clinical setting. For life-threatening hemorrhage, platelet transfusion may be used, although this may be of limited value because of the persistence of slowly dissociating drug-antibody complexes. A sensitized individual is presumed to remain at lifelong risk for additional episodes of drug-induced thrombocytopenia, so further use of the offending drug is contraindicated.

Heparin-Induced Thrombocytopenia/Thrombosis

HIT is a complex clinical syndrome with an overall estimated incidence of 1% to 5% in adult patients exposed to heparin; the incidence in children is probably less.[186,187] The thrombocytopenia usually begins 5 to 10 days after heparin therapy is started, but it can occur within hours if the patient previously received heparin. The risk of HIT is higher for therapeutic than for low drug doses, for bovine than for porcine heparin, and for unfractionated than for low-molecular-weight heparin (LMWH).[188] In contrast to drug-induced thrombocytopenia caused by quinine or sulfonamides, severe thrombocytopenia (platelet count < 10,000/μL) is rare in HIT. Typically, platelet counts range from 20,000 to 150,000/μL, with a median of 50,000/μL.[177,189] The thrombocytopenia itself is rarely severe enough to cause bleeding symptoms and resolves after heparin therapy is discontinued. However, as many as 30% of patients with HIT experience arterial or venous thromboses. The development of thrombosis in patients with HIT is known as thrombocytopenia with thrombosis syndrome (HITTS), and this condition is associated with significant morbidity and mortality.

Pathogenesis. The antibodies responsible for HIT recognize the complex of heparin and platelet factor 4 (PF4), an alpha granule constituent.[190] After treatment with heparin, PF4 is released into the circulation and binds with heparin to form a reactive antigen on the platelet surface.[189] The heparin-PF4 complex is immunogenic in some patients. IgG against this complex triggers platelet activation by binding to FcγRIIA receptors on the surface membrane. The activated platelets release substances that stimulate other platelets and result in thrombin generation.[191] PF4 bound to glycosaminoglycans on the surface of endothelial cells may also serve as a target for antibody binding and lead to antibody-mediated injury to the endothelium and a predisposition to thrombosis.[192]

Approximately 50% of patients exposed to heparin during cardiac catheterization and subsequently during cardiac surgery form antibodies against heparin-PF4 complexes, but HITTS develops in only a small percentage.[193] It is unclear why heparin-PF4 complexes, which are composed of two substances normally present in the body, are so immunogenic. Moreover, it is not known why thrombocytopenia or thrombosis develops in some patients and not in others.

Diagnosis. The diagnosis of HIT is based on the interpretation of clinical findings together with laboratory confirmation of heparin-PF4 antibodies. A scoring system has been proposed to assess the pretest probability of HIT,[194] although this system has not been validated for pediatric patients. The gold standard laboratory test for diagnosing HIT is a platelet [^{14}C]serotonin release assay. Unfortunately, the complexity and availability of this assay limit its usefulness. An enzyme-linked immunosorbent assay (ELISA) for detection of antibodies against heparin-PF4 complexes is available, and results obtained with the serotonin release assay and ELISA are generally in agreement in patients with a clinical diagnosis of HIT.[188,195] However, ELISA has a more limited specificity and therefore produces false-positive results.

Treatment. It is standard practice to discontinue heparin in patients in whom HIT is suspected, but many of these patients will have thrombotic complications over the subsequent days. Therefore, ongoing antithrombotic therapy is indicated. Patients with HIT should not be given warfarin as a substitute for heparin during the acute episode because this can cause an abrupt decrease in the level of protein C and put the patient at greater risk for thromboembolic complications such as warfarin-induced limb gangrene.[196] LMWH is not recommended for the treatment of HIT because unfractionalted heparin and LMWH preparations display significant platelet aggregation cross-reactivity in vitro and in vivo.[188,197] Danaparoid, a low-molecular-weight heparinoid consisting of a mixture of heparan sulfate, dermatan sulfate, and small amounts of chondroitin sulfate, has been used for more than a decade to treat patients with HIT.[198] For pediatric patients with HIT, the recommended dosing scheme for danaparoid is an intravenous bolus of 30 IU/kg followed by an infusion of 1.2 to 2.0 IU/kg/hr to obtain anti–factor Xa levels of 0.4 to 0.8 IU/mL.[186] Hirudin, a compound originally purified from the leech salivary gland, inactivates thrombin by forming a 1:1 complex. A recombinant hirudin, lepirudin, is effective in the treatment of HIT or HITTS.[199] In children, lepirudin should be started as a continuous infusion at 0.1 mg/kg/hr without a preceding bolus, with a target activated partial thromboplastin time (APTT) of 1.5 to 2.5 times the patient's baseline value (first assessed 4 hours after infusion).[186] Other agents that are effective in this clinical setting are the synthetic antithrombin argatroban[200] and the synthetic pentasaccharide fondaparinux.[201]

Thrombotic Microangiopathic Disorders

This spectrum of disorders is characterized by destructive thrombocytopenia, disseminated capillary thrombosis, and microangiopathic hemolytic anemia (Box 33-4). Often there is organ dysfunction because of microvascular thrombosis and ischemic necrosis. Thrombotic microangiopathic disorders may be primary or secondary. There are both acute and chronic (familial) relapsing forms.

Box 33-4	Causes of Schistiocytic Hemolysis and Thrombocytopenia

Thrombotic thrombocytopenic purpura
Hemolytic-uremic syndrome
Disseminated intravascular coagulation
Vasculitis, including systemic lupus erythematosus and sclerodermal kidney
Drug-induced (cyclosporine, mitomycin C, etc.)
Dysfunctional prosthetic heart valves
Endocarditis
Bone marrow transplant–associated microangiopathy

TABLE 33-3	Clinical Manifestations of Thrombotic Thrombocytopenic Purpura	
Symptoms	**Cases**	**%**
Fever	237/243	98
Pallor or anemia	246/256	96
Hemorrhage	241/251	96
Neurologic abnormalities	250/271	92
Renal abnormalities	191/217	88
Jaundice	113/271	42
Fatigue, malaise	92/271	34
Nausea and vomiting	69/271	25
Abdominal pain	36/271	13
Chest pain or arrhythmias	21/271	8

Adapted from Amorosi EL, Ultman JE. Thrombotic thrombocytopenic purpura. Medicine (Baltimore). 1966;25:139.

The two major thrombotic microangiopathic disorders affecting children and adolescents are thrombotic thrombocytopenic purpura (TTP), a classic disease of hematology, and hemolytic-uremic syndrome (HUS), a classic disease of nephrology. Patients with TTP always have thrombocytopenia and schistiocytic hemolysis, frequently with central nervous system and renal impairment. In HUS, the microangiopathic process is usually, but not always limited to the kidneys. However, the boundary between these two clinical syndromes may be nebulous. Renal impairment can be prominent in TTP, and neurologic injury can occur in HUS. In adults, these two microangiopathic syndromes are often viewed as a joint entity termed TTP-HUS.[202] In pediatrics, however, the two syndromes are generally considered to be distinct, albeit overlapping entities. In addition to TTP and HUS, other conditions can produce schistiocytic hemolysis and thrombocytopenia, including bone marrow transplant–associated microangiopathy (see Box 33-4).

Thrombotic Thrombocytopenic Purpura. TTP is a syndrome characterized by reversible aggregation of platelets in the microvasculature that results in waxing and waning ischemia in various organs.[203-205] The defining clinical features of TTP are listed in Table 33-3. The pentad of thrombocytopenia, microangiopathic hemolytic anemia, neurologic abnormalities, fever, and renal abnormalities is present in many patients. Before the development of an effective therapy, the risk of mortality associated with the disease was greater than 90%. With the advent of plasma infusion/exchange therapy, TTP has become a curable disease. There are two major forms of TTP: an acute, acquired form and a rare, inherited, chronic relapsing form. Acute TTP can be further subcategorized into primary (idiopathic) and secondary forms. Drugs, infections, and other factors have been associated with secondary TTP.

Pathophysiology. The characteristic pathologic lesion of TTP is a hyaline thrombus composed of aggregated platelets in the absence of a perivascular inflammatory response. The thrombotic lesions of TTP typically involve terminal arterioles and capillaries and are most commonly seen in the brain, abdominal viscera, and heart,

but not the lungs. Red blood cells are damaged as a result of interactions with microthrombi in the small vessels.

Immunohistochemistry of early lesions of TTP reveals an abundance of von Willebrand factor (VWF) but little fibrin.[206,207] VWF within these thrombi is thought to be critical in pathogenesis. In 1982, unusually large multimers of VWF (UL-VWF) were observed in the plasma of patients with chronic relapsing TTP (Fig. 33-6).[208,209] UL-VWF multimers are most prominent in plasma samples taken from these patients during remission and decrease at the time of relapse. These UL-VWF multimers, which are synthesized by endothelial cells, are composed of increased numbers of mature VWF subunits. Under conditions of shear stress, the UL-VWF forms are more efficient than other VWF multimers at binding to the GPIb/IX/V and GPIIb/IIIa complexes on platelets and inducing aggregation.[208,210,211] These findings, coupled with the observation that VWF was abundant in the early thrombotic lesions of TTP, led to the hypothesis that intravascular platelet aggregation in TTP was due to either excessive release of UL-VWF multimers into plasma or impaired degradation of these UL-VWF multimers into smaller, nonaggregating forms.

Under ordinary circumstances, UL-VWF multimers are processed into multimers of normal size through the action of ADAMTS13, a VWF-cleaving metalloproteinase in normal plasma.[212,213] This protease cleaves a specific Tyr-Met bond in the second of the three A domains in VWF subunits (Fig. 33-7).[214] Physiologically, UL-VWF multimers are thought to be cleaved by ADAMTS13 under conditions of high shear stress, which partially unfolds the molecules. In vitro this partial denaturation can be mimicked by guanidinium or urea treatment.

Acquired or constitutional deficiency of the VWF-cleaving protease predisposes individuals to TTP. Chronic relapsing TTP, which usually begins in early childhood, is due to loss-of-function mutations in the ADAMTS13 gene.[215-219] The acute TTP more commonly seen in adults
FIGURE 33-6. Autoradiogram demonstrating unusually large multi-mers of von Willebrand factor (VWF) near the top of the gel (*arrow*) in the plasma of a patient (thrombotic thrombocytopenic purpura [TTP]) obtained early during a single episode of TTP. Normal pooled plasma (NP) and the culture supernatant from human umbilical vein endothelial cells (EC) are shown for comparison. Ethylenediaminetet-raacetic acid (EDTA)-anticoagulated samples were subjected to agarose gel electrophoresis in sodium dodecyl sulfate–urea-EDTA. VWF mul-timers were visualized by incubation with ^{125}I-labeled rabbit antihuman VWF antibody followed by autoradiography. *(From Moake JL, Chow TW. Thrombotic thrombocytopenic purpura: understanding a disease no longer rare. Am J Med Sci. 1998;316:108.)*

is usually due to an acquired deficiency in VWF-cleaving protease activity resulting from an IgG autoantibody against ADAMTS13.[220,221] The reasons for this transient immune dysregulation and for the selective antigenic targeting of ADAMTS13 are unknown. Fresh frozen plasma, cryoprecipitate-poor plasma (cryosupernatant), and plasma treated with solvent or detergent all contain the VWF-cleaving protease activity, which presumably accounts for the efficacy of plasma exchange therapy (see later).

Clinical Features. TTP is a relatively rare disorder with an estimated annual incidence of 1 to 4 per million popu-lation.[222,223] TTP is more common in women than in men (ratio of 3:2) and has a peak incidence in persons between the ages of 30 and 40 years. The condition has been reported in adolescents; indeed, the first instance reported in the literature was a teenage female.[204] The incidence of the disease is increasing, in part because of increased
FIGURE 33-7. Pathogenesis of thrombotic thrombocytopenic purpura (TTP). von Willebrand factor (VWF) multimers facilitate platelet adhe-sion to the subendothelium by binding to exposed connective tissue and then to platelet glycoprotein Ib (GPIb). In flowing blood, shear stress unfolds ultralarge VWF multimers in the platelet-rich thrombus and enables ADAMTS13 to cleave a specific Tyr-Met bond in the second of the three A domains in VWF subunits. Cleavage reduces VWF multimer size and limits thrombus growth. In the absence of ADAMTS13, VWF-dependent platelet accumulation continues and eventually results in microvascular thrombosis and TTP. *(Courtesy of Dr. Evan Sadler, Washington University.)*

awareness of the condition and the availability of effective therapy.[202,224]

TTP usually develops in previously healthy individu-als (idiopathic TTP). In approximately 15% of patients, the syndrome is associated with an underlying condition (secondary TTP), such as bacterial or viral infection,[225,226] pregnancy,[227] collagen vascular disorders,[228] or pancreati-tis.[229] Several drugs[230] have been associated with the development of secondary TTP, including ticlopidine, clopidogrel, lopidogrel, quinine, mitomycin C, cyclospo-rine, and tacrolimus. The mechanisms by which these drugs promote TTP are not well understood. Inhibitory antibodies against ADAMTS13 have been observed in ticlopidine- and clopidogrel-associated TTP.[231]

In the usual occurrence of TTP, the onset of symp-toms is abrupt. The most common initial manifestations are bleeding and neurologic abnormalities. The neuro-logic symptoms can progress rapidly and may include headache, confusion, stupor, coma, hemiparesis, cranial nerve palsies, and seizures. Fever is uncommon initially but invariably develops during the course of the disease. TTP is a clinical diagnosis that rests on the signs and symptoms presented in Table 33-3. The primary diagnos-tic criteria are thrombocytopenia and microangiopathic hemolytic anemia. Some patients may not be anemic initially, although their hematocrit levels may fall sharply afterward, and in some patients red cell fragmentation may not be apparent.[232] Therefore, the diagnosis of TTP initially is often provisional. Serum lactate dehydroge-nase (LDH) levels are increased, frequently to very high levels, because of not only hemolysis but also diffuse tissue ischemia. If considerable tissue ischemia and necrosis are present, disseminated intravascular coagula-tion (DIC) may ensue.

The diagnosis of TTP can be confirmed by measuring ADAMTS13 activity and by screening for inhibitory antibodies against this enzyme.[219] These tests may also provide prognostic information in cases of idopathic TTP. In one prospective study,[233] 6 of 14 patients (43%) with severe ADAMTS13 deficiency later relapsed, whereas only 2 of 25 patients (8%) without severe ADAMTS13 deficiency relapsed. In two other series,[234,235] patients with detectable anti-ADAMTS13 antibodies had a higher mortality rate than patients without detectable antibodies did. More recently, the presence of high-titer anti-ADAMTS13 IgA has been associated with a higher mortality rate.[236]

Though less common than acquired TTP secondary to autoantibodies, TTP caused by mutations in the ADAMTS13 gene is an autosomal recessive disease (also referred to as Upshaw-Schulman syndrome) that can be manifested at birth or in early childhood, with rare patients remaining asymptomatic until adulthood. The age at onset and severity can be highly variable, even among patients in the same family (carrying the same ADAMTS13 mutation).[214-219] Congenital TTP occurring in early childhood may be misdiagnosed as chronic ITP or Evans' syndrome.[219]

Treatment. Congenital TTP typically exhibits a chronic relapsing course that usually requires long-term treatment with fresh frozen plasma to replace the deficient ADAMTS13 protein. The regimen is determined empirically, and stable remission can generally be maintained with plasma infusions as infrequently as once every few weeks to months.[208,209,214-217]

Plasma exchange is the mainstay of therapy for acquired TTP (secondary to anti-ADAMTS13 autoantibodies). At least 50% to 80% of patients recover with this therapy. A randomized trial demonstrated the superiority of plasma exchange over plasma infusion.[237] This finding has been attributed to removal of antibody against VWF-cleaving protease. Another randomized study showed that fresh frozen plasma and cryoprecipitate-poor plasma were equally effective in the initial treatment of adults with TTP.[238] Glucocorticoid therapy is often used as an adjunct to plasma exchange therapy, but there is no direct evidence that the addition of glucocorticoids produces results that are superior to those of plasma therapy alone.[202]

Although TTP in most patients responds to plasma exchange therapy, the response is varied. Mental status changes may resolve immediately. Typically, the initial recovery from thrombocytopenia requires several days. Serum LDH levels may improve promptly, but patients often remain dependent on red cell transfusion for days. Recovery from renal failure is generally slow. Chronic renal insufficiency, defined as creatinine clearance of less than 40 mL/min/1.73 m^2 at 1 year after diagnosis, occurs in about 25% of patients.

Preliminary studies[239-241] suggest that rituximab can induce a complete response in patients with idiopathic TPP who are refractory to plasma exchange. This agent may also be beneficial as prophylatic therapy in patients with idiopathic TTP who are at high risk for relapse.[239-241]

Patients with secondary TTP caused by dose-related drug toxicity (e.g., mitomycin C) or allogeneic marrow transplantation may not benefit from plasma exchange treatment. Likewise, the course in a patient who has a clinically apparent additional condition, such as SLE, is unpredictable. Management of plasma exchange treatment is often dictated by the activity of the associated condition.

Hemolytic-Uremic Syndrome. HUS is another microangiopathic hemolytic anemia characterized by capillary thrombosis and ischemic necrosis. The kidneys are the end organs most severely affected, but ischemic injury of the intestines, central nervous system, or other organs may occur. HUS typically follows a diarrheal illness (mainly *Escherichia coli* O157:H7 infection) but also occurs in nonenteropathic settings. HUS occurs most often in infants and young children and is the most common cause of acute renal failure in this age group. The annual incidence is approximately 1 in 100,000 and may be increasing.[242] HUS can also occur in adults, particularly in the elderly, thus suggesting that susceptibility to HUS is greatest at the extremes of age.

Enteropathic Hemolytic-Uremic Syndrome

PATHOGENESIS. Certain strains of enteric bacteria produce a toxin that is cytopathic to Vero cells, a monkey kidney cell line. In the early 1980s, Karmali and associates[243] reported that 75% of children with HUS had evidence of gastrointestinal infection by verotoxin-producing *E. coli*. Subsequent studies showed that strains of other enteric pathogens, including *Shigella*, *Salmonella*, and *Campylobacter*, produce verotoxin and can cause HUS.

The term *verotoxin* has been replaced by the term *Shiga toxin* or *Shiga-like toxin* (Stx). This toxin is the key factor that differentiates infection with enterohemorrhagic *E. coli* (EHEC), which is associated with watery diarrhea, hemorrhagic colitis, and HUS, from enteropathic *E. coli* (EPEC), which is associated only with watery diarrhea and vomiting. Stx1 and Stx2, the two most prevalent forms of the toxin found in EHEC strains, are encoded by bacteriophages. Stx1 is identical to Shiga toxin produced by *Shigella dysenteriae* type I. Stx2 is immunologically distinct from Stx1.[244]

Stx is structurally related to ricin and cholera toxin. Each of these toxins is composed of a single A subunit noncovalently associated with a pentamer of identical B subunits.[244] The enzymatic activity of the toxin resides in the A subunit, whereas the B subunits are required for cellular uptake. Stx is taken up via endocytosis and transported to the endoplasmic reticulum via retrograde trafficking through the secretory pathway.[245] The A subunit enters the cytosol and targets 28S ribosomal RNA, which is depurinated by the toxin at a specific adenine residue

and causes protein synthesis to cease and the infected cells to die by apoptosis. Renal microvascular endothelial cells appear to be particularly sensitive to Stx.[246,247] Hemorrhagic enterocolitis has been ascribed to the action of Stx on endothelial cells in vessels of the intestinal submucosa. The toxin also inhibits protein synthesis in certain nonendothelial cells, including renal mesangial and cortical tubular cells.[248,249] Because EHEC is not invasive, it has long been assumed that HUS-related tissue damage results from the spread of bacterial products from the intestine to the kidney and other target organs. It is thought that Stx enters the systemic circulation after translocation across the intestinal epithelium.[250]

CLINICAL AND LABORATORY FEATURES. Approximately 50% of cases of acquired HUS appear after gastrointestinal infection with *E. coli* O157:H7. For unclear reasons, in only 9% to 30% of persons with *E. coli* O157:H7 colitis does HUS develop. Elevated leukocyte counts and C-reactive protein levels have been identified as risk factors for progression to HUS.[251,252] Other risk factors are the extremes of age, the presence of bloody diarrhea, and the use of antimotility drugs.[253]

Gastrointestinal symptoms can range from mild to severe. The colonic mucosa is hemorrhagic and edematous; ischemic infarcts can occur in the colon, and perforations have been reported. Stool cultures may be positive for the pathogenic organism.[254] Other diagnostic techniques include demonstration of Stx or specific bacterial DNA in stool samples or a rise in the titer of specific antibodies.

The anemia and thrombocytopenia associated with HUS tend to be less severe than those associated with TTP. The platelet count is greater than 100,000/μL in half of the patients, and bleeding is uncommon. Laboratory evidence of DIC is not usually present, but it can occur, especially in HUS associated with *Shigella*. The serum LDH level is less elevated than in TTP. A study of 16 children in whom HUS developed after *E. coli* O157:H7 infection showed normal levels of VWF-cleaving protease activity in plasma.[255] This finding has been confirmed by other investigators.[213]

Acute renal failure with oliguria, hypertension, and proteinuria usually develops in affected patients. Renal histopathologic examination reveals a preglomerular and glomerular thrombotic microangiopathy.[256] Mental status changes attributable to uremia are common. More rarely, focal neurologic signs are evident.

TREATMENT. Supportive care is the mainstay of therapy. Parenteral volume expansion with isotonic fluid during acute *E. coli* O157:H7 enteritis may attenuate the renal injury.[257] Dialysis and renal transplantation are performed when necessary. Independent trials have shown that antimotility agents increase the risk for HUS after *E. coli* O157:H7 infection.[253]

The role of antimicrobial agents in the treatment of HUS is controversial. There is no compelling evidence that antibiotics are beneficial, and there is some indirect evidence that the use of antimicrobials may be dangerous. Antibiotics increase the amount of Stx released from EHEC in vitro, so antibiotic therapy might paradoxically increase the risk for HUS in vivo. A prospective, controlled study[258] evaluated the effect of trimethoprim-sulfamethoxazole in children with *E. coli* O157:H7 enteritis. There was no statistically significant effect of treatment on progression of symptoms, fecal pathogen excretion, or the incidence of HUS. A prospective study of 71 children with diarrhea caused by *E. coli* O157:H7 suggested that antibiotic therapy was associated with an increased risk for HUS.[252]

Other treatments that have been tried without obvious benefit include infusion of fresh frozen plasma, glucocorticoids, heparin, thrombolytic agents, and prostacyclin.[259,260] Although plasma infusion or exchange has no proven role in the management of diarrhea-associated HUS in children, this therapy may be beneficial in adults with HUS or children with nonenteropathic HUS (see later).[196] Despite treatment, approximately 5% of children with HUS die of the disease and 10% have severe, chronic renal impairment.[261,262]

Atypical Hemolytic-Uremic Syndrome. Approximately 10% of pediatric patients seen with an HUS-like illness do not have antecedent bloody diarrhea and are classified as having atypical HUS (aHUS). There are both familial and sporatic forms of aHUS. The associated mortality rate is higher than that of enteropathic HUS. About half of survivors have a relapse, and a third require chronic dialysis.[263]

PATHOGENESIS. Deficiency of complement regulators is a major risk factor for the development of aHUS. More than 50% of patients with aHUS have a mutation in one of three complement control proteins: factor H (fH), membrane cofactor protein (MCP; CD46), or factor I (fI).[264,265] Additionally, autoantibodies against fI have been described in patients with sporatic aHUS.[265] MCP and fH serve as cofactors for fI, a serine protease that inactivates C3b (and C4b) through limited proteolytic cleavage (Fig. 33-8). Deficiency of fH, MCP, or fI results in excessive complement deposition, which promotes the development of microthrombi in the kidneys and other tissues.[266]

Invasive infection with certain strains of pneumococcus can also cause aHUS.[267] These strains produce neuraminidase, which exposes the normally hidden Thomsen-Freidenreich antigen on erythrocytes, platelets, and renal glomerular cells. Naturally occuring IgM antibodies in human plasma bind the exposed antigen, promote complement fixation, and trigger anemia, thrombocytopenia, and uremia.[267] Other nondiarrheal infections have also been linked to aHUS.[268]

TREATMENT. Although plasma therapy is often used in the management of aHUS secondary to complement
FIGURE 33-8. Role of complement regulatory proteins in the pathogenesis of atypical hemolytic-uremic syndrome. **A,** Membrane cofactor protein (MCP), a complement regulatory protein, is expressed on the surface of endothelial cells and other cell types and binds to C3b that has been deposited on the cell surface either spontaneously or in response to injury. In cooperation with MCP, the plasma serine protease factor I then cleaves C3b into its inactive form C3bi, thereby preventing further complement activation via the alternative pathway. In patients with MCP or factor I deficiency, excessive complement deposition occurs and leads to further cellular injury, endothelial cell necrosis, and ultimately thrombosis. **B,** Endothelial cell necrosis exposes basement membranes that are devoid of complement regulators. Factor H, a plasma-derived complement regulatory protein, binds to exposed basement membranes and, in cooperation with factor I, inactivates C3b that is deposited at these sites. Factor H deficiency leads to excess complement deposition on basement membranes. *(Courtesy of Dr. J. P. Atkinson, Washington University.)*

regulator deficiency, its benefit in preventing progression to end-stage renal disease or relapse is questionable.[269-271] Patients with an MCP mutation have a satisfactory outcome after renal transplantation because MCP is a transmembrane protein and the allografts are protected by wild-type MCP.[264] In contrast, recurrent aHUS develops in patients with a deficiency of fH or fI after renal transplantation because the allograft cannot compensate for deficiency of these plasma proteins, which are produced primarily in the liver. Therapeutic complement inhibition with monoclonal antibodies or recombinant regulators may be the treatment of choice in the future.[272]

Patients with aHUS caused by neuraminidase-producing pneumococcus should receive only washed red blood cells or platelets if transfusion is required.[267] Plasma products should be avoided in these patients.

Bone Marrow Transplant–Associated Thrombotic Microangiopathy

Thrombotic microangiopathy has emerged as one of the major complications of bone marrow transplantation (BMT).[273] The incidence ranges from 6% to 21%.[274] It is seen after allogeneic and less commonly after autologous BMT. The diagnosis may be difficult to make because of the presence of coexisting complications of BMT, such as graft-versus-host disease, cytomegalovirus infection, and hepatic veno-occlusive disease. Although BMT-associated microangiopathy (BMT-MA) shares features with other microangiopathies such as TTP and HUS, it has a distinctive clinical course and response to therapy. The pathogenesis of BMT-MA is unknown but appears to be distinct from that of primary TTP.

The condition ranges in severity from self-limited microangiopathic hemolytic anemia to a fulminant, usually fatal disorder. The fulminant form of the disease is more common in adults than children. In one adult series,[275] the incidence of BMT-MA was 2% with matched sibling donor transplants and 6% with unrelated donor transplants. Risk factors for the development of BMT-MA in adults include the use of unrelated or mismatched donors, grade II through IV acute graft-versus-host disease, and systemic bacterial or fungal infection.[274] In contrast to primary TTP, plasma exchange therapy appears to be of limited benefit in BMT-MA.[274] Most pediatric patients primarily exhibit signs of renal insufficiency. The mainstay of management is supportive care and, if feasible, a reduction of the dose of cyclosporine or tacrolimus. If the patient's clinical condition deteriorates (worsening hemolysis, progressive renal insufficiency, or neurologic symptoms), plasma exchange should be considered.[273]

Other Causes of Increased Platelet Destruction

Systemic bacterial or fungal infections are also commonly associated with thrombocytopenia. The degree of thrombocytopenia may range from moderate to severe. Thrombocytopenia associated with systemic bacterial or fungal infection is usually due to increased platelet destruction. A variety of mechanisms contribute to this destruction,

including immune mediated, direct effects of bacterial toxins, DIC, and hypersplenism.

Acute viral infections in children are commonly complicated by thrombocytopenia. For example, thrombocytopenia develops in about 75% of patients with infectious mononucleosis caused by Epstein-Barr virus.[276] Viral-induced thrombocytopenia may be immediate or delayed, and the decrease in platelet count may range from mild to severe. Thrombocytopenia can follow immunization with live virus vaccines. Viruses may cause thrombocytopenia through both nonimmune and immune mechanisms, including cytotoxic effects on megakaryocytes, direct injury to platelets, immune complex–mediated destruction (see earlier discussion of ITP and HIV), and hyperspenism. Thrombocytopenia is a manifestation of hemophagocytic lymphohistiocytosis. Thrombocytopenia caused by increased platelet destruction is a uniformly seen complication of malaria and African trypanosomiasis.[277]

Thrombocytopenia commonly accompanies extracorporeal membranous oxygenation, cardiopulmonary bypass, hemodialysis, and apheresis.[278] There are many causes, including adherence of platelets to synthetic materials in the perfusion device, hemodilution, hemorrhage, and drug effects (e.g., heparin). The thrombocytopenia associated with hemodialysis or apheresis is generally mild, but more severe thrombocytopenia may be seen in association with extracorporeal membranous oxygenation.

A healthy fetus has a platelet count of greater than 150,000/μL by the second trimester of pregnancy, and only 2% of term infants are thrombocytopenic at birth.[279] Severe thrombocytopenia, defined as a platelet count lower than 50,000/μL, is evident in fewer than 3 of 1000 term infants, the most important cause being NAIT. In contrast, thrombocytopenia is common among patients in neonatal intensive care units. Thrombocytopenia is also common in patients with intrauterine growth retardation and has been ascribed to placental insufficiency or chronic hypoxia. Thrombocytopenia is seen in preterm neonates with respiratory distress syndrome. Neonatal viral infections, including rubella, herpes, cytomegalovirus, and enterovirus, have also been associated with thrombocytopenia. Acute thrombocytopenia commonly accompanies necrotizing enterocolitis and is often an early sign of the disease. Thrombocytopenia is commonly seen in neonates with polycythemia, especially if they have associated cyanotic heart disease, although this phenomenon is probably multifactorial.[280] Infants with severe Rh hemolytic disease of the newborn may exhibit thrombocytopenia along with neutropenia.[281]

Kasabach-Merritt Syndrome. Kasabach-Merritt syndrome is the association between thrombocytopenia and a giant hemangioma of infancy. Most patients are seen in the first few weeks of life, although rare occurrences have been described in later childhood.[282] The vascular lesions are usually solitary and involve the extremities,

FIGURE 33-9. Drawing of an affected infant in the original article by Kasabach and Merritt. *(From Kasabach HHM, Merritt KK. Capillary hemangioma with extensive purpura. Report of a case. Am J Dis Child. 1940;59:1063-1070.)*

neck, or trunk (Fig. 33-9). Sometimes the lesions are located in the viscera, including the retroperitoneum. The possibility of an occult hemangioma should be considered in a neonate with unexplained thrombocytopenia. Detection may require radiographic imaging of the brain, liver, spleen, or gastrointestinal tract.

The hemangiomas associated with Kasabach-Merritt syndrome have a natural history of rapid growth for several months, followed by spontaneous regression. The thrombocytopenia subsides as the hemangioma regresses. Kasabach-Merritt syndrome, which is marked by severe thrombocytopenia and spontaneous regression in the first few years of life, is distinct from the mild, chronic thrombocytopenia associated with venous malformations, which are lifelong lesions (Box 33-5).

The pathogenesis is poorly understood, but platelets are thought to be trapped by abnormal endothelium within the hemangioma. Usually, the platelet count is less than 50,000/μL, and schistocytes are frequently present on the peripheral blood film. In a majority of cases there is laboratory evidence of DIC. These tumors grow rapidly

Hemangiomas and Kasabach-Merritt syndrome.
Thrombocytopenia is evident in only a small
proportion of infants with hemangiomas (0.3%).[282,283]
Kasabach-Merritt syndrome is not associated with the
common infantile capillary/cavernous hemangioma,
which is seen in 5% to 10% of children. Rather,
Kasabach-Merritt syndrome appears to be a
complication of two rare, aggressive histopathologic
subtypes: kaposiform hemangioendothelioma and
tufted hemangioma.[284-286] The histologic features of
kaposiform hemangioendothelioma and tufted
hemangioma are abnormal when compared with the
relatively well organized vessels evident in capillary
hemangiomas. These abnormal histologic features
may contribute to platelet trapping and activation.

to a large size and are often characterized by cutaneous
purpura, edema, and an advancing ecchymotic margin.
Imaging studies are essential in delineating the extent of
the lesion and determining whether it is surgically resect-
able. In contrast to common hemangiomas, magnetic
resonance imaging shows diffuse enhancement with ill-
defined margins, cutaneous thickening, stranding of sub-
cutaneous fat, hemosiderin deposits, and small feeding
and draining vessels.[282]

The mortality rate is as high as 40%,[287] and the
development of a life-threatening consumptive coagu-
lopathy warrants aggressive treatment. Surgical removal
may be effective, but most lesions are not able to be
resected. Radiation therapy can be effective but carries
serious long-term risks for a young infant[288] and is not
appropriate for most patients. Vascular ligation or embo-
lization has been used to promote regression of a large
hemangioma, especially in patients in whom a solitary,
major feeding vessel can be obliterated.[282] Glucocorticoid
therapy may be beneficial in some patients.[282] Interferon
alfa has been shown to be effective if no response to glu-
cocorticoid therapy is seen.[289] Vincristine is another treat-
ment option in the management of patients with
Kasabach-Merritt syndrome.[290]

Thrombocytopenia Caused by Decreased Platelet Production

The second major etiologic classification of acquired
thrombocytopenia of childhood is impaired platelet pro-
duction. Box 33-1 lists clinical conditions associated with
decreased platelet production. Patients with thrombocy-
topenia caused by a production defect are more likely to
have serious bleeding than patients with destructive
thrombocytopenia are.

A common cause of thrombocytopenia in patients
with cancer is chemotherapy-induced bone marrow sup-
pression. This is an expected complication of therapy and
rarely poses a diagnostic problem. Traditional manage-

ment is straightforward and relies on transfusion of plate-
let concentrates and adjustment of chemotherapy doses.
Considerable effort has also been put into the clinical
study of cytokines that promote thrombopoiesis (see
Chapter 35).

Valproic acid is commonly used in the treatment of
childhood epilepsy, bipolar disorder, and other condi-
tions. Hematologic toxicity, including thrombocytopenia,
is often seen in patients treated with valproate.[291] Valpro-
ate causes direct bone marrow suppression that may vary
in onset and severity and is more common in patients
with serum valproate levels greater than 100 µg/mL.[291]
In addition to bone marrow suppression, valproate
may have other effects on platelets, including immune-
mediated destruction and impaired function.[291]

Thrombocytopenia can result from replacement of
normal marrow elements by abnormal cells, as seen in
leukemia, solid tumors (neuroblastoma, rhabdomyosar-
coma, Ewing's sarcoma), storage diseases, and dissemi-
nated Langerhans cell histiocytosis. Other acquired
disorders of hematopoietic cells that are associated with
thrombocytopenia include myelodysplastic syndrome,
aplastic anemia, paroxysmal nocturnal hemoglobinuria,
and osteopetrosis. In osteopetrosis, the bone marrow
space is obliterated by new bone formation. This condi-
tion can be diagnosed by x-ray studies but may not be
clinically obvious in a neonate with thrombocytopenia.
Peripheral smear findings include teardrop cells and
nucleated erythrocytes.

Although iron deficiency is usually associated with
thrombocytosis, thrombocytopenia may accompany
severe iron deficiency in children and adults[292] (see
Chapter 12). Anemia caused by folate or vitamin B_{12}
deficiency (see Chapter 11) is also often associated with
thrombocytopenia. Severe thrombocytopenia secondary
to impaired hematopoiesis has been reported in associa-
tion with anorexia nervosa.[293] The thrombocytopenia
reverses with improved nutrition.

Thrombocytosis

Thrombocytosis is defined as a platelet count greater
than 2 SD above the mean. Conditions associated with
thrombocytosis in childhood are listed in Box 33-6.

When the platelet count is elevated, the clinician
must determine whether the patient has a true increase
in total body platelet mass. Under normal circumstances,
a third of the body's platelets are sequestered in the
spleen. Individuals with surgical or functional asplenia
who have a normal total body platelet mass will have
an elevated platelet count. This situation is normal for
an asplenic individual and no therapy is warranted.
Spuriously elevated automated platelet counts may
be caused by the presence of microspherocytes,
Pappenheimer bodies, red cell and leukocyte fragments,
or bacteria.

