood coming from the cut is gently blotted away while taking care to not touch the filter paper to the cut (which would remove the fragile platelet plug). A normal BT is 3 to 9 minutes. The BT is an approximate measure of the relationship between platelet number and function, as originally demonstrated by Harker and Slichter.[45] With normally functioning platelets, the BT begins to prolong at a platelet count of less than 100,000/µL. The BT can also be prolonged with congenital and acquired platelet function defects (the latter include acquired defects resulting from certain drugs, uremia, and cyanotic congenital heart disease), VWD, vasculitis (e.g., Henoch-Schönlein purpura), and connective tissue disorders such as Ehlers-Danlos syndrome.

PFA-100

Current platelet function tests are often viewed as inaccurate and unreliable (BT) or labor intensive and time consuming (platelet aggregation studies). Recently, a range of new instruments have been developed that attempt to simulate in vivo platelet adhesion and aggregation. The Platelet Functional Analyzer 100 (PFA-100; Dade Behring, Mahburg, Germany) is a commercially available instrument that uses test cartridges containing collagen/adenosine diphosphate (CADP)- or collagen/epinephrine (CEPI)-coated membranes with a small aperture (150 µm). Citrated blood is aspirated under high shear (5000 to 6000/sec) from the sample reservoir through a capillary tube onto the membrane, and blood flow is monitored through the aperture. Platelets begin to adhere and aggregate primarily through interactions of von Willebrand factor (VWF) with glycoprotein Ib and IIb/IIIa, thereby resulting in closure of the aperture. The instrument monitors the drop in flow rate with time as the aperture gradually occludes and records the final closure time (CT) with either cartridge. Although the test is reproducible between cartridge lots and instruments, each laboratory should establish normal control times. Citrate samples have been shown to be stable for up to 4 hours after sample collection, but transport through a pneumatic vacuum transport system ("tube system") is not recommended.[46]

The test is sensitive to the platelet count, hematocrit, platelet function, and VWF level and function. Generally, a platelet count of less than 80 to 100×10^9/L and a hematocrit of less than 30% lead to a prolonged CT.[46] The PFA-100 CT is inversely proportional to the VWF level and has been used by some as a screening test for VWD.[47] Consumption of flavinoid-rich foods (red wine, cocoa, or chocolate) can prolong CEPI CT. Other dietary effects (e.g., fish oil consumption) on the PFA-100 CT have not been studied. In congenital platelet disorders, PFA-100 CT depends on the severity of the disorder. Severe platelet function defects in glycoprotein Ib/V/IX (Bernard-Soulier syndrome or platelet-type VWD) and glycoprotein IIb/IIIa (Glanzmann's thrombasthenia) result in a markedly prolonged CT (see Chapter 29). In platelet dense granule deficiency or secretion defects, the prolongation in CT is variable and is often seen in the CEPI cartridge. Thus, although the PFA-100 CT is abnormal in some forms of platelet disorders, the test does not have sufficient sensitivity or specificity to be used as a screening tool for platelet disorders in general.[48] Additionally, PFA-100 CT may be altered by drugs that affect platelet function. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) prolong the CEPI CT by inhibition of thromboxane generation. The role of the PFA-100 in therapeutic monitoring is currently being investigated.[48]

Other Assays

Specific Coagulation Factors

Each of the coagulation factors of the intrinsic pathway (prekallikrein, high-molecular-weight kininogen, and factors VIII, IX, XI, and XII) can be measured by one-stage, APTT-based methods. A specific factor assay measures the clotting time of a mixture of diluted test plasma and a specific factor–deficient substrate plasma that supplies all factors except the one being measured.[49] Though

seldom performed in U.S. clinical laboratories, a chromogenic substrate assay kit for factor VIII (as well as chromogenic kits for certain other clotting factors) that is based on measuring the generation of factor Xa is also commercially available.

Each of the extrinsic and common pathway coagulation factors (V, VII, and X) can be measured by specific one-stage assays based on the PT. The patient's diluted test plasma is incubated with commercially available plasma that is deficient in either factor V, VII, or X; a mixture of tissue factor and calcium chloride is added, and the clotting time is determined.[49]

For each clotting factor assay based on the APTT or PT, the clotting times of serial dilutions of a plasma sample representing a pool obtained from a large number of normal individuals is used to construct a standard curve. The concentration of the specific factor in each of the several dilutions of patient plasma is determined from the standard curve and is used to calculate the level of that clotting factor in the patient's undiluted plasma.[49] In most laboratories, automated instruments are used to perform the assays, and many of these instruments are preprogrammed with a statistical package for plotting the data. The reference pooled plasma should be calibrated with a commercial or national standard that has been assayed against an international standard when available.[50]

Covalent stabilization of fibrin by factor XIIIa is essential for normal hemostasis (Chapter 26). Factor XIIIa catalyzes the formation of covalent cross-links between the γ and α chains of fibrin, which results in increased mechanical stability of the fibrin clot and resistance to its degradation by plasmin. Congenital deficiency of factor XIII is a rare hereditary (autosomal recessive) cause of moderate to severe hemorrhage, often with a characteristic pattern of delayed bleeding (see Chapter 31). None of the routine screening tests (PT, APTT, or BT) detect factor XIII deficiency.[51] A screening test for factor XIII deficiency can be done with the clot solubility test: solubility of the patient's recalcified plasma clot in 5 mol/L urea or monochloroacetic acid is assessed after 30 minutes and periodically at 1, 2, 4, and 24 hours. Clots from patients with less than 1% factor XIII activity are soluble. Quantitation of factor XIII can be done with specific amine incorporation assays, although these tests are generally performed only in specialized research laboratories.[51]

Recommended tests for VWD include APTT, factor VIII assay, ristocetin cofactor assay as a measure of VWF activity, VWF antigen assay, and ABO blood group typing. If these tests are suggestive of VWD, VWF multimer analysis should be performed. Treatment of VWD depends on accurate subtype diagnosis (see Chapter 30).

Antiphospholipid Antibodies

Antiphospholipid antibodies (APAs) include LAs, anticardiolipin antibodies, antiphosphatidylserine antibodies, and antiphosphatidylethanolamine antibodies. APAs are immunoglobulins (IgG, IgM, and IgA) directed against anionic phospholipids or phospholipid–plasma protein complexes. Approximately 30% of APAs are found in association with thromboembolic events, recurrent abortions, or thrombocytopenia (referred to as the APA syndrome).

APAs have been associated with autoimmune disorders, infectious disease processes, acquired immunodeficiency syndrome, hematologic malignancies, lymphoproliferative disorders, seizure disorders, migraine, stroke, and subdural hematomas. Anticardiolipin antibodies are distinct from LAs. The antigenic target for anticardiolipin antibodies is thought to be cardiolipin, β_2-glycoprotein I, or a complex of the two. Cardiolipin is an important lipid component of mammalian cell membranes. LAs are often seen in persons with no underlying disease and no history of abnormal bleeding. They may be detected in pediatric patients receiving certain drugs, particularly antibiotics. LAs are immunoglobulins that interfere with one or more phospholipid-dependent coagulation tests, such as the APTT, PT, dilute Russell viper venom time, and kaolin clotting time. Coagulation tests for LAs are based on their interference with reactions that depend on the phospholipid added to substitute for platelets when citrated plasma is recalcified in vitro. The presence of LAs may be chronic (as in autoimmune disorders) or transient.[52]

The APTT is the test generally used to screen for LAs, although the sensitivity of the APTT for LAs depends on the reagent and method used. Many modifications of the APTT have been recommended in an attempt to increase its sensitivity to LAs, including the addition of less phospholipid. The PT is often normal in the presence of LAs. The dilute Russell viper venom time performed with dilute phospholipid can also be used to detect LAs, as can the STACLOT LA.[52] LAs must be differentiated from inhibition caused by heparin, from a clotting factor deficiency, or from an acquired inhibitor to a clotting factor (usually factor VIII). LAs can also occur in patients with hemophilia A. In one study, 21% of subjects with hemophilia A were found to have LAs.[53] According to guidelines developed by the Scientific and Standardization Subcommittee on Lupus Anticoagulants of the International Society on Thrombosis and Hemostasis, the minimum diagnostic criteria for LAs are (1) an abnormal phospholipid-dependent coagulation assay, (2) demonstration of an inhibitor as a cause of the abnormality, and (3) demonstration that the inhibitor is directed against a phospholipid and not a specific coagulation factor.[52] Genetic determinants may play a role in the development of clinical manifestations related to APAs and the APA syndrome.[54]

If the APTT is prolonged, a mixing study is performed. Failure of the APTT to correct on mixing indicates an inhibitor, and confirmatory studies can then be performed. Such tests typically alter the phospholipid content of the assay, either increasing it, as in the platelet

neutralization procedure, or decreasing it, as in the dilute Russell viper venom time.

Fibrinogen

Fibrinogen's concentration in plasma can be measured immunologically (fibrinogen antigen) or by a chemical method in which the ability of fibrinogen to clot does not influence the assay. Normal fibrinogen antigen levels are between 200 to 400 mg/dL. Fibrinogen is an acute phase reactant, and elevated levels are commonly seen in stress or acute illness.

The level of functional fibrinogen or fibrinogen activity can also be measured. The von Clauss kinetic assay uses a dilute solution of patient plasma and an excess of thrombin, which makes fibrinogen the rate-limiting step in the clotting reaction.[55] The resulting clotting time in seconds is compared with a standard dilution curve to determine the concentration of clottable fibrinogen. Fibrinogen is decreased in congenital afibrinogenemia, hypofibrinogenemia, and consumptive states such as DIC. The assay is also sensitive to abnormalities in fibrinogen function (dysfibrinogenemia) or the presence of inhibitors of fibrin formation such as FDPs.

Fibrin(ogen) Degradation Products and D-Dimer

FDPs are usually measured in serum samples because these degradation products consist predominantly of non-clottable derivatives that remain in solution after clot formation. These global tests involve the use of flocculation, tanned red cell hemagglutination, radioimmunoassay, or radioautograph analysis. Latex bead and enzyme-linked immunosorbent assays based on monoclonal antibodies specific to cross-linked D-dimer fragments are commercially available and in widespread use. The D-dimer assay will identify only cross-linked FDPs (indicating that fibrin has formed intravascularly, has been cross-linked, and has then been cleaved into D-dimers by plasmin; see Chapter 27). The patient's plasma or serum sample is serially diluted, and each dilution of the sample is mixed with latex beads coated with antibody to D-dimer. The end point of the assay is determined by the highest dilution of patient serum or plasma that produces visible agglutination. This titer is then used to calculate the D-dimer concentration in the patient's sample.[56,57]

Euglobulin Clot Lysis Time

The euglobulin clot lysis time (ECLT) is a screening test for excessive fibrinolysis. It is performed by using the plasma euglobulin fraction prepared from fresh, citrated, platelet-poor plasma. After clot formation, lysis is measured. The normal ECLT is 60 to 300 minutes. It is shortened in conditions characterized by increased fibrinolysis (e.g. α_2-antiplasmin deficiency, plasminogen activator inhibitor 1 deficiency, or systemic fibrinolysis).

Platelet Function Tests

When ordering tests of platelet function, one must be aware that a wide variety of drugs can affect the platelet count and alter test results. Drugs such as aspirin irreversibly affect platelet function for the entire life span of the platelet (10 to 11 days). Thus, tests of platelet function should be scheduled at a time when the individual has not taken any relevant drugs for at least 10 days.

The most common test of platelet function is platelet aggregometry. Platelet aggregation can be performed in whole blood by impedance technique or in platelet-rich plasma (PRP) by the turbidometric technique. Whole blood platelet aggregation can be combined with release of adenosine triphosphate (ATP) by using a lumi-aggregometer. A variety of platelet agonists (ristocetin, epinephrine, collagen, adenosine diphosphate, and arachidonic acid) can be added to an aliquot of the patient's sample. The rapidity and extent of platelet agglutination are detected by changes in optical density (PRP) or impedance (whole blood) and are graphically recorded for each agonist used.[58] In Glanzmann's thrombasthenia, the patient's platelets will agglutinate normally with ristocetin but not at all with the addition of adenosine diphosphate, epinephrine, collagen, or arachidonic acid. In Bernard-Soulier syndrome, platelet agglutination will occur normally on addition of each of these agonists except ristocetin.[58]

Global Tests for the Evaluation of Bleeding

As knowledge of the coagulation system developed in the 1950s, specific assays were devised to measure the individual clotting factors. However, it soon became apparent that individual clotting factor assays were inadequate to assess the true nature of the hemostatic system. It was obvious that static end point laboratory tests such as the PT or APTT were also not accurately reflective of the patient's overall hemostatic status and could not assess the dynamic clotting cascade. The common clinical observation that hemophilia patients have great phenotypic variation in bleeding despite identical factor levels stresses this point. This has led to a revival of interest in global clotting assays. In addition, the development of technical innovations and computer-assisted methods of analysis has improved the reliability and reproducibility of global assays. Two such techniques are described here: thromboelastography (TEG) and thrombin generation assays (TGAs). TEG is usually performed on whole blood and quantitatively measures the dynamics of fibrin formation. TGAs are generally performed on plasma and measure thrombin formation.

Thromboelastography

Hartert first described TEG as a global test for blood coagulation more than 50 years ago.[59] TEG monitors the whole dynamic process of hemostasis from clot formation to its dissolution and also provides information about platelet function. TEG produces a continuous profile of the overall rheologic changes occurring during coagulation while using a small amount of whole blood.
FIGURE 28-2. Tracing of a normal thromboelastogram.

R: Time to initial clot formation.
K: Measure of the speed to reach a certain level of clot strength.
Alpha angle: Measure of rapidity of fibrin cross linking.
MA: Maximum amplitude, depends on function of fibrin and platelets, represents clot strength.

By processing the data, the viscoelastic changes occurring during whole blood clot formation can be transformed into a dynamic velocity profile that is then recorded as a tracing (Fig. 28-2). Currently, reagent-modified TEG with various activators (tissue factor, kaolin) and inhibitors is used with the aim of accelerating the coagulation cascade and obtaining differential diagnostic information.[60] The two commonly used instruments are the TEG (Haemoscope Corp, Skokie, Illinois) and the rotating thromboelastometer ROTEM (Pentapharm, Munich).[61] Currently used primarily as a tool to decrease transfusion requirement during cardiac[62] and hepatic surgery, these instruments are also being investigated as a screening tool for bleeding disorders.[63,64]

Thrombin Generation Assays

TGAs have been used extensively in research laboratories but are cumbersome to perform.[65] A more recently developed test, calibrated automated thrombography (CAT), may be applicable to the routine clinical laboratory. CAT measures the concentration of thrombin in clotting plasma by monitoring the splitting of a fluorogenic substrate and comparing the results with known constant thrombin activity in a parallel nonclotting sample (control).[66] Application of TGAs is currently being investigated for monitoring of hemophilia treatment and anticoagulation therapy and to better understand the differing clinical patterns in bleeding disorders.[67]

Laboratory Findings in Disseminated Intravascular Coagulation

DIC is an acquired systemic disorder characterized by widespread activation of coagulation and deposition of fibrin leading to the formation of thrombi in the microcirculation accompanied by secondary activation of fibri-

Box 28-2	**Conditions Associated with Disseminated Intravascular Coagulation**

  Drug overdose
Immunologic reactions
  Severe anaphylaxis
  Acute hemolysis
  Acute transplant rejection

nolyis[68] (see Chapter 34). DIC can be acute or chronic, compensated or decompensated, and can be caused by a wide variety of conditions (Box 28-2). DIC should be suspected in children with shock and bleeding manifestations. In DIC, the PT and APTT are usually both prolonged, with decreased fibrinogen, factor VIII, and factor V. A concomitant decrease in natural anticoagulants (protein C, protein S, and antithrombin III) may also be seen. Examination of the peripheral smear usually reveals the presence of schistocytes and thrombocytopenia.[69] There is also an increase in D-dimer and FDPs secondary to the formation of plasmin (Fig. 28-3).

Inherited Platelet Disorders

Michele P. Lambert and Mortimer Poncz

Platelets are small (1 to 4 µm in diameter) cells once thought to be fragments of other mature blood cells and dismissed as "blood dust." They are now known to be highly specialized and organized fragments released by a still poorly understood process from intramedullary megakaryocytes within the bone marrow. Platelets are a critical component for the first phase of hemostasis (formation of the platelet plug), which can halt the loss of blood from vessels whose endothelial integrity has been interrupted. If platelets are deficient in number or defective in function, excessive bleeding may occur. The clinical manifestations of platelet-type bleeding typically involve the skin or mucous membranes and include petechiae, ecchymosis, epistaxis, menorrhagia, and gastrointestinal hemorrhage (Box 29-1). Intracranial bleeding can occur, but it is infrequent. The deep muscle hematomas and hemarthrosis typically seen in patients with defects in the fluid-phrase (plasma) hemostatic system infrequently occur in platelet disorders.

Inherited platelet disorders can involve a qualitative or quantitive defect and can be broadly classified according to one of these two categories. In this chapter these disorders are classified by their predominant feature, although many involve defects in both platelet number and function. For example, Bernard-Soulier syndrome (BSS) results from defects in the platelet receptor glycoprotein Ibα/Ibβ/IX/V (GPIb/IX) complex, which binds von Willebrand factor (VWF) and is critical for adherence of platelets at sites of vascular injury. This receptor is anchored to the cytoskeleton and is critical in platelet formation from megakaryocytes. Thus, many of these patients have macrothrombocytes and low platelet counts, as well as a defect in platelet function. Furthermore, although many inherited platelet disorders have been described, most are extremely rare, and even the well-known disorders such as BSS and Glanzmann's thrombasthenia (GT) are uncommon, with a frequency in the general population of 10^{-5} to 10^{-6}, and are mostly seen in inbreeding populations or consanguineous relationships. In aggregate, however, these disorders are not uncommon and, given the diverse nature of the underlying defects, may pose a significant diagnostic challenge.

QUALITATIVE DISORDERS

Platelet Membrane

Sensing abnormalities in their microenvironment, adhering to damaged vascular wall, and aggregating to each other are central functions of circulating platelets. Over the past 20 years many of the membrane receptors in these processes have been cloned. Initially, many of these protein receptors were classified by their electrophoretic mobility and molecular mass and numbered sequentially. Now, it is clear that many of these proteins are members of several large families of receptors, including the integrin α/β heteroduplexes, the leucine-rich receptors, the G protein–coupled receptors (GPCRs), and the immunoglobulin superfamily. Such a classification takes advantage of the similar structure and function of members of these families. Frequently, family members share a common family of ligands or activate cells by a common pathway. Table 29-1 lists the members of these families of receptors that are found on platelets, as well as several receptors that do not belong to any of these families. Many of these receptors have other historical names, and these, as well as their cluster differentiation (CD) antigen nomenclature, are noted in the table. Many of the receptors involved in inherited platelet disorders are described in the following text.

Glanzmann's Thrombasthenia: Defective Platelet Integrin $\alpha_{IIb}\beta_3$

In 1918, a Swiss pediatrician named Glanzmann described a heterogeneous group of disorders that he termed "thrombasthenie" ("weak platelets"); these disorders were characterized by normal platelet counts but abnormal clot retraction.[1] In 1956 it was noted that these platelets failed to spread onto a surface or to stick to each other (aggregate).[2,3] GT is now known to be a rare, inherited, autosomal recessive bleeding disorder, the hallmark of which is failure of platelets to bind fibrinogen and aggregate after activation. The underlying defect is an abnormality in the genes encoding either chain of the integrin $\alpha_{IIb}\beta_3$ fibrinogen receptor (see Table 29-1). GT is the most common of the inherited platelet disorders.[4]

Biology of the $\alpha_{IIb}\beta_3$ Receptor

The α_{IIb} and β_3 subunits are encoded by separate genes that are closely linked on chromosome 17q21-23.[5] α_{IIb} is approximately 145 kd in size and contains 18 cysteine residues arranged into nine disulfide bonds that are rather evenly spaced throughout its length (Fig. 29-1). The α_{IIb} prochain complexes with the β_3 subunit in the endoplasmic reticulum. During maturation in the Golgi body, the α_{IIb} prochain is cleaved into the α_{IIb} heavy fragment and the α_{IIb} light fragment, with the two fragments remaining linked by a disulfide bond.[6] Like most other integrin α chains, α_{IIb} contains four calcium-binding domains near its N-terminal.[7] This region in all α subunits contains seven homologous repeats[8] that fold into a β-propeller structure[9,10]; portions of the surface loops of this structure are critical for ligand binding (in interaction with the βA domain of the β_3 subunit).[9,11]

TABLE 29-1	Major Platelet Membrane Receptors			
Class of Receptor	**Receptor**	**Other Names**	**Number of Receptors per Platelet**	**Ligand**
Integrins	$\alpha_{IIb}\beta_3$	GPIIb/IIIa, CD41b	≈80,000	Fibrinogen, VWF, fibronectin
	$\alpha_V\beta_3$		≈500	Vitronectin, osteopontin
	$\alpha_2\beta_1$	CD49b	≈2,000	Collagen
	$\alpha_5\beta_1$	CD49e	≈4,000	Fibronectin
	$\alpha_6\beta_1$	CD49f		Laminin
Leucine-rich repeats receptor	GPIb-IX	CD42a, b, c	≈25,000	VWF, thrombin, P-selectin
G protein–coupled receptors	PAR-1		≈2,000	Thrombin
	PAR-4		Low	Thrombin
	P2Y1			ADP
	P2X1			ADP
	P2Y12			ADP
	α_{2A}		≈700	Epinephrine
	TP		≈1,000	Thromboxane
	IP			Prostaglandin I_2
	CXCR1 and CXCR2		≈2,000 each	Interleukin-8
	CXCR4		≈2,000	Stromal-derived factor 1
	CCR4		≈2,000	CCL22
Immunoglobulin superfamily receptors	GPVI		1,000-3,000	Collagen
	P-selectin	GMP-140, PADGEM, MARK		P-selectin, glycoprotein-1
	PECAM-1	CD31	≈10,000	PECAM-1
	FcγRIIA	CD32	1,000-5,000	Immune complexes
Others	GPIV	CD36	≈25,000	Collagen
	p65			Collagen

ADP, adenosine diphosphate; GPIIb, glycoprotein IIb; PADGEM, platelet activation-dependent granule-external membrane protein; MAPK, mitogen-activate protein kinase; PAR, protease-activated receptor; PECAM-1, platelet–endothelial cell adhesion molecule 1; VWF, von Willebrand factor.
FIGURE 29-1. Structure of the $\alpha_{IIb}\beta_3$ receptor. Both units of the $\alpha_{IIb}\beta_3$ heteroduplex contain a transmembrane domain with short intracellular tails. The α_{IIb} extracellular domain is cleaved into two parts: the α_{IIb} heavy chain, which has the N-terminal β-propeller domain, and the α_{IIb} light chain, which spans from the extracellular to the intracellular compartment. The β_3 chain contains multiple cysteine disulfide bonds represented by the *gray lines*. The MIDAS (metal ion–dependent adhesion site) domain is indicated. The pocket on $\alpha_{IIb}\beta_3$ that may represent the ligand-binding domain is shown as a *gray ball*. EGF, epidermal growth factor.

Similar to other integrin β chains, β_3 is approximately 90 kd and contains 762 amino acid residues in its mature form (see Fig. 29-1).[12] β_3 contains five cysteine-rich regions for a total of 56 cysteine residues, including a large disulfide-bonded loop, termed the βA region, that extends from amino acids Cys5 to Cys435.[9] This loop participates in fibrinogen binding and contains three divalent cation-binding domains that appear to be important in ligand binding. One of these cation-binding sites (the βA MIDAS—metal ion–dependent adhesion site), interacts directly with ligand,[9] and binding of cations to the βA domain may stabilize the ligand-occupied conformation.

There are about 8×10^4 $\alpha_{IIb}\beta_3$ receptors per platelet, the most abundant receptor on platelets (see Table 29-1).[12] Most of these receptors are located on the platelet surface, although a portion are found on the inner surface of alpha granules and are involved in the localization of fibrinogen to these granules.[13] On resting platelets, $\alpha_{IIb}\beta_3$ exists in a folded, inactive state that does not interact with its ligand. However, upon platelet activation, an "inside-out" signaling event takes place in which the $\alpha_{IIb}\beta_3$ complex is activated and unfolded like a switch blade,[9] thereby resulting in binding of fibrinogen at the N-terminals of the two proteins and platelet aggregation. After ligand binding, an "outside-in" signal mediates integrin-cytoskeleton interactions and platelet spreading.[14]

Many integrin ligands contain an arginine-glycine–aspartic acid (RGD) motif[15] that participates in integrin binding. Conversely, RGD-containing peptides act as competitive inhibitors of ligand binding.[15,16] For example, the RGD motif located in the C1 domain of VWF[17] appears to be necessary for binding of VWF to $\alpha_{IIb}\beta_3$. In contrast, deletion of the two RGD sequences in the fibrinogen α chain does not impair its ability to bind to $\alpha_{IIb}\beta_3$.[18] Rather, binding of fibrinogen to $\alpha_{IIb}\beta_3$ requires a KQAGD sequence located at the carboxyl-terminal of the fibrinogen γ chain.[18]

Whereas expression of the α_{IIb} chain is restricted to megakaryocytes, the β_3 subunit is expressed more widely as a component of the $\alpha_V\beta_3$ (vitronectin) receptor. Mouse studies have shown that deletion of $\alpha_V\beta_3$ function results in placental defects and osteosclerosis,[19] although to date no differences have been noted between patients with GT caused by an α_{IIb} or β_3 defect.[4]

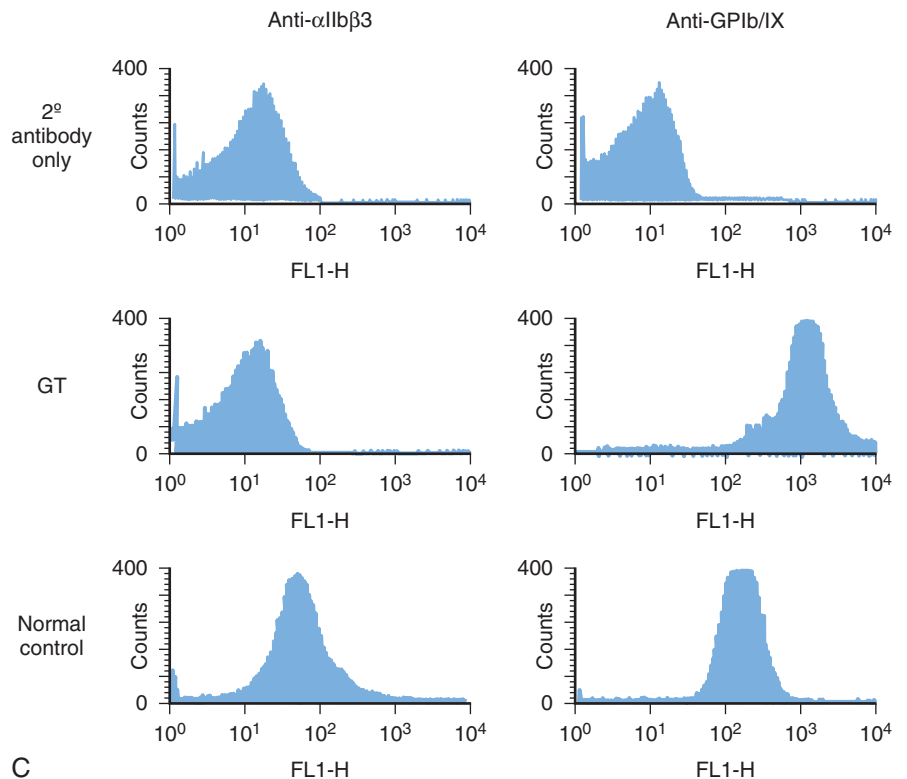
Clinical Features

Thrombasthenia is characterized by repeated mucocutaneous bleeding beginning at an early age (Fig. 29-2A). Epistaxis and gastrointestinal bleeding are frequent issues in early childhood that often require intervention, as well as iron supplementation. Menorrhagia is a critical problem in teenage girls.[21] The bleeding that normally accompanies pregnancy, surgical procedures, tooth extraction, or physical trauma can be excessive in GT patients. Unprovoked intracranial or gastrointestinal hemorrhage occurs and accounts for a significant portion of the observed 5% to 10% lifelong mortality rate. In addition, some patients experience joint bleeding or muscle hematomas more characteristic of the hemophilias.[21] Frequently, local compression strategies or topical application of thrombin is useful when bleeding occurs. DDAVP (1-deamino-8-D-arginine vasopressin) has been used as well, and oral contraceptive management of menorrhagia is generally sufficient. Platelet transfusions may be useful until resistance to platelet infusions develops, although patients do not necessarily form antibodies to the $\alpha_{IIb}\beta_3$ receptor. Antibodies may be particularly problematic because they may not only result in increased platelet clearance or platelet refractoriness but may also directly interfere with platelet function.[22] Recent evidence suggests that recombinant activated factor VII may be a useful supplement to platelet transfusions.[23] We have also successfully used embolic block of arterioles feeding the nose and uterus in cases of recurrent, life-threatening hemorrhage.

Incidence

Though infrequent worldwide, GT is found at high incidence among certain isolated populations and in the setting of consanguineous relationships, particularly among Arab populations,[24] Iraqi Jews,[25] French gypsies,[26] and individuals from southern India.[27] Obligate heterozygotes for this disease have approximately 50% of the normal number of $\alpha_{IIb}\beta_3$ receptors, but no evidence of platelet dysfunction or clinically significant bleeding.[21] Although most cases are observed in specific populations or in the setting of consanguinity and are thus homozygous for a shared mutation inherited from both parents, about a third of patients with identified mutations are compound heterozygotes.

Classification and Laboratory Diagnosis

In 1972, Caen classified GT according to platelet intracellular fibrinogen content and the ability of platelets to retract a fibrin clot.[28] Type I patients, representing 80% of those studied, lacked platelet fibrinogen and had an absence of clot retraction. Type II thrombasthenic platelets contained appreciable levels of platelet fibrinogen and maintained some clot retraction capability. Soon thereafter, the technique of sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) became widespread, and it became clear that there were three different patterns seen with thrombasthenic platelet membrane glycoproteins.[29,30] Type I platelets lacked detectable levels of $\alpha_{IIb}\beta_3$, whereas type II platelets expressed moderate (15% to 25%) levels of these glycoproteins. Adding to the complexity of this classification was the identification of variant forms of thrombasthenia characterized by normal to nearly normal levels of a dysfunctional form of $\alpha_{IIb}\beta_3$.[31,32] Another integrin dysfunction syndrome in which β_1, β_2, and β_3 integrins are involved results in a GT-like syndrome with leukocyte adhesion deficiency type 1 and immune dysfunction.[33] All three groups fail to aggregate in response to physiologic agonists such as adenosine diphosphate (ADP),
FIGURE 29-2. Glanzmann's thrombasthenia. The patient shown has a mutation in the fourth cysteine-binding domain of α_{IIb} secondary to a Gly273Asp substitution.[35] **A,** Representative ecchymosis seen in the patient at the age of 6 years. **B,** Platelet aggregation studies show an absence of secondary aggregation to adenosine diphosphate (ADP), epinephrine, and collagen but a normal response to ristocetin. **C,** Flow cytometric platelet analysis using an anti-$\alpha_{IIb}\beta_3$ primary antibody (*left*) or an anti-GPIb/IX antibody as a positive control (*right*), followed by a fluorescein isothiocyanate–labeled secondary antibody. Shown at the *top* is the fluorescence with the secondary antibody only on normal platelets. In the *middle* is a patient with primary followed by secondary antibody, and at the *bottom* is the same with normal platelets. The patient's platelets show little $\alpha_{IIb}\beta_3$ antibody binding when compared with the control. The patient's platelets do express high levels of glycoprotein Ib/IX (GPIb/IX).


thrombin, or epinephrine (see Fig. 29-2B) because they all have a functional deficiency of platelet surface $\alpha_{IIb}\beta_3$ receptors. The failure to bind fibrinogen and other adhesive ligands is the reason for the inability of platelets to cohere. No correlation exists between any of the proposed subtypes of GT and the severity of bleeding symptoms in patients.[21] Some patients with no $\alpha_{IIb}\beta_3$ have relatively mild clinical symptoms, whereas others with a full complement of $\alpha_{IIb}\beta_3$, albeit dysfunctional, can have

frequent bleeding episodes requiring repeated platelet transfusions.

Currently, the most common method used for determining levels of $\alpha_{IIb}\beta_3$ on thrombasthenic platelets involves flow cytometry[34] and immunoblot analysis.[35] Figure 29-2C illustrates flow cytometric analysis of the $\alpha_{IIb}\beta_3$ content of both a normal control and a GT patient with a severe deficiency of $\alpha_{IIb}\beta_3$ secondary to a mutation in one of the Ca^{2+}-binding domains of her α_{IIb} chain.[20]

This mutation blocks export of the $\alpha_{IIb}\beta_3$ receptor out of the endoplasmic reticulum and into the Golgi body for final processing, as indicated by failure to cleave the α_{IIb} prochain into an α_{IIb} heavy chain.

Several hundred individuals with GT have been described in the literature. To date, more than a hundred of these cases have been solved at the molecular level. As in most genetic disorders, the molecular abnormalities have been found to range from major deletions and inversions to single point mutations (for review, see elsewhere[36] and http://sinaicentral.mssm.edu/intranet/research/glanzmann). Some of the better-characterized subgroups of mutations are described in the following text.

The earliest and largest group of thrombasthenic mutations described failed to express $\alpha_{IIb}\beta_3$ on the cell surface. Several of these patients had major deletions or inversions in their α_{IIb} or β_3 genes. In addition, a number of point mutations or small deletions in the α_{IIb} or β_3 genes have been described with no surface expression of $\alpha_{IIb}\beta_3$; both chains are formed intracellularly and complex but fail to undergo intracellular processing or reach the cell surface. These defects result in a type 1 form of thrombasthenia. One major subgroup of these patients involves missense mutations in the N-terminal β-propeller repeats of α_{IIb} near the proposed Ca^{2+}-binding sites on its lower surface as exemplified by the patient in Figure 29-2.[20,37]

Another group of mutations occur in the same β-propeller region of α_{IIb} but take place on the upper surface and have a different phenotype. These mutations are located within three upper loops of β-propeller, the connecting loop between the second to the third blade, the loop in the middle of the third blade, and the loop connecting the third and fourth blade.[38] These mutations occur within the RGD ligand binding pocket of α_{IIb}.[9]

Another group of thrombasthenic defects with significant levels of $\alpha_{IIb}\beta_3$ surface expression (although the complex is not able to interact with its natural ligands) involve the β_3 chain. These mutations result in a surface $\alpha_{IIb}\beta_3$ that is easily dissociable by chelation of external calcium ions.[39] Many of these missense mutations have been identified within the cation-binding MIDAS domain.[9] The importance of these sites was reinforced by the identification of a group of in vitro–generated mutant $\alpha_{IIb}\beta_3$ receptors expressed in Chinese hamster ovary (CHO) cells, which provided independent support for the importance of the MIDAS domain in ligand binding.[40]

A second group of mutations with normal levels of surface $\alpha_{IIb}\beta_3$ receptors have mutations in the cytoplasmic domain of β_3, thus demonstrating the importance of this domain for integrin activation and regulation of ligand binding.[41,42] These mutations do not affect surface expression of platelet $\alpha_{IIb}\beta_3$ complexes, but mutant receptors are unresponsive to agonist stimulation. Mammalian cell expression studies show normal adhesion to immobilized fibrinogen but abnormal platelet spreading. These mutations provide compelling evidence for the role of the β_3 cytoplasmic tail in downstream platelet activation by $\alpha_{IIb}\beta_3$.

Other Integrins in Inherited Platelet Disorders

Integrin $\alpha_2\beta_1$ is an Mg^{2+}-dependent collagen receptor on many cells, including platelets.[43] In platelets, collagen not only serves as an adhesive substrate but also functions as an agonist for platelet aggregation. Two patients with histories of bleeding have been reported whose platelets failed to respond normally to collagen and lacked $\alpha_2\beta_1$, thus suggesting that binding of collagen to $\alpha_2\beta_1$ is a necessary component for collagen-induced signaling.[44] In addition, a recent report described several families with autosomal dominant thrombocytopenia and mild platelet dysfunction associated with mutations in the α_2 subunit.[45]

There is substantial variability in the density of $\alpha_2\beta_1$ on the surface of platelets from different individuals.[46] These differences in $\alpha_2\beta_1$ expression are associated with the inheritance of three different α_2 alleles. The higher the receptor density, the greater the attachment of platelets to type I collagen.[47] Some, but not all epidemiologic surveys suggest that increased $\alpha_2\beta_1$ density is a risk factor for cardiovascular disease in younger individuals.[48,49] An increased prevalence of the allele with lower $\alpha_2\beta_1$ density has been reported in patients with type 1 von Willebrand's disease (VWD), which suggests that this allele may contribute to bleeding symptoms in these patients.[50]

Bernard-Soulier Syndrome: Defective Glycoprotein Ib/IX Complex

BSS was first described in 1948 in a 5-month-old infant with a prolonged bleeding time, giant platelets on blood smear, and a sibling who had died of hemorrhage.[51] Over the following years, additional patients with the combination of mucocutaneous bleeding; enlarged platelets; normal platelet aggregation with ADP, collagen, and epinephrine with a delayed response to thrombin; and absent platelet aggregation with human VWF and ristocetin or with bovine VWF alone were described as having BSS, now the second most recognized inherited platelet disorder.

Biology of the Glycoprotein Ib/IX Complex

Adhesion through the GPIb/IX complex involves binding of VWF to the subendothelium. Platelet membranes contain two binding sites for VWF (see Table 29-1). One of these sites requires previous platelet activation and is located on the platelet membrane $\alpha_{IIb}\beta_3$ complex. The second binding site involves the GPIb/IX complex, and it is this membrane complex that is crucial for initial attachment and proper adhesion to the extracellular matrix of a damaged vessel wall. It should be pointed out

FIGURE 29-3. Structure of the glycoprotein Ib/IX (GPIb/IX) receptor. Each receptor consists of two GPIbα chains, each disulfide linked to a GPIbβ chain. There are two GPIX chains and one GPV chain in each complex as well. The leucine-rich repeats on all the chains are indicated, as are the sites for binding of von Willebrand factor (VWF) and thrombin. Known intracellular interactions or modification sites are also indicated. SS, cysteine disulfide bond.
that the GPIb/IX complex may also bind to other ligands, including P-selectin,[52] thrombospondin-1,[53] high-molecular-weight kininogen, and Mac-1.[54] Furthermore, GPIb/IX also binds thrombin, and its role in the activation of platelets by thrombin is discussed later.

The GPIb/IX complex is the second most abundant receptor on the platelet membrane surface, with approximately 25,000 copies per platelet.[55] This complex actually consists of four different proteins (Fig. 29-3), all of which have one or more leucine-rich repeats composed of a 24–amino acid motif with seven conserved leucine residues. Other proteins have been described with this leucine-rich repeat, and these regions mediate ligand binding.[56]

GPIbα is the largest subunit (135 kd, 610 amino acids, chromosome 17p12) and has seven leucine repeats.[57] It is susceptible to cleavage by trypsin or calpain, which gives rise to a heavily glycosylated 135-kd fragment known as "glycocalicin."[58] In addition to containing the binding site for VWF, the glycocalicin portion of GPIbα also binds thrombin.[59] In vivo, plasma VWF does not bind to the GPIb complex,[60] but under shear stress conditions, VWF simultaneously binds to collagen and the GPIb/IX complex.[60] In clinical assays, the antibiotic ristocetin or the venom-derived protein botrocetin are used to mimic this effect by inducing conformational changes in VWF that promote binding to GPIb/IX in stirred platelet-rich plasma.[61]

GPIbα is disulfide-bonded to GPIbβ (25 kd, 181 amino acids, chromosome 22q11.2)[57] through a single cysteine residue located in each subunit near the transmembrane domains of GPIbα and GPIbβ (see Fig. 29-3). This peptide has only one leucine repeat. The cytoplasmic tail of GPIbβ contains a filamin binding site that links the receptor complex to F-actin below the membrane[62] and a binding site for 14-3-3ζ.[63] The disulfide-bound GPIbα-β is noncovalently associated with platelet GPIX and GPV.[64] GPIX is the smallest member of the GPIb complex (22 kd, 160 amino acids, chromosome 3q29), with only one leucine repeat.[65] GPV (82 kd, 344 amino acids, chromosome 3q21) is a transmembrane protein with 15 leucine repeats.[66] This protein is a proteolytic substrate for thrombin and releases a 69-kd soluble fragment.[67] GPV is present in only a single copy per complex, whereas there are two copies of the other three subunits in a single receptor (see Fig. 29-3). Furthermore, cleavage of the GPV extracellular domain by thrombin bound to GPIbα activates platelets.[68] Consistent with this observation, the GPV-knockout mouse has a mild prothrombotic state.[69]

Binding of activated VWF to the GPIb/IX complex activates platelets through activation of phospholipase C (PLC) and mobilization of protein kinase C, which together with increases in $[Ca^{2+}]_i$, promotes platelet secretion and potentiates platelet aggregation.[70] The GPIb-IX complex also appears to activate the cell by binding to the cytoskeleton protein 14-3-3ζ[63] and by interacting with the FcγRIIA receptor on platelets, where it activates an intracellular tyrosine–based activation motif (ITAM) receptor[71] (see Fig. 29-3).

Clinical Features

The bleeding manifestations of patients with BSS are similar to those of other patients with severe platelet dysfunction and center on mucocutaneous bleeding with purpura, epistaxis, gastrointestinal hemorrhage, and menorrhagia.[72] Alloantibodies to components of the GPIb/IX complex can develop after platelet transfusions with resulting platelet refractoriness.[72] Care of bleeding in these patients is similar to that of patients with GT discussed earlier, including the use of DDAVP.[73] Studies evaluating DDAVP have demonstrated improved bleed-

ing times, although the improvement did not correlate with the ability of DDAVP to increase the level of circulating VWF. Activated factor VIIa has also been reported to be useful in patients with BSS,[74] but we believe that this factor is best used as a supplement to platelet infusions.