Causes of true thrombocytosis fall into two catego-
ries: autonomous (or primary) thrombocytosis and

---

reactive (or secondary) thrombocytosis. In primary thrombocytosis, platelet production is unresponsive to normal regulatory processes.[294] The decrease in megakaryocyte size that normally results from an increase in platelet mass is not seen. In childhood, most occurrences of thrombocytosis are secondary. In general, occurrences of reactive thrombocytosis are moderate in degree and asymptomatic and respond with treatment of the underlying disorder. Reactive thrombocytosis is often seen in association with inflammatory disorders (see Box 33-6). In these situations, the degree of thrombocytosis usually parallels the activity of the underlying condition. Therapy to decrease the platelet count is not indicated. Iron deficiency is often associated with an increase in the platelet count (see Chapter 12). Moderate thrombocytosis that persists for 1 to 2 weeks occurs commonly after major trauma or surgery.[295]

Rarely, a child with thrombocytosis will have a primary myeloproliferative disorder such as essential thrombocythemia or chronic myelogenous leukemia. These patients may be predisposed to thrombosis or hemorrhage.

ACQUIRED DEFECTS IN PLATELET FUNCTION

Drug-Induced Platelet Dysfunction

Many substances have been shown to inhibit platelet function, including both prescription drugs and medicinals such as garlic and various Chinese herbs.[296,297] In otherwise normal individuals, the impairment in platelet function produced by these substances is of no clinical significance. On the other hand, these agents may cause serious hemorrhage in patients with underlying coagulopathies, such as uremia, hemophilia, or thrombocytopenia, or in patients taking anticoagulants such as heparin or warfarin.[298]

Oxygenated metabolites of arachidonic acid, collectively termed eicosanoids, are involved in a variety of processes, including thrombosis, inflammation, and allergy. Eicosanoids include prostaglandins, thromboxanes, and other compounds. Interference with eicosanoid synthesis is the basis for the action of many therapeutic agents, including analgesics, anti-inflammatory agents,

and antithrombotic drugs. The first enzyme in the synthetic pathway of prostaglandins and thromboxanes is cyclooxygenase (COX). There are two isoforms of his enzyme, COX-1 and COX-2. The former is constitutively expressed in most cells, including platelets. The latter is not normally present but may be induced in certain cells after stimulation with cytokines or other factors. In platelets, thromboxane X_2 (TxA_2) is the major product of COX. TxA_2 induces platelet aggregation and vasoconstriction. Aspirin blocks production of TxA_2 by covalently acetylating a serine residue near the active site of COX.[299] Because platelets do not synthesize new proteins, the action of aspirin is permanent and lasts the life of the platelet. Complete inactivation of platelet COX-1 is achieved when adults take 160 mg of aspirin daily. In pregnant women, aspirin may cross the placenta and impair platelet function in the fetus.[300,301] Aspirin prolongs the bleeding time but seldom produces values above the normal range.

Most other anti-inflammatory drugs act on platelets in a manner similar to that of aspirin, although the majority are less potent. Such agents include ibuprofen, naproxen, phenylbutazone, indomethacin, sodium salicylate, and related drugs. In contrast to those of aspirin, the effects of these medications are reversible.

Dipyridamole is a vasodilator that interferes with platelet function by increasing the intracellular concentration of cyclic adenosine monophophate (cAMP). This effect is mediated by inhibition of cyclic nucleotide phosphodiesterase.[302] In combination with warfarin, dipyridamole is used to inhibit embolization from prosthetic heart valves. Other drugs that raise cAMP levels by inhibiting phosphodiesterase, such as methylxanthines, also inhibit platelet function.

The thienopyridine derivative class of drug, including ticlopidine, inhibits platelet activation[303] and prolongs the bleeding time by blocking signaling through the $P2Y_{12}$ platelet adenosine diphosphate (ADP) receptor. Abnormal platelet function continues for several days after use of the drug is discontinued. A newer member of this class, clopidogrel, has supplanted ticlopidine because of its efficacy and better safety profile.[304-306]

Though used sparingly in pediatrics, GPIIb/IIIa antagonists are now widely used as anticoagulants in adult patients with heart disease.[307,308] These agents inhibit the final common pathway of platelet aggregation mediated by fibrinogen or VWF binding to GPIIb/IIIa. Therefore, GPIIb/IIIa antagonists more completely inhibit platelet aggregation than aspirin or clopidogrel does, each of which inhibits only one initiating pathway of platelet activation (COX and ADP receptors, respectively). Several GPIIb/IIIa inhibitors are commercially available for use in coronary intervention procedures or unstable angina.[307,308]

A number of antibiotics inhibit platelet aggregation and the release reaction,[309] although the mechanisms are not well understood. Penicillin causes platelet dysfunction when administered at high doses, but this effect is usually clinically insignificant. However, certain semisynthetic penicillins, notably carbenicillin, may cause clinically significant bleeding when administered at the usual therapeutic doses.[310-313] Bleeding times are prolonged in patients receiving carbenicillin therapy, and serious episodes of hemorrhage have been reported.

Calcium channel blockers, such as verapamil and nifedipine, interfere with both adrenergic receptors and TxA_2 receptors in the platelet membrane[314] but do not prolong the bleeding time. Some antidepressants, including amitriptyline, imipramine, and chlorpromazine, interfere with platelet function through ill-defined effects on platelet membranes.[315] Propranolol and other β-adrenergic receptor antagonists mildly inhibit platelet function through effects on the cell membrane and serotonin transport.[316] Sulfonylureas used in the management of hyperglycemia have been associated with mild qualitative platelet defects.[317] Valproic acid, in addition to causing thrombocytopenia, can directly inhibit platelet function.[291]

Platelet Abnormalities Associated with Systemic Diseases

Uremia

Platelet dysfunction is a well-recognized and potentially serious complication of uremia. Patients with severe renal insufficiency may experience petechiae, purpura, gastrointestinal hemorrhage, and other forms of bleeding. Dialysis can correct the platelet dysfunction associated with uremia.[318] The precise cause of the platelet defect in uremia is unknown. A dialyzable substance in plasma causes platelet dysfunction, but the identity of this factor (or factors) remains controversial.

Bleeding may be severe, although the incidence of serious hemorrhage has declined in recent years because of more intensive dialysis and avoidance of drugs that further impair platelet function. If there is symptomatic bleeding or surgery is planned, patients should be treated with dialysis or desmopressin. Typically, only partial correction is achieved. The anemia of chronic renal insufficiency should be treated with erythropoietin because this has been shown to reduce the risk of serious bleeding.[318-323] If these approaches are not effective, cryoprecipitate may be added.

Liver Disease

Patients with liver disease have a multifactorial bleeding disorder. A reduction in plasma coagulation factors synthesized by the liver contributes to the increased risk of bleeding in these patients. Moderate thrombocytopenia is a common finding in liver disease and is well tolerated in most instances. Thrombocytopenia in cirrhotic liver disease has long been ascribed to portal hypertension and concomitant hypersplenism. Recent studies suggest that altered thrombopoietin production may contribute to the thrombocytopenia in liver disease. Qualitative platelet

Vasculitis
   Henoch-Schönlein purpura
   Kawasaki's syndrome
   Polyarteritis nodosa
Purpura fulminans
Connective tissue diseases
   Ehlers-Danlos syndrome
   Marfan's syndrome
   Osteogenesis imperfecta
   Minkes' disease
   Pseudoxanthoma elasticum
Hereditary hemorrhagic telangiectasia (Osler-Weber-
   Rendu syndrome)

defects have also been reported to occur in adult patients with liver failure,[324-327] although the mechanisms responsible are not well understood.

Vascular Purpuras

The vascular purpuras, also termed the nonthrombocytopenic purpuras, are mentioned in this chapter because these diseases share features with ITP. These conditions often follow acute infection. A list of childhood vascular purpuras is presented in Box 33-7.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP), also known as allergic purpura or anaphylactoid purpura, is a vasculitis affecting capillaries of the skin, synovial membranes, renal mesangium, and small intestine. The purpuric manifestations of the disease are usually self-limited.

HSP is presumably the result of an autoimmune process. The basic lesion is a microvasculitis with endothelial cell injury. Deposits of IgA are evident on capillary endothelial cells of the skin, kidney, and gastrointestinal tract. The renal manifestations of HSP are indistinguishable from those of so-called IgA nephropathy.[328]

The median age at diagnosis is 5 years (range, 0.4 to 15 years). Males predominate at a ratio of 3:2. An acute febrile illness precedes the syndrome in a majority of cases. In about 50% of patients, raised purpuric papules (palpable purpura) are evident over the lower extremities and buttocks, whereas in the remainder of patients the purpuric rash is more extensive.[329] Bullae, urticaria, diffuse erythema, and ulceration may also be seen. Joint pain or swelling is evident in about 80% of cases. Two thirds of patients exhibit abdominal signs or symptoms, including pain, hematemesis, or melena. Intussusception occurs in about 4% of patients with HSP. Edema, including scrotal swelling, is common. Renal involvement is evident in 40% of patients, many of whom exhibit severe proteinuria. The manifestations of this syndrome resolve within 1 to 6 weeks in the vast majority of patients. In a small subset of patients, permanent renal or joint damage may ensue.[330]

Glucocorticoid therapy can reduce the skin, joint, and gastrointestinal manifestations of the disease but should be reserved for those with severe symptoms. There is little evidence that glucocorticoids prevent renal involvement[331,332] or intussusception.

Purpura Fulminans

Purpura fulminans is a potentially fatal disorder that follows infection with meningococcus, streptococcus, varicella, and rubella. Thrombosis of small arterioles leads to infarction and hemorrhage of skin, subcutaneous tissues, and muscle. The disease occurs suddenly 2 to 4 weeks after a relatively mild infection such as varicella or scarlet fever. It begins with purpuric lesions on the skin that coalesce and then become necrotic. Patients become extremely ill with fever, hypotension, and laboratory evidence of DIC. The disease resembles pupura fulminans neonatalis, a disorder associated with homozygous protein C or protein S deficiency (see Chapter 32).

34 Acquired Disorders of Hemostasis

Steven W. Pipe and Neil A. Goldenberg

The application of clinical skills forms the cornerstone for assessment of a potential bleeding disorder. After confirming that a bleeding disorder is present through a comprehensive medical history and physical examination, the clinician should next address whether the condition is probably familial or acquired, which is sometimes difficult because some patients with mild underlying heritable hemostatic defects (e.g., mild von Willebrand's disease or platelet function defects) may not demonstrate suspicious clinical symptoms until faced with a traumatic injury or a surgical challenge at a later age. Nevertheless, acquired bleeding disorders remain a frequent clinical scenario with findings varying between acute unexpected bleeding during or immediately after surgery to unusual or excessive clinical manifestations of bruising, petechiae, epistaxis, gum bleeding, or hematoma formation that occur over a period of weeks to months. Distinguishing whether the bleeding most likely represents an abnormality in primary hemostasis, fibrin formation, or fibrinolysis provides a framework for the generation of a differential diagnosis (see Chapter 28). For example, petechiae are seen almost exclusively with defects in platelet number or function, whereas deep tissue hematomas are more likely to be associated with defects in fibrin formation, as would occur with clotting factor deficiencies. Standard laboratory screening tests such as the prothrombin time (PT) and activated partial thromboplastin time (APTT) are most often used in the initial evaluation but are insensitive to mild but clinically significant reductions in hemostatic capacity.[1] In addition, a platelet count does not provide any assessment of platelet function. Therefore, the clinician must rely on the history and physical findings to guide the extent of additional coagulation studies. The most common causes of acquired hemorrhagic disorders include drug-induced bleeding (e.g., anticoagulants), disseminated intravascular coagulation (DIC), liver disease, vitamin K (VK) deficiency, massive transfusion, renal disease, and rarely, acquired inhibitors to coagulation proteins.

ACQUIRED HEMORRHAGIC DISORDERS

Drug-Induced Bleeding

Many drugs have been associated with abnormal platelet function, although not all result in bleeding manifestations. The major classes include anti-inflammatory agents, antibiotics, cardiovascular drugs, psychotropic drugs, anticonvulsants, and anticoagulants. Aspirin is the most common example; it acts by irreversibly acetylating a serine residue at the active site of cyclooxygenase,[2] whereas other nonsteroidal anti-inflammatories (e.g., ibuprofen, naproxen) are reversible inhibitors.[3] β-Lactam antibiotics can interfere with platelet function through binding to the platelet membrane.[4,5] Calcium channel blockers, such as nifedipine,[6] and tricyclic antidepressants, such as amytriptyline,[7] can give rise to decreased

platelet aggregation responses but are unlikely to result in clinical bleeding. Valproic acid has become one of the most commonly used anticonvulsants in children. Interestingly, several mechanisms of relevant valproate-induced coagulopathy have been described, including thrombocytopenia and platelet dysfunction, acquired von Willebrand's disease, decreased VK-dependent clotting factors, hypofibrinogenemia, and decreased factor XIII levels.[8] Therapeutic anticoagulants (heparin, low-molecular-weight-heparin [LMWH], warfarin) should be the most readily apparent cause of drug-induced bleeding and in most patients can be correlated with laboratory monitoring. Platelet receptor antagonists (IIb/IIIa inhibitors, e.g., abciximab, eptifibatide, tirofiban; adenosine diphosphate receptor antagonists, e.g., clopidogrel) are increasingly being used in patients with congenital heart disease and those undergoing interventional studies.[9]

In most cases, discontinuation of the offending drug should resolve the hemorrhagic manifestations, but resolution will depend on the reversibility and half-life of the drug. Administration of VK will in most cases rapidly reverse warfarin-induced bleeding. Alternatively, fresh frozen plasma (FFP) can be used to replace VK-dependent clotting factors rapidly. Recently, recombinant factor VIIa (rVIIa) has proved effective at rapidly reversing warfarin-induced coagulopathy.[10] Transfusions of fresh platelets are indicated in patients with life-threatening or unremitting bleeding as a result of drug-induced platelet dysfunction. In cases of minor bleeding in which the drug cannot readily be discontinued (e.g., anticonvulsants), desmopressin has been used with some success.[11]

Disseminated Intravascular Coagulation

DIC is a pathologic syndrome in which the normal physiology of coagulation is disturbed by the simultaneous action of four mechanisms: increased thrombin generation, suppressed physiologic anticoagulant pathways, activation and subsequent impairment of fibrinolysis, and activation of the inflammatory pathway.[12] It leads to widespread intravascular deposition of fibrin with resultant thrombotic end-organ complications and consumption of platelets and coagulation proteins, all of which combine to result in severe bleeding. Associated damage to the microvasculature can contribute to organ dysfunction, capillary leak, and shock.

Etiology

DIC is always a secondary phenomenon and not a disease entity in its own right. Thus, recognition of it should prompt the clinician to identify and treat the underlying cause rather than merely react to the bleeding manifestations. It most frequently occurs in the settings of sepsis, trauma, and systemic inflammatory syndrome at an approximate frequency of 0.4% to 1% in hospitalized children, with sepsis accounting for approximately 95% of cases.[13,14] It is primarily a clinical diagnosis based on

the evaluation of laboratory results in patients with a clinical condition known to be associated with DIC (Box 34-1).

Clinical Manifestations

The clinical manifestations of DIC include bleeding, thrombosis, or both, although bleeding typically predominates. Early indicators are bleeding from venipuncture sites, intravascular access, and surgical wounds. Mucocutaneous bleeding may be manifested as bruising, petechiae, epistaxis, gum bleeding, blood from tracheal aspirates, gastrointestinal bleeding, and hematuria. In fulminant cases, DIC may lead to bleeding into vital organs. However, with increasingly sensitive diagnostic tests that can detect endogenous activation of the hemostatic process, the clinical spectrum of DIC is broad. Nonovert DIC describes a stressed but compensated hemostatic system in which laboratory test results are abnormal but there are no clinical manifestations.[15] Overt DIC is described as a stressed and decompensated hemostatic system in which laboratory test results are abnormal and clinical bleeding or microvascular thrombosis and organ dysfunction are noted. Overt DIC may be controlled or uncontrolled, depending on whether the process will resolve when the underlying stimulus is removed.

Diagnosis

The clinical findings of a profoundly ill child with bleeding believed to be secondary to DIC can be supported by laboratory tests showing evidence of a consumptive coagulopathy with activation of the fibrinolytic cascade. Moderate to severe thrombocytopenia with or without anemia will be evident from the complete blood count. Thrombocytopenia is present in approximately 50% of patients and suggests consumption of platelets.[16] Anemia could be caused by bleeding or, when accompanied by schistocytes on the blood smear, by microangiopathic hemolysis. The PT and APTT are prolonged in 50% to 60% of patients[17] as a result of consumption of many coagulation proteins, including prothrombin, factors V, VII, and VIII, and fibrinogen. Fibrinogen/fibrin degradation products and D-dimers are both increased in most patients with DIC, thus suggesting activation of the fibrinolytic process.[18] Marked reductions in plasma anticoagulants, including proteins C and S and antithrombin, have also been described.[12,19] The most sensitive tests for the diagnosis of DIC are markers of endogenous thrombin generation: prothrombin fragment 1.2 and thrombin-antithrombin complexes (TATs).[20] Prothrombin fragment 1.2 is released when thrombin is generated from prothrombin. TATs are generated by binding of thrombin

---

Box 34-1	**Causes of Disseminated Intravascular Coagulation**

INFECTIOUS

Meningococcemia (purpura fulminans)
Other gram-negative bacteria (*Haemophilus*, *Salmonella*)
Gram-positive bacteria (group B streptococci)
Rickettsia (Rocky Mountain spotted fever)
Viruses
Malaria
Fungi

TISSUE INJURY

Central nervous system trauma (massive head injury)
Multiple fractures with fat emboli
Crush injury
Profound shock or asphyxia
Hypothermia or hyperthermia
Massive burns

MALIGNANCY

Acute promyelocytic leukemia
Acute monoblastic or myelocytic leukemia
Widespread malignancies (neuroblastoma)

VENOM OR TOXIN

Snake bites
Insect bites

MICROANGIOPATHIC DISORDERS

"Severe" thrombotic thrombocytopenic purpura
Hemolytic-uremic syndrome
Giant hemangioma (Kasabach-Merritt syndrome)

GASTROINTESTINAL DISORDERS

Fulminant hepatitis
Severe inflammation bowel disease
Reye's syndrome

HEREDITARY THROMBOTIC DISORDERS

Homozygous protein C deficiency

MISCELLANEOUS

Severe graft rejection
Acute hemolytic transfusion reaction
Severe collagen vascular disease
Kawasaki's disease
Heparin-induced thrombosis
Infusion of "activated" prothrombin complex concentrates
Hyperpyrexia/encephalopathy, hemorrhagic shock
    syndrome

with its inhibitor antithrombin. The standard assays (PT, APTT, platelet count, and D-dimers) are relatively rapid and simple to perform. However, changes in these test results do not always occur at the same time, and laboratory values can change rapidly, depending on the patient's clinical status. This may create confusion in patient management and make the diagnosis of DIC at an early stage particularly difficult. The International Society on Thrombosis and Haemostasis Scientific Standardization Subcommittee on DIC proposed a scoring system developed from a previously described set of diagnostic criteria.[15] The five-step algorithm assigns a score based on the severity of abnormality of each of the following: platelet count ($>100 \times 10^9$/L = 0; $<100 \times 10^9$/L = 1; $<50 \times 10^9$/L = 2), elevated fibrin-related markers (no increase = 0; moderate increase = 2; strong increase = 3), prolonged PT (<3 seconds = 0; >3 seconds but <6 seconds = 1; >6 seconds = 2), and fibrinogen level (>1 g/L = 0; <1 g/L = 1). A total score of 5 or more is considered compatible with overt DIC. The sensitivity and specificity of this scoring system are greater than 90%. However, the algorithm should be applied only in the presence of an underlying disorder known to be associated with DIC. A modified algorithm that scores for rates of change in the PT, platelet count, and D-dimer and incorporation of antithrombin, protein C, and TAT complexes may help identify nonovert DIC in its early stages.[15]

Treatment

The fundamental principle of treatment of DIC is specific and vigorous management of the underlying disorder. In some cases, DIC will completely resolve within hours after resolution of the underlying condition (e.g., appropriate control of sepsis with antimicrobials). However, in other cases, supportive measures are required to control the DIC until the underlying condition is resolved (e.g., the use of all-*trans*-retinoic acid and chemotherapy for the treatment of acute promyelocytic leukemia and DIC[21]). Therapeutic interventions remain controversial and need to be individualized according to the underlying basis of the DIC and the severity of the clinical symptoms. For example, in nonovert DIC, children do not usually require therapy for the DIC itself. However, in the presence of uncontrolled overt DIC, therapeutic intervention, including administration of blood replacement products, may be indicated to improve hemostasis while waiting for effective therapy for the underlying condition. Treatment modalities investigated include blood component therapy, anticoagulants, restoration of the natural anticoagulant pathways, and other agents.

Blood Component Therapy. In general, the more severe the laboratory abnormalities, in particular, the degree of thrombocytopenia and depletion of coagulation factors, the greater the risk of bleeding complications with DIC. Hence, treatment with FFP, fibrinogen, cryoprecipitate, platelets, or any combination of these components appears to be a rational therapy in bleeding patients or those at risk for bleeding because of significant depletion of these hemostatic factors. However, blood component therapy should not be instituted on the basis of laboratory results alone and is indicated only for patients with active bleeding, those who require an invasive procedure, or those who are otherwise at risk for bleeding complications.[22] Large volumes of plasma may be necessary to correct the coagulation defect. Reasonable goals are to maintain platelet counts above 50×10^9/L, fibrinogen concentrations greater than 1 g/L, and PT values less than double the normal range.

Anticoagulant Therapy. In view of the central role played by thrombin in DIC, the use of heparin or other anticoagulants to inhibit thrombin generation appears reasonable. Heparin can at least partly inhibit the activation of coagulation in sepsis and other causes of DIC.[23] However, a beneficial effect of heparin on clinically important outcome events in patients with DIC has never been demonstrated in controlled clinical trials and is not a standard of care in overt cases of DIC. Nonetheless, therapeutic doses of heparin may be indicated in patients with clinically overt thromboembolism (TE), chronic DIC, or extensive fibrin deposition, such as seen in purpura fulminans or acral ischemia.[24]

Replacement of Natural Anticoagulant Pathways. Depleted levels of antithrombin, protein C, and protein S cannot be effectively replaced with FFP alone because of the short plasma half-life of these proteins. Antithrombin and protein C concentrates have been extensively evaluated in patients with DIC.[25-29] Trials of antithrombin therapy have not yet provided conclusive evidence sufficient to make treatment recommendations.[30] However, the double-blind, placebo-controlled, phase III trial of recombinant human activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) demonstrated a significant decrease in mortality in the protein C–treated group when compared with placebo.[28] The dose of recombinant activated protein C is 24 μg/kg/hr.[31] Bleeding is the only recognized adverse effect with this therapy, so maintaining the platelet count above 30×10^9/L is prudent. Interestingly, activated protein C was equally effective in patients with reduced or normal plasma levels of protein C, thus suggesting that activation of protein C may be a limiting factor in sepsis.

Other Agents. Recently, rVIIa has become an attractive strategy to control bleeding in various scenarios.[32] In situations in which volume overload is an issue or bleeding persists despite adequate blood component support, use of rVIIa has been shown to be effective.[33] However, these data have been generated mostly from anecdotal

reports, and given the potential adverse thrombotic complications with this agent, controlled randomized trials are required to address its safety and efficacy in the setting of DIC. Newer anticoagulants directed against the tissue factor/factor VIIa complex, such as recombinant nematode anticoagulant protein c2 (rNAPc2), are currently being evaluated in phase II/III clinical studies.[34-36]

Liver Disease

Pathophysiology

The liver is the main site of synthesis for most hemostatic components. However, the hemostatic impairment in liver disease involves a variety of mechanisms, including impaired hepatic synthesis, activation of the coagulation and fibrinolytic systems, poor clearance of activated hemostatic components, loss of hemostatic proteins into ascitic fluid, concurrent VK deficiency, thrombocytopenia, and impaired platelet function.[37,38] When both procoagulant and anticoagulant levels are reduced, the resulting hemostatic dysregulation can lead to pathologic hemorrhage, as well as thrombosis. Along with reduced synthesis, abnormal forms of the hemostatic proteins may be secreted that might function as inhibitors of coagulation. For example, abnormal fibrinogens (dysfibrinogenemia) are very common in liver disease.[39] Similarly, VK-dependent proteins (factors II, VII, IX, and X and proteins C, S, and Z) decrease in liver disease. However, they may also be secreted as forms with incomplete γ-carboxylation (see Chapter 26), thereby leading to reduced functional activity.[40]

Clinical Manifestations

Clinical symptoms are variable and depend, to some extent, on the etiology of the liver failure. Symptoms include ecchymosis and petechiae, mucous membrane bleeding, hemorrhage from gastrointestinal varices, and hemorrhage into the abdomen or central nervous system (CNS). Coagulation screening tests (APTT, PT, thrombin clotting time) are usually prolonged, platelet counts are reduced, and the bleeding time is increased. Plasma concentrations of factors VII and V and, less commonly, fibrinogen are decreased.[37] Levels of factor VIII may be normal or elevated, possibly reflecting reduced clearance via low-density lipoprotein receptor–related protein,[41] and can be helpful in distinguishing severe liver disease from DIC. However, both conditions may occur simultaneously.[42] Fibrin degradation products or D-dimer levels are often increased in hepatic failure and contribute to prolongation of the thrombin clotting time and impaired platelet function.[43] Dysfibrinogenemia will contribute to prolongation of the PT and APTT, but the thrombin time and reptilase assays are more sensitive. Dysfibrinogenemia may be confirmed by demonstrating an abnormal ratio of clottable fibrinogen (functional assay) to fibrinogen antigen (immunoassay).

Treatment

Treatment of the hemostatic manifestations of severe hepatic failure is difficult. The enhanced hemostasis after replacement therapy is usually transient because adequate volumes of FFP cannot be infused as a result of the associated hypervolemia. In addition, many coagulation proteins are cleared rapidly, thereby limiting any beneficial effect. Usually, therapy specifically directed at the coagulopathy is reserved for active bleeding or to facilitate invasive procedures. A common indication for FFP is an international normalized ratio (INR) higher than 2 or PT prolongation greater than 4 seconds.[44] Desmopressin can induce the release of factor VIII and von Willebrand factor and thereby result in a shortened bleeding time. However, in randomized trials, desmopressin failed to control bleeding from acute variceal hemorrhage[45] or decrease blood loss with hepatectomy.[46] Cryoprecipitate can be administered to increase plasma fibrinogen concentrations if necessary. Secondary VK deficiency caused by impaired VK utilization or absorption, the latter often resulting from intrahepatic and extrahepatic biliary atresia, requires treatment with VK.[47] rVIIa has been shown to correct the prolonged PT in nonbleeding cirrhotic patients, but randomized trials in the setting of liver biopsy or variceal bleeding have shown either no difference in hemostasis or only early, modest reductions in the rebleeding rate with no difference in overall bleeding or transfusion requirements.[40] Larger studies are still required to evaluate the efficacy and safety of this agent in liver disease.

Patients requiring liver transplantation invariably have severe, end-stage hepatic failure with its associated hemorrhagic complications. Additional risk factors that contribute to bleeding in children during transplantation include extensive scar tissue from previous surgery, prolonged duration of the surgery, downsizing the donor organ to fit the small patient, dilutional coagulopathy, and excessive activation of the fibrinolytic system during the anhepatic phase.[48-50] Although treatment with antifibrinolytic agents is an attractive option, this approach should be used with caution because either hemorrhagic or thrombotic complications may develop in children after liver transplantation. The prophylactic use of rVIIa to reduce blood loss and transfusion requirements in patients undergoing liver transplantation has been studied in two multicenter randomized controlled trials.[51,52] These trials failed to demonstrate a benefit to support its use as a universal preemptive therapy for liver transplantation. rVIIa could be considered in individual cases as "rescue therapy" for patients with life-threatening coagulopathy and bleeding during transplantation or in situations in which blood products are unavailable or unacceptable (e.g., Jehovah witnesses).[53]

Vitamin K Deficiency

The role of VK in coagulation is detailed in Chapter 26, and bleeding as a result of VK deficiency in newborns is discussed in Chapter 5.

Clinical Manifestations

Symptoms of VK deficiency include mild to moderate bleeding, ecchymoses, oozing from intravenous puncture sites, and rarely, internal bleeding. Primary VK deficiency in healthy children is uncommon because of a relatively low VK requirement and the widespread distribution of VK in plant and animal tissues. In plants, the only important molecular form is phylloquinone (VK_1). Bacteria synthesize a family of vitamin K compounds called menaquinones (VK_2). The contribution of microbiologic flora of the gut to VK dietary intake is unknown but may be as high as 50%.[54] Although broad-spectrum antibiotics may reduce VK_2 production by intestinal bacteria, VK deficiency is rare in individuals consuming a normal diet.

Groups of children at high risk for VK deficiency include breast-fed newborns, chronically ill children with inadequate dietary intake of VK, children with disorders that interfere with the absorption of VK (diarrhea, cystic fibrosis, cholestatic liver disease, celiac disease), and children with poor nutrition who are receiving broad-spectrum antibiotics.[55-58] Cystic fibrosis, biliary atresia, and obstructive jaundice interfere with the absorption of fat-soluble vitamins and transport to the liver, with resultant VK deficiency. Therapeutic drugs can interfere with vitamin K metabolism (e.g., phenytoin and warfarin). However, at least in the case of warfarin, this side effect is expected. Accidental exposure to toxic doses may occur in small children with access to warfarin in the home. Anticoagulant rodenticides can be another source of accidental exposure. Because of the emergence of warfarin-resistant strains of rats, newer "long-acting" second-generation compounds have been used. These so-called "superwarfarins" have higher affinity for VK_1-2,3-epoxide reductase, are able to disrupt the VK_1-epoxide cycle at more than one point, exhibit hepatic accumulation, and have unusually long biologic half-lives because of high lipid solubility and enterohepatic circulation. Upon accidental ingestion, these compounds can cause anticoagulation for several days or even weeks. However, in most cases involving small children, the exposure is low and bleeding manifestations are rare.[59,60]

VK deficiency has been described in bone marrow transplant and oncology patients, in whom the cause is multifactorial as a result of drug antagonism, liver dysfunction, fat malabsorption, anorexia, or inadequate dietary intake (or any combination of such causes). A study of children evaluated before bone marrow transplantation identified 31% (8 of 26) with evidence of VK deficiency (as detected by circulating abnormally carboxylated forms of prothrombin), although only 1 patient had a prolonged PT, thus highlighting that PT alone is an insensitive marker of VK deficiency. Six of the eight affected patients exhibited peritransplant bleeding.[61]

Laboratory Diagnosis

The PT and APTT may both be abnormal in VK deficiency but should correct in a 1 : 1 mix with normal plasma. Other acquired or congenital coagulopathies can result in similar screening test abnormalities, and thus specific coagulation factor assays need to be performed. Decreased levels of more than one VK-dependent factor should raise suspicion of VK deficiency. A normal factor V level together with normal liver function study results would argue against significant liver disease as the underlying explanation. Normal factor VIII and fibrinogen levels and absence of elevated D-dimers would make DIC unlikely. However, VK deficiency can complicate other coagulopathies, such as DIC or liver disease. If there is any doubt about the diagnosis, the patient should receive VK therapy in conjunction with other supportive care.

Treatment

The route and specific type of therapy are dictated by the urgency of the clinical situation and the potential side effects of treatment. For example, severe anaphylactoid reactions, though rare, have complicated intravenous VK administration, even when the solution is diluted and infused slowly. Therefore, intravenous administration of VK, at a rate no faster than 1 mg/min, should be restricted to situations in which other routes are not feasible and the risk is justified. Intramuscular VK should be avoided because it can result in pain, swelling, and hematoma formation. The preferred systemic route is subcutaneous injection because it is safe and effective. Oral VK is effective if absorption is unimpaired. Although oral administration is generally thought to produce slower correction of the PT (6 to 8 hours) than achieved with parenteral VK (2 to 6 hours), a study in adults suggested that the oral route may actually be faster, at least in reversing the effect of warfarin.[62]

Asymptomatic patients with mildly abnormal coagulation results that are presumed secondary to VK deficiency should be given VK subcutaneously (1 to 5 mg, depending on size). This approach is both therapeutic and diagnostic, with correction of coagulation abnormality generally expected within 2 to 6 hours. A patient bleeding because of VK deficiency should receive 2 to 10 mg of VK subcutaneously. FFP (10 to 20 mL/kg) is particularly useful when the precise nature of the coagulopathy is unknown and the bleeding is severe. However, the amount of plasma needed for total correction of severe VK deficiency is so great that it may result in volume overload. A patient with life-threatening hemorrhage or an intracranial hemorrhage would probably benefit from administration of prothrombin complex concentrates at a minimum dose of 50 U/kg, in addition to systemic VK (5 to 20 mg). Prothrombin complex concentrates contain relatively uniform amounts of factors

II, IX, and X, with amounts of factor VII/VIIa varying.[63] rVIIa has been used anecdotally.[64,65]

Prevention

Prophylactic VK should be given to patients at risk, such as patients with inadequate nutrition and those receiving broad-spectrum antibiotics. Most patients requiring total parenteral nutrition (TPN) are supplemented with VK. There has been concern in the past that maternal anti-convulsant therapy may be associated with an increased risk of neonatal bleeding related to enzymatic degradation of vitamin K.[66] This suggestion has prompted recommendations that VK prophylaxis be given to pregnant mothers taking anticonvulsants. However, recent studies have demonstrated that the incidence of bleeding in infants exposed to these drugs antenatally is no higher than in controls,[67] with no benefit seen for routine VK prophylaxis in this setting.[68]

Massive Transfusion Coagulopathy

Uncontrolled bleeding can be a clinical problem associated with the management of trauma and surgical patients and often necessitates transfusion of large amounts of blood and blood derivatives. Massive transfusion has commonly been defined as replacing at least one blood volume in 24 hours.[69] Patients with this degree of bleeding are at risk for defective hemostasis related to the transfusions, in addition to the underlying precipitating trauma or surgical insult. The resulting bleeding diathesis may be complex and include evidence of DIC, depletion of hemostatic factors through blood loss, tissue injury, and consumption of factors, dilutional coagulopathy secondary to aggressive blood component resuscitation, hypothermia, platelet dysfunction, and excessive fibrinolysis.[69] In surgical procedures with a high risk for blood loss, aprotinin has been used because it inhibits multiple protease targets.[70-73] Prospective studies in adults have shown that it reduces the proportion of patients who require blood transfusion.[74] A meta-analysis of prospective trials in children undergoing cardiac surgery involving cardiopulmonary bypass showed that aprotinin reduced the proportion of children requiring transfusion by 33% but did not have an effect on the volume of blood transfused or the volume of chest tube drainage.[75] rVIIa has demonstrated effectiveness in patients with bleeding associated with massive transfusion who were refractory to conventional treatments.[76] The limited experience with rVIIa in pediatric patients undergoing cardiopulmonary bypass and extracorporeal membrane oxygenation suggests efficacy as rescue therapy, but it has not been studied prospectively.[77-80]

Acquired Inhibitors of Coagulation Proteins

Acquired inhibitors directed against coagulation factors are either circulating alloantibodies or autoantibodies that specifically neutralize procoagulant activity or increase clearance and thereby lead to deficiency of plasma coagulation factors, often accompanied by bleeding.[81] Examples of alloantibodies include those directed against infused factor VIII, as observed in 15% to 25% of patients with hemophilia A (discussed in Chapter 30). Autoantibodies directed against endogenous factor VIII have also been observed in individuals without hemophilia and typically occur in postpartum women, elderly individuals, or those with autoimmune disorders. However, autoantibodies to other coagulation proteins have been described as well, including factors II, V, VII, IX, and XI and von Willebrand factor. Antiphospholipid antibodies (APAs), including lupus anticoagulants (LAs), are a heterogeneous group of antibodies that react with proteins bound to phospholipids. Though primarily functioning as inhibitors of in vitro phospholipid-dependent clotting assays, these antibodies paradoxically predispose to thrombosis rather than hemorrhage. However, a unique LA coagulopathy has been observed as a hemorrhagic syndrome associated with hypoprothrombinemia (see later).

Acquired Inhibitors to Factor VIII

Anti–factor VIII autoantibodies are rare in children but can result in severe bleeding and significant morbidity. These antibodies are associated with underlying medical conditions in half of those affected, including malignancy, autoimmune disease, lymphoproliferative disorders, or drugs (e.g., penicillin).[82] Patients can exhibit bleeding symptoms ranging from easy bruising to intracranial hemorrhage. In one patient, the clinical course was also complicated by nephrotic syndrome.[83] Laboratory screening studies will show a prolonged APTT that does not fully correct upon mixing with normal plasma in a 1 : 1 mix ("inhibitor screen"). Factor VIII inhibitors can also be distinguished from LAs by performing the APTT 1 : 1 mix again with an incubation phase (typically 30 minutes at 37° C). The latter study will show further prolongation of the APTT, indicative of progressive neutralization of factor VIII provided by the normal plasma mixing. This additional prolongation will not be seen with incubation in the presence of an LA.