Classification and Laboratory Diagnosis

BSS patients have a variable degree of thrombocytopenia. Most patients are thrombocytopenic to some degree, but some patients may have platelet counts as low as 20,000/μL.[72] The platelets have a mean diameter ranging from 3 to 20 times normal (Figs. 29-4B and 29-5A).[75] Other cell types appear normal. In general, the circulating total platelet mass in people is more precisely conserved than the platelet count is,[76] and part of the decrease in platelet count in BSS may well reflect this compensa-

tory mechanism. Megakaryocytes in this disorder appear normal in size and appearance by light microscopy. However, on electron microscopy, a striking feature in these cells is the variable and intermittent nature of the demarcation system, which is often vacuolar.[77] Absence of GPIbα results in an abnormal demarcation membrane in a mouse model of BSS, whereas restoration of the protein returns the electron microscopic structure of the megakaryocyte to normal.[78] Studies have shown that GPIb/IX contributes to platelet formation in that this complex lines up with the cytoskeleton during thrombopoiesis[79] and plays a role in cell cycle regulation.[80]

Bleeding times and Platelet Functional Analyzer 100 (PFA-100) measurements[81] are prolonged in these patients, but the distinctive abnormality of BSS platelets is the failure of agglutination in the presence of ristocetin, an abnormality that cannot be corrected by the addition
FIGURE 29-4. Light microscopy. **A,** Normal peripheral smear showing typical-size platelets (original magnification ×100). **B,** Peripheral smear of a patient with Bernard-Soulier syndrome showing a decreased number of enlarged platelets (original magnification ×100). **C,** Dysmorphic megakaryocyte (Meg) with the nuclei pushed to the side in a patient with a *GATA1* mutation (original magnification ×50). **D,** Bone marrow in a patient with Chédiak-Higashi syndrome showing inclusion bodies in a myelocyte (M), neutrophil (N), and lymphocyte (L) (original magnification ×100). *(Courtesy of Marybeth Helfrich, The Children's Hospital of Philadelphia.)*
FIGURE 29-5. Electron microscopy. **A,** Platelet in a patient with Bernard-Soulier syndrome that is as large as a lymphocyte (L). Otherwise, platelet morphology is normal (original magnification ×18,000). **B,** Platelets in patients with Wiskott-Aldridge syndrome are half to two thirds the normal size but otherwise normal in appearance (original magnification ×38,500). **C,** Platelets in patients with Fechtner's syndrome are enlarged and the canalicular system is exuberant, but otherwise the platelets look normal (original magnification ×13,000). **D,** Platelets in patients with gray platelet syndrome vary in granule content. Most of the platelets seen have an absence of alpha granules, whereas others (such as the large platelet here) may have identifiable granules (original magnification ×16,500). **E,** Neutrophil in a patient with May-Hegglin anomaly showing an inclusion body (I) below the nucleus (N) forming longitudinally oriented filaments (original magnification ×14,000). **F,** Megakaryocyte from a patient with a *GATA1* mutation showing the nucleus (N) pushed to the side by exuberant endoplasmic reticulum (ER), which fills most of the cytoplasm (original magnification ×38,000). *(All electron micrographs courtesy of Dr. James White, University of Minnesota.)*

of normal plasma.[82] Aggregation by other agonists such as ADP, collagen, and epinephrine is normal, although the response to low-dose thrombin may be delayed.[82] Flow cytometric analysis of platelet glycoproteins may also aid in the diagnosis.[83]

Molecular Abnormalities

More than 30 molecular defects in BSS have been defined.[84] These disorders can be classified by whether any complex reaches the platelet membrane and by the specific subunit affected. The first described mutation was a chain termination mutation within GPIbα that results in a protein lacking a portion of the extracellular domain and the entire transmembrane and cytoplasmic domains.[85]

Mutations in the GPIbα chain are most common in patients with BSS[86]; however, mutations in GPIbβ and GPIX have also been described in patients with similar clinical phenotypes.[87,88] Most of the mutations described are missense or nonsense mutations. Deletions are uncommon but do occur, as in one patient who had partial deletion of the GPIbβ gene on chromosome 22q11.2 in association with velocardiofacial syndrome.[89] Compound heterozygotes have also been described.[90] The disease is most commonly autosomal recessive, but autosomal dominant mutations have likewise been reported.[91]

Platelet-Type (Pseudo-) von Willebrand Disease

Platelet-type VWD is an autosomal dominant bleeding disorder often associated with a prolonged bleeding time, mild thrombocytopenia, and decreased circulating levels of high-molecular-weight VWF multimers.[90,91] Patients with this disorder have a mild to moderate bleeding diathesis. Platelet-type VWD is very similar to type 2B VWD (see Chapter 30) in that both are characterized by platelet agglutination in the presence of low concentrations of ristocetin and by decreased circulating levels of high-molecular-weight VWF. Binding of VWF to circulating platelets results in the reduced levels of VWF seen in these patients, as well as some degree of platelet activation, mild thrombocytopenia, and an increased risk of clotting.

Unlike type 2B VWD, where mutations in VWF result in increased affinity for normal platelet GPIb/IX complex, pseudo-VWD is caused by an alteration in the platelet GPIb/IX complex that leads to increased affinity for normal VWF multimers. Platelet-type VWD can be distinguished from type 2B VWD by the addition of normal VWF to patient platelet-rich plasma, which results in spontaneous aggregation of pseudo-VWD platelets but not type 2B VWD platelets.[90,92] It is important to distinguish patients with platelet-type VWD from other VWD patients because care of patients with VWD often involves infusion of cryoprecipitate or DDAVP. This therapy can worsen the thrombocytopenia in patients with platelet-type VWD.[92] A patient with mild thrombocytopenia and a prolonged bleeding time should be evaluated for this disorder as described earlier.

The molecular basis of platelet-type VWD has been defined in several patients.[92,93] Mutations, such as Gly-233Val and Met239Val, occur in the region of GPIbα that has been previously shown to be important in VWF binding. It has been hypothesized that these mutations alter GPIbα such that it maintains an adhesive conformation much as wild-type GPIb/IX receptor becomes activated on exposure to components of the extracellular matrix at sites of vascular injury and flow.

Other Inherited Defects of Platelet Receptors

G Protein–Coupled Receptors

Many agonists that activate platelets, such as thrombin, ADP, and thromboxane A_2 (TxA_2), activate cells through a GPCR (see Table 29-1). These seven-transmembrane receptors are linked to a heterotriplex of intracellular guanosine diphosphate (GDP)/guanosine triphosphate (GTP)-binding proteins, $G\alpha,\beta,\gamma$. The strongest platelet agonist is thrombin. As mentioned previously, one receptor for thrombin is the GPIb/IX complex. However, thrombin appears to have its greatest effect on human platelets through two GPCRs, protease-activated receptor 1 (PAR-1) and PAR-4, with PAR-1 being the major human receptor.[94] Thrombin binds to PAR-1, releases an N-terminal peptide, and leaves a new N-terminal. An oligopeptide of this N-terminal sequence, SFLLRN, can mimic the effects of thrombin and activate platelets. Surprisingly, no patients with defects in PAR-1 have been described. In mice, PAR-1 is not important for platelet biology, although its absence does have in vitro consequence because it is expressed on other tissues.[95] Instead, on murine platelets PAR-3 and PAR-4 are biologically relevant.[96]

ADP is stored in platelet dense granules and released upon platelet activation. When added to platelets in vitro, ADP causes TxA_2 formation, protein phosphorylation, an increase in cytosolic Ca^{2+}, shape change, aggregation, and secretion. ADP also inhibits the formation of cyclic adenosine monophosphate (cAMP). Several patients with bleeding defects have been described whose platelets showed greatly diminished responsiveness to ADP and reduced numbers of binding sites for ADP analogues,[97,98] a phenotype not dissimilar from that produced by ADP antagonists such as ticlopidine or clopidogrel. ADP receptors on human platelets include P2Y1, P2Y12, and P2X1.[99-101] P2Y1 is a GPCR that activates PLC. P2Y12 inhibits cAMP formation by adenyl cyclase. P2X1 is a ligand-gated nonspecific cation channel that may contribute to the influx of extracellular Ca^{2+} that occurs in response to ADP. Mutations in each of these receptors

have been reported in patients and have resulted in mild to moderate bleeding symptoms.[97]

In several respects, epinephrine is unique among human platelet agonists in that it causes aggregation and secretion, but not the cytoskeletal reorganization that underlies shape change. Activation of PLC by epinephrine appears to be dependent on TxA_2 formation and can be suppressed with aspirin.[102] Aspirin also blocks second-wave, or secretion-dependent, platelet aggregation in response to epinephrine. This gives rise to a characteristic aggregometer tracing in which epinephrine-induced primary aggregation is followed by disaggregation of the platelet clumps. Platelet responses to epinephrine are mediated by α_2-adrenergic receptors.[103] There are reports of families in which a mild bleeding disorder was associated with impaired epinephrine-induced aggregation and reduced numbers of α_2-adrenergic receptors.[104] However, platelets from up to 10% of apparently normal people may fail to aggregate when challenged with epinephrine, and the clinical significance of this finding is unclear.

TxA_2 is produced from arachidonate in platelets by the aspirin-sensitive cyclooxygenase pathway. When the stable thromboxane analogue U46619 is added to platelets in vitro, the platelets undergo shape change, aggregation, secretion, phosphoinositide hydrolysis, protein phosphorylation, and an increase in $[Ca^{2+}]_i$. Similar responses are seen when platelets are incubated with exogenous arachidonate.[105] Platelets express TP, a GPCR for TxA_2.[106] Platelets also contain a receptor for prostacyclin (PGI_2), an endothelial cell prostaglandin that is a potent platelet inhibitor. Binding of PGI_2 to this receptor stimulates adenylate cyclase activity and inhibits platelet function.[107] A few patients have been described who have a mild bleeding disorder caused by congenital absence of the TxA_2 receptor. Two Japanese patients have had their mutations defined and were found to have an R60L substitution in the first cytoplasmic loop of TxA_2.[108] In addition, three patients have been described who have normal TxA_2 binding but absent platelet aggregation in the presence of this agonist, thus suggesting uncoupling between the receptor and downstream signaling events.[109] There are as yet no known clinical disorders ascribed to the PGI_2 receptor, but deletion of the gene in mice increases their risk for thrombosis after arterial injury.[110]

Immunoglobulin Superfamily Receptors

GPVI, a 62-kd protein encoded by a gene on human chromosome 19q13.4,[111] is a member of the immunoglobulin superfamily of receptors. It is the platelet signaling receptor for collagen, and patients with a mild bleeding disorder have been described whose platelets could not be activated by fibrillar collagen types I and III and lacked GPVI despite having normal levels of the other platelet collagen receptor $\alpha_2\beta_1$.[112] Unlike $\alpha_2\beta_1$, GPVI's interaction with collagen initiates the intracellular signaling that results in platelet activation. GPVI exists on the platelet surface complexed with the FcR γ chain,[113] and

signaling seems to occur via phosphorylation of PLCγ2 and Syk through the FcR γ chain.[114,115] Fab antibodies derived from GPVI-deficient individuals who had received platelet transfusions recognize GPVI and are capable of blocking activation of platelets by collagen, thereby resulting in thrombocytopenia and internalization of surface GPVI.[116] Convulxin, a snake venom protein isolated from a South American rattlesnake, is also a potent activator of platelets that is capable of desensitizing platelets to collagen and has been demonstrated to bind specifically to GPVI.[117]

GPVI seems to be the major collagen receptor on platelets,[118] although a few patients[119,120] have been described who lack GPVI and show a mild bleeding tendency. These patients have some residual platelet aggregation to collagen, which is likely to be through the $\alpha_2\beta_1$ receptor.[121] In addition, autoantibodies to GPVI have been described in patients with immune thrombocytopenic purpura[116,122] and systemic lupus erythematosus.[123] These patients lack surface GPVI on their platelets and show a mild bleeding diathesis with abnormal platelet aggregation to collagen. Interestingly, several genetic polymorphisms affecting GPVI surface expression have been described and suggested to be a risk factor for myocardial infarction. Platelets with less GPVI showed less vigorous aggregation in vitro, although further study is ongoing on the true relevance of these findings.[124,125]

Scott's Syndrome

The platelet surface also functions as one of the principal sites for plasma coagulation reactions by providing a surface on which coagulation factor complexes assemble and accelerate these important reactions several thousand-fold. This property of activated platelets has been termed platelet factor 3 activity. In a resting platelet, there is little anionic phospholipid on the platelet's surface. Activation by agonists such as thrombin or collagen is thought to reorient membrane phospholipids and bring anionic phospholipids, chiefly phosphatidylserine, to the outer leaflet. Activation also induces membrane vesiculation and the production of platelet microparticles with procoagulant activity.[126]

Deficiency in platelet coagulant activity is a rare clinical event that has been termed Scott's syndrome, named after the propositus of a well-studied family.[126,127] The patient had prolonged bleeding after dental extractions, bleeding after surgical procedures, and a spontaneous retroperitoneal hematoma.[127] The patient secreted a normal quantity of factor V, a platelet alpha granule constituent, but had only 25% of the normal number of binding sites for factor Xa on activated platelets.[128] When her platelets were challenged with such agonists as thrombin and collagen, aggregation and secretion were normal, but fewer anionic phospholipid-binding sites were translocated to the platelet surface.[129] In addition, the formation of microparticles is defective in patients with Scott's syndrome.[126] Standard screening tests for plasma coagulation, such as the prothrombin time and partial throm-

boplastin time, which use artificial lipid micelles, are normal. A patient has been described who had aberrant expression of the adenosine triphosphate (ATP)-binding cassette transporter AI (ABCA1), which is important in translocation of phosphatidylserine.[130] This patient had a single–base pair substitution in exon 42 that was predicted to substitute R1925 with glutamine. The diagnostic abnormality is a shortened serum prothrombin time as a result of reduced consumption of prothrombin. Additionally, these patients have a prolonged dilute Russell viper venom time that corrects when the patient's plasma is added to normal platelets, but not when normal plasma is added to the patient's blood.[131] This is due to the inability to generate normal platelet procoagulant activity. Patients can be readily treated with platelet transfusions, which improves hemostasis and reduces postoperative blood loss.

Platelet Storage Granule Defects

Human platelets contain several types of intracellular granules that can be distinguished by electron microscopy, including dense granules, alpha granules, and lysosomes.[132] Dense granules are the most rapidly secreted granules after platelet activation and contain ADP, ATP, serotonin, and calcium.[133] Two thirds of platelet adenine nucleotides are stored in these granules, with an ADP/ATP ratio of 3:2, as opposed to 1:8 in the cytoplasm.[132] Platelet alpha granules contribute many of the proteins involved in the formation of a platelet plug. After platelet activation, the alpha granules centralize in the platelet and release their contents via membrane fusion with the open canalicular system.[134] Interestingly, not all proteins present in alpha granules have the same origin. Some, such as VWF, thrombospondin, and platelet factor 4 (PF4), are synthesized in and packaged by megakaryocytes,[135] whereas others, such as albumin, IgG, and fibrinogen, are endocytosed from plasma.[136]

Dense Granule Defects

Patients with defects in platelet dense granules have a form of storage pool deficiency (δ-SPD).[132,137] Patients with δ-SPD exhibit a mild to moderate bleeding diathesis, as well as abnormalities in platelet aggregation. The second wave of aggregation is absent in response to ADP and epinephrine and virtually absent in response to collagen. Bleeding times in these patients are often prolonged. In 1969 it was shown that these patients have a deficiency in total platelet ADP,[138] and this deficit was subsequently localized to the ADP pool of the dense granule.[139] The abnormalities in the ultrastructure of the dense granules are heterogeneous,[140] but most patients show a characteristic lack of dense granules by electron microscopy[141] (see Fig. 29-5).

Some individuals have other associated defects. The two most common SPDs are Hermansky-Pudlak syndrome (HPS)[142] and Chédiak-Higashi syndrome (CHS).[143,144] HPS is characterized by tyrosinase-positive, severe oculocutaneous albinism in association with photophobia, rotatory nystagmus, loss of visual acuity, excessive accumulation of ceroid-like material in reticuloendothelial cells, and a mild to moderate hemorrhagic diathesis. This disease is inherited as an autosomal recessive disorder, and although it occurs in many populations, it is seen with high frequency in people from the northwest part of Puerto Rico.[145,146] Patients exhibit bruising and epistaxis in early childhood. Fatal bleeding is rare, but a significant proportion of patients will have received packed red cell or platelet transfusions in their lifetime.[142,147] The major cause of death is progressive pulmonary fibrosis, which generally begins in their late twenties or early thirties,[142,148] perhaps secondary to higher plasma serotonin levels because of failure to package the serotonin into dense granules.[149] This disease is also associated with a 15% incidence of granulomatous colitis.[147] One of the genes involved is located at chromosome 10q23.1-23.3[150] and encodes a 700–amino acid protein termed HPS-1 that has one transmembrane domain but little homology with other known proteins, although the transcript appears to be present in multiple tissues. The northwest Puerto Rican mutation is a 16–base pair insert at codon Pro496 that results in a frameshift, and patients from northwest Puerto Rico with HPS are homozygous for the same mutation, thus suggesting a founder effect.[151] About a quarter of patients from other parts of Puerto Rico have other mutations in HPS-1.[152] Additionally, cases of HPS have been described throughout the world, and only 25% to 40% of these patients have disease caused by a mutation in a gene known to be associated with HPS. Mutations in other genes that have been described to cause HPS include changes in ADTB3A (HPS-2), which is important in vesicle formation from existing membrane.[153] To date, mutations in eight different genes (termed HPS-1 to HPS-8) have been described in patients with phenotypic HPS. Some genotype/phenotype associations have also been documented. For example, pulmonary fibrosis develops in patients with mutations in HPS-1 and HPS-4, whereas this life-threatening complication does not develop in patients with HPS-3, HSP-5, and HSP-6 mutations. In addition, patients with HPS-2 mutations also have associated neutropenia and a predilection for infections, particularly in childhood.[154]

CHS is a rare autosomal disorder that has been described in approximately 200 affected individuals.[142] It is characterized by immune dysfunction, platelet storage pool defects, and partial albinism. Patients often have a white forelock or ashen hair secondary to abnormally large melanosomes.[137,142] Hematologic manifestations of this disease are characterized by the presence of large intracytoplasmic granules in leukocytes, lymphocytes, monocytes, and platelets (see Fig. 29-4D), with a concurrent defect in mobilization of the marrow leukocyte pool,[155] defective chemotaxis,[156] and decreased bactericidal activity.[157] Many other tissues also contain abnormal granules.[158,159] CHS patients often die in the first 2 decades

of life of either overwhelming infections or an unusual lymphoproliferative disorder called the "accelerated phase," which involves fever, anemia, neutropenia, and occasionally, thrombocytopenia, hepatosplenomegaly, lymphadenopathy, and jaundice.[160] These patients are particularly susceptible to Epstein-Barr virus infections.[155] The gene involved in CHS is located on chromosome 1q42.1-42.2 and encodes a 3801–amino acid protein called LYST (lysosomal trafficking regulator).[160] This complex protein has several repeated series of hydrophobic helices interspersed with hydrophobic membrane association domains. The helical regions resemble the previously defined HEAT and ARM elements involved in vesicular transportation[161] and membrane associations,[160] respectively. Mutations have been defined in an increasing number of affected patients and involve truncated products,[162,163] although there is no correlation between residual protein length and clinical phenotype.[142]

Diagnosis of dense granule defects is difficult because it requires expertise in proper preparation of specimens for electron microscopy, as well as competence in interpretation of the findings. It is also complicated by the fact that a small percentage of these rare patients may have a prolonged bleeding time but normal platelet aggregation studies.[164] Recent studies have begun to use flow cytometry on quinacrine-loaded platelets to aid in the diagnosis because quinacrine is selectively taken up by dense granules.[165]

Alpha Granule Defects

Patients with alpha granule deficiencies have a bleeding phenotype similar to that of patients with dense granule deficiencies, with mild to moderate bleeding, mild thrombocytopenia, and a prolonged bleeding time. Because of the initial light microscopic observation of gray platelets in the peripheral blood smear of these patients after Romanovsky stain, this disorder was termed gray platelet syndrome.[166] On electron microscopy, these platelets are most notable for the absence or marked reduction of alpha granules (see Fig. 29-5D).[167] These platelets are also deficient in alpha granule–specific proteins such as PF4, VWF, factor V, and fibronectin.[168] Gray platelet aggregation to various agonists, especially thrombin, is impaired.[169] These platelets have a delayed and blunted Ca^{2+} mobilization response.[170] The vacuolar structures seen in gray platelets appear to be aborted alpha granules that contain both P-selection and $\alpha_{IIb}\beta_3$ in their membranes.[170] They also contain a significant amount of proteins, including immunoglobulin and albumin,[171] that are normally endocytosed into alpha granules. Endogenously synthesized alpha granule–specific proteins such as PF4 leak out.[172] This latter phenomenon may contribute to the observed myelofibrosis and pulmonary fibrosis associated with this disease.[172]

Other Granular Defects

A small number of patients have been described with a combined alpha/dense granule deficiency.[173] The dense granule deficiency was often much more severe than the alpha granule deficiency. These patients also have mild to moderate bleeding histories, and laboratory results are similar to those of dense granule–deficient patients, with a decreased platelet ADP/ATP ratio in the cells and low levels of serotonin. In one patient with a severe deficiency in both alpha and dense granules, there was a deficiency in total platelet P-selectin,[174] thus suggesting that unlike the gray platelet syndrome, in which there may be an alpha granule–targeting defect, platelet granule formation itself may be defective in this disorder.

Quebec platelet syndrome is a rare disorder that results from the degradation of alpha granule contents within the platelet because of expression of ectopic urokinase-type plasminogen activator in developing megakaryocytes.[175,176] This disorder, inherited in an autosomal dominant pattern within two large kindreds in Quebec,[175,177] was previously known as factor V Quebec because the initial observations in these patients revealed a relative intraplatelet deficiency of factor V.[177] These patients manifest moderate to severe *delayed* bleeding after surgery or trauma.[178] Bleeding can be controlled by antifibrinolytic therapy with tranexamic acid, but platelet transfusions are generally ineffective.[175,177] The molecular abnormality responsible for this disorder has not yet been defined.

Defects in Signal Transduction

With multiple overlapping pathways of platelet activation, it has been difficult to define specific defects in patients with inherited disorders of platelet signal transduction. Nonetheless, a small number of patients have been described with phenotypes and abnormal platelet aggregation patterns consistent with such a diagnosis.[179] One such group of patients lack the ability to liberate arachidonic acid.[180] This may be due to deficiency of phospholipase A_2.[181] Another patient appears to have difficulty with tyrosine phosphorylation through the ADP receptor system.[182]

Other patients have diminished cyclooxygenase enzyme activity that mimics an aspirin-like defect.[183,184] These patients have abnormal platelet aggregation in response to ADP, epinephrine, collagen, and arachidonic acid while responding normally to prostaglandin G_2, consistent with a defect in cyclooxygenase-1 and subsequent TxA_2 synthesis. Most patients with this disorder have normal antigen levels of a functionally abnormal prostaglandin synthetase.[185] Other patients have been described who have decreased protein expression.[186] Additionally, patients have been reported who appear to lack the thromboxane synthetase that converts prostaglandin H_2 to TxA_2.[187,188] Over the past few years, other models of platelet dysfunction secondary to a signaling defect have been recognized, including the Wiskott-Aldrich syndrome (WAS), which is described later under disorders of platelet size and numbers. For all these signaling disorders,

platelet transfusions are effective in the management of bleeding.

QUANTITATIVE DISORDERS

General Comments

Megakaryocytes are large, polyploid, terminally differentiated hematopoietic cells that release platelets into the bloodstream.[189] These cells arise from self-regenerating pluripotent stem cells that also give rise to all other hematopoietic lineages. Megakaryocyte lineage commitment involves a number of precursor stages, including CFU-GEMM (colony-forming unit–granulocyte, erythrocyte, monocyte, megakaryocyte), which in culture results in a mix of granulocytes, erythrocytes, monocytes, and megakaryocytes; CFU-EMM, which gives rise to mixed colonies of erythrocytes, monocytes, and megakaryocytes; BFU-Meg (burst-forming unit–megakaryocyte), which gives rise to a burst of 10 to 20 megakaryocytes; and CFU-Meg, which gives rise to a smaller megakaryocyte colony.[190]

Various growth factors regulate megakaryocyte differentiation at different points of their development. Certain cytokines stimulate proliferation of megakaryocytic progenitors, such as interleukin-3 (IL-3), IL-6, IL-11, IL-12, granulocyte-macrophage colony-stimulating factor (GM-CSF), and erythropoietin (EPO)[191,192]; however, all the aforementioned growth factors and cytokines have very broad effects on all hematopoietic cell lines. The discovery and cloning of thrombopoietin (TPO), the ligand for the myeloproliferative ligand receptor (Mpl), opened a new perspective in megakaryocyte differentiation study. TPO was found to be a specific factor controlling megakaryocytic cell proliferation and maturation and platelet reactivity.[193,194] This 353–amino acid protein is homologous at its N-terminal with EPO. Either the full-length protein, a truncated N-terminal TPO, or even mimetic peptides can dimerize Mpl and stimulate megakaryocytopoiesis.[195] On immature progenitor cells, activation of Mpl stimulates proliferation, much like IL-11 or c-kit ligand. On megakaryocyte precursors and megakaryocytes it leads to increased megakaryocyte differentiation and platelet formation. Targeted disruption in murine models of either the Mpl or TPO genes results in a decrease in platelet count to approximately 20% of normal with normal-appearing megakaryocytes.[196-198] Thus, this cytokine pathway appears to be permissive for megakaryocytopoiesis but is not absolutely required for this differentiation process.

The end product of differentiation is the megakaryoblast, a small lymphocyte-like cell that undergoes the process of nuclear endoduplication, cytoplasmic enlargement, and differentiation to form the mature megakaryocyte with a cell volume of approximately 10^4 to 10^5 μm^3. Each of these huge cells eventually results in the formation of approximately 10^3 to 10^4 platelets. The finding of naked megakaryocyte nuclei in marrow[199] and the presence of proplatelets in central venous blood[200] support the hypothesis that platelets are formed in bone marrow. It is also possible that platelets are, in part, released from megakaryocytes that have migrated to the pulmonary bed.[201,202] Studies have demonstrated that there are more circulating megakaryocytes in the pulmonary artery than in the pulmonary venous system and that the opposite is true for platelet numbers.[203]

The process by which platelets actually derive from megakaryocytes is beginning to be understood, but it does not appear to involve the extensive membrane system termed the "demarcation membrane system" (DMS) that may represent inverted membranes. Rather, extensive pseudopods form and re-form in a dynamic process that eventually leads to a beaded appearance that fragments to form particles with the size and ultrastructural appearance of platelets.[204] This process can be inhibited by agents that disrupt microtubules[205] and promoted by actin filament–depolymerizing agents,[205,206] thus suggesting involvement of the cytoskeleton in this process. Targeted disruption of the murine hematopoietic transcription factor NF-E2 results in severe thrombocytopenia and very large, bizarre megakaryocytes.[207] Loss of NF-E2 expression results in altered expression of multiple proteins, including the cytoskeletal protein β-tubulin.[208]

The normal range of platelet counts is 150 to 400 × 10^3/μL. Even more constant than the circulating platelet count is the circulating thrombocrit, which is the platelet count multiplied by the mean platelet volume, so there is an inverse relationship between platelet count and platelet size.[76] Regulation of megakaryocytopoiesis by TPO is in large part regulated by the platelet mass. TPO produced by the liver is secreted at a relatively constant level.[209] As platelet mass rises, the amount of bound TPO increases and less is available for stimulation of marrow megakaryocytes. The inverse situation would also be true: as platelet mass falls, there is more free TPO to stimulate marrow megakaryocyte development.

The molecular basis for the regulated expression of genes during megakaryocytopoiesis is only beginning to be understood. This understanding has grown with the development of targeted disruption of hematopoietic genes in mice, which has demonstrated the importance of the transcription factors GATA-1, NF-E2, and FOG-1 in megakaryocyte development.[208,210,211] Both GATA-1 knockdown and NF-E2 knockout result in viable mice with large and dysmorphic megakaryocytes and very low platelet counts.[212,213]

Disordered Platelet Production

Disorders involving platelet production include congenital amegakaryocytic thrombocytopenia (CAMT), characterized by a complete absence of megakaryocytes; thrombocytopenia with absent radii (TAR), in which there is a decrease in megakaryocytes in infancy; amega-

karyocytic thrombocytopenia with radioulnar synostosis (ATRUS), characterized by skeletal anomalies and thrombocytopenia that improves with time; and disorders of hematopoietic transcription factors, often associated with an excess of dysmorphic megakaryocytes.

Thrombopoietin-Mpl Axis

CAMT is a rare disorder associated with very low platelet counts, absence of megakaryocytes in bone marrow, and risk for the development of aplastic anemia. These children have no skeletal abnormalities, and the platelet count does not improve with age and often necessitates bone marrow transplantation because of the severe bleeding.[214] CAMT results from mutations in the Mpl gene.[215] These patients demonstrate the importance of TPO in normal hematopoiesis in that patients who survive long enough exhibit pancytopenia during the first or second decade of life.[216] In addition, no TPO mutations have been found in this disorder or in other disorders associated with thrombocytopenia, including TAR (see later).

In contrast, excessively high platelet counts ($>600 \times 10^3/\mu L$) are seen in essential thrombocythemia, an acquired myelodysplastic disorder seen primarily in adults that in approximately 20% of cases is associated with a JAK2 V617F mutation.[217] A rare congenital form of familial thrombocytosis occurs in children that can be associated with enhancing mutations in the TPO promoter[218] or activating mutations in Mpl.[219] Unlike the adult form, myelodysplastic conversion is rare,[220] so it is unclear whether therapeutic intervention (suppression of the platelet count with hydroxyurea or anagrelide[221]) is necessary, although antithrombotic strategies are often still used in the management of these children.

Thrombocytopenia and Skeletal Abnormalities

TAR is one of the more common inherited disorder of platelet number and was first described in 1951.[222] This disorder involves hypomegakaryocytic thrombocytopenia and bilateral absence of the radii. Patients are born with platelet counts in the approximate $10^4/\mu L$ range, which improves slowly and reaches normal levels after the first year of life. During infancy, environmental stress, such as viral illness, can precipitate episodes of severe thrombocytopenia.[223] Several TAR patients have an associated storage pool defect and bleed out of proportion to their platelet count.[224] In addition, these patients have other hematologic changes, including leukemoid reactions to the approximate 30,000/μL range and anemia, partly as a result of blood loss.[223] In addition, 30% of patients have recurrent gastroenteritis and bleeding.[223] The major skeletal manifestation is complete absence of the radii, but with functional thumbs. Other orthopedic abnormalities are seen in about 50% of cases, and the more severe the upper limb deformity, the more likely the patient is to have a lower limb deformity. Approximately 30% of patients have cardiac anomalies, including the tetralogy of Fallot and atrial septal or neural defects.

The etiology of this disorder is unknown. Megakaryocytes are present in the bone marrow, although there may be some decrease in comparison to what one would see in thrombocytopenia secondary to increased peripheral destruction.[225] Serum levels of TPO in patients with TAR are elevated despite normal Mpl levels on hematopoietic cells.[226] Bone marrow cultures from these patients reveal reduced numbers of megakaryocytes,[227] and CFU-Meg do not grow in response to TPO.[228] Together, these findings suggest a disconnection between the TPO receptor and downstream signaling events. Certainly other disorders, such as Fanconi's anemia and Schwachman's syndrome, also have skeletal abnormalities and hematopoietic defects. Whether a common growth factor or shared environmental factors underlie these disorders is unknown.

ATRUS is an autosomal dominant disorder characterized by amegakaryocytic thrombocytopenia, skeletal anomalies (including radioulnar synostosis, hip dysplasia, and clinodactyly or syndactyly), and sensorineural hearing loss.[229] The thrombocytopenia in these patients occurs in the neonatal period and may be severe but will often resolve within the first few years of life.[230] Mutations of HOXA11 have been demonstrated as the molecular abnormality in most patients with ATRUS.[231] HOXA11 is a member of the homeobox group of regulatory proteins that play a role in hematopoietic proliferation and differentiation. Studies in animal models have shown the role of HOXA11 in forearm skeletal development. However, although bone marrow from HOXA11-overexpressing mice shows increased immature megakaryocyte colonies,[232] a clear role in megakaryocytopoiesis has not been defined.

Platelet Disorders Secondary to Transcription Factor Defects

X-linked anemia with severe thrombocytopenia secondary to defects in GATA-1 has been reported.[233,234] The first of these cases involved a site on GATA-1 in which GATA-1 binds to FOG, whereas the second case involved a mutation in one of the DNA-binding domains. The megakaryocytes in the marrow of these patients are similar to those described in GATA-1–knockdown mice[212] and were numerous and large with poorly organized granular content and nuclei pushed off to the side (see Figs. 29-4C and 29-5F).

Familial platelet deficiency/acute myelogenous leukemia (FPD/AML) is a dominantly inherited thrombocytopenia of approximately 100,000/μL that is often associated with a bleeding diathesis out of proportion to the decreased platelet count.[235,236] Platelet studies in some families show a classic and profound storage pool defect, but the precise defect can vary between families. There is about a 50% lifetime risk of AML developing in any affected family member, as well as an increased risk for other cancers. Recent studies have shown that in many of these extended families the defect resides in the *CBFA2* (AML-1) gene (chromosome 21q22.1-22.2).[237]

CBFA2 is a nuclear transcription factor often involved in translocations that results in AML or related cancers.[238] This gene is involved in early hematopoietic differentiation from endothelial cells and is also important for myeloid differentiation.[239] How CBFA2 haploinsufficiency results in a qualitative and quantitative platelet deficiency is not understood.

Thrombocytopenia Associated with Microthrombocytes or Macrothrombocytes

WAS patients have microthrombocytes and thrombocytopenia, but the phenotype involves multiple aspects of platelet and lymphocyte biology (Chapter 23). WAS was first recognized in two case reports as a sex-linked disorder with thrombocytopenia and eczema.[240,241] Platelets are small, usually half-normal volume, and the platelet mass is decreased.[242] There appears to be an associated platelet storage pool defect. The thrombocytopenia seen is severe and can be less than 10,000 platelets/μL. These patients also have a severe immune defect. Many die during the first decade of overwhelming infection or immune-based disorders such as immune thrombocytopenia or hemolytic anemia and from lymphoma-like illnesses during the second decade of life.[243] These patients have an impaired ability to form antibodies to carbohydrate antigens[244] and appear to have a defect in B and especially T lymphocytes.[245] Splenectomy, although it increases the risk for opportunistic infection, often alleviates the thrombocytopenia and bleeding diathesis in this disorder. Immune-related complications respond variably to steroids, intravenous immunoglobulin, vincristine, or plasmapheresis.[246] Bone marrow transplantation has been efficacious in treating this disorder.[247]

The gene involved in WAS (and X-linked thrombocytopenia) has been localized to the short arm of the X chromosome (Xp11.22), and the encoded protein WASP is 501 amino acids long, has no transmembrane domain, but has two highly charged C-terminal domains.[248] In addition, there is a potential nuclear localization signal. There is a pleckstrin homology domain and a cofilin domain by which WASP can depolymerize actin. WASP expression is limited to lymphocytes and platelets. WASP binds to a number of intracellular signaling proteins such as the Rho family member guanosine triphosphatase (GTPase) Cdc42.[249,250] Tyrosine phosphorylation signaling in the cell appears to cause WASP to become bound to cytoskeletal proteins such as PSTPIP (WIN)[251,252] and to be involved in megakaryocytopoiesis.[251,253]

Additional proof that WASP was involved in WAS came from the original description of the gene. One affected patient had a single base deletion, a second had a G→T transversion that led to an Arg86Leu substitution, and a third had a G→A transition of the same Arg leading to a His substitution.[248] Since then, the number of defined mutations has increased and their relationship to the genetic severity has been better defined.[254] Patients have been described with X-linked thrombocytopenia not associated with the severe immunologic defects of full-blown WAS.[254] In particular, patients have been described with isolated X-linked microthrombocytopenia, and these patients have missense mutations in the WASP gene, only some of which overlap with the mutations seen in WAS.[254] To complicate matters, the GATA-1 gene is closely linked to the WASP gene, and this may limit the usefulness of linkage studies for defining which of these two genes is affected in a patient with X-linked thrombocytopenia.[234]

There are also a number of inherited platelet disorders involving large platelets and thrombocytopenia. The most common of these is the autosomal dominant May-Hegglin anomaly (MHA), in which macrothrombocytes are associated with thrombocytopenia and normal coagulation studies.[255,256] In addition, leukocytes contain large spindle-shaped inclusions known as Döhle bodies[255] (see Fig. 29-5E). For a long time, MHA was known to overlap with Sebastian's syndrome, in which the inclusions were thought to be somewhat different in appearance[257]; with Epstein's syndrome associated with sensorineural deafness and nephritis[258]; and with Fechtner's syndrome (Fig. 29-5C) associated with sensorineural deafness, nephritis, and ocular abnormalities.[259] However, it is now clear that all are due to mutations in the cytoskeletal protein nonmuscle myosin heavy chain IIA (MYH9).[260] Another macrothrombocyte disorder, Montreal platelet syndrome (MPS), is characterized by macrothrombocytes, a prolonged bleeding time, and spontaneous aggregation of platelets at pH 7.4. The molecular basis of this abnormality is unknown, although there appears to be a defect in calpain metabolism in MPS.[261,262]

30 Hemophilia and von Willebrand Disease

Robert R. Montgomery, Joan Cox Gill, and Jorge Di Paola

The clinical and laboratory features of the three most common hereditary bleeding disorders—hemophilia A (factor VIII deficiency), hemophilia B (factor IX deficiency), and von Willebrand disease (VWD)—are discussed in this chapter. Hemophilia A and hemophilia B are both caused by a functional deficiency of a plasma protein inherited in an X-linked manner. Because these two proteins, factor VIII and factor IX, form the complex that subsequently activates factor X, the clinical features and many of the diagnostic considerations for hemophilia A and B are similar. Thus, these two types of hemophilia are discussed together, although the treatment of each is presented separately. Factor XI deficiency, sometimes referred to as hemophilia C, is discussed in Chapter 31 because its clinical manifestations are markedly different from those of hemophilia A and hemophilia B. The last part of this chapter is devoted to VWD, which is the most common, albeit usually less symptomatic bleeding disorder. Because von Willebrand factor (VWF) and factor VIII exist as a circulating noncovalent complex in plasma, historically they copurified during plasma fractionation. Thus, for many years, severe VWD and hemophilia A were treated with the same plasma-derived therapeutic products. As the therapeutic product to treat hemophilia A became more pure, factor VIII was subfractionated away from its carrier protein VWF, thereby making high-purity factor VIII products unsatisfactory for the treatment of VWD. The most commonly used products to treat hemophilia A contain recombinant factor VIII and do not contain VWF. To treat severe VWD, intermediate-purity plasma-derived concentrate containing both VWF and factor VIII or, in some regions of the world, purified plasma-derived VWF concentrates are available to treat deficiency of VWF when replacement therapy is indicated. In the not too distant future, recombinant VWF will probably be available, but its formulation, either with or without factor VIII, is not yet known.

HEMOPHILIA A AND HEMOPHILIA B

Hemophilia A and hemophilia B are the most common severe inherited bleeding disorders. Historically, hemophilia has been recognized as an entity since biblical times.[1] Use of the term *hemophilia* was ascribed to Schönlein in the 1820s.[2] Progressive insight into the pathophysiologic course of the disease has led to the development of powerful tools for diagnosis and agents for improved therapy, as well as the need to minimize the primary and secondary complications of the disease and its therapy.[3] The prolonged clotting time of hemophilic blood was first noted in 1893,[4] and the associated decrease in factor VIII levels in hemophilia A was initially identified in 1947.[5,6] In 1952, levels of factor IX were found to be decreased in *Christmas disease*, which was the early term used to denote hemophilia B.[7]

Early therapy for hemophilia was primarily supportive, but after the observation in the 1930s that adminis-

tration of plasma corrected the clotting time of hemophilic blood, treatment evolved to include transfusion with whole blood and plasma to achieve improved clotting function.[8,9] The modern era of treatment began in 1964 with the discovery of cryoprecipitate[9] and plasma fractions containing factor IX[10] and their use to treat bleeding episodes in hemophilia. More purified products were introduced in 1965 and were referred to as factor VIII concentrates (containing both factor VIII and VWF).[11,12] The next major improvements in replacement therapy were the result of attempts to limit transfusion-related viral infections during the 1980s, which included improved donor selection, heat treatment of the product, and further refined purification schemes.[13-15]

In 1985 the genes for both factor VIII and factor IX were cloned,[16-19] and in 1989, recombinant factor VIII was first used clinically.[20,21] In recent years, more highly purified factor IX and recombinant factor IX products have been developed. With the advent of recombinant products, patients with hemophilia could more readily and safely be treated with primary[22-26] and secondary prophylactic therapy.[27] Such vigorous treatment programs markedly reduce the likelihood of spontaneous bleeding episodes and the progression of hemophilic arthropathy. Although much attention today is focused on gene therapy as a potential, efficient means of preventing a bleeding episode without the need for regular prophylactic therapy, there have been no major successes. Thus, prophylaxis continues to be the preferred approach to patients with severe hemophilia.

Pathophysiology

The structure and function of factors VIII and IX in the coagulation pathway were outlined in Chapter 26. Both factors are crucial for normal thrombin generation. The classic representation of hemostasis shows factor VII together with tissue factor activating factor X; however, recent studies suggest that the primary physiologic pathway of activation of factor X by tissue factor and factor VII is through the activation of factor IX.[28,29] Activated factor IX complexes with factor VIIIa, calcium, and phosphatidylserine on physiologic membranes to generate factor Xa, which subsequently participates in formation of the prothrombinase complex. Thus, physiologically, the tissue factor pathway of factor X activation requires factor VIII and factor IX for normal thrombin generation, and the absence of either protein severely impairs the ability to generate thrombin and fibrin. This absence is not identified by use of the classic prothrombin time; the prothrombin time is normal in patients with hemophilia A or hemophilia B.

After injury, the initial hemostatic event is formation of a platelet plug, and the subsequent generation of fibrin is crucial to prevent continued oozing. Because of the primary clotting factor deficiency in either hemophilia A or hemophilia B, clot formation is delayed and is not robust. Thus, patients with hemophilia do not bleed more

rapidly; rather, there is delayed formation of an abnormal clot.[30] Thrombin is crucial for platelet aggregation, fibrin generation, clot retraction, and activation of factor XIII. Because thrombin generation in hemophilia is markedly delayed, hemorrhage may occur after minimal or unknown trauma. Deep bleeding into joints and muscles is characteristic of hemophilia. When bleeding occurs in a closed space such as a joint and is untreated, it ceases by tamponade, whereas open wounds in which tamponade cannot occur may bleed profusely with the potential for significant blood loss. In hemophilia, the clot formed is often friable, and rebleeding is a common observation in inadequately treated patients. Medications such as aspirin may alter platelet function and further impair hemostasis in affected individuals and are therefore contraindicated.[31]

Demographics and Classification

Hemophilia occurs in approximately 1 in 5000 males.[32-34] Of all patients with hemophilia, 80% to 85% have hemophilia A, and 10% to 15% have hemophilia B. Hemophilia shows no apparent racial predilection and appears in all ethnic groups.

The severity of hemophilia is classified on the basis of the patient's baseline level of factor VIII or factor IX. One unit of each factor is defined as the amount found in 1 mL of normal plasma. Factor levels are often expressed as a percentage of activity, with a 100% level (100 U/dL) being equal to the activity found in 1 mL of normal plasma. Severe hemophilia is characterized by a factor level of less than 1 U/dL (<1%). In moderate hemophilia, the clotting factor level is between 1 and 5 U/dL, and in mild hemophilia, factor VIII or IX levels are greater than 5 U/dL. This classification provides a rough guide for the patient's expected rate of occurrence of bleeding episodes. Patients with severe hemophilia often have bleeding episodes after minimal or unknown trauma, with children experiencing unprovoked muscle and joint bleeding between one and six times per month. With more aggressive prophylactic administration of factor VIII, instances of bleeding are markedly reduced. Patients with moderate hemophilia will have bleeding after mild to moderate injuries, whereas mild hemophilia may often be undiagnosed for many years and these patients may have bleeding only after significant trauma or at the time of surgery.

Clinical Manifestations

Approximately 30% of male infants with hemophilia have bleeding with circumcision.[35] In some reports as many as 1% to 2% of neonates with hemophilia may experience an intracranial hemorrhage.[36,37] It is important to avoid head trauma during delivery. Forceps or vacuum extraction should be avoided.[36,38] In the majority of patients hemophilia is diagnosed at birth because of a family history, although in approximately a third of patients the occurrence of hemophilia represents a new mutation.[39]

In these latter patients, the diagnosis is often made when the child begins to crawl and walk. The usual initial symptoms include easy bruising; oral bleeding, especially from a torn frenulum; hemarthrosis; and intramuscular hemorrhage. When the diagnosis of hemophilia is suspected on the basis of either clinical findings or a positive family history, the initial diagnostic studies should include determination of the prothrombin time, partial thromboplastin time (PTT), bleeding time, and fibrinogen or thrombin time; a platelet count; and studies to identify VWD (see Chapter 28). If the PTT is prolonged, assays for factor VIII and factor IX should be performed. The presence of an antibody inhibiting either factor VIII or IX can be ruled out by mixing normal plasma in equal volume with the test plasma, incubating the mixture for 30 to 60 minutes, and repeating the PTT to be sure that it has been normalized. The specific assays for factor VIII and factor IX are not as easily affected by difficult venipuncture and are therefore more reliable. Factor VIII and VWF levels may be elevated by stress and inflammation, however, and repeated studies may be necessary to establish the diagnosis and the severity of the disorder.

Specific types of bleeding are described in the following paragraphs. In general, the clinical bleeding episodes associated with deficiency of factor VIII or factor IX are identical.

Musculoskeletal Bleeding

Although patients with hemophilia may bleed in any area of the body, the hallmark of hemophilia is deep bleeding into joints and muscles.[40] The occurrence of such hemorrhage usually corresponds to the severity of the clotting factor deficiency in patients with either hemophilia A or hemophilia B. Patients with severe hemophilia may have a bleeding episode as often as once or twice per week. Bleeding occurs most commonly into the joint space, a condition referred to as *hemarthrosis*. These joint hemorrhages usually begin when the child reaches the toddler age. As the toddler attempts to maintain an upright position, the ankle becomes particularly prone to hemorrhage. Thus, in toddlers the ankle is the most common site of hemorrhage, with the knee being the second most common. As the child grows older, the most frequent bleeding sites are the knees and elbows.

Patients who sustain hemarthrosis usually first note an aura of tingling or warmth, followed shortly thereafter by increasing pain and decreased range of motion of the joint as the joint capsule becomes progressively distended.[41-43] As children get older, they are often able to tell their parents and the physician when a hemorrhage is beginning to occur, even in the absence of significant signs on physical examination. In young children who are unable to verbalize symptoms, severe pain and distention of the joint space often occur before the location of the hemorrhage can be easily determined. On examination, pain and limitation of range of motion of the joint are obvious and followed by the development of warmth,

swelling, and tenderness. Prompt, early coagulation factor replacement therapy is the key to minimizing long-term complications of these hemorrhages. Patients with severe hemophilia are increasingly being treated prophylactically to prevent most bleeding episodes (see later). Prompt aspiration of hip hemarthrosis should be performed if joint distention is present to reduce the risk for avascular necrosis of the femoral head. As children and their parents become familiar with the early symptoms of bleeding, aggressive early treatment can be given to reduce the degree of joint damage. If the child experiences repeated hemorrhage within a joint, chronic effusion and hyperemia often occur, and an aggressive secondary prophylactic therapy program may be needed to return the joint to a more normal state of recovery.[27] Severe chronic arthropathy may develop in older children and adults who have not received aggressive early treatment. These individuals often experience pain very early with little swelling. The joints of younger children are usually more distensible, and massive joint swelling may be observed. Splinting and application of ice packs as auxiliary measures may provide a modicum of relief but are not substitutes for early coagulation factor replacement therapy. When one has doubts, treatment should be initiated; it is not appropriate to watch and wait.

The clinical diagnosis of intramuscular hematoma is often elusive. Such hemorrhage occurs deep within the body of the muscle and is associated with a vague feeling of pain on motion. Because the bleeding is not in a closed space, the mass may be difficult to palpate, although the circumference of the affected limb is generally increased. Muscle hemorrhage should be considered to be as severe as hemarthrosis because it may result in severe muscular contractures as a result of fibrosis and atrophy or even pseudotumor formation. Muscle weakness also predisposes patients to joint hemorrhage. Appropriate replacement therapy is critical for reducing the size of the hematoma, and physical therapy is important to restore normal range of motion and prevent fibrosis of the muscle.

Iliopsoas bleeding is a particularly troublesome form of intramuscular hemorrhage. A patient with an iliopsoas hemorrhage is generally seen with vague symptoms of lower abdominal or upper thigh discomfort. The patient may have a characteristic gait; the hip is flexed and inwardly rotated. On examination the patient is unable to extend the hip, but usually both internal and external rotation of the hip joint is normal; the latter finding often distinguishes an iliopsoas hemorrhage from a true hemarthrosis of the hip joint. The diagnosis is made clinically by these findings and should be confirmed by either ultrasonography or computed tomography.[44] Appropriate treatment is crucial; iliopsoas hemorrhages may be life threatening because large volumes of blood can be lost into the retroperitoneal space. Physical examination demonstrates loss of hyperextension of the hip. If an iliopsoas hemorrhage is identified, an aggressive infusion program should be initiated and maintained for at least 10 to 14 days or longer, followed by at least several months of prophylactic therapy until clinical and radiographic evidence demonstrates resolution.

Life-Threatening Hemorrhages

Bleeding episodes of the central nervous system (CNS), bleeding into and around the airway, and exsanguinating hemorrhage are the most common causes of life-threatening hemorrhage in hemophilia. The first element of treatment is prompt therapy with clotting factor concentrate to bring the plasma clotting factor level to normal. CNS hemorrhage may occur without known trauma, and early symptoms may be minimal. Thus, therapy should be initiated before radiologic evaluation or lumbar puncture. Rarely, an infant who has bloody cerebrospinal fluid on lumbar puncture is seen with "meningitis." If this is the initial finding, a markedly prolonged PTT will usually suggest the diagnosis.[45-47] Prompt performance of computed tomography is often critical in the early diagnosis of intracranial bleeding, although an astonishingly large volume of blood can be present within the cranium in infants with relatively few neurologic findings. Treatment of life-threatening hemorrhage involves replacement therapy to achieve a level of 100 U/dL for factor VIII and 80 U/dL for factor IX, maintenance of adequate hemostatic levels (>50 to 60 U/dL) for a minimum of 14 days, and a more prolonged period of prophylactic therapy for an additional 2 to 3 weeks or longer to ensure resolution of the underlying event (Table 30-1). Patients with intracranial hemorrhage should receive prophylaxis for at least 6 months after the more intense initial therapy.

Preparation for Surgery

Preparation of a hemophilic patient for surgery includes a careful history and physical examination, measurement of inhibitor titer, careful determination of the incremental recovery and half-life after infusion of the appropriate clotting factor (VIII or IX), and assurance that adequate amounts of coagulation factor replacement material and red cells are available for transfusion.[48] Before surgery, the replacement materials should be infused to achieve a level of 80 to 100 U/dL for factor IX and 100 to 150 U/dL for factor VIII; levels should be maintained at greater than 50 to 60 U/dL for 7 to 10 days postoperatively. Lower doses to maintain levels at greater than 20 to 30 U/dL for an additional 1 to 2 weeks may then be used and continued until healing has occurred (see Table 30-1). Because recovery of recombinant factor IX activity is less than that of therapeutic plasma-derived factor IX, 1.2 to 1.5 times the dose should be administered if using recombinant factor IX.[49,50]

Miscellaneous Hemorrhages

A common manifestation of hemophilia is oral bleeding, whether from a torn frenulum in a young child or after

TABLE 30-1   Treatment of Specific Hemorrhages in Hemophilia

Type of Hemorrhage	Hemophilia A	Hemophilia B*
Hemarthrosis[†]	*50 U/kg* factor VIII concentrate initially,[‡] 20 U/kg the following day; consider additional treatment every other day, depending on response	*80 U/kg* factor IX concentrate initially, 40 U/kg the following day; consider additional treatment every other day, depending on response
Muscle or significant subcutaneous hematoma	*50 U/kg* factor VIII concentrate; may need 20 U/kg every other day until well resolved	*80 U/kg* factor IX concentrate; may need 40 U/kg every other day until well resolved
Mouth, deciduous tooth, or tooth extraction	*20 U/kg* factor VIII concentrate (40 U/kg if molar extraction), antifibrinolytic therapy; remove loose deciduous tooth	*40 U/kg* factor IX concentrate (80 U/kg if molar extraction), antifibrinolytic therapy; remove loose deciduous tooth
Epistaxis	*Apply pressure* for 15-20 min, Nosebleed QR, pack with petrolatum gauze, antifibrinolytic therapy; 20 U/kg factor VIII concentrate if above fails	*Apply pressure* for 15-20 min, Nosebleed QR, pack with petrolatum gauze, antifibrinolytic therapy[§]; 30 U/kg factor IX concentrate if above fails
Major surgery, life-threatening hemorrhage (e.g., central nervous system, gastrointestinal, airway)	*50-75 U/kg* factor VIII concentrate, then initiate continuous infusion of 3 U/kg/hr to maintain factor VIIII > 100 U/dL for 24 hr, and then give 2-3 U/kg/hr for 5-7 days to maintain the level greater than 50 U/dL and an additional 5-7 days at a level >30 U/dL (bolus dosing to maintain these levels is acceptable); monitor factor VIII levels	*80-100 U/kg* factor IX concentrate, then 20-40 U/kg every 12-24 hr to maintain factor IX > 40 U/dL for 5-7 days, and then >30 U/dL for 5-7 days[‖]; monitor factor IX levels
Iliopsoas hemorrhage	*50 U/kg* factor VIII concentrate, then 25 U/kg every 12 hr until asymptomatic, and then 20 U/kg every other day for a total of 10-14 days[¶]	*80 U/kg* factor IX concentrate, then 20-40 U/kg every 12-24 hr to maintain factor IX > 40 IU/dL until asymptomatic, and then 30 U/kg every other day for a total of 10-14 days[‖,¶]
Hematuria	*Bed rest*, 1.5 × maintenance fluids; if not controlled in 1-2 days, 20 U/kg factor VIII concentrate; if not controlled, prednisone if human immunodeficiency virus negative	*Bed rest*, 1.5 × maintenance fluids; if not controlled in 1-2 days, 30 U/kg factor IX concentrate; if not controlled, prednisone if human immunodeficiency virus negative

*Dosing of recombinant factor IX should be increased to 1.3 to 1.5 times the recommended doses or, preferably, be based on an individual in vivo recovery study.

[†]For hip hemarthrosis, orthopedic evaluation for possible aspiration is advisable.

[‡]For mild or moderate hemophilia, desmopressin, 0.3 µg/kg, should be used instead of factor VIII concentrate if patient is known to respond with a hemostatic level of factor VIII; if repeated doses are given, monitor factor VIII levels for tachyphylaxis.

[§]Do not give antifibrinolytic therapy until 4 to 6 hours after a dose of prothrombin complex concentrate.

[‖]If repeated doses of factor IX concentrate are required, use highly purified, specific factor IX concentrate.

[¶]Repeat radiologic assessment should be performed before discontinuation of therapy.

tooth extraction in an older patient. Replacement therapy to achieve a factor level of 30 to 40 U/dL is adequate for initial therapy. Because the oral cavity contains abundant fibrinolytic activity, therapy with antifibrinolytic agents (aminocaproic acid [Amicar] or tranexamic acid [Cyklokapron]) is useful to stabilize the clot until the wound has healed.[51-53]

Hematuria can be a particularly troublesome problem. Blood in the urine may arise spontaneously, and determination of an actual bleeding site is often difficult. Therapy is also controversial. Replacement therapy with 40 to 50 U/kg of factor VIII or IX followed by bed rest is generally advisable after other common causes of hematuria have been ruled out. Treatment with corticosteroids may be helpful.[54] Sudden abdominal or flank pain should be investigated for the possibility of ureteral obstruction and hydronephrosis secondary to bleeding.

Gastrointestinal bleeding is an occasional complication of hemophilia. All of the common causes of gastrointestinal bleeding can occur in patients with hemophilia, as well as spontaneous hemorrhage after no known insult. An initial episode of gastrointestinal hemorrhage requires that the patient receive a thorough gastrointestinal evaluation after the acute bleeding is controlled with replacement therapy. If substantial blood loss has occurred, patients should be treated with high doses of concentrate as though they were at risk for life-threatening hemorrhage.

Long-Term Complications of Joint Bleeding

Chronic arthropathy is the major long-term disabling complication of hemophilia. The articular surface of a normal joint is lined with cartilage that is lubricated by

synovial fluid produced by the synovial lining of the joint. A thick fibrous capsule protects the joint. The natural history of hemophilic arthropathy is one of a cycle of recurrent hemorrhage into a "target" joint leading to synovial thickening and friability, followed by additional hemorrhage into the joint.[41,42,55] After a joint hemorrhage, proteolytic enzymes are released by granulocytes into the joint space.[56] In addition, heme iron is ingested by macrophages and may contribute to inflammation by the release of oxidative products. The synovium of the joint, originally the width of a single cell, proliferates in response to inflammation and develops frond-like projections into the joint. These projections are by nature friable and bleed with minimal trauma, thus setting up a vicious cycle of recurrent hemorrhage. With recurrence of hemorrhage, there is further release of substances injurious to the joint cartilage that causes it to develop a roughened, lunar landscape–like surface. As the cartilage erodes, the joint space becomes narrowed.

On examination, the clinical findings depend on the stage of arthropathy that has developed. The early stages are characterized by synovial thickening with little evidence of joint damage. With synovitis alone, the range of motion of the joint is nearly normal, although recurrent bleeding episodes usually result in weakness of the proximal muscles. With time, however, proliferative changes become associated with erosion of the cartilage. The patient at this stage may note the development of arthritic symptoms that are often difficult to distinguish from joint bleeding. Crepitus and decreased range of motion are prominent findings on physical examination. At this stage, proximal muscle weakness is accentuated because of inability of the joint to attain full range of motion. Finally, with progressive bleeding and further narrowing of the joint space, the joint fuses.

This progression of joint disease was once commonly seen in hemophilia centers throughout the United States and other countries. The most commonly affected joints were the knees, ankles, and elbows. With the development of modern concentrates for replacement therapy, home therapy, and prophylactic therapy, this cycle has now been disrupted in the vast majority of children with severe hemophilia. Primary prophylactic therapy and early diagnosis and treatment of joint hemorrhage have limited the number of "target joints" that develop. When a joint becomes a target, hemorrhage into that joint must be treated vigorously and the joint must be carefully watched for the cycle of rebleeding every 1 to 2 weeks that is characteristic of incompletely treated hemarthrosis. If evidence of early synovitis or loss of range of motion is present, a secondary prophylactic therapy program of every-other-day treatment for 30 to 90 days is often helpful for "cooling down" the affected joint and allowing healing to occur.[27,57] Alternatively, a lifelong prophylactic therapy program to prevent spontaneous, severe joint bleeding may be started in young infants (see later). If medical therapy fails, synovectomy frequently reduces the occurrence of bleeding and may prevent progression of the joint disease. With the advent of arthroscopic means to perform synovectomy, this procedure has been more readily performed with reduced morbidity; equally important, early mobilization of the affected joint allows more rapid return of range of motion.[58,59] Another procedure in which various radioisotopes are used to reduce the mass of inflamed synovium is termed *radioactive synovectory*.[60] This approach is recommended for patients with inhibitors. Fewer radioactive synovectomies are now performed because of the development of acute lymphoblastic leukemia in two children who underwent this procedure.[61] When aggressive medical and "less" invasive surgical management fails to halt progression of the joint disease, some adults have benefited from joint replacement.[62-64] If pain and bleeding are severe in a joint with minimal range of motion, joint fusion may provide a significant decrease in pain and rebleeding. A critical element in the care of patients with chronic joint disease is the need for a team approach to the problem because the care of these children requires the combined expertise of an orthopedic surgeon, physical therapist, nurse, social worker, and hematologist to achieve optimal results.

Symptomatic Carriers

Although the usual patient with hemophilia A or hemophilia B is a male, carriers of a factor VIII gene mutation may also be symptomatic. Known carriers should have their levels of clotting factor measured at least once to determine whether they are at increased risk for clinical bleeding episodes. There are several potential explanations for the observation of a female with moderate or severe deficiency of factor VIII or factor IX.[65-68] Skewed lyonization of a carrier female is the most commonly accepted explanation. As predicted by the Lyon hypothesis, the X chromosome in each female cell is randomly inactivated early in embryonic development; by chance, some carriers of hemophilia will have a high percentage of inactivated normal X chromosomes. The active abnormal X chromosome will result in deficient synthesis of factor VIII or factor IX. Other explanations for the presence of hemophilia A or B in a phenotypic female include testicular feminization of a genotypic male,[69,70] Turner's syndrome with the genotype XO,[71-73] and a daughter of a maternal carrier and a father with hemophilia A. Factor VIII deficiency is also found in type 2N VWD as a result of mutations in the factor VIII–binding region of the VWF protein.[74]

Laboratory Evaluation

Severe hemophilia A or hemophilia B is easily identified by a markedly prolonged PTT and the absence of either factor VIII or factor IX. The diagnosis of mild hemophilia A or hemophilia B may be more difficult to make because the newborn has a slightly prolonged PTT secondary to a physiologic reduction in vitamin K–dependent factors

such as factor IX. In addition, the stress of delivery and other neonatal problems may transiently elevate factor VIII levels into the normal or nearly normal range. Thus, in the absence of clinical bleeding, mild deficiencies may be identified only after repeated testing in the weeks or months after birth (see Chapter 28). VWF testing must be done to distinguish mild or moderate factor VIII deficiency secondary to hemophilia from deficiencies of factor VIII secondary to VWD.

Partial Thromboplastin Time

The PTT measures all of the procoagulant clotting factors except factor VII and factor XIII (see Chapters 26 and 28). In general, the PTT is most sensitive for deficiencies of the "intrinsic" pathway.[75] Deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen give the longest clotting times, although paradoxically, these deficiencies are not associated with clinical bleeding episodes. In general, commercial PTT reagents have good sensitivity for factor VIII deficiency, but their sensitivity for factor IX deficiency is more variable.[76-78] Use of some of these reagents will give normal PTTs even with factor IX levels of 15 to 20 U/dL. Because the hemostatic level of factor IX is approximately 30 U/dL, mild or moderate factor IX deficiency may be missed. Thus, if hemophilia is suspected, a factor IX assay should be performed even if the PTT is normal. The clinical laboratory should study the sensitivity of each lot of PTT reagent to be able to advise the clinician about the likelihood that a normal PTT implies normal clotting factor levels. In patients with severe hemophilia A or hemophilia B, the PTT is generally prolonged to two to three times the upper limit of the normal range. The prolonged PTT will correct to within the normal range when the reagent is mixed 1:1 with normal plasma. Failure of the PTT to correct on 1:1 mixing of the reagent with normal plasma implies the presence of an anticoagulant (e.g., lupus inhibitor, antibody to factor VIII or IX, or heparin). The presence of a specific anti–factor VIII or anti–factor IX inhibitory antibody is described in more detail later.

Specific Assays for Factor VIII and Factor IX

Functional assays for factor VIII and factor IX are performed on plasma samples that contain no factor VIII or factor IX, respectively (either hemophilia A or hemophilia B plasma); alternatively, normal plasma from which the respective clotting factor is selectively removed by a monoclonal antibody can be used.[79] If adsorbed plasma is used for factor VIII–deficient plasma, the VWF content of that plasma should be normal. A standard curve is constructed with the use of normal plasma, with the 100% point being a 1:10 dilution of normal plasma. Serial dilutions of this normal plasma should usually be linear through a dilution of 1:640 or 1:1280 when plotted semilogarithmically versus the clotting time. Serial dilutions of the patient's plasma are compared with this normal curve and expressed in units per deciliter.

One unit is the amount of factor VIII or factor IX present in 1 mL of normal plasma.

Immunoassays for factor VIII and factor IX are sometimes performed to identify dysfunctional proteins or dysproteinemias. The majority of patients with severe hemophilia A have undetectable levels of factor VIII protein, but some patients with mild or moderate hemophilia A possess levels of factor VIII protein that are detectable with an immunoassay.[80-82] In hemophilia B, about 50% of patients will have detectable or even normal levels of factor IX antigen and therefore have true dysproteinemias.[83,84] Immunoassays are not usually required for the clinical management of these disorders because the coagulant-based assays predict the functional concentration of these clotting factors.

Inhibitory Antibodies to Factor VIII or Factor IX

The presence of a factor VIII or factor IX inhibitory antibody is usually suspected when the PTT does not correct to normal after being mixed 1:1 with normal plasma. Because of the kinetics of the inhibitory antibody, this mixture should be incubated 60 minutes before the PTT is performed. When a low-titer inhibitory antibody is identified, the PTT performed on a 1:1 mixture with normal plasma may initially be prolonged only by several seconds, but when the mixture is incubated for 1 hour, the PTT may be as long as or even longer than the PTT when it was originally performed on the patient's plasma.

Specific assays for factor VIII or factor IX antibodies are performed with the Bethesda assay. Dilutions of the test plasma are mixed with normal plasma and incubated for 120 minutes. A standard factor VIII or factor IX assay is then performed. One Bethesda unit is defined as the amount of antibody that will inactivate 50% of the normal factor VIII or factor IX in 2 hours when the residual factor VIII or factor IX level is between 25 and 75 U/dL.[85] The dilution of the test plasma that inhibits this amount of factor VIII is determined. If a 1:10 dilution of test plasma has this effect, the inhibitor plasma is said to contain 10 Bethesda units.

Genetic Testing

The genes for both factor VIII and factor IX are located near the terminus of the long arm of the X chromosome.[86-89] Therefore, both hemophilia A and B are inherited as X-linked traits. Genetic testing for hemophilia A and hemophilia B is now widely available.[86-88,90-92] Such testing is usually performed on the propositus and potential carriers of hemophilia. Prenatal testing for hemophilia is performed by amniocentesis or chorionic villus biopsy[90] and may be useful for the perinatologist and neonatologist in the management of pregnancy, delivery, and immediate neonatal care. Databases of the known mutations causing hemophilia A are available on the Internet (http://europium.csc.mrc.ac.uk/WebPages/Main/main.htm). The most common genetic alteration is

inversion. Gene inversion occurs in approximately 45% of patients with severe hemophilia A, with most inversions originating in male germ cells. In families in which the propositus has a known molecular abnormality, genetic screening and carrier detection are highly accurate. Direct DNA sequence analysis is available for families in which the results of testing for the factor VIII gene inversion are negative. If genetic testing is uninformative, a coagulation-based assay to detect the carrier state may be also useful[93,94] and is approximately 90% accurate.

In contrast to the complexity of the factor VIII gene, the factor IX gene is considerably smaller (≈33 versus 187 kilobases [kb]). More than 60% of factor IX gene defects are due to missense point mutations, and an identifiable defect in the gene can be found in nearly all patients[95] (http://www.kcl.ac.uk/ip/petergreen/haem Bdatabase.html). In approximately 50% of patients with hemophilia B, a factor IX protein that is nonfunctional is produced, whereas in the other patients no factor IX protein is produced.

Other Laboratory Studies

Laboratory evaluation of a patient with hemophilia also includes a search for transfusion-transmissible diseases and their secondary complications, such as hepatitis and liver disease (see Chapter 34).

Fundamentals of Treatment

Knowledge of the half-life, volume of distribution, patient's inhibitor status, and appropriate replacement material is necessary to make intelligent decisions for the treatment of bleeding episodes.[96-98] Prompt and appropriate treatment of hemorrhage and prophylactic therapy are the key to excellent care of patients with hemophilia. The use of home therapy and prophylactic therapy has revolutionized the care of children and adults with hemophilia. Early or prophylactic treatment prevents the long-term morbidity of hemophilia. For mild to moderate hemorrhage, it is necessary that factor VIII levels of 30 to 50 U/dL or factor IX levels of 30 U/dL be achieved.

For patients with mild hemophilia A who have previously shown a satisfactory response to desmopressin acetate (DDAVP, 1-deamino-8-ᴅ-arginine vasopressin), this drug is the treatment of choice for bleeding episodes of mild to moderate severity.[99-101] For life-threatening hemorrhage, the immediate aim is to correct the patient's clotting factor level to normal (100 to 150 U/dL) and to maintain a nadir level between 50 and 60 U/dL for 5 to 7 days, followed by a vigorous maintenance treatment program.

Table 30-1 summarizes the treatment of specific types of hemorrhage in hemophilia A and hemophilia B. Calculation of the dose, recommendations concerning prophylaxis, and the specific treatment products for hemophilia A and hemophilia B are reviewed later.

Hemophilia A

Calculation of Dose

Calculation of the dose required to achieve a desired hemostatic level is based on a convenient formula derived from the work of Abildgaard and colleagues[11]:

Dose factor VIII (units) =
    U/dL desired rise in plasma factor VIII ×
                Body weight (kg) × 0.5

Thus, for treatment of hemarthrosis in a 20-kg child with severe hemophilia A, to achieve a plasma level of 60 U/dL, the dose would be 60 U/dL × 20 kg × 0.5 = 600 units of factor VIII.

For patients undergoing major surgery or with serious hemorrhage, the plasma factor VIII level should be initially corrected to 100 to 150 U/dL (immediately before the procedure if given for surgery) and maintained at greater than 50 to 60 U/dL for 5 to 7 days and then at greater than 30 U/dL for an additional 5 to 7 days. This can be accomplished by infusion of intermittent doses of factor VIII based on a half-life of 12 hours (e.g., administration of 30 U/kg [60-U/dL correction] every 12 hours).

Alternatively, a level of 50 to 60 U/dL can be maintained by continuous infusion of factor VIII at a rate of 2 to 3 U/kg/hr.[102,103] The level of factor VIII should be monitored periodically to ensure that the expected levels are attained. Immediately after surgery, it is advisable to administer 25 U/kg of factor VIII concentrate to compensate for the loss of factor VIII by increased consumption and blood loss during the surgical procedure. For surgical procedures and limb- or life-threatening hemorrhage, factor VIII levels should be monitored at least every 24 hours. CNS bleeding should be treated for a 2- to 3-week course of therapy. Such patients have a risk of recurrence of CNS bleeding for approximately 6 months after an episode, and these patients often continue to receive prophylactic therapy. At the conclusion of therapy for CNS hemorrhage, computed tomography should be performed to provide a baseline scan for comparison if any subsequent CNS symptoms appear and to demonstrate resolution of the previous hemorrhage.

For treatment of more routine bleeding episodes, such as hemarthrosis, often only one to two doses of clotting factor replacement (plasma factor VIII level of 80 to 100 U/dL), initially followed by infusions as recommended in Table 30-1, are required to produce significant clinical improvement. Nevertheless, many centers are now using a more aggressive approach to managing severe joint hemorrhage by administering follow-up infusions daily until the signs and symptoms have resolved and then every other day for 7 to 10 days to limit the potential development of chronic joint disease.

For dental extractions, mouth lacerations, or recurrent epistaxis, adjuvant antifibrinolytic therapy is used (see later).

Prophylactic Factor VIII Therapy

Prophylactic therapy with plasma-derived factor VIII was not previously considered for all patients because of the cost, the limited amount of plasma and blood products donated by volunteer donors, and the inherent risk of transfusion-transmitted diseases. However, most centers are now routinely giving individuals factor VIII prophylactic replacement therapy with recombinant factor VIII.[27,104,105] Most centers initiate prophylactic therapy as soon as joint bleeding occurs. This therapy is usually administered through a subcutaneous access port after the insertion of a central venous line.[106,107] Insertion of such lines is often associated with catheter infections or thrombosis (or both), so patients and family members need to be aware of the signs and symptoms.[107] In general, a dose of 20 to 40 U/kg of factor VIII is administered every other day or three times a week. The dose and rate are adjusted to ensure that the nadir before the next infusion is greater than 1 U/dL. The levels attained by use of this regimen usually prevent spontaneous bleeding, although hemorrhage caused by trauma may still require additional replacement therapy. The goal is to prevent recurrent hemarthrosis and associated chronic hemophilic arthropathy and thereby promote a normal lifestyle. A number of centers throughout the world have initiated prophylactic therapy programs and have demonstrated their cost-effectiveness when productivity and lifestyle are used as indicators of success.[25,108] However, this long-term vision is not always shared by administrators of managed health care systems, and the most successful programs have been carried out in countries with nationalized health care.

Factor VIII Treatment Products

Clotting factor replacement products should be rendered as free as possible of transfusion-transmissible agents, but vigilance is still necessary. As a result, recombinant products are generally considered to be preferable to plasma-derived products. Because even recombinant products may contain human albumin added as a stabilizer, products have recently been developed that contain no human plasma–derived protein.[109,110] The question of which product to use, the rate of administration, and the potential use of prophylaxis are decisions that need to be made by the health care provider, the family, and the patient.

Recombinant Factor VIII Concentrates. The factor VIII gene has been cloned, sequenced, and used to successfully transfect mammalian cells to produce recombinant factor VIII,[111] and several recombinant factor VIII products have been licensed. Clinical trials have documented that the half-life, recovery, and efficacy of these recombinant factor VIII products are similar to those for plasma-derived factor VIII.[20,21] Advantages of these recombinant factor VIII products are their freedom from human viral contamination and their production by methods that do not require human blood or plasma

donors. There was initial concern that there may be an increase in the incidence of inhibitor development in previously untreated patients, but this appears to not be warranted.[112-117] Careful study of patients receiving recombinant products identified inhibitors in 20% to 25%, as opposed to the previously reported 14% prevalence of inhibitors.[118] The difference is now thought to be due to detection of transient inhibitors that subsequently disappear and not due to differences between the immunogenicity of recombinant factor VIII and plasma-derived factor VIII. Recent studies have revived interest in this issue, and a number of studies are re-evaluating whether factor VIII in the presence of VWF might be less immunogenic.[119-122] A recombinant factor VIII product missing the B domain has been licensed, which may require a different approach to laboratory monitoring because its activity differs between one- and two-stage factor VIII assays.[123,124] Recently developed products are formulated so that other human proteins are removed.[109,110]

Plasma-Derived Factor VIII Concentrates. Several commercial plasma-derived factor VIII concentrates are available. Intermediate-purity concentrates are produced from large pools of donor plasma by a combination of cryoprecipitation or precipitation with glycine, polyethylene glycol, or ethanol.[125] These intermediate-purity products contain 2 to 5 units of factor VIII per milligram of protein. Products of higher purity have also been developed and are produced by immunopurification of factor VIII with the use of monoclonal antibodies to factor VIII[126] or VWF.[127] All these products undergo multiple purification steps that involve heat treatment, as well as other modalities, to reduce the risk of viral transmission. As a result, the risk of human immunodeficiency virus (HIV) infection, hepatitis B, hepatitis C, and more recently, transmission of hepatitis A and parvovirus B19 has been markedly reduced or eliminated.[128-130] In the 1990s, one lot of plasma-derived product was found to be associated with a very high frequency of factor VIII inhibitors in patients who had previously been treated extensively with plasma-derived products. This was thought to be due to an alteration in the factor VIII product during fractionation and purification.[120]

With the improved purity of plasma-derived products, the incidence of complications has greatly diminished. Allergic reactions, isohemagglutinin-induced hemolytic anemia, immune complex–mediated hematuria, and granulocyte antibody–induced lung injury are rarely seen. The use of immunoaffinity-purified factor VIII concentrates and recombinant factor VIII concentrates appears to stabilize CD4$^+$ counts in HIV-infected patients with hemophilia.[131,132]

To minimize the risk for hepatitis B and hepatitis A, unimmunized patients should be immunized at the time of diagnosis.[133,134] If clotting factor replacement therapy is needed at the time of diagnosis, hepatitis B immune

globulin can be administered along with the first dose of vaccine to maintain passive protection until vaccine-induced antibodies are formed. Family members of patients with hemophilia who are chronic carriers of hepatitis B and those who assist in administration of clotting factor should be immunized as well.

Cryoprecipitate. The first widely used preparation of factor VIII was made by Judith Graham Poole in 1965 by a method called cryoprecipitation.[135] Each bag of cryoprecipitate contains only 100 units of factor VIII, and thus 10 to 20 donor units are required for the treatment of joint hemorrhage in an adult. Because cryoprecipitate lacks any active method of viral inactivation, possesses significant amounts of other human proteins, and is inconvenient to administer, it is no longer considered a viable alternative to purified factor VIII products, except in areas of the world where other forms of therapy are unavailable or in short supply.

Desmopressin. Desmopressin is a synthetic vasopressin analogue that increases plasma factor VIII and VWF levels, thereby allowing successful treatment of bleeding episodes associated with dental and surgical procedures in patients with mild and moderate hemophilia A and VWD.[136,137] Desmopressin is now considered the treatment of choice in patients with mild and moderate hemophilia A who have shown a response to the drug during a therapeutic trial. It is not effective in the treatment of severe hemophilia A, severe VWD, or any form of hemophilia B.

The individual response to desmopressin is varied,[138] with the range of increase in factor VIII level being between 2- and 15-fold over baseline in patients with mild or moderate hemophilia A. It is therefore recommended that patients undergo a therapeutic trial of desmopressin with laboratory measurement of response to factor VIII before it is used for the treatment of bleeding episodes or as prophylactic therapy before dental and other surgical procedures. A similar degree of response is generally seen in an individual patient with subsequent doses,[139] and thus the factor VIII level attained after a trial dose can be used to predict the response to future therapy. The level of response to factor VIII is not usually sufficient to treat life- or limb-threatening hemorrhage. Tachyphylaxis may occur with repeated doses of desmopressin, but this varies from patient to patient.[140] Consequently, if repeated doses of desmopressin are to be administered, factor VIII levels should be monitored, and if necessary, exogenous factor VIII should be administered. In general, if several days has elapsed between doses, a response similar to that for the baseline infusion can be expected. Side effects from the administration of desmopressin are minimal and include headache, flushing, a slight change in pulse rate or blood pressure, and rarely, hyponatremia. Because hyponatremia after the administration of desmopressin may cause a seizure in rare instances,[141] fluid intake should be restricted to maintenance levels for at least 24 hours. If repeated doses of the drug are given, serum sodium levels should be monitored. Because of rare reports of thrombosis after the use of desmopressin,[142] the drug should be used with caution in patients with an increased risk for thrombosis.

The recommended intravenous dose of desmopressin is 0.3 µg/kg, and it is administered in 25 to 50 mL of normal saline over a period of 20 to 30 minutes.[100,136] If desmopressin is being given before a procedure such as a dental extraction, it should be administered as close to the procedure as possible because the maximal response occurs 30 to 60 minutes after administration. A concentrated form of desmopressin (Stimate) is available for intranasal administration to treat bleeding disorders. This preparation should not be confused with the far less concentrated formulation (brand name DDAVP) that is used to treat enuresis; the latter formulation is ineffective for the treatment of hemophilia and VWD. The appropriate dose of intranasal Stimate is 150 µg (1 puff) for persons weighing less than 50 kg and 300 µg (1 puff in each nostril) for persons weighing more than 50 kg.[143] It is particularly important to document the response to intranasal desmopressin before it is used for the treatment of bleeding.

Antifibrinolytic Therapy

Bleeding from mucosal surfaces in patients with hemophilia is often problematic because of the increased fibrinolytic activity associated with the mucosa. Antifibrinolytic therapy has been found to be effective in controlling mucosal bleeding, especially from the oral mucosa. Although hemostasis is generally achieved with either factor VIII replacement or desmopressin, the risk of recurrent bleeding from oral mucosal surfaces is dramatically reduced with the administration of antifibrinolytic agents. Use of these agents for nasal bleeding or for bleeding from the urinary tract or gastrointestinal surfaces has not been studied extensively. The clearest demonstration of their efficacy is with dental extractions, for which transfusion therapy was previously required for 10 to 12 days. With the use of antifibrinolytic therapy, a single infusion of factor VIII and 7 to 10 days of antifibrinolytic therapy are usually sufficient to prevent recurrent hemorrhage after dental extractions.[51,144] In addition, tranexamic acid has been shown to be effective when used topically as a mouthwash.[145] The intravenous form of ε-aminocaproic can also be used as an effective mouthwash.

Two antifibrinolytic agents, aminocaproic acid and tranexamic acid, are available. Aminocaproic acid is formulated in an intravenous form, oral tablets, and an elixir.[146,147] The tablets contains 500 or 1000 mg, and the elixir contains 250 mg/mL. Because the tablets are large and the usual dose is 5 g (5 to 10 tablets), most adult patients prefer taking the elixir. The oral dose of

ε-aminocaproic acid is 100 to 200 mg/kg initially (maximum dose, 10 g), followed by 50 to 100 mg/kg per dose every 6 hours (maximum dose, 5 g). The second agent, tranexamic acid, is available in 500-mg capsules. The dose of tranexamic acid is 25 mg/kg every 6 to 8 hours. No elixir is available for tranexamic acid. Both tranexamic acid and aminocaproic acid are available in intravenous forms.

Treatment of Patients with Hemophilia A Who Have Inhibitory Antibodies to Factor VIII

In 14% to 25% of patients with severe hemophilia A, antibodies develop that inactivate the procoagulant activity of factor VIII; these antibodies are referred to as factor VIII inhibitors.[112-118] The clinical hallmark of inhibitor development is failure to respond to routine replacement therapy. Patients with factor VIII inhibitors can be divided into two general categories: high responders and low responders. High responders are those in whom high-titer antibody develops with exposure to factor VIII and in whom an anamnestic response usually occurs with subsequent exposure. The titer of their antibody is in excess of 5 Bethesda units and may increase to hundreds or thousands of Bethesda units after repeat exposure. In low responders, a titer of inhibitory antibody is maintained at less than 5 Bethesda units, even when they are exposed to repeated doses of factor VIII. The clinical approach is different for these two groups.

Low-Responding Factor VIII Inhibitors

Patients with inhibitor titers of less than 5 Bethesda units[148] can generally be treated with factor VIII concentrates at higher doses. Because the effect of hemophilic factor VIII inhibitor is usually time dependent, the Bethesda titer in plasma is determined after a 2-hour incubation period. As a result of this time delay, continuous administration of factor VIII is usually found to be effective.[149] For a serious limb- or life-threatening bleeding episode, a bolus infusion of 100 U/kg of factor VIII is administered, and the level is maintained by treatment at a rate of 20 U/kg/hr. An assay for factor VIII should be performed 1 hour after the bolus infusion and at least daily thereafter. As the antibody titer drops (caused by the formation of an immune complex with the high-dose factor VIII), the daily level of factor VIII may rise and thus require downward adjustment of the continuous infusion rate. For routine joint and muscle hemorrhage, patients can usually be managed[144] with infusions at twice the usual dosage. A survival study can be performed to determine the peak and half-life of the infused factor VIII. Routine inhibitor assays should be performed after exposure to factor VIII to determine whether an anamnestic response has occurred. Whether the patient remains a low responder or becomes a high responder will determine how the patient is treated for future bleeding episodes.

High-Responding Factor VIII Inhibitors

Treatment of patients with high-responding factor VIII inhibitors requires a much more aggressive approach with one of several alternative therapies. Such treatment is usually performed in sophisticated tertiary care centers by experts in the management of hemophilia.

Continuous Factor VIII Infusion. Most clinicians caring for patients with limb-threatening or life-threatening bleeding episodes prefer to use products for which therapeutic levels can be monitored. As described earlier, continuous administration of factor VIII is often effective because of the time delay in inhibition by the antibody. An initial dose of 100 to 200 U/kg can be administered, and factor VIII levels can be determined 1 hour after initiation of continuous infusion at a rate of 20 to 40 U/kg/hr. If a factor VIII level cannot be obtained (i.e., patients with Bethesda titers greater than 5 to 10 Bethesda units), alternative approaches are usually indicated.

Porcine Factor VIII Concentrate. In patients whose Bethesda titer is less than 50 Bethesda units, a therapeutic factor VIII level can usually be attained by using a porcine factor VIII concentrate. Porcine factor VIII is a highly purified material produced by polyelectrolyte ion exchange chromatography.[150,151] Because of contamination of porcine factor VIII with parvovirus, plasma-derived factor VIII is no longer available. Recombinant porcine factor VIII is being explored as a new therapeutic option for factor VIII inhibitor patients, but it is not yet licensed.[152] The recommended starting dose of porcine factor VIII is 100 to 150 U/kg, and the response is measured with a standard factor VIII assay. Alternatively, continuous infusion of porcine factor VIII can be initiated after the bolus infusion. Factor VIII levels should be monitored frequently (at least daily) with a standard one-stage PTT-based assay. The clinician should measure the antiporcine factor VIII titer with a Bethesda-type assay to determine the anamnestic response. Knowing that the porcine titer is low or undetectable permits the clinician to form a rational plan for using porcine factor VIII during future bleeding episodes.

Recombinant Factor VIIa. A recombinant factor VIIa (activated factor VII) concentrate has been developed and demonstrated to produce hemostasis in patients with high-responding inhibitors.[153,154] It is thought to interact with tissue factor and platelets at the site of vascular injury and thereby activate factor X and promote thrombin generation in a manner that bypasses the factor VIII–dependent steps.[155]

The initial dose is 90 to 120 μg/kg of factor VIIa, with additional doses administered every 2 hours. The subsequent rate of infusion and duration of therapy must then be individualized on the basis of the clinical response and severity of bleeding. Recently, the use of higher bolus

doses of 180 to 270 µg/kg has been advocated to presumably establish a higher "thrombin burst" at the site of vascular injury.[156]

Prothrombin Complex Concentrate. Prothrombin complex concentrates may sometimes be used to treat routine joint and muscle hemorrhage in patients with hemophilia A and inhibitors. The exact mechanism by which the beneficial effects of these concentrates are produced is still not fully understood. A multicenter controlled study of hemarthrosis demonstrated that these concentrates promoted hemostasis in 50% of bleeding episodes. The initial dose is 75 U/kg of factor IX. If there is no response after two or three infusions given 12 hours apart, it is unlikely that additional treatments will be successful. If repeated doses of these concentrates are administered, consideration should be given to the addition of heparin.