Treatment is two-pronged and directed at stopping the bleeding and eradicating the inhibitor. Hemostasis can be achieved with high doses of factor VIII concentrates, activated prothrombin complex concentrates, and rVIIa. Immunosuppression may be accomplished with cytotoxic agents such as cyclophosphamide or prednisone or with gamma globulin. Inhibitors have also been eradicated by extracorporeal immunoadsorption and immune tolerance through regular exposure to high-dose factor VIII infusions. Review of the available literature suggests that in contrast to adults, anti–factor VIII autoantibodies in children may resolve more quickly and easily and do not necessarily require steroids and cytotoxic agents.[82,84] Recombinant factor VIII should be considered in the initial treatment and additional hemostatic

support with activated prothrombin complex concentrates and rVIIa administered as needed. Withdrawal of instigating drugs such as penicillin may also facilitate resolution.

Acquired Inhibitors to Factor IX

Few cases of spontaneous factor IX inhibitors have been reported in nonhemophiliacs, and most adult cases have been related to underlying systemic disorders such as systemic lupus erythematosus (SLE), hepatitis, multiple sclerosis, rheumatic fever, collagen vascular disease, postpartum status, and prostatectomy. Descriptions in children are limited to a few case reports.[85-87] Bleeding manifestations have included cutaneous ecchymoses and soft tissue hematomas. Diagnostic studies are similar to those for anti–factor VIII inhibitors. Treatment has included any combination of corticosteroids, gamma globulin, or cyclophosphamide, with rapid resolution of the inhibitor. One child underwent spontaneous resolution.[86] Recombinant factor IX and rVIIa can be considered for the acute management of bleeding.

Acquired Inhibitors As a Result of Exposure to Bovine Thrombin

Topical preparations of bovine thrombin are widely used for surgical hemostasis and contain fibrinogen, as well as small amounts of factor V and other proteins. The development of acquired inhibitors to coagulation factors as a consequence of exposure to this highly immunogenic agent is a frequent occurrence, though often unrecognized. In this context, antibodies directed against factor V are most frequent, although antiprothrombin and anti–factor X antibodies have also been described.[88,89] The incidence of symptomatic inhibitors is not known. In a study of 151 adult patients exposed to bovine thrombin during cardiac surgery, antibodies directed against human coagulation proteins developed in 56% of the patients.[88] However, adverse clinical outcomes did not correlate with antibody formation. A literature review identified 12 cases of inhibitors in pediatric patients after exposure to thrombin.[89] In eight cases, the antibodies were directed against human coagulation proteins, with hemorrhagic complications developing in five patients. Bleeding manifestations included cutaneous, gastrointestinal, pulmonary, and cerebral hemorrhages. Patients exhibited prolongation of both the PT and APTT and mixing studies consistent with an inhibitor. Specific factor activity assays revealed the target for the inhibitor, but there was no correlation between laboratory studies and clinical bleeding. Corticosteroids and gamma globulin have been used, with resolution of the inhibitor over a period of days to weeks. Platelet transfusions are another option inasmuch as approximately 20% of factor V activity is present in platelet granules, which are shielded from circulating antibodies.[90] Coagulation factor inhibitors should be suspected in any postoperative patient who is exposed to topical bovine thrombin and has a prolonged PT and APTT.

Acquired von Willebrand's Syndrome

Acquired von Willebrand's syndrome (AVWS) is a rare bleeding disorder with clinical and laboratory findings similar to those of inherited von Willebrand's disease. Since its original description in 1968 in a patient with SLE, more than 300 cases have been reported.[91] AVWS usually occurs in individuals with no personal or family history of von Willebrand's disease and is accompanied by bleeding symptoms in about three quarters of patients. Diagnosis in the remaining patients is based on abnormalities found during routine hemostasis screening tests.[92] As would be expected, mucocutaneous bleeding symptoms predominate. Underlying disorders are identified frequently and fall into six main categories: lymphoproliferative and myeloproliferative disorders, solid tumors, immunologic and cardiovascular disorders, and other miscellaneous conditions, including drug associations. Though typically a syndrome of advanced age, AVWS has also been reported in children, primarily associated with congenital heart disease, collagen vascular diseases, Wilms' tumor, hypothyroidism, and certain drugs. Drug-associated AVWS has been described in up to 20% of pediatric patients taking valproic acid, although bleeding manifestations were mild and did not require discontinuation of the anticonvulsant.[93]

Four main pathogenic mechanisms can lead to AVWS: (1) specific or nonspecific autoantibodies that form immune complexes with von Willebrand factor leading to inactivation and increased clearance of this factor, (2) absorption of von Willebrand factor onto malignant cell clones, (3) loss of high-molecular-weight von Willebrand factor multimers because of high shear stress, and (4) increased proteolytic degradation of von Willebrand factor by circulating proteases.[91] Laboratory studies can include a prolonged bleeding time, reduced functional von Willebrand factor (ristocetin cofactor activity, collagen-binding assay), and reduced high-molecular-weight multimers (see Chapter 30). A search for evidence of an inhibitor should be performed by measuring von Willebrand factor activity after mixing experiments involving patient plasma and normal plasma incubated at 37° C.

The three goals of treatment should be control of active bleeding, prevention of bleeding with invasive procedures as needed, and treatment of the underlying disease. Desmopressin and factor VIII/von Willebrand factor concentrates have provided only short-term control of bleeding in the presence of autoantibodies,[91] and gamma globulin, corticosteroids, or other immunosuppressive agents have been used. rVIIa may also be effective in this situation.[94] In non–inhibitor-associated AVWS, desmopressin is the preferred therapy, with factor VIII/von Willebrand factor concentrates being reserved for those who do not achieve sufficient control with desmopressin alone. Ultimately, normalization of hemostasis may not be seen until the underlying precipitating condi-

tion is treated effectively (e.g., surgery or chemotherapy, or both, for Wilms' tumor).

Acquired Inhibitors to Prothrombin— Hemorrhagic Lupus Anticoagulant Syndrome

LAs represent a diverse group of antibodies directed against proteins bound to phospholipids. They may be found in patients with SLE and other autoimmune disorders, as well as in otherwise healthy individuals, and have been implicated in thrombotic complications. However, in children, LAs are most often identified after investigation of a prolonged APTT noted during presurgical evaluation or associated with a history of infection.[95] In the vast majority of cases, the patients are asymptomatic (including no bleeding manifestations), and the LA usually resolves spontaneously over a period of days to weeks, without interfering with any required invasive procedure.

However, a rare hemorrhagic LA syndrome (ecchymoses, epistaxis, gastrointestinal bleeding, hematomas, and even hemarthroses) has been observed with associated low prothrombin levels.[96-101] Such patients exhibit concurrent prolongation of the PT (unusual for uncomplicated LA), which is thought to be caused by antiprothrombin antibodies. These antibodies are not typically neutralizing, and mixing studies may thus not indicate the presence of an inhibitor. Instead, the reduced prothrombin level is thought to result from the formation of immune complexes and subsequent increased plasma clearance.[102] Antibodies directed against the carboxy-terminal portion of the prothrombin molecule have been detected.[103] Bleeding symptoms usually resolve without therapy, although patients with significant bleeding may be treated with prothrombin complex concentrates. Corticosteroids and other immunosuppressants have been used in some cases.

ACQUIRED THROMBOEMBOLIC DISEASE

TE has been diagnosed increasingly in children in recent years because of enhanced survival from serious underlying illnesses, heightened use of invasive vascular procedures and devices, and a growing (albeit still suboptimal) awareness that TE does indeed occur in children. The remainder of this chapter summarizes the clinical spectrum and characterization of pediatric TE, key considerations for diagnostic evaluation and antithrombotic management, and long-term outcomes. Emphasis is also placed on unresolved and emerging clinical/investigative issues in the field.

Characterization of Thromboembolism in Children

TE is anatomically classified by vascular type (i.e., venous versus arterial), distribution (e.g., distal, proximal, or central part of the lower extremity; superficial versus deep vasculature), and organ system affected, if applicable (e.g., renal vein thrombosis [RVT], cerebral sinovenous thrombosis [CSVT], pulmonary embolism [PE]). TE is also distinguished by the additional clinically relevant factors of first-episode versus recurrent, symptomatic versus asymptomatic, acute versus chronic (a distinction that can be difficult at times), veno-occlusive versus nonocclusive, and idiopathic versus risk associated. This last category includes both clinical prothrombotic risk factors (e.g., exogenous estrogen administration, indwelling central venous catheter, reduced mobility) and blood-based thrombophilic conditions (e.g., transient or persistent APAs, acquired or congenital anticoagulant deficiencies, factor V Leiden or prothrombin 20210 mutations), as discussed in greater detail later under "Etiology." Because of the frequency of indwelling central venous catheters as a clinical risk factor for TE in children, TE is also often classified as catheter related versus non–catheter related.

Venous Thromboembolism

Epidemiology

Several national and international registries have evaluated the incidence of venous thromboembolism (VTE) in children over the past 13 years. From these data a cumulative incidence of 0.07 per 10,000 (5.3 per 10,000 hospitalizations) was estimated for extremity deep venous thrombosis (DVT) or PE (or both) in non-neonatal Canadian children,[104] and an incidence rate of 0.14 per 10,000 children per year was reported for all forms of VTE in the Netherlands.[105] More recently, evaluation of the National Hospital Discharge Survey and census data for all forms of VTE in the United States disclosed an overall incidence rate of 0.49 per 10,000 per year.[106]

Closer examination of the epidemiologic data reveals that the age distribution of VTE in children is bimodal, with a peak incidence in the neonatal period and adolescence. With regard to the newborn period, the cumulative incidence of venous or arterial TE (or both) was reported to be 0.51 per 10,000 births in Germany[107] and 24 per 10,000 admissions to neonatal intensive care units in southern Ontario.[108] The Dutch registry indicated a VTE-specific incidence rate of 14.5 per 10,000 per year in the neonatal period, approximately 100 times greater than the overall rate in childhood.[105] Among adolescents 15 to 17 years of age, the VTE-specific incidence rate in the United States was determined to be 1.1 per 10,000 per year, a rate nearly threefold that observed overall in childhood.[106]

Although differing selection criteria have contributed to the considerable variability in incidence estimates just presented, it is clear that the incidence of VTE in children is lower than that in middle-aged and elderly adults. Nevertheless, as discussed later in this chapter, the sequelae of VTE in children, particularly with regard to

post-thrombotic syndrome (PTS), appear to be at least as frequent and severe as sequelae in adults.

Etiology

The pathogenesis of VTE can be readily appreciated by considering Virchow's triad, which consists of venous stasis, endothelial damage, and the hypercoagulable state. In children, more than 90% of VTE episodes are associated with risk factors[105,109,110] (versus approximately 60% in adults), with risk factors often being derived from more than one component of this triad. Specific examples of VTE risk factors in children are shown in Figure 34-1. Among the most common clinical prothrombotic risk factors in childhood is an indwelling central venous catheter. More than 50% of DVT cases in children and more than 80% of cases in newborns occur in association with central venous catheters.[104,108] The reported cumulative incidence or prevalence of catheter-related thrombosis (CRT) in children receiving home TPN ranges widely from 1% to 80%[111-116]; this broad variation is largely influenced by differing study designs, selection criteria, and diagnostic imaging modalities. Indwelling central venous catheters, an underlying malignancy or disorder for which bone marrow transplantation was undertaken, and congenital cardiac disease and its corrective surgery were all highly prevalent in the Canadian pediatric thrombosis registry,[110] whereas underlying infectious illness and the presence of an indwelling central venous catheter were identified as pervasive clinical risk factors in a recent cohort study analysis from the United States.[109] It is likely that differences in the composition of referral populations strongly contribute to differences in observed causes of VTE across major pediatric thrombosis centers.

With regard to blood-based risk factors for VTE, potent thrombophilic conditions (e.g., anticoagulant deficiencies such as protein C deficiency, APAs) in children are frequently acquired and, more rarely, may be congenital. By contrast, mild congenital thrombophilic traits (e.g., the factor V Leiden and prothrombin 20210 mutations, see Chapter 32) are common in white children, as in adults. Thrombophilia can potentially be caused by any alteration in hemostatic balance that increases thrombin production, enhances platelet activation/aggregation, mediates endothelial activation/damage, or inhibits fibrinolysis. Common examples of acquired thrombophilia in children include increased factor VIII activity with significant infection and inflammatory states, anticoagulant deficiencies as a result of consumption in bacterial sepsis and DIC, production of inhibitory antibodies in acute viral infection, and para-infectious development of APAs. A panel of thrombophilia traits and markers that have been identified as risk factors for VTE in pediatric studies, and as such are recommended by the Subcommittee for Perinatal and Pediatric Thrombosis of the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis for the diagnostic laboratory evaluation of acute VTE in children,[117] is presented in Table 34-1. To provide an appreciation of the magnitude of the increase in risk for VTE associated with several congenital/genetically influenced thrombophilia traits, population-based estimates of risk for VTE derived from the adult literature are presented in Table 34-2 (also see Chapter 32).

Clinical Manifestations

The degree of clinical suspicion for acute VTE in children should be influenced principally by clinical prothrombotic risk factors and a family history of early VTE or other vascular disease elicited by thorough interview, known thrombophilia traits and risk factors, and clinical signs and symptoms. The signs and symptoms of VTE depend on the anatomic location and organ systems affected and are influenced by the characteristics of veno-

Venous stasis
Postoperative state

Factor V Leiden mutation, heterozygous	2-7×	
Factor V Leiden mutation, heterozygous, plus oral contraceptive pill use	35×	
Factor V Leiden mutation, homozygous	80×	

occlusiveness and chronicity. The classic manifestation of *acute extremity DVT* is painful unilateral limb swelling. The lack of other findings on physical examination (e.g., Homan's sign or the presence of a palpable cord in the popliteal fossa) should not reduce clinical suspicion for DVT. In upper extremity DVT with extension into and occlusion of the superior vena cava (SVC), signs and symptoms may include swelling of the neck and face, bilateral periorbital edema, and headache.

PE is classically manifested by sudden-onset, unexplained shortness of breath and pleuritic chest pain. When PE is proximal or bilaterally extensive in the distal pulmonary arterial tree, hypoxemia is often present. Associated right heart failure may be manifested as hepatomegaly, peripheral edema, or both. Proximal PE and especially saddle emboli can be accompanied by cyanosis or sudden collapse. However, in many cases, PE may be asymptomatic or produce only subtle symptoms in children,[118-121] especially when involving limited segmental branches of the pulmonary arteries. In one retrospective series, only 50% of affected children had clinical symptoms attributable to PE.[119]

Acute *CSVT* may cause unusually severe and persistent headache, blurred vision, neurologic signs (e.g., cranial nerve palsy, papilledema), or seizures. The classic findings in *RVT* are hematuria and thrombocytopenia, sometimes associated with uremia (especially when bilateral). Initial signs include oliguria (especially when bilateral), and in the neonatal period (the time at which RVT is most common during childhood) a flank mass is often palpable on examination.[122] RVT in older children is frequently associated with nephrotic syndrome (a risk factor for VTE in general because of loss of anticoagulant proteins) and hence may be accompanied by stigmata of peripheral and periorbital edema when diagnosed in conjunction with nephrosis.[120] Thrombocytopenia may be an initial manifestation not only of RVT but also of *intracardiac* (e.g., right atrial) *thrombosis*, particularly CRT associated with sepsis.[123] Isolated intracardiac thrombosis in association with cardiac surgery or central venous catheter placement is most often asymptomatic.[124] *Portal vein thrombosis* is one of the most common causes of portal hypertension in children and is characteristically manifested as splenomegaly in association with findings of hypersplenism (anemia, neutropenia, and thrombocytopenia); gastrointestinal bleeding typically signals the presence of gastroesophageal varices.[125,126] *Internal jugular vein thrombosis* may be manifested as neck pain or swelling and, when part of Lemierre's syndrome, is classically also associated with fever, trismus, pain on lateral rota-

tion of the neck, and a palpable mass in the lateral triangle of the neck.[127]

Chronic VTE may be diagnosed incidentally without signs or symptoms (as sometimes occurs for CSVT during unrelated brain imaging) or may be accompanied by signs and symptoms of chronic venous obstruction or PTS, including pain and edema of the dependent extremities, dilated superficial collateral veins, venous stasis dermatitis, frank ulceration of the skin, or any combination of these findings.

Diagnosis

Although venography has historically been the gold standard for diagnosis of venous thrombosis, this modality is invasive and has experienced a diminishing role in recent years with the development of effective noninvasive or minimally invasive radiologic imaging technologies. Radiologic imaging is used not only to confirm the clinical diagnosis of VTE but also to define both the extent and occlusiveness of the thrombosis. For suspected DVT of the distal or proximal end of the lower extremity, compression ultrasound with Doppler is typically used for objective confirmation. When the thrombus may affect or extend into deep pelvic or abdominal veins, computed tomography (CT) is often necessary. For circumstances in which radiation exposure is a significant concern or alternative diagnoses (e.g., myositis) are being evaluated, magnetic resonance imaging (MRI) may be performed instead. MR venography may be useful in documenting May-Thurner syndrome, an uncommon cause of lower extremity DVT in which the iliac vein is compressed by an overriding right common iliac artery.[128] In suspected DVT of the upper extremity, compression ultrasound with Doppler effectively evaluates the limb, but echocardiography or CT (or both) is required to disclose involvement of more central vasculature (e.g., right atrial thrombosis). In the case of asymptomatic nonocclusive extremity DVT, venography may be used as an alternative to CT. It is important to recognize that venography (in which radiographic contrast material is administered into a vein in the limb) should not be confused with "line-o-grams" (in which radiographic contrast material is instilled into a central venous catheter). The latter studies are useful for delineating catheter tip thrombi but cannot reliably detect DVT along the intravascular length of a central venous catheter.[129] MR venography has replaced traditional venography in most centers. However, dynamic venography may be required to evaluate patients for thoracic outlet syndrome (mechanical compression and entrapment of the subclavian vessels in the region of the first rib).[130] To establish a diagnosis of DVT of the jugular venous system, compression ultrasound with Doppler is typically sufficient.

PE in children is commonly diagnosed by spiral CT or, alternatively, by ventilation-perfusion scanning. The latter is generally suboptimal in the presence of other lung pathology or at centers with limited availability or expertise in this modality. CSVT is typically diagnosed

by standard CT or CT venography and, alternatively, by MRI or MR venography. The diagnosis of RVT is most often made clinically in neonates and is supported by Doppler ultrasound findings of intrarenal vascular resistive indices; however, in some cases a discrete thrombus may be suggested by Doppler ultrasound, especially when extending into the inferior vena cava (IVC). When RVT occurs in older children, Doppler ultrasound or CT is often diagnostic. Similarly, portal vein thrombosis is typically visualized by Doppler ultrasound or CT.

When new-onset venous thrombosis is being evaluated in patients with areas of anatomic abnormality of the venous system (e.g., extensive collateral venous circulation because of a previous VTE episode, May-Thurner anomaly, atretic IVC with azygous continuation), more sensitive methods such as CT or MR venography are frequently required to adequately delineate the vascular anatomy, as well as the presence, extent, and occlusiveness of the thrombosis.

Diagnostic laboratory evaluation for pediatric acute VTE includes a complete blood count, comprehensive thrombophilia panel (see "Etiology," earlier), and β-human chorionic gonadotropin (β-HCG) in postmenarchal females. Additional laboratory studies may be warranted depending on associated medical conditions and involvement of specific organ systems by VTE.

Treatment

A summary of conventional antithrombotic agents and corresponding target anticoagulant levels, based on recent pediatric recommendations,[131] is provided in Table 34-3 for both initial (i.e., acute phase) and extended (i.e., subacute phase) treatment. Conventional anticoagulants attenuate hypercoagulability, thereby decreasing the risk for progression of thrombosis and embolism, and rely on intrinsic fibrinolytic mechanisms to break the thrombus up over time. The most commonly used conventional anticoagulants in children are heparins and warfarin. Heparins, including unfractionated heparin and LMWH, enhance the activity of antithrombin III, an intrinsic anticoagulant that serves as a key inhibitor of thrombin (Chapter 26). Warfarin acts through antagonism of VK, thereby interfering with γ-carboxylation of the VK-dependent procoagulant factors II, VII, IX, and X.

Initial Anticoagulation. Initial anticoagulant therapy (i.e., acute phase) for VTE in children uses unfractionated heparin or LMWH. LMWH has become increasingly used as a first-line agent for initial anticoagulant therapy in children given the relative ease of subcutaneous over intravenous administration, the decreased need for blood monitoring of anticoagulant efficacy, and decreased risk for the development of heparin-induced thrombocytopenia. Unfractionated heparin is typically preferred in circumstances of heightened bleeding risk or labile acute clinical status as a result of rapid extinction of anticoagulant effect after cessation of the drug. In addition, because of renal excretion of LMWH, unfrac-

TABLE 34-3	Recommended Intensities and Durations of Conventional Antithrombotic Therapy in Children, by Etiology and Treatment Agent		
	Agents and Target Anticoagulant Activity		
Episode	**Initial Treatment**	**Extended Treatment**	**Duration of Therapy, by Etiology**
First	UFH, 0.3-0.7 anti-Xa U/mL LMWH, 0.5-1.0 anti-Xa U/mL	Warfarin, INR of 2.0-3.0 LMWH, 0.5-1.0 anti-Xa U/mL	Resolved risk factor: 3-6 months No known clinical risk factor: 6-12 months Chronic clinical risk factor: 12 months Potent congenital thrombophilia: indefinite
Recurrent	UFH, 0.3-0.7 anti-Xa U/mL LMWH, 0.5-1.0 anti-Xa U/mL	Warfarin, INR of 2.0-3.0 LMWH, 0.5-1.0 anti-Xa U/mL	Resolved risk factor: 6-12 months No known clinical risk factor: 12 months Chronic clinical risk factor: indefinite Potent congenital thrombophilia: indefinite

INR, international normalized ratio; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

tionated heparin is used for acute VTE therapy in patients with renal insufficiency.

Common initial maintenance dosing for unfractionated heparin in non-neonatal children ranges from 15 to 25 U/kg/hr preceded by a loading dose of 50 to 75 U/kg. In full-term neonates, a maintenance dose of up to 50 U/kg/hr may be required, especially if the clinical condition is complicated by antithrombin consumption. The starting dose for the LMWH enoxaparin in non-neonatal children commonly ranges between 1.0 and 1.25 mg/kg; no bolus dose is given. In full-term neonates, an enoxaparin starting dose of 1.5 mg/kg is typically necessary.[132] For the LMWH dalteparin, initial maintenance dosing of 1.0 to 1.5 mg/kg (100 to 150 anti-Xa U/kg) appears appropriate based upon available pediatric data.[133] Heparin therapy is monitored most accurately by anti–factor Xa activity. It is essential that the clinical laboratory be made aware of the type of heparin being administered so that the appropriate assay standard (unfractionated heparin versus LMWH) is used. For unfractionated heparin, the therapeutic range is 0.3 to 0.7 anti-Xa activity U/mL, whereas for LMWH, the therapeutic range is 0.5 to 1.0 U/mL. When anti-Xa assay is not available, the APTT may be used, but it is distinctly suboptimal in the pediatric age group, in whom APAs may interfere with or artifactually prolong the clotting end point; indeed, one study of pediatric heparin monitoring demonstrated inaccuracy of the APTT approximately 30% of the time.[134] When dosed by weight in childhood, LMWH does not require frequent monitoring, but anti-Xa activity should be evaluated with changes in renal function. In addition, in cases of acute VTE in which acquired antithrombin deficiency is related to consumption in acute infection or inflammation, anti-Xa activity may rise as antithrombin levels normalize with resolution of the acute illness; in this circumstance, follow-up evaluation of anti-Xa activity is warranted in the subacute period.

The recommended duration of initial heparin therapy for acute VTE, 5 to 10 days, has been extrapolated from adult data.[135] Unfractionated heparin treatment is rarely maintained beyond the acute period given the risk of osteoporosis with extended administration[131] and the inconvenience of continuous intravenous administration. Although adult data suggest efficacy of subcutaneous administration of unfractionated heparin for acute VTE,[136] this route has been evaluated only for the acute therapy period before extended therapy with warfarin, and the appropriateness of such an approach in children has not been established.

Extended Anticoagulation. Extended anticoagulant therapy (i.e., subacute phase) for VTE in children may be achieved with LMWH or warfarin. Warfarin may be started during the acute phase; however, because severe congenital deficiencies involving the protein C pathway can be manifested as VTE in early childhood and are associated with warfarin-related skin necrosis,[137] warfarin should ideally be initiated only after therapeutic anticoagulation has been achieved with heparin-based treatment. Warfarin is monitored by the INR, which is derived from the measured PT. The therapeutic INR range for warfarin anticoagulation in patients with VTE is 2.0 to 3.0.[131] Recent adult data do not agree with the historical evidence for maintaining a higher INR (2.5 to 3.5) in the presence of APA[138,139]; however, maintaining an INR of 2.5 to 3.0, when feasible, satisfies both the older and the more recent literature with regard to appropriate safety and efficacy in this subset of patients.

Duration of Therapy. Pediatric recommendations for the duration of antithrombotic therapy in acute VTE[131] are largely derived from evidence from adult trials. For first-episode VTE in children in the absence of potent chronic thrombophilia (e.g., APA syndrome, homozygous anticoagulant deficiency, or homozygous factor V Leiden), the recommended duration of anticoagulant therapy is 3 to 6 months in the presence of an underlying reversible risk factor (e.g., postoperative VTE), 6 to 12 months when idiopathic, and 12 months to lifelong when

a chronic risk factor persists (e.g., SLE). Recurrent VTE is treated for 6 to 12 months in the patients with an underlying reversible risk factor, 12 months to lifelong when idiopathic, and lifelong when a chronic risk factor persists. In the setting of APA syndrome or potent congenital thrombophilia, the duration of treatment for first-episode VTE is often indefinite. Children with SLE and persistence of an LA have a 16- to 25-fold greater risk for TE than do children with SLE and no LA.[140] However, in children with primary (i.e., idiopathic) or secondary (i.e., associated with SLE or other underlying chronic inflammatory condition) VTE, it is possible that the autoimmune disease will become quiescent in later years such that the benefit of continued VTE prophylaxis may be re-evaluated. Some experts have recommended consideration of low-dose anticoagulation as secondary VTE prophylaxis after a conventional 3- to 6-month course of therapeutic anticoagulation for VTE in children with SLE who have APA syndrome.[141] However, further study to optimize the intensity and duration of therapy/secondary prophylaxis for VTE in children with APA syndrome is urgently needed, especially given the recent evidence in adult VTE that secondary prophylaxis with low-dose warfarin may not only offer little risk reduction beyond no anticoagulation but also is associated with bleeding complications despite a reduced warfarin dose.[142,143]

Thrombolytics. Although the aforementioned anticoagulant therapies are conventional in acute pediatric VTE, thrombolytic approaches are gaining increasing attention and use during acute VTE therapy in children with hemodynamically significant PE or extensive limb-threatening VTE. Unlike conventional anticoagulants, thrombolytics directly promote fibrinolysis. Tissue-type plasminogen activator is an intrinsic activator of the fibrinolytic system (Chapter 27) and has been administered exogenously as a systemic bolus or short-duration infusion, a systemic low-dose continuous infusion, or a local catheter-directed infusion with or without interventional mechanical thrombectomy/thrombolysis. A recent cohort study analysis of children with acute lower extremity DVT who had an a priori high risk for poor post-thrombotic outcomes (by virtue of a completely veno-occlusive thrombus and plasma factor VIII activity >150 U/dL or D-dimer concentration >500 ng/mL) revealed that a thrombolysis regimen followed by standard anticoagulation may substantially reduce the risk for PTS when compared with standard anticoagulation alone.[144] Further investigation via a randomized controlled trial of the efficacy and safety of the thrombolytic regimen versus standard anticoagulation for high-risk acute lower extremity DVT in children will be necessary to confirm these findings.

Other Anticoagulants. Other antithrombotic agents include factor Xa inhibitors and direct thrombin inhibitors. Fondaparinux is a selective factor Xa inhibitor. It is a synthetic pentasaccharide that rapidly binds to anti-

thrombin in the blood and potentiates the natural inhibitory effect of antithrombin against factor Xa, thus indirectly inhibiting thrombin.[145] Fondaparinux is administered once daily as a subcutaneous injection. Dosing is based on weight and generally does not require monitoring, although anti-Xa assays have been used by some investigators.[146]

A variety of modified factor Xa inhibitors are under evaluation in clinical trials or are in preclinical development with enhancements in half-life[147] and oral bioavailability.[148] Direct thrombin inhibitors, by contrast, inhibit thrombin directly by binding to exosite I or the active site of thrombin, or both.[149] These drugs include hirudin and recombinant hirudins such as lepirudin. Argatroban is a synthetic small molecule derived from L-arginine that functions as a reversible direct thrombin inhibitor.[150] All of the currently available direct thrombin inhibitors are administered intravenously and are routinely monitored by the APTT, with the therapeutic goal ranging from a 1.5- to 3.0-fold prolongation of the APTT. Oral direct thrombin inhibitors have been developed as a possible alternative to warfarin. They have the advantage of oral bioavailability, low intersubject variation, no metabolism by the hepatic cytochrome P-450 system, a low incidence of drug-drug interactions, and no dietary influence. However, an early candidate was not approved by the U.S. Food and Drug Administration for clinical use because of concerns of potential liver toxicity and failure to prove noninferiority to warfarin in clinical trials.[149] Other such agents are under ongoing development and investigation. At present, intravenous direct thrombin inhibitors are indicated for the treatment of heparin-induced thrombocytopenia, particularly when associated with acute thrombosis.

Other Therapeutic Agents. Other products may have antithrombotic roles in selected circumstances but await demonstration of efficacy in clinical trials. For example, plasma replacement with protein C concentrate is a useful adjunctive therapy for VTE or purpura fulminans secondary to microvascular thrombosis in severe congenital protein C deficiency[151-153] and may play a beneficial role in the treatment of microvascular thrombosis–related purpura fulminans in children with sepsis, particularly those with meningococcemia.[154-156] In addition, case series have suggested a role for antithrombin replacement in prevention of VTE in children and young adults with congenital severe antithrombin deficiency,[157] for the prevention of L-asparaginase–associated VTE in pediatric acute lymphoblastic leukemia (ALL),[158,159] and as combination therapy with defibrotide for the prevention and treatment of hepatic sinusoidal obstruction syndrome (formerly termed veno-occlusive disease) in children undergoing hematopoietic stem cell transplantation.[160] The potential benefit of a regimen of antithrombin replacement combined with daily prophylactic LMWH in reducing the risk for VTE during the induction and consolidation phases of therapy for ALL has

now also been suggested by a historically controlled cohort study of the BFM 2000 protocol experience in Europe.[161] Antithrombin replacement may also be worthy of consideration in patients with acute VTE undergoing heparinization in whom significant antithrombin deficiency prevents the achievement of therapeutic anti-Xa levels (i.e., heparin "resistance"). This may be seen in neonates with clinical conditions complicated by antithrombin consumption superimposed on the physiologic relative deficiency of this key intrinsic thrombin inhibitor in the newborn period. However, antithrombin replacement in preterm neonates has been investigated as a means of improving the outcome of respiratory distress syndrome, intracranial hemorrhage, and sepsis but has failed to demonstrate benefit and may contribute to adverse events.[162]

Vena Cava Filters. Vena cava filters may serve an adjunctive role in the antithrombotic management of children in selected circumstances. The use of vena cava filters should be considered in children of appropriate size in whom contraindications to anticoagulation exist or in whom recurrent VTE (especially PE) has occurred despite therapeutic anticoagulation and in the absence of a reversible risk factor. In addition, "temporary" or retrievable vena cava filters may be considered during times of especially heightened risk for PE or at times when therapeutic anticoagulation is thought to transiently engender a heightened risk for hemorrhagic complications (e.g., recent neurosurgery). The presence of the filter alone is not an indication for long-term anticoagulation because the risk for vena cava thrombosis related to the device is low. Long-term outcomes in adult series have shown a failure rate (clinically relevant, symptomatic PE) of 3.3% to 5.6%.[163-165] Major complications were infrequent (<1%) and included rare cases of caudal migration, filter fracture, or perforation of the cava wall.[165] A retrospective review of 15 children 18 years or younger suggested efficacy of long-standing vena cava filters with regard to primary and secondary prevention of PE.[166] Follow-up was a mean of 9.2 years (range, 19 months to 16 years), and there were no significant complications, thus complementing similar findings in other small case series.[167,168] However, until the impact of such nonretrievable devices on the vena cava of a developing child has been studied better, use of such filters in preadolescents should be undertaken with caution. Experience with surgical removal of retrievable vena cava filters is quite limited in children, with unknown risks and costs of extraction. Surgical removal of permanent vena cava filters should be strongly discouraged because vena cava ligation is frequently required.[169]

Outcomes

Complications of VTE can occur both acutely and over the long term and are germane to both CRT and non-CRT. *Short-term adverse outcomes* include the major hemorrhagic complications of antithrombotic interventions, as well as complications of the thrombotic event itself, such as post-thrombotic hemorrhage in the brain or adrenal gland; early recurrent VTE, including DVT and PE[170]; SVC syndrome in DVT of the upper venous system[170,171]; acute renal insufficiency in RVT[172]; catheter-related sepsis[173], PE,[174,175] and catheter malfunction (sometimes necessitating surgical replacement) in CRT; severe acute venous insufficiency leading to venous infarction with limb gangrene in rare cases of occlusive DVT involving the extremities; and death from hemodynamic instability in patients with extensive intracardiac thrombosis or proximal PE.[104] *Long-term adverse outcomes* in pediatric VTE have recently been reviewed[176] and include recurrent VTE, chronic hypertension and renal insufficiency in RVT, variceal hemorrhage in portal vein thrombosis,[104] chronic SVC syndrome in CRT involving SVC occlusion, loss of availability of venous access in recurrent or extensive CRT of the upper venous system, and development of PTS, a condition of chronic venous insufficiency after DVT. Manifestations of PTS (in order of increasing severity) include edema, visibly dilated superficial collateral veins, venous stasis dermatitis, and venous stasis ulcers (Fig. 34-2). Given the long-term and sometimes lifelong risk of disease sequelae as in RVT and functional impairment as in PTS, venous thrombosis is best considered a chronic disorder in children.

Long-term Outcomes. The long-term outcomes of VTE in children, with specific regard to recurrent VTE, PTS, major hemorrhage, and death, are summarized in Table 34-4. Registry[104,110,179] and cohort study[109] data in pediatric VTE of all types indicate that children appear to have a lower risk for recurrent thromboembolism than adults do (cumulative incidence at 1 to 2 years of 6% to 11% versus 12% to 22%,[181,182] respectively). However, the risk for PTS in children with DVT of the limbs appears to be at least as great as that in adults (cumulative incidence at 1 to 2 years of 33% to 70%[105,109] versus 29%, respectively[182]). In addition, in a German cohort study of children with spontaneous VTE[177] (i.e., VTE in the absence of identified clinical risk factors), the cumulative incidence of VTE at a median follow-up of 7 years was 21%, thus suggesting that in this subgroup of pediatric VTE, the risk for recurrent VTE is long-lived. Although VTE-specific mortality in children is quite low, ranging from 0% to 2% in these and other[181,182] studies, a considerably higher all-cause mortality is indicative of the severity of the underlying conditions (e.g., sepsis, cancer, congenital cardiac disease) in pediatric VTE. Neonate-specific outcomes data in pediatric non-RVT VTE reflect an all-cause mortality of 12% to 18%,[107,108,183] including one series of premature infants with CRT treated with enoxaparin.[183] The frequency of major bleeding complications during the anticoagulation period in children range from 0% to 9% in recent studies.[109]

Outcomes by Anatomic Site. Outcomes of VTE in children may differ depending on the specific anatomic

FIGURE 34-2. Manifestations of post-thrombotic syndrome (PTS) in children. **A,** Stage 1: chronic edema with iliofemoral deep venous thrombosis (DVT) at 16 years of age. The patient was heterozygous for factor V Leiden and was taking oral contraceptive pills. **B,** Stage 2: dilated superficial venous collateral circulation in a 14-year-old adolescent with inferior vena cava (IVC) DVT as a result of antiphospholipid antibody (APA) and prolonged travel. **C,** Stage 3: chronic venous stasis dermatitis in a 13-year-old with IVC DVT who was heterozygous for factor V Leiden and exhibited APA. **D,** Stage 4: chronic venous ulceration in a 10-year-old with femoral-popliteal DVT, homozygous protein C deficiency, and a tibial fracture.

sites and organ systems affected, as well as the presence/absence of a central venous catheter. Analyses devoted specifically to CRT in children are limited; however, given the high prevalence of CRT in registries and cohort studies of pediatric VTE, outcomes of CRT are likely to considerably influence the data discussed earlier for VTE in general. In a Canadian study of CRT in children from 1990 to 1996,[175] VTE-specific mortality was 4% and, in PE cases, 20%. No major bleeding episodes were observed. At a median follow-up duration of 2 years, the cumulative incidence of symptomatic recurrent VTE was 6.5%, and PTS developed in 9% of the children. In published series of RVT[122,172,184-186] (primarily in neonates), VTE-related death has been very rare, and the cumulative incidence of recurrent VTE has ranged from 0% to 4%, albeit with wide variation in duration of follow-up across studies. The cumulative incidence of chronic hypertension in RVT in these studies was reported to be 22% to 33%. The pediatric literature devoted to CSVT[187-190] is somewhat smaller than that for RVT and suggests a broad range of VTE-specific mortality of 4% to 20%, with a cumulative 8% incidence of recurrent

TABLE 34-4 Outcomes of Venous Thromboembolism in Children

N/A, not available; PTS, post-thrombotic syndrome; VTE, venous thromboembolism.

VTE for neonatal CSVT cases and 17% for CSVT occurring in older children.[189] Long-term neurologic sequelae were noted in 17% to 26% of CSVT cases diagnosed in the neonatal period and 8% to 47% of those occurring later in childhood. It is worthy of note that in the aforementioned pediatric series of RVT and CSVT, both the proportion of children who received anticoagulation and the duration of the anticoagulation course varied considerably across studies. Few pediatric series reporting outcomes of portal vein thrombosis have been published; however, it appears that the risk for recurrent gastrovariceal bleeding in this population is substantial, often despite surgical interventions to reduce portal hypertension.[191] The long-term outcomes of PE in childhood, including the prevalence of chronic pulmonary hypertension and pulmonary function, remain to be determined.

An additional outcome of interest to patients and families of children with VTE is persistence versus resolution of thrombosis. Data to date, largely from adult VTE populations, suggest that persistence of thrombosis after a therapeutic course of anticoagulation of appropriate duration does not appreciably increase the risk for recurrent VTE, including PE. However, some evidence[192] indicates that persistent thrombosis is associated with the development of venous valvular insufficiency, an important risk factor for the development (albeit an imperfect correlate[193]) of PTS. The prevalence of persistence of thrombosis despite adequate anticoagulation in neonatal VTE has ranged from 12% in premature newborns with CRT[175] (representing one of eight patients with VTE in whom extension of thrombosis led to progressive SVC syndrome and death) to 62% in full-term neonatal VTE survivors.[110] Among primarily older children, the prevalence of persistent thrombosis has ranged broadly from 37% to 68% in the few longitudinal studies to date that have systematically evaluated thrombus evolution radiologically.[109,133]

Prognostic Indicators. The ability to predict clinically relevant long-term outcomes of VTE at diagnosis and during the acute phase of treatment is essential for implementation of a future risk-stratified approach to anti-

thrombotic management in children. Historically, few prognostic indicators have been defined in pediatric VTE. The presence of homozygous anticoagulant deficiencies and the persistence of APAs after the diagnosis of VTE have been associated with an increased risk for recurrent VTE. More recently, the presence of multiple thrombophilia traits has been associated with an increased risk for recurrent VTE. In addition, the radiologic finding of complete veno-occlusion at diagnosis of DVT has been linked to an increased risk for persistent thrombosis[194] (which in turn has been associated with the development of venous valvular insufficiency,[193] as noted earlier). Most recently, plasma factor VIII activity greater than 150 U/dL and a D-dimer concentration higher than 500 ng/mL at the time of diagnosis of VTE in children, as well as after 3 to 6 months of standard anticoagulation, have been defined as markers of a composite adverse thrombotic outcome characterized by persistent thrombosis, recurrent VTE, or the development of PTS[109]; similar prognostic findings have been observed in adult VTE.[195-197]

Ischemic Arterial Stroke

Epidemiology

The incidence of perinatal and neonatal ischemic arterial stroke (IAS) has recently been estimated from U.S. National Hospital Discharge Survey data to be approximately 18 per 100,000 per year or 1 in 5000 live births annually.[198] The rate of stroke in later childhood is about a 10th of that for the neonatal period, approximately 2 in 100,000 children per year in the United States.[199] Similar estimates have been provided by the Canadian and Swiss pediatric stroke registries.[200] An early Mayo Clinic retrospective analysis of cases in Rochester, Minnesota, in the late 1970s yielded an equivalent incidence rate for all pediatric IAS of 2.5 per 100,000 per year.[201] However, just as for VTE in children, these epidemiologic data for pediatric IAS probably represent underestimates because of the relatively low index of suspicion for cardiovascular and cerebrovascular events in children as opposed to adults, as well as inaccuracies engendered by

International Classification of Diseases, 9th revision (ICD-9), coding.[202]

Etiology

Causes of IAS in children are less well characterized than in adults, largely as a result of challenges posed by the lower incidence of the disorder in the pediatric population. Whereas in adults, hypertension, diabetes, smoking, and hypercholesterolemia are prominent risk factors for cerebrovascular disease, in children, sickle cell disease, infection, cerebral arteriopathy,[203-205] head/neck trauma (with or without identified arterial dissection),[206-208] congenital cardiac disease, previous transient ischemic attack (TIA),[209] and thrombophilia[209-213] appear to be the most prevalent identified risk factors for IAS. Whether anemia and polycythemia are independent risk factors for pediatric IAS or instead constitute epiphenomena of underlying acute and chronic diseases remains unclear. The subsequent discussion focuses principally on IAS in children without sickle cell disease; for a detailed discussion of IAS in children with sickle cell disease, see Chapter 19.

Vasculopathy in pediatric IAS may be characterized by arterial dissection, narrowing, thrombosis, and an irregular arterial contour (suggestive of possible arteritis). Overall, vasculopathy may be identified in as many as half of non-neonatal IAS cases.[214] Dissection has been demonstrated in 7% to 20% of children with acute IAS.[209,214] Distinction between dissective and nondissective causes of arterial narrowing and thrombosis may be difficult, with variables including the imaging technology used (e.g., CT with angiography, MR angiography, cerebral angiography), the timing in relation to the event, and the experience of the neuroradiologist. Dissection may be due to head/neck trauma or may be spontaneous; limited data suggest that the prevalence of underlying connective tissue disorders may be increased in IAS cases associated with spontaneous dissection, but further controlled studies are needed.[215] Although some studies have indicated that antecedent head trauma appears to be prevalent in pediatric IAS cases, minor head trauma is not infrequent in active children, and there is also considerable potential for recall bias in such studies. A minority of cases of childhood IAS with vasculopathy represent moyamoya syndrome (defined as stenosis in the terminal portion of the internal carotid arteries bilaterally with the formation of collateral arteries, which produces the classic angiographic "puff of smoke") or possible moyamoya syndrome (recently characterized as either unilateral stenosis in the terminal segment of an internal carotid artery with collaterals or the presence of bilateral stenosis of the terminal portion of the internal carotid arteries without collaterals[205]). Other causes of nondissective cerebral arteriopathy in children include a history of recent varicella-zoster infection (i.e., within the previous year),[189] neurofibromatosis type 1, and cranial irradiation for malignancy.[205,216] Despite the high prevalence of vasculopathy in IAS, its etiology in most cases remains unclear and cannot be attributed to moyamoya, dissection, or defined infections such as varicella. Efforts to further define the causes and natural history of vasculopathy-associated IAS will be fundamental to determining optimal therapeutic interventions in the future.

Infection as an underlying cause of pediatric IAS has been classically associated with tuberculous meningitis, human immunodeficiency virus infection, and primary herpes simplex and varicella virus infection, as well as secondary herpes zoster and varicella-zoster infections. Local bacterial and fungal infections of the head and neck may also contribute to the development of IAS in some pediatric patients. The pathophysiologic mechanisms of infection-associated IAS in children may include direct angioinvasion by the pathogen, local arteritis without direct angioinvasion, and systemic inflammatory and hypercoagulative responses. It is likely that in many instances more than one process contributes to the genesis of IAS. To what extent vasculopathy in pediatric IAS is para-infectious in nature remains poorly understood.

Thrombophilia Risk Factors. Thrombophilia may contribute to risk for IAS by arterial thrombosis or by cerebral embolism of a venous thrombus via a cardiac lesion with a right-to-left shunt. Thrombophilia risk factors in children with IAS include anticoagulant deficiencies (particularly deficiency of protein C[210]), APAs (particularly anticardiolipin antibodies[211,213]), and hyperhomocysteinemia.[217,218] In some cases of IAS developing after acute varicella infection, antibody-mediated acquired protein S deficiency has been demonstrated.[219] It is likely that as is the case for VTE in children, anticoagulant deficiencies are most commonly acquired in the setting of pediatric IAS and are most often para-infectious in nature. However, as in VTE, severe congenital anticoagulant deficiencies may be most likely to be manifested as IAS at an early age. Although homozygosity for the factor V Leiden or prothrombin 20210 mutation is a strong risk factor for VTE in children and hence is probably a risk factor for thromboembolic IAS, it remains unclear whether heterozygosity for the factor V Leiden or prothrombin 20210 mutation confers a meaningful increase in the risk for pediatric IAS.[210-213] Markedly elevated levels of homocysteine are classically associated with metabolic disorders such as homocysteinuria (secondary to cystathionine β-synthase deficiency) and appear to be rare in individuals possessing the thermolabile variant of methylenetetrahydrofolate reductase (MTHFR C677T) in countries in which routine folate supplementation of the diet is undertaken. Therefore, most evidence suggests that this highly prevalent polymorphism is not an independent risk factor for IAS. Although a recent single-institutional U.S. study[220] may contradict this evidence, no contemporaneous control group was used, and further study is therefore necessary. It remains possible that an alternative mechanism other than hyperhomocysteinemia may mediate the risk for IAS, if substantiated.

Another thrombophilia trait, an elevated lipoprotein(a) concentration, has been associated with increased odds for spontaneous IAS (i.e., IAS occurring in the absence of identified clinical risk factors) in non-neonatal German children[212] when a conventional lipoprotein(a) threshold of the 75th percentile derived from previous data in healthy adults was used. This work was recently supported by findings in a U.S. case-control study of porencephaly and IAS in children in which the same lipoprotein(a) threshold was used.[221] However, the magnitude of risk for acute neonatal and childhood IAS (both in the majority of cases with and in the minority without identified clinical risk factors) conferred by elevated levels of lipoprotein(a) remains unclear. In addition, it is unknown whether the adult-derived threshold for lipoprotein(a) concentration historically used clinically and in case-control and cohort studies is appropriate for children. These are key clinically relevant issues that warrant further study.

Clinical Manifestations

The clinical findings in neonates and older children with IAS are largely dependent on the territory and extent of the CNS affected by ischemia/infarction. The most common manifestation of perinatal and neonatal IAS is seizure, sometimes associated with subtle hemiparesis when IAS involves a unilateral middle cerebral artery distribution. Apnea and poor feeding in a term infant should also raise concern for possible perinatal/neonatal IAS. Prenatal IAS in the distribution of the middle cerebral artery, by contrast, is frequently asymptomatic until noted by parents as one-sided weakness, spasticity, or disuse as development of motor activity progresses, frequently with asymmetric reaching for objects or gross motor delay between 4 and 12 months of age.

Manifestations of acute IAS occurring after the neonatal period (i.e., later childhood) include acute- or subacute-onset focal neurologic deficit (e.g., hemiparesis, cranial nerve palsy, dysphasia, incoordination), severe headache, or unexplained new-onset seizure, sometimes accompanied by altered mental status. In cases of dissection-associated IAS in children, a recent history of head/neck trauma is common (see also "Etiology," earlier). Interestingly, a recent single-center retrospective series of IAS in non-neonatal children found that a "nonabrupt" pattern of neurologic symptoms/signs (including those in whom the maximum severity of symptoms/signs in acute IAS developed more than 30 minutes after the onset of symptoms, the symptoms/signs were waxing and waning or were preceded by recurrent transient symptoms/signs with intercurrent resolution) was significantly associated with findings of arteriopathy on diagnostic neuroimaging.[222] Ischemic stroke that is not clearly arterial in distribution (i.e., is not AIS) may be due to global hypoxic-ischemic injury (e.g., with a watershed distribution), may be a regional complication of CNS venous thrombosis, or might be metabolic in etiology.

A classic example of ischemic stroke of metabolic etiology occurs in the syndrome of mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS). MELAS is caused by mitochondrial DNA defects encoding tRNA involved in the generation of adenosine triphosphate via the electronic transport chain in the mitochondrion. The clinical manifestation of MELAS is ischemic stroke, often recurrent in nature, in preschool or school-age children. Imaging most often reveals persistent ischemia or an infarct in the posterior cerebral hemispheres, with relative sparing of the deep white matter; the affected territory often results in hemianopia.[223] Unlike the cerebral lesions in patients with acute IAS, acute abnormalities at the time of stroke in those with MELAS are bright on apparent diffusion coefficient (ADC) maps of diffusion-weighted MRI.[224] Associated symptoms and signs in MELAS, which are of varying severity and penetrance in affected individuals because of a threshold effect and heteroplasmy in mitochondrial DNA disorders,[225] include short stature, hearing loss, recurrent seizure, proximal muscle weakness, and optic atrophy.[223]

Diagnosis

Imaging Studies. Diagnostic evaluation for suspected acute IAS in children involves either urgent CT of the head with CT angiography of the head and neck or, alternatively, MRI of the brain with diffusion-weighted imaging and MR angiography of the head and neck. Although routine CT and MRI studies evaluate for ischemia, hemorrhage, mass/mass effect, and other non-IAS pathologies, the addition of angiography permits evaluation for arteriopathy, including dissection, stenosis, irregular contour, or intra-arterial thrombosis. CT is often more readily available on an urgent basis than MRI is; however, CT engenders greater radiation exposure than MRI does (especially if angiography is performed) and is less sensitive for the diagnosis of IAS, especially in the acute phase. For the latter reason, if CT is performed initially and is unremarkable in the setting of an acute focal neurologic deficit of unclear etiology, it should be followed by MRI of the brain with diffusion-weighted imaging and MR angiography of the head and neck. In circumstances in which the presence or extent of vasculopathy is unclear or in cases of moyamoya syndrome, the more invasive approach of cerebral angiography is warranted to establish a definitive diagnosis and guide subsequent management.

The pattern of ischemia/infarction may be informative with respect to etiology and consequent management of IAS. For example, multifocal infarction may suggest a thromboembolic cause. A subcortical distribution of ischemia/infarction may suggest disease of small arteries. A watershed distribution of ischemia/infarction may suggest an alternative diagnosis of hypoxic-ischemic injury related to hypotension and other global causes of poor perfusion.

An additional important component of diagnostic imaging in pediatric IAS is echocardiography (either transthoracic, with peripheral intravenous saline injection, or transesophageal) to evaluate for a right-to-left shunting cardiac lesion, with potential implications for management.

Laboratory Studies. Diagnostic laboratory evaluation in children with acute IAS involves a complete blood count, toxicology screen, complete metabolic panel, erythrocyte sedimentation rate/C-reactive protein, β-HCG testing in postmenarchal females, fasting lipid profile, and a comprehensive thrombophilia panel (see the section on VTE diagnosis, earlier). Given that TE is a mechanism for IA and that the cause and pathogenesis of IAS in children are often unclear at the time of diagnosis, thrombophilia testing during diagnostic evaluation for IAS should probably consist of the same comprehensive assessment recommended for acute VTE in children by the Subcommittee for Perinatal and Pediatric Thrombosis of the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis (see Table 34-1). As clinical/translational research studies demonstrate the validity of additional IAS-specific thrombophilia risk factors, these should be included as well.

A particularly important issue of thrombophilia testing specific to perinatal IAS involves APA testing. When APA is positive in a neonate with IAS, it is informative to evaluate for APA in the mother to establish a possible cause of vertical (i.e., transplacental) transmission of IgG APA. It is plausible that in some instances APA may be induced by an inflammatory response to IAS rather than representing the cause of the IAS; in such instances, the APA may persist longer than observed for a vertically acquired APA. In IAS with vasculopathy, consideration should be given to investigation for infectious diseases, including serology for viral infections such as varicella-zoster virus, herpes simplex virus, Epstein-Barr virus, parvovirus, and enterovirus; a thorough workup may also include enteroviral cultures of the mouth and rectum and blood testing for *Helicobacter pylori*. If there is associated meningitis or relevant clinical risk factors, testing for tuberculosis should also be undertaken. In the setting of arteritis, rheumatologic evaluation should be considered, including testing for antinuclear antibodies and other markers as warranted. In certain circumstances, additional studies may be warranted, including evaluation for metabolic (including mitochondrial DNA–based) disorders, particularly in IAS with encephalopathy of unclear etiology, nonarterial distribution, lactic acidosis, or other multisystem disorders of unclear cause (e.g., hearing loss, myalgia, endocrinopathy).

The role of lumbar puncture, especially when weighed against the need to withhold anticoagulation periprocedurally, is controversial. Unfortunately, the circumstances in which risk for progression or early recurrence of IAS is among the greatest (e.g., acute/subacute period of IAS with vasculopathy) and therefore in which maintenance of effective anticoagulation may be most critical are also the same circumstances in which lumbar puncture for investigation of infectious diseases would be among the most informative (yet requires suspension of anticoagulation).

Treatment

Initial management of IAS in children must emphasize appropriate control of blood pressure, temperature, glycemia, oxygenation, and hydration. Unfortunately, there is no evidence from clinical trials on which to base specific interventions for acute IAS in children who do not have sickle cell disease. Nevertheless, pediatric IAS treatment recommendations[131,226] have been developed on the basis of registry and cohort study data in neonates and older children, as well as to some extent on evidence extrapolated from studies in adult IAS.

In the absence of a thromboembolic etiology, underlying vasculopathy, or potent thrombophilia, antithrombotic therapy is rarely used for perinatal/neonatal IAS, as appropriate for the low risk (cumulative incidence of approximately 3% at a median follow-up duration of 3.5 years[227]) for recurrent IAS/VTE. Therefore, for most cases of perinatal IAS, an emphasis on future treatments directed toward minimization of infarction during the acute and subacute period of IAS is likely to be more beneficial than reduction in risk for recurrent IAS.

In contrast to neonates, antithrombotic intervention in older children with acute IAS is generally recommended as secondary IAS prophylaxis, given the relatively high recurrence rate (cumulative incidence of approximately 40% at 5 years[209]). A nonrandomized prospective cohort-based study of LMWH versus aspirin as secondary IAS prophylaxis detected no significant difference in the cumulative incidence of recurrent IAS between the these two therapies.[228] The optimal type of antithrombotic strategy and duration of antithrombotic therapy for a given IAS subtype in this age group remain unclear in the absence of evidence from randomized controlled trials. Antiplatelet therapy with daily aspirin is widely used in childhood IAS, with variable intensity (e.g., 1 to 5 mg/kg per dose) and duration (3 months, 1 year, indefinitely). In the setting of childhood IAS with non–moyamoya-associated vasculopathy, either antiplatelet therapy or therapeutic anticoagulation with LMWH or warfarin (often initially with unfractionated heparin in the acute period given its rapid reversibility should bleeding complications arise) is often considered for a period of at least 3 months, especially in the presence of thrombophilia. Patients who experience recurrent IAS while maintained on antiplatelet therapy should be considered for therapeutic anticoagulation.

Pediatric IAS with moyamoya syndrome presents a particular challenge in optimal management. Anticoagulation and antiplatelet agents have been considered possible therapies. However, in view of the heightened risk

for recurrent IAS, neurosurgical approaches at revascularization (including indirect means, such as encephalo-duroarteriomyosynangiosis [EDAMS],[229] and direct means, such as superficial temporal artery branch–to–middle cerebral artery branch or anterior cerebral artery branch bypass[230]) are generally preferred, and anticoagulation or antiplatelet therapy is perhaps best reserved for children with appropriately defined "possible moyamoya" in the absence of recurrent symptoms or recurrent IAS/TIA events.

Thrombolytic approaches have been used in isolated cases of pediatric IAS.[231] Because only a minute proportion of cases of acute IAS in children are diagnosed within the first few hours of symptomatic onset, a multicenter collaborative clinical trial approach with stringent uniform exclusion criteria will be required to address whether adult evidence for a beneficial role of systemic administration of tissue plasminogen activator in the immediate period after onset of IAS may also apply to children. Other thrombolytic approaches include interventional pharmacomechanical thrombolysis/thrombectomy for acute IAS associated with arterial thrombosis. However, technical limitations (i.e., size constraints) are posed by the small-caliber pediatric cerebral vasculature, and the safety and efficacy of this approach warrant formal study.

In the subacute period after IAS in children and over the long term, treatment to optimize outcomes includes rehabilitation services (physical therapy, occupational therapy, speech therapy) and neuropsychological interventions (educational, vocational, and mental health services). The need for these services should be assessed on a case-by-case basis and provided in accordance with the findings of comprehensive multidisciplinary assessment involving the expertise of pediatric neurology, rehabilitation medicine, and neuropsychology. Furthermore, the impact of rehabilitative and neuropsychological interventions on the progress and future need of pediatric IAS patients should be regularly reassessed in extended follow-up.

Outcomes

Complications. Complications of IAS can occur both acutely and over the long term. Short-term adverse outcomes include death from uncontrolled increased intracranial pressure with uncal herniation, status epilepticus, or hemodynamic instability in patients with extensive intracardiac thrombosis associated with cardioembolic IAS and major hemorrhagic complications, including those related to antithrombotic interventions, as well as postischemic CNS hemorrhage, acute neurologic deficits, and early recurrence of IAS or VTE. Long-term sequelae of IAS in children include residual neurologic deficits, cognitive impairments, and recurrent IAS or VTE.

The outcomes of pediatric IAS, stratified by diagnosis in the neonatal period versus older childhood, are summarized in Tables 34-5 and 34-6.[189,200,209,214,227,232-236] In brief, death as a result of perinatal/neonatal IAS is quite rare, and for childhood IAS the case fatality rate (i.e., cumulative incidence) ranges between 2% and 16% in various analyses, although the time period over which death was attributable to IAS has not been well delineated in most studies. The risk (i.e., cumulative incidence) of recurrent IAS/VTE in perinatal/neonatal IAS is approximately 3% at a median follow-up duration of 3.5 years,[227] whereas the risk for recurrence after non-neonatal IAS varies widely between 19% and 40% at a fixed follow-up duration of 5 years. With regard to neurologic and rehabilitative (neuromotor, speech) outcomes, the prevalence of neuromotor deficits after perinatal/neonatal IAS varies widely between 36% at a median follow-up of 19 months and approximately 60% at average follow-up times of 2 to 6 years across studies. Furthermore, the prevalence of either hemiplegia or asymmetric tone without hemiplegia has been shown in

one study to be 30% at approximately 5 to 7 years of age.[236] By comparison, the prevalence of persistent neuromotor deficits for IAS diagnosed in later childhood is approximately 70% at average follow-up durations ranging from 6 months to 2.5 years across studies. Expressive speech impairments have been noted in 12% of perinatal/neonatal and 18% of non-neonatal IAS cases in one study.[189] As for neuropsychological outcomes, cognitive or behavioral deficits have been discerned in a few studies in 3% to 14% of children with perinatal/neonatal IAS at 2 to 6 years' average follow-up and in 17% of children at 2 years' follow-up in whom IAS occurred later in childhood.

Long-Term Outcomes. As in pediatric VTE, the ability to predict clinically relevant long-term outcomes of IAS at diagnosis and during the acute phase of treatment is essential to the development of appropriate management paradigms in children. However, such efforts have been particularly challenged by the relative infrequency of pediatric IAS cases and the heterogeneity in causes and IAS subtypes in this complex disorder. In perinatal/neonatal ischemic stroke, a cohort study[237] of 24 neonates with ischemic stroke, including IAS mostly in the middle cerebral artery territory but some with primarily watershed area involvement, suggested that an abnormal background on early neonatal encephalography (as opposed to focal epileptiform discharges) and a distribution that includes a cerebral hemisphere along with both the internal capsule and basal ganglia (as opposed to only one or two of these regions) serve as factors that are each associated with the development of a persistent neurologic deficit. The deficits consisted of either hemiplegia or asymmetry of tone without hemiplegia. These data were subsequently substantiated at later follow-up in early childhood.[232] In a smaller series, the presence of signal abnormalities in the posterior limb of the internal capsule

or in the cerebral peduncles on MRI with diffusion-weighted imaging and ADC mapping in acute perinatal/neonatal IAS was recently found to be associated with the development of either hemiplegia or asymmetry of tone without hemiplegia at a median follow-up of longer than 18 months[238] and is supported by similar findings in a separate cohort at a median follow-up of 5.5 years. Most recently, the use of computer-assisted quantitation of the degree of descending corticospinal tract signal abnormality on MRI with diffusion-weighted imaging in a series of 14 neonates with IAS demonstrated that the proportion of the cerebral peduncle affected and the total length of the descending corticospinal tract involved correlate with the development of hemiparesis.[233] Whereas correlates of neuromotor outcome in perinatal/neonatal IAS are becoming better defined, predictors of recurrent stroke in this group have been elusive, particularly given the infrequency of recurrent IAS after perinatal/neonatal IAS.

Prognostic Indicators. A single-center retrospective study in the 1990s demonstrated a statistically significant increase in the odds of recurrent IAS in patients with more than one IAS risk factor (e.g., vasculopathy, thrombophilia traits, cardiac disorders, infection) identified at the time of the acute event as opposed to children with one or no risk factors.[232] In addition, patients with moyamoya are at greatly increased risk for recurrent IAS and persistent neurologic deficits.[209,214,239] In a large single-center cohort study of mixed prospective-retrospective design,[209] moyamoya was one of only two independent risk factors for recurrent ischemic events (consisting of IAS, TIA, or death with reinfarction). The association of vasculopathy with increased risk for recurrent IAS in children has recently been demonstrated in a U.S. population-based cohort,[234] thus confirming previous findings from a large multicenter German prospective cohort

study of childhood IAS.[227] In the German study, elevated serum levels of lipoprotein(a), congenital protein C deficiency, and vasculopathy were each found to be independent risk factors for recurrent IAS. Although APAs were not evaluated in the multivariate model of the German cohort study, a two-center British-Canadian cohort study of non-neonatal IAS in 185 children reported that no increased risk for recurrent IAS appears to exist with respect to persistently positive IgG-type anticardiolipin antibody titers.[240] Although the statistically nonsignificant unadjusted difference in 3-year recurrence rates between groups positive and negative for anticardiolipin IgG, 38% versus 26%, might nevertheless be considered clinically meaningful, the difference in proportional hazard functions for recurrence of IAS between the two groups was also not statistically significant after adjustment for covariates of IAS causes and treatment types. However, few cases of high-titer antibodies were represented in the cohort. Clearly, further basic and translational research is needed to discern which subtypes of anticardiolipin antibodies may be most vasculopathic and thrombogenic, and such research will probably involve secondary characterization of APAs with functional assays.

Future studies should seek to validate the predictive capacity of these potentially quite meaningful associations in pediatric IAS cohorts distinct from those in which these associations have been derived. Collaborative multicenter cohort studies and trials groups, such as the International Pediatric Stroke Study Group, offer optimism for the establishment of more robust evidence of predictors of outcome in neonatal and childhood IAS according to common causes and vascular pathologies so that risk-stratified approaches to the management of pediatric IAS in future years can be optimized.

Transfusion Medicine

Steven R. Sloan, David F. Friedman, Grace Kao, Richard M. Kaufman, and Leslie Silberstein

Transfusion medicine focuses on the administration of blood, blood components, and purified blood proteins to patients for therapeutic purposes. Red blood cells (RBCs) are the most frequently used blood component, and RBC transfusions have been studied extensively. In this chapter, RBC transfusions are discussed first and issues that pertain to all transfusions, such as transfusion reactions and transfusion-transmitted diseases, are discussed in this section. Platelets are often transfused to some patients such as oncology patients and are discussed in the next section of this chapter. Hematopoietic progenitor cells (HPCs) are the most recently blood-derived component to be developed for transfusion. Although these cells are often said to be transplanted rather than transfused, they are also discussed in this chapter. Finally, granulocyte components collected by apheresis for transfusion and other apheresis procedures that allow simultaneous removal and transfusion of blood components are discussed at the end of the chapter.

RED BLOOD CELL TRANSFUSIONS

Indications for Transfusion

The primary function of RBCs is to bind oxygen as they circulate through the pulmonary bed and to release oxygen in the capillaries at a pressure high enough for diffusion into tissues. The configuration of the oxyhemoglobin dissociation curve provides proper diffusion as long as only part of the oxygen is released during capillary transit. The oxygen tension of fully oxygenated blood in the arteries is approximately 100 mm Hg; release of 20% of the oxygen in the capillaries maintains a pressure of 40 mm Hg, which is sufficient to propel oxygen to all cells within a truncated cone segment around the capillary.[1] RBCs compensate for a loss in oxygen-carrying capacity relatively rapidly by a shift in the oxyhemoglobin dissociation curve to the right, which decreases oxygen's affinity for hemoglobin. In addition, cardiac output increases. On a more chronic basis, blood volume, the size of the vascular bed, and the rate of production of RBCs increases. These compensatory mechanisms permit states of mild to moderate anemia without significant symptoms.

For most patients the only indication for RBC transfusion is to provide a patient with sufficient RBCs to prevent or reverse tissue hypoxia as a result of insufficient compensation. One large multicenter randomized controlled study of adult critically ill patients is probably applicable to some pediatric patients, especially adolescents.[2] That trial compared a liberal transfusion strategy, in which patients received RBC transfusions when their hemoglobin level was less than 10.0 g/dL, with a restrictive transfusion strategy, in which patients were transfused when their hemoglobin was less than 7.0 g/dL. Among patients younger than 55 years, those who were transfused according to the more restrictive strategy had significantly lower 30-day mortality. A similar study of

stable critically ill pediatric patients in intensive care units found similar outcomes in patients transfused at a hemoglobin level of 7 g/dL or less and patients transfused at level of 9.5 g/dL or less.[3] Additionally, experience with sickle cell patients undergoing surgery in Jamaica suggests that otherwise healthy young people can tolerate a hematocrit of 20% without experiencing short-term adverse consequences.[4]

Two prospective randomized controlled studies have compared transfusion strategies for low-weight premature infants. The triggers used for transfusion depended on the oxygen support requirements in both studies,[5,6] as well as the baby's age in one of the studies.[6] One study by Bell and colleagues found in that neonates on the liberal transfusion strategy, intraventricular hemorrhage or periventricular leukomalacia was less likely to develop and the neonates were less likely to have more than one apnea episode per day.[5] Patients randomized to the liberal transfusion strategy were transfused when their hematocrit was less than 46% if they were tracheally intubated for assisted ventilation. They received transfusions when their hematocrit was less than 38% if they were receiving nasal continuous positive airway pressure or supplemental oxygen, and transfusions were administered when their hematocrit was less than 30% if they required no oxygen support. The other study by Kirpalani and associates used different liberal and restrictive transfusion algorithms and found no differences in outcomes between patients assigned to liberal and restrictive groups.[6] Because neonates often receive multiple aliquots from the same RBC unit, there was no statistically significant difference in donor exposure between the liberal and restrictive transfusion groups in either study. As no harm has been seen with a more liberal transfusion strategy in premature infants, some have argued that it is safer to transfuse more liberally for premature infants, especially since one study found a neurologic risk associated with undertransfusion.[7]

Children who are chronically anemic from thalassemia may also benefit from a more liberal transfusion policy. These patients benefit from a hypertransfusion program that maintains their hemoglobin level higher than 9 to 10 g/dL. Hypertransfusion of these patients allows them to attain normal height and weight and improves hepatosplenomegaly, osteoporosis, and cardiac dilation.[8-12] Transfusions benefit these patients by increasing tissue oxygenation and particularly by suppressing endogenous erythropoiesis.

Acute Blood Loss

RBC transfusions are frequently used to replace blood lost either in the operating room or after trauma. In practice, diagnosis of the presence and degree of blood loss is quite difficult, especially in a young, otherwise healthy child. In fact, a child may sustain a relatively large hemorrhage with few external signs of distress. Signs of impending shock, such as pallor, anxiety, and tachypnea, are frequently subtle and easily overlooked or attributed

Box 35-1	Diseases Requiring Intermittent or Chronic Red Cell Transfusion in Childhood

  Transient erythroblastopenia

to other causes. By the time that signs of cardiovascular compromise become evident (i.e., stupor, tachycardia or bradycardia, hypotension, coolness of the extremities, weak peripheral pulses, and decreased capillary filling), the patient has most probably lost at least 25% of total blood volume. Hypotension is one useful clinical sign of moderate to severe blood loss. Patients who have lost more than 25% of their blood volume frequently manifest age-related systolic hypotension: less than 65 mm Hg in children younger than 4 years, less than 75 mm Hg in children 5 to 8 years of age, less than 85 mm Hg in children 9 to 12 years of age, and less than 95 mm Hg in adolescents and adults.

Chronic Transfusion Therapy

In chronic anemia, the body is deficient in RBCs, whereas plasma volume is normal or increased. Box 35-1 lists the childhood conditions that are likely to require intermittent or long-term transfusion therapy.

The following guidelines apply when planning for chronic transfusions (months to years):

1. If possible, transfusion should be avoided or minimized by aggressive treatment of the underlying disorder (e.g., administration of recombinant human erythropoietin to patients maintained on dialysis or with chronic renal failure).
2. Leukocyte-reduced RBCs should be used to avert or delay sensitization to leukocyte alloantigens, the most common cause of febrile nonhemolytic transfusion reactions.
3. RBCs should be administered in an amount sufficient to prevent symptomatic anemia and allow normal growth.
4. The patient's iron status should be monitored by determination of serum ferritin, iron, and iron-binding capacity and liver iron stores.

Packed Red Blood Cells

A packed cell product is the component of choice for replacement during surgery, red cell loss, and chronic transfusion therapy. The hematocrit of the cells varies with the preservative solution used by the collection facility. Blood collected in citrate-phosphate-dextrose-adenosine (CPDA-1) and stored as red cells has an average hematocrit of approximately 75%.[13] Red cells stored in an additive nutrient solution such as Adsol or Nutricel have a hematocrit of 50% to 60%. Adsol contains mannitol. Some institutions avoid units containing Adsol for large transfusions to neonates because of concerns about the effects of mannitol. However, mannitol has no adverse consequences with standard simple transfusions of 5 to 20 mL/kg per dose in premature infants.[14]

Blood Storage

During storage, red cell metabolism continues and some leakage through red cell membranes occurs. This results in changes such as decreasing plasma dextrose and increasing plasma potassium. These changes are acceptable for most transfusions, but in some situations the increased potassium in solution may cause problems. In such cases, fresh blood (<7 to 10 days old) may be beneficial and is indicated when small patients receive large amounts of blood, such as neonates undergoing exchange transfusion or infants receiving large transfusions rapidly during surgery. However, neonates can tolerate 5- to 20-mL/kg transfusions of older units of RBCs, and some blood banks dedicate a unit of blood for repeated transfusions to one infant to minimize the number of donors to which the infant is exposed.[14]

Leukoreduction of Red Cells

Transfusion of allogeneic cellular blood products is associated with deleterious effects caused by the presence of residual leukocytes, including alloimmunization to histocompatibility antigens, transmission of viruses, febrile reactions, and graft-versus-host disease (GVHD).[15,16] Filters are used to reduce the number of leukocytes in whole blood, red cells, and platelets.[17,18] Routine leukoreduction of red cells to less than 5×10^6 leukocytes per unit reduces the frequency of febrile nonhemolytic transfusion reactions in patients who are transfusion dependent.[19,20] Removal of leukocytes from blood also reduces the risk of leukocyte-associated transmission of viruses such as cytomegalovirus (CMV). Leukoreduction of red cells and platelets to a level less than 5×10^6 has been demonstrated to substantially reduce CMV transmission in neonates and transplant patients.[21,22]

In addition, allogeneic lymphocytes may modulate the immune system and be immunosuppressive.[23] The use of leukoreduction has been recommended to prevent immune modulation in neonates and surgical patients, especially those undergoing surgery for a malignancy. Until more definitive studies have been performed, these situations can be considered only possible indications.[24,25]

Irradiation of Red Cells

Transfusion-associated GVHD is a rare complication after the transfusion of cellular products. Patients most

susceptible to GVHD include premature neonates, some patients with congenital immunodeficiency syndromes, immunosuppressed oncology patients undergoing chemotherapy or radiation therapy (or both), and patients receiving certain immunosuppressive drugs after solid organ transplantation and some other indications.[26-28] In addition, normal recipients who are heterozygous for HLA antigens do not reject lymphocytes that are transfused from a donor who is homozygous for one of the recipient's haplotypes.[29] This is not merely theoretical because transfusion-associated GVHD has developed in normal recipients undergoing surgery who received unirradiated directed donor blood from a first-order relative.[30,31] Because of the wide variety of patients at risk for GVHD, some transfusion services have chosen to irradiate all cellular blood products to ensure that this life-threatening complication does not develop in any patient.