Activated Prothrombin Complex Concentrates. There is currently one commercially available "activated" prothrombin complex concentrate, FEIBA (factor eight inhibitor–bypassing activity). This product has been purposefully activated during the fractionation process to achieve increased amounts of activated factor VII, factor X, or thrombin. Double-blind controlled trials have demonstrated that this product has small but significant advantages over standard prothrombin complex concentrates.[157] In contrast to porcine factor VIII or continuous-infusion factor VIII, these products are effective even in patients with high-titer inhibitors. The initial dose of 75 U/kg can be repeated in 6 to 12 hours. If multiple doses are administered, the patient should be monitored for the development of disseminated intravascular coagulation or even myocardial infarction, which has been reported with the use of these concentrates.[158] The simultaneous use of antifibrinolytic therapy should be avoided in these patients. If this treatment is not successful, recombinant factor VIIa treatment is usually considered.

Immune Tolerance to Factor VIII. Immune tolerance was first attempted in the 1970s and was achieved by the administration of high doses of factor VIII (100 to 150 U/kg) twice daily and the use of activated prothrombin complex concentrates for acute bleeding episodes.[159] After a period of months to even years, the titer of factor VIII antibodies was markedly reduced, and the dose could be decreased to a smaller daily dose or even doses given every other day. A less aggressive approach using lower doses of factor VIII has generally been demonstrated to be less effective.[160] Various reports have also described the use of intravenous gamma globulin, immunosuppressive therapy, removal of the antibody by extracorporeal immunoadsorption on *Staphylococcus* protein A columns, or a combination of these modalities.[161] Immune tolerance in four of five patients treated with porcine factor VIII on a home-based infusion program has also

been reported.[162] Reports suggest that early treatment of patients with inhibitors to induce immune tolerance is more successful.[163-165]

Hemophilia B

Calculation of Dose

Because factor IX has a volume of distribution different from that of factor VIII, the amount of plasma-derived factor IX that is required to achieve a similar plasma level is approximately twice that for factor VIII:

Dose of factor IX (units) =
U/dL (percent) desired rise ×
Body weight (kg)

Thus, for the treatment of hemarthrosis in a 20-kg child in whom a level of 80 U/dL is desired, the dose would be 80 U/dL × 20 kg = 1600 units of factor IX.

If recombinant factor IX concentrate is used, the dose must be increased 1.2- to 1.5-fold because of the poorer recovery of recombinant factor IX.[166] Thus, in the example just presented, the dose of recombinant factor IX would be 1920 to 2400 units. It is recommended that the recovery of factor IX after an infusion be established for each patient to accurately determine subsequent therapeutic doses. The half-life of factor IX (18 to 24 hours) is much longer than that of factor VIII (10 to 12 hours), and therefore factor IX does not need to be administered as often. Whereas the minimal hemostatic level of factor VIII is 30 to 40 U/dL, that of factor IX appears to be 25 to 30 U/dL.[167]

Factor IX Concentrates

Plasma-Derived Factor IX Concentrates. Hemophilia B can now be treated with highly purified factor IX products derived from plasma through purification or monoclonal immunoaffinity.[168] These highly purified factor IX concentrates are preferred over prothrombin complex concentrates for the treatment of major bleeding episodes, especially in patients with impaired liver function, massive crush injury, or a history of thrombosis. As discussed later, prothrombin complex concentrates are much more likely to be thrombogenic because of the presence of activated vitamin K–dependent clotting factors. Anaphylaxis in association with inhibitor development has been reported in patients receiving high-purity factor IX concentrates.[169,170] It is therefore usually recommended that administration of the first several doses of factor IX be observed in an emergency department where anaphylaxis can be treated if necessary.

Recombinant Factor IX Concentrates. Recombinant factor IX is considered the preferred product for treating patients with hemophilia B. As mentioned earlier, there is reduced recovery of recombinant factor IX, so 20% to 50% more factor IX must be used to achieve the same plasma concentration as plasma-derived factor IX.[171,172]

Prothrombin Complex Concentrates

The vitamin K–dependent clotting factors are of similar size and have similar biochemical and physical chemical properties. Thus, fractionation procedures such as barium sulfate precipitation and column chromatography with various adsorbents purify many of the vitamin K–dependent clotting factors together.[173,174] This material is therefore called prothrombin complex concentrate. These concentrates have been found on rare occasion to cause life-threatening thrombotic complications, including deep venous thrombosis, myocardial infarction, pulmonary emboli, and disseminated intravascular coagulation.[175,176] The risk of thrombosis is increased in patients receiving high or repetitive doses, in patients with impaired fibrinolysis (liver disease or after treatment with antifibrinolytic agents), and in those with impaired ability to clear activated clotting factors (i.e., patients with liver disease). When prothrombin complex concentrates are used repetitively, especially in high doses, the International Society of Thrombosis and Hemostasis (ISTH) has recommended the addition of 100 units of heparin to each 500 units of factor IX concentrate.[177] When factor IX is replaced, this level of heparin is not a problem. Rather than adding heparin to the prothrombin complex concentrates, most physicians currently prefer to use the more purified factor IX products or recombinant factor IX to treat patients with factor IX deficiency when high or repetitive doses are required. Factor IX concentrates and prothrombin complex concentrates have undergone dry heating or vapor heating at high temperatures to reduce the risk of HIV infection and hepatitis C.[178]

Fresh Frozen Plasma

Although fresh frozen plasma was historically used to treat hemophilia B, its use today is limited to areas of the world where factor IX concentrates are unavailable or in emergency situations when factor IX concentrates are not available. If large amounts of fresh frozen plasma are used, the plasma should be ABO blood type compatible to avoid the complication of hemolytic anemia caused by the infusion of isohemagglutinins. Patients with a normal cardiovascular system can safely tolerate a dose of 15 to 20 mL/kg.[179]

Treatment of Hemophilia B Patients with Factor IX Inhibitors

The incidence of inhibitory antibodies to factor IX is much lower than that seen with factor VIII. When such antibodies are identified, activated prothrombin complex concentrates and factor VIIa have been found to be the most successful therapies. However, the use of activated prothrombin concentrates is contraindicated in patients in whom anaphylaxis has developed along with the inhibitor because they too contain factor IX. Recombinant factor VIIa does not contain any factor IX and is therefore the preferred therapeutic approach. The induction of immune tolerance has been disappointing in patients

with factor IX inhibitors. In several patients, nephrotic syndrome has developed when factor IX was given in high doses for induction of tolerance.[180,181]

Complications of Transfusion Therapy for Hemophilia A and Hemophilia B

Transfusion-transmitted infectious diseases are a complication of transfusion therapy with plasma-derived therapeutic products in patients with hemophilia A and hemophilia B. Such diseases include HIV infection, hepatitis B, hepatitis C, and more recently, hepatitis A (see Chapter 35). With the use of recombinant factor VIII and factor IX and the newer methods of viral attenuation, many of the secondary problems associated with these complications can be avoided or minimized. As discussed earlier, hepatitis B and hepatitis A vaccines should be administered to patients before or concomitant with initial therapy.

Comprehensive Care and Home Therapy

Care of patients with hemophilia requires a comprehensive team of health care providers that includes a hemophilia specialist, nurse coordinator, social worker, psychologist, physical therapist, dentist, orthopedic surgeon, financial counselor, primary care physician, and sometimes an infectious disease specialist.[182-184] This approach is considered to be the standard of care and is provided primarily through comprehensive hemophilia treatment centers. The occurrence of primary and secondary complications of hemophilia is reduced, and patient performance both at school and in the workplace is improved.[182]

A revolution occurred in hemophilia care with the development of factor concentrates and the potential for treatment of bleeding episodes at home. This has become the standard venue for the administration of replacement therapy for the majority of hemorrhages in patients with hemophilia. With home therapy, treatment can be administered sooner, which can reduce the long-term morbidity of hemophilia and thereby reduce the total cost of the disease. Home care programs should be monitored closely by the comprehensive hemophilia team and requires the physician, nurse coordinator, and patient and family to have a close working relationship.[185] Today, many patients receive routine primary prophylactic therapy at home administered through a subcutaneous port and a central venous access line.

Future Gene Therapy for Hemophilia A and Hemophilia B

Gene therapy for either hemophilia A or hemophilia B is not yet available.[172,186] Animal models of hemophilia A and hemophilia B have been developed or maintained in dogs and mice. Early success with gene therapy in these animal models has been achieved, but long-term maintenance of a satisfactory plasma level of clotting factor continues to be a problem. Human gene therapy trials have been carried out for both hemophilia A[187-189] and

hemophilia B.[190-192] Although extensive preclinical studies have demonstrated the potential for gene therapy in hemophilia, the clinical trials to date are disappointing. Because inhibitory antibodies will develop in more than 25% of patients treated with clotting factor concentrates, it is not yet clear whether gene therapy will have a similar incidence or whether continuous release by the transgene will provide tolerance in these patients. One recent preclinical approach consists of directing factor VIII expression to platelets where the factor VIII is stored and can be released locally by platelets.[193-197] One group has demonstrated that this approach appears to be effective even in the presence of high-titer inhibitory antibodies.[196] Gene therapy is expected to be available in the next 5 to 10 years, but many problems remain, including selection of both appropriate vectors and the appropriate cell in which to express the gene. Control of potential deleterious side effects must still be solved.[186]

VON WILLEBRAND DISEASE

VWD is a disorder of VWF, a large multimeric glycoprotein that (1) contributes to the adherence of platelets to damaged endothelium and (2) serves as a carrier protein for plasma factor VIII. Deficiency of VWF results in mucocutaneous and post-traumatic or postsurgical bleeding, but if VWF is absent or markedly reduced, the secondary reduction in plasma factor VIII may also result in muscle and joint bleeding similar to hemophilia A. This disorder was first described by Erik von Willebrand in 1925 in persons living on the Åland Islands off the coast of Finland.[198-200] VWD is a very common, but heterogeneous disorder that is the result of a variety of genetic defects ranging from congenital absence of VWF to major dysproteinemias in which the structure and function of the molecule are markedly abnormal. It is inherited autosomally; thus, in contrast to hemophilia A and hemophilia B, the incidence of VWD in men and women is comparable, although more women may be assigned this diagnosis because of menorrhagia being a common symptom.

Pathophysiology

VWF is a large multimeric glycoprotein that is synthesized in megakaryocytes and endothelial cells and stored in specific cellular storage granules: the Weibel-Palade body in endothelial cells and the alpha granule in platelets.[201-204] It is present in plasma, but reduced levels can be significantly increased by administering drugs such as desmopressin that induce the release of VWF from endothelial storage sites into plasma.[136] Figure 30-1 depicts the role of VWF in localizing and facilitating the hemostatic process. After an injury to the endothelial cell wall of the blood vessel, the local concentration of VWF is increased by the interaction of VWF with components of the subendothelial matrix such as collagen.[205] This bound VWF

changes conformation and binds to the platelet glycoprotein Ib (GPIb) receptor, thereby resulting in adherence of circulating platelets to the site of damaged endothelium.[206,207] VWF is also capable of interacting with the GPIIb-IIIa receptor on platelets, and this action may be promoted by shear stress.[208-210] Once VWF causes the platelet to adhere by means of its GPIb receptor, these platelets are activated, which causes the recruitment of additional platelets.[211] This is termed platelet aggregation and results in the formation of a platelet plug (see Fig. 30-1). Formation of the platelet plug also depends on the presence of plasma fibrinogen, the primary ligand for platelet aggregation. The surface of aggregated platelets is altered with the externalization of phosphatidylserine, which interacts with plasma clotting factors (prothrombinase and factor X-ase) that catalyze generation of the local fibrin clot (see Figs. 30-1). Thus, in the absence of VWF (or in the presence of VWF with abnormal structure), platelets are poorly targeted to the area of endothelial cell damage, and less than optimal hemostasis results.

VWF also serves as a carrier protein for the plasma factor VIII molecule and, in fact, is necessary for the normal recovery and survival of factor VIII.[212-214] In the absence of VWF, lack of the carrier molecule function results in a secondary deficiency of plasma factor VIII. This deficiency of factor VIII is the result of accelerated clearance.[74,215] Recombinant factor VIII is produced more efficiently within cells transfected with genes for both VWF and factor VIII.[216,217] Thus, patients with severe VWD (type 3) usually have a prolonged bleeding time and a prolonged PTT caused by a decrease in both VWF and factor VIII. Milder forms of this disorder can differ and are described in more detail later.

Variant forms of VWF have been characterized in patients with type 2 variants (see later) that cause reduced binding of VWF to factor VIII, reduced binding to platelets, and reduced size of VWF multimers. Each of these forms can therefore lead to abnormal hemostasis and clinical VWD.

Genetics

VWD is an autosomal disorder, but some patients exhibit a classic recessive inheritance (type 3 and type 2N VWD) and others exhibit dominant inheritance (type 2B and 2A VWD).[218-220] The most common form, type 1 VWD, has variable penetrance and symptoms even within the same family.[218,221] Studies have been carried out that suggest that VWD may occur in as many as 1% or 2% of the general population,[222,223] but this high frequency has been challenged recently and will be discussed later.[224-226] VWF gene defects are rare in individuals with VWF antigen (VWF:Ag) levels just below the normal range.[218,221,227-229]

The VWF gene spans 178 kb and contains 52 exons.[230-232] It results in an 8.5-kb message that directs the synthesis of a 22–amino acid signal peptide and a 2791–amino acid pro-VWF monomer that is subsequently cleaved into a 741–amino acid propeptide and a

FIGURE 30-1. After vascular injury, plasma von Willebrand factor (VWF) binds to the subendothelial matrix. Under shear stress, VWF changes conformation, which enables the adherence of circulating platelets (platelet adhesion) through the glycoprotein receptor GPIb. Platelets are activated and recruit other platelets through platelet aggregation (platelet cohesion and aggregation). These activated platelets alter their surface phospholipids so that factor VIII (FVIII) binds, interacts with FIXa to activate the X-ase complex, and facilitates formation of the fibrin clot (coagulation). *(Courtesy of R. R. Montgomery.)*
2050–amino acid mature VWF monomer. The propeptide was initially termed von Willebrand antigen II,[233] but the VWF propeptide is currently referred to as VWFpp.[234,235] Figure 30-2 illustrates the relationship of the complementary DNA (8.5 kb) to structural and functional regions of the VWF protein. The areas of this gene that have been found to contain clusters of genetic defects that cause similar phenotypes are illustrated and include type 2A,[236,237] type 2B,[238,239] type 2N variants with abnormal interaction between VWF and factor VIII,[74,240,241] hereditary persistence of pro-VWF,[242] and a type 1 variant of VWD with accelerated clearance of VWF (Vicenza variant or type 1C VWD).[235,243,244] These genetic defects can be identified either by sequencing segments of the gene after amplification by polymerase chain reaction (PCR) or by reverse transcription of messenger RNA from circulating platelets and sequencing the "derived" complementary DNA after amplification by PCR.[236,239,240] Confirmation that these point mutations are responsible for the disease requires expression of the abnormal protein after transfection in vitro.[240] Many laboratories are now carrying out such DNA analysis on unusual variants. Three recent studies of relatively large cohorts of families have identified a number of VWF mutations associated with the most common type of VWD—type 1 VWD.[218,228,245-248] A summary of the mutations and polymorphisms in the VWF gene has been established by the VWF Subcommittee of the ISTH (maintained on http://www.vwf.group.shef.ac.uk/), and a summary of the variant types of VWF has been published by the VWF Subcommittee of the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis (SSC/ISTH).[220] Genetic

diagnosis is complicated by a partial, unprocessed 25-kb pseudogene located at chromosome 22q11.2.[249] Because this duplication has greater than 96% homology with VWF and spans the A1 to A3 domains, PCR primers need to be designed to avoid amplification of this pseudogene for identification of mutations in this region of VWF.[250] In the mouse, extragenic causes of low VWF have been found and are the result of accelerated clearance of VWF because of abnormal glycosylation.[251] In humans, extragenic causes of VWD are being sought, but to date, the major modifier of plasma VWF is the ABO blood group,[252] thought to be the result of glycosylation differences in the ABH antigens that have been known for many years.[253] Additional modifiers of VWF:Ag levels or of clinical bleeding symptoms are being sought.

Low von Willebrand Factor Versus Type 1 von Willebrand Disease

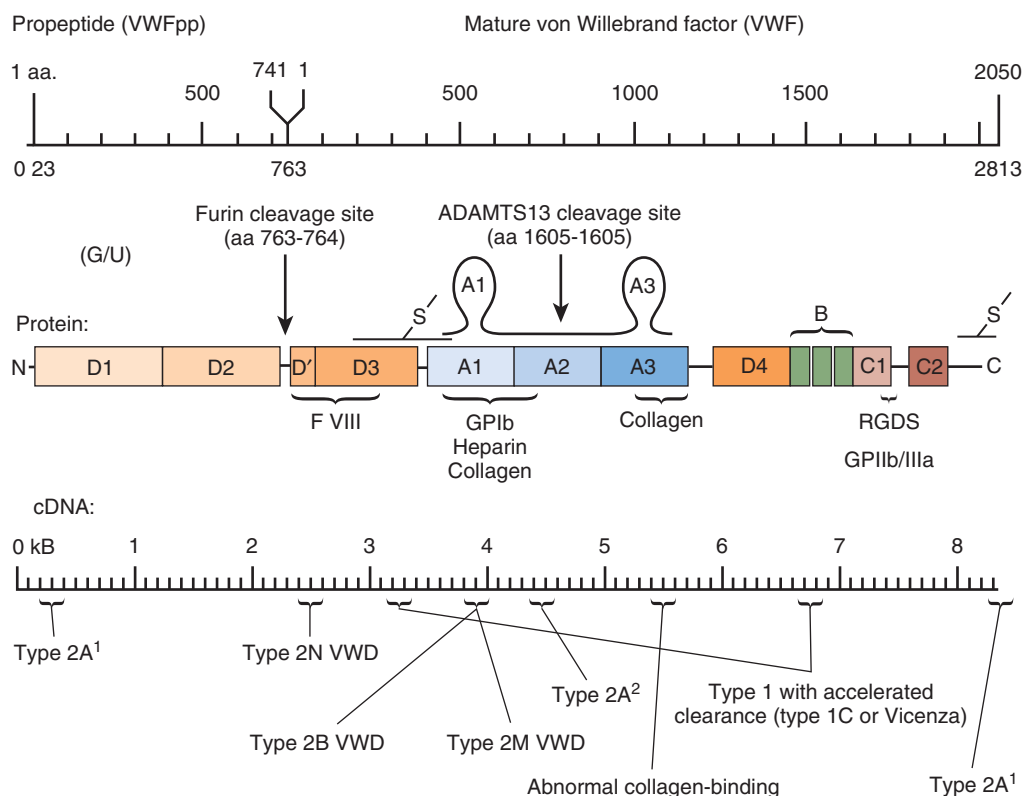
As mentioned earlier, patients with VWF levels below 2 SD of normal VWF have historically been used to define the level for diagnosis of VWD. However, a 2-SD normal range by definition leaves 2.5% of the population above that range and 2.5% below that range. Some studies suggest that VWD is present in 1% to 2% of the general population.[222,223] The diagnosis of mild type 1 VWD has been challenged based on the argument that the plasma level of VWF is a continuous variable and may be a risk factor for bleeding and not necessarily a defined disease state.[224,225,254] Recently, guidelines have been published by the National Institutes of Health (www.nhlbi.nih.gov/guidelines/vwd) in which the suggested level for the designation of type 1 VWD was a VWF:Ag or plasma ristocetin cofactor (VWF:RCo) level of less than 30 IU/dL,


FIGURE 30-2. Protein structure and its relationship to von Willebrand disease (VWD) variant subtype mutation location. von Willebrand factor (VWF) contains specific domains that have been shown to have discrete functions, including (1) the interaction with factor VIII (FVIII; D′ and D3), glycoprotein Ib (GPIb; A1), collagen (A1 and A3), ADAMTS-13 (A2), platelet GPIIb/IIIa (C1), and furin (D2-D′). The *lower panel* localizes hot spots for DNA mutations that cause VWF variants that tend to correlate with the functional domains. The variants include type 2A[1] (2A variants that fail to multimerize properly), type 2N (decreased interaction with FVIII), type 2B (increased binding to platelet GPIb), type 2M (decreased binding to GPIb but with normal VWF multimers), type 2A[2] (2A variants caused by increased spontaneous proteolysis of VWF by ADAMTS-13), abnormal binding to collagen, and type 1C (type 1 VWD variant with accelerated VWF clearance). aa, amino acid. *(Courtesy of R. R. Montgomery.)*

but patients with bleeding and VWF levels below the normal range may still benefit from therapy such as DDAVP to raise the level of plasma VWF. Controversy therefore remains over this issue, and many clinicians still use the term "mild type 1 VWD" to refer to individuals with VWF:Ag levels between 30 and 50 IU/dL. Low VWF or even clinical bleeding symptoms are not always associated with a clearly identifiable VWF gene mutation. Conversely, not all patients inheriting a VWF gene mutation will manifest bleeding symptoms (referred to as variable penetrance),[255,256] and among those who do bleed, severity can vary widely (variable expressivity).[218,246,257] Alternatively, low VWF or clinical bleeding symptoms in the absence of a VWF gene mutation may result from the effects of mutations in another gene (or genes) (locus heterogeneity). Research is still necessary to characterize these complex genetic factors in greater detail.

Demographics and Classification

While males and females should have a similar prevalence; VWD is diagnosed more frequently in boys in childhood but then more commonly in teenage and adult females because of the frequent complication of menor-rhagia. VWD occurs in all racial groups, although localized pockets with a very high incidence of VWD do exist, such as those in the Åland Islands of Finland and areas of Sweden, Israel, and Iran.[258-260] African Americans have been shown to have higher levels of plasma VWF:Ag, but their VWF:RCo level is not similarly increased.[261,262]

VWD has numerous subtypes that can be defined by structural, functional, and molecular genetic techniques. Of patients with VWD, 65% to 80% have type 1 VWD, characterized by a parallel reduction in both VWF antigen and VWF activity as measured by the ristocetin cofactor assay.[263-265] This assay is described in more detail later. The second most common variant is type 2A VWD, in which the multimeric structure of VWF is altered such that only the smallest VWF multimers are present in plasma.[266,267] This results in a marked reduction in ristocetin cofactor activity with a somewhat milder reduction in the level of VWF antigen. Figure 30-3 summarizes the more common variants of VWD and their relative prevalence. Descriptions of types 1, 2A, 2B, 2N, 2M, and 3 VWD and platelet-type pseudo-VWD are provided later.

Because VWD is common, the possibility of inheriting VWD from both parents is significant. These patients

with severe homozygous or compound heterozygous or type 3 VWD have undetectable levels of VWF and a significant reduction in factor VIII (1 to 6 U/dL). Such patients have a much more severe bleeding tendency.

Clinical Screening Using a Semiquantitative Bleeding Assessment

Several recent studies have focused on the clinical symptoms associated with VWD and have attempted to quantify these symptoms in the hope of improving the specificity of the diagnosis.[268-270] These scoring systems evaluated epistaxis, skin bleeding, oral/dental bleeding, gastrointestinal bleeding, muscle/joint bleeding, and CNS bleeding. Even though the two reports are similar, the second one was modified to give weight to surgical, dental, or delivery procedures that were not treated and did not result in excessive bleeding. Although these scoring systems were extensive, they have not been vali-

dated or carried out in children. Currently, there is a great deal of interest in developing such an assessment for use in children, but increasing specificity and sensitivity may be difficult.

Laboratory Evaluation

Laboratory evaluation of VWD often requires multiple assays to quantitate VWF and characterize its function and structure. Because results of screening tests (bleeding time and PTT) may be normal in patients with mild or moderate VWD, more specific assays for VWF are performed to diagnose VWD in patients with a history of significant bleeding episodes. VWD cannot be ruled out on the basis of a normal PTT and bleeding time or even with a platelet function analyzer such as the PFA-100.[271,272]

Immunoassay for von Willebrand Factor Antigen

VWF can be measured by using a variety of quantitative immunoassays. The most widely used assays are the enzyme-linked immunosorbent assay (ELISA)[273-275] and the quantitative immunoelectrophoretic assay (Laurell assay).[276] Nearly all large laboratories use the ELISA assay. Despite a great deal of variability in the measurement of VWF:Ag, the problem is probably not due to the assay but to the standard that is used in the assay. The World Health Organization (WHO) and ISTH have established standards for these assays and recommend reporting of results in international units standardized by the WHO.[277]

Determination of von Willebrand Factor Activity by the Ristocetin Cofactor Assay

The activity of VWF is most commonly measured in vitro with the antibiotic ristocetin (VWF:RCo).[264,265] Ristocetin induces binding of VWF to the GPIb receptor on platelets.[208] This assay is usually carried out with formalin-fixed platelets. The amount of plasma VWF activity is proportional to the slope of the agglutination curve. Some laboratories perform ristocetin-induced platelet aggregation, which is a measure of both binding of VWF to the GPIb receptor and the ability of this binding to induce aggregation. This test is not nearly as sensitive as the ristocetin cofactor assay and should not be used to rule out the diagnosis of VWD. Various methods have been developed to automate the ristocetin cofactor assay.[278-280] Ristocetin is an antibiotic that induces a conformational change in VWF so that it agglutinates platelets. Because this is a nonphysiologic activity assay, a number of alternative assays attempt to use shear as the stimulus for platelet binding, but to date, VWF:RCo remains the most widely used assay for VWF function. Large multimers of VWF have more VWF:RCo activity than do the intermediate and small VWF multimers. Newer assays for ristocetin cofactor are being developed that use bound GPIb in an ELISA format to determine that amount of patient plasma VWF that binds in the presence of ristocetin.[281,282]

Low-Dose Ristocetin-Induced Platelet Aggregation

One specific use for the low-dose ristocetin-induced platelet aggregation (LD-RIPA) assay is to diagnose the hyperresponsiveness of VWF with platelets in either type 2B VWD or platelet-type, pseudo-VWD (see Fig. 30-3).[283,284] These variants are important to differentiate appropriately because their response to the administration of desmopressin may be suboptimal. Each variant requires specific treatment to correct the qualitative abnormality. Differentiation of these types from one another can be done by a method devised to use frozen plasma to identify the increased binding of plasma VWF to platelets in patients with type 2B VWD.[285]

Collagen-Binding Assay for von Willebrand Factor

Assays have been developed to measure the binding of plasma VWF to collagen. In general, large multimers of VWF bind preferentially, although the type of collagen may affect this specificity. Some have advocated replacement of the VWF:RCo assay with a collagen-binding assay (VWF:CB),[286,287] but the two assays measure different "activities"—one with platelets and the other with subendothelial matrix collagen. A few families have been identified who lack binding of VWF to collagen. This mutation has been identified in the D3 region of VWF.[288,289] Some patients with type 2M VWD will show low binding in ristocetin cofactor assays but normal results with collagen-binding assays.[290,291]

von Willebrand Factor Multimers

VWF is present in plasma in multimers ranging from dimers of approximately 600,000 daltons to very large multimers of up to 20 million daltons.[267] The full range of VWF multimers is best demonstrated through the use of low concentrations of agarose (0.65 percent) and staining the multimers with radiolabeled antibody to VWF. The multimers are visualized by luminography.[266,292,293] Figure 30-4 demonstrates the multimers in type 1 VWD, as well as in types 2A, 2B, and 3. Acquired alteration of VWF multimers may also occur in various clinical disorders, with the loss of high-molecular-weight multimers seen in patients with disseminated intravascular coagulation or ventricular septal defects.[294] Larger than normal multimers can be identified in patients with recurrent thrombotic thrombocytopenia purpura.[295,296] Figure 30-4 also illustrates an additional method for multimer analysis in which satellite bands of the lower-molecular-weight multimers are identified. The individual multimers are resolved into five discrete bands, but the overall multimeric structure is not so well depicted as with the lower-agarose–containing gels. Patients with some type 2 variants may have increased satellite bands (see Figure 30-4).[297] Because these assays are difficult to

LOW-RESOLUTION GEL

HIGH-RESOLUTION GEL
FIGURE 30-4. Multimeric analysis of von Willebrand factor (VWF) with low (0.65%) and high (3%) concentrations of agarose. Representative samples are compared and demonstrate that the low-agarose gels are preferable for detecting the loss of high-molecular-weight multimers, as seen in some VWF variants, and the increased size of VWF multimers seen in patients with thrombotic thrombocytopenic purpura (TTP). The gels with higher agarose concentration (*left*) demonstrate that single multimer bands (*left*) can be resolved into multiple satellite bands that may be selectively increased in plasma from patients with variant forms of VWD. NP, normal plasma. *(Courtesy of R. R. Montgomery.)*

perform, multimeric analysis is often performed at specialized centers.

Assay for von Willebrand Factor Propeptide

A number of laboratories now offer quantitation of VWFpp. Because this 741–amino acid propeptide of VWF is synthesized on a 1:1 basis with VWF monomer, quantitation of this protein is useful in characterizing clinical states in which VWF has accelerated clearance by identifying individuals whose plasma VWFpp/VWF:Ag ratio is markedly elevated. This is possible because the accelerated clearance affects only the VWF:Ag level and not the level of VWFpp. One recent study reported four families with accelerated clearance of VWF who had VWFpp/VWF:Ag ratios between 2.3 and 6.8.[298] This ratio is also markedly elevated in acquired VWD associated with an autoantibody that promotes rapid clearance of VWF.[299] Quantitation of VWFpp and VWF:Ag has also been suggested as a marker to differentiate acute and chronic endothelial purtubation.[300]

Other Assays to Define Variants of von Willebrand Disease

Several more assays are available at specialized centers to help classify variant forms of VWD. In type 2B VWD, the VWF spontaneously binds to platelets in the presence of low-dose ristocetin and is termed a *type 2B platelet-binding assay*.[239,301] In type 2N VWD, VWF has reduced affinity for factor VIII, and this is best studied with a *type 2N*

VWF factor VIII–binding assay.[240,302] The *VWF:RCo/ VWF:Ag ratio* has been studied and helps identify patients with type 2M VWD.[290] These latter two assays are depicted in Figure 30-5.

Approximately half of the patients with type 2A VWD have reduced VWF multimer size and VWF:Ag secondary to mutations in the VWF A2 domain that make the molecule more susceptible to spontaneous proteolysis by a metalloproteinase termed ADAMTS-13.[303-305] Such proteolysis results in cleavage of VWF between amino acids 1605 and 1606 in the A2 domain (see Fig. 30-2).[306] A number of assays have been developed for ADAMTS-13.[307-310]

Variables That Affect Laboratory Assays for von Willebrand Factor

A large number of preinstrument variables may affect the determination of VWF. Standardization of assays for VWF has only recently been initiated, and a number of clinical reference plasma samples may have altered ratios of VWF antigen to activity, as well as loss of the high-molecular-weight multimers; therefore, it is imperative that each laboratory establish its own normal range and perform careful quality control. Alternatively, samples can be sent to laboratories that specialize in testing for VWF. When frozen samples are shipped, meticulous attention must be paid to the presence of contaminating platelets in the frozen plasma. If plasma is centrifuged only at 1500*g* for 5 to 10 minutes, the residual

Ristocetin included platelet binding for type 2B VWD

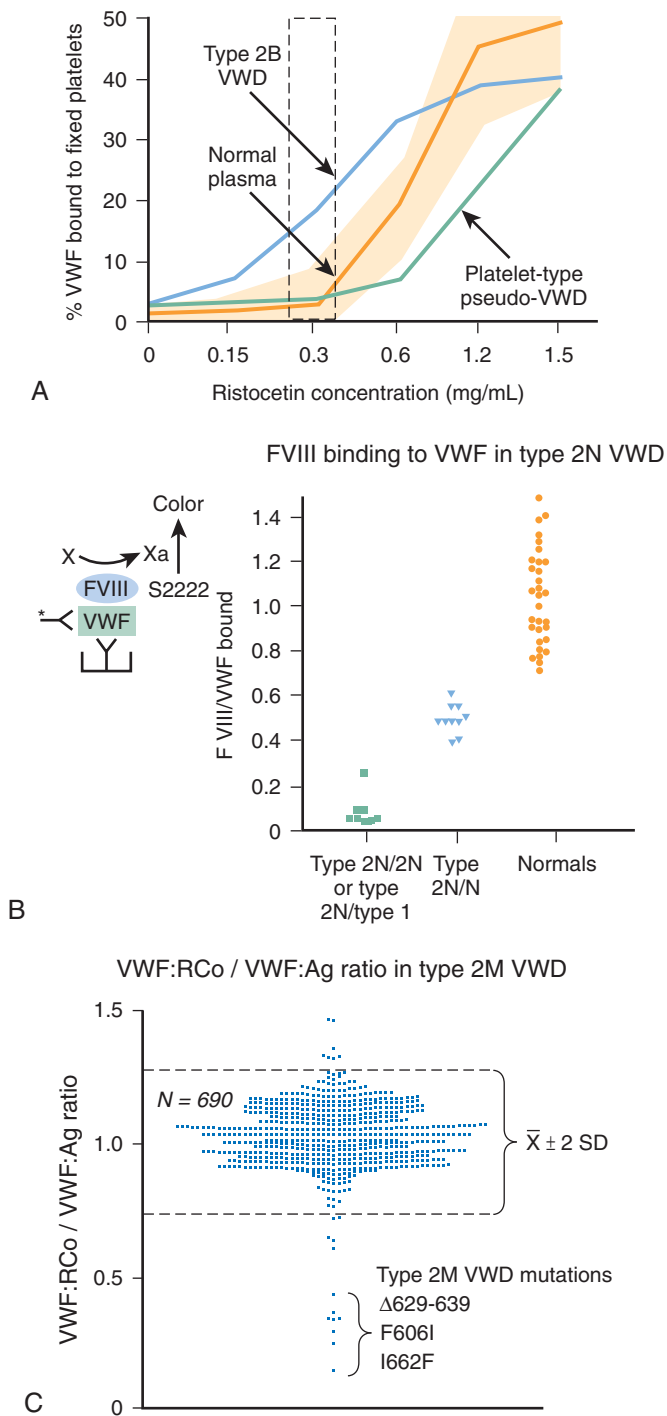
C


FIGURE 30-5. Variant forms of von Willebrand disease (VWD) can be identified by specialized phenotypic assays of patient plasma. **A,** A non-inhibitory, radiolabeled antibody is added to patient plasma, and binding to normal formalin-fixed platelets is determined with various concentrations of ristocetin. At a low concentration of ristocetin (0.3 mg/mL), normal von Willebrand factor (VWF) does not bind, but type 2B VWF exhibits increased binding that is due to a shift of the dose-response curve to the left. In contrast, plasma from a patient with platelet-type pseudo-VWD shifts to the right. Thus, if platelet aggregation with platelet-rich plasma (PRP) exhibits increased aggregation to low-dose ristocetin, type 2B VWD can be clearly differentiated from platelet-type pseudo-VWD with this dose-response curve. **B,** Patient VWF is bound to a microtiter well with a monoclonal antibody to VWF after patient factor VIII (FVIII) is removed. Recombinant FVIII is added and the activity of the bound FVIII determined by chromogenic (S2222) assay. The ratio of bound FVIII to captured VWF:Ag is determined and identifies heterozygous type 2N VWF (usually asymptomatic) and type 2N patients with absent FVIII binding (homozygous or compound heterozygous with a 2N allele and a "VWF-null" mutation allele). **C,** Ristocetin cofactor–antigen (VWF:RCo/VWF:Ag) ratio in a large group of patients evaluated with low-normal or abnormally low VWF levels. The ratios of eight patients with type 2M VWD are clearly below 2 SD of normal, and each of these patients has an identified point mutation (F1379I or I1425F) or a deletion (?1392-1402) in the A1 domain of VWF. Patients with ratios below 0.7 and normal VWF multimers are considered to have type 2M VWD. *(Courtesy of R. R. Montgomery.)*

platelet count in plasma may be as high as 30,000 to 40,000/mL. When this plasma containing platelets is frozen, platelet proteases are released, which alters the multimeric structure of VWF and results in an increase in the apparent amount of von Willebrand antigen and a decrease in the amount of activity.[311] Furthermore, refrigeration of samples of whole blood before separation of plasma at a central reference laboratory may result in reducing the amount of VWF in the plasma to be tested.[312]

Clinical Disorders That Affect Assays for von Willebrand Factor

A variety of clinical disorders may affect the level of VWF. VWF behaves as an acute phase reactant protein.[313-315] Its level is markedly elevated in collagen vascular disorders, after surgery, in pregnancy, and in conditions associated with marked endothelial stimulation, such as intravascular clotting or liver disease. The VWF level is reduced in hypothyroidism and increased in hyperthy-

roidism.[316-319] In hypothyroidism, VWF levels as low as 15 to 20 U/dL have been observed and therefore may be associated with clinical bleeding. The multimeric structure of plasma VWF from patients with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, or ventricular septal defects may be altered with the loss or gain of high-molecular-weight multimers. Pregnancy and even the clinical stress of a difficult phlebotomy, especially in anxious young children, may double or triple the level of VWF, thus making it impossible to rule out VWD without repeated testing. The stress of normal vaginal delivery has a marked stimulatory effect on levels of VWF in newborns,[320,321] hence making it difficult to rule out VWD in the neonatal period.

Clinical Manifestations and Medical History

The clinical manifestations of VWD are primarily epistaxis, ecchymoses, menorrhagia, and postoperative or postpartum bleeding.[322] Because this disorder is often mild, the initial manifestation may be bleeding after surgery such as tonsillectomy and adenoidectomy. Although both hemophilia and VWD may be accompanied by ecchymoses, large hematoma formation is more commonly associated with hemophilia, and it is rare to find hemarthrosis in VWD except in patients with severe (type 3) disease. In eliciting the patient's clinical history, it is important to determine whether the size and distribution of ecchymoses are proportional to the severity of the initiating trauma. Because both bruising and epistaxis are moderately common complaints in children and are usually a result of normal childhood trauma, identification of either severe recurrent epistaxis or bruising in unusual places (back and shoulders, upper part of the arms, and thighs) may be more suggestive of a hereditary bleeding disorder. In a normal active child, minor trauma to the anterior tibial region or the forearm may result in small ecchymoses. Recurrent epistaxis is a common complaint in childhood, but in an older child or adult it is an unusual symptom that may require further evaluation. Although screening for VWD is often performed in such patients, in the absence of ecchymoses, isolated epistaxis is not usually the result of VWD. Even though petechiae are more commonly associated with mild platelet function defects, occasional patients with VWD have petechiae.

A careful family history may identify symptoms in the parents or a sibling that are similar to the patient's. The presence of recurrent epistaxis and excessive bruising in an adult is more often abnormal and suggestive of a familial bleeding disorder. The clinician should determine whether either of the parents has experienced postoperative bleeding after major surgery, particularly tonsillectomy. Because VWD is often mild and some families learn to accept increased bruising as the norm

in their family, they may not seek medical attention until bleeding occurs in the postoperative state after either routine surgery or dental extractions. In teenagers, epistaxis or menorrhagia, when excessive, will sometimes lead to iron deficiency anemia; therefore, iron deficiency, particularly in menstruating teenage girls, may trigger evaluation for the presence of VWD. In a patient with severe (type 3) VWD, profuse epistaxis may occur and even result in shock,[323] although replacement therapy is generally needed less often in patients with type 3 VWD than in patients with hemophilia. In rare instances, VWD has been reported in association with congenital hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome); telangiectases should be sought in a patient with recurrent epistaxis or significant gastrointestinal bleeding.[237,324,325] Gastrointestinal blood loss may result from either occult or overt bleeding. Although bleeding may be associated with telangiectasia, usually no such anatomic cause can be determined. Such gastrointestinal bleeding may be more common in elderly patients with VWD than in children.

In patients with mild VWD, the stress associated with certain operations (e.g., ruptured appendix) may minimize clinical bleeding symptoms, whereas relatively minor surgery, such as cosmetic or mucosal surgery, may induce a major hemorrhage in a nonstressed individual.

Fundamentals of Treatment

Appropriate treatment of VWD requires a specific diagnostic laboratory workup and correct classification of the type of VWF deficiency. If the patient produces normal VWF but its concentration is reduced, the plasma level can usually be increased by administering desmopressin (see later). If the protein that is present is abnormal (dysproteinemia), mild bleeding episodes might still be resolved with increased concentrations of the "abnormal" VWF (induced by desmopressin), but severe bleeding episodes may require the administration of or replacement with normal VWF from plasma-derived products.

Whereas in the past most products used to treat hemophilia A (factor VIII deficiency) could also be used to treat bleeding episodes in VWD, the factor VIII products most commonly used at present (recombinant factor VIII or monoclonal antibody–purified factor VIII) do not contain VWF. Today, physicians use licensed VWF/factor VIII concentrates to treat VWD because these products are labeled for both VWF and factor VIII content. Clinical trials have demonstrated their efficacy in the cessation of bleeding in patients with VWD.[326-329] It is important to emphasize that the ratio of VWF to factor VIII varies in the currently licensed VWF products Humate-P and Alphanate. The ratio of VWF to factor VIII varies from 2.0 to 0.5 and has an impact on the initial and maintenance treatment of patients with these products.[326-329] Cryoprecipitate contains substantial levels of VWF but is not used regularly because of the lack of viral attenuation

treatment. The use of cryoprecipitate is reserved for areas of the world where VWF-containing concentrates are not available.

Treatment of VWD variants is discussed separately to emphasize their differences and how the molecular abnormality might affect the patient's clinical response to treatment.

Type 1 von Willebrand Disease

Type 1 VWD, the easiest and safest variant to treat, is also the most common variant (70% to 80% of all occurrences of VWD). Type 1 VWD is generally due to heterozygous deficiency of VWF. The VWF produced is structurally normal but its concentration is reduced. Most patients have levels of VWF antigen and ristocetin cofactor activity of between 20 and 40 U/dL, although the lower range of normal must be established in each individual laboratory. Patients with mild deficiencies of VWF generally do not experience spontaneous hemor-

rhage unless it is provoked by a major injury, surgical procedure, or dental extraction.