Immunologic Considerations

Multiple antigens expressed on erythrocyte cell surfaces can be recognized by the immune system of a transfusion recipient. Before an RBC transfusion, erythrocytes that are immunologically compatible with the patient must be identified. Erythrocyte antigens are polymorphic inherited structural characteristics located on proteins, glycoproteins, or glycolipids on the outside surface of the RBC membrane. Erythrocyte antigens are clinically important in the immune destruction of RBCs in allogeneic blood transfusions, maternal-fetal blood group incompatibility, autoimmune hemolytic anemia, and organ transplantation. Our ability to detect and identify antibodies to erythrocyte antigens and identify compatible donor RBCs lacking the specific antigens has contributed significantly to the safe supportive blood transfusion practices used today.

The ABO and H System

The H Antigen

A and B antigens on RBCs are defined by a terminal sugar attached to a carbohydrate chain on membrane glycosphingolipids. The H antigen is the precursor molecule on which A and B antigens are built. The H antigen on RBCs is defined by fucose at the terminus of carbohydrate chains.[32] Expression of the H antigen is determined by a fucosyltransferase that transfers a fucose to an oligosaccharide side chain attached to integral membrane proteins on red cells. This fucoslytransferase is encoded by a gene on chromosome 19.[33,34] The fucosyltransferase and thus the H antigen are present in all persons except those with the rare Bombay (O_h) phenotype.[35]

The A and B Antigens

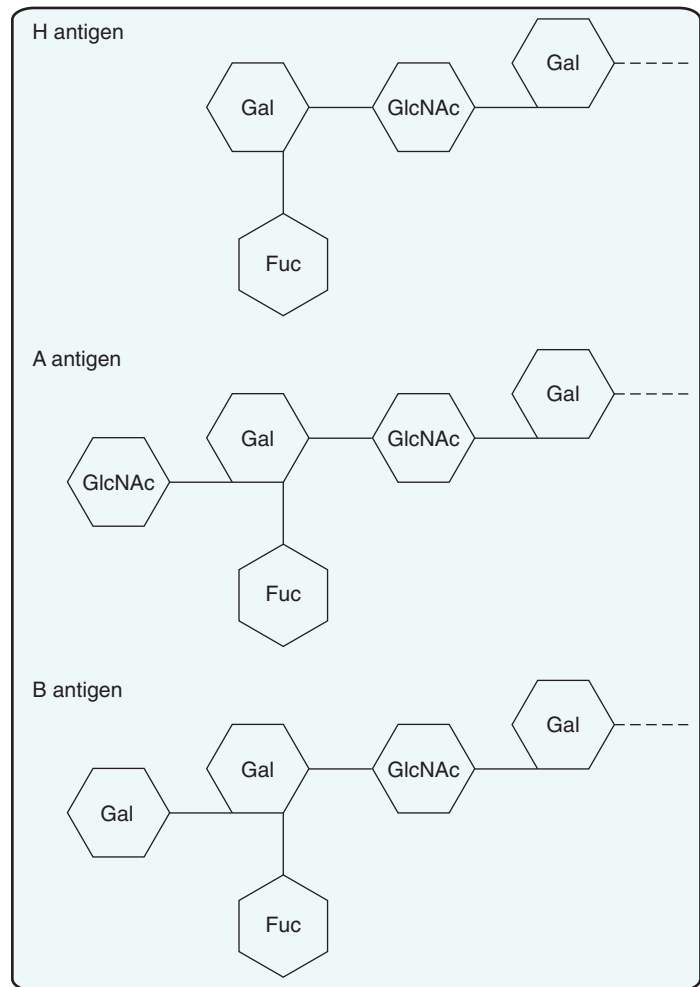
Transferases responsible for the A or B antigens add N-acetylgalactosamine or galactose, respectively, to the


FIGURE 35-1. Structure of the precursor H structure and the A and B antigens. GlcNAc, N-acetylglucosamine.

precursor chain carrying the H antigen (Fig. 35-1).[32,36-40] The genes encoding these transferases reside on chromosome 9.[41] The genes for the A and B blood group antigens are codominant because people with both transferases will transfer galactosamine and galactose and thus express A and B antigens. Group O is the amorph of the ABO blood group system. RBCs from group O persons have H antigens but lack A and B antigens.[42] It is likely that falciparum malaria has shaped the distribution of the ABO blood groups in humans.[43]

Although ABO antigens are detectable on the RBCs of 5- to 6-week-old embryos, these antigens are not fully developed until 2 to 4 years of age.[44-47] RBCs from infants carry A, B, and H antigens on linear oligosaccharide chains that have only one terminus to which the A, B, and H sugars can be added.[32,36,38,48-50] The fact that the A and B antigens are not fully developed at birth may be a reason why ABO hemolytic disease of the newborn (HDN) is usually a mild disease.[50,51] As the infants grow older, the oligosaccharides branch and create additional termini to which the A, B, and H sugars can be added.[39]

After 2 to 4 years of age, expression of A and B antigens remains fairly constant throughout life.

Antibodies to A and B antigens, also known as iso-hemagglutinins, may develop as a result of environmental stimulants, such as bacteria that carry similar antigens.[52] Because isohemagglutinins are naturally occurring, it is essential to select ABO-compatible blood for transfusion.[53] Indeed, ABO incompatibility is the most frequent cause of fatal hemolytic transfusion reactions.

Isohemagglutinin production begins several months after birth, reaches a peak at 5 to 10 years of age, and declines with increasing age.[54] Thus, infants younger than 4 months who have isohemagglutinins will have acquired them through placental transfer of maternal IgG anti-A, anti-B, or anti-A,B.[50]

Isohemagglutinins from group A and B individuals are predominantly IgM and do not usually cross the placenta and cause HDN.[55] However, because group O serum contains IgG isohemagglutinins, ABO HDN is most frequently seen in non–group O infants of group O mothers.

The Lewis System

The Lewis antigens, Le[a] and Le[b], are not intrinsic to RBCs but instead are carried on plasma glycosphingo-lipids that are adsorbed onto the red cell membrane.[56] These antigens are structurally related, with the Le[b] antigen containing an additional fucose that is not present on the Le[a] antigen. Furthermore, the one additional fucose present on the Le[b] antigen is not very different from the Le[a] antigen. Thus, Le[a] individuals rarely make anti-Le[b]. Hence, in most cases Lewis antibodies are made only in individuals who are Le(a–b–).[50]

In most cases, Lewis antibodies do not cause hemolysis, and donor RBCs lacking the Lewis antigens do not usually need to be selected.[50] However, rare hemolytic transfusion reactions have been reported when Le(a+) RBCs were transfused to recipients with anti-Le[a].[57] This may occur when the antibody reacts at 37° C. In such cases it is not difficult to identify Le(a–) donor units because the RBCs in almost 80% of donors are Le(a–).[58] Anti-Le[a] and anti-Le[b] are not known to cause HDN; they are usually IgM, and fetal RBCs have the phenotype Le(a–b–).[50] Interestingly, Lewis antigens are also expressed on *Helicobacter pylori*, a causative agent of gastric ulcers, and play a role in adhesion and colonization of the bacteria in the gastric mucosa.[59,60]

The Ii Collection

The I and i antigens reside in the subterminal portions of carbohydrate chains on glycolipids or glycoproteins of the RBC membrane. The i antigen appears on fetal RBCs when disaccharide units are linked in a straight chain.[61] In the first 2 years of life, many of these linear chains are modified into branched chains.[39] I specificity results at the expense of i antigens when the branched structures appear. Adults have RBCs with predominantly I antigen and little or no i antigen, whereas newborns have RBCs with strong expression of i antigen and small amounts of I antigen.[62]

Anti-I is a common autoantibody that is reactive at room temperature and below and generally produces no hemolysis.[63,64] In cold agglutinin disease, anti-I causes in vivo hemolysis, and such pathologic autoantibodies often react at 30° C in albumin.[65] Adult I-negative RBCs are not readily available for transfusion, and patients with cold agglutinin disease secondary to anti-I are transfused with I-positive RBCs through a blood warmer.[50] The titer and thermal range of anti-I are often increased after infection with *Mycoplasma pneumoniae*.[50] The presence of a cold agglutinin secondary to an anti-I antibody frequently occurs in *M. pneumoniae* infection, but this finding is neither a specific nor a sensitive test for this infection.[66]

Analogously, cold agglutinins caused by anti-i anti-bodies are sometimes present in Epstein-Barr virus (EBV) infection, but this is also neither a sensitive nor a specific test for this infection.[67]

Levels of the i antigen can aid in differentiating Diamond-Blackfan anemia from transient erythroblasto-penia of childhood. The i antigen is enhanced on RBCs from patients with Diamond-Blackfan anemia and is absent or of reduced strength on RBCs from children with transient erythroblastopenia of childhood.[68-70] However, the enhanced i antigen associated with Diamond-Blackfan anemia reflects stress hematopoiesis[71] and is not a specific aspect of the disease. In transient erythroblastopenia of childhood, the reduced levels of I antigen reflect the selective suppression of erythro-poiesis secondary to infection, but during recovery from this disorder, the patient's marrow is active and the I antigen may be enhanced as a result of hemato-poietic stress.[70]

The P System

Like the A, B, and H antigens, the P blood group antigens are defined by sugars added to precursor glycosphingo-lipids. Antigens in this group include P1, P, and P[k]. Among whites, 21% have the P1-negative phenotype and they commonly produce anti-P1. This cold reactive IgM antibody does not cross the placenta and has rarely been reported to cause hemolysis in vivo.[72] An autoantibody, autoanti-P, is found in patients with paroxysmal cold hemoglobinuria and in some patients with acquired immune hemolytic anemia. It is called the Donath-Land-steiner antibody and is most frequently seen in children.[73] This IgG autoantibody is a biphasic hemolysin that binds to RBCs in the cold and then hemolyzes them when warmed. The patient's serum causes hemolysis of RBCs that have been incubated first in melting ice and then at 37° C.[74] This antibody should be considered when the patient has hemoglobinuria and C3 alone is present on the RBCs.

The P antigen serves as a receptor for parvovirus B19[75] and pyelonephritic *Escherichia coli*.[76,77] Persons with the very rare p phenotype lack the antigens P₁, P,

and P^k and are not susceptible to infection by parvovirus B19.

People with the rare p phenotype may produce anti-P1+P+P^k, a potent hemolytic IgM antibody that can cause immediate hemolytic transfusion reactions.[50,78] This antibody has also been associated with HDN, fetal death, and miscarriages during early pregnancy in women whose RBCs have the p phenotype.[79]

The Rh System

The Rh blood group system includes D, C, c, E, e, and 40 other antigens.[80] The terms *Rh positive* and *Rh negative* refer to the presence and absence of the D antigen, respectively. The D antigen is, after A and B, the most important RBC antigen in transfusion practice. Persons who lack the D antigen do not have anti-D unless exposed to D antigen by pregnancy or transfusion. In more than 80% of persons who lack the D antigen, anti-D will develop after transfusion of a unit of D-positive donor blood.[81,82] Although this statistic probably does not apply to infants younger than 4 months, some young infants can probably respond to the Rh(D) antigen.[83]

The RBCs of 0.2% to 1% of white individuals and a greater percentage of African Americans carry reduced expression of the D antigen known as weak D. Weak D that is not detected by routine anti-D reagents can be identified by a more sensitive test, the indirect antiglobulin test. There is no hard and fast line between D and weak D; weak D RBCs are merely ones with a relatively smaller number of D antigen sites[84] that is usually due to point mutations in the gene encoding the Rh(D) antigen, the *RHD* gene.[85,86] Most patients with the weak D phenotype can safely receive blood transfusions from individuals who are Rh(D) positive. However, there are different types of weak D based on the specific genetic polymorphisms that are present, and patients with two weak D types can make anti-D antibodies.[87] Often only reference laboratories can determine the specific type of weak D that is present; sometimes molecular testing that is not yet widely available is necessary to determine the weak D type. All D-negative donor blood is tested for weak D by the antiglobulin test.[52] Donor RBCs that are agglutinated by this test are labeled Rh(D)+, and RBCs that are not agglutinated by this test are labeled Rh– for transfusion.

There are rare reports of fetuses with weak D having HDN when born to a mother with anti-D formed during an earlier pregnancy.[50] In practice, an infant at birth is designated Rh(D) negative when negative results are obtained with the routine anti-D test, as well as antiglobulin tests.[51] Similarly, during and after pregnancy, a woman is designated Rh negative only if negative results are obtained with the routine anti-D test, as well as by the indirect antiglobulin test.[53] This is to prevent possible misinterpretation of the D typing result in the event of fetal-maternal hemorrhage.[42,50]

Rh antigens are carried on Rh proteins that pass through the RBC membrane 12 times and are encoded by at least two genes on chromosome 1.[88-91] These Rh proteins associate with the RhAG protein required for cell surface expression of the Rh antigens D, C, c, E, and e, which are associated with specific amino acid substitutions on the Rh proteins.[90,91] Erythrocytes totally deficient in Rh proteins exhibit spherocytosis and stomatocytosis and have a diminished life span that results in a mildly hemolytic state known as Rh deficiency syndrome.[92,93] Although the function of the Rh proteins is unknown, RhAG may play a role in ammonium transport.[94]

The MNS System

The M, N, S, s, and U antigens are carried on sialoglycoproteins on the RBC membrane. M and N are encoded by paired allelic forms of the glycophorin A gene (*GPA*) and are the result of amino acid substitutions at residues 1 and 5 of GPA.[95-97] Human RBCs type as M+N–, M–N+, or M+N+, which represents homozygosity for M, homozygosity for N, and heterozygosity for both genes, respectively. S and s antigens are encoded by alternative forms of the glycophorin B gene (*GPB*). GPA and GPB are encoded by homologous genes on chromosome 4q28-q31.[98] GPA binds *E. coli*[99] and plays a role in malarial invasion of RBCs. RBCs lacking glycophorin A, B, or C are resistant to invasion by *Plasmodium falciparum* to varying degrees.[100]

Anti-M and anti-N can be IgG, IgM, or a mixture of both. These antibodies are usually clinically insignificant and are often present in persons who have not previously been transfused or pregnant. Antibodies that react at 37° C may cause hemolysis of transfused cells. Antibodies to S, s, and U usually occur after stimulation and are capable of causing hemolytic transfusion reactions and HDN.[50]

The Kell System

The Kell system antigens reside on two transmembrane proteins, the Kell protein and the XK protein, that are linked by a single disulfide bond. The Kell protein is a 93-kd glycoprotein that carries more than 20 antigens, and the XK protein is a 440–amino acid protein that carries just one antigen known as Kx.

The major antigen of the Kell blood group system resides on the Kell protein. This antigen is the K antigen, which is present in 9% of white donors.[78] Anti-K is the most common immune RBC antibody after those in the ABO and Rh systems. However, because more than 90% of donors are K–, it is not difficult to find compatible blood for patients with anti-K antibodies. The molecular basis of antithetical K and k antigens has been shown to be an amino acid substitution of methionine to threonine at residue 193 of the Kell protein.[101] This allows prenatal testing for K and k antigens on amniocytes from a mother whose fetus is at risk for HDN because of anti-K or anti-k. Antibodies to other antigens on the Kell protein, such as Kp^a, Kp^b, Js^a, and Js^b, are less common but are also clinically significant.[78,102] The Kell protein is a member of a large family of zinc-dependent endopeptidases.[103]

The other protein of the Kell system, the XK protein, carries one antigen, the Kx antigen.[104] The function of the XK protein is unknown, but its absence, known as the McLeod phenotype, is associated with a variety of abnormalities. Absence of membrane XK protein results in diminished expression of Kell protein on the membrane and reduced expression of all antigens in the Kell blood group system. In addition, these patients have acanthocytotic erythrocytes and hemolytic anemia. The McLeod phenotype is X-linked because the gene for the XK protein resides on the X gene. Some patients with the X-linked McLeod phenotype have concomitant chronic granulomatous disease (CGD) as a result of deletion of a region of the X chromosome that includes genes encoding XK and the gene associated with CGD.[102] Patients with CGD and McLeod's syndrome usually make antibodies to the XK and Kell proteins if they are transfused with RBCs containing the XK and Kell proteins. This can lead to major problems in transfusing these patients.[105] To avoid this problem, patients with McLeod's syndrome should be transfused with blood of the McLeod phenotype. Ko blood that lacks the Kell protein is not appropriate because such RBCs have increased expression of the Kx antigen that is expressed on the XK protein. However, males with the McLeod phenotype and no concomitant CGD (non-CGD McLeod's syndrome) do not make anti-Kx and can be transfused with McLeod- or Ko-type blood.[102,106]

The Duffy System

The Duffy antigens are epitopes present on a cell surface glycoprotein. The Duffy glycoprotein is a chemokine receptor that is expressed on many cell types and can bind a variety of chemokines.[107] Although the Duffy chemokine receptor can bind chemokines, its function is unknown and people lacking the receptor on their red cells, or on all cells, are totally healthy.[108]

The two most common alleles in people of European or Asian descent are Fy^a and Fy^b, which differ by a single amino acid substitution. Anti-Fy^a and anti-Fy^b have been implicated in transfusion reactions.[50] Anti-Fy^a has caused mild HDN, but anti-Fy^b has not been implicated.[50] Anti-Fy^a is commonly encountered, but because a third of donors are Fy(a–), compatible blood is not difficult to find.

The red cells of many people of African descent lack the Fy^a and Fy^b antigens (Fy[a–b–]) on their erythrocytes. However, the Fy^b allele is usually expressed in the lung, colon, and spleen of these individuals.[109] Thus, these individuals cannot mount an immune response to the Fy^b antigen but can produce anti-Fy^a.[50,78] In West Africa, most blacks are Fy(a–b–) because of natural selection; these RBCs are resistant to *Plasmodium vivax* malaria because the Duffy protein is a receptor for *P. vivax*.[107,109-111]

The Kidd System

The Kidd gene encodes two antigens, Jk^a and Jk^b, that represent a single amino acid substitution (Asp280Asn)

in the Kidd glycoprotein.[112] They are usually expressed in one of three phenotypes: Jk(a+b–), Jk(a–b+), or Jk(a+b+). The fourth phenotype, Jk(a–b–), is exceedingly rare.[78] Antibodies to both Kidd antigens can cause delayed hemolytic transfusion reactions. Because these antibodies are often weak and may become undetectable over time, they may escape detection in a sensitized patient's serum before transfusion. If the patient is then transfused with antigen-positive RBCs, the anamnestic response causes an increase in titer of the antibody and hemolysis of the transfused antigen-positive RBCs.[50] Once the antibody is identified, compatible blood is not difficult to find because a fourth of donors are negative for each antigen.

The Kidd glycoprotein is a urea transporter that prevents red cells from shrinking and swelling as they pass into and out of the high urea concentration of the renal medulla.[113-115] The Kidd urea transporter also prevents red cells from carrying urea away from the renal medulla and decreasing the urea-concentrating efficiency of the kidney.[115] Individuals who have RBCs with the Jk(a–b–) phenotype are unable to concentrate urine as efficiently as those who have the Kidd glycoprotein.[116-118]

The Lutheran System

The Lutheran blood group antigens are carried on a cell surface glycoprotein. The Lu^a antigen is present on the RBCs of 8% of people, whereas the antithetical antigen, Lu^b, is present in more than 99% of random blood samples. Antibodies in this system are variable and rarely encountered.[50] The glycoprotein carrying these antigens has five extracellular immunoglobulin superfamily domains that serve as laminin-binding receptors.[119,120] The Lu(a–b–) phenotype of the dominant type is associated with acanthocytosis.[121]

Other Systems

Other systems are included in Table 35-1.[80] Antibodies to antigens in these systems are less common than those just described, and information regarding their clinical significance is summarized in Table 35-2.

Maturation of Blood Group Antigens

Several blood group antigens are not expressed or are only weakly expressed on cord RBCs and have usually reached adult levels in children 2 years of age. Antibodies to these antigens are unlikely to cause HDN. Cord RBCs do not express Le^a, Sd^a, Ch, Rg, or AnWj antigens. Cord RBCs express the following antigens more weakly than RBCs from adults do: A, B, H, I, Le^b, P1, Lu^a (but not Lu^b), Yt^a, Vel, Do^a, Do^b, Gy^a, Hy, Jo^a, Xg^a, and Bg.[50,78,122]

Clinical Significance of Blood Group Antibodies

A blood group antigen has no immediate untoward effect on blood transfusion. It is the corresponding antibody that has clinical relevance and dictates the need for tests

in a transfusion service to detect blood group antibodies.

Antibodies recognizing antigens in the ABO blood group system are by far the most clinically significant. With antibodies in the other blood group systems, as a general rule, the more immunogenic an antigen, the more clinically significant its corresponding alloantibody. Other clinically significant antibodies occur in the following order, from most to least commonly encountered in transfusion practice: anti-D, anti-K, anti-E, anti-c, anti-Fyª, anti-C, anti-Jkª, anti-S, anti-Jkᵇ.[123,124] All other clinically significant antibodies occur at an incidence of less than 1% of serum-containing antibodies,[123,124] which explains why orders for blood lacking different combinations of the aforementioned antigens are by far the most common. Anti-P1, anti-M, anti-N, anti-Luª (Lutheran), anti-Leª, anti-Leᵇ, and anti-Sdª are all considered clinically insignificant unless the alloantibodies are reactive in tests performed strictly at 37° C.[50,122] Clinically insignificant antibodies that react at 37° C by the indirect antiglobulin test are those of the Knops and Ch/Rg systems and anti-JMH.[50,123] Other alloantibodies are clinically significant in some patients but not in others; examples

are anti-Vel, anti-Ge (Gerbich), anti-Ytª, and anti-Coª (Colton).[50] Table 35-2 summarizes the clinical significance of antibodies to RBC blood group antigens.

The clinical significance of an antibody to a low-incidence antigen depends on whether it was found during crossmatching or prenatal testing. Such an antibody detected during compatibility testing need not be identified to locate antigen-negative blood with which to transfuse that patient because the full crossmatch will be positive in the rare event that another unit of donor blood from the stock supply carries the low-incidence antigen. In contrast, if an antibody to an uncommon antigen is detected in the serum of a pregnant woman, identification of the antibody or determination of the antigen carried by fetal or paternal RBCs can be used as a predictor of the likelihood and severity of HDN. Blood for exchange transfusion will not be hard to find.[50]

If a patient's serum contains alloantibodies to a high-incidence antigen, blood may be hard to find. Examples are anti-U, anti-Kpᵇ, anti-Jsᵇ, anti-Luᵇ, and all antigens in the high series recognized by the International Society for Blood Transfusion (ISBT) working party.[80] Regardless of whether the investigation is for transfusion purposes or prediction of HDN, the antibody should be identified to aid in both assessing its clinical significance and locating appropriate blood for transfusion.

Blood group antibodies in donor plasma present almost no hazard to an antigen-positive recipient. Donor blood is always tested for the presence of blood group antibodies in plasma.

Sera from some patients contain autoantibodies that recognize antigenic determinants on RBCs from the majority of individuals, as well as their own. In such cases it may be impossible to locate compatible blood and only incompatible blood will be available. Instances in which this situation may arise include autoimmune hemolytic anemia, cold agglutinin disease, and paroxysmal cold hemoglobinuria, and these scenarios are discussed later in this chapter.[50]

Testing Donor Blood

Donor blood is routinely tested for its ABO and Rh blood group status. More extensive typing for other antigens is performed either when antigen-negative RBCs are required for a recipient whose serum contains clinically significant antibodies or when building an inventory of donors with certain antigenic profiles for future use, such as in the transfusion management of sickle cell disease (see later). In a patient with multiple alloantibodies, it is useful to estimate the time needed to locate compatible blood. The more alloantibodies present, especially to high-frequency antigens, the longer the time needed to locate compatible units.

Compatibility Procedures

The routine approaches used involve testing a blood sample from a prospective recipient for ABO and Rh

blood groups and for detection of blood group antibodies.[53] In most cases no unexpected antibodies are detected, and donor RBCs of the appropriate ABO and Rh blood type will be selected for transfusion. A sample of this blood may be crossmatched with the patient's serum by an immediate spin procedure or an "electronic crossmatch" in which a validated computer system verifies that the patient is receiving an RBC unit that is ABO and Rh(D) compatible with the patient's blood group.

When an antibody is detected, it should be identified if possible. Knowing the specificity of an antibody will establish whether it is likely to be clinically significant and the approach that will be necessary to provide an adequate supply of compatible blood.

Compatibility in ABO and Rh

Determination of the ABO and Rh(D) type of the patient is the first step in compatibility testing. In neonates, the ABO group is determined by testing the neonate's RBCs only because the plasma may contain maternal antibodies and young neonates' immune systems do not make isohemaglutinins. In patients older than 4 months, the ABO group is determined by testing both the patient's RBCs (forward group) and the plasma or serum (reverse group). The forward and reverse groups should correspond, except that infants younger than 9 months may not yet be making isohemaglutinins. In all other patients, until any discrepancy is resolved, only group O RBCs and AB plasma should be given.

Blood and blood components must be selected to be ABO and Rh compatible (Table 35-3). In general, for patients older than 4 months, type-specific RBCs and whole blood are selected, which means that the donor and recipient have the same ABO and Rh type; it is acceptable to transfuse ABO- and Rh-compatible but not identical RBCs. For transfusion of a fetus, group O Rh(D–), irradiated, CMV antibody–negative or leukoreduced RBCs (or both) are usually given regardless of the ABO group of the recipient. For neonates, some centers transfuse type-specific whereas others transfuse group O RBCs to all infants. If the RBCs selected for transfusion are not group O, the neonate's serum or plasma should be tested for anti-A and anti-B.[53] If anti-A or anti-B is detected, ABO-compatible RBCs should be transfused.[53]

*For massive transfusions and directed donor transfusions, compatible red blood cells (RBCs) may be used when type-specific RBCs are unavailable. Crossmatch-compatible group O Rh(D−) donor RBCs can be given to any recipient. Group AB Rh(D+) patients can receive RBCs of any ABO and Rh type.
FIGURE 35-2. Antibody screen. Reagent red blood cells (RBCs) of known antigenic phenotypes are mixed with a patient's serum and Coombs' reagent. If the patient's cells agglutinate, the patient has an antibody to an antigen present on the reagent cells.

Treatment with Rh immune globulin for prevention of immunization to D may be appropriate for a Rh(D−) patient who has received Rh(D+) RBCs, including those transfused with platelet or granulocyte products because these products contain RBCs.[53]

Compatibility in Other Blood Groups

Compatibility testing for blood groups other than ABO is achieved by antibody screen and crossmatch (Figs. 35-2 and 35-3). These tests detect unexpected RBC antibodies in the patient's serum. The patient's serum or plasma or, in the case of a neonate, maternal serum or plasma may be used for the antibody screen.[53] In the antibody screen, the patient's serum is mixed with group O reagent RBCs, which have most of the important blood group antigens. Because neonates are unlikely to produce new antibodies, the antibody screen needs to be performed only once per admission if the initial antibody screen is negative.[53] In the crossmatch, the patient's serum is mixed with donor RBCs or "electronically" crossmatched with a validated computer system.[53] In patients older than 4 months, crossmatch is performed for every unit of RBCs or whole blood transfused. In neonates, if the initial antibody screen is negative, it is unnecessary to crossmatch donor RBCs.[53]

If a blood group alloantibody is detected in the recipient's serum, every attempt should be made to identify the antibody. The clinical significance of an antibody is based on knowledge of the specificity of the alloantibody and the reported experience in other patients whose serum contains the same antibody specificity (see Table 35-2).[50] If the antibody has potential clinical significance, antigen-negative blood should be selected and crossmatched by a procedure that includes the antiglobulin phase.[42,53]

Selection of Blood for Transfusion to Patients with Blood Group Alloantibodies

Many alloantibodies detected in vitro in human sera do not have the potential to induce in vivo destruction of incompatible RBCs. No technical procedure is able to differentiate, with certainty, between clinically benign and clinically significant antibodies. Although the in vitro characteristics of an antibody may not reflect its behavior
FIGURE 35-3. Compatibility procedures. Red blood cells (RBCs) from a donor unit are mixed with a patient's serum. If agglutination of the cells occurs, the cells are incompatible by the immediate spin technique. If a full crossmatch is performed, Coombs' reagent is added to the cells and serum and the cells are examined for agglutination.

in vivo, the following features can be used to help establish its potential significance in that patient. In general, antibodies of the IgG class are more clinically significant than those of the IgM class.[50] In addition, the higher the titer of an antibody, the more likely it is to destroy antigen-positive RBCs in vivo. An antibody that causes in vitro hemolysis because of complement activation (see Table 35-2) of antigen-positive RBCs is likely to be clinically significant. Antibodies that react at 37° C are more likely to be clinically significant than those that do not.[50] For cold-reacting IgM antibodies, the wider the thermal range of reactivity in vitro, the more clinically significant it is likely to be. Alloantibodies that react in the cold and are not usually clinically significant include antibodies to M, N, P1, Le^a, and Le^b antigens.[123] In difficult cases, a few reference laboratories can also perform a monocyte monolayer assay, which has some value in predicting whether an antibody will cause a hemolytic transfusion reaction.[125]

Once a patient is actively immunized to an RBC antigen and produces a clinically significant alloantibody, the patient is considered immunized for life and must be transfused with antigen-negative RBCs for life. Neonates with passively acquired maternal antibody are not actively

immunized and thus need to be transfused with antigen-negative RBCs only while the antibody is still present.

Emergency Need

When RBC transfusion is urgently needed in a rapidly bleeding patient, compatibility testing should be abbreviated so that transfusion is not delayed. The clinician should indicate the need for emergency release of blood. A pretransfusion sample is obtained from the patient, the blood bank rapidly determines the ABO and D type on this sample, and the patient receives type-specific blood. However, if time is not available, the blood bank will issue group O Rh(D–) RBCs and AB plasma. In some cases of severe inventory shortages, these patients, especially males, may receive group O Rh(D+) RBCs. In cases of emergency transfusion, the antibody screen and crossmatch may be performed after the blood has been transfused, and the clinician is notified if any antibodies are identified.[53]

Massive Transfusion

When a child or neonate is massively transfused (i.e., one blood volume or more within 24 hours), the usual guidelines for selection of compatible blood may not apply. For alloimmunized patients, blood not tested for antigen may be used during an acute bleeding period and antigen-negative blood reserved for the late transfusion period.[53] If the supply of Rh(D–) blood is very limited, the patient's clinical situation should be assessed. If the expected amount of further bleeding is small, such as at the end of a surgical procedure, every effort should be made to avoid transfusion of Rh(D+) blood. However, in some cases the expected amount of further bleeding is large and the patient's transfusion needs clearly cannot be met by the limited amount of Rh(D–) blood available. In such cases it may be better for the Rh(D–) patient to switch to Rh(D+) RBCs early during the period of bleeding and reserve the Rh(D–) RBCs for the end of the bleeding episode.

Autologous Blood

Autologous blood transfusion is possible for some children who undergo elective surgery for which transfusion is anticipated. Transfusion of such blood reduces the risk of transfusion-transmitted viral diseases, but no blood transfusion is without risk. For example, autologous blood transfusions can be contaminated with bacteria or can cause volume overload, and there is always the risk that an incorrect unit could be transfused. Intraoperative RBC salvage can be used if tumor cells or bacteria are not expected to contaminate the surgical field.

To donate autologous blood before surgery, a child must meet the size or age requirements of the blood donor center, have adequate venous access, and have a hemoglobin concentration of 11 g/dL or greater and a hematocrit of 33% or greater.[53] Some blood donor centers will collect small units that are proportional to the child's size. Donation should begin 4 to 5 weeks before surgery

to allow time for RBC regeneration. Oral iron supplementation should be given. Recombinant erythropoietin is not routinely recommended for autologous blood donors and has not been licensed by the Food and Drug Administration (FDA) for autologous donation. However, it may be useful in selected circumstances.[126-129]

Directed Donations

Some institutions allow family and friends to direct their blood donations to be used for a child or infant. This is no safer than random banked blood and adds additional administrative expense. GVHD can occur when the patient shares an HLA haplotype with an HLA homozygous blood donor, and it is more likely to occur if a patient receive blood from a relative.[30,31,130] Hence, directed donations from blood relatives should be irradiated, and most institutions irradiate all blood donated by directed donors.

Choice of Blood for the Fetus

For intrauterine transfusions, group O Rh(D−) (and antigen negative if mother has an alloantibody) blood should be used. To prevent graft-versus-fetus disease, the blood is irradiated. To prevent CMV infection, CMV antibody–negative blood or leukocyte-reduced blood, or both, should be used.

Choice of Blood for the Neonate

Cellular components should be selected from CMV antibody–negative donors for neonate recipients weighing less than 1200 g at birth if their mothers are CMV antibody negative.[1310] Alternatively, leukocyte-reduced blood can also be used to prevent CMV infection if the blood product has less than 5×10^6 donor leukocytes.[132] Cellular blood components should be irradiated to prevent GVHD in these low-weight premature infants.[133]

In exchange transfusions for a neonate with HDN, the RBCs used must be negative for the implicated antibody (e.g., Rh[D−] RBCs when hemolysis is due to anti-Rh[D]). In terms of ABO group selection, group O RBCs and plasma of the infant's ABO group are often used. Group-compatible RBCs and plasma can likewise be used if the RBCs are also compatible with any maternal antibodies that are present in the infant's circulation.[50]

Choice of Blood for Patients with Sickle Cell Anemia

Two important principles must be followed in the transfusion of sickle cell patients: (1) avoidance of excessive viscosity and (2) prevention of sensitization to red cell antigens.

Sickle cells are intrinsically less deformable than normal cells; thus, elevating the hematocrit without significantly reducing the proportion of sickle cells may raise blood viscosity to dangerous levels.[134] Simple transfusion must be used with caution, particularly in children with hematocrits greater than 30%.

The question of what to use for transfusion of patients with sickle cell anemia has been the subject of many heated debates.[135-137] There is still no consensus regarding the best and most practical approach. Sickle cell patients, like all patients, are at risk for the development of alloantibodies, and alloantibodies may pose specific hazards to patients with sickle cell disease. Sickle cell patients usually need many transfusions throughout their lives, and an antibody to a blood group alloantigen that develops in childhood may be undetectable later in their lives. If they are then transfused with blood expressing that antigen, an anamnestic response to the antigen and a delayed hemolytic transfusion reaction are likely to develop. Sickle cell patients have been reported to suffer painful crises secondary to delayed hemolytic transfusion reactions. Additionally, a sickle cell patient in whom red cell alloantibodies develop may be at increased risk for the development of red cell autoantibodies, which can significantly complicate the disease.[137] For these reasons, some transfusion services provide phenotype-matched blood for sickle cell patients. Approaches that are used include those described in Table 35-4. Note that none of these approaches will prevent the production of antibodies to high-incidence antigens, such as U, Js[b], Cr[a], hr[S], and hr[B]. African Americans tend to be null for antigens commonly expressed in the general donor population, which consists of mostly whites in the United States. For this reason, some blood donor facilities have programs to recruit African Americans to donate blood to support the transfusion needs of sickle cell patients.

Choice of Blood for Patients with Thalassemia

In thalassemia, the goals of transfusion therapy are prevention of anemia and maintenance of a circulating hemoglobin level that is sufficient to suppress endogenous erythropoiesis. For most patients, maintenance of a pretransfusion hemoglobin level of 9 to 10 g/100 mL is sufficient.[138] Red cell alloantibodies are not a significant problem in most thalassemia patients, probably because transfusions are usually initiated at an early age when tolerance may develop. Therefore, most institutions in the United States do not provide red cells that are phenotypically matched to the patient's red cells.[139,140]

Choice of Blood for Allogeneic Hematopoietic Progenitor Cell Transplants

Because an HLA-identical donor is usually required for allogeneic HPC transplantation, the donor may not have the same ABO and Rh type as the patient.[42] In major ABO incompatibility, the recipient has antibodies against donor RBCs (e.g., the recipient is group O and has anti-A and anti-B; the donor is group A). In minor ABO incompatibility, the donor has antibodies against the recipient's RBCs (e.g., the donor is group O and has anti-A and anti-B; the recipient is group A). These incompatibilities may produce hemolysis,[50] but the hemolysis is often minimized by proper selection of blood products for transfusion.