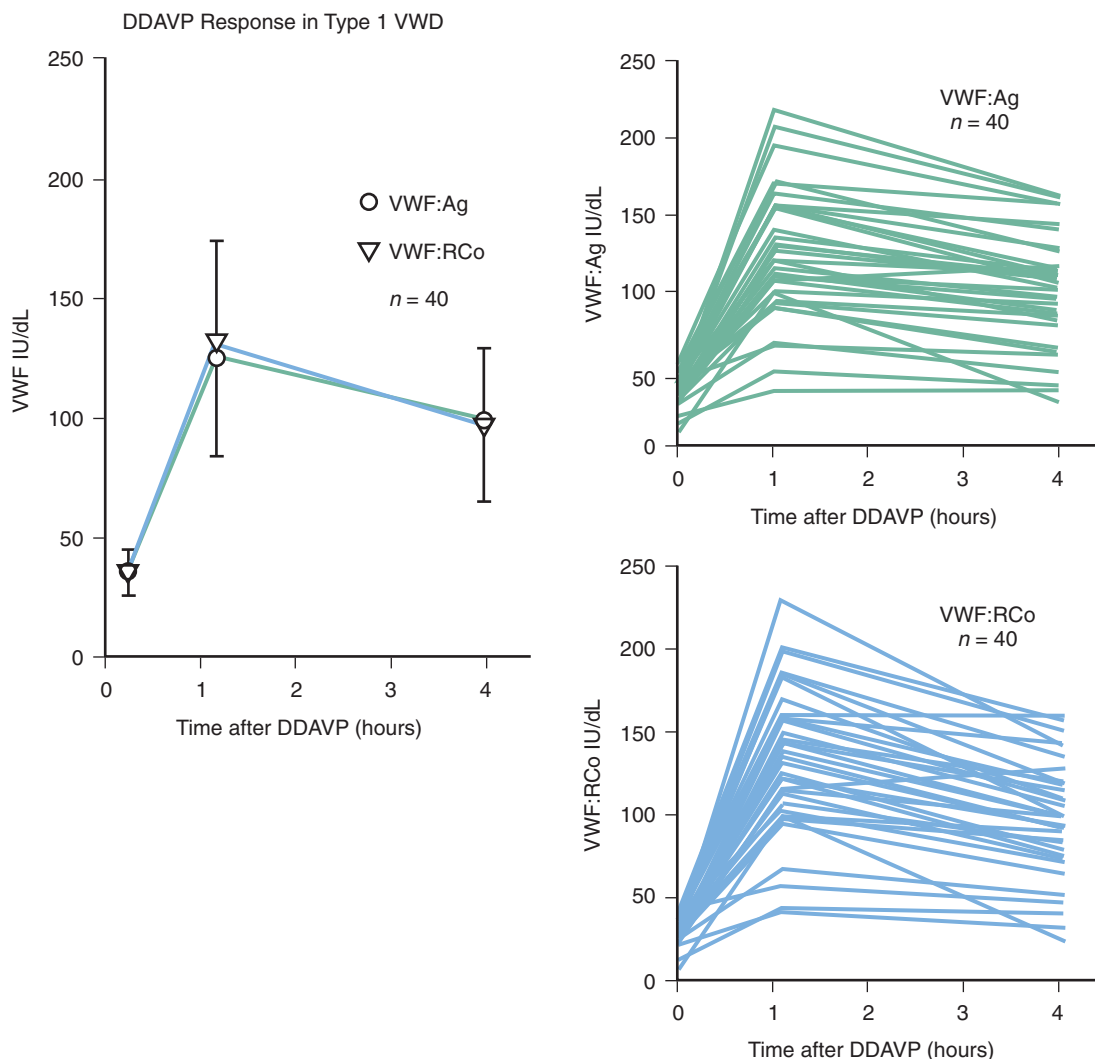
The safest therapy is to augment the patient's plasma VWF concentration by stimulating the endogenous release of VWF. This is achieved with desmopressin as described earlier in this chapter for treating mild hemophilia A.[136] More than 90% of patients with type 1 VWD have a twofold to fourfold increase in their plasma levels of VWF (Fig. 30-6) and factor VIII within 15 to 30 minutes of infusion, and they usually have the same half-life as transfused VWF or factor VIII (approximate half-life of 12 hours). Occasionally, patients are encountered who do not mount an adequate response to the infusion of desmopressin. This is particularly true for children younger than 1 to $1\frac{1}{2}$ years of age, who may exhibit a diminished response or symptoms of hyponatremia, or both.[141] It is usually recommended that patients in whom VWD is diagnosed be given a therapeutic trial of desmopressin to determine their responsiveness to the drug so


FIGURE 30-6. Desmopressin (DDAVP, 0.3 µg/kg intravenously) was administered to 40 patients with type 1 von Willebrand disease (VWD). Plasma samples were obtained before infusion and at 1 and 4 hours after infusion. The *left-hand* panel illustrates the mean and 1-SD range for these 40 individuals. The *right-hand* panels illustrate the consistency of the response in these 40 individuals for both von Willebrand factor antigen (VWF:Ag) and ristocetin cofactor (VWF:RCo) activity. *(Courtesy of J. P. Scott and R. R. Montgomery.)*

that when future therapy is required, the clinician knows that this form of treatment will be effective. The treatment of choice for type 1 VWD is the administration of desmopressin. The dose of desmopressin is 0.3 μg/kg of body weight administered intravenously in 25 to 50 mL of saline over a period of 20 to 30 minutes. This represents the most effective route of administration. Alternatively, subcutaneous injections of desmopressin at approximately the same dose have been used effectively.[330] Stimate (1.5 mg/mL DDAVP) is a concentrated form of desmopressin that has been shown to be effective.[331,332] The effective dose in teenagers and adults is 2 puffs—1 puff (150 μg) in each nostril for a total dose of 300 μg. Children weighing less than 50 kg should receive 1 puff containing 150 μg. For the drug to be effective, the child should be old enough to be able to cooperate with administration of the drug. The clinician should be aware that a diluted intranasal solution of desmopressin (100 μg/mL) (DDAVP) is available for patients with diabetes insipidus and enuresis. This latter dilute form is ineffective in patients with bleeding disorders.

Although one or two doses dose of desmopressin combined with either aminocaproic acid or tranexamic acid (see discussion under hemophilia A earlier) is generally effective for dental extractions, major surgery usually requires maintenance of increased levels of VWF and factor VIII until healing has occurred. For most patients, repeated infusions of desmopressin at 12- to 24-hour intervals are effective, but tachyphylaxis may develop.[140,333] Thus, preinfusion and 30- to 60-minute postinfusion measurements of either VWF:RCo or VWF:Ag should be performed to establish the continued clinical responsiveness of the patient to desmopressin if used repeatedly. If a patient with type 1 VWD has a very low level of VWF (15 to 20 U/dL) and is to undergo major surgery, the levels achieved after desmopressin may be insufficient even though a twofold increase is achieved. Such patients, like those who either show no response to desmopressin or have tachyphylaxis, must be treated with plasma-derived VWF/factor VIII.

The current Food and Drug Administration (FDA)-licensed products that contain both VWF and factor VIII for the treatment of VWD are Humate-P and Alphanate. Studies have compared these and other products for VWF and factor VIII content, as well as for VWF multimer content.[219] In these comparative studies, Humate-P usually has the larger forms of VWF multimers, similar to normal plasma. The two products also differ in their relative concentration of factor VIII, with Humate-P containing approximately 0.5 IU factor VIII per IU VWF:RCo and Alphanate containing 2.0 IU factor VIII per IU VWF:RCo. Currently, Humate-P is approved by the FDA for surgery and urgent bleeding in patients with types 1, 2, and 3 VWD, and Alphanate is approved for surgery in patient with types 1 and 2 VWD. Other intermediate-purity factor VIII and VWF concentrates are sometimes used off-label, but such use is not currently recommended.

The dose of VWF concentrate is calculated as follows:

Dose of VWF : RCo =
U/dL (percent) desired rise in plasma VWF ×
Body weight (kg) × 0.75

One unit per kilogram of VWF will increase the plasma level 1.5 U/dL. In preparing a patient for surgery, one usually tries to correct the plasma level to about 100 U/dL; plasma levels should be maintained at greater than 50 to 60 U/dL for 3 to 7 days after major surgery. For dental extractions or minor surgery, such as the procedure for a laceration, the patient can generally be treated with one or two infusions of VWF concentrate along with antifibrinolytic therapy.

Type 1C or the Vicenza Variant of von Willebrand Disease

Within the type 1 VWD group are individuals with accelerated clearance of their VWF who usually have plasma VWF:Ag and VWF:RCo levels below 12 to 20 IU/dL and factor VIII below 30 IU/dL. The initial prototype for this disorder was termed the Vicenza variant because of a number of families who were identified in Italy and subsequently shown to have a common mutation (R1205H in the VWF D3 domain).[244,334,335] These patients have also been shown to have larger than normal VWF multimers and normal levels of platelet VWF. Recently, four additional families were identified with this phenotype and different mutations in the D3 and D4 domains (W1144G and S2179F).[235] This group is now referred to collectively as type 1C because they have type 1 laboratory results secondary to increased clearance. This group of individuals has a normal level of VWF synthesis. When DDAVP is administered, they exhibit hyperresponsiveness, and their plasma VWF will increase 5- to 10-fold, but the half life is 2 to 3 hours rather than the normal 10 to 14 hours.[235,336] Furthermore, the half-life of factor VIII released by DDAVP is similarly accelerated.[235] Infused VWF and factor VIII have a normal half-life reflecting the origin of the clinical phenotype to the presence of endogenous abnormal VWF. Thus, treatment with DDAVP will normalize the plasma concentration of VWF and factor VIII, but not for the normal time period. Minor bleeding can be approached with DDAVP, but major bleeding or surgery may require VWF concentrates to maintain the level of VWF activity and factor VIII in the normal range. In this group, assays of VWFpp versus VWF:Ag are diagnostically elevated in the plasma of these patients and reflect the accelerated clearance of VWF but not VWFpp.[235]

Type 3 von Willebrand Disease

Type 3 VWD is usually due to autosomal recessive or compound (double) heterozygous inheritance of a null VWF allele. Thus, the level of plasma VWF is usually undetectable, but the factor VIII level is generally less than 6 U/dL. This plasma level of factor VIII is the steady-

state level of factor VIII in the absence of its carrier protein VWF. Giving such patients desmopressin is not effective because their cells do not contain endogenous VWF and the DDAVP-induced release of factor VIII is dependent on endogenous synthesis of VWF.[215] Sometimes a therapeutic trial of desmopressin in these patients is worthwhile because it might identify patients with type 1C who might have VWF:Ag levels below the detection limit for VWF:Ag in some laboratories.[336] In patients with undetectable VWF or an inadequate response to desmopressin, bleeding symptoms must be managed with plasma-derived VWF or factor VIII/VWF concentrates. Patients with type 3 VWD may have spontaneous bleeding, including profound epistaxis, subcutaneous hemorrhage, or rarely, joint bleeding as seen in patients with hemophilia.[337,338] In such situations, management is similar to that for patients with severe hemophilia and consists of factor VIII concentrates that contain normal or nearly normal VWF. Survival of the transfused VWF is virtually identical to that for factor VIII (see earlier). Levels similar to those used for treatment of hemophilia, both preoperatively and postoperatively, should be maintained for adequate hemostasis. Because the licensed concentrates Humate-P and Alphanate have different ratios of factor VIII to VWF, care must be exercised to ensure adequate factor VIII levels with the first infusion and to avoid excessively high factor VIII levels after several days of intensive or postsurgical treatment.[339]

A number of centers are now using prophylaxis to prevent bleeding in type 3 VWD patients if clinically indicated because of the number or severity of recurrent bleeding.[340-343] Since the half-lives of VWF and factor VIII are comparable, the approach is similar to that used in hemophilia A.

In Europe a concentrate containing very little factor VIII is approved, but these products are not available in the United States.[344-348] Because synthesis of factor VIII is normal in a type 3 VWD patient, providing VWF alone avoids the problems of elevated factor VIII in patients treated with factor VIII containing VWF concentrates.[349,350] Figure 30-7 illustrates the delayed rise in endogenous factor VIII when a patient with severe type 3 VWD is administered a concentrate primarily containing just VWF. Currently, clinical trials using recombinant VWF are being initiated, and it is hoped that this product will be available in the near future.

In patients with type 3 VWD and large gene deletions, there is an increased likelihood of antibody development.[351,352] Recombinant VIIa has been reported to be effective in some patients with severe VWD with alloantibodies.[353-355]

Type 2 Variant Types of von Willebrand Disease

Type 2A von Willebrand Disease

In type 2A VWD, there is a loss of intermediate- and high-molecular-weight multimers as a result of two dif-
Sample	1	2	3	4	5	6	7	8	9

FIGURE 30-7. A patient with severe type 3 von Willebrand disease was infused with a von Willebrand factor (VWF) concentrate containing minimal amounts of factor VIII (FVIII). Within 15 minutes after infusion, VWF antigen (VWF:Ag) and ristocetin cofactor (VWF:RCo) are markedly increased. At 24 hours the factor VIII level in the patient has increased to 71 U/dL because of the endogenous production of factor VIII. NP, normal plasma. *(Courtesy of D. Menache-Aronson, J. C. Gill, and R. R. Montgomery.)*

ferent mechanisms that were defined in the first molecular report of VWF mutations in this variant form of VWD.[356] One group is characterized by failure to synthesize intermediate- and high-molecular-weight VWF multimers (referred to as type 2A[1] in Fig. 30-2); in the other group, full-length VWF is synthesized, stored, and released, but the VWF undergoes rapid proteolysis by ADAMTS-13 (referred to as 2A[2] in Fig. 30-2).[305,356] Thus, if desmopressin is administered, the correction of VWF multimers is transient, and the bleeding time may

or may not shorten.[357] Therefore, patients with type 2A VWD may require treatment with plasma-derived factor VIII/VWF concentrate containing normal VWF multimers (see earlier). It may be possible to treat minor bleeding episodes and bleeding after dental extractions with the brief increase in plasma levels that follows desmopressin administration, but a trial of DDAVP and measurement of in vitro survival of VWF:RCo are required to determine potential efficacy.

Type 2B von Willebrand Disease

Type 2B VWD is due to a mutant VWF molecule that binds spontaneously to platelets under physiologic shear; it results in clearance of the highest-molecular-weight multimers and usually mild thrombocytopenia.[238,239,358-360] The thrombocytopenia is caused by spontaneous agglutination and clearance of platelets as a consequence of the abnormal VWF and results in loss of the high-molecular-weight multimers. Thus, stress, pregnancy, or surgery can trigger increased levels of VWF with resultant increased agglutination of platelets and enhanced thrombocytopenia.[361,362] Although one might assume that desmopressin would not be efficacious, studies have demonstrated its effectiveness in some patients.[363,364] Therefore, for mild bleeding, a trial of desmopressin can be initiated and the platelet count and bleeding monitored. For internal bleeding or major surgery, administration of VWF/factor VIII concentrate is generally required. Although thrombocytopenia is present, therapy should be focused on correcting the plasma VWF level. The dose is identical to that used for the treatment of severe type 1 or type 3 VWD. If profound thrombocytopenia is present, concomitant administration of platelets may be necessary. Administration of platelets alone without replacement of VWF is not usually effective. Sometimes, pseudothrombocytopenia may be present and cause the platelet count to be lower because of platelet clumping.[363,365,366]

Although *platelet-type pseudo-VWD* is due to a defect in the platelet GPIb receptor[367,368] (Chapter 29), it is considered in the differential diagnosis of type 2B VWD because of the loss of high-molecular-weight VWF multimers and reduced levels of VWF. The plasma assays of VWF are identical to those for patients with type 2B VWD, but these disorders must be distinguished because of the markedly different approaches to therapy (see Fig. 30-3). Platelet-type pseudo-VWD should be treated with platelets.[369] Although the plasma level of VWF is reduced and the distribution of multimers is abnormal, these findings are secondary to the abnormal GPIb receptor on platelets. Thus, as platelets are appropriately used to treat the bleeding disorder, the secondary VWF abnormalities will actually lessen. Standard doses of platelets should be used to treat hemorrhage. If the hemorrhage is severe or if bleeding persists, VWF/factor VIII concentrates may be needed to correct the secondary deficiency of VWF. Similar to the normal platelet counts found in patients with intrinsic platelet disorders, the increment in platelets is not necessarily a good measure of the response to therapy because a nearly normal number of abnormal platelets will remain in the circulation. Improvement in the hemostatic abnormality may not become evident until a large proportion of the platelets are replaced by normal platelets from transfusion.

Type 2N von Willebrand Disease

Type 2N VWD is the result of an abnormal VWF molecule with reduced binding of factor VIII.[74,370,371] This leads to accelerated clearance of the unbound factor VIII and a resultant reduction in plasma factor VIII as compared with the level of VWF.[372] In fact, mild hemophilia A may be misdiagnosed in some of these patients. It appears that the phenotype is clinically expressed only in the presence of a second allele carrying a *null* allele or a second type 2N VWD allele (see Fig. 30-5). Therefore, if the plasma VWF level is reduced modestly and the factor VIII level is even more reduced or if a patient with mild hemophilia A is given factor VIII and the half-life is markedly shortened, type 2N VWD should be considered. A specific assay has been developed in which the patient's VWF is captured with a monoclonal antibody in a microtiter well, factor VIII is removed by changes in pH or salt concentration or the addition of thrombin, and binding of recombinant factor VIII is determined. Decreased affinity is the hallmark of type 2N VWD (see Fig. 30-5).[74,240,302] Because symptomatic patients are either homozygous or compound heterozygous, administration of desmopressin might have only a transient effect on factor VIII levels.[372] Administration of recombinant or monoclonal factor VIII would similarly have only transient effects. For a major bleeding episode or for preparation for surgery, the preferred treatment is a plasma-derived VWF/factor VIII concentrate.

Type 2M von Willebrand Disease

Type 2M VWD is the result of a mutation in VWF that decreases the interaction of VWF with the platelet GPIb receptor, thereby resulting in reduced VWF:RCo—the converse of that seen with type 2B VWD.[290,291,373,374] Similar to type 2A, plasma VWF exhibits discordance between VWF:Ag and VWF:RCo (see Fig. 30-3), but patients with type 2M VWD have normal VWF multimers, whereas those with type 2A VWD have abnormal multimers. If the VWF:Ag and VWF:RCo assays are carefully standardized, the ratio of VWF ristocetin cofactor to VWF antigen may be used to diagnose type 2M VWD. Figure 30-5 demonstrates the relationship of these two assays in 690 persons with normal VWF multimers and VWF:Ag or VWF:RCo levels of less than 55 IU/dL. The VWF protein can be released by DDAVP, but the released VWF exhibits abnormal interaction with platelets. Thus, for major bleeding episodes or in preparation for surgery, replacement therapy with VWF concentrates should be given. Recently, a study of type 1 VWD in two large cohorts has identified patients with mild type 2M VWD,[218,227,375] but whether clinical treatment is different in these patients will require additional study.

Acquired von Willebrand Disease

Acquired VWD may be caused by at least three pathophysiologic mechanisms: (1) an acquired clinical state such as hypothyroidism resulting in decreased VWF synthesis, (2) an acquired autoimmune state in which an autoantibody develops against VWF and results in accelerated clearance of VWF (and usually factor VIII), or (3) a clinical disease develops in which VWF structure and function may be altered.

Congenital or acquired hypothyroidism can result in reduced VWF and bleeding symptoms.[318,376-379] Treating these patients to make them euthyroid results in normalization of the VWF level. If acute bleeding is present, the patient can generally be managed as would a patient with type 1 VWD—by administration of DDAVP or VWF concentrate. In hypothyroid patients, the VWFpp level is usually reduced in parallel with the VWF level and suggests normal clearance of VWF.

Acquired VWD can also be the result of an isolated acquired autoantibody to VWF, autoantibody to VWF in autoimmune diseases (e.g., systemic lupus erythematosus), or monoclonal gammopathies.[380-382] Assays for an inhibitor of VWF:RCo activity are generally negative because the autoantibody is directed against other regions of VWF and promotes only clearance. An abnormal VWFpp/VWF:Ag ratio can be used to demonstrate increased clearance of VWF.[235,299,383] In monoclonal gammopathies, VWF multimers may demonstrate loss of high-molecular-weight multimers.[384-387] Either plasmapheresis or a trial of intravenous immunoglobulin, or both, may sometimes be beneficial.[388,389] Desmopressin may also induce a transient rise in the VWF level, but its survival may be markedly reduced. Recently, some success has been achieved with recombinant VIIa.[390-392]

Wilms' tumor has been reported to cause acquired VWD. In at least one case, synthesis of VWF was still present in endothelial cells in the removed kidney, and in another study, the elevated hyaluronidase resulted in a reduced amount of VWF by Laurell quantitative immunoelectrophoresis.[393-396] Acquired loss of high-molecular-weight VWF multimers has been identified in children with ventricular septal defects[294] and in others with pulmonary hypertension.[397-399]

Von Willebrand Disease without Known Subtyping

Occasionally, a clinician is called on to treat VWD when the appropriate subtype is not known and the patient's acute condition does not permit taking the time to collect appropriate samples to determine the subtype. In such instances, a blood sample should be obtained for appropriate subtyping of VWD, followed by a carefully monitored therapeutic trial of desmopressin, VWF concentrates, or both. The response to such treatment should be monitored by close observation of the platelet count and the response of VWF activity and its survival. In a patient with known but untyped VWD and major

hemorrhage, VWF/factor VIII concentrates are probably the preferred treatment. This therapeutic approach will appropriately treat all forms of VWD, with the exception of platelet-type pseudo-VWD. The use of desmopressin may be either ineffective or exacerbate thrombocytopenia in patients with type 2A or 2B VWD, respectively.

Thus, therapy for VWD must be closely integrated with the correct laboratory diagnosis and often requires intensive laboratory evaluation through one episode of the treatment. However, once an appropriate response is obtained with a given therapy, laboratory monitoring can be greatly curtailed.

General Comments on the Treatment of von Willebrand Disease

Although the previous section presents the current clinical approach to VWD, many unanswered questions remain. Our current clinical approach may overdiagnose type 1 VWD because of the presence of low plasma VWF levels (see the earlier section on low VWF versus type 1 VWD). Because these patients in general have a preexisting history of excessive bleeding, we do not always know the contribution of their low VWF to these symptoms. We therefore generally treat them as having VWD. However, in postsurgical states in normal individuals, it is not uncommon to have VWF and factor VIII levels in excess of 200 to 300 IU/dL, yet we usually focus our therapy only to achieve a hemostatic level above 60 to 100 IU/dL. Whether the normal postsurgical elevation is a pathologic state brought on by surgical stress or a physiologic response to adapt to the surgical stress remains unknown. Normally, VWF is present in plasma, endothelial cells, platelets, and subendothelial matrix. When we treat a patient with type 3 VWD, we normalize only plasma VWF; endothelial cells, platelets, and subendothelium remain abnormal and their relative contribution to hemostasis is not fully defined. If clinical bleeding continues in the absence of adequate plasma VWF and factor VIII, consideration should be given to platelet transfusion as a means of providing normal platelet VWF.[400]

Future of Gene Therapy for von Willebrand Disease

Although effective gene therapy for hemophilia has still not been realized, VWD gene transfer into endothelial cells ex vivo has been achieved.[401-403] Some of the early studies using chimeraplasty offered potential hope for bypassing some of the point mutations that result in VWD.[404] More recent studies have brought into question whether this approach will optimally be successful.[405]

In the porcine model of VWD, bone marrow transplantation has been demonstrated to be a successful means of replacing platelet VWF; however, platelet VWF does not result in a detectible level in plasma even thought there may be some benefit from platelet VWF alone.[406-409]

31 Rare Hereditary Coagulation Factor Abnormalities

Kenneth A. Bauer

Although von Willebrand's disease, hemophilia A, and hemophilia B represent the majority of hereditary bleeding disorders caused by clotting factor deficiencies, hereditary abnormalities of other coagulation factors may occasionally be encountered. Each of these latter disorders is reviewed in the following chapter; however, the reader is referred to reviews or hemostasis texts in the references for a more complete description of these abnormalities.

FIBRINOGEN DISORDERS

Fibrinogen deficiency states (afibrinogenemia and hypofibrinogenemia) and hereditary functional abnormalities of fibrinogen (dysfibrinogenemias) are infrequently encountered but should be considered when a prolonged thrombin time (TT) is found in a patient with a bleeding history who is otherwise essentially healthy. Prolongations of the prothrombin time (PT) and activated partial thromboplastin time (APTT) are found in patients with afibrinogenemia, in severely hypofibrinogenemic patients, and in patients with some types of dysfibrinogenemia.

Hypofibrinogenemia and Afibrinogenemia

Genetic abnormalities causing decreased fibrinogen synthesis may occur either as a heterozygous deficiency (hypofibrinogenemia) or as a homozygous deficiency (afibrinogenemia).[1] Clinical findings include ecchymoses, hemarthroses, and subcutaneous hematomas. Patients with a virtual absence of fibrinogen are frequently seen in the neonatal period with gastrointestinal bleeding, hemorrhage, or major hematomas from delivery trauma. Surprisingly, symptoms in patients with afibrinogenemia are not as severe as those seen in the classic hemophilic disorders.

Laboratory evaluation of a patient with afibrinogenemia reveals prolongations of the TT, PT, and APTT (see Chapter 28). With automated clotting instruments, the amount of fibrin clot needed for clot detection is greater than that needed with manual methods. Thus, these tests are frequently prolonged to the limits of the instrument even though some fibrinogen may be present and a clot detected by manual methods. Because fibrinogen is the ligand for the glycoprotein IIb-IIIa receptor that enables platelet aggregation, both the bleeding time and platelet aggregation tests are usually abnormal. Interestingly, in the absence of fibrinogen, von Willebrand factor is able to bind to the glycoprotein IIb-IIIa complex on platelets and provides a backup mechanism for platelet aggregation.[2,3] This may result in a reduction in symptoms associated with this disorder. In many patients, a small amount of platelet fibrinogen might facilitate some of these interactions, although this fibrinogen is not believed to be derived from synthesis by megakaryocytes.

Thus, the presence of fibrinogen in platelets may result from the acquisition of a small amount of fibrinogen that is acquired from plasma by circulating platelets. The best screening tests to detect fibrinogen deficiency are the TT and reptilase time, which measure the time required for conversion of fibrinogen in plasma to a fibrin clot. Reptilase is a thrombin-like enzyme obtained from snake venom. Unlike the TT, the reptilase time is unaffected by heparin treatment. Thus, if one encounters a very prolonged TT, the possibility of heparinization must be considered, but marked prolongation of the reptilase time is suggestive of fibrinogen deficiency. Fibrinogen may be detected by functional, precipitation, or immunologic assays. However, patients with afibrinogenemia generally have undetectable levels of fibrinogen.

Clinical bleeding episodes in patients with afibrinogenemia, similar to those observed in hemophilia, require episodic replacement therapy. Because of the long plasma half-life of fibrinogen, prophylactic infusions of fibrinogen should be considered in patients with severe symptoms. The only readily available sources of fibrinogen are fresh frozen plasma and cryoprecipitate.[4] Cryoprecipitate is currently the most practical source for replacement and contains approximately 200 mg of fibrinogen per bag, or "unit," of cryoprecipitate. Hemorrhagic symptoms are usually controlled by initially achieving plasma levels of 80 to 100 mg/dL and maintaining this level above 50 to 60 mg/dL until the bleeding subsides. To raise the fibrinogen level in an afibrinogenemic patient to 100 mg/dL, approximately 0.17 unit of cryoprecipitate per kilogram of body weight must be infused. Because of the prolonged half-life of fibrinogen, replacement therapy can be given at intervals of 3 to 4 days.

Dysfibrinogenemia

Numerous dysfibrinogenemias have been reported and are named after the city in which they were originally identified.[1] Dysfibrinogenemias are associated either with no clinical symptoms or with hemorrhage, whereas others, interestingly, are associated with a predisposition to venous or arterial thrombosis (see Chapter 32). Functional abnormalities of fibrinogen are generally inherited in an autosomal dominant manner. Occasionally, however, index cases are associated with consanguinity and major hemorrhagic or thrombotic symptoms. Hereditary dysfibrinogenemia that is associated with hemorrhage usually results in a prolonged TT. Laboratory evaluation for dysfibrinogenemia includes functional and immunologic assays for fibrinogen, which should show a normal level of fibrinogen antigen with a reduction in fibrinogen when measured by functional coagulation assays. The reptilase time may also be prolonged. An occasional individual with dysfibrinogemia may have a prolonged PT or APTT. The inability of some abnormal fibrinogen to clot completely in vitro can result in false-positive results in fibrin(ogen) degradation product tests. Infusion of fibrinogen in the form of cryoprecipitate may be indicated in

patients with clinical bleeding, and survival of this fibrinogen can be expected to be normal. Further evaluation usually requires the assistance of a specialized laboratory that studies fibrinogen at the molecular level.

A small number of variant fibrinogens have been reported in association with thrombotic complications.[1] These defects can be detected with the TT and reptilase time, which are often prolonged. Occasionally, the TT is substantially shortened.[5,6] Functional fibrinogen measurements are generally substantially lower than antigenic measurements in the plasma of these individuals, similar to those in patients with a hemorrhagic tendency. Severe liver disease is occasionally associated with acquired dysfunction of fibrinogen.[7] Studies usually demonstrate that this is not hereditary in nature, and the liver disease is generally overt.

PROTHROMBIN DEFICIENCY

Hereditary prothrombin deficiency, similar to congenital abnormalities of fibrinogen, may be present either as a markedly reduced prothrombin level (hypoprothrombinemia) or as an abnormal prothrombin (dysprothrombinemia).[8] Congenital hypoprothrombinemia results in levels of prothrombin as low 6 U/dL. A variety of dysprothrombinemias have been reported that are associated with abnormalities in calcium binding and γ-carboxylation, although specific abnormalities in the thrombin portion of the molecule have also been reported. Symptoms generally consist of post-traumatic hemorrhage and mild mucocutaneous bleeding. However, one child with a dysprothrombinemia lost approximately 20% of his blood volume into his thigh after a routine injection of diphtheria and tetanus toxoid and pertussis (DPT) vaccine given at 6 weeks of age.[9] Although the APTT may be slightly prolonged, the hallmark is usually a prolonged PT and a normal TT. In some cases of dysprothrombinemia, such as prothrombin Cardeza, the PT may be nearly normal (12 seconds) even though prothrombin activity is markedly reduced.[10] Thus, specific assays comparing the immunologic levels of prothrombin with the functional levels of prothrombin are required to diagnose dysprothrombinemias. The lack of deficiencies of other vitamin K–dependent factors (factors VII, IX, and X) and liver-dependent factors (factor V and fibrinogen) usually direct attention to the diagnosis of a hereditary deficiency of prothrombin. Immunoassays and assays of electrophoretic mobility help identify dysprothrombinemia.

Although prothrombin is contained in prothrombin complex concentrates, fresh frozen plasma is generally effective in decreasing hemorrhagic symptoms because of the 60-hour plasma half-life of prothrombin. Treatment can therefore be accomplished without significant volume overload. Achievement of plasma levels of prothrombin in excess of 20 to 30 U/dL is usually associated with cessation of symptoms.

Factor V Deficiency

Factor V deficiency, first reported by Owren in 1947 and termed parahemophilia, is associated with a mild to moderate bleeding disorder.[11] It is transmitted autosomally and is generally symptomatic only in the homozygous or doubly heterozygous state. Mucocutaneous bleeding and hematomas are the most common symptoms, and hemarthroses are rarely encountered. Menarche is frequently associated with severe menorrhagia. Both the PT and the APTT are prolonged, which usually prompts specific factor assays. Immunoassays for factor V are not readily available, and thus most cases are defined by functional deficiencies of factor V with the use of clotting assays.

Clinical bleeding can be controlled with fresh frozen plasma, the only currently available source of factor V. Normal hemostasis is achieved with levels above 25 U/dL. In a patient with severe factor V deficiency, hemostasis can be achieved with a loading dose of 20 mL of plasma per kilogram of body weight followed by infusions of approximately 6 mL/kg every 12 hours. Because factor V is more labile in frozen plasma than other hemostatic factors are, it is important to use fresh frozen plasma that is less than 1 to 2 months old.

Occasionally, one may encounter a patient with an acquired antibody to factor V who has a negative family history. Even though the PT is markedly prolonged, some of these patients do not have major hemorrhagic symptoms.[12] In rare instances, antibodies to factor V arise in patients with congenital absence of factor V. This latter group of patients is, of course, quite symptomatic but can generally be managed by infusing fresh platelets that contain normal platelet factor V.

Combined Deficiency of Factor V and Factor VIII

More than 50 pedigrees with an autosomal recessive bleeding disorder characterized by a combined deficiency of both factor V and factor VIII have been reported.[13-15] In some cases, the mutations responsible for this disorder are in the *LMAN1* gene (also known as endoplasmic reticulum [ER]-Golgi intermediate compartment protein or ERGIC-53), which functions as a molecular chaperone from the ER to the Golgi apparatus in the biosynthesis of both factor V and factor VIII.[16,17] In other kindreds, this disorder is associated with mutations in the multiple coagulation factor deficiency 2 gene.[18] *MCFD2* encodes a protein that forms a calcium-dependent stoichiometric complex with LMAN1 and acts as a cofactor in the intracellular trafficking of factors V and VIII. The disease is associated with a moderate bleeding tendency and plasma factor V and factor VIII levels of 5% to 30% of normal. Combined factor V and factor VIII deficiency is usually accompanied by fewer symptoms than hemophilia A is, but when required, hemostasis can generally be achieved with fresh frozen plasma.

Factor X Deficiency

Factor X deficiency is a rare autosomal disorder that results in mucocutaneous and post-traumatic bleeding.[8] Deficiency of factor X may be caused by either a deficiency of factor X antigen or a functionally abnormal factor X molecule. Both cause prolongation of the PT and APTT. A reduced factor X level is identified by a factor X clotting assay. In patients with dysfunctional factor X, the factor X clotting assay is prolonged, but results of the immunoassay are normal.[19,20] Russell viper venom contains a procoagulant enzyme that can activate factor X, thereby bypassing the need for clotting factors other than factor X, factor V, prothrombin, and fibrinogen. Some dysfunctional factor X molecules may be associated with normal Russell viper venom times and thus will be detected only by PT assay in affected family members.

The biologic half-life of factor X is about 40 hours. Infusion of approximately 20 mL of fresh frozen plasma per kilogram of body weight followed by 6 mL/kg every 12 hours increases the level of factor X sufficiently to achieve hemostasis for minor bleeding episodes. In instances when major surgery must be undertaken, prothrombin complex concentrates can be used to correct the factor X deficiency. However, the amount of factor X is not usually assayed in these products and they can be thrombogenic. If elective surgery is anticipated and it is decided to use prothrombin complex concentrate, several different preparations should be obtained and measured for their content of factor X. Although factor X is a vitamin K–dependent factor, vitamin K has no therapeutic effect on factor X in congenitally deficient patients. Factor X levels of 20 to 30 U/dL are generally associated with the cessation of hemorrhagic symptoms.

Though not usually a pediatric problem, amyloidosis may be associated with factor X deficiency because of adsorption of factor X to the amyloid material.[21,22] Therapeutic infusions are not generally efficacious in patients with acquired deficiency of factor X secondary to amyloidosis.

Factor VII Deficiency

Factor VII deficiency has an estimated incidence of 1 per 500,000 in the general population and an autosomal recessive pattern of inheritance. The hemorrhagic predisposition in affected patients is highly variable and correlates poorly with plasma factor VII activity levels.[23,24] Patients with levels that are less than 1% of normal can experience severe bleeding episodes, including hemarthroses and crippling arthropathy, comparable to patients with the classic hemophilias. Neonates with factor VII deficiency are at increased risk for the development of intracranial hemorrhage, which is attributable to trauma at the time of delivery.[23]

Hemostasis screening tests in patients with factor VII deficiency reveal a prolonged PT with a normal PTT and a normal TT. Heterozygotes typically have normal PTs and are identified only after specific factor VII assays are performed in family members of patients with homozygous or compound heterozygous factor VII deficiency. Heterozygous deficiency is not usually associated with hemorrhagic symptoms. Laboratory evaluation of factor VII deficiency relies on specific assay of plasma factor VII coagulant activity (VII:C) with the use of animal or human thromboplastin, as well as immunologic quantitation of factor VII antigen.[25,26] Patients have been categorized by their plasma level of factor VII antigen (VII:Ag) or cross-reacting material (CRM⁻, low or absent antigen; CRM^R, reduced antigen; CRM⁺, normal antigen). CRM⁻ defects result from defective factor VII biosynthesis or accelerated clearance in vivo, CRM⁺ defects are structurally abnormal factor VII molecules, and CRM^R defects may result from a combination of these mechanisms. Some CRM^R or CRM⁺ factor VII molecules give variable VII:C results when assayed with tissue factor from different animal species (e.g., rabbit brain, ox brain, simian brain, human brain).[24,27-29] As anticipated, the molecular basis of factor VII deficiency is heterogeneous, and several different types of mutations have been described in patients with factor VII deficiency.[30] Most have been missense mutations, but nonsense mutations, small deletions, splice site abnormalities, and promoter mutations have also been identified.

Factor VII is a vitamin K–dependent factor, but vitamin K administration is of no therapeutic benefit in the treatment of hereditary deficiencies. Although commercial prothrombin complex concentrates may contain some factor VII, the amount is highly variable among the different commercial preparations. The factor VII content also varies between different lots produced by a single manufacturer. Because the plasma half-life of factor VII is short (approximately 3 to 6 hours), plasma infusions may not achieve adequate levels for normal hemostasis. Factor VII concentrates have been available for patients with factor VII deficiency in clinical trials or on a compassionate-use basis.[31] The use of activated recombinant factor VII, which has a half-life similar to that of factor VII, has also been shown to provide effective hemostasis in patients with factor VII deficiency[32] and has received regulatory approval for this indication in the United States. Anecdotally, the therapeutic effect of factor VII infusions appears to be longer than the time during which measurable factor VII levels can be identified in plasma. In one patient treated with prothrombin complex concentrates on a regular basis, mucocutaneous bleeding was controlled for 3 to 4 days after a single infusion, even though factor VII was not measurable after 24 hours. Whether this results from surface binding of factor VII to endothelial cells or platelets, removal of it from plasma, or some nonspecific effect from the concentrate infusion was not clear.

Factor XI Deficiency

Factor XI deficiency is usually inherited as an autosomal recessive disorder. The APTT is prolonged in factor XI deficiency, whereas the PT is normal. A specific assay for factor XI coagulant activity is necessary to make the diagnosis. Factor XI assays are best performed on fresh plasma because the apparent factor XI level may be increased after freezing plasma.[33]

Although factor XI deficiency is most frequently encountered in Jewish persons of Ashkenazi descent, it is occasionally found in other ethnic groups, and the mutations have been characterized.[34-36] In Israel, 1 to 3 per 1000 Ashkenazi Jews are homozygous or doubly heterozygous for this deficiency, which calculates to a gene frequency of 4.3%.[37] Sephardic Jews, on the other hand, are rarely affected by factor XI deficiency. Three different point mutations in the factor XI gene account for nearly all cases of factor XI deficiency in Ashkenazi Jews: a splice site mutation at the last intron that disrupts normal mRNA processing (type I), a nonsense mutation in exon 5 resulting in a premature stop codon (type II), and a missense mutation in exon 9 resulting in substitution of Leu for Phe at amino acid 238.[38] Although the genotype correlates well with plasma factor XI levels, there is not good correlation with the hemorrhagic tendency.[39] In Ashkenazi Jewish patients who are homozygous or doubly heterozygous for factor XI deficiency, the APTT is often longer than it is in patients with either severe factor VIII or factor IX deficiency.

Although factor XI deficiency has been termed *hemophilia C*, the bleeding tendency is highly variable and bleeding almost always occurs in association with surgery or trauma. Epistaxis, soft tissue hemorrhage, and bleeding after dental extractions may occur, but hemarthroses and concomitant arthropathy are not seen. Affected women may experience menorrhagia. Even though low factor XI levels are not always associated with bleeding, patients with a significant personal or familial history of bleeding should probably receive fresh frozen plasma before major surgery. In the absence of such a history, prophylaxis with fresh frozen plasma should probably be administered for ear, nose, and throat (e.g., tonsillectomy), neurosurgical, cardiac, or urologic procedures. Patients who have previously undergone major surgery without bleeding or who are having minor procedures that can be controlled easily by local pressure (e.g., dental extraction) may be monitored closely and treatment initiated only if hemorrhage occurs. Heterozygous patients with factor XI levels greater than 20% of normal may also occasionally experience bleeding.[40]

Plasma infusions of 1 U/kg body weight can increase the circulating factor XI concentration by about 1.5 U/dL. A loading dose of 15 to 20 mL of plasma per kilogram will result in plasma levels of 20 to 30 U/dL, a level that is usually sufficient to control moderate hemorrhage. Additional plasma infusions of 7.5 to 10 mL/kg can be administered at 12- to 24-hour intervals until hemostasis is achieved. The half-life of factor XI is in excess of 48 hours. In factor XI–deficient patients deemed to be at risk for bleeding, antifibrinolytic agents such as ε-aminocaproic acid or tranexamic acid can be used to prevent hemorrhage after minor surgical procedures (e.g., dental extractions).

Factor XIII Deficiency

Factor XIII (fibrin-stabilizing factor) is responsible for clot stabilization and cross-linking of the fibrin polymer. Deficiency of this factor is associated with reduced clot stability.[41] Factor XIII deficiency is an autosomal recessive disorder that results in delayed hemorrhage. A typical patient will sustain trauma on one day, and a bruise or hematoma will develop on the following day. Other symptoms of factor XIII deficiency include delayed separation of the umbilical stump in the neonatal period (beyond 3.5 to 4 weeks), intracranial hemorrhage with little or no trauma, poor wound healing, and recurrent spontaneous abortions in women.

Laboratory evaluation reveals normal hemostasis screening test results, including bleeding time, APTT, PT, and TT. For a patient with normal screening test results but clinical symptoms of a bruising disorder, one should perform a factor XIII assay. Screening tests for factor XIII deficiency are based on the observation that there is increased solubility of the clot because of the lack of cross-linking. Thus, a normal clot remains insoluble in 5 mol/L urea, whereas a clot formed from a patient with factor XIII deficiency is soluble.

Because factor XIII has a very long half-life of 5 to 7 days and a hemostatic level of only 2 to 3 U/dL is required, infusion of 5 to 10 mL/kg of fresh frozen plasma is usually effective therapy. Cryoprecipitate may also be used. One bag of cryoprecipitate contains 75 units of factor XIII. If a patient is particularly symptomatic, prophylaxis is also easily achieved with infusions of plasma every 2 to 4 weeks.

Contact Factor Deficiencies

Although factor XI deficiency may be associated with bleeding symptoms, deficiency of the other contact factors (factor XII, prekallikrein, and high-molecular-weight kininogen) is not associated with bleeding symptoms.[42,43] Thus, these factors do not appear to play a major physiologic role in normal hemostasis (see Chapter 26). Because these contact factors function at the initiation step of the intrinsic system, the APTT in severely deficient individuals (contact factor activity less than 1% of normal) frequently demonstrates prolongations beyond those seen with hemophilia A and hemophilia B. As a result, one encounters the paradoxical situation in which an extremely prolonged PTT is not associated with a bleeding disorder.

The clinician usually encounters contact factor deficiency when asked to evaluate a patient without bleeding

symptoms who has a markedly prolonged APTT obtained as a preoperative screening test. It is frequently advisable to carry out these same screening tests on other family members once the specific contact factor deficiency is determined to identify affected family members who could have future surgery inappropriately delayed because of such clotting studies.

Paradoxically, there have been a number of case reports of venous thromboembolism or myocardial infarction in factor XII–deficient patients,[44] including the initial patient described with the abnormality.[45] This thrombophilic tendency has been attributed to reduced plasma fibrinolytic activity.[46] A literature review of 121 patients with factor XII deficiency found an 8% incidence of thromboembolism, including several myocardial infarctions in relatively young individuals.[44] Interpretation of such data is difficult because these complications are likely to be reported in the literature, unlike asymptomatic patients with factor XII deficiency. This led some groups to perform cross-sectional analyses of thromboembolic events in larger numbers of unselected families with factor XII deficiency.[47,48] In Swiss families with factor XII deficiency, 2 of 18 homozygous or doubly heterozygous patients had sustained deep venous thrombosis, although each occurred at a time that other predisposing thrombotic risk factors were present.[47] Among heterozygotes with factor XII deficiency, only 1 in 45 had a possible history of venous thrombosis. These investigators concluded that heterozygous factor XII deficiency does not constitute a major thrombotic risk factor, although a severe deficiency may predispose some affected persons to venous thrombosis. Other groups have found a 10% to 20% incidence of thrombotic episodes in heterozygotes.[48,49] Thus, it remains uncertain whether an increased thrombotic risk is associated with factor XII deficiency.

ANTIPLASMIN DEFICIENCY

Antiplasmin is a major regulatory protein that controls the activity of plasmin, the pivotal enzyme in the fibrinolytic system that cleaves fibrin. In familial α_2-antiplasmin deficiency, the plasmin activity generated under physiologic conditions is poorly regulated and results in a bleeding disorder.[50] These patients have mucocutaneous bleeding as well as joint hemorrhage and must be differentiated from those with mild hemophilia. The usual hemostatic screening test results are normal, including the PT, APTT, and TT. The euglobulin clot lysis time, a measure of fibrinolytic activity, is generally shortened. Although fresh frozen plasma contains α_2-antiplasmin, this clinical disorder is most commonly treated with the intermittent administration of antifibrinolytic agents, including ε-aminocaproic acid and tranexamic acid.

Plasminogen Activator Inhibitor 1 Deficiency

Deficiency of plasminogen activator inhibitor 1 (PAI-1) has been shown to cause a hereditary bleeding disorder.[51,52] In one homozygous case, the genetic defect was shown to be a frameshift mutation.[53] Affected patients can experience recurrent bleeding, especially after surgery or trauma. The PT, APTT, and TT are normal in such patients. The euglobulin clot lysis time can be abnormally short. Specific assays for PAI-1 antigen and activity are required to make a diagnosis of PAI-1 deficiency. Treatment with antifibrinolytic agents, such as tranexamic acid and ε-aminocaproic acid, is effective in treating bleeding complications.

Antitrypsin Pittsburgh

Antitrypsin is not normally a significant regulatory protein of hemostasis. A family has been described, however, with an alteration in the α_1-antitrypsin molecule such that the protein has spontaneous antithrombin activity.[54] Continuous inactivation of thrombin results in delayed clot formation and a hemorrhagic syndrome that like α_2-antiplasmin deficiency, resembles mild hemophilia. Therapy for a disorder in which there is excessive activity is often more difficult than replacement of a protein in a patient with a familial deficiency.

MULTIPLE FACTOR DEFICIENCIES

Hereditary deficiencies of multiple factors are rare clinical disorders that are associated with a bleeding diathesis of variable severity. Combined deficiency of the vitamin K–dependent factors (i.e., factors II, VII, IX, and X) can result from deficient vitamin K–dependent γ-carboxylase activity, which mediates post-translational modifications of these proteins,[55,56] or defective vitamin K metabolism secondary to mutations in vitamin K 2,3-epoxide reductase (VKOR).[57] VKOR is the target of the oral anticoagulant warfarin. As mentioned earlier, factor V and factor VIII deficiency has been reported in more than 50 families. In general, when a patient with multiple factor deficiencies is identified, it is imperative to rule out acquired causes such as liver disease or vitamin K deficiency and to perform a family study before one assumes that such a defect is hereditary.

32 Inherited Disorders of Thrombosis and Fibrinolysis

Kenneth A. Bauer

For many years, researchers suspected that hereditary coagulation defects underlie a large percentage of venous thromboembolic events that could not be attributed to identifiable acquired risk factors. Acquired risk factors for venous thrombosis consist of a heterogeneous group of conditions and clinical disorders with diverse and poorly understood prothrombotic mechanisms. With expanding scientific knowledge of the hemostatic mechanism and the regulatory role of natural anticoagulants, major advances have been made in identifying hereditary defects in the heparan sulfate–antithrombin and protein C pathways over the last 3 decades. This chapter reviews the hereditary disorders of thrombosis and fibrinolysis associated with an increased risk for thrombosis. Issues relating to diagnosis and treatment of the hereditary thrombophilias are also discussed.

HEREDITARY THROMBOTIC DISORDERS
(Box 32-1)

Before 1980, there were only isolated reports of thrombosis in the pediatric population. This paucity of thrombotic events might be related to the incompletely understood protection against thrombosis in young children through the mid-teen years, notwithstanding the fact that some of the physiologic inhibitors do not attain their full normal adult levels until mid-childhood (protein C and protein S) (see Chapters 5 and 28). Even patients with hereditary deficiencies of natural physiologic anticoagulants, such as antithrombin, protein C, and protein S, have few thrombotic symptoms during early childhood. Over the past 30 years, however, more vigorous supportive and specific treatment for sick preterm infants has resulted in a markedly improved survival rate of even very preterm infants. Because these infants are quite prone to thrombotic events, the physiologic "hypercoagulability" of the developing hemostatic system has received increased attention and is discussed elsewhere (see Chapter 5). Thus, the newborn infant can be expected to be at greater risk for thrombosis if there is also an underlying hereditary deficiency of an anticoagulant protein.

Antithrombin Deficiency

Antithrombin is a plasma protein synthesized by the liver that binds and neutralizes the serine proteinases generated by the coagulation cascade, including thrombin, factor Xa, and factor IXa (see Chapter 26). Inhibition of these coagulation serine enzymes by antithrombin is relatively slow but is markedly enhanced by binding to heparin. Antithrombin has two major active functional sites: the reactive center toward the carboxyl end and the heparin-binding site located at the amino-terminal of the molecule. Thrombin cleaves the reactive site followed by the formation of an inactive complex, which is rapidly cleared from the circulation.

Antithrombin deficiency was the first hereditary hypercoagulable disorder identified. In 1965, Egeberg investigated a Norwegian family with a strong history of thrombosis and found that affected individuals had plasma antithrombin concentrations that were 40% to 50% of normal.[1] Subsequent studies described families with similar clinical and laboratory abnormalities.[2,3] Heterozygosity for antithrombin deficiency can be found in approximately 4% of families with inherited thrombophilia and in 1% of consecutive patients with a first episode of deep venous thrombosis.[4]

The thrombotic risk associated with antithrombin deficiency depends on the population selected. In older reviews of antithrombin deficiency that included families with a high penetrance of thrombosis, more than 50% of affected patients experienced venous thrombotic episodes.[5,6] The initial clinical manifestations occur spontaneously in about 42% of subjects but are related to pregnancy, parturition, ingestion of oral contraceptives, surgery, or trauma in 58% of patients.[5] The most common sites of disease are the deep veins of the leg and the mesenteric veins. Recurrent thrombotic episodes occur in approximately 60% of affected persons, and clinical signs of pulmonary embolism are evident in 40%.[5] Although cases have been reported in which antithrombin-deficient infants sustained cerebral venous thrombosis,[7-9] thrombotic episodes are rare in affected children before puberty, at which time thrombotic events start to occur with some frequency and the risk of thrombosis increases substantially with advancing age.[5] First-degree relatives of symptomatic individuals with antithrombin deficiency have an 8- to 10-fold increased risk for thrombosis over that in noncarriers.[10,11] In the Leiden Thrombophilia Study, a case-control study of 474 consecutive patients after an initial episode of deep venous thrombosis,[12] the prevalence of antithrombin deficiency was just 1.1%, and the odds ratio for thrombosis was 5.0.[13]

Antithrombin deficiency is inherited in an autosomal dominant fashion and thus affects both sexes equally. Two major types of inherited antithrombin deficiency have been delineated (Table 32-1). The type I deficiency state is a result of reduced synthesis of biologically normal protease inhibitor molecules.[14] In these cases the antigenic and functional activities of antithrombin in blood

are reduced in parallel. The molecular basis of this disorder is either deletion of a major segment of the antithrombin gene or, more commonly, the occurrence of small deletions/insertions or single base substitutions. These mutations introduce a frameshift, a direct termination codon, a change in mRNA processing, or unstable translation products. The antithrombin mutation database includes more than 100 distinct mutations in patients with type I deficiency.[15]

The second type of antithrombin deficiency is produced by a discrete molecular defect within the protease inhibitor (type II). Plasma levels of antithrombin are greatly reduced as judged by functional activity, whereas antithrombin immunologic activity is essentially normal. The first family with type II antithrombin deficiency was described in 1974.[16] Many families with this type of deficiency state have been reported, and they have been further subcategorized on the basis of two different functional assays of antithrombin activity. The first is the antithrombin–heparin cofactor assay, which measures the ability of heparin to bind to lysyl residues on the inhibitor and catalyze the neutralization of coagulation enzymes such as thrombin and factor Xa. The second test is the progressive antithrombin activity assay, which quantitates the capacity of this inhibitor to neutralize the enzymatic activity of thrombin in the absence of heparin. Heterozygous type II patients with both diminished heparin cofactor activity and progressive antithrombin activity have mutations near the thrombin-binding site at the carboxy-terminal end of the molecule; those with reductions only in heparin cofactor activity have mutations in the heparin-binding domain at the amino-terminal end of the molecule. The distinction between type II defects is clinically relevant because variants with heparin–binding site defects are infrequently associated with thrombotic events, except when present in the homozygous state.[17] The latter patients with homozygous antithrombin deficiency were young children in whom severe venous or arterial thrombosis, or both, developed along with plasma antithrombin–heparin cofactor levels below 10%.[18,19] In each instance, there was a history of parental consanguinity and the parents had type II antithrombin deficiency with heparin–binding site defects.

The prevalence of type I antithrombin deficiency in the adult population is approximately 1 in 2000.[20,21] Studies of healthy blood donors with functional assays that measure heparin cofactor activity have found a preva-

lence of antithrombin deficiency in the general population of 1 in 250 to 1 in 500[22,23]; a substantial number, however, have a type II defect with mutations at the heparin-binding site.[21] The best single screening test for the disorder is the antithrombin–heparin cofactor assay, which measures inhibition of factor Xa; it is the functional antithrombin assay that is most widely used today.

The mean concentration of antithrombin in normal pooled plasma is approximately 140 µg/mL. Most laboratories report a normal range between 75% and 120% of normal pooled plasma for antithrombin–heparin cofactor determinations and a somewhat wider range for immunoassay results. A variety of pathophysiologic conditions can reduce the concentration of antithrombin in blood. Antithrombin levels can drop substantially in patients with disseminated intravascular coagulation (DIC), sepsis, burns, and severe trauma but less commonly in the setting of acute thrombosis.[24] Reduced levels can also be seen in liver disease as a result of decreased synthesis or in nephrotic syndrome as a result of urinary protein loss.[25,26] Modest reductions are also found in users of oral contraceptives or estrogens.[27,28] In addition, the administration of heparin decreases plasma antithrombin levels, presumably by accelerated clearance of the heparin-antithrombin complex.[29] Thus, evaluation of plasma samples from individuals during a period of heparinization can potentially lead to an erroneous diagnosis of antithrombin deficiency.

Healthy newborns have about half the normal adult concentration of antithrombin[30,31] and gradually reach the adult level by 6 months of age.[32] Levels may be considerably lower in infants born at 30 to 36 weeks of gestation[32] and are even further reduced in infants with respiratory distress, necrotizing enterocolitis, sepsis, or DIC.[33] Thromboembolic events are rare in children with hereditary antithrombin deficiency. In the absence of heparin, antithrombin contributes approximately 80% of the thrombin-neutralizing capacity of normal adult plasma.[34,35] The levels of a second thrombin inhibitor, α_2-macroglobulin, are higher during the first 2 decades of life than in adults, and this may lessen the risk for thromboembolic complications in antithrombin-deficient patients during childhood.[36]

A number of clinical disorders can be associated with reductions in the plasma concentration of antithrombin, thus often making a definitive diagnosis of the hereditary state difficult. Although an antithrombin level in the

normal range is usually sufficient to exclude the disorder, low levels should be confirmed at a later date. This determination is ideally performed when the individual is no longer receiving warfarin because plasma antithrombin concentrations can occasionally be elevated into the normal range in individuals with the deficiency state. In such situations, clinical assessment of the individual's risk for recurrent thrombosis will determine whether discontinuation of warfarin is feasible. In most antithrombin-deficient subjects, however, this effect of oral anticoagulants is not of sufficient magnitude to obscure the diagnosis.[37] Confirmation of the hereditary nature of the disorder requires the investigation of other family members. Diagnosis of other affected family members also allows appropriate counseling regarding the need for prophylaxis against venous thrombosis.

Protein C Deficiency

Protein C is a vitamin K–dependent protein synthesized by the liver that circulates as a zymogen. It exerts its anticoagulant function after activation to the serine protease activated protein C (APC). This process can be mediated by thrombin alone but occurs more efficiently when thrombin is bound to thrombomodulin on endothelial cells (see Chapter 26).

In 1981, Griffin and associates[38] described low levels of protein C in a family with recurrent thrombotic events. Subsequently, many other families with heterozygous protein C deficiency were reported.[39-41] Heterozygous protein C deficiency is inherited in an autosomal dominant fashion; a more severe form of protein C deficiency is an autosomal recessive disorder. The phenotype of patients with heterozygous protein C deficiency is similar to that of persons with hereditary antithrombin deficiency. In severely affected families, approximately 75% of protein C–deficient individuals experienced one or more thrombotic events. The initial episode occurs spontaneously in approximately 70% of those experiencing such events. The remaining 30% have the usual associated risk factors (pregnancy, parturition, contraceptive pill use, surgery, or trauma) at the time that the acute thrombotic events take place. Patients are infrequently symptomatic until their early twenties, with increasing numbers experiencing thrombotic events as they reach the age of 50.

The most common sites of disease are the deep veins of the legs, the iliofemoral veins, and the mesenteric veins. Approximately 63% of affected patients experience recurrent venous thrombosis, and approximately 40% exhibit signs of pulmonary embolism.[42] Superficial thrombophlebitis of the leg veins, as well as cerebral venous thrombosis, can occur in protein C–deficient patients.[39] There have been reports of nonhemorrhagic arterial stroke in young adults with hereditary protein C deficiency, but a causal relationship is unproven.

The prevalence of protein C deficiency in outpatients who have experienced an initial episode of venous thromboembolism ranges from 0.5% to 4%.[4,13,43] In earlier reports of more selected patient populations, protein C deficiency was more frequently identified and occurred in 2% to 9%. Initial estimates placed the prevalence of protein C deficiency between 1 in 16,000 and 1 in 32,000 within the general population based on the assumption that protein C was an autosomal dominant disorder with high penetrance and that at least half the individuals with the deficiency would demonstrate symptomatic thrombosis. However, it was difficult to reconcile this figure with the infrequent history of thrombosis in the parents of infants with purpura fulminans, which is due to the homozygous or doubly heterozygous form of protein C deficiency. This disparity led to studies of healthy blood donors in which a much higher prevalence of heterozygosity for protein C deficiency was found than previously estimated, with a range of 1 in 200 to 1 in 500.[44,45]

The risk of thrombosis initially attributed to protein C deficiency was subject to selection bias in that it was overestimated from familial reports. Data from the Leiden Thrombophilia Study indicate that heterozygous protein C deficiency is associated with about a sevenfold increased risk for an initial episode of deep venous thrombosis over that in normal persons.[13] Among Italian patients, protein C deficiency is associated with a similar sevenfold increase in venous thrombotic risk.[10] In asymptomatic carriers of protein C deficiency, the incidence of thrombosis is fairly low at 0.4% to 1.0% annually.[46] Similar to other inherited thrombophilias, this variability in phenotypic expression of protein C deficiency is not explained by differences in the particular genetic defect alone and probably represents a complex interaction with other modulating factors.

Two major subtypes of heterozygous protein C deficiency have been identified with the use of immunologic and functional assays (Table 32-2). The type I deficiency state is the most common form and is characterized by a reduction in both the immunologic and biologic activity of protein C to approximately 50% of normal. More than 195 different mutations have been identified, most commonly missense or nonsense mutations.[47] The functional or type II deficiency state is characterized by normal

synthesis of an abnormal protein. The functional capacity of protein C is most often assessed by using a snake venom protease (Protac)-based assay to directly activate the protein. After activation, an amidolytic assay can assess the functionality of the catalytic site of the protein. A few individuals have been described with normal levels of protein C antigen and amidolytic activity but with substantial reductions in protein C anticoagulant activity.[48] In such cases, protein C anticoagulant activity can be measured with a clotting assay (based on prolongation of the activated partial thromboplastin time [APTT]), and abnormalities presumably reflect a reduced ability of activated protein C to interact with the platelet membrane or its substrates such as factor Va and factor VIIIa. The coagulant assay thus has the highest sensitivity in screening patients for hereditary protein C deficiency.

Levels of protein C antigen in the heterozygous deficiency state overlap with those in the normal population, thus making it difficult to define the diagnosis in some patients. In general, antigen levels of 60% to 70% of normal represent borderline values and warrant repeat testing. Protein C antigen levels can also vary with age. Protein C levels in newborns are 20% to 40% of normal adult levels,[49] and preterm infants have even lower levels.[50] Neonates with significant perinatal thrombosis can have levels suggestive of homozygous deficiency.[51] In adults, protein C levels typically increase 4% per decade.[44]

Acquired protein C deficiency is found in numerous disease states, including liver disease, DIC, and sepsis. A particularly severe form of acquired protein C deficiency has been reported in association with purpura fulminans and DIC in individuals with acute meningococcal infections.[52,53] In contrast to antithrombin, antigenic concentrations of vitamin K–dependent plasma proteins, including protein C, are often elevated in individuals with nephrotic syndrome.[54] Most individuals with uremia have low levels of protein C anticoagulant activity but normal levels of protein C amidolytic activity and antigen.[55] This is attributable to a dialyzable moiety in uremic plasma that interferes with most clotting assays for protein C activity.[56]

As for other γ-carboxylase coagulation proteins (see Chapter 26), warfarin therapy reduces functional and, to a lesser extent, immunologic measurements of protein C, thus complicating diagnosis of the deficiency state.[48] Several researchers have proposed that the diagnosis can still be made in this setting based on the ratios of protein C antigen to factor II or factor X antigen. This method, however, will not detect patients with type II deficiency, and it can be used only in subjects in a stable phase of oral anticoagulation.[57] Other groups have used protein C activity assays in conjunction with functional measurements of factor VII, a vitamin K–dependent zymogen with a similar plasma half-life.[58] In practice, it is preferable to investigate individuals suspected of having the deficiency state after oral anticoagulation has been discontinued for at least 1 week and to perform family studies. If it is not possible to discontinue warfarin because of the severity of the thrombotic diathesis, such individuals can be studied while receiving heparin therapy, which does not alter plasma protein C levels.

Warfarin-induced skin necrosis has been associated with the presence of heterozygous protein C deficiency.[59-61] This syndrome typically occurs during the first several days of warfarin therapy, often in association with the administration of large loading doses of the medication. Skin lesions occur on the extremities, breasts, and trunk, as well as on the penis, and marginate over a period of hours from an initial central erythematous macule. If a product containing protein C is not administered rapidly, the affected cutaneous areas become edematous, central purpuric zones develop, and the lesions ultimately become necrotic. Biopsies demonstrate fibrin thrombi within cutaneous vessels with interstitial hemorrhage. The dermal manifestations of warfarin-induced skin necrosis are clinically and pathologically similar to those seen in infants with purpura fulminans resulting from severe protein C deficiency (see later).

The pathogenesis of warfarin-induced skin necrosis is attributable to the emergence of a transient hypercoagulable state. Initiation of the drug at standard doses leads to a decrease in protein C anticoagulant activity to approximately 50% of normal within 1 day.[48] Although factor VII activity follows a pattern similar to that of protein C, levels of the other vitamin K–dependent factors decline at slower rates, consistent with their longer half-lives. Increased thrombin generation has been documented in patients during this early phase of warfarin therapy.[62] During this period the drug's suppressive effect on protein C has a greater influence on the hemostatic mechanism than its reduction of factor VII does. These effects are augmented when a large–loading dose schedule (i.e., >10 mg of warfarin daily) is used to initiate oral anticoagulation or the patient has an underlying hereditary deficiency of protein C. However, only about a third of patients with warfarin-induced skin necrosis have an inherited deficiency of protein C,[63] and this complication is a rather infrequently reported event in individuals with the heterozygous deficiency state. This syndrome has been reported in association with an acquired functional deficiency of protein C.[64] There are also reports of hereditary protein S deficiency and the factor V Leiden mutation in association with warfarin-induced skin necrosis.[65-68]

The long-established syndrome of purpura fulminans is classically described as a complication of meningococcal infection in children. However, newborns rarely exhibit a syndrome of purpura fulminans, which is associated with laboratory evidence of DIC and protein C antigen levels less than 1% of normal.[69-78] In some instances there is a history of consanguinity in the family, thus making it highly likely that the affected infants were homozygous for the deficiency state.[70,73,76] Such newborns can also be double heterozygotes, as was demon-

strated in a Chinese patient[74] who had a five-nucleotide deletion in one protein C allele and a missense mutation in the other.[79] The heterozygous parents of infants with purpura fulminans in association with severe protein C deficiency only infrequently have thromboses, in contrast to patients with thrombotic histories and a hereditary partial deficiency of protein C. There are, however, numerous reports of older patients with homozygous or doubly heterozygous protein C deficiency in whom purpura fulminans was not present. These individuals generally have protein C levels under 20% of normal in the absence of oral anticoagulant therapy, and their clinical manifestations were similar to that of severely affected subjects from thrombophilic kindreds with the heterozygous deficiency state.[80,81]

Protein S Deficiency

Protein S is a vitamin K–dependent protein that enhances the anticoagulant effect of APC. Primarily synthesized by hepatocytes but also by endothelial cells, megakaryocytes, and brain cells, protein S serves as a cofactor for APC, which then inactivates factors Va and VIIIa. Factor Va inactivation occurs by an ordered series of peptide bond scissions in the molecule's heavy chain: first, rapid cleavage at Arg506 takes place, followed by slower cleavage at Arg306 and then Arg679 (see Chapter 26).[82] Interaction of protein S with APC results in both an increased affinity for negatively charged phospholipids and a 20-fold enhancement of the slower phase of factor Va inactivation. In plasma, only 40% of protein C is available in the "free" form, whereas the remainder is bound to C4b-binding protein and cannot interact with APC.

Protein S deficiency is an autosomal dominant disorder that was originally described in 1984 in several kindreds with low levels of protein S and a striking history of recurrent thrombosis.[83,84] There is a reported frequency of approximately 10% in families with inherited thrombophilia[10,85]; however, the prevalence is lower (between 1% and 7%) in consecutive outpatients with a first episode of deep venous thrombosis.[4,13] Protein S deficiency is generally considered to confer a risk of thrombosis similar to that in protein C deficiency, although the association has been complicated by considerable phenotypic variability.

The clinical findings in patients with heterozygous protein S deficiency are similar to those outlined for deficiencies of antithrombin and protein C. Among 71 protein S–deficient members from 12 Dutch pedigrees,[86] 74%, 72%, and 38% of the individuals sustained deep venous thrombosis, superficial thrombophlebitis, and pulmonary emboli, respectively. The mean age at the first thrombotic event was 28 years, with a range of 15 to 68; 56% of the episodes were apparently spontaneous, and the remainder were precipitated by an identifiable factor. Thrombosis has also been reported in the axillary, mesenteric, and cerebral veins. Although there have been case reports of young patients with arterial thrombosis and

TABLE 32-3	Assay Measurements in Heterozygous Protein S Deficiency

Types	**Total**	**Free**	**Protein S Activity**
I	Low	Low	Low
II	Normal	Normal	Low
III	Normal	Low	Low

protein S deficiency, current data do not support an association between hereditary protein S deficiency and an increased risk for arterial thrombosis.[87]

Three types of protein S deficiency states can be identified based on measurements of total and free antigen, as well as functional activity (Table 32-3). The type I deficiency state is associated with approximately 50% of the normal total protein S antigen level[84] and greater reductions in free protein S antigen and protein S functional activity.[88] This defect is most often secondary to missense mutations and base pair insertions or deletions. The type II qualitative deficiency state, characterized by normal total and free protein S levels but abnormal functional activity, has been identified infrequently, thus suggesting that current functional assays may not screen for all such defects. In type III deficiency, total protein S antigen levels are normal, with disproportionately decreased free protein S and functional activity.

The biologic basis of the type III protein S deficiency state is uncertain. Furthermore, coexistence of type I and type III deficiency has been reported in some protein S–deficient families, which has led to the proposal that the two types of protein S deficiency are phenotypic variants of the same genotype and are not the product of distinct genetic mutations.[89] In a follow-up analysis of one large family with a high prevalence of both type I and type III deficiency, total protein S antigen, but not free protein S antigen levels, were shown to directly correlate with age.[90] These findings were independent of gender and were also seen in nondeficient family members. The researchers concluded that a single point mutation in the protein S gene was responsible for the quantitative type I deficiency but that the type III phenotype was actually due to an age-dependent free protein S deficiency; with increasing age, the relative concentrations of free protein S to total protein S decreased. However, a Dutch cohort study of first-degree family members with protein S deficiency found that affected relatives of probands with type I deficiency were at increased risk for venous thromboembolism whereas affected relatives of probands with type III deficiency were not.[87]

There are multiple causes of acquired protein S deficiency, including pregnancy and oral contraceptive use. Protein S levels are commonly low in inflammatory states,

including DIC and acute thrombosis, largely because of protein S interaction with C4b-binding protein. C4b-binding protein is an acute phase reactant and shifts protein S to the complexed, inactive form, which leads to decreased protein S activity.[91] Levels of total and free protein S are significantly reduced in men infected with human immunodeficiency virus (HIV).[92] Although total protein S antigen measurements are generally increased in individuals with nephrotic syndrome, functional assays are often reduced[54] because of loss of free protein S in urine and elevated C4b-binding protein levels.

The lower limit of normal total and free protein S in plasma is approximately 65%; however, there is considerable overlap between the heterozygous deficiency state and low normal. Such overlap is largely due to the influence of age, which leads to an increase in protein S levels, and the influence of sex, with females having a lower normal limit for plasma protein S levels than males do. Thus, it is difficult to diagnose heterozygous protein S deficiency by performing a single assay; repeat sampling and family studies are usually required to make the diagnosis.

Young patients with recurrent venous thromboembolic disease associated with doubly heterozygous or homozygous protein S deficiency have been identified.[83] The parents of these patients were asymptomatic and had laboratory studies consistent with type I protein S deficiency. Neonatal purpura fulminans has been described in association with homozygous protein S deficiency.[93,94]

Resistance to Activated Protein C and the Factor V Leiden Mutation

Before 1993, hereditary deficiencies were infrequently identified in patients with familial thromboembolic disease. Dahlbäck and colleagues[95] identified several probands with venous thrombosis that appeared to be resistant to APC in an APTT-based clotting assay. When compared with controls, many family members of the probands also had a blunted anticoagulant response to APC. The following year, Bertina and associates[96] identified the genotype underlying most cases of APC resistance as a single point mutation in the factor V gene leading to substitution of Arg506 by glutamine. This mutation at an APC cleavage site renders factor Va relatively resistant to inactivation by APC.[82,96]

After Dahlbäck and coworkers' description of APC resistance, several studies revealed that this defect was relatively common in individuals with venous thrombosis. Svensson and Dahlbäck[97] screened 104 consecutive Swedish individuals referred for evaluation of venous thrombosis and found that 33% of the subjects demonstrated APC resistance. In a U.S. referral population of individuals younger than 50 years with unexplained venous thromboembolic disease, Griffin and colleagues[98] found that approximately 50% exhibited APC resistance.

Dutch investigators had previously initiated the Leiden Thrombophilia Study to identify risk factors for a first episode of venous thrombosis. Excluding patients with known malignancies, 345 consecutive outpatients younger than 70 years with confirmed deep venous thrombosis were initially reported.[99] Using a screening APTT-based assay, APC resistance was identified in 21% of individuals with thrombosis and in 5% of age- and sex-matched healthy controls. The factor V Arg506Gln (or factor V Leiden) mutation was found in more than 80% of the patients who had been found to be APC resistant.[96] The lower frequency of APC resistance seen in the Leiden Thrombophilia Study than in previous studies is attributable to differences in selection criteria and referral cohorts.

The U.S. Physicians' Health Study has also provided valuable data regarding factor V Leiden as a risk factor for venous and arterial thrombosis. In a retrospective case-control study of 14,916 healthy men older than 40 with a mean follow-up period of 8.6 years, heterozygosity for the factor V Leiden mutation was identified in 12% of patients (14/121) with a first episode of deep venous thrombosis or pulmonary embolism and in 6% of controls.[100] The relative risk for venous thromboembolism was increased 3.5-fold in those with no other concomitant risk factors but was reduced to 1.7-fold in patients with preexistent cancer or recent surgery. This study also showed that elderly patients with venous thrombosis frequently have the mutation.[100] Among men older than 60 years with initial episodes of venous thrombosis and no identifiable triggering factors, 26% (8/31) were heterozygotes for factor V Leiden.

A cohort study of more than 9000 randomly selected adults in Denmark found that the simultaneous presence of smoking, obesity (body mass index > 30 kg/m²), older age (>60 years), and the factor V Leiden mutation resulted in absolute 10-year venous thromboembolism rates of 10% in heterozygotes and 51% in homozygotes.[101]

A prospective cohort study determined the incidence of venous thromboembolism in asymptomatic carriers of the factor V Leiden mutation identified through family studies of symptomatic probands. Nine events occurred in 1564 observation-years, for an annual incidence of 0.58%. It was concluded that the absolute annual incidence of venous thromboembolism in asymptomatic carriers of the mutation is low.[102]

A number of studies have examined whether factor V Leiden, a prevalent abnormality in white populations, leads to an increased risk for arterial thrombotic events. There are no convincing data that other thrombophilic states such as deficiencies of antithrombin, protein C, and protein S confer an increased risk for arterial thrombosis, but evaluation of these associations is complicated by the relative infrequency of these defects. In a cohort of men older than 40 years with a low prevalence of smoking, the U.S. Physicians' Health Study did not find an association between the factor V Leiden mutation and myocardial infarction or stroke.[100] In a younger cohort of

Italian patients with myocardial infarction occurring before 45 years of age, an increased incidence of the factor V Leiden mutation relative to that in controls also was not found.[103]

Because of the frequency of heterozygosity for the factor V Leiden mutation in white individuals, homozygosity is not a particularly rare occurrence, and its presence is compatible with normal gestational survival. However, homozygotes for factor V Leiden are at significantly higher risk for venous thrombosis than heterozygotes are[104,105] and demonstrate heightened APC resistance in APTT assays.[96,104,106] Patients with heterozygosity for the factor V Leiden mutation along with deficiencies of protein C, antithrombin, or protein S[107-111] are also at significantly greater risk for venous thromboembolism than individuals with only a single genetic defect are. The genes for factor V and antithrombin are both located on the long arm of chromosome 1, thereby allowing coinheritance of the factor V Leiden mutation and an antithrombin mutation within all affected members of a family. This situation is expected to lead to an even more severe thrombotic diathesis.[109]

Obstetric complications, such as severe preeclampsia, abruptio placentae, fetal growth retardation, and stillbirth, are associated with intervillous or spiral artery thrombosis and consequent placental insufficiency. Factor V Leiden, as well as other hereditary thrombophilias, is associated with an approximate tripling of the risk for late fetal loss.[112,113] An increased incidence of factor V Leiden, as well as other thrombophilias, was also reported in women in association with other obstetric complications[114]; associations with preeclampsia and intrauterine growth restriction/retardation have, however, not been corroborated.[115,116]

The prevalence of heterozygosity for the factor V Leiden mutation in whites, including European, Jewish, Israeli Arab, and Indian populations, ranges between 1% and 8.5%. The mutation apparently is not present in African blacks or in Chinese, Japanese, or Native American populations.[117] In Europe, the mutation has been found to be more prevalent in northern countries such as Sweden than in southern countries such as Spain and Italy. By using dimorphic sites in the factor V gene to perform haplotype analysis, data have been provided that support the existence of a single founder allele among whites of differing ethnic background.[118] It was also estimated that the mutation originated approximately 30,000 years ago, which came after the evolutionary divergence of white, African, and Asian populations.

Two mutations at the Arg306 residue in factor V, the second APC cleavage site in the activated cofactor, have been described in patients with a history of thrombosis. These mutations are replacement of Arg306 with threonine (factor V Cambridge)[119] and with glycine (in Hong Kong Chinese).[120] The latter mutation, however, evidently has no clinical relevance because it is not associated with APC resistance and the mutation is as common in healthy Chinese blood donors as in patients with thrombosis (4.5% and 4.7%, respectively).[121] The factor V Cambridge mutation is extremely rare among whites with venous thromboembolic disease.

Cosegregation of heterozygous APC resistance as a result of the factor V Leiden mutation and type I factor V deficiency has been reported in some patients.[122-124] The plasma of these individuals manifests severe APC resistance in partial thromboplastin time (PTT) assays, as found in homozygous factor V Leiden patients (i.e., the patients with such cosegregation are pseudohomozygous). These patients were seemingly more prone to thrombosis than were heterozygous relatives with factor V Leiden alone, thus suggesting that their clinical phenotype is similar to that of homozygous factor V Leiden patients.

Several polymorphisms are present in the factor V gene.[125,126] An extended factor V gene haplotype (HR2) containing the R2 polymorphism (His1299Arg) is associated with mild APC resistance and occurs with increased frequency in heterozygous patients with the factor V Leiden mutation and the lowest APC resistance ratios.[126] Although one case-control study found that the R2 allele was a risk factor for venous thromboembolism with an odds ratio of 2.0 after excluding subjects with genetic defects such as factor V Leiden,[127] another case-control study found no significant increase in risk.[128]

The initial observations of Dahlbäck and associates[95] facilitated the development of a PTT-based assay that serves as a screening test for APC resistance. The PTT assay is performed in the presence or absence of a standardized amount of APC, and the two clotting times are converted to an APC ratio. Results can be interpreted by comparing the ratio with the normal range or by normalizing it to the APC resistance ratio obtained with normal pooled plasma. Although this first-generation APC resistance assay was conceptually quite simple and easy to perform in a coagulation laboratory, it required careful standardization and determination of the normal range in at least 50 controls. The level of APC, the PTT reagent, and the instrumentation used for clot detection affected the performance characteristics of the assay. Some assays using this format therefore had inadequate sensitivity and specificity for the factor V Leiden mutation. Moreover, patients who were receiving anticoagulants or had an abnormal PTT because of other coagulation defects could not be evaluated with this assay, and the test was not validated in patients with acute thrombosis or in pregnant women.

The discovery that factor V Leiden is the dominant genetic defect responsible for APC resistance facilitated the development of second-generation coagulation tests that with proper standardization can give nearly 100% sensitivity and 100% specificity for detection of the muta-

tion. For these tests, patient plasma is diluted in a sufficient volume of factor V–deficient plasma, and then a PTT-based assay is performed. This modification also permits evaluation of the plasma of patients who are receiving anticoagulants or have abnormal PTT results because of coagulation factor deficiencies other than factor V.

The fact that the dominant mutation underlying APC resistance is factor V Leiden makes it attractive to diagnose this defect by analyzing genomic DNA in peripheral blood mononuclear cells. This can readily be accomplished by amplifying a DNA fragment containing the factor V mutation site by polymerase chain reaction (PCR) and analyzing the cleavage products on ethidium bromide–stained agarose gels after restriction enzyme digestion with MnlI.[96] The substitution of an A for a G at nucleotide 1691 in factor V cDNA (CGA to CAA) results in the Arg506Gln mutation and loss of a MnlI cleavage site. Other diagnostic approaches include hybridization with allele-specific oligonucleotide probes.

Prothrombin G20210A Mutation

In 1996, investigators from Leiden reported that a G-to-A substitution at nucleotide 20210 in the 3′-untranslated region of the prothrombin gene is associated with elevated plasma prothrombin levels and an increased risk for venous thrombosis.[129] This mutation, which was discovered by directly sequencing the prothrombin gene of selected patients with venous thrombosis, is located in the 3′-untranslated region at the cleavage site for poly-adenylation of prothrombin mRNA. The prothrombin 20210A mutation changes the position of the 3′-cleavage/polyadenylation reaction in prothrombin mRNA, thereby leading to increased prothrombin biosynthesis by the liver[130]; this finding is in contrast to previous data that the mutation changes mRNA stability by increasing mRNA 3′-end formation.[131]

Investigation of a referral population with a personal and family history of venous thrombosis demonstrated that 18% had the mutation in the 3′-untranslated region of the prothrombin gene whereas it was present in only 1 of 100 healthy controls.[129] Among these thrombosis patients, 40% also carried the factor V Leiden mutation, thus emphasizing the current view of venous thrombosis as a multigene disorder.

In the Leiden Thrombophilia Study, 6.2% of venous thrombosis patients and 2.3% of healthy matched controls had the prothrombin gene mutation.[129] This mutation independently confers a 2.8-fold increased risk for venous thrombosis, and the effect is operative in both sexes and all age groups. Among heterozygotes with the prothrombin gene mutation, 87% of patients with thrombosis and controls in the study had prothrombin activity levels that were greater than 1.15 U/mL, whereas only

23% of those with a normal prothrombin genotype had levels elevated to this degree.

The prothrombin G20210A mutation has been documented in numerous studies to have a significantly higher incidence in patients with venous thrombosis than in healthy controls.[132-134] Large population studies have shown an overall prevalence of about 2% in the general white population, with significant geographic variation. In southern Europeans the prevalence is about 3%, but it was only very rarely identified in individuals of Asian or African descent.

PCR methods have been used to detect the prothrombin G20210A mutation in genomic DNA.[129] In addition, methods are available to detect both the prothrombin G20210A mutation and factor V Leiden in the same reaction.[135] Although plasma prothrombin activity and antigen levels are significantly higher in individuals with the prothrombin G20210A mutation, prothrombin concentrations cannot be used to screen for the defect because of significant overlap with the normal population.[129,136]

HYPERHOMOCYSTEINEMIA

Homocysteine is a sulfur-containing amino acid involved in metabolic pathways leading to the formation of other amino acids; methionine is generated through the remethylation of homocysteine or metabolized to cysteine via trans-sulfuration. The normal plasma homocysteine concentration is 5 to 16 µmol/L.

Homocystinuria is a rare autosomal recessive inborn error of metabolism that occurs in childhood. The most frequent cause is homozygous cystathionine β-synthase deficiency, which has a frequency in the general population of approximately 1 in 250,000. As a result of impaired intracellular metabolism of homocysteine, increased amounts of the amino acid accumulate in blood and are excreted in urine. Children with homocystinuria exhibit premature atherosclerosis and venous thromboembolism, along with mental retardation, ectopic lenses, and skeletal abnormalities. A small number of cases are due to homozygous defects in the gene encoding methylenetetrahydrofolate reductase (MTHFR), and persons so affected are similarly afflicted with premature vascular disease and thrombosis along with neurologic problems. The mechanisms by which hyperhomocysteinemia acts as an atherogenic and thrombogenic risk factor have been only partially elucidated.[137,138]

During the last 2 decades, mild or moderate hyperhomocysteinemia was identified as a seemingly independent risk factor for venous and arterial thrombotic events.[139-141] Mild (16 to 24 µmol/L) or moderate (25 to 100 µmol/L) hyperhomocysteinemia results from genetic and acquired abnormalities. Although heterozygous cystathionine β-synthase deficiency is found in only approxi-

mately 0.3% of the general population, a MTHFR variant with an alanine-to-valine substitution at amino acid 677 is common[142] and can be present in 1.4% to 15% of the population, depending on their origin.[141] This mutation causes thermolability of MTHFR and a 50% reduction in its specific activity. The most common causes of acquired hyperhomocysteinemia are deficiencies of vitamin B_{12}, folate, or vitamin B_6, which are cofactors in homocysteine metabolism. There is a strong inverse correlation between hyperhomocysteinemia and folate levels and, to a lesser extent, with vitamin B_{12} and B_6 concentrations. Elderly patients frequently have elevated plasma homocysteine concentrations, even in the absence of vitamin deficiencies, as do patients with renal failure. Cigarette smoking is also associated with acquired hyperhomocysteinemia.

Whereas patients with homocystinuria secondary to cystathionine β-synthase deficiency have levels higher than 100 μmol/L, individuals with heterozygous defects in this gene or inadequate vitamin B_6 levels may have normal or only slightly elevated levels of fasting homocysteine. Discrimination of such patients from normal individuals can be improved by demonstrating an abnormal increase in plasma homocysteine 4 hours after an oral methionine load. Defects in the remethylation pathway as a result of MTHFR gene defects or inadequate folate or vitamin B_{12} levels tend to cause elevated homocysteine levels under fasting conditions. The prevalence of hyperhomocysteinemia is almost twice as high when based on homocysteine measurements performed after methionine loading as when based on fasting levels. Genetic testing for the common Ala677Val mutation in MTHFR is also possible.

Because folic acid, vitamin B_6, and vitamin B_{12} supplementation can decrease plasma homocysteine levels, it was hypothesized that treatment with these supplements would reduce the risk for arterial and venous thrombosis. Large randomized placebo-controlled clinical trials, however, reported that clinical outcomes are not improved by providing supplements of these vitamins to patients with histories of ischemic stroke,[143] myocardial infarction,[144] vascular disease,[145] or venous thrombosis.[146]

Because there are currently no data that persons with mild hyperhomocysteinemia and a history of venous or arterial thrombosis should be managed any differently from those with normal homocysteine levels, there is no longer justification for routinely determining homocysteine levels in such patients. In addition, results from the Leiden MEGA (Multiple Environmental and Genetic Assessment of risk factors for venous thrombosis) study indicate that the presence of homozygosity for the MTHFR C6777T polymorphism, which mildly increases homocysteine levels, is not associated with an increased risk for venous thrombosis.[147] It should furthermore be noted that the prevalence of hyperhomocysteinemia in the U.S. population has declined since the wheat supply was fortified with folic acid in the late 1990s. Although

there were previous reports that hyperhomocysteinemia significantly increased the risk for a first venous thrombotic event in patients with the factor V Leiden mutation,[148] a recent publication found no additive or multiplicative interaction between these abnormalities for the risk of venous thrombosis.[149]

DYSFIBRINOGENEMIAS

Qualitative fibrinogen abnormalities are inherited in an autosomal dominant manner. The dysfibrinogenemias are a heterogeneous group of disorders that may be asymptomatic or be manifested as a bleeding diathesis or recurrent venous or arterial thromboembolism. A small number of variant fibrinogens have been reported to be associated with thrombotic complications. These defects can be detected with thrombin and reptilase times, which are often prolonged. Functional fibrinogen measurements are usually substantially lower than antigenic measurements in the plasma of affected patients. An occasional patient with dysfibrinogenemia may have a prolonged prothrombin time or PTT, and the inability of some abnormal fibrinogens to clot completely in vitro can result in false-positive results in fibrin(ogen) degradation product tests.