TABLE 35-4	Approaches to Antigen Typing of Blood for Patients with Sickle Cell Disease	
Approach	**Advantages**	**Disadvantages**
Treat like other patients (i.e., avoid antigens to which the patient has made antibodies)	Simple. Avoids unnecessary work	Some patients will make antibodies that can result in serious transfusion reactions that may be especially dangerous in these patients Patients are probably at increased risk for the development of autoantibodies
Provide fully antigen-matched blood before the patient makes antibodies (i.e., matched for D, C, E, c, e, K, Fy^a, Fy^b, Jk^a, and Jk^b antigens). Note that antigen matching for Fy^b is not needed for patients of African descent who are Fy(a–b–) because they have the *FYB* gene, which is expressed in the lung and colon, and do not mount an immune response to the Fy^b antigen on transfusion of Fy(b+) RBCs	Reduces the risk of alloantibody and autoantibody formation and the risks associated with these antibodies	Significant work to reduce the risk for an antibody that may never develop There may be difficulty identifying units with extended phenotype matches
Provide antigen-matched blood after the first antibody is made	Reduces the chance of multiple antibodies with less work than extended phenotype matching for all patients	Some patients will make multiple antibodies quickly
Provide partially antigen-matched blood (i.e., matched for D, C, E, and K antigens)	Reduces the chance of multiple antibodies with less work than extended phenotype matching that includes antigens that are not very immunogenic	Some patients will make antibodies against unmatched antigens

In major ABO incompatibility (e.g., the donor is group A; the recipient is group O), host-versus-graft reactions can cause delayed erythropoiesis and even RBC aplasia.[141] To prevent recipient destruction of donor RBCs at the time of HPC infusion, donor RBCs are removed from the HPC preparation before infusion. A group O recipient may continue to produce anti-A and anti-B after transplantation, which can cause hemolysis of the newly produced donor group A RBCs. If transfusions are necessary during this period, group O RBCs can be given (Table 35-5). Before transplantation, the group O recipient has anti-A and anti-B. After engraftment of group A donor marrow, the anti-B will persist but the anti-A will become undetectable. Donor group A RBCs are given only after the recipient stops producing anti-A, that is, when the recipient's group O blood type changes to the donor group A and anti-A is not detected in the patient's serum.

In minor ABO incompatibility, hemolysis of recipient RBCs by donor antibody is usually preventable. To prevent hemolysis of recipient RBCs by passively transfused donor antibody during HPC infusion, plasma is removed from the HPC preparation before infusion. In addition, passenger B lymphocytes in the donor HPC unit may produce antibodies that could destroy the recipient RBCs. To prevent hemolysis of transfused RBCs, group O RBCs are used for transfusion during the posttransplant period if the antibody is detected. If the donor or recipient has a clinically significant antibody to an erythrocyte antigen, blood lacking the antigen should be given after transplantation.[53]

O	AB	O

Choice of Blood for Organ Transplantation

The ABO antigens are strong histocompatibility antigens and thus are of major importance in organ transplantation. Because ABO antigens are expressed on vascular endothelium, the recipient can reject and damage the vascular endothelium of a donor organ that is a major ABO mismatch. For this reason, major ABO-incompatible vascular organ transplants (liver, kidney, heart, lungs, pancreas) are not usually performed. However, ABO-incompatible heart transplants may be performed in infants and young children who have not yet produced isohemagglutinins or who have produced only low levels of isohemagglutinins.[142]

When organ transplants are performed in the presence of minor ABO incompatibility, the same hemolytic problems as in HPC transplantation may occur.[143] Passenger B lymphocytes may produce antibodies against the recipient's RBCs. Hemolysis of transfused RBCs can usually be prevented when an antibody is detected by transfusion of group O RBCs for ABO incompatibility and transfusion of antigen-negative RBCs for incompatibility caused by other blood groups.

Selection of Blood for Transfusion to Patients with Blood Group Autoantibodies

Autoimmune hemolytic anemia is described in detail in Chapter 14. In hemolytic anemia secondary to warm-reactive autoantibodies, no compatible blood can usually be found. The direct antiglobulin test (DAT, Fig. 35-4) will almost always be positive in autoimmune hemolytic anemia. Blood bank serologic testing is aimed at determining whether any underlying clinically significant alloantibodies are present and identifying the specificity of any such antibodies that are detected. This can be determined, with time, at a hospital transfusion service, which may need to have the testing performed at an immunohematology reference laboratory. Patients without a history of immunization are unlikely to have underlying alloantibodies. Transfused RBC units should be compatible with any underlying clinically significant alloantibodies. However, the blood is still usually incompatible with the patient's serum, and the clinically necessary amount of red cells should be transfused with careful monitoring but without delay. In some patients, the warm autoantibody has a clear-cut specificity for an antigen, and antigen-negative RBCs may be compatible in the crossmatch test.[144]

In paroxysmal cold hemoglobinuria associated with the Donath-Landsteiner antibody, transfusion is rarely necessary. The antibody binds RBCs only at cold temperatures (<20° C). In theory, it is reasonable to transfuse blood through a blood warmer; however, in practice, crossmatch-compatible, unwarmed random RBCs have been given without problem.[145] Only rarely is transfusion of RBCs of the rare phenotype p needed.[146,147] Most cases of paroxysmal cold hemoglobinuria in children are transient and occur after viral infection.
In cold agglutinin disease, a rare condition in children, RBCs should be transfused through a blood warmer. As described previously, the same issue of testing for underlying alloantibodies pertains here.

Adverse Effects of Transfusion

All reactions other than mild allergic (urticarial) reactions require immediate cessation of the transfusion and delivery of a fresh blood sample from the patient to the blood bank for serologic evaluation.

Allergic Reactions

The typical urticarial reaction is characterized by itching and hives. Localized urticaria simply requires interrupting the transfusion and administering an antihistamine. If the symptoms resolve within 30 minutes, the transfusion can be continued. Recurrent allergic reactions may require pretreatment with antihistamine.

Some children exhibit more severe allergic reactions, such as laryngospasm and bronchospasm. These patients may require steroids or epinephrine, or both (Table 35-6). The same unit of blood should not be restarted, even after the symptoms have responded to treatment. Saline-washed blood products may be helpful in patients with severe or recurrent allergic reactions. Anaphylactic reactions may occur if the patient is IgA deficient and has formed an IgE anti-IgA antibody. In these cases, either washed blood products or products drawn from rare IgA-deficient donors are indicated.

Febrile Nonhemolytic Reactions

The occurrence of fever, chills, or diaphoresis is usually due to cytokines released from leukocytes. Cytokines can be released from leukocytes during storage or on infusion in a patient who has antibodies that react with antigens on foreign white blood cells. Febrile nonhemolytic transfusion reactions are not associated with serious sequelae and may be treated with antipyretics. Of note, fever during a transfusion may represent another, more serious type of transfusion reaction: acute hemolysis, sepsis from a bacterially contaminated unit, or transfusion-related acute lung injury.

Acute Hemolytic Transfusion Reactions

Acute hemolytic transfusion reactions are most often due to donor-recipient ABO incompatibility. These reactions are generally caused by managerial errors, such as misidentification of a transfusion recipient.[148,149] The clinical manifestations of acute hemolytic transfusion reactions vary. Signs and symptoms may include any or all of the

FIGURE 35-4. Direct antiglobulin test (DAT). Red blood cells (RBCs) are incubated with Coombs' reagent; if the cells agglutinate after incubation, the DAT is positive.

TABLE 35-6	Guidelines for the Management of Transfusion Reactions		
Agent	**Use**	**Dose**	**Comment**
Diphenhydramine	Treating pruritus and rash (hives)	6.25-25 mg IV over period of 10-20 min	Diphenhydramine cannot prevent and has no place in the treatment of severe transfusion reactions
Epinephrine	Severe reactions characterized by bronchospasm, hypotension, and shock	0.1-0.4 mg SC (or IV if the patient is hypotensive)	For patients in shock not responding to epinephrine, treatment with an initial fluid bolus should be initiated. As in patients with shock from other causes, fluids, vasopressors, airway protection, and oxygenation should also be used
1:20 Aqueous suspension of epinephrine	After stabilization with epinephrine	0.05-0.2 mg SC	
Fluids			For hypotensive patients, a bolus of 20 mL/kg of normal saline should be administered simultaneously with epinephrine and steroids
Narcotics	Specific and effective treatment of rigors	0.1 mg/kg of morphine IV (or equivalent dose of meperidine hydrochloride)	
Acetaminophen (Tylenol)	Prevention or reversal of elevations in temperature in mild to moderate febrile reactions	Appropriate for age	
Steroids	In moderate to severe reactions; may occasionally be required for severe urticaria; indicated in all reactions characterized by fever, shaking chills, diaphoresis, and pallor	1-2 mg/kg of methylprednisolone (or equivalent dose of dexamethasone or hydrocortisone by IV push)	

IV, intravenously; SC, subcutaneously.

following: fever, chills, dyspnea, tachycardia, hypotension, flank pain, abdominal pain, pain at the infusion site, apprehension, nausea, vomiting, and hemoglobinuria. Other serious sequelae may include acute renal failure, shock, or disseminated intravascular coagulation (DIC), which may be manifested as bleeding. Some acute hemolytic reactions are characterized by only minor initial symptoms. In anesthetized recipients, the only findings may be diffuse bleeding (secondary to DIC) or red urine (hemoglobinuria). When an acute hemolytic transfusion reaction is suspected, the transfusion should be stopped immediately and an investigation initiated. The identity of the patient and unit should be reconfirmed. The remainder of the unit and a fresh blood sample should be sent to the blood bank, where the required workup includes (1) a clerical check, (2) visual inspection of the recipient's plasma for hemolysis, and (3) a DAT. If there is no visible hemolysis in the patient's plasma and the DAT result is negative, immune-mediated hemolysis can be excluded. A fresh urine specimen should be tested for hemoglobinuria.

Therapy for an acute hemolytic reaction is supportive. Depending on the size of the child, urine output of 40 to 100 mL/hr should be maintained. Early consultation with a nephrologist is warranted. Intravenous administration of furosemide or mannitol, which increase renal blood flow, may be required.

Delayed Hemolytic Transfusion Reactions

Delayed hemolytic transfusion reactions consist of two types: primary immunization and anamnestic response. Primary immunization is mild and occurs weeks after transfusion. It rarely causes significant hemolysis and may be suspected after an unexplained decrease in the patient's hemoglobin level 2 to 3 weeks after transfusion.

Secondary immune responses occur in patients who have been sensitized to one or more non-ABO blood group antigens during a previous transfusion or pregnancy. When a patient is re-exposed to the antigen, an anamnestic response occurs and results in a rapid rise in antibody level and accelerated clearance of the transfused

antigen-positive red cells. These patients experience some of the symptoms of a hemolytic reaction 3 to 10 days after transfusion. The clinical syndrome is generally mild, but delayed transfusion reactions can result in profound anemia. These reactions should be suspected in patients who have received multiple transfusions and unexplained anemia, bilirubinemia, or both develop 3 to 10 days after transfusion. The diagnosis is confirmed by a positive DAT result and identification of red cell alloantibodies in the patient's serum or on the patient's RBCs, or both.

Transfusion-Transmitted Diseases

Because of improvements in both donor screening and product testing, blood products are currently extremely safe. However, although the risks of transfusion-transmitted disease have been greatly reduced, they have not been eliminated entirely. Currently, all blood donations in the United States are tested for the presence of human immunodeficiency virus 1 and 2 (HIV-1/2), hepatitis B virus (HBV), hepatitis C virus (HCV), human T-cell lymphotropic virus 1 and 2 (HTLV-1/2), West Nile virus (WNV), and syphilis, and testing for Chagas' disease (*Trypanosoma cruzi*) is initiated. The battery of tests performed includes a combination of serologic testing and nucleic acid testing (NAT). The tests are exquisitely sensitive. However, very recent infections may be missed (so-called window period donations). The risks listed in the following sections and summarized in Table 35-7 are based on mathematical models estimating the number of infectious donors whose blood tests negative for a disease because they are in the window period.

Post-transfusion Hepatitis

Hepatitis B Virus. The estimated risk of post-transfusion HBV infection is presently 1 in 200,000 to 1 in 500,000 units transfused.[150] Acute HBV infection is symptomatic in about 50% of adults, and 5% to 10% of those infected become chronic carriers. In contrast, HBV infection acquired in early childhood is usually asymptomatic and leads to a chronic carrier state in more than 70% of those infected.[151]

Hepatitis C Virus. With the routine use of screening by NAT, the per-unit risk for HCV infection is currently

estimated to be about 1 in 2,000,000.[150] Children who receive HCV-infected blood products have a 30% to 50% chance of spontaneously clearing their infection.[152] Most others become chronically infected. In approximately 20% of children who have been infected with HCV, signs of cirrhosis develop after 18 years of age.[153,154]

Human Immunodeficiency Virus

All units are tested for HIV-1/2 by immunoassay, as well as by NAT. With NAT, the window period for HIV has been reduced to about 10 days. The per-unit risk of HIV infection is currently estimated to be 1 in 2,000,000.[150]

Human T-Cell Lymphotropic Virus

HTLV is the causative agent of both adult T-cell leukemia and endemic spastic myelopathy.[155,156] Most cases have been reported in residents of or emigrants from Japan, Africa, and the Caribbean region. The most comprehensive report of transfusion-transmitted HTLV indicated that 65% of patients who received whole blood or cellular products from HTLV antibody–positive donors seroconverted. Blood from all donations is tested for HTLV-1/2; the current per-unit risk is estimated to be 1 in 641,000.[157]

West Nile Virus

West Nile virus (WNV) is a flavivirus common in Africa, western Asia, and the Middle East. A febrile illness will develop in approximately 20% of infected individuals. Rarely, WNV infection causes an encephalitis syndrome; elderly and immunocompromised individuals are those primarily at risk. WNV has recently become established in North America. The vast majority of cases are transmitted by mosquito bites, but transfusion-related transmission does occur rarely. In 2003, nationwide routine screening for WNV by NAT was begun. As with HIV and HCV, NAT has almost completely eliminated WNV from the U.S. blood supply.

Cytomegalovirus

CMV is carried in and transmitted via lymphocytes. In most patients, transfusion-associated CMV infection causes no symptoms, although it may induce a mild mononucleosis-type illness 3 to 4 weeks after transfusion. Transfusion of CMV-containing blood products into an immunocompromised host with no serologic evidence of previous exposure to CMV can result in a lethal systemic infection. Patients at risk for severe CMV infection include bone marrow transplant patients, organ transplant candidates and recipients, and high-risk neonates. Therefore, patients who have never been infected with CMV and have an inherited or acquired immunodeficiency states should receive CMV-negative or leukoreduced red cells.[158]

Bacteria (Platelet Units)

Platelets are associated with the same range of infectious pathogens as any other blood component, but septic

TABLE 35-7	Estimated Risk of Transfusion-Transmitted Diseases
Agent	**Number of Infections/Million Units**
HIV	0.5
HCV	0.5
HBV	2-5
HTLV	0.5-4

HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus.

transfusion reactions, caused by bacterially contaminated units, are a unique risk of platelet transfusion. In contrast to all other blood components, which are either stored at 4° C or frozen, platelets are stored at room temperature. The reason is that if platelets are chilled before transfusion, they are cleared rapidly from the recipient's circulation.[159] Although room-temperature storage dramatically improves platelet survival in vivo, it also tends to promote bacterial growth. Currently, bacteria can be cultured from approximately 1 in 5000 apheresis platelet units.[160] In the United States, large donor centers generally use culture methods to screen for bacteria in all platelet products. With current screening methods, the per-unit risk of a clinically apparent septic transfusion reaction is estimated to be 1 in 75,000 platelet transfusions.[150]

PLATELET TRANSFUSION

Platelets are prepared for transfusion from a single unit of freshly collected whole blood (a platelet concentrate) or from apheresis by means of continuous-flow centrifugation (single-donor platelets). Regardless of the technique used, platelets must always be collected and stored at 20° C to 24° C and in anticoagulant containing citrate-phosphate-dextrose (CPD) or CPDA-1. Citrate anticoagulates the blood by binding plasma calcium, whereas dextrose is a nutrient source for actively metabolizing platelets.

Random-Donor Platelet Concentrates

In the United States, platelet concentrates are prepared from whole blood by the platelet-rich plasma (PRP) method. PRP is separated from packed RBCs by centrifugation of whole blood ("soft spin"). The PRP is then centrifuged again ("hard spin"). All but 50 to 70 mL of the platelet-poor plasma is transferred to an adjoining bag to be used for the production of fresh frozen plasma or other blood components such as cryoprecipitate or albumin. When optimal centrifugation techniques are used, approximately 85% of the platelets (5.0 to 7.0 × 10^{10} platelets) are recovered from a unit of whole blood.[161-163] In Canada and Europe, the alternative "buffy coat" method is used to generate platelet concentrates from whole blood.

Single-Donor Apheresis Platelets

Automated blood collection for the production of apheresis platelets may be accomplished with either continuous or discontinuous flow centrifugation.[164,165] Apheresis platelets from one individual should yield more than 3.0 × 10^{11} platelets in 200 to 300 mL of plasma. This preparation may also be called single-donor apheresis platelets as opposed to pooled platelet concentrates from random donors. Modern apheresis equipment is often able to yield more than 6.5 × 10^{11} platelets per procedure and

typically incorporates a leukoreduction step that leaves fewer than 1×10^6 leukocytes per product. This allows units to be split into two doses, each with six platelet concentrate equivalents.

Once they are processed, platelet units are stored on elliptical, circular, or flat-bed agitators.[166,167] This constant mild agitation prevents platelet clumping or activation as platelets settle to the bottom of the bag.[168,169] Constant agitation also facilitates gas exchange, which is important for maintaining an optimal pH range for platelet metabolism and function at 20° C.[170] Because of the risk of bacterial growth associated with room-temperature storage, platelet units are generally stored for only 5 days. In some settings, the FDA has allowed bacterially tested platelets to be stored for up to 7 days.[171]

Prophylactic Platelet Transfusion

Today, the vast majority of platelet transfusions are given prophylactically to prevent bleeding in nonbleeding patients, as opposed to therapeutically to treat active bleeding. If there is no evidence of platelet dysfunction, patients do not usually experience active bleeding if the platelet count is greater than 10,000/mm^3 and have minimal risk for spontaneous life-threatening hemorrhage until the count is 5000/mm^3 or less.[172-176] However, additional coagulation abnormalities, such as acquired or congenital platelet dysfunction, clotting protein deficiencies, or vascular or tissue defects, require more aggressive platelet support to decrease the risk for hemorrhage.

Risk assessment for surgical patients is somewhat more difficult. Retrospective data suggest that a platelet count of 50,000/mm^3 or greater is acceptable for a patient to undergo major surgery.[177] Certain circumstances may warrant more aggressive correction of thrombocytopenia before or after surgery. In areas in which even a small amount of bleeding might cause permanent deficits, such as the eye or central nervous system, it is traditional to aim for a platelet count of greater than 100,000/mm^3. During prolonged procedures in which the patient will be maintained on cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO), platelets may be dysfunctional because of activation after passage through the extracorporeal perfusion equipment. In general, there is no need to administer platelets to patients after extracorporeal circulation if there is no evidence of bleeding and the platelet count is at least 50,000/mm^3.[178-180] When bleeding is present, it is more commonly due to heparin, inadequate protamine correction, fibrinolysis, or problems with surgical closure.

Minor procedures such as liver biopsy have been performed safely with platelet counts greater than 25,000/mm^3.[181] Similarly, lumbar puncture has been shown to be safe in the setting of thrombocytopenia. Howard and co-workers[182] reported a series of 956 consecutive pediatric patients with newly diagnosed acute lymphoblastic leukemia who underwent lumbar puncture. No serious bleeding complications occurred in 5223 lumbar

punctures, including 170 performed when the platelet count was 11,000 to 20,000/µL. The authors concluded that prophylactic platelet transfusion was unnecessary in patients with platelet counts above 10,000/µL. These procedures were performed in only 29 patients with platelet counts of 10,000/µL or less, so it was not possible to assess the risk of bleeding in patients with extremely low platelet counts with confidence.

Platelet Dosing

Guidelines for determining the platelet dose have been published in a number of reviews.[183-185] In general, 1 unit of random-donor platelets (5.0 to 7.0 × 10^{10} platelets) per 10 kg of body weight should increase the platelet count by 40,000 to 50,000/mm^3 within 1 hour after the infusion. In an average-sized adolescent or adult, 6 units of platelet concentrate, or 1 single-donor apheresis unit (3 to 5 × 10^{11}), will increase the platelet count by 50,000/mm^3 or greater.

To determine the effectiveness of platelet transfusion, a platelet count should be obtained before infusion, at 1 hour, and at 24 hours after infusion. There is no significant difference in the post-transfusion platelet count when measured 10 minutes versus 60 minutes after transfusion.[186] These estimates assume normal spleen function and size; approximately 30% of transfused platelets are removed from circulation in the spleen.[185,187]

Normally, a third of the platelets released into circulation from the bone marrow are stored in the spleen. This platelet pool is mobilized when patients are treated with corticosteroids, which results in an increase in circulating platelet number. Hypersplenism causes a larger percentage of transfused platelets to be sequestered in the spleen. This condition results in a decrease in platelet recovery immediately after platelet infusion but does not have an effect on platelet survival once a steady state has been achieved.[188]

Since the mid-1950s, clinicians have recognized that fever may reduce platelet recovery by 20% to 40%.[189,190] In one study, decreased platelet recovery was documented in bone marrow transplant patients with fever and negative blood cultures. Although occult infection cannot be ruled out, fever alone was the only change associated with poor platelet increment in these patients.[190]

Consumptive coagulopathy (DIC) refers to excessive activation of thrombin resulting in accelerated conversion of fibrinogen to fibrin. This process may be acute and accompanied by rapid consumption of procoagulant factors and platelets in association with extensive bleeding, as in sepsis, shock, or certain forms of malignancy.[191,192] A chronic form of DIC may occur if the procoagulant consumption is slow enough for the liver to compensate for limited consumption, as found in hemangiomas or a necrotic lesion in the lung or brain, for example. In either form of DIC, recovery plus survival of transfused platelets is shortened.[193-195] Diseases associated with primary endothelial cell damage, such as hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP), are also associated with decreased platelet recovery because of the formation of microaggregates in areas of vascular damage.[196] Additional bleeding may be seen with these syndromes as result of the acquired platelet dysfunction associated with renal failure and uremia.[184,197]

Errors in calculating the expected increment in platelet count may occur if one overestimates the number of platelets in a platelet concentrate or single-donor unit. Local manipulation in hospital pharmacies or blood services, such as filtering, concentrating, or washing of platelets, results in a variable amount of platelet loss, thus making calculations of platelet increment difficult.

Older platelets may not remain in circulation as long as freshly collected platelet concentrates because of excessive activation during storage or the metabolic effects of acidosis.[170] Platelets also express small amounts of ABO antigens, which makes ABO-incompatible transfusions less effective than ABO-matched transfusions. Finally, analysis of multiply transfused patients shows that there is a tendency for decreased average count increments with successive transfusions. A patient's 1st platelet transfusion may result in a 30% higher count increment than their 15th transfusion despite equal numbers of platelets being transfused and the absence of other factors. No definitive cause of this decrease has been discerned other than the hypothesis that patients subjected to multiple rounds of chemotherapy may sustain subtle endothelial damage that consumes transfused platelets.[198]

To compare the effectiveness of platelet transfusion on different occasions or with different donors and recipients, a commonly used ratio is the corrected count increment (CCI):

$$CCI = \frac{\begin{array}{c}(\text{Post-transfusion count} - \text{Pretransfusion count}) \\ (\text{Body surface area}\,[\text{m}^2])\end{array}}{\text{Number of platelets given }(\times 10^{11})}$$

With this equation one can correct for the variations in number of platelets infused and for differences in patient size.[184,185] For example, if the platelet count is increased from 5000 to 65,000/mm^3 after the transfusion of 3 × 10^{11} platelets in a child with a body surface area of 1.2 m^2,

$$CCI = \frac{60,000 \times 1.2}{3.0} = 24,000$$

This formula is most commonly used to define platelet refractoriness (CCI < 5000 at 1 hour), but it has limited use in comparing single transfusions directly because it does not factor in the multitude of other issues that may affect platelet count increments, as outlined earlier (Table 35-8).

TABLE 35-8	Variables Resulting in Decreased Post-transfusion Platelet Counts
Platelet Component	**Clinical Condition**
Donor platelet count	Fever
Technique of platelet collection	Sepsis
	Amphotericin B therapy
Temperature of storage	Disseminated intravascular coagulation
Platelet component age	
Storage conditions	Hepatosplenomegaly
Infusion time	Alloantibodies
Blood filter type	Autoantibodies
Leukocyte removal	Massive blood loss
Reducing platelet plasma volume	Hemolytic-uremic syndrome
	Thrombotic thrombocytopenic purpura
Washing platelets	Necrotizing enterocolitis
ABO match	Multiple previous platelet transfusions

Clinical Indications for Transfusion

Bone Marrow Failure

Bone marrow failure resulting in thrombocytopenia is the major reason for patients to receive platelet transfusions. Iatrogenic induction of bone marrow failure, secondary to chemotherapy or irradiation, is the most common cause of bone marrow failure in all age groups. Patients with malignancies involving the bone marrow (e.g., leukemia, lymphoma, neuroblastoma, metastatic disease from solid tumors, or myelofibrosis) may also require platelet support. The decreased marrow production in these diseases is due to displacement of megakaryocytes by malignant elements. In some cases, the tumor cells produce substances (e.g., tumor necrosis factor) that inhibit the growth of normal marrow cells. In the absence of other coagulation deficiencies, uremia, or vascular disease, patients do not have significant spontaneous bleeding until the platelet count is less than 20,000/mm³.[172,173] The original studies that examined the utility of prophylactic platelet transfusion in children with thrombocytopenia secondary to chemotherapy were published in 1962. During this period, aspirin was used routinely for management of pain and fever in all thrombocytopenic patients. Similarly, blood donors were not aware of the detrimental effects of aspirin ingestion on platelet function. Now that aspirin use is less prevalent in both patients and donors, it should be possible to lower the level for prophylactic infusion to 10,000/mm³.[175,200]

Patients with primary bone marrow failure caused by a constitutional defect such as Fanconi's anemia will also be thrombocytopenic. However, platelets are usually withheld from these patients unless they are actively bleeding because they are rapidly alloimmunized, which in turn will significantly reduce the success of future transfusions. The incidence of sensitization to platelets is higher in patients with aplastic anemia because prior to

definitive treatment these patients are not receiving immunosuppressive chemotherapy concurrent with platelet transfusions, as is the case with oncology patients. Furthermore, long-term cure for aplastic anemia, regardless of the cause, is best achieved with bone marrow transplantation.[200] Studies before the introduction of modern leukoreduction filters found that exposure to more than five platelet donors results in a significant reduction in successful transplantation because of rejection of donor bone marrow.[201] Although it is unclear whether this finding applies to current leukoreduced platelets, it is still recommended that if these patients do require therapy for bleeding, it is best to use irradiated, single-donor, filtered platelets in an attempt to minimize sensitization. The decision to transfuse a patient with newly diagnosed aplastic anemia should not be taken lightly because even a single exposure to transfused platelets may adversely affect long-term survival if bone marrow transplantation fails. Once the patient has become refractory to single-donor and HLA-matched platelets, family donors might also undergo plateletpheresis if these patients are *not* candidates for bone marrow transplantation.

Platelet Destruction

Shortened platelet survival may be due to immune-mediated destruction or nonimmune mechanisms that result in accelerated platelet consumption. In general, prophylactic platelet transfusions are contraindicated in these patients because the infused platelets are rapidly destroyed and thus a "safe" platelet count cannot be maintained. Therefore, platelet transfusions are reserved for episodes of active bleeding or in preparation for surgical procedures.

Nonimmune Mechanisms

Nonimmune mechanisms include the consumption of platelets in areas of endothelial damage, such as occurs with HUS, TTP, or necrotizing enterocolitis. DIC results in decreased platelet life span as a result of consumption of platelets and activated clotting factors, such as fibrinogen in the formation of microthrombi in association with sepsis, shock, acidosis, or severe head trauma. In these syndromes it is essential to assess the risk for bleeding when determining the need for transfusion. Infants with necrotizing enterocolitis are transfused more aggressively because many demonstrate marked gastrointestinal blood loss and may have a preexisting central nervous system hemorrhage associated with prematurity. Similarly, even though their counts may not be less than 10,000/mm³, patients with DIC are often given platelets because of consumption of clotting factors and evidence of ongoing bleeding. Successful outcomes for these patients depend on elimination of the underlying disease, for example, treating sepsis with antibiotics, restoration of organ perfusion in states of shock, or removal of necrotic tissue. Patients with large cavernous sinus hemangiomas (Kasabach-Merritt syndrome) have a localized consump-

tion of platelets and clotting factors that results in a laboratory picture of DIC.[193-195] Until the lesion is removed or begins to involute, the platelet and clotting factor consumption will continue. These patients do not usually require transfusion for thrombocytopenia because the high rate of platelet turnover results in younger and more hemostatically effective platelets in the circulation. Finally, in TTP and HUS, platelet infusions are withheld as long as possible because it is thought that the infused platelets would lead to further hemolysis and organ damage by contributing to the formation of microthrombi in areas of endothelial damage.[196] Many of these patients have renal involvement and may be uremic with secondary platelet dysfunction. In this setting, patients undergoing peritoneal catheter placement often require platelet transfusions to control active bleeding.

Hypersplenism may result in poor platelet survival as a result of trapping of platelets in the expanded splenic bed. A more complex clinical situation arises with acute or chronic liver disease.[192] Splenic pooling, DIC, and poor platelet production may all contribute to the thrombocytopenia of hepatic disease. The presence of portal hypertension and esophageal varices from cirrhosis may push clinicians to consider platelet transfusion in the presence of gastrointestinal bleeding or when the platelet count falls below 20,000/mm^3.[181,202] Acquired platelet dysfunction is associated with both acute and chronic liver disease secondary to decreased hepatic clearance of circulating fibrin degradation products. When platelet transfusion is required, splenomegaly may affect initial platelet recovery measured in the first hour after transfusion, but not platelet survival as determined by the platelet count 24 hours later.[181,188,197,202]

Immune-Mediated Thrombocytopenia

Immune thrombocytopenia is mediated by antibodies that bind to epitopes on the platelet membrane and result in their rapid removal from the circulation. These antibodies are either "self-reactive" autoantibodies or specific for alloantigens, polymorphic epitopes expressed on platelet membrane receptors. Alloantibodies cause thrombocytopenia in neonatal alloimmune thrombocytopenia (NATP) and post-transfusion purpura (PTP), both of which are discussed later in this chapter. Alloantibodies responsible for poor response to platelet transfusion are discussed in the section on the platelet refractory state.

Autoantibody-Mediated Thrombocytopenia

Autoantibody to platelets may be present in association with other diseases such as systemic lupus erythematosus, EBV infection, CMV infection, varicella virus infection, multiple sclerosis, diabetes, thyroid disease, or drug-induced autoantibody as seen with valproic acid. It may also be present without other disease associations, as in idiopathic thrombocytopenic purpura. In either setting there is rapid removal of antibody-coated platelets in the spleen and, to a lesser extent, in the liver. Immune complexes may nonspecifically adhere or bind by means of Fc receptors on the platelet surface. A particularly interesting example of the latter is the entity heparin-induced thrombocytopenia.[203] In this case patients exposed to heparin therapy produce antibodies directed to platelet factor 4 (PF4) bound to heparin. Immune complexes of PF4-heparin and antibody bind via Fc receptors to platelets and cause platelet activation and a prothrombotic state in which platelets are consumed. This could be a devastating complication of heparin therapy that may be suspected in patients with falling platelet counts a few days after initiating heparin therapy. Platelet transfusions are generally contraindicated because they may exacerbate the prothrombotic state.

In states that increase platelet turnover, bone marrow responds by increasing megakaryocyte number, size, and ploidy. This, in turn, results in fresher platelets that are slightly larger in size and represent a younger population than normal because of the rapid turnover of thrombocytes. Thus, the bleeding time in patients with immune-mediated thrombocytopenia is shortened relative to the absolute number of platelets, and they rarely experience major bleeding even though the platelet count may fall below 10,000/mm^3.[204] Autoantibodies that interfere with functional epitopes on platelet glycoprotein receptors, such as in acquired Glanzmann's thrombasthenia, are a notable exception to this rule. In this setting, patients manifest bleeding even with platelet counts greater than 20,000/mm^3.

In patients with rapid consumption of platelets by autoantibody, physicians withhold transfusions until there is evidence of bleeding, regardless of the platelet count. Central nervous system and gastrointestinal bleeding may be the initial feature of autoantibody-mediated thrombocytopenia and requires immediate aggressive therapy, including platelet transfusion. Although the platelets are consumed rapidly, active bleeding may stop or decrease significantly. Platelet transfusions should be used judiciously in combination with therapy aimed at reducing autoantibody production and blocking reticuloendothelial cell clearance of antibody-coated cells. Therapy for immune-mediated thrombocytopenia is discussed at length elsewhere in this textbook.

When medical management fails, splenectomy may be required to decrease platelet destruction and autoantibody production. Administration of intravenous immunoglobulin (IVIG) before surgery may obviate the need for platelet transfusion; however, in patients who are profoundly thrombocytopenic, platelets may be given to decrease the risk for major bleeding. If possible, platelets should be given after clamping of the splenic pedicle because survival of the transfused platelets is markedly improved once the splenic circulation is blocked.

Alloantibody-Mediated Thrombocytopenia

Neonatal Alloimmune Thrombocytopenic Purpura

In NATP, maternal antiplatelet alloantibody has crossed the placenta and caused thrombocytopenia in the fetus

TABLE 35-9	Platelet Alloantigen Phenotype and Frequency		
Alloantigen System	**Glycoprotein Location**	**Allelic Forms**	**Phenotypic Frequency**
HPA-1 (Pl[A], Zw)	GPIIIa Leu–Pro33	HPA-1a (Pl[A1])/HPA-1b (Pl[A2])	72% a/a 26% a/b 2% b/b
HPA-2 (Ko, Sib)	GP1b Thr–Met145	HPA-2a (Ko[b])/HPA-2b (Ko[a])	85% a/a 14% a/b 1% b/b
HPA-3 (Bak, Lek)	GPIIb Ile–Ser843	HPA-3a (Bak[a])/HPA-3b(Bak[b])	37% a/a 48% b/b 15% b/b
HPA-4 (Pen, Yuk)	GPIIIa Arg–Gln143	HPA-4a (Pen[a])/HPA-4b(Pen[b])	99% a/a <0.1% a/b <0.1% b/b
HPA-5 (Br, Hc, Zav)	GPIa Glu–Lys505	HPA-5a (Br[b])/HPA-5b (Br[a])	80% a/a 19% a/b 1% b/b
HPA-6 (Ca, Tu)	GPIIIa Arg–Gln489	HPA-6a (Ca[b])/HPA-6b (Ca[a])	99% a/a <1% a/b <1% b/b
HPA-7 (Mo)	GPIIIa Pro–Ala407	HPA-7a (Mo[b])/HPA-7b (Mo[a])	99% a/a <1% a/b <1% b/b
HPA-8 (Sr[a])	GPIIIa Arg–Cys636	HPA-8a (Sr[b])/HPA-8b (Sr[a])	99% a/a <1% a/b <1% b/b

or neonate. Harrington and associates first reported the observation that pregnant women may become alloimmunized to antigens expressed on fetal platelets.[205] Even during the first pregnancy, maternal antiplatelet alloantibodies can cross the placenta and cause profound thrombocytopenia in the fetus and newborn. In North America, the alloantibodies identified are most commonly directed against Pl[A1]. A complete list of platelet alloantigens and their frequency in populations that have been studied thus far are listed in Table 35-9. The finding of thrombocytopenia in a healthy infant whose mother has a normal platelet count is often due to maternal alloantibodies.

The diagnosis of NATP is made with the demonstration of antiplatelet antibody in maternal plasma that is reactive with *paternal* platelets. Maternal plasma is also screened to rule out the presence of autoantibody. More than 50% of the platelet-specific alloantibodies in NATP are reactive with the Pl[A1] epitope on glycoprotein IIIa, which is also known as human platelet antigen 1 (HPA-1).[206] The predominance of Pl[A1] alloantibodies in reported cases of NATP suggest that this epitope is more immunogenic than other platelet alloantigens. Based on the high probability that these Pl[A1]-negative women, who constitute less than 2% of the population, would marry Pl[A1]-positive men, it is surprising that the actual incidence of NATP is so low at 1 to 4 per 10,000 live births.[207,208] Perhaps mild cases of NATP are missed in the absence of routine screening of newborn platelet counts. Healthy infants may not bleed or exhibit petechiae until the platelet count drops below 20,000/mm[3].

Reports suggest that immune response genes may also play a role in platelet alloimmunization.[209-211] Based on these studies, there appears to be an increased incidence of alloimmunization against Pl[A1] in mothers positive for HLA-B8 and HLA-DR3.

The diagnosis of maternal alloimmunization is usually made after the birth of her first thrombocytopenic infant. Women who are then identified as being sensitized to a platelet-specific alloantigen should be monitored very closely throughout subsequent pregnancies. Intermittent screening of maternal serum should be performed similar to prenatal Coombs' testing in women who are Rh negative. All women in the mother's family should also be evaluated before or during their pregnancies to determine whether they might likewise be at risk for alloimmunization. If a Pl[A1]-negative woman is also positive for HLA-DR3 (DRw52), she has a greatly increased risk of alloimmunization, even during her first pregnancy.[211-213]

To determine whether the infant is at risk for thrombocytopenia secondary to maternal alloantibody, it is advantageous to establish the platelet phenotype of the fetus early in pregnancy. As early as the eighth week of gestation, DNA from nucleated cells obtained from chorionic villus sampling can be amplified through the use of polymerase chain reaction. DNA typing is then determined with glycoprotein-specific oligonucleotide primers and probes unique for each alloantigen sequence or phenotype.[213-215] A prospective study reported 100% correlation between DNA typing and subsequent serologic response in mothers with alloantibodies to Pl[A1] or Bak.[216] This technique is useful only when the nucleotide

sequences that define the polymorphisms are known, as listed in Table 35-9.[214] This is an important technologic advance because if the obstetrician knows that the fetal phenotype is negative for these alloantigens, it is *not* necessary to obtain cord blood samples to monitor fetal thrombocytopenia, a procedure that is associated with risks for both the mother and child.

Because of the high frequency of these alloantigens, random-donor platelets are usually ineffective in treating alloimmune thrombocytopenia in the neonate. When platelets are given, it is best to use washed, irradiated *maternal* apheresis platelets because they lack the alloantigen. Washing is required to remove maternal plasma that contains the alloantibody. *Irradiation is routinely performed on all blood products from first-degree relatives when there is an increased risk for GVHD, particularly in neonates.* When severe thrombocytopenia is anticipated in the newborn, maternal platelets may be harvested before elective delivery and made available for transfusion shortly after birth to infants with NATP diagnosed prenatally. Alternatively, many blood donor centers maintain lists of Pl[A1]-negative donors who may be called on at short notice to donate. IVIG has also been used successfully in the newborn and is particularly helpful in areas in which plateletpheresis and washing are unavailable.[217-220] In families with a history of prenatal intracranial hemorrhage, the fetal platelet count should be monitored closely and ultrasonography performed to rule out bleeding before delivery.[221]

Post-transfusion Purpura

PTP occurs 7 to 10 days after blood product infusion in a patient who has previously been transfused or pregnant.[207] Paradoxically, alloantibodies are produced that destroy not only any transfused platelets but also the patient's own platelets. Though extremely rare, PTP occurs most commonly in the less than 2% of the population who are Pl[A1] negative.[206] The post-transfusion plasma usually has high-titer anti-Pl[A1] activity, but the mechanism of autologous platelet destruction is unclear. Hypotheses suggesting the presence of a cross-reactive alloantibody that binds to autoepitopes in close proximity to the Pl[A1] site have yet to be proved. There are individual cases reported of PTP secondary to alloantibody to Bak[a] and Pen[a] and two cases of anti-Pl[A2] antibody.[222-224] Of the approximately 100 cases reported since its description in 1959, only four men have been described as having PTP.[206] A series of PTP patients with anti-Pl[A1] alloantibody were HLA-typed, and more than 90% were HLA-DR3 positive, with the supertype HLA-DRw52 predominating in these individuals.[210,211] Patients are usually in their late forties or older, but PTP has been reported in a 16-year-old girl not previously pregnant.[224]

Platelet transfusions are contraindicated in PTP patients, in whom the treatment of choice is IVIG or plasmapheresis, or both.[225] The frequency of transfusion reactions in these patients is quite high, with 46% experiencing chills and fever during blood product infusion.

Therefore, red cells should be washed and filtered whenever possible. If platelets must be given for life-threatening hemorrhage, they should be Pl[A1] negative, washed, and filtered. Further discussion of therapy and possible mechanisms of autologous platelet destruction in PTP is more thoroughly addressed in two extensive reviews of this disorder.[207,214]

Platelet Transfusion in Selected Clinical Situations

Patients with congenital platelet dysfunction, such as Glanzmann's thrombocytopathy or Bernard-Soulier syndrome, may experience episodes of profuse bleeding. In this setting, platelets may be administered to control massive hemorrhage. Because normal platelets express proteins that these individuals lack, isoantibodies to these receptors develop in some patients and they eventually become refractory to all platelet transfusions. Efforts to minimize menstrual bleeding by hormonal suppression may decrease the number of platelet infusions in women. Bleeding in patients with congenital platelet dysfunction secondary to abnormal platelet secretion may respond to desmopressin, thereby avoiding exposure to blood.[226,227]

Acquired platelet dysfunction in children is most commonly due to drugs, chronic renal failure, or antiplatelet antibodies. Rarely, children exhibit platelet dysfunction as a manifestation of myelodysplastic syndrome or chronic leukemia. Platelet transfusions may be used if the patient is actively bleeding, but eventually the transfused platelets will be affected by exposure to drug, uremia, or antiplatelet antibodies, which limits their survival and function. For this reason, platelets are not given prophylactically to these patients. Every effort should be made to ameliorate the platelet dysfunction so that exposure to blood product is avoided. Patients with uremia may respond to infusion of desmopressin, and those with antiplatelet autoantibodies may respond to immunoglobulin infusion or corticosteroid therapy. When possible, alternative medications should replace those known to cause platelet dysfunction.

Neonatal Thrombocytopenia

Platelet transfusions in the neonatal unit are a common event. In acutely ill premature infants, DIC or platelet consumption often develops in association with perinatal asphyxia, respiratory distress syndrome, sepsis, intracranial hemorrhage, necrotizing enterocolitis, and acidosis. A chronically ill newborn with poor caloric intake and growth may also require platelet support because of inadequate platelet production. Platelets are often given after double-volume exchange transfusion if dilutional thrombocytopenia occurs. To minimize the problems of blood-borne infection and possible GVHD from transfused lymphocytes in an immunocompromised host, platelets given to newborns are CMV negative and irradiated. In centers in which single-donor platelets are available, units can be split, similar to packed RBCs, and transfused over

a period of 4 days to minimize exposure to multiple donors.

Platelet Refractory State

When a patient no longer achieves the expected rise in platelet count after a platelet transfusion, one must first assess whether the shortened platelet recovery and survival are due to immune or nonimmune mechanisms. Examples of nonimmune mechanisms are listed in Table 35-8; they are responsible for the majority of cases in which post-transfusion count increments are lower than expected. The most notable of these mechanisms includes splenomegaly, DIC, and fever.

Alloimmune Mechanisms

Alloimmunization is characterized by increasingly poor recovery and survival of platelets in a multiply transfused patient. The majority of alloantibodies react to determinants on HLA class I molecules, ABO blood group antigens, and platelet-specific antigens expressed primarily on membrane glycoproteins.[228] Although alloantibody does not not develop in every patient exposed to platelets, those who eventually become refractory present a very serious challenge to the skills of physicians and blood centers. Production of antiplatelet alloantibodies does not depend on the number of exposures or transfusions. However, there is an association with the underlying disease state. For example, only 30% to 60% of patients with leukemia become alloimmunized, in contrast to 80% to 90% of aplastic anemia patients.[29,230] This suggests that the aggressive chemotherapy used to eliminate the malignant cells also plays a role in prevention of alloimmunization. Thus, it would appear that the true rate of alloimmunization is further influenced by the individual's immune responsiveness and competence.

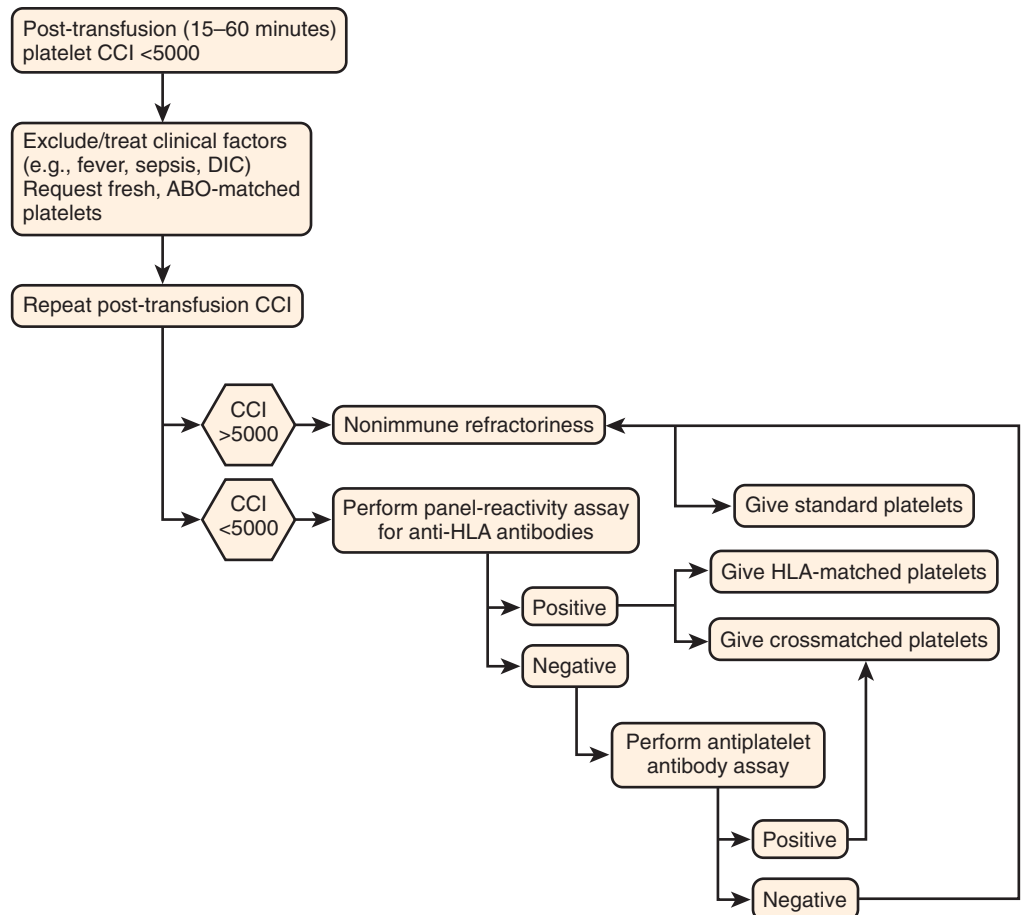
Unlike RBCs, it is not practical or efficient to crossmatch platelet donors and recipients in most blood centers or hospitals. The antigens known to elicit an immune response on platelets are allelic molecules. Such antigens include a variety of class I HLA alloantigens, platelet-specific alloepitopes such as PlA1, and blood group antigens. There is rarely any problem in providing ABO-compatible platelets in most blood centers. However, it is not reasonable to match all donors and recipients for HLA or platelet-specific alloantigens. As seen in Table 35-9, the platelet-specific alloepitopes are diallelic with a high frequency of expression of one allele in the general population. Therefore, the incidence of alloimmunization to platelet-specific antigens after a single transfusion may be a serious problem for only a very small percentage of the population, depending on which epitope is involved.[185,230] An algorithm for dealing with patients who appear to be refractory to platelet transfusions is presented in Figure 35-5. The role of


FIGURE 35-5. Algorithm for the management of patients refractory to platelet transfusion. CCI, corrected count increment; DIC, disseminated intravascular coagulation.

platelet-specific alloantibodies in NATP was discussed in the section on clinical indications for platelet transfusions.

The majority of alloantibodies that mediate rapid clearance of transfused platelets in a refractory patient bind to epitopes on class I HLA molecules. Platelets express the class I (HLA-A, -B, and -C) gene products,[231] but class II molecules (HLA-DR, -DP, -DQ) have been shown only on platelets in a high-turnover state, such as immune thrombocytopenic purpura, in which the majority of circulating platelets have just been released from the bone marrow.[232] As with other precursor cells, early megakaryoblasts express HLA-DR in normal individuals[233,234]; however, this antigen is not generally detectable on circulating platelets.

Initially, class I HLA alloantigens were defined serologically, that is, with plasma from patients or postpartum women with high-titer alloantibodies. Subsequently, molecular typing and monoclonal antibodies (MoAbs) helped clarify the number and types of epitopes associated with the HLA-A, HLA-B, and HLA-C loci. Interestingly, it is the serologic definitions that are important in platelet refractoriness. In categorizing the alloantigens serologically, it became clear that two categories of epitopes were expressed. The first group of alloantibodies recognizes private epitopes, or antigens that are uniquely associated with only one HLA gene product. The second category contains alloantibodies that recognize public epitopes, or those expressed on more than one class I HLA gene product. The broad reactivity associated with the platelet refractory state is most commonly caused by alloantibodies that recognize *public* epitopes shared by many HLA gene products.[235,236] By categorizing HLA-A and HLA-B loci according to these public epitopes or cross-reactive groups (CREGs), blood centers may be able to provide single-donor platelets based on reactivity to CREG subsets. Blood centers take advantage of this observation to provide "HLA-compatible" platelets (type B matches) when HLA-identical donors are limited in number.[237] Although the platelets may not be identical at the HLA-A or HLA-B loci, if the CREGs shared by a subset of class I allotypes can be avoided, non–HLA-identical product can still be used with adequate platelet recovery and survival. By using this system, blood centers can expand their pool of volunteers and provide single-donor platelets for multiply transfused patients; however, it remains difficult to provide fully HLA-matched platelets consistently. Consequently, the overall success rate for attaining suitable post-transfusion count increments with HLA-matched platelets is only about 50% in alloimmunized patients, even in major centers.[237]

Methods for Preventing Platelet Alloantibodies

When a physician can anticipate that an individual will be multiply transfused, every effort to prevent alloimmunization will ultimately result in better recovery and survival of later platelet transfusions and may delay the onset of platelet refractoriness. Three blood procedures have been introduced to reduce alloimmunization: (1) single-donor pheresis platelets, (2) leukocyte-poor platelets, and (3) ultraviolet (UV)-irradiated platelets. Although UV irradiation has been shown to be effective in preventing alloimmunization, it is no more effective than the use of leukocyte-reduced products and has not been introduced into widespread clinical practice.[238]

Supported by a huge network of community volunteers, many centers can provide single-donor platelets to patients who have not been previously transfused. As single-donor platelets became more readily available, prospective trials were initiated to assess relative rates of alloimmunization. These studies demonstrated that in patients receiving ABO-matched, single-donor platelets, lymphocytotoxic antibodies were less likely to develop than in individuals receiving pooled platelet concentrates.[239] This seems inherently obvious because the exposure rate to alloantigens with single-donor platelets would be roughly a sixth to an eighth that seen in patients receiving pooled platelet concentrates.[240] However, these studies were performed in patients with acute leukemia in Europe, where patients receive very few platelet transfusions in comparison to practice in the United States. Additionally, the rate of alloimmunization is relatively low in acute leukemia patients because of the immunosuppressive effect of their chemotherapy.[241,242] Probably for these reasons, similar results have not been demonstrated in the United States; nevertheless, the additional benefit of decreased exposure to blood-borne pathogens in single-donor units makes this a preferred product, particularly for younger patients.

Although platelets express class I gene products, it is the class II molecules expressed on contaminating leukocytes that are primarily responsible for the induction of alloantibodies.[243,244] With the use of washed platelets devoid of white cells, lymphocytotoxic antibodies failed to develop in multiply transfused animals.[245,246] These studies were eventually repeated in patients with the use of pooled random-donor platelets, with or without leukocyte depletion. At least 90% of the contaminating leukocytes had to be removed ($<10^6$ remaining), but there was a striking decrease in the rate of alloimmunization from 93% to 24%.[247-251] Prospective studies in humans suggest that the leukocyte threshold for alloimmunization is 5.0×10^6 cells or less per infusion. As outlined earlier, the Trial to Reduce Alloimmunization to Platelets (TRAP)[238] has conclusively demonstrated in a randomized, prospective study that the use of leukocyte-reduced products can effectively decrease but not eliminate the risk of alloimmunization. Most centers recommend leukoreduction in the blood center during collection,[252] which may also decrease the accumulation of cytokines produced by white cells during storage.[253,254]

PRINCIPLES OF HEMATOPOIETIC CELLULAR THERAPY

With advancement of molecular technology, better understanding of human immunology, and increased interest in regenerative medicine, the use of cellular therapy is no longer limited to HPC transplantation. Current applications have expanded to include the use of cells as adoptive immunotherapy and cancer vaccines. Future applications may also include the use of cells as drug delivery vehicles or as source of tissue engineering for regenerative medicine.[255] However, HPC transplantation is still the best-established type of hematopoietic-based cellular therapy. In this section, the sources, processing, and complications associated with hematopoietic cell–based therapy are reviewed.

Hematopoietic Cell Sources

Donors of therapeutic hematopoietic cells can be autologous or allogeneic. Autologous donors are usually patients who will be undergoing HPC transplantation. These donors have their own cells collected and cryopreserved, and their own cells are infused during transplantation. Because the donor and recipient are the same, complications from major histocompatibility complex (MHC) or human leukocyte antigens (HLA) disparities are negligible for autologous cell infusion. The MHC/HLA molecules are displayed on cell surfaces and are responsible for lymphocyte recognition and "antigen presentation." They control the immune responses through recognition of "self" and "nonself" and, consequently, serve as targets in transplantation. However, during allogeneic transplantation, the degree of HLA disparity is extremely important for donor selection because large numbers of lymphocytes are transfused. These donor lymphocytes can recognize the recipient's tissue as foreign or "nonself" and mediate GVHD. In humans, HLA molecules are located on chromosome 6. There are two classes of HLA antigens, class I and class II. The class I antigens HLA-A and HLA-B and the class II antigen HLA-DR are the three most important molecules contributing to GVHD. Given that each person has two alleles of chromosomes, a minimum

of six out of six HLA antigen matches are often required for transplantation. Donors of allogeneic HPCs are often siblings of the recipients and are referred to as related donors. For patients who do not have related donors, cells from HLA-matched unrelated donors are used frequently. These donors are obtained from international donor registries such as the National Marrow and Donor Program (NMDP), and the amount of time spent searching for appropriate and available donors can be unpredictable. Because only 50% to 60% of patients have an HLA-matched sibling or unrelated donor, not all patients who may benefit from an HPC transplant can proceed to transplantation. Timely search for an appropriate donor is essential for successful allogeneic HPC transplantation.[256] A prolonged donor search period can lead to death, increased risk, or ineligibility of patients. The incidence of GVHD is also significantly increased when HPC transplantation is performed with unrelated donors.[257,258]

Bone marrow, cytokine-stimulated peripheral blood, and umbilical cord blood (UCB) are the sources of HPCs for transplantations. Unstimulated peripheral blood cells are either used in an unmanipulated state or can be further processed to be used as adoptive immunotherapy. Characteristic differences between various HPC sources will be discussed individually in detail.

HPC transplants can be performed with unmanipulated bone marrow, peripheral blood, or UCB. Depending on the source of cellular products used, they can be contaminated with different degrees of RBCs and leukocytes. When compared with peripheral blood–derived HPCs, bone marrow products have higher RBC contamination and lower T-cell and CD34+ HPC content. The original HPC transplants were performed with bone marrow. In recent years, investigators have routinely use mobilized peripheral blood for transplantation[259-261] because of a higher CD34+ HPC content and faster post-transplant hematopoietic recovery (Table 35-10).

Mobilized peripheral blood collected by leukapheresis has become the most commonly used HPC component for both autologous and allogeneic HPC transplantation because of the ease of collection and ample number of CD34+ stem cells.[262] In the autologous setting, the benefits of peripheral blood over bone marrow

TABLE 35-10	Differences in Transplanted Cell Dose and Hematopoietic Recovery between Cell Sources			
Hematopoietic Stem Cell Source	**TOTAL CELL DOSE TRANSPLANTED**		**DAYS TO HEMATOPOIETIC RECOVERY**

From Dana-Farber Cancer Institute adult hematopoietic stem cell data, 2005.

have been well documented[263] and include more rapid engraftment, decreased need for transfusions, decreased incidence of infection and antibiotic use, and shorter hospital stay. To mobilize stem cells into the peripheral blood, patients are treated with cytokines such as granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF), in many cases after receiving chemotherapy, and the cells are collected in the outpatient setting. After chemotherapy, patients undergo leukapheresis when their cell counts recover from the nadir. Circulating peripheral blood CD34$^+$ cell levels may be used to predict yield.[264,265] If cytokines are used in patients without previous chemotherapy, collection is begun on a predetermined day during the course of administration. In approximately 10% of autologous donors, peripheral blood stem cell cannot be mobilized successfully. Risk factors for poor mobilization include patients' disease status, nonconducive marrow environment secondary to a history of heavy chemotherapy, and radiation therapy.[266-269] In these patients the risks for delayed engraftment is higher, and they are often deferred from autologous HPC transplantation.

If peripheral blood collections are used for allogeneic transplantation, collection is begun on the fourth or fifth day of G-CSF administration. As in the autologous setting, engraftment may be more rapid with allogeneic peripheral blood than with bone marrow. However, peripheral blood components typically contain at least 1 log more T cells than bone marrow components do, thus potentially increasing the risk for GVHD. Nonetheless, the incidence of acute GVHD has not been found to be significantly elevated.[270] This may be due in part to effects of the G-CSF used for mobilization on the T cells. However, reports have suggested that chronic GVHD may be more frequent in recipients of peripheral blood components.[271]

The biology of CD34$^+$ stem cell mobilization is now better understood. The bone marrow environment heavily regulates the movement of these CD34$^+$ HPCs. Cytokines such as G-CSF stimulate the generation of granulocytes in both bone marrow and peripheral blood.[272,273] These granulocytes release serum proteases such as cathepsin G and neutrophil elastase. Studies have reported that accumulation of these serum proteases coincides with increased inhibition of adhesion molecule interaction between the very late antigen 4 (VLA-4) on the CD34$^+$ HPCs and the vascular cell adhesion molecule 1 (VCAM-1) on the surface of bone marrow stromal cells.[274] This adhesion molecule disruption allows the CD34$^+$ HPCs to float free within the bone marrow environment, and their movement can then be influenced by chemokines. Interestingly, proteolysis of the chemokine receptor CXCR4 on the CD34$^+$ cell surface and the chemokine stromal cell–derived factor 1 (SDF-1), also known as CXCL12, was also observed to coincide with accumulation of serum proteases during G-CSF treatment and chemotherapy such as cyclophosphamide

in human bone marrow.[275] With decreased chemotaxis signals within the marrow, the free-floating CD34$^+$ HPCs can traffic toward the peripheral blood compartment.[276] With G-CSF and chemotherapy mobilization, peripheral blood circulating CD34$^+$ HPCs can be increased to approximately 10- to 100-fold.

Many centers are also evaluating the use of UCB as a source of allogeneic HPCs. The use of UCB as an alternate source of allogeneic HPCs was first reported by Gluckman and co-authors in 1989.[277] Since that time, hundreds of UCB transplants have been performed in North America and Europe.[278] Because of the success of UCB transplantation in both related and unrelated donor settings, many cord blood banks (CBBs) have been established worldwide. UCB is collected from the umbilical cord or placental veins (or both) after delivery of the infant and is therefore a readily available component. Parents/mothers have the option of banking the cells for their own use in a private CBB or donate to a public CBB. If the UCB samples are donated to public CBBs, these cells will undergo stringent quality control evaluation and only qualified products will be processed and cryopreserved for use. The UCB products stored in public CBBs will be available for public use when requested and prescribed by appropriate transplantation physicians. As UCB transplantation becomes more widely accepted, the number of CBBs and the size of the inventory within the CBBs have been increasing.[279] There are at least 15 public CBBs in the United States. UBC transplantation offers many advantages, and various reports have suggested that UCB is less immunogenic and transplants may be performed across HLA barriers with less GVHD than would be anticipated if a bone marrow donor with the same HLA type were used.[280] The low dose of UCB may contribute to the decreased incidence of GVHD. Therefore, UCB transplantation is an attractive alternative for patients requiring allogeneic transplantation who do not have an HLA-matched donor. From a donor's point of view, when compared with mobilized peripheral blood stem cells and bone marrow, collection of UCB after birth carries no risk for the donor. The collected UCB is HLA-typed, tested for infectious agents, and banked for use; it is therefore available immediately on request and can be shipped to any transplant center in the world. Despite the ease of availability and safety of the donation procedure, UCB transplants have their limitations. Studies continue to show that an appropriate stem cell infusion dose is essential for speedy hematopoietic cell engraftment and successful transplantation.[280-283] The limited cell dose in the UCB products poses problems, especially for large adult recipients. In the case of disease progression or relapse, it is also impossible to go back to the original UCB donor for lymphocyte or additional stem cell collections. Research working on expansion of cord blood stem cells is ongoing.[284,285] Most recently, the successful use of double UCB transplantation in adult patients may overcome the dosing limitation issues.[286]

Infusion-Related Toxicities

Infusion of HSC products can be associated with either immediate reactions or long-term side effects. The immediate infusion toxicities are similar to blood transfusion reactions and include febrile reactions from the infusion of a large number of leukocytes and related cytokines, allergic reactions secondary to plasma protein content, and occasional hemolytic reactions as a result of donor-recipient erythrocyte ABO incompatibility. To reduce the occurrence of febrile and allergic reactions, patients are always premedicated with antipyretic medication and antihistamines before HSC infusion. Special manipulation to reduce the erythrocyte contents can be performed to prevent hemolytic reactions. The type of manipulations used to reduce the erythrocyte content is described in detail later. For HSC products or lymphocytes that are cryopreserved in dimethyl sulfoxide (DMSO) for storage in liquid nitrogen, infusion of thawed products can lead to frequent DMSO-related toxicities. In the Dana-Farber Cancer Institute, DMSO-related toxicity is a frequently described reaction related to HSC infusion. Common symptoms attributed to DMSO include nausea, vomiting, flushing, and headaches. Anaphylactoid symptoms caused by the release of histamine are also common. Embolic events associated with the infusion of bone marrow and apheresed HSC products have been reported. Most of the cases described involved infusion of products with particulate matter secondary to cell clumps or bone débridement in recipients with congenital cardiac septal defects.[287,288]

GVHD is the most common long-term toxicity associated with allogeneic HSC transplantation. Approximately 30% to 70% of patients undergoing allogeneic HSC transplantation can anticipate experiencing GVHD.[289] GVHD is mediated primarily through donor graft lymphocytes (T-cell population). Graft lymphocytes target tissues with alloantigens and cause alloimmune reactions in recipient organs.[290,291] Severe GVHD is observed when donors are not fully identical with the recipient at MHC antigens (HLA-A, -B, -DR). However, most allogeneic HSC transplantations are conducted with donors and recipients who are identical at MHC antigens. In these recipients, minor histocompatibility antigens (mHAs) are thought to be the primary targets of donor alloimmunity.[292-294] Studies have shown that mHAs can be expressed on hematopoietic tumor cells. When donor T cells target leukemia mHAs, alloimmunity results in a graft-versus-leukemia effect and can contribute to eradication of leukemia cells.[295,296] The use of donor lymphocytes as adoptive immunotherapy for patients with relapse of chronic myelogenic leukemia has shown to be successful in a population of patients with cytogenetic relapse after allogeneic HSC transplantation.[297-299] Conversely, depletion of T-cell content in the graft has been shown to reduce the incidence of GVHD, but at the expense of losing the graft-versus-leukemia effect.[291]

Component Assessment

For customized cell therapy such as HSC transplantation, each product is donor-patient specific. The quality of the product can vary for different donors and even changes daily for a product that came from the same donor. As mentioned earlier, the content of the product can lead to various types of infusion reactions, immunologic effects, and time to hematopoietic cell engraftment. Most importantly, like any blood product, infusion of products with microbial or viral contamination can lead to transmission of infectious diseases.

Achieving rapid hematopoietic cell engraftment is essential for successful HSC transplantation. Insufficient infusion of HSCs is linked to prolonged hematopoietic cell recovery. Patients who experienced delayed hematopoietic engraftment will require long-term blood component support and are more likely to contract severe bacterial, fungal, and other opportunistic infectious diseases because of prolonged neutropenia and lack of proper immune function. Functional assays such as granulocyte-macrophage colony-forming unit (CFU-GM), granulocyte-erythrocyte-macrophage-megakaryocyte colony-forming unit (CFU-GEMM), and long-term culture–initiating cell (LTC-IC) content have been described as measures of HSC quality and content. The results of these assays correlate well with post-transplantation hematopoietic recovery. However, these culture-based assays have a long turnaround time and are unable to rapidly quantify the number of stem cells. Enumeration of CD34$^+$ cells via flow cytometry analysis is now commonly performed as a measure of HSC content because of its fast turnaround time and proven correlation with clinical engraftment data. As with other assays, CD34$^+$ cell enumeration methods vary between centers, thus making characterization of an HSC component adequate to achieve hematologic engraftment difficult.[300,301] Standardized protocols for CD34$^+$ cell enumeration have been proposed in an attempt to limit variability and permit comparison of the HSC content of components collected and infused at different centers.[302] Methodologies to determine absolute cell concentrations instead of percentages may further improve the accuracy of the CD34$^+$ cell enumeration procedure.[303] Analysis of graft T-cell content by flow cytometry in HSC or donor lymphocyte products is now also used to correlate with GVHD outcome.

In addition to quantifying HPC content, components must be tested for contaminants. Contamination rate increases with component manipulation, such as ex vivo cell isolation or depletion and long-term cell culture, and may be associated with adverse clinical sequelae. This emphasizes the need to include bacterial cultures as a component of quality control of hematopoietic cell collection, processing, cryopreservation, thawing, and reinfusion procedures.[304]

Finally, critical evaluation of the donor of the product is also an essential quality assessment of the product. All

allogeneic and autologous donors should be tested for infectious disease markers just like routine blood donors. Donor who are positive for certain viral markers can still donate their cells for transplantation if the transplantation was deemed to be the only lifesaving procedure and the patient was informed of the risk by the transplant physicians. However, the practice of using high-risk allogeneic donors for transplantation should be discouraged.

Processing and Storage of Hematopoietic Progenitor Cell Components

Autologous and, occasionally, allogeneic HPC components are collected before the patient receives myeloablative therapy and are cryopreserved. Cells are suspended in a mixture of an electrolyte solution, a protein source, and a cryoprotectant such as DMSO or hydroxyethyl starch.[305] Cryopreserved cells are infused rapidly when thawed, with the freezing solution being infused along with the cells. Premedication is required to minimize toxicity.[306-308]

In the allogeneic setting, processing may be performed to avoid acute hemolysis associated with the infusion of an ABO-incompatible component.[309] If there is a major ABO incompatibility, defined as the recipient's plasma containing antibodies against donor red cells, many centers will deplete the donor component of RBCs. If there is a minor ABO incompatibility in which the donor plasma contains antibodies against recipient red cells, the component will be washed or volume-reduced to remove plasma. Alternatives to these procedures include plasma or red cell exchange in the recipient, as well as the infusion of sources of donor blood group antigens to absorb recipient antibodies.[310,311]

Laboratories are increasingly performing more extensive procedures in an attempt to deplete unwanted cell populations from the HSC component. Tumor cells are removed from autologous components in an effort to decrease the risk of relapse, whereas T lymphocytes are removed from allogeneic components to abrogate acute GVHD. The majority of these procedures are performed with either negative or positive selection methods.

Negative selection targets the cells to be removed from the component while preserving other cell populations.[312] Methods for negative selection that have been used include attempts to separate cells based on physical characteristics, in vitro sensitivity to chemotherapeutic agents, and MoAb-mediated separation or damage. Density gradient centrifugation and centrifugal elutriation have been used to separate cells based on size. Trials have used 4-hydroxycyclophosphamide or mafosfamide to kill tumor cells. Cells can bind to MoAbs conjugated to magnetic beads, dense particles, or surfaces and be physically separated from the other cell populations within a component. In addition, MoAbs may be used to destroy tumor cells or T cells by conjugation with toxins or complement-mediated lysis.[313]

In contrast, positive selection enriches the cell population to be retained while nonspecifically depleting all other cell populations. The systems currently available for positive selection use MoAbs directed against various hematopoietic cell surface antigens. Cells are incubated with the MoAbs, and separation is achieved by biotin-avidin, magnetic bead, or high-speed cell sorting methods.[314-317] Most of these cell manipulation techniques were initially designed to reduce the incidence of GVHD or disease relapse associated with HSC transplantation. Recently, some of these techniques have also been applied to the development of cell-based immunotherapy. For example, monocytes or CD34$^+$ cells from peripheral blood can be isolated by selection techniques and educated ex vivo into potent antigen-presenting cells called dendritic cells. Animal models have shown that dendritic cells can act as tumor vaccines to stimulate and enhance cell-mediated immunity in patients who may have defective tumor immunity.[318-320] Specialized lymphocytes can also be isolated and expanded with appropriate growth factors and antigen stimulation to target specific tumor cells or infectious agents. Most of the cell-based immunotherapies are still under investigation and considered experimental. Encouragingly, early clinical data on dendritic cell therapy in melanoma, prostate cancer, and EBV-specific T cells targeting post-transplant lymphoproliferative diseases have shown immunologic responses with potential clinical effects.[321-324]

Standards and Regulations

The use of various types of cellular therapy has increased over the last few decades as a result of abundant research findings, the development of novel technologies, and interest in innovative therapeutic modalities. Consequently, the regulations associated with processing and administration of cell-based therapy are in evolution. Principles of current good manufacturing practice (cGMP) and total quality management should be applied to the production of therapeutic cellular products. In 1991, the 14th edition of *Standards for Blood Banks and Transfusion Services* by the American Association of Blood Banks (AABB) was extended to include HPCs. In 1996, the AABB published a separate *Standards for Hematopoietic Progenitor Cells*.[325,326] These standards include sections concerning donor selection, component collection, processing, testing, labeling, storage, transportation, issue, infusion, and record keeping for HPCs, including autologous as well as allogeneic bone marrow, peripheral blood progenitor cells, and cord blood. Furthermore, the Foundation for the Accreditation of Cell Therapy (FACT) was formed in 1993 and created programs for inspection and accreditation of HSC collection and processing facilities, as well as transplantation programs. The FACT standards represent a consensus document of several organi-

zations working together in the field of clinical conduct of HPC transplantation, including the International Society for Hematotherapy and Graft Engineering (ISHAGE), the American Society for Blood and Marrow Transplantation (ASBMT), and nine others.[327] The U.S. FDA has been recognizing the need for regulatory oversight of these products and finally published, in the *Federal Register* on November 24, 2004, a document that represents a comprehensive system for regulating human cells and cellular and tissue-based products referred to as the Current Good Tissue Practice for Human Cell, Tissue and Cellular and Tissue-based Product Establishments; Inspection and Enforcement; Final Rule (cGTP rule). The purpose of the cGTP rule is to prevent documented evidence of transmission of communicable disease to recipients of infected donor tissue through tissue and organ transplantation, as well as bacterial and fungal infections. Second, this regulation will provide more oversight for a therapeutic cell-based industry with its increased demand for international commerce and increased risk of intercontinental transmission of disease. Finally, the cGTP rule will legally enforce the voluntary standards established by cell therapy organizations not uniformly followed by all cell-processing facilities.[327-329]

Future Directions

Several areas regarding the use of hematopoietic stem cells are actively being investigated. First, definitive trials are necessary to clarify whether there is any clinical benefit associated with CD34+ cell selection or tumor cell or T-cell depletion. Second, by building on platforms in which cells have been expanded but differentiated,[330] it may be possible to expand primitive hematopoietic stem cells as new cytokines are identified and new systems are developed. Expanded populations of primitive cells would be useful for infusion in patients whose autologous graft contains insufficient numbers for transplantation. In addition, the ability to expand HSCs could make UCB components available to larger recipients with less perceived risk. Furthermore, expanded cells may be useful for gene therapy approaches.

Much effort has taken place in recent years to use HPCs as a strategy for clinical gene therapy or to use other cells therapeutically. Stable expression of a transgene in a primitive HPC would, in theory, be an ideal method to replace missing gene products in a patient. However, despite numerous attempts, until very recently there were no durable results. Consequently, when Cavazzana-Calvo and co-workers reported successful treatment of severe combined immune deficiency (SCID) with gene therapy,[331] interest was renewed. Unfortunately, some SCID patients who received genetically engineered autologous HPCs later suffered leukemia because of insertional mutagenesis of CD34+ cells. The occurrence of these adverse events raises the safety concern of gene therapy.[332]

APHERESIS

Apheresis (from the Greek *aphairesis*, meaning "removal") refers to a technique of drawing peripheral blood, separating it, and selectively removing one or more of the components while returning the remainder. Apheresis techniques may be manual or automated, and the phases of drawing, separating, removing, and returning blood and components may be continuous or discontinuous. The technique of apheresis may be used for collecting transfusable blood components from donors, and it may be used to treat patients with conditions for which removal or replacement of a portion of the blood may be therapeutic. The terms cytapheresis, erythrocytapheresis, leukapheresis, plateletpheresis, and plasmapheresis refer to the use of apheresis to remove, respectively, cells, RBCs, white cells, platelets, and plasma. The terms plasma exchange and RBC exchange imply that the component removed is replaced in like amount with normal plasma or RBCs. In practice, nearly all donor and therapeutic apheresis is performed via automated techniques with specialized programmable separation devices designed for this purpose.