The functional and biochemical defects of a number of abnormal fibrinogens associated with thromboembolic disease have been characterized.[150,151] The conversion of fibrinogen to fibrin by thrombin results in the proteolytic cleavage of fibrinopeptides A and B from the molecule. Defects in the release of these two peptides[152-155] or abnormalities in fibrin polymerization[156-159] have been reported. Such functional defects do not, however, offer a ready explanation for the thrombotic diathesis seen in these subjects. Abnormalities in the binding of thrombin to fibrin have also been found in some dysfibrinogenemias.[160-163] In one of these kindreds, three homozygous siblings with a Bβ-chain substitution of Ala by Thr at position 68 had a severe clinical phenotype and sustained both arterial and venous thrombosis at a young age.[162,164] It has been suggested that decreased binding of thrombin by this mutant fibrinogen may lead to the presence of excessive thrombin in the circulation and the occurrence of thrombosis.[164] Other fibrinogen mutants have been shown to cause abnormal fibrin polymerization.[156-158,161] Some abnormal fibrinogens have been evaluated for their ability to resist or promote fibrinolysis upon incorporation into a fibrin clot. The fibrin formed from fibrinogen "Chapel Hill III" has been demonstrated to be abnormally resistant to lysis by plasmin.[156] Activation of plasminogen is decreased in the presence of the fibrin formed from fibrinogen Dusart despite normal binding of tissue plasminogen activator to the substrate.[165-169] These abnormalities clearly have the potential for decreasing fibrinolytic activity in vivo, which results in a familial thrombotic diathesis in biochemically affected persons. The coexistence of factor V Leiden may predispose

individuals with certain dysfibrinogenemias to thromboembolism.[170]

INHERITED ABNORMALITIES OF FIBRINOLYSIS

Although investigators have identified a few individuals with inherited abnormalities of the fibrinolytic mechanism and recurrent venous thromboembolism, the clinical association is considerably less striking than that in many kindreds with deficiencies of antithrombin, protein C, or protein S or with the prothrombin gene mutation or APC resistance as a result of the factor V Leiden mutation. Dysplasminogenemia or hypoplasminogenemia has been reported in a number of individuals with thromboembolic disease; the first case of an abnormal plasminogen was identified in Japan.[171] The propositus had a history of recurrent thrombosis, and family studies demonstrated that the biochemical abnormality followed an autosomal dominant inheritance pattern. Despite the hereditary nature of the defect, none of the other biochemically affected members of the kindred had experienced a thrombotic event. Other Japanese pedigrees without thrombosis have since been described with the same biochemical defect; the gene frequency of this variant in the Japanese population was 0.018.[172] Population studies in the United States have not uncovered any cases of this dysplasminogenemia. The non-Japanese cases of dysplasminogenemia and hypoplasminogenemia have also been characterized by the absence of thrombotic episodes in biochemically affected family members other than the propositi.

Severe type 1 plasminogen deficiency is associated with a rare chronic inflammatory disease of the mucous membranes. The disorder is characterized by the presence of fibrin-rich pseudomembranous lesions, and the most common clinical manifestations are ligneous conjunctivitis (80%) and ligneous gingivitis (34%); less common sites of involvement are the vagina, respiratory tract, ears, and gastrointestinal tract.[173] Patients with this disorder have been found to be homozygous or compound heterozygous for a number of different mutations in the plasminogen gene.[173] Although this disorder can occasionally be life threatening, venous thrombosis was not observed in these patients. A severely affected infant with ligneous conjunctivitis has been treated successfully with a purified plasminogen concentrate,[174] but this product is not generally commercially available.

There have been reports documenting the existence of thrombophilic families with impaired fibrinolysis.[175,176] Re-evaluation of several of these families demonstrated the presence of hereditary protein S deficiency and no association between elevations in plasminogen activator inhibitor 1 (PAI-1) activity and a history of thrombosis.[177,178]

MANAGEMENT OF PATIENTS WITH INHERITED THROMBOTIC DISORDERS

Acute Thrombosis and Long-Term Management

When a patient with one of the inherited thrombotic disorders is discovered, family studies should be conducted because approximately half the members of a given kindred may be affected. Institution of long-term anticoagulation is not generally recommended for individuals who have not yet sustained thrombotic episodes. Affected individuals, however, should receive counseling regarding the implications of the diagnosis and advice regarding the symptoms that require immediate medical attention. In women of childbearing age, oral contraceptives are generally contraindicated in view of the increased thrombotic risk associated with the use of these medications. All biochemically affected individuals should be carefully evaluated before surgical, medical, or obstetric procedures that carry an increased thrombotic risk. These subjects should then receive appropriate prophylactic anticoagulation regimens. If specific concentrates are available for a patient with a particular deficiency state, these concentrates can also be administered to raise plasma levels of the protein to the normal range during the perioperative period. All women with previous thrombotic episodes should receive prophylactic heparin throughout pregnancy, and asymptomatic women should also generally receive such treatment.

Management of an acute thrombotic event in patients with a hereditary thrombotic disorder is generally similar to that for patients without an identifiable risk factor. Anticoagulant therapy is initiated with appropriate doses of heparin, low-molecular-weight heparin, or fondaparinux for 5 to 10 days, and warfarin (or another vitamin K antagonist) is begun within 24 hours to produce an international normalized ratio (INR) of 2.0 to 3.0. The indications for thrombolytic therapy in patients with these disorders are similar to those in other patients with acute venous thrombosis or pulmonary embolism. Standard therapy for patients with deep venous thrombosis or pulmonary embolism typically includes anticoagulation with warfarin for 3 to 12 months at a target INR of between 2 and 3; this regimen results in more than a 90% reduction in risk of recurrence.

In patients with a first episode of symptomatic venous thromboembolism, Prandoni and colleagues[179] found the cumulative incidence of recurrent venous thrombosis after the cessation of anticoagulant therapy to be 24.8% at 5 years and 30.3% at 8 years. Other investigators have confirmed that this risk is about 5% to 15% per year for the first several years after a first or even a second episode of unprovoked venous thrombosis. Recurrences are less common when the initial event is associated with a transient risk factor (e.g., surgery, trauma, pregnancy). Despite the relatively high recurrence risk in patients with

a first episode of unprovoked venous thrombosis, anticoagulation with warfarin has not proved to have sufficient benefit in terms of bleeding risk to support long-term prophylaxis for all patients at substantial risk for recurrence. For example, one controlled trial evaluated the efficacy of long-term warfarin therapy (INR of 2 to 2.85) for 6 months or indefinitely in 227 patients with a second venous thrombotic episode, but not specifically inherited thrombophilia.[180] Long-term warfarin was highly effective in preventing recurrences when compared with 6 months of therapy (2.6% versus 21% over a period of 4 years); this benefit was partially counterbalanced by a trend toward an increased incidence of major hemorrhage (8.6% versus 2.3%), and there was no difference in mortality rate between the two groups.

Because of the relatively high frequency of the factor V Leiden mutation in patients with a first episode of venous thromboembolism, there is a substantial amount of data on the risk of recurrence. Although two groups initially reported that patients with factor V Leiden who had a first venous thrombotic event were more than twice as likely to have a recurrent episode than those without the mutation were,[148,181] several other groups have not found that heterozygosity for this defect or the prothrombin G20210A mutation confers a higher risk for recurrence.[182-186] Thus, the consensus view is that neither of these defects alone is predictive of recurrence, and several studies have argued against the use of long-term warfarin therapy after a first thromboembolic episode in these patient populations. There is no increase in mortality among patients with the factor V Leiden mutation.[187] The recurrence risk appears to be significantly higher in the small subset of patients who are heterozygous for two hereditary prothrombotic defects or homozygous for factor V Leiden.[107-110,185,188]

As a result of the relatively low frequency of antithrombin, protein C, or protein S deficiency in unselected cohorts with an initial episode of venous thromboembolism, randomized clinical trials have included too few patients with these deficiencies to draw firm conclusions. A literature review and retrospective cohort study suggested that they have a high annual incidence of recurrent venous thromboembolism during the years immediately after a first episode and that this incidence declines thereafter.[189] Retrospective studies are unable to demonstrate an increase in mortality in patients with antithrombin[190] or protein C deficiency.

For the individual patient, the decision to continue anticoagulation indefinitely requires estimation of the quantitative risk over time for recurrent thrombosis (including fatal pulmonary embolism) and major bleeding (including fatal bleeding). Patient compliance has a major impact on the success of therapy, and patient preferences must be factored into the decision. Thus, given that future events in a patient with only one previous thrombotic episode cannot currently be accurately predicted and because there is a finite risk of bleeding associated with warfarin therapy, recommendations regarding long-term anticoagulation are individualized. The following clinical features should be considered in making this decision:

1. The number, sites, and severity of thrombosis. A patient who previously sustained massive pulmonary embolism is more likely to receive long-term warfarin than is a subject in whom deep venous thrombosis developed in a calf vein unless there are symptoms or signs of a significant postphlebitic syndrome.
2. Whether the thrombotic episodes were spontaneous or whether precipitating factors were present. If a precipitating event such as a major abdominal operation was present when the initial venous thrombotic event occurred, the risk of recurrence is substantially lower than if the event was spontaneous, and the patient does not require long-term oral anticoagulation after the initial episode is adequately treated.
3. The patient's risk of bleeding while receiving warfarin. A history of bleeding or difficulty accurately monitoring and controlling warfarin therapy because of altered gastrointestinal function will lead to an increased risk for bleeding.
4. The sex and lifestyle of the individual. Situations in which these factors may influence the decision to recommend long-term anticoagulation include women of childbearing age planning to conceive (warfarin is generally contraindicated in women bearing a fetus, especially during the 6th to 12th weeks of gestation because of the teratogenic risk), occupations that entail prolonged periods of immobilization and therefore might be associated with an increased risk for thromboembolism, and jobs with a higher than average chance of trauma that might lead to thrombotic or bleeding complications, or both.
5. A history of thromboembolism in other biochemically affected members of the family. Although marked intrafamilial and interfamilial heterogeneity has been observed in the phenotypic expression of inherited thrombotic disorders, it is reasonable for biochemically affected patients from severely affected kindreds with a single thrombotic episode to take oral anticoagulants indefinitely.

Antithrombin Deficiency

Patients with antithrombin deficiency can usually be treated successfully with intravenous heparin,[191] although in some situations unusually high doses of the drug are required to achieve adequate anticoagulation. In patients with antithrombin deficiency who are receiving heparin for the treatment of acute thrombosis, the adjunctive role of antithrombin concentrate purified from human plasma is not clearly defined because controlled trials have not been performed.[191] The latter product should probably be administered when difficulty is encountered in achieving adequate heparinization or recurrent thrombosis is observed despite adequate anticoagulation. It is also rea-

sonable to treat subjects who are antithrombin deficient with concentrate before major surgery or in obstetric situations in which the risks of bleeding from anticoagulation are unacceptable. The manufacturing processes used to prepare antithrombin concentrate result in a product that is greater than 95% pure; they also inactivate hepatitis B virus and HIV type 1.[192,193] Hence, it is preferable to administer antithrombin concentrate rather than fresh frozen plasma. A human antithrombin concentrate has also been produced from the milk of transgenic goats by recombinant DNA technology[194] and is commercially available in Europe.

The biologic half-life of antithrombin is approximately 48 hours.[14] Infusion of 50 units of plasma-derived antithrombin concentrate per kilogram of body weight (1 unit is defined as the amount of antithrombin in 1 mL of pooled normal human plasma) will usually raise the plasma antithrombin level to approximately 120% in a congenitally deficient individual with a baseline level of 50%.[193,195-198] Plasma levels should be monitored to ensure that they remain above 80%; administration of 60% of the initial dose at 24-hour intervals is recommended to maintain inhibitor levels in the normal range.[198]

Coumarin-Induced Skin Necrosis

Because coumarin-induced skin necrosis is a rare complication, therapy has been guided primarily by knowledge regarding its pathogenesis. The diagnosis should be suspected in patients with painful, red skin lesions developing within a few days after initiation of the drug, and immediate intervention is required to prevent rapid progression and reduce complications. Therapy should consist of immediate discontinuation of warfarin, administration of vitamin K, and infusion of heparin at therapeutic doses. Lesions have been reported to progress, however, despite adequate anticoagulation with heparin. In patients with hereditary protein C deficiency, administration of a source of protein C should be seriously considered, and it may also be appropriate in other patients with coumarin-induced skin necrosis because they invariably have reduced plasma levels of functional protein C when the skin lesions first appear. Fresh frozen plasma has been used, but improved results can be expected after the administration of a highly purified protein C concentrate, which facilitates rapid and complete normalization of plasma protein C levels.[199]

Because of the infrequent occurrence of coumarin-induced skin necrosis, it may be advisable to take special precautions when initiating oral anticoagulant treatment in a patient who is previously known or likely to have protein C deficiency. Warfarin should be started only when the patient is fully heparinized, and the dose of the drug should be increased gradually, starting at a relatively low level (e.g., 2 mg for the first 3 days and then in increasing amounts of 2 to 3 mg until therapeutic anticoagulation is achieved). Patients with heterozygous

protein C deficiency and a history of warfarin-induced skin necrosis have been successfully retreated with oral anticoagulants. Protein C administration either in the form of fresh frozen plasma or protein C concentrate provides protection against the development of recurrent skin necrosis until a stable level of anticoagulation is achieved.[60,200]

Homozygous or Doubly Heterozygous Protein C Deficiency and Neonatal Purpura Fulminans

Management of neonatal purpura fulminans in association with homozygous or doubly heterozygous protein C deficiency is complicated, and neither heparin therapy nor antiplatelet agents have been shown to be effective.[69,71-75] Administration of a protein C source appears to be critical in the initial treatment of these patients. Fresh frozen plasma has been used successfully to treat these infants. However, the half-life of protein C in the circulation is only about 6 to 16 hours,[48,201] and frequent administration of plasma is limited by the development of hyperproteinemia or hypertension, loss of venous access, and the potential for exposure to infectious viral agents. A highly purified concentrate of protein C has been developed and is efficacious in treating neonatal purpura fulminans.[202] Warfarin has been administered to these infants without the redevelopment of skin necrosis during the phased withdrawal of fresh frozen plasma infusions,[69,74,76,203,204] and this medication has been used chronically to control the thrombotic diathesis. A 20 month-old child with liver failure and homozygous protein C deficiency successfully underwent liver transplantation, which normalized his protein C levels and resolved the thrombotic diathesis.[205]

33 Acquired Platelet Defects

David B. Wilson

Platelets play a critical role in hemostasis. When the vascular endothelium is disrupted, platelets adhere to the subendothelium and initiate primary hemostasis. The details of normal platelet physiology and function are presented in Chapter 25. Excessive bleeding occurs if primary hemostasis is abnormal because platelets are either deficient in number or defective in function. Acquired platelet defects, both quantitative and qualitative in nature, are discussed in this chapter and the corresponding inherited disorders in Chapter 29.

The normal circulating platelet count for all ages ranges from 150,000 to 400,000/μL. Circulating platelets constitute two thirds of total body platelets; the remaining platelets are located within the spleen.[1] Platelets exhibit marked heterogeneity in size. Two factors have been proposed to account for this heterogeneity.[2] First, as platelets age, they may become smaller as a result of fragmentation or loss of granule contents or membrane proteins. Second, megakaryocytes produce platelets of varying size. In thrombolytic states, megakaryocytes preferentially produce large platelets, a phenomenon analogous to stress erythropoiesis.[2] The average life span of platelets is 7 to 10 days, although survival of transfused platelets in a thrombocytopenic recipient is reduced proportionately to the severity of the thrombocytopenia.[3] These findings suggest either that there is increased platelet utilization in thrombocytopenic states or that a fixed number of platelets are removed from the circulation each day, irrespective of the platelet count.[4]

QUANTITATIVE PLATELET ABNORMALITIES

Thrombocytopenia

The clinical manifestations of thrombocytopenia typically involve the skin or mucous membranes and include petechiae, ecchymoses, prolonged bleeding at incision or venipuncture sites, epistaxis, gastrointestinal hemorrhage, hematuria, and menorrhagia. Intracranial hemorrhage (ICH) can occur but is rare. As discussed in Chapter 28, the deep muscle hematomas and hemarthroses typically seen in individuals with deficiencies of factor VIII or factor IX generally do not occur with platelet disorders. Causes of thrombocytopenia fall into three broad categories: platelet sequestration (usually in the spleen), increased platelet destruction, or decreased platelet production. The differential diagnosis of thrombocytopenia in children is outlined in Box 33-1. Discriminating among these diagnoses is important because the cause of thrombocytopenia affects the choice of therapy.

When a patient with thrombocytopenia is assessed, the risk of bleeding episodes should be estimated. If the risk is significant, treatment is warranted. Unfortunately, there is a lack of direct correlation between the platelet count and the risk of bleeding episodes, which confounds treatment decisions. The risk of hemorrhage is affected by many factors, such as coexisting coagulation defects,

trauma, and surgery. In older children and adults, serious spontaneous bleeding does not occur until the platelet count is less than 20,000/μL. Many physicians use a platelet count of 10,000 to 20,000/μL as the threshold for intervention. This threshold was derived from a study of children with leukemia and may not be relevant for all cases of thrombocytopenia. For example, because of the increased risk for ICH in neonates, a threshold of 20,000 to 50,000/μL is often used. In addition, patients with a defect in production are more likely to have serious bleeding than those with a destructive platelet problem because in the latter patients, platelets tend to be larger and more functional.

Thrombocytopenia Reflecting Laboratory Artifact or Sequestration

Spurious Thrombocytopenia

Thrombocytopenia may be an incidental finding. If the history and physical examination do not suggest a defect in primary hemostasis, a low platelet count may represent a laboratory artifact. Potential causes of a falsely low platelet count include platelet activation during blood collection, undercounting of megathrombocytes,[5] or pseudothrombocytopenia as a result of in vitro agglutination by ethylenediaminetetraacetic acid (EDTA)-dependent antibodies.[6] In a patient with artifactual thrombocytopenia, large clumps of agglutinated platelets may be found at the periphery of the blood film, or platelets may be adherent to leukocytes and form platelet "satellites" (Fig. 33-1).[7]

Pseudothrombocytopenia secondary to EDTA-dependent antibodies can be confirmed by repeating the platelet count with another anticoagulant (e.g., citrate, oxalate, or heparin) or by preparing a blood film directly from a finger or heel puncture sample. The cause of EDTA-associated pseudothrombocytopenia is an IgG or IgM directed against a cryptic platelet antigen exposed only in the presence of this anticoagulant.[6] The phenom-

DESTRUCTIVE THROMBOCYTOPENIAS

Primary Platelet Consumption Syndromes

Immune thrombocytopenias
  Acute and chronic ITP
  Autoimmune diseases with chronic ITP as a
  manifestation
    Cyclic thrombocytopenia
    ALPS and its variants
    SLE
    Evans' syndrome
    Antiphospholipid antibody syndrome
    Neoplasia-associated immune thrombocytopenia
  Thrombocytopenia associated with HIV
  Neonatal immune thrombocytopenia
    Alloimmune
    Autoimmune (e.g., maternal ITP)
  Drug-induced (including HIT)
  Post-transfusion purpura
  Allergy and anaphylaxis
Nonimmune thrombocytopenias
  Thrombocytopenia of infection
    Bacteremia or fungemia
    Viral infection
    Protozoan infection
  Thrombotic microangiopathic disorders
    TTP
    HUS
    BMT–associated microangiopathy

  Drug-induced
  Platelets in contact with foreign material
  Congenital heart disease
  Drug-induced via direct platelet effects (ristocetin,
   protamine)
  Type 2b VWD or platelet-type VWD

Combined Platelet and Fibrinogen Consumption Syndromes

DIC
Kasabach-Merritt syndrome
HLH

IMPAIRED PLATELET PRODUCTION

Hereditary disorders (see Chapter 29)
Acquired disorders
  Aplastic anemia
  MDS
  Marrow infiltrative process
  Nutritional deficiency states (Fe, folate, vitamin B_{12},
   anorexia nervosa)
  Drug- or radiation-induced thrombocytopenia
  Neonatal hypoxia or placental insufficiency

SEQUESTRATION

Hypersplenism
Hypothermia
Burns

ALPS, autoimmune lymphoproliferative syndrome; BMT, bone marrow transplant; DIC, disseminated intravascular coagulation; HLH, hemophagocytic lymphohistiocytosis; HIT, heparin-induced thrombocytopenia; HIV, human immunodeficiency virus; HUS, hemolytic-uremic syndrome; ITP, immune thrombocytopenic purpura; MDS, myelodysplastic syndrome; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura; VWD, von Willebrand's disease.

---

enon is not associated with any particular pathology and may be observed in both healthy subjects and patients with diseases. In some individuals the antibodies responsible persist indefinitely, whereas in others the antibodies are transient. No abnormalities in hemostasis or thrombosis have been reported in any of these patients.

Other causes of pseudothrombocytopenia include drugs[8] and EDTA-independent cold agglutinins.[9] The overall incidence of pseudothrombocytopenia in hospitalized adult patients is approximately 1%, but it is less common in pediatric patients.[6] No further evaluation or treatment is indicated for a patient documented as having a spuriously low platelet count.

Apparent Thrombocytopenia Caused by Hypersplenism

The spleen normally retains about a third of the body's platelets in an exchangeable pool.[1] The fraction of platelets sequestered in the spleen increases in proportion to spleen size. Thus, an apparent thrombocytopenia can result from increased pooling in an enlarged spleen—a condition referred to as *hypersplenism*. In patients with hypersplenism, recovery of transfused autologous platelets is only 10% to 30%, whereas in normal individual it is 60% to 80% and in asplenic patients it is 90% to 100%. Splenic blood flow is the major determinant of the size of the exchangeable splenic platelet pool in splenomegalic states.[10] Administration of intravenous epinephrine causes constriction of the splenic artery and results in passive emptying of platelets into the circulation. This increase in platelet count is proportionately greater in patients with splenomegaly than in normal subjects.

In general, the apparent thrombocytopenia that results from pooling in an enlarged spleen is mild (50,000 to 150,000/µL). Platelet counts of less than 50,000/µL should not be attributed to splenomegaly alone without further investigation. The degree of hypersplenism is proportional to spleen weight, whether the splenomegaly is due to congestion (e.g., cirrhosis with portal hypertension), hemolytic anemia (e.g., hemoglobin SC disease),

or other causes. Because thrombocytopenia secondary to splenic pooling is not usually clinically important, no treatment is warranted, although splenectomy may be indicated for patients with severe thrombocytopenia, as can occur in Gaucher's disease or other storage diseases.

Apparent Thrombocytopenia Caused by Hypothermia

Platelets are transiently sequestered in the spleen, liver, and other organs of experimental animals subjected to hypothermia. Upon rewarming of the animal, these platelets return to the circulation. A similar phenomenon has been observed in hypothermic patients. Transient thrombocytopenia (platelet counts of 7000 to 62,000/μL) has been reported in hypothermic patients of various age.[11,12] Less significant thrombocytopenia has been observed in patients undergoing cardiac surgery with hypothermic perfusion. Treatment of the thrombocytopenia associated with hypothermia consists of rewarming and documentation of return of the platelet count to the normal range, which usually occurs in 4 to 10 days.

Thrombocytopenia Caused by Increased Platelet Destruction

A major etiologic classification of acquired thrombocytopenia of childhood is increased platelet destruction. Clinical conditions associated with increased platelet destruction are listed in Box 33-1. These conditions can be further subgrouped into immune and nonimmune causes.

Immune Thrombocytopenias

Autoantibodies, alloantibodies, or drug-dependent antibodies may associate with platelet membranes and target the cells for accelerated destruction by phagocytes of the reticuloendothelial system. An antibody mediating immune destruction of platelets may be directed against a platelet membrane antigen, or it may be part of an immune complex that binds Fc receptors on platelets.

Platelet antigens fall into two general classes. Glycoproteins that occur predominantly on platelets, such as the glycoprotein IIb/IIIa (GPIIb/IIIa) or GPIb/IX/V complexes, are often termed *platelet-specific antigens*. The glycoproteins (e.g., human leukocyte antigen [HLA] class I) and glycolipids (e.g., blood group ABH antigens) expressed on platelets, leukocytes, and other cell types are termed *platelet-nonspecific antigens*. Antibodies against platelet-specific and platelet-nonspecific antigens are responsible for a number of clinical syndromes, including autoimmune thrombocytopenia, neonatal alloimmune thrombocytopenia (NAIT), post-transfusion purpura (PTP), and platelet transfusion refractoriness. Antibodies directed against platelet integrins are common in immune thrombocytopenias. For example, autoantibodies directed against GPIIb/IIIa are seen in immune thrombocytopenic purpura (ITP)[13,14] and in drug-induced thrombocytopenia.[15,16] Several clinically significant alloantigens are

located on GPIIb/IIIa, including HPA-1a, the human platelet antigen most frequently implicated in NAIT (see later). Autoantibodies against GPIb or GPIX also have been reported in patients with ITP[13,14] and drug-induced thrombocytopenia.[15,17]

HLA class I antigens are expressed on a wide range of cells, including platelets, and are important for the recognition of self by cytotoxic T cells. HLA-A and HLA-B antigens are strongly expressed on platelets.[18] Alloantibodies against HLA-A or HLA-B antigens frequently form in multiparous women and multiply transfused patients, and these alloantibodies contribute to platelet transfusion refractoriness. HLA-C antigens are weakly expressed on platelets and are far less likely to induce alloantibodies, thus making it less necessary to match the HLA-C locus for donor-recipient compatibility in platelet transfusions. HLA class II antigens, which function in antigen presentation by macrophages and B lymphocytes, are not expressed on platelets.

ABH blood group antigens are carried on a number of platelet glycoproteins, including the GPIIb/IIIa and GPIb/IX/V complexes.[19] ABH antigens are also expressed on glycolipids.[19] In rare instances, these antigens have been implicated as the cause of immune-mediated platelet destruction, but in general, these platelet-nonspecific antigens play only a minor role in immune thrombocytopenias.

Platelet Antibody Testing. A large number of assays have been developed to detect antibodies directed against or associated with platelet membrane antigens.[20] These assays can be categorized into direct (detecting antibody associated with the patient's platelets) or indirect (detecting antibody in the patient's serum that binds to control platelets). Indirect tests may detect, in addition to autoantibodies, alloantibodies (e.g., HLA related), particularly in multiparous women and individuals who have received multiple transfusions, and thus give false-positive results. Autoantibodies tend to be associated with the patient's platelets and are usually present in low concentration in serum. Therefore, a direct test is the preferred test for autoimmune thrombocytopenias such as ITP.[20]

A number of direct assays measure immunoglobulin on platelets, regardless of whether the immunoglobulin is specifically or nonspecifically bound to the platelet surface. These assays generally detect platelet-associated IgG (PAIgG), but they can also be engineered to detect IgM or IgA. PAIgG is increased in immune disorders such as ITP and in nonimmune thrombocytopenic disorders such as leukemia and myelodysplastic syndrome. Thus, the specificity of these tests is limited. Moreover, the sensitivity of these tests is limited because autoantibodies, such as those responsible for ITP, represent only a small fraction of the total PAIgG. Megakaryocytes nonspecifically take up plasma proteins, including IgG and albumin, and incorporate these proteins into the alpha granules of platelets, especially in disease states associated with increased thrombopoiesis.[21] Therefore, increased

PAIgG can result from elevated antibody production for any reason.

More recent assays use antigen capture techniques to detect platelet glycoprotein–specific antibodies, such as those that recognize GPIIb/IIIa and GPIa/IX/V, and have high specificity. Unfortunately, the sensitivity is generally too low for these assays to be used for the routine serologic diagnosis of most immune thrombocytopenias.[20] A newly developed method is based on flow cytometric detection of autoantibodies reacting with specific platelet proteins immobilized on microbeads.[22]

Macrophage and Platelet Fcγ Receptors. Receptors for the Fc domain of IgG (Fcγ receptors) are found on a variety of cell types, including macrophages and platelets. These receptors have been shown to play a critical role in immune complex–mediated platelet destruction. Fcγ receptors are diverse in structure and function and fall into two major classes: those that activate effector functions, such as phagocytosis or platelet activation, and those that inhibit effector functions.[23]

Activating Fcγ receptors on macrophages include the low-affinity receptors FcγRIIA and FcγRIIIA and the high-affinity receptor FcγRI (Fig. 33-2).[23] As discussed later, cross-linking of the activating receptor FcγRIII promotes phagocytosis of antibody-coated platelets in certain disease states, including ITP. One of the drugs used to treat ITP, intravenous IgG (IVIG), acts by inducing expression of the inhibitory receptor FcγRIIB on phagocytes.[24]

The only Fcγ receptor expressed on platelets is the activating receptor FcγRIIA. Binding of IgG complexes to this receptor results in receptor cross-linking, which in turn initiates platelet aggregation and activation. This process is involved in heparin-induced thrombocytopenia (HIT), the most common drug-induced thrombocytopenia.

Immune Thrombocytopenic Purpura

ITP is a disorder characterized by accelerated destruction of antibody-sensitized platelets by phagocytic cells, especially those of the spleen. ITP is the most common autoimmune disorder affecting a blood element. The annual incidence is about 1 in 10,000 children. Two major forms are seen: acute ITP and chronic ITP. Acute ITP is usually a benign, self-limited condition that occurs in young children, typically those younger than 10 years Often a viral infection or vaccination precedes the onset of acute ITP. In the majority of these patients, the thrombocytopenia resolves within weeks or a few months of the original manifestation. Chronic ITP is defined arbitrarily as persistence of thrombocytopenia (platelet count >150,000/μL) for longer than 6 months after the initial manifestation, although some hematologists advocate a later cutoff point (Box 33-2).

Children in whom ITP is diagnosed have an excellent chance of spontaneous recovery, irrespective of therapy. The platelet count returns to normal in 4 to 8 weeks in approximately half of the patients and by 3 months after diagnosis in two thirds of children.[30] In a review[31] of 12 publications involving more than 1500 children with ITP, 76% achieved complete remission within 6 months of initial evaluation. Spontaneous recovery was documented in 37% of the remaining patients with thrombocytopenia persisting longer than 6 months. These findings have been confirmed in other large

FIGURE 33-2. Activating Fcγ receptors on macrophages. Fcγ receptors signal phagocytosis via their phosphorylated ITAM (immunoglobulin gene–related tyrosine activation motif) domains. Receptor cross-linking stimulates src family kinases to phosphorylate tyrosine (Y) residues within the ITAM domain of FcγRIIA or within the dimerized γ subunits of FcγRI or FcγRIIIA. The tyrosine kinase syk is then recruited to the phosphorylated ITAM domains and activated. Syc mediates phagocytosis by activating phosphatidylinositol 3′-kinase and phospholipase C. PI(4,5)P$_2$, phosphatidylinositol 4,5-bisphosphate. *(Adapted with permission from Aderem A, Underhill DM. Mechanisms of phagocytosis in macrophages. Annu Rev Immunol. 1999;17:595 © 1999 by Annual Reviews. Available at www.AnnualReviews.org.)*
Box 33-2	Controversial Issues Involving Immune Thrombocytopenic Purpura

CONTROVERSIAL ISSUE 1

What is the definition of chronic ITP? Traditionally, chronic ITP has been defined as thrombocytopenia lasting longer than 6 months. Many pediatric hematologists take exception to this definition because a significant fraction of children with ITP recover in 6 to 12 months. The Intercontinental Childhood ITP Study Group has recommended that a 12-month rather than a 6-month cutoff point be used to define chronicity.[25]

CONTROVERSIAL ISSUE 2

Is it necessary to perform bone marrow aspiration in patients with suspected ITP before starting glucocorticoid therapy? Although the diagnosis of leukemia is extremely unlikely when the clinical history, physical examination, and peripheral smear are consistent with ITP, many hematologists routinely perform bone marrow aspiration before initiating glucocorticoid therapy. Retrospective studies[26-28] suggest that this may not be necessary. Bone marrow aspiration or biopsy is warranted for children with atypical laboratory features and for those in whom initial therapy fails.

CONTROVERSIAL ISSUE 3

Where does splenectomy belong in the therapeutic decision tree for chronic ITP? There is a consensus that splenectomy should be deferred as long as possible and be reserved for patients with severe, symptomatic thrombocytopenia. The favorable safety profile of rituximab and the possibility of a sustained response could justify its use instead of splenectomy in the decision tree, but this has yet to be demonstrated in a prospective clinical trial. Despite the invasive and irreversible nature of splenectomy, some pediatric hematologists[29] advocate the use of rituximab only after splenectomy has failed.

studies.[25,32] Factors associated with the development of chronic ITP include age older than 10 years, insidious onset, and female gender.[32]

Pathogenesis. ITP is caused by autoantibodies that interact with membrane glycoproteins on the surface of platelets and megakaryocytes. These antibodies result in accelerated platelet destruction and may also impair thrombopoiesis. More than a third of adults with ITP have inadequate platelet production despite increased numbers of megakaryocytes in their bone marrow.[33] Certain antiplatelet antibodies have been shown to inhibit megakaryocytopoiesis or egress of platelets from the marrow space.[34,35] The GPIIb/IIIa complex is the autoantigen implicated most often as the cause of childhood and adult ITP.[14,36] Autoantibodies directed against the GPIb/IX/V[36] and GPIa/IIa[37] complexes have also been

reported. In rare instances, platelet glycolipids have been implicated as autoantigen targets in chronic ITP.[38] Autoantibodies diminish or disappear when platelet levels are restored to normal.[39]

Factors that trigger platelet autoantibody formation in acute ITP are not well understood. Although various mechanisms by which viruses may induce autoimmune disease have been suggested, the link between the immune response initiated by infection (or vaccination) and the subsequent production of platelet autoantibodies has not been established. Proposed mechanisms include adsorption of virus to platelets, deposition of virus-containing immune complexes onto platelet membranes, or exposure of cryptic neoantigens on the platelet surface.[40] There are data to both support[41] and refute[42] the hypothesis that acute ITP is triggered by antiviral antibodies that cross-react with platelet antigens.

Recent studies suggest that T lymphocytes also play a role in the pathogenesis of ITP. Dysregulated helper T cells can promote the expansion of antiplatelet antibody–producing B-cell clones.[43] Cytotoxic T cells from some ITP patients have the capacity to destroy platelets ex vivo.[44] CD3+ T lymphocytes from ITP patients are resistant to glucocorticoid-induced apoptosis, thus suggesting that disturbed apoptosis may contribute to defective clearance of autoreactive T lymphocytes.[45]

Genetic factors have been proposed to influence the development of ITP. Studies have failed to detect linkage of the disease to particular HLA genotypes. Polymorphisms in genes encoding phagocyte Fcγ receptors or proinflammatory cytokines may influence the development of ITP.[46] Immunodeficiency states, including inherited conditions, that have been associated with chronic ITP are discussed later.

Clinical and Laboratory Features. The typical manifestation of acute ITP is the abrupt onset of bruising and bleeding in an otherwise healthy child. Frequently, there is a history of a viral illness in the weeks preceding the onset of bruising. Seasonal fluctuation in the diagonsis of ITP has been noted, with a peak during spring and a nadir in the autumn.[47] Petechiae and ecchymoses are evident in most patients. Epistaxis and oral mucosal bleeding are seen in less than a third of patients. Hematuria, hematochezia, or melena is evident in less than 10%. Menorrhagia may be observed in adolescent girls with ITP. Although children with ITP may have extremely low platelet counts, bleeding episodes are less severe in these patients than in those with hypoproductive thrombocytopenia. This finding has been attributed to enhanced platelet production and young, large, hemostatically effective circulating platelets.[48] A palpable spleen is present in about 10% of reported cases of childhood ITP. Malaise, bone pain, and adenopathy are uncommon and should raise concern for another cause, such as acute leukemia.

The peak age at diagnosis is 2 to 6 years. Although acute ITP may be diagnosed in children of any age, ado-

TABLE 33-1	Characteristics of Childhood versus Adult Immune Thrombocytopenic Purpura
Childhood ITP	**Adult ITP**

<20% chronic	>50% chronic

lescents and infants are more likely to have chronic ITP develop in combination with some other immune disorder. In children, ITP is seen equally in males and females, whereas in adults, ITP is seen predominantly in females by a 2:1 ratio (Table 33-1).

Roughly 80% of children have platelet counts below 20,000/μL, often less than 10,000/μL.[25,32] Leukocyte and red cell counts are usually normal, although anemia may be seen in as many as 15% of these children, especially those with a significant history of epistaxis, hematuria, or gastrointestinal bleeding. A review of the peripheral blood film is mandatory in every child suspected of having ITP; features inconsistent with a diagnosis of ITP should prompt further investigation. Bone marrow aspiration or biopsy reveals normal or increased numbers of megakaryocytes. Increased numbers of eosinophils and their precursors may be noted, although this is not predictive of outcome.

The need for bone marrow examination in children with typical features of acute ITP is a subject of debate. There is a consensus that bone marrow aspiration is not necessary if the initial management is observation alone or administration of IVIG or anti-D. Controversy exists regarding whether bone marrow aspiration needs to be performed in all children before glucocorticoid therapy is started to exclude the possibility of acute leukemia (see Box 33-2).

Additional tests that may be considered in the initial evaluation and management of suspected ITP include serologic testing for human immunodeficiency virus (HIV), a direct Coombs test, and antinuclear antibody testing. Retrospective studies have shown that the antinuclear antibody test is positive in approximately 30% of pediatric patients with otherwise uncomplicated ITP and may predict a subset of patients at risk for the development of further autoimmune symptoms.[49]

Options for the Initial Management of Immune Thrombocytopenic Purpura. Childhood acute ITP is usually a benign, self-limited disorder that requires minimal or no therapy in the majority of cases.[25,31,50] There is no convincing evidence that medical therapy alters the natural history of the disease. Indications for treatment vary among practitioners and are a source of debate.[31,50,51] One set of practice guidelines put forth by the American Society of Hematology (ASH)[31] recommends that chil-

dren with ITP and platelet counts less than 20,000/μL plus significant mucosal membrane bleeding or those with platelet counts less than 10,000/μL and minor purpura be treated with IVIG or a glucocorticoid. However, many pediatric hematologists take exception to this recommendation.[50,52] In treatment guidelines put forth by the British Paediatric Haematology Group,[53] a child's condition rather than the platelet count steers management; children with bruising but without mucosal or more severe hemorrhage may be treated by observation alone, irrespective of the platelet count.

At the heart of the treatment debate is the perceived risk for ICH, a rare but potentially life-threatening complication in children with ITP. In a review of 12 case series involving 1293 children, the incidence of ICH was 0.9%.[31] Other surveys[32,54,55] suggest that this may be an overestimate and that the true incidence of ICH in children with ITP is between 0.1% and 0.5%. The subgroup of children with ITP who appear to be at greatest risk for ICH are those with platelet counts less than 20,000/μL and additional risk factors such as a history of head trauma, aspirin use, or arteriovenous malformation.[31] However, the platelet count alone has never been shown to predict the severity of bleeding symptoms.[30]

There is no evidence that medical therapy, such as administration of a glucocorticoid or IVIG, reduces the incidence of ICH. Indeed, retrospective studies[54-56] have shown that ICH may occur despite previous or concomitant therapy with IVIG or a glucocorticoid. The low incidence of ICH in children with ITP precludes a randomized clinical trial to determine whether treatment reduces the risk.

The results of randomized trials for various treatment approaches have been summarized previously.[31] Regardless of whether pharmacologic therapy is used, detailed education and careful follow-up should be provided to the patient and family. The child's activities should be limited, and aspirin-containing medications should be avoided. Although hospitalization is appropriate for the treatment of a child with a severe bleeding episode, there is no evidence to support routine hospitalization of patients with otherwise uncomplicated ITP.

Observation Only. For a patient with ITP and only minor purpura, medical therapy may not be necessary. There is uniform consensus that patients with platelet counts greater than 20,000/μL and only minor purpura do not require therapy. As noted earlier, management of patients with platelet counts lower than 20,000/μL and minor bleeding is controversial.

First-Line Medical Therapies

GLUCOCORTICOIDS. Glucocorticoids are presumed to act through several mechanisms, including inhibition of both phagocytosis and antibody synthesis, improved platelet production, and increased microvascular endothelial stability.[57] The latter effect may explain why symp-

tomatic bleeding episodes often subside before the platelet count increases.

In randomized trials, prednisone therapy has been shown to induce more prompt normalization of the platelet count than placebo does.[58-60] Although various doses have been used, the traditional glucocorticoid regimen is prednisone at 2 mg/kg/day (maximum of 60 to 80 mg) for approximately 21 days.[58] A regimen of 4 mg/kg/day for 7 days and then tapered to day 21 is equally effective and appears to have fewer side effects.[60] Prednisone at a dose of 4 mg/kg/day orally for 4 days with no tapering is also effective.[61] An alternative to these regimens is megadose pulse therapy (methylprednisolone, 30 mg/kg/day intravenously or orally for 3 days).[62] Side effects of glucocorticoid therapy include cushingoid facies, weight gain, fluid retention, acne, hyperglycemia, hypertension, moodiness, pseudotumor cerebri, cataracts, growth retardation, avascular necrosis, and osteoporosis.

INTRAVENOUS IMMUNOGLOBULIN. Imbach and associates[63] first reported the successful use of IVIG for the treatment of acute ITP in a small series of children. This was followed by many reports that documented the ability of IVIG to effect a rapid increase in the platelet count in patients with acute and chronic ITP.[64-66]

IVIG slows the clearance of antibody-coated blood cells from the circulation by inhibiting the phagocytic activity of cells of the reticuloendothelial system.[67] Studies in the early 1980s suggested that this effect is mediated primarily through the Fc portion of IgG. Specially treated preparations of intravenous IgG lacking the Fc portion of the molecule were inferior to unmodified IgG at increasing the platelet count in ITP patients. The proposed mechanism for this effect was Fc receptor blockade.[67] More recent studies in FcγR-deficient mice[24] suggest that IVIG elicits its effect via activation of inhibitory pathways and not simply receptor blockade (Fig. 33-3). Although there are some data to support the notion that anti-idiotypic antibodies may also be present in commercial preparations and contribute to the action of IVIG,[68] the clinical importance of this mechanism remains unproved.

The traditional dose of IVIG is 2 g/kg divided over a period of 2 to 5 days. However, several studies suggest that lower doses are effective. In a randomized trial,[65] pediatric patients who received 0.8 g/kg IVIG had at least as rapid a response rate as those who received 2 g/kg over a 2-day period. In more recent randomized trials,[66,69] favorable results have been seen with even lower doses of IVIG (250 mg/kg/day for 2 days). Among pediatric
FIGURE 33-3. Mechanism of action of intravenous IgG (IVIG) in immune thrombocytopenia. Binding of antibody-coated platelets to activating Fcγ receptors (FcγRIII) on macrophages results in the production of phosphatidylinositol 3,4,5-triphosphate (PI[3,4,5]P_3) via the action of phosphatidylinositol 3′-kinase (PI3K). These activated macrophages phagocytose the platelet-antibody complexes. IVIG induces expression of the inhibitory Fc receptor (FcγRIIB) on macrophages. Stimulation of the inhibitory receptor results in recruitment of SHIP, a 5-phosphatase that degrades PI(3,4,5)P_3 into phosphatidylinositol 3,4-bisphosphate PI(3,4)P_2. *(Adapted with permission from Lin SY, Kinet JP. Immunology: giving inhibitory receptors a boost. Science. 2001; 291:446. © American Association for the Advancement of Science.)*

patients in whom a response is seen, IVIG produces a more rapid increase in platelet count than do traditional doses of a glucocorticoid (2 mg/kg/day of prednisone), as documented in controlled trials.[60,70]

Several other general conclusions have emerged from studies on IVIG in pediatric patients.[71] First, both splenectomized and nonsplenectomized patients may respond to IVIG. Second, responses to IVIG are generally reproducible. Third, the duration of the response is brief, approximately 2 to 4 weeks.

Enthusiasm for the use of IVIG is offset by cost considerations. IVIG is considerably more expensive than prednisone or anti-D.[72] One study concluded that IVIG may be cost-effective if it reduces hospital stay or if splenectomy is avoided.[64]

Complications associated with IVIG are common and occur in 15% to 75% of patients.[31] Frequent side effects include flu-like symptoms such as headache, nausea, lightheadedness, and fever. Some of these adverse effects can be alleviated by pretreatment with analgesics or antihistamines. Approximately 10% of patients treated with IVIG (2 g/kg) experience aseptic meningitis manifested as a severe, protracted headache and photophobia.[73] These symptoms, which can cause considerable anxiety in patients, parents, and physicians, may spur additional diagnostic studies (e.g., computed tomography) or result in prolonged hospitalization. A rare but serious side effect of IVIG infusion is anaphylaxis, which can occur in patients who are totally deficient in IgA.[74] Most preparations of IVIG contain small amounts of IgA, and IgE antibodies responsible for anaphylaxis form after an initial exposure to IgA in these preparations.

ANTI-D. Anti-D is a plasma-derived immunoglobulin prepared from donors selected for a high titer of anti-$Rh_0(D)$ antibody. Anti-D elicits a rise in platelet count, along with mild to moderate anemia, in most patients with ITP.[65,72,75-78] A role for anti-D in the treatment of chronic ITP is now well established. Its utility in acute ITP has been studied less extensively, but it is also effective in this clinical setting.[76,78,79]

Anti-D can be used to treat only $Rh_0(D)$-positive patients with ITP because $Rh_0(D)$-negative patients do not show a response. The presumed mechanism of action is phagocytic cell blockade. Patients with intact spleens are more likely to respond to anti-D than splenectomized patients are.

The generally recommended dose is 50 to 75 µg/kg as a short intravenous infusion[76] or subcutaneous injection.[80] Uncontrolled studies have demonstrated that anti-D treatment increases the platelet count in approximately 80% of $Rh_0(D)$-positive children.[75,77] The therapeutic effect of anti-D lasts for 1 to 5 weeks. A controlled trial showed that anti-D therapy was less effective than IVIG or a glucocorticoid in terms of days required to attain a platelet count of 20,000/µL.[65] Anti-D is less expensive than IVIG, with an estimated cost savings of 35% per

episode of ITP.[72] The shorter administration time required for anti-D therapy also makes the medication more convenient to use than IVIG.

Adverse reactions of headache, nausea, chills, dizziness, and fever have been reported in 3% of infusions, and these adverse reactions were classified as severe in only a minority of cases.[75,81] Some degree of hemolysis, the main adverse reaction with anti-D, is inevitable because of binding of anti-D antibody to $Rh_0(D)$-positive erythrocytes. There is laboratory evidence of hemolysis in most patients. The average decline in hemoglobin ranges from 0.5 to 1 g/dL,[76-78] and most cases of hemolysis do not require medical intervention. In a small subset of patients, more significant hemolysis has been observed, which has tempered enthusiasm for use of the drug. Postmarketing surveillance by the U.S. Food and Drug Administration[82] documented 15 cases of hemoglobinemia or hemoglobinuria after anti-D therapy. Of these patients, six required transfusion, eight experienced an onset or exacerbation of renal insufficiency, and two underwent dialysis. The incidence of intravascular hemolysis was estimated to range from 0.1% to 1.5%. Why certain patients experience severe intravascular hemolysis after anti-D therapy is unclear. Subcutaneous delivery of anti-D may be associated with a lower incidence of severe hemolytic reactions.[80]

Relapses or Treatment Failures. Many patients treated with a glucocorticoid, IVIG, or anti-D will become thrombocytopenic again after a few weeks. These patients are likely to respond again to the therapy used initially. Patients who require therapy and whose thrombocytopenia does not respond to initial treatment with a glucocorticoid, IVIG, or anti-D are usually treated with one of the alternative front-line therapies. There are no clinical studies that document the response rate in these instances. Patients with persistent mild hemorrhage may benefit from low-dose glucocorticoid therapy.

Management of Chronic Immune Thrombocytopenic Purpura. In about 20% of children in whom ITP is diagnosed, thrombocytopenia persists for longer than 6 months. In adolescents and adults, chronic ITP is more common in females than in males. Chronic ITP sometimes occurs in association with other autoimmune diseases or in conjunction with an underlying condition known to predispose to disorders of autoimmunity, such as lymphoma (Box 33-3).

In up to a third of children with chronic ITP, spontaneous remission will occur months or years later. It is unclear why the condition resolves in these individuals. An estimated 5% of children have recurrent ITP characterized by intermittent episodes of thrombocytopenia followed by lengthy periods of remission. This is presumed to reflect a chronic compensated state of ITP. During periods of remission, increased platelet production balances the increased rate of platelet destruction. During exacerbations, platelet production by the marrow is sup-

pressed by viral infections or other factors and is unable to offset the rate of destruction.

Evaluation of patients with chronic ITP should include bone marrow aspiration, if not already done; screening tests for immunodeficiency (e.g., quantitative immunoglobulin levels/subsets, specific antibody titers, or lymphocyte subsets), systemic lupus erythematosus (SLE), and other autoimmune diseases (antinuclear antibody tests, direct Coombs test, antiphospholipid antibody tests, thyroid function tests); and serologic testing for HIV. Obtaining blood counts and peripheral blood smears from the parents may help exclude familial disorders.

The primary goal of treatment in patients with chronic ITP is to prevent bleeding, not cure the disease. As with acute ITP, therapy decisions should be based more on symptoms than on platelet count. In formulating a treatment plan, one must balance the potential side effects of treatment with the risk of bleeding episodes caused by the disease. Because the goal of treatment is a safe platelet count, not necessarily a normal platelet count, observation alone is an appropriate approach for many patients, especially those with minimal symptoms.[83]

Splenectomy. Splenectomy is thought to be effective because in most patients the spleen is the major site of both platelet destruction and autoantibody production. Platelet survival studies indicate improved platelet life span after splenectomy.[57]

Splenectomy should be considered in a pediatric patient with chronic ITP whose risk for hemorrhage precludes the use of observation alone. However, there is debate about where splenectomy belongs in the therapeutic decision tree for chronic ITP (see Box 33-2). Because remissions are often delayed in children and the risk of postsplenectomy sepsis is significant, especially in those younger than 5 years, splenectomy is deferred longer in children with ITP than in adults. ASH practice guidelines[31] recommend that splenectomy be considered for children in whom ITP has persisted for at least 1 year

and who have bleeding symptoms and a platelet count of less than 10,000/μL (ages 3 to 12) or 10,000 to 30,000/μL (ages 8 to 12 years). Practice guidelines in the United Kingdom are similar.[53]

Laparoscopic splenectomy is preferred over open splenectomy in children with chronic ITP.[84,85] Advantages of the laparoscopic procedure include less postoperative pain, earlier return of gastrointestinal function, shorter hospitalization, more rapid resumption of normal activities, and smaller incisions. To ensure adequate hemostasis, the platelet count can be raised preoperatively with a glucocorticoid, IVIG, or anti-D. Despite these interventions, many patients will still have thrombocytopenia at the time of splenectomy; however, most will not exhibit excess bleeding. Accordingly, prophylactic platelet transfusions are not warranted. Instead, platelet transfusions should be reserved for patients with intraoperative bleeding. Most experienced surgeons have become comfortable performing laparoscopic splenectomy on patients with platelet counts in the range of 50,000 to 100,000/μL. Overall perioperative mortality is less than 1%.

The majority of children with chronic ITP will have a response to splenectomy. In a review[31] of 16 case series involving 271 children undergoing elective splenectomy for chronic ITP, a complete remission rate of 72% was reported. The platelet count usually rises immediately after splenectomy and reaches a maximum 1 to 2 weeks postoperatively. If the peak platelet count achieved after splenectomy is greater than 500,000/μL, permanent remission is likely.[86] Certain patient characteristics are associated with a higher probability of response to splenectomy, including a previous response to glucocorticoid therapy.[87-89] However, there is no single factor or combination of factors that will predict the response to splenectomy in all cases.[90]

Relapse after an immediate response to splenectomy may be due to transient viral suppression of thrombopoiesis. If the thrombocytopenia persists, an accessory spleen should be considered. Approximately 40% of patients with persistent thrombocytopenia will have a residual accessory spleen that can be seen with sensitive imaging techniques such as [99m]Tc sulfur colloid scans (Fig. 33-4) or [111]In platelet localization studies.[91] Many of these patients will achieve complete remission after removal of the accessory spleen.[91] The presence of Howell-Jolly bodies on a peripheral blood smear does not rule out an accessory spleen.

The major risk after splenectomy is fatal sepsis caused by encapsulated organisms. The risk of septicemia in splenectomized patients is estimated to be 1 per 300 to 1000 patient-years.[92] To lessen the risk of future sepsis, patients should receive vaccinations for pneumococcus, *Haemophilus influenzae* type b, and meningococcus at least 2 weeks before surgery.[93] In addition, penicillin prophylaxis is indicated for splenectomized patients younger than 5 years. The benefit of penicillin prophylaxis in older asplenic children is controversial.[94]
FIGURE 33-4. Detection of accessory spleens after splenectomy. A sulfur colloid scan shows accessory spleens (*arrows*) in a teenage girl with chronic immune thrombocytopenic purpura and persistent thrombocytopenia after splenectomy. (*Courtesy of Dr. Robert Minkes, Louisiana State University.*)

Phagocyte Blockade. Intermittent maintenance therapy with a glucocorticoid, IVIG, or anti-D can be used to delay splenectomy. These medications may also be useful in the management of patients with chronic ITP who experience symptomatic thrombocytopenia after splenectomy.

In some patients a safe platelet count can be maintained with low doses of prednisone. However, even low doses of prednisone, comparable to physiologic cortisol secretion, can cause osteoporosis.[95] In 1994, Andersen[96] reported a striking response rate in a series of 10 adults with chronic ITP treated with pulses of high-dose oral dexamethasone (adult dose, 40 mg/day for 4 sequential days per month for 6 months). These results have not been confirmed in subsequent studies of adults and children; the complete response rate in children at doses of approximately 20 mg/m^2 was approximately 17%.[97-99]

IVIG (1 to 2 g/kg total dose administered) elevates the platelet count in most children with chronic ITP.[63,64] Periodic doses of IVIG may be used as maintenance therapy to defer splenectomy in young children with chronic ITP.[64] This approach is cost-effective in young children.[100] In about 25% of children, ITP will become refractory to maintenance therapy with IVIG.[101] Low-dose alternate-day prednisone therapy can be used as an adjunct to maintenance IVIG therapy. Although repeated infusions of IVIG induce short-term platelet responses in most patients with chronic ITP, there is no evidence that such therapy will affect the natural history of the disease and induce a long-lasting remission.

Anti-D administration raises the platelet count in most Rh$_0$(D)-positive children with chronic ITP. However, the benefit is usually transient, with a median duration of 3 to 5 weeks.[102] Anti-D can be effective as maintenance therapy in patients who are not appropriate candidates for splenectomy or other therapies because of young age or other factors.[102,103] In Rh$_0$(D)-positive patients with chronic ITP, anti-D is preferred over IVIG because of ease of administration, comparable efficacy, and lower cost.

Monoclonal Antibodies That Target B Cells or T Cells

RITUXIMAB. Rituximab, a humanized monoclonal antibody directed against CD20, is now commonly used to treat chronic ITP despite limited clinical trial data documenting its efficacy in children with this condition (see Box 33-2).[104] Rituximab is generally administered in four weekly intravenous infusions of 375 mg/m^2 each. This agent causes rapid depletion of pre-B cells and B cells that lasts for 6 to 12 months. Pre-B cells efficiently present antigen to T cells, and disruption of this interaction may attenuate the autoimmune response. Approximately 30% to 60% of patients with chronic ITP respond to rituximab, and in many cases these responses are sustained.[105-110] The initial response may be immediate (within 1 week) or delayed (up to 3 months).[105-110] Side effects of rituximab include fever, urticaria, pruritus, throat tightness, and serum sickness.[110]

ALEMTUZUMAB. Alemtuzumab (Campath 1H) is a humanized monoclonal antibody that targets CD52, a protein on both B and T cells. There are anecdotal reports of its use in patients with chronic ITP.[111] Part of the effect of alemtuzumab can be attributed to B-cell depletion, analogous to rituximab, and part to depletion of T cells. Unlike rituximab, alemtuzumab induces profound generalized immunosuppression associated with opportunistic infections.[104]

Other Immunosuppressive Agents. A large number of other immunosuppressive medications have been used to treat refractory ITP, as reviewed elsewhere.[49,112,113] No randomized studies have evaluated the effectiveness of these various therapies. The choice of therapy must be individualized to the patient.

AZATHIOPRINE. Azathioprine acts preferentially on lymphocytes and was one of the first drugs reported to be effective in the treatment of chronic refractory ITP.[114,115] Recommended doses range from 50 to 200 mg/m^2/day orally. Continuous therapy for 4 to 6 months is required before a patient is considered unresponsive. Once a response is obtained, the dose should be tapered to the lowest level that results in a hemostatic platelet count. In adults with refractory ITP treated with azathioprine, approximately 20% achieve a complete response and 45% exhibit a partial response. Relapse often occurs when the therapy is stopped. The combination of azathioprine and oral steroids may be synergistic, and azathioprine therapy may allow a reduction in the dose of glucocorticoids. Toxicities include dose-related leukope-

nia, opportunistic infection, and an increased risk for malignancy.

CYCLOPHOSPHAMIDE. The alkylating agent cyclophosphamide has also been used to treat chronic refractory ITP, with a response rate similar to that with azathioprine.[115] Greater risks are associated with the use of cyclophosphamide than with azathioprine. Side effects include myelosuppression, alopecia, nausea, infertility, teratogenecity, hemorrhagic cystitis, and an increased risk for malignancy.

CYCLOSPORINE. The potent immunosuppressive agent cyclosporine disrupts T-cell function through calcineurin inhibition. There are case reports of patients with refractory ITP who had increases in platelet counts after treatment with cyclosporine.[116] Response rates vary. A starting dose of 5 mg/kg/day given in divided oral doses is recommended, with the aim of maintaining a serum cyclosporine level of 200 to 400 ng/mL. The drug should be discontinued after 4 weeks if there is no response. Hypertension, renal insufficiency, hirsutism, and liver dysfunction are common side effects.

TACROLIMUS. Though not structurally related to cyclosporine, tacrolimus has a similar mechanism of action and has been used anectodally to treat chronic ITP.[43] Initial dosing recommendations for tacrolimus in children are 0.15 to 0.3 mg/kg/day given in divided oral doses. Doses should be adjusted to maintain trough tacrolimus concentrations of 5 to 20 ng/mL in whole blood. Common adverse effects associated with tacrolimus include hypertension, tremor, headache, and hyperglycemia.

MYCOPHENOLATE MOFETIL. There are reports showing the effectiveness of another immunomodulatory drug, mycophenolate mofetil (MMF), in patients with steroid-resistant chronic ITP.[117,118] MMF is a prodrug of mycophenolic acid, a noncompetitive inhibitor of inosine-5α-monophosphate dehydrogenase, a key enzyme in the purine biosynthetic pathway. MMF inhibits proliferation of both T cells and B cells. In one series,[118] a sustained platelet increase to a level greater than 50,000/μL was seen in 7 of 18 patients with refractory ITP. For adults, the usual starting dose is 250 mg orally twice daily, with an increase to 1 g twice daily by 3 weeks. MMF has few side effects and is generally well tolerated.

VINCA ALKALOIDS. The vinca alkaloids vincristine and vinblastine may induce a response in some patients with chronic refractory ITP.[119] These drugs bind tubulin and inhibit microtubule polymerization, which is presumed to disrupt phagocytosis. Either vincristine or vinblastine may be used; the efficacy of the two drugs is comparable. The usual dose of vincristine is 1.5 mg/m^2 (maximum of 2 mg) intravenously, whereas the dose of vinblastine is 6 mg/m^2 (maximum of 10 mg) intrave-

nously. These doses are repeated weekly for a month. If no response is seen, additional doses are unwarranted because subsequent improvement is unlikely. Patients who show a response often require repeated doses at 2- to 3-week intervals to maintain a safe platelet count. In adults, the response rate is approximately 12% and the partial response rate is 35%. The response rate in children is not established and varies considerably in the reports available. Adverse effects include peripheral neuropathy, constipation, and alopecia. Vinblastine causes dose-related myelosuppression.

DANAZOL. Danazol, an attenuated androgen with mild virilizing effects, has been shown to increase the platelet count in patients with refractory ITP, although the mechanism of action is uncertain. Approximately 40% of adult patients will respond to danazol with an increase in platelet count to greater than 50,000/μL.[120] A typical dose is 300 to 400 mg/m^2/day orally, although smaller doses (50 mg/m^2) have been reported to be effective.[121] In general, 2 months of therapy is required before a response is seen. Often the medication must be continued to maintain the platelet count, although effort should be made to minimize the dose. Danazol may be especially useful for the treatment of older adolescent or adult women with chronic, refractory ITP and uncontrollable menorrhagia. Side effects of danazol include acne, fluid retention, hirsutism, deepening of the voice in women, headache, nausea, rash, breast tenderness, and oligomenorrhea or amenorrhea. Patients should be monitored for the development of liver toxicity.

INTERFERON ALFA. Although the mechanism is unknown, 25% of adults with chronic ITP treated with interferon alfa display a significant, albeit transient increase in platelet count.[122] Interferon alfa has also been used to treat children with chronic ITP.[123] The recommended dose is 3 million U/m^2 subcutaneously three times per week for 4 weeks. Adverse effects of interferon alfa include flu-like symptoms and neutropenia.

COMBINATION CHEMOTHERAPY. Combination chemotherapy with or without autologous stem cell transplantation has been used successfully to treat some adults with chronic, refractory ITP, with an overall sustained remission rate of approximately 40%.[124,125]

Thrombopoiesis-Stimulating Agents. In ITP the rate of platelet production is inadequate to offset the increased rate of platelet destruction.[33] Two new drugs for the treatment of chronic ITP act by stimulating thrombopoiesis. AMG 531 is a recombinant protein that contains two domains: a peptide that binds to the thrombopoietin receptor c-Mpl and an antibody Fc domain that increases the half-life in circulation.[126] In a placebo-controlled, phase II study this agent was efficacious when administered subcutaneously on a weekly basis (1 to 3 μg/kg) to adults with chronic ITP.[127] Toxicity was minimal. Another

small-molecule c-Mpl agonist in clinical testing for chronic ITP is eltrombopag.[126] This agent is given orally once daily. A phase II trial on adults with chronic ITP showed that eltrombopag at doses of 50 and 75 mg was significantly better than placebo at increasing platelet counts to greater than 50,000/µL. The drug appears to have few side effects.

Management of Life-Threatening Hemorrhage in Immune Thrombocytopenic Purpura. ICH or another life-threatening form of bleeding mandates intervention with multiple therapeutic modalities, including IVIG (1 g/kg), anti-D (50 to 75 µg/kg), high-dose glucocorticoids (e.g., methylprednisolone, 30 mg/kg intravenously), platelet transfusions, or a combination of these interventions. Because IVIG and anti-D act to inhibit phagocytosis by distinct and potentially synergistic mechanisms (see Fig. 33-3), these two agents may be used together for instances of severe bleeding. Recombinant factor VIIa has also been used in the management of ICH in patients with thrombocytopenia refractory to platelet-enhancing agents.[128] If a craniotomy is required, consideration should be given to splenic artery embolization[129] or emergency splenectomy,[130] although most hematologists reserve splenectomy for patients in whom ITP does not respond rapidly to therapy with glucocorticoids, IVIG, anti-D, and platelet transfusions.[31,131] Optimal therapy for ICH also includes supportive care with mechanical ventilation and mannitol.

Thrombocytopenia Associated with Lymphoproliferative and Autoimmune Disorders

Chronic ITP may be a manifestation of an associated autoimmune disease or immunodeficiency state. This is especially true in young children in whom chronic, refractory ITP develops or in adolescent girls with systemic symptoms.

Autoimmune lymphoproliferative syndrome (ALPS) is a rare syndrome that occurs in early childhood and is characterized by massive, nonmalignant lymphadenopathy, splenomegaly, hypergammaglobulinemia, and autoimmune manifestations, including immune thrombocytopenia.[132] ALPS has been linked to inherited defects in *FAS* and other genes that regulate lymphocyte apoptosis. An abnormal accumulation of lymphocytes results in lymphadenopathy, hepatosplenomegaly, and hypersplenism. In young children the lymphadenopathy may be pronounced and then wane later in life. Impaired elimination of autoreactive lymphocytes also causes autoimmune manifestations, including autoantibody formation. Patients with ALPS commonly exhibit episodic autoimmune cytopenia, including thrombocytopenia, hemolytic anemia, neutropenia, or combined cytopenias.

A significant proportion of young children with chronic ITP may have a variant of ALPS.[133-135] For example, in one survey[134] of 20 pediatric patients with chronic cytopenia, 25% were found to have profound defects in Fas-mediated lymphocyte death. Two of these patients, aged 4 and 9 years, had chronic refractory ITP without other clinical manifestations of ALPS. Neither patient had an identifiable mutation in *FAS* or caspase-10, and it is presumed that they may have defects in one of the molecules involved in Fas signaling. Similar results have been reported in other studies,[133,135] thus suggesting that altered Fas signaling, independent of *FAS* mutations, is associated with and may precipitate chronic hematologic autoimmunity, including ITP. The lymphadenopathy and cytopenias associated with ALPS generally respond to glucocorticoid therapy.

Thrombocytopenia occurs at some time in approximately 25% of patients with SLE and may be the first manifestation of autoimmunity.[136] Both autoantibodies and complement-fixing immune complexes have been implicated in the pathogenesis of thrombocytopenia in SLE.[137] In addition, antiphospholipid antibodies are frequently observed in the sera of patients with SLE.[138] Antibodies against antigens nonspecifically adsorbed to the surface of platelets, such as DNA, have also been reported.[139]

The initial therapy for thrombocytopenia in patients with SLE is administration of a glucocorticoid, but there is a high incidence of recurrent thrombocytopenia when the steroid dose is tapered. Long-term use of low doses of glucocorticoids may be justified, especially if these drugs also control the other symptoms of SLE. Splenectomy can be used in the management of patients with SLE and chronic, symptomatic thrombocytopenia. In some case series,[140] splenectomy for SLE has been shown to yield response rates comparable to those for ITP, whereas in other series[141] the response rate has been lower.

Thrombocytopenia may be associated with an antiphospholipid antibody syndrome, whether the syndrome occurs as a primary disorder or in association with SLE or another autoimmune disorder. Patients with antiphospholipid antibody syndrome often experience recurrent venous or arterial thrombotic complications rather than bleeding (see Chapter 34). Autoantibodies against GPIIb/IIIa, GPIa/IIa, and GPIb/IX have been documented in this syndrome.[142] Enhancement of platelet activation by antiphospholipid antibodies may contribute to the prothrombotic state in these patients.[143] In general, the degree of thrombocytopenia is moderate. A variety of therapies have been used to treat antiphospholipid antibody syndrome and the accompanying thrombocytopenia, including glucocorticoids and other immunosuppressive agents.

Evans' syndrome is the coexistence of autoimmune hemolytic anemia and thrombocytopenia. Autoimmune neutropenia also develops in many of these patients.[144] Frequently, patients with Evans' syndrome have associated disorders, such as dysgammaglobulinemia. Distinct antiplatelet and antierythrocyte antibodies rather than cross-reactive antibodies are responsible for the association of autoimmune hemolytic anemia and thrombocy-

topenia. In many patients the course of the disorder is marked by exacerbations of thrombocytopenia, anemia, or neutropenia. Unlike the majority of patients with ITP or isolated autoimmune hemolytic anemia, therapy with glucocorticoids, IVIG, or splenectomy often fails in patients with Evans' syndrome.[144] Patients with Evans' syndrome have been treated with rituximab, which induces remission in the majority, although relapses tend to occur within 12 months.[144] For severe and refractory cases, hematopoietic stem cell transplantation is a consideration.

Immune thrombocytopenia can complicate other autoimmune diseases, including dermatomyositis, juvenile rheumatoid arthritis, Hashimoto's thyroiditis, Graves' disease, myasthenia gravis, inflammatory bowel disease, sarcoidosis, and protein-losing enteropathy.[145-148] Immune thrombocytopenia can also precede, accompany, or follow neoplastic disease, especially lymphoproliferative disorders such as Hodgkin's and non-Hodgkin's lymphoma.[149] Immune thrombocytopenia has also been seen in association with childhood acute lymphoblastic leukemia.[150] In some patients, the thrombocytopenia of neoplastic disease resolves in response to antineoplastic therapy, whereas in others the thrombocytopenia requires specific treatment.

Thrombocytopenia occurs in 5% to 10% of patients with HIV infection. Immune-mediated platelet destruction is a major contributor to the thrombocytopenia seen in patients with HIV. The antibodies in HIV-associated thrombocytopenia are directed against the same target epitopes commonly seen in idiopathic ITP, namely, epitopes on GPIIb/IIIa.[151] Immune complexes composed of anti-idiotype antibodies and antibodies directed against the HIV antigen gp160/120 may also induce platelet destruction.[151] Whereas half of patients with ITP have normal or increased platelet production, most patients with HIV-associated thrombocytopenia have decreased platelet production.[152] Infection of megakaryocytes or bone marrow stromal cells may account for the reduced platelet production noted in HIV-associated thrombocytopenia.

Thrombocytopenia may occur early in the course of HIV infection and is often seen within the first 2 years.[153] Platelet counts are rarely lower than 50,000/µL, and symptomatic bleeding is uncommon. However, in HIV-infected patients with hemophilia, the bleeding can be more severe, even life threatening. Therapy is similar to that for ITP, except that HIV-associated thrombocytopenia may respond to antiviral therapy. Patients with severe or symptomatic thrombocytopenia despite antiviral therapy should be managed in the same way as patients with severe ITP.

Neonatal Alloimmune Thrombocytopenia

NAIT is a syndrome in newborns characterized by transient, isolated, severe thrombocytopenia. The syndrome results from placental transfer of maternal alloantibodies directed against paternally inherited antigens present on fetal platelets but absent from maternal platelets. Hence, this condition is the platelet counterpart of hemolytic disease of the newborn.

Alloantigens. Platelet alloantigens and the platelet membrane glycoproteins on which they reside are listed in Table 33-2. Most of the antigens were originally named on the basis of the patient's surname. In many cases, duplicate names were assigned to the same alloantigens (e.g., Pl^A1 = Zw^a, Pen^a =Yuk^b). The HPA, or human platelet antigen, nomenclature was proposed in the 1990s to systemize platelet alloantigens.[156] Each HPA system represents a biallelic polymorphism caused by a single amino acid substitution (see Table 33-2).

TABLE 33-2   Platelet Alloantigen Systems

Current Designation	Original Designation	Platelet Localization	Polymorphism	PHENOTYPE FREQUENCY Whites	PHENOTYPE FREQUENCY Japanese
HPA-1a	Pl^A1, Zw^a	GPIIIa	Leu33	0.98	0.99
-1b	Pl^A2, Zw^b		Pro33	0.027	0.037
HPA-2a	Ko^b	GPIb_α	Thr145	0.99	ND
-2b	Ko^a, Sib^a		Met145	0.017	0.25
HPA-3a	Bak^a, Lek^a	GPIIb_α	Ile843	0.85	0.79
-3b	Bak^b, Lek^b		Ser843	0.66	0.71
HPA-4a	Pen^a, Yuk^b	GPIIIa	Arg143	>0.999	>0.999
-4b	Pen^b, Yuk^a		Gln143	<0.0001	0.017
HPA-5a	Br^b, Zav^b	GPIa	Glu505	0.99	0.99
-5b	Br^a, Zav^a		Lys505	0.021	0.087
HPA-6b	Tu^a, Cu	GPIIIa	Gln489	<0.01	ND
HPA-7b	Mo^a	GPIIIa	Pro407	<0.01	ND
HPA-8b	Sr^a	GPIIIa	Cys636	<0.01	ND

Other low-frequency human platelet alloantigens exist but are not listed here. Comprehensive reviews are available.[154,155]
GPIb_α, glycoprotein Ib_α; GPIa, glycoprotein Ia; GPIIIa, glycoprotein IIIa; HPA, human platelet antigen; ND, not determined.

In white populations the most frequently implicated alloantigen in NAIT is HPA-1a (Pl^{A1}), which accounts for 78% of serologically confirmed cases.[157] Incompatibility for the HPA-5b alloantigen is the next most common cause. Approximately 98% of white individuals express the HPA-1a antigen on their platelets; most of the remaining 2% are homozygous for an alternative allele that encodes the HPA-1b (Pl^{A2}) antigen. The protein products of these two alleles differ only by a single amino acid (Leu33 versus Pro33). The incidence of NAIT is approximately 1 in 2000 births,[158] which is much lower than the predicted incidence based on distribution of the HPA-1a and HPA-1b alleles in the population. Other immune response genes appear to regulate HPA-1a alloantibody formation. Women with the HLA-DR3 antigen have about a 20-fold relative risk of forming HPA-1a alloantibodies. In the Asian population, incompatibility of the HPA-4 system is the most common cause of NAIT (80%), followed by incompatibility of the HPA-3 system.[159] HLA class I antigens are expressed on platelets, and maternal sensitization to HLA has been implicated as a cause of NAIT in a few patients.[160] HLA alloantibodies are present in 10% to 30% of pregnant women, especially multiparous women. The relative rarity of NAIT secondary to HLA alloantibodies may be due to binding of these antibodies to the placenta or other tissues. Blood group ABH alloantibodies have been found in a small number of patients with NAIT.[161]

Clinical and Laboratory Features. The degree of thrombocytopenia in NAIT can be severe, with platelet counts of less than 10,000/μL on the first day of life.[161] Common hemorrhagic manifestations include petechiae (90%), hematomas (66%), and gastrointestinal bleeding (30%). The maternal platelet count is normal, an important laboratory value for distinguishing this condition from neonatal thrombocytopenia secondary to maternal ITP[162] (see later). Unlike Rh disease of the newborn, NAIT can occur in both the first and subsequent pregnancies. A history of a previously affected infant provides strong supportive evidence for a diagnosis of NAIT.

Patients with NAIT are at increased risk for ICH, both prenatally and postnatally.[158,161] About 15% of affected neonates have ICH, and 50% of these cases occur antenatally. In utero bleeding can result in hydrocephalus, porencephaly, seizures, or fetal loss.[163] The pronounced bleeding diathesis associated with anti–HPA-1a alloimmune thrombocytopenia may reflect the combination of severe thrombocytopenia and antibody-mediated interference with the function of the GPIIb/IIIa complex on the few remaining platelets.

Treatment. The diagnosis of NAIT is confirmed by serologic or genotypic testing, including immunophenotyping of maternal, paternal, and occasionally neonatal platelets; maternal or fetal serum also can be examined for the presence of antiplatelet antibody. Several sensitive assays have been developed for platelet antigen typing and detection of alloantibody.[164] Despite the availability of sensitive tests, serologic evidence of alloantibodies is lacking in a least a third of cases identified by clinical criteria; therefore, NAIT is a clinical diagnosis. Because delays may be associated with serologic testing, therapy should be initiated as soon as the diagnosis is suspected.

The treatment of choice for severe NAIT (platelet count < 30,000/μL or clinically significant bleeding) is transfusion of washed, irradiated, maternal platelets (Fig. 33-5).[156] Irradiation prevents transfusion-associated graft-versus-host disease. In the interest of time, normal donor screening procedures may have to be abridged. Random-donor platelet infusions can be used in a neonate with active bleeding if maternal platelets are not immediately available.[165] However, only a modest and short-lived increase in the platelet count may be observed after the infusion of random-donor platelets. IVIG (1 g/kg daily for 2 days) or a glucocorticoid (methylprednisolone, 2 mg/kg/day) can also be used as a temporary measure, although these interventions may have limited benefit. If

the offending alloantigen is known, platelets from an antigen-negative unrelated donor may be used. In white populations, the use of HPA-1a– and HPA-5b–negative donors has been advocated because these two antigens are responsible for more than 95% of cases of NAIT. To provide transfusion support for fetuses and neonates with NAIT, the National Blood Service of England has established an accredited platelet donor panel of HPA-1a–negative individuals with no antibodies to HLA, HPA, or red cell antigens.[166] The majority of these donors are HPA-5b negative.

Platelets produced by neonates with alloimmune thrombocytopenia may exhibit accelerated clearance for weeks, until antiplatelet antibody is removed from the circulation (see Fig. 33-5). Consequently, it is not unusual for additional transfusions of maternal (or an antigen-compatible unrelated donor) platelets to be required after the first few weeks of life.

Management of Future Pregnancies. The likelihood is high that subsequent infants born to mothers of infants with NAIT will be affected. Moreover, the severity of antenatal and postnatal hemorrhage tends to increase in later pregnancies.[167] Therefore, detailed counseling on the risk of recurrence should be provided to the family at the time that thrombocytopenia is diagnosed in the first infant. Although the neonate's thrombocytopenia may have resolved before completion of the full diagnostic laboratory evaluation, it is important that the diagnosis and presumed antigen incompatibility be confirmed by formal serologic and genotypic testing to guide the management of future pregnancies. Antibody titers begin to decline after delivery; thus, the evaluation should ideally be initiated in the postpartum period. Because the likelihood of thrombocytopenia in subsequent infants depends on whether the father is HPA-1a homozygous or HPA-1a/1b heterozygous, performance of DNA-based genotyping is desirable.

Fetuses at risk for ICH should be monitored with serial ultrasound examinations, although fetal ICH may not always be detected by this method. In some centers, prenatal diagnosis of the platelet alloantigen genotype has been performed with DNA obtained by chorionic villus sampling or amniocentesis. More commonly, percutaneous umbilical blood sampling is performed at 20 to 22 weeks of gestation to obtain a fetal platelet count and perform platelet antigen typing. However, this procedure may be associated with fetal loss because of exsanguination; thus, compatible antigen-negative (e.g., maternal) platelets should be available when percutaneous umbilical blood sampling is performed and should be infused if the fetus is severely thrombocytopenic.[158]

When the diagnosis of alloimmune thrombocytopenia is confirmed in the fetus, two treatment approaches are available. In most North American centers, the favored approach is weekly maternal infusion of IVIG.[168,169] In some European centers, the preferred approach for severe cases of alloimmune thrombocytopenia is repeated in utero platelet transfusions; administration of IVIG and a glucocorticoid is reserved for mildly affected fetuses.[164]

Neonatal Autoimmune Thrombocytopenia

This condition can occur in infants of mothers with immune thrombocytopenia as a result of ITP, SLE, or other autoimmune disorders and is caused by placental transfer of maternal autoantibodies.[162] Antigens implicated as causes of neonatal autoimmune thrombocytopenia mirror those seen in ITP. In general, this condition is less serious than NAIT.

This diagnosis should be considered when both the neonate and the mother have evidence of thrombocytopenia or in infants of mothers with a previous history of immune thrombocytopenia. Neonatal thrombocytopenia has been observed in infants of mothers rendered asymptomatic for chronic ITP by splenectomy. Maternal ITP must be distinguished from the mild decrease in platelets that frequently accompanies pregnancy at term, presumably because of plasma volume expansion.[170]

The thrombocytopenia associated with maternal immune thrombocytopenia is generally milder than NAIT. The incidence of cord platelet counts lower than 50,000/μL is only about 3%,[171] and the incidence of ICH is only about 1%.[162] Although clinically significant bleeding episodes are rare, newborns with this condition should be monitored closely because platelet counts often decrease in the days after birth. The threshold for medical intervention in neonates with thrombocytopenia differs from that in older children with ITP because of concern about ICH in the newborn. A platelet count of less than 40,000 to 50,000/μL in a neonate is considered by many to be a useful indicator for starting therapy. IVIG (1 g/kg daily for 2 days) elevates the platelet count in most patients.[172] A glucocorticoid (methylprednisolone, 2 mg/kg/day) may be used in addition to or in lieu of IVIG therapy.

Perinatal management of mothers with immune thrombocytopenia, including the mode of delivery of a thrombocytopenic fetus, is controversial. Because the cord platelet count rarely is below 50,000/μL, perinatal ICH is uncommon and not necessarily related to delivery. The degree of maternal thrombocytopenia is a poor predictor of the degree of neonatal thrombocytopenia, although the clinical course of thrombocytopenia in the first sibling does predict that of the next sibling.[162] Otherwise, there are no reliable predictors of severe thrombocytopenia in the newborn. Direct determination of the fetal platelet count by percutaneous umbilical venous sampling can be performed, but this procedure is rarely justified for this condition.

Post-transfusion Purpura

PTP is a very rare syndrome in childhood. Typically, this syndrome affects a multiparious woman with HPA-1a–negative platelets who is reimmunized with that

alloantigen via blood transfusion.[173] Severe, acute thrombocytopenia ensues 1 week later, presumably reflecting an anamnestic response to the platelet alloantigen. PTP has been reported to develop in males and in nulligravida females as a result of initial exposure to the alloantigen through a previous blood transfusion. HPA-1a is the alloantigen found in 90% of occurrences of PTP.

Alloantibodies cause PTP, but the mechanism of platelet destruction is unclear. A variety of hypotheses[173] have been put forward to explain how alloantibody promotes destruction of autologous platelets, including immune complex–mediated platelet destruction; adsorption of allogeneic platelet antigens onto autologous platelets, which renders them susceptible to alloimmune destruction; and transient induction of autoantibodies. Because on average 2% of transfusion recipients have an HPA-1a incompatibility and PTP is very rare, other factors probably influence the development of this syndrome. Thrombocytopenia is usually severe (platelet count <10,000/µL), and hemorrhage is common. A high-titer alloantibody is often detectable. Patients generally recover in a few weeks. However, life-threatening bleeding, including ICH, may occur. Prednisone and plasma exchange have been used, but IVIG is probably the treatment of choice for severe occurrences.[174] Random-donor platelet infusions are ineffective and should not be administered. The efficacy of compatible, alloantigen-negative platelet transfusions is controversial.

Severe, transient thrombocytopenia has been associated with passive transfusion of plasma-containing products that have high-titer alloantibodies against HPA-1a or HPA-5b.[175] This condition has been reported in neonates.[176] The thrombocytopenia occurs within hours of transfusion. Most patients recover spontaneously, but treatment with IVIG or a glucocorticoid should be considered for severely affected patients.[176]

Drug-Induced Immune Thrombocyopenia

Numerous drugs have been implicated as causes of antibody-mediated thrombocytopenia.[177] In general, the risk associated with any drug is low, but some drugs cause immune thrombocytopenia more commonly than others do. The thrombocytopenia generally resolves when use of the drug is discontinued, but the severity of bleeding symptoms and the duration of thrombocytopenia vary widely among patients. In some instances, the sensitizing drug induces a second, drug-independent antibody (autoantibody) in addition to a drug-dependent one.[178] Usually, these drug-induced autoantibodies are transient and disappear when treatment with the drug is discontinued. Occasionally, however, autoantibody production may be sustained and lead to a clinical picture indistinguishable from that of ITP.[178] Once established, sensitivity to a drug generally persists indefinitely.[177]

Pathogenesis. Several mechanisms have been implicated in drug-induced immune thrombocytopenia.[177]

Hapten Formation. Small compounds can become covalently linked to blood cell membrane proteins and stimulate the production of antibodies specific for the hapten-protein complex. This mechanism is responsible for the hemolytic anemia seen in some patients treated with penicillin (see Chapter 14). Similarly, antibodies directed against hapten-protein complexes appear to be responsible for cases of penicillin-induced thrombocytopenia.[179]

Compound Epitope Formation. In patients with quinine-induced thrombocytopenia, antibodies that bind to normal platelets can be detected only when quinine is present in the soluble phase. These antibodies are usually specific for GPIIb/IIIa[180,181] or GPIb/IX.[182] The mechanism by which quinine promotes binding of antibody to platelets is not well understood. It is postulated that this agent binds noncovalently to one or more platelet membrane proteins and creates a "compound epitope" recognized by an antibody. Alternatively, the drug may interact with the target protein and cause a conformational change elsewhere in the molecule for which antibody is specific.[183] In addition to quinine, sulfonamide antibiotics and certain other drugs have been shown to induce antibodies that bind to platelets only when the sensitizing drug or one of its metabolites is present in the soluble state.[177] Among children, sulfamethoxazole is one of the more common causes of drug-induced immune thrombocytopenia.

Drug-Induced Autoantibodies. Certain drugs, such as gold salts, procainamide, levodopa, and interferon alfa, induce true autoantibodies that bind to platelet membrane targets in the absence of the drug.[177,184] The mechanisms by which these drugs induce autoantibodies is poorly understood.[178]

Clinical Features. Severe thrombocytopenia generally develops within 1 day of ingestion of quinine in a previously sensitized individual. A minimum of 1 week is required for initiation of the primary immune response in individuals taking this drug for the first time. Prodromal symptoms such as fever and chills may be observed. Bleeding may be severe, and its onset is abrupt. Hemorrhagic vesicles are common in the oral mucosa. The presence of a platelet antibody may be verified by a variety of techniques. Readministration of a suspected drug in an attempt to confirm an etiologic relationship is not recommended as a routine diagnostic measure.

Treatment. Discontinuation of treatment with the offending drug is the main therapy. With quinine, the thrombocytopenia usually begins to abate in 1 day if no additional drug is taken, and a normal platelet count is restored within 1 week. In patients with severe drug-induced thrombocytopenia, IVIG or glucocorticoid has been used to ameliorate bleeding.[185] However, there is little evidence that these medications are effective in this