The principle by which most apheresis instruments fractionate the components of whole blood is simple density centrifugation. The instrument contains a sterile, closed, and disposable centrifugation chamber in which whole blood is separated into RBC, plasma, and buffy coat layers. The densest component (RBCs) is segregated to the bottom of the centrifugal field, the least dense component (plasma) is pushed to the top, and the other layer of cellular components remains in between, as shown in Figure 35-6. The efficiency of separation depends not only on the density of the components but also on the geometry and rotational speed of the centrifugal chamber, as well as the specific technique for isolating the separated layers. Pure separation of plasma from RBCs and concentrated suspensions of platelets nearly devoid of RBCs can be achieved reliably. Because the
FIGURE 35-6. A, Separation of anticoagulated whole blood. **B**, Specific gravity of blood components. PBPC, peripheral blood progenitor cells; Polys, polymorphonuclear leukocytes; RBCs, red blood cells.

white cell layer is much smaller than either the RBC or plasma layer and close in density to the RBC layer, both the RBC and the platelet components will contain leukocytes. For the same reason, although it is possible to use apheresis to isolate leukocyte fractions that are enriched in granulocytes or mononuclear cells, these fractions will also contain other types of white cells, as well as RBCs and platelets.

Apheresis instruments also exist that separate blood by filtration rather than centrifugation. Because this technique cannot separate cellular elements, it is used primarily in donor applications for collection of plasma.

Donor Apheresis

Overall, the most common medical use of automated apheresis technology is for donor procedures, that is, collection of platelet concentrates or plasma from individual volunteer donors. The principal reason to use apheresis techniques to collect these products, rather than deriving them from whole blood donations, is that the yield per donation is much higher. Six to eight times the number of platelets can be harvested in one apheresis donation than can be isolated from 1 unit of whole blood. Automated systems can be programmed to collect two or even three separate blood components (i.e., units of packed cells, plasma, or single-donor platelets) from one donor during a single apheresis procedure. The same advantage applies to these apheresis collection techniques—a much larger yield is obtained per donation, with little or no compromise in donor safety. The blood products derived from these donor procedures have slightly different quality control characteristics from whole blood–derived components, but in clinical use they are as efficacious as those derived from whole blood donations.

Granulocyte concentrates drawn by apheresis technology to treat refractory fungal or bacterial infections in patients with profound neutropenia are once again being evaluated.[333] Studies in the 1970s showed that granulocyte transfusions had limited efficacy and considerable toxicity. However, the advent of a granulocyte-specific hematopoietic cytokine (G-CSF) in concert with apheresis technology has made it possible to collect up to 10-fold more granulocytes for transfusion than were available for the older studies.[334] Unlike products from unstimulated donors, granulocyte concentrates collected with cytokine stimulation of the donor can yield substantial increments in peripheral granulocyte counts in the recipient.[335,336] Whether these greater increments correspond to greater efficacy has yet to be proved.[337-340]

Apheresis technology can also facilitate obtaining multiple units of plasma from the same donor to provide single-donor plasma support to a recipient with a congenital coagulation factor deficiency treatable with plasma, such as factor X or XIII deficiency.

Although adult donor apheresis, especially for platelet collection, has a large impact on the blood banks that supply blood products for pediatric patients, child donor apheresis is rarely used. The one exception is donor apheresis collections of peripheral blood progenitor cells, described later.

Therapeutic Apheresis

A broad spectrum of indications exist for automated apheresis used for therapeutic effect in children. For some indications, the mechanism of the therapeutic benefit is readily apparent and the efficacy of the treatment well substantiated. For many other indications, the rationale for the use of apheresis to treat a disease condition is less clear and based on extrapolation from studies in adults or on anecdotal evidence. It is important to remember that the therapeutic value may be derived from removal of a portion of the patient's blood, from administration of a fluid to replace what was removed, or from both. In some cases, the therapeutic value of an apheresis procedure is derived from the ability to control the patient's blood volume independent of the rate and total volume of blood product administered, as with complete exchange of the RBC mass or plasma volume.

Manual Apheresis

Although it is theoretically possible to carry out most apheresis procedures by entirely manual techniques, with steps analogous to those used to derive blood components from donated whole blood, in practice, manual methods are usually reserved for situations in which the automatic equipment is not available or the volume of blood to be processed is too small to warrant use of the automated cell separator. For example, for a newborn with isoimmune thrombocytopenia, it might be possible to obtain an adequate dose of platelets by drawing 1 unit of whole blood from the mother, isolating the platelets manually, and transfusing the residual RBCs and plasma back into the mother rather than subjecting the mother to an automated plateletpheresis procedure. Another manual apheresis procedure is whole blood exchange for neonatal hyperbilirubinemia, typically performed in a discontinuous fashion with reconstituted whole blood, an empty blood collection bag, a three-way stopcock, and a syringe to remove and replace blood in 10-mL cycles. Occasionally, manual exchange of red cells or plasma may be the only alternative in a patient whose venous access is inadequate for automated exchange and for whom a simple transfusion is not an alternative.

Automated Apheresis

The development of mechanical devices to perform selective collections and blood component exchanges was truly an individual inspiration. The son of IBM engineer George Jackson contracted leukemia and was treated at the National Cancer Institute. Recognizing the need for a better way to produce the large number of platelet concentrates required by oncology patients, Jackson

developed the first mechanical blood cell separator. Over the subsequent 3 decades, numerous improvements have led to the automated units found in every blood center today.[341] Modern blood separators offer the advantages of a sterile, closed, single-use system, automated control of volume balance, traps to prevent air embolism, and other safety features. Each machine can perform several types of apheresis procedures, with highly automatic modes as well as the capacity to modify procedure parameters for individual patient needs. By comparison, manual exchanges are more awkward to perform, generally use open systems, involve manual tracking of intake and output, and are therefore potentially less safe.

Apheresis devices may be either continuous or discontinuous. A discontinuous device withdraws a volume of blood, separates it, removes the selected component, and returns the remainder, all in serial steps. The sole advantage of a discontinuous device is that it requires only a single site of vascular access. In the donor setting, this is often reason enough to use a discontinuous device. However, when compared with a continuous device, the discontinuous apheresis technique requires longer processing time and involves larger volume shifts in the donor or patient. The latter consideration may be critically important in pediatric patients and imposes a practical limitation on the use of these devices in children. In contrast, continuous devices withdraw, separate, and return blood simultaneously, thus permitting apheresis procedures that affect the patient's intravascular volume only minimally. Separators that operate in a continuous mode include the COBE Spectra, the Baxter-Fenwal CS 3000, the Fresenius AS104, and the Amicus. The COBE Spectra and the Amicus can be operated in either continuous or discontinuous mode.

For any apheresis procedure, there is a fixed extracorporeal blood volume and extracorporeal RBC mass that must be taken into account in planning the procedure. The extracorporeal blood volume depends on the specific make and model, as well as the type of procedure planned, but all devices fall into a range of 200 to 400 mL. A detailed comparison of the features of each automated cell separator is beyond the scope of this chapter.

Unique Aspects of Apheresis in Pediatrics

Performing apheresis procedures in pediatric patients is often more challenging than performing analogous procedures in adults. Specific challenges include vascular access, anticoagulation, volume shifts, hypothermia, and patient cooperation.

Vascular Access

The vessel used for the apheresis draw line, through which whole blood is drawn into the extracorporeal system, must be large and resilient enough to accommodate a large catheter and sustain the required flow rate without collapsing. When peripheral veins are used, a rigid needle, 18 gauge or larger, is used for drawing the blood. In adults and older children, it is usually possible to find veins in the antecubital fossae large enough to accommodate this needle, but children younger than 7 years often do not have adequate access. Because access requirements for returning blood are less demanding, a smaller-gauge (20- to 22-gauge) flexible catheter may be used. Although every child undergoing apheresis should be evaluated first for peripheral access, it is often necessary to obtain access to a larger central vessel. Such access may be accomplished in several ways: a single-lumen central venous catheter or an arterial line to draw the blood and a peripheral vein to return it, or a double-lumen venous catheter. The catheters, often referred to as "dialysis catheters" because the same access issues apply in hemodialysis, may be designed either for temporary placement (usually stiff, straight catheters intended for bedside percutaneous placement) or for permanent placement (softer, tunneled catheters with cuffs that require placement in the operating room).[342] Temporary polyurethane catheters as small as 7 French are available for patients as small as 5 to 10 kg. Permanent catheters designed for apheresis are available in sizes as small as 8 French for children as small as 10 to 12 kg.[343] It is important to realize that most of the double- and triple-lumen catheters available for general purpose central access in children may fail under the draw pressure of an apheresis procedure because the lumen is too small or the catheter wall too soft. Some multiple-lumen catheters also have inadequate separation of the openings of the lumens, thereby permitting recirculation and decreasing the efficiency of apheresis.[343] Hence, it is imperative to consider the possibility that apheresis will be required before placement of a central catheter. Finally, there is growing experience with successful use of implanted access devices (ports) to support chronic apheresis therapy in children.[344,345]

Anticoagulation

Because the blood is exposed to artificial surfaces, apheresis procedures usually require an anticoagulant to prevent activation of platelets, initiation of the coagulation cascade, and the formation of clots within the extracorporeal circuit. The standard anticoagulants used in apheresis are sodium citrate, heparin, or combinations of these two. The anticoagulant is added to the circuit at a controlled rate just at the point where the blood is drawn, and a portion of the anticoagulant is eventually returned to the patient. The amount of anticoagulant that the patient receives depends on the type of procedure, the replacement fluid, and the rates of blood drawing and replacement.

Citrate chelates the available calcium, a necessary cofactor for the clotting cascade, and also prevents platelet aggregation. The infusion of citrated plasma or blood does not cause systemic anticoagulation in the donor or patient, but it may reduce the ionized calcium level in plasma. Pediatric patients are particularly subject to citrate toxicity, in part because the flow rates used during

apheresis procedures—and therefore the citrate doses—are often higher on a per-kilogram basis than for adults. Citrate toxicity is first manifested as tingling around the mouth and fingers and sometimes nausea and abdominal discomfort. More serious citrate toxicity includes hypotension and cardiac rhythm disturbances.[346] Because a young or critically ill child may be unable to inform the operator about the earlier warning signs of citrate toxicity, the use of citrate as an anticoagulant requires careful attention to ionized calcium levels, calcium replacement by mouth or intravenous infusion,[95] and cardiac monitoring.

Alternatively, citrate may be either replaced or supplemented with heparin anticoagulation, which may be monitored by the activated clotting time, a crude measure of whole blood clotting time.[347,348] Heparin anticoagulation may be achieved with a bolus, with or without subsequent continuous infusion. The dose of heparin used for an apheresis procedure is similar to those used for therapeutic anticoagulation, and the patient may be expected to have a systemic anticoagulation effect lasting 4 to 6 hours after the end of the procedure, a side effect that may be significant in a patient who has recently undergone surgery or is otherwise at risk for bleeding.

Volume Considerations

The extracorporeal volume for an apheresis procedure, including the centrifugation chamber, tubing, filters, air traps, and possibly a blood warmer, may exceed 400 mL, depending on the machine and tubing configuration. Because the majority of this extracorporeal volume will consist of whole blood or packed cells within the centrifugation chamber, there is also an obligate extracorporeal RBC mass. Discontinuous machines carry out stepwise cycles of removal and return of extracorporeal volume. In a continuous apheresis machine, extracorporeal volume is filled at the start by drawing blood from the patient and remains fixed through the duration of the procedure. An older child or an adult with a blood volume of around 5000 mL can generally tolerate the temporary loss of 300 to 400 mL of blood in either a discontinuous or a continuous technique. At the other extreme, for a child of 12 kg with a blood volume of about 800 mL, the extracorporeal volume represents roughly half the patient's blood. Thus, for younger children, the discontinuous apheresis technique is not feasible, and continuous apheresis procedures may require priming with exogenous RBCs to compensate for the extracorporeal volume and RBC mass.

Many apheresis devices have automated modes that at completion of the procedure return the RBCs in the circuit to the patient by flushing with saline. This return cycle results in the rapid reinfusion of up to 450 mL over a period of several minutes. An older child or adult who was able to tolerate the temporary loss of volume and RBC mass incurred during a discontinuous or unprimed continuous apheresis procedure will usually tolerate rapid return of the volume. However, a younger patient may not tolerate the return cycle, so some or all of the obligate extracorporeal RBC mass must be left in the machine. This loss of RBC mass must be compensated for by using packed RBCs as the priming fluid at the start of the procedure.

Beyond the principles that have been described here, there are also strategies to avoid fluid overload without the use of RBC priming, to administer or remove intravascular fluid, and to administer blood products during the course of an apheresis procedure. The apheresis physician must take into consideration the patient's size, the extracorporeal volume of the apparatus in use, the patient's RBC mass and volume status, and disease factors that may affect the patient's ability to tolerate rapid changes in blood volume and RBC mass. Management of volume and RBC balance during apheresis procedures in children requires careful, individualized planning and thorough understanding of the operation and programming of the automated cell separator.

Hypothermia

Because a portion of the patient's blood volume circulates outside the body during apheresis, considerable heat loss to the environment can occur. Adult platelet donors may lose enough heat to require blankets by the end of a 90-minute collection. For children undergoing apheresis, the physiologic impact of this heat loss is much greater, and the use of a blood warmer may be required to prevent life-threatening hypothermia. The amount of heat loss is a function of (1) the ratio of extracorporeal volume to the patient's blood volume, (2) the rate of blood removal or replacement, and (3) the thermal properties of the system. A blood warmer reduces this heat loss at the expense of increasing the extracorporeal volume, albeit modestly. Only approved devices should be used to warm the blood.

Other hazards of therapeutic apheresis are rare. Some severe complications can occur, but they appear to be largely related to the underlying disorder as opposed to the apheresis itself.[348,349] This is consistent with the rarity of serious complications in apheresis platelet donors. Pediatric series have also reported complications. However, more were related to the need for vascular access than the procedure itself.[347,350]

Cooperation

The staff of a pediatric apheresis unit must be facile with age-appropriate communication and psychosocial support. The aspects of the apheresis procedure that are most upsetting to children are needle sticks, the need to remain seated, immobilization of one or both arms, frequent squeezing of the blood pressure cuff, and boredom with a prolonged procedure. Expertise in phlebotomy and intravenous line placement is a basic requirement for the staff. The other issues can usually be managed with age-appropriate explanations, parental involvement, and distracting entertainment. Sedation is almost never necessary, except for extremely uncooperative patients, such

as those with a significant psychiatric diagnosis or movement disorder.

Indications

Every 7 years a consensus committee of the American Society for Apheresis has reviewed the apheresis literature supporting and refuting the use of apheresis-based therapies in a variety of disorders in which it has been tried (Table 35-11).[351-353] For each disorder, the strength of the evidence supporting the efficacy of apheresis was evaluated and the indication placed into one of five categories. Category I means that efficacy is well documented and the use of therapeutic apheresis is "standard and acceptable"; in category II, apheresis is probably efficacious and its use is "generally accepted," but as an adjunct to primary therapy; in category III, efficacy is debatable, and the evidence is mostly anecdotal or conflicting; in category IV, apheresis has been shown to be ineffective and use of apheresis should be "discouraged"; and in category P (for pending), an apheresis device is not approved for use in the United States, although trials may be under way. Table 35-11 is excerpted from the consensus review, with only diagnoses listed that are usually encountered in the practice of pediatric apheresis.[354]

Erythrocytapheresis: Red Cell Exchange

Sickle Cell Disease

In sickle cell disease, small vessels become occluded when RBCs deformed (sickled) by polymerized hemoglobin S obstruct blood flow in capillaries. If the percentage of cells that can be deformed in this way is reduced below 30% to 50% by transfusion with normal RBCs, there is usually a substantial decrease in many of the clinical manifestations of sickling. Such reduction can be accomplished either by serial simple transfusion or by erythrocytapheresis. When rapid reduction in the percentage of hemoglobin S–containing cells is desirable, such as in the acute management of stroke or chest syndrome or in preparation for emergency surgery, erythrocytapheresis is the method of choice. A series of two to four simple transfusions given over a period of 2 to 3 weeks can also reduce the percentage of hemoglobin S–containing cells to less than 30%, an approach suitable for preparation for elective surgery.

Acute Chest Syndrome

Acute chest syndrome is a leading cause of premature death in patients with sickle cell disease. Transfusion with

*I: Therapeutic apheresis is standard and acceptable, either as primary therapy or as a valuable first-line adjunct to other initial therapies. Efficacy is documented by controlled clinical trials and published experience.

II: Therapeutic apheresis is generally accepted as supportive to other more definitive treatments; there is some literature support of its efficacy.

III: Anecdotal reports may suggest the use of therapeutic apheresis; however, no controlled trials have documented its efficacy. No consensus can be reached regarding its risk-benefit ratio.

IV: Controlled trials show lack of efficacy of therapeutic apheresis. Anecdotal studies suggesting efficacy have not been reproduced.

P: Pending.

ANCA, antineutrophil cytoplasmic antibody; GBM, glomerular basement membrane; NS, not specified; PANDAS, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections; RPGN, rapidly progressive glomerulonephritis.

RBCs is commonly used to treat acute chest syndrome both to increase the oxygen-carrying capacity of the blood and to reduce the percentage of hemoglobin S. Although controversy exists about the advantages of exchange transfusion over simple transfusion (see Chapter 19), their efficacy in acute chest syndrome is probably similar.[355] In practice, exchange transfusion by automated apheresis is often performed in patients with severe acute chest syndrome to reduce the hemoglobin S percentage in a shorter time than possible with simple transfusion or manual exchange and without the accompanying fluid loading.[135]

Stroke

The observed incidence of stroke in sickle cell patients varies from 6% to 34%. Although transfusion therapy is not thought to affect the neurologic outcome of completed strokes, it remains the mainstay of acute management as a measure to halt progression of cerebral vasculopathy. Considerable evidence exists that long-term transfusion after a central nervous system event is effective prophylaxis against progression of central nervous system disease and against recurrence of clinical stroke (secondary stroke prevention).[356] Transfusion has also been shown to be effective in primary prevention of stroke in patients with sickle cell disease who have been identified as high risk based on transcranial Doppler ultrasound studies of blood flow velocity in the circle of Willis.[357] Although the standard target hemoglobin S percentage for prevention of stroke is less than 30%, for secondary stroke prevention, some neurologically stable patients may be maintained safely at a target hemoglobin S of less than 50%, which is generally easily achievable with a program of chronic erythrocytapheresis.[358] For primary stroke prevention, the standard approach is to maintain the hemoglobin S percentage at less than 30%, which is also achievable with erythrocytapheresis. Very recent published evidence suggests that hydroxyurea treratment may reduce the risk for stroke, as well as the need for chronic apheresis or chronic simple RBC transfusion.[359]

Priapism

Although prepubescent priapism has a good prognosis for eventual potency, episodes of postpubescent priapism are associated with eventual impotence. In addition, there is some correlation with the duration of the episode of priapism and loss of erectile function. Whether this is due to efficacious therapeutic intervention or simply because the worst cases last longer and are more likely to cause irreversible damage remains unclear. Some authors advocate RBC exchange for severe cases,[360] but the efficacy of exchange transfusion for priapism in patients with sickle cell disease is unclear.

Transfusion before General Anesthesia

Although it has been a widely accepted practice to perform RBC transfusions or exchanges in patients with sickle cell anemia before most surgical procedures that require general anesthesia, it is increasingly apparent that not all procedures warrant such large exposure to blood. In one study that examined postoperative complications in patients subjected to surgery without prior transfusion, the complications tended to occur after procedures that adversely affected postoperative oxygenation, specifically, procedures affecting the airway (e.g., tonsillectomy/adenoidectomy) or major abdominal surgery.[361] Investigators in one study prospectively randomized patients with sickle cell disease undergoing surgery either to aggressive transfusion, with a therapeutic goal of a hemoglobin S content of less than 30%, or to simple transfusion, with a therapeutic goal of a hemoglobin level above 10 g/dL. They observed no benefit with the more aggressive transfusion regimen, which was complicated by a higher rate of alloimmunization and hemolytic transfusion reaction (acute and delayed).[362]

Red Cell Exchange for Chronic Transfusion

Erythrocytapheresis has an important role to play in chronic transfusion therapy for patients with sickle cell disease. Children with sickle cell disease in whom complications develop for which chronic, lifelong RBC transfusion is indicated are at risk for the development of transfusional iron overload. Although this can be successfully managed by chelation therapy with deferoxamine, compliance with nightly infusions of the chelator must be high to achieve negative iron balance. Compliance with the oral iron chelator deferasirox may prove to be better. Even though the efficacy and safety of this agent in sickle cell disease have not yet been well established, it is likely that this orally active drug will largely replace deferoxamine. The iron overloading of long-term simple transfusion therapy can be substantially reduced or eliminated by a program of erythrocytapheresis.[363] This approach involves removal and replacement of approximately half of the patient's RBC mass every 3 to 4 weeks. Transfusion by erythrocytapheresis will generally require 23% to 73% more donor units and exposure than is the case with simple transfusion. Because the general risk for transmission of infectious disease and for transfusion reactions is low, the additional risk of these donor exposures may be outweighed by the benefit of reducing or avoiding iron overload and chelation therapy. Of greater concern is the relatively high risk for RBC alloantibody formation in patients with sickle cell disease. It is not clear whether patients chronically transfused by erythrocytapheresis have a greater risk for alloimmunization than do those treated by simple transfusion because both populations will eventually be exposed to a large number of donors.

Normovolemic Red Cell Transfusion. RBC transfusion in hemodynamically unstable patients may be accomplished in a normovolemic fashion with apheresis technology. For example, thalassemia patients with end-stage cardiac failure secondary to transfusional iron overload may better tolerate transfusion to raise the hemoglobin level if the blood volume is not increased rapidly. Exchange transfusion in the setting of overwhelming hemolysis has also been advocated when transfusion requirements would exceed the patient's ability to handle the volume to be transfused. This may occur in autoimmune hemolytic processes (especially IgM mediated), as well as in infectious hemolytic processes, including malaria and babesiosis.[364,365]

Erythrocytapheresis may also be used to remove RBCs from a patient or donor. Patients with polycythemia secondary to chronic cyanotic congenital heart

disease complicated by Eisenmenger's syndrome may have improved hemodynamic function and symptomatic relief after phlebotomy, which is well tolerated with apheresis technology.[366] Finally, more than 1 unit of RBCs at a time can be drawn safely from a donor if normovolemia is maintained.[367] This technique is being used increasingly in routine red cell collection[368,369] and autologous red cell collection[160] and is especially useful when obtaining rare blood from donors or from a single donor to support a specific recipient.

Leukapheresis

Leukocytosis is a negative prognostic indicator in childhood leukemia, especially when the initial white cell count exceeds 200,000/μL. In many centers it is standard practice to perform leukapheresis or whole blood exchange in patients who have extremely high counts with the goal of treating or preventing symptoms related to hyperviscosity and tumor lysis syndrome.[370] Although the leukocyte count can be reduced rapidly, typically dropping by 50% to 75% immediately after the procedure, a long-term survival advantage for patients treated by leukapheresis for hyperleukocytosis has not been demonstrated. The value of this intervention may depend in part on the initial immunophenotype. Specifically, complications of hyperleukocytosis, such as cerebral thrombosis and hemorrhage, may be more common in acute myeloblastic leukemia than in acute lymphoblastic leukemia.[371] Furthermore, in one retrospective study, electrolyte abnormalities during induction chemotherapy were reduced in the group of patients with acute lymphoblastic leukemia and hyperleukocytosis who underwent leukapheresis or exchange transfusion, thus suggesting that leukapheresis may reduce the severity of tumor lysis syndrome.[372] Some authors propose that all patients with acute myeloblastic leukemia or acute undifferentiated leukemia with initial white blood cell counts in excess of 200,000/μL undergo exchange or leukapheresis and that only selective patients with acute lymphoblastic leukemia require this intervention.[373] Technically, leukapheresis may be performed either by using specific tubing sets designed to remove the buffy coat layer or by using the tubing set for plasmapheresis and collecting down into the RBC interface. It is often desirable to maintain a relatively low hematocrit during therapeutic leukapheresis because the RBC mass contributes to viscosity of the blood.

PERIPHERAL BLOOD PROGENITOR CELLS

Peripheral blood progenitor cells, or stem cells, are hematopoietic progenitors with potential for self-renewal that circulate in the blood. At steady state they are present in very low numbers, but during the early phase of recovery from chemotherapy-induced myelosuppression or as a result of exogenous hematopoietic cytokine mobilization (e.g., G-CSF), their relative numbers may increase 10- to 100-fold. This observation has made it possible to collect sufficient numbers of progenitor cells by apheresis to allow autologous hematopoietic rescue after high-dose chemotherapy and to serve as the sole source of stem cells, in lieu of bone marrow, for allogeneic transplantation.[374-377] Collection of peripheral progenitor cells for autologous transplantation in children has been reported by several centers.[375-378] Early engraftment of granulocytes and platelets after high-dose chemotherapy was observed, similar to the findings in adult trials.[378] (See Chapter 9 for discussion of the role of HSC transplants and evaluation of progenitor harvests.) Growth in the number of clinical protocols involving their use has had a profound effect on most clinical apheresis units.[379] Hence, some discussion of the unique aspects of pediatric peripheral progenitor cell apheresis is warranted.

Because almost all pediatric peripheral blood progenitor protocols are directed toward treatment of aggressive cancer with a high risk of relapse (advanced-stage neuroblastoma, leukemia, relapsed lymphoma, high-risk brain tumors), the protocols have most commonly timed the collection of cells to occur during the initial rise in white blood cell count after chemotherapy-induced myelosuppression. Most protocols also use mobilization with a hematopoietic cytokine (GM-CSF or G-CSF).[380-384] The general considerations for access for progenitor cell collections are the same as have previously been described. Because many of the candidates for peripheral blood progenitor cell collections will have central lines for their chemotherapy and supportive care placed at the time of diagnosis or relapse, it is important to select a catheter stiff enough to use for leukapheresis. As with large-volume leukapheresis collections in adults, four to seven blood volumes may be processed by the cell separator in a single 4-hour apheresis collection. More prolonged collections are technically feasible and do increase the net yield, but they may tax the patience of the child and apheresis staff. The adequacy and quality of collections are usually monitored with a complete blood cell count and a measure of progenitor content consisting of tissue culture assays for CFU-GM or, more commonly, counts of $CD34^+$ cells by fluorescence-activated cell sorter analysis, or both. A typical yield from a single collection might be 2.5×10^6 $CD34^+$ cells per kilogram of recipient body weight. Actual yields vary widely, depending on factors such as a history of previous chemotherapy, timing of collections, intercurrent illness, precollection counts, and other factors.[381-384] Cytopenias, especially thrombocytopenia, have been reported after progenitor cell collections,[385] but catheter-related problems such as mechanical obstruction, thrombosis, and infection are the most common difficulties.[386]

Extracorporeal Photopheresis

Extracorporeal photopheresis is a therapeutic use of apheresis technology that takes advantage of the conversion by UVA light (spectrum, 320 to 400 nm) of

8-methoxypsoralen from an inactive molecule to an agent that can induce irreversible lesions in the DNA of leukocytes. The intended target for this DNA damage is T cells that may have a role in pathogenesis. Disorders mediated by excessive autoreactivity or alloreactivity might theoretically be treated by this approach. Some photopheresis protocols involve performing leukapheresis to collect mononuclear cells, ex vivo psoralen treatment and UV irradiation of the cells, and reinfusion of the treated cells. In other protocols, the patient is treated with the psoralen systemically before leukapheresis and UV irradiation of the product. The best-documented therapeutic effect of photopheresis is in the treatment of cutaneous T-cell lymphomas (Sezary's syndrome found exclusively in adults), in which response rates greater than 60% and cure rates of 10% to 15% have been achieved.[387]

More recently, photopheresis has been applied to treat rejection of solid organ grafts in which immunosuppressive interventions have failed and to treat chronic GVHD, especially skin GVHD, after bone marrow transplantation, including treatment in children.[388-393] Anecdotal reports have described striking responses in patients with cardiac rejection refractory to standard treatment, and a randomized pilot study demonstrated the efficacy of photopheresis in preventing cardiac allograft rejection.[394] Controlled trials are needed before the efficacy of this application can be evaluated.[395] Additional reports of control of rejection of other solid organ transplants (including lung transplants) by extracorporeal photopheresis have emerged.[396,397] Wider application of this technology in pediatrics is currently limited in the United States by the lack of an approved photopheresis instrument that uses continuous-flow cell separation.

PLASMA EXCHANGE

Plasma exchange is performed either to remove harmful constituents of plasma (such as autoantibodies or excess cholesterol) or to replace missing plasma proteins, such as coagulation factors in liver failure. The extent of removal of a particular molecule or compound by plasmapheresis is a function of the amount of plasma removed and the distribution of the molecule in the body. The most efficient clearance is achieved for substances (such as IgM) that are limited to the intravascular compartment. If the molecule is distributed within the compartment defined by extracellular water (such as IgG), the efficiency of removal is also affected by the rate of re-equilibration between the extravascular and the intravascular space. Plasmapheresis is least efficient when the molecule targeted for removal is distributed over the entire body (many drugs and toxins). Similarly, the efficiency of replacement of missing plasma factors is a function of the factors' distribution and ongoing rate of consumption.[345]

For some indications, the underlying mechanism of an observed therapeutic effect of plasmapheresis may be unknown. For example, in TTP, controlled clinical trials[387] have documented the superiority of plasma exchange over simple plasma transfusion well before the pathogenesis of the disease was understood. This result was commonly extrapolated to the treatment of HUS because it shares certain clinical features with TTP, even though the empirical evidence supporting the use of plasma exchange in adult HUS[398] and pediatric HUS[347,399,400] was not well founded. In light of the demonstration in patients with TTP (but not HUS) of an autoantibody that removes the activity of a serum metalloproteinase responsible for cleaving von Willebrand factor,[401-403] it appears that plasma exchange treats TTP by removal of the autoantibody, as well as by replacement of the serum metalloproteinase and normal von Willebrand factor. Although this discovery has provided a sound explanation of how plasma exchange helps in TTP, it has invalidated the previous assumption that HUS and TTP represent a spectrum of a single disease process that will respond to plasma exchange.

The role of plasma exchange in liver failure is controversial. In acute severe liver failure, metabolic toxins (the so-called middle molecules, which are not effectively removed by conventional dialysis) accumulate and lead to hepatic encephalopathy, coma, and death. Furthermore, failure of production of intravascular proteins, including albumin and coagulation factors, leads to ascites, edema, and bleeding. Plasma exchange can offer temporizing supportive care by providing the missing plasma components in larger doses than could be delivered by simple transfusion. However, plasmapheresis is inefficient for removal of the toxins that accumulate in liver failure and has not been shown to prevent or forestall the development of hepatic encephalopathy. The use of plasma exchange to provide a bridge to support patients awaiting liver transplantation or to normalize coagulation parameters immediately before transplant surgery is well documented.[404]

Autoimmune Disorders

Guillain-Barré Syndrome

Several controlled studies comparing plasmapheresis with conventional therapy for Guillain-Barré syndrome (GBS) have documented a therapeutic benefit from plasmapheresis, especially when initiated early in the course of the illness.[405] Lack of a uniform response to plasmapheresis had led some researchers to speculate whether the syndrome may be a common outcome of diverse causes.[406] Because children with GBS have a somewhat better prognosis than adults do, plasmapheresis is generally reserved for those who deteriorate rapidly or who require ventilator assistance.[407] High-dose IVIG has also been shown to have efficacy in treatment of GBS, and a randomized trial in adults demonstrated that IVIG may be slightly superior to plasma exchange for GBS.[408] This result has led neurologists to treat with IVIG first and

reserve plasmapheresis for refractory or especially severe cases. Both IVIG and plasmapheresis have efficacy in childhood GBS but have not been compared in a randomized trial.[409,410] Patients with chronic inflammatory demyelinating polyradiculopathy, an insidious peripheral neuropathy with a waxing and waning course and some similarities to GBS, may also benefit from plasmapheresis.[411,412]

Myasthenia Gravis

Myasthenia gravis is a neuromuscular disorder characterized by progressive proximal muscle weakness. It follows damage to motor end plates caused by an autoantibody directed against postsynaptic acetylcholine receptors. Plasmapheresis has been shown to provide acute temporary relief of myasthenic crises and to be a useful adjunct along with immunosuppressive therapies for longer-term treatment.[413,414]

Systemic Lupus Erythematosus

Systemic lupus erythematosus is an autoimmune disorder with protean manifestations that may affect many organ systems, especially the skin, kidney, central nervous system, and blood. Controlled trials of plasmapheresis in systemic lupus erythematosus have generally failed to show long-term benefit.[415] Nonetheless, some authors advocate the use of plasmapheresis to treat certain acute flares of the disease, especially when they are severe or threaten the function of vital organs (kidney, central nervous system). Flares during pregnancy, for example, when other more toxic treatments might be contraindicated, have been proposed as appropriate indications for apheresis.[416]

Immune Hemolysis

Cold agglutinin disease, a form of autoimmune hemolytic anemia mediated by an RBC antibody of the IgM isotype, may be effectively treated in the acute phase by plasmapheresis because IgM antibodies are efficiently removed by plasmapheresis.[417] Plasmapheresis has also been used in life-threatening IgG-mediated autoimmune hemolysis, even though removal of IgG is much less efficient. The reduction in hemolysis is transient in either case, and in general, apheresis is warranted only to buy time until other treatments, such as splenectomy, can be performed or to treat disease refractory to other therapies.[418]

Other Autoimmune Disorders

Rasmussen's encephalitis, a rare disease resulting in an intractable seizure disorder previously treated by hemispherectomy, has been shown to result from autoantibodies directed against the glutamate receptor (GluR3) in the brain.[419] The antibodies reportedly act as constitutive agonists and result in excessive neuronal activation and subsequent seizures.[420,421] Case reports suggest that plasmapheresis has a role in acute treatment. A syndrome called pediatric autoimmune neuropsy-chiatric disorders associated with streptococcal infections (PANDAS) consists of a movement disorder with involuntary tics and a behavioral disorder with obsessive-compulsive features.[422] The pathophysiology is thought to involve group A β-hemolytic streptococci triggering antibodies that cross-react with the basal ganglia of genetically susceptible individuals, a mechanism parallel to the pathophysiology of Sydenham's chorea.[423] One randomized trial has demonstrated that both IVIG and plasma exchange have efficacy in treating the symptoms of PANDAS,[424] and another trial suggested that plasmapheresis and IVIG may have efficacy in Sydenham's chorea.[425]

Hyper-IgE syndrome (Job's syndrome) is a rare autosomal recessive disorder characterized by extremely high IgE levels, recurrent infections (typically with *Staphylococcus*), and chronic dermatitis. Plasmapheresis results in a reduction in IgE levels and correspondingly decreases inflammatory lesions. It is generally reserved for patients who have failed to respond to other therapies, including antibiotics and IVIG replacement.[426] An unusual complication of hyper-IgE syndrome is keratoconjunctivitis, which may threaten vision; it has reportedly been improved with apheresis.[427]

Other Coagulopathies

A preexisting coagulopathy has historically been a contraindication to managing a patient by ECMO because of the additional anticoagulation required to prevent clotting in the membrane oxygenation circuit and the high risk of intracranial hemorrhage. Several centers have observed that it is possible to perform plasmapheresis via the ECMO circuit itself, thereby replacing the missing coagulation factors in the hope of decreasing the risk for hemorrhage.[428,429]

Renal Disease. Cryoglobulinemia, a disorder rare in pediatrics, involves the pathologic production of proteins that reversibly precipitate or gel on exposure to cold. In general, they are antibodies, although they are not necessarily limited to the IgM class. These immune complexes may be deposited in the kidney and result in end-organ damage. Because immune complexes are largely intravascular, they are efficiently cleared by apheresis.[430] Apheresis has also been advocated in Goodpasture's syndrome, an autoimmune disorder caused by antibodies against glomerular basement membranes. Controlled trials to measure the efficacy of plasmapheresis, often as an adjunct to other immunosuppressive agents, have yielded conflicting results. Some appear to show clear benefit,[431] whereas the benefit in other studies appears to be marginal.[432]

Although plasmapheresis has not been shown to prevent renal allograft rejection, it may prove useful as an adjunctive therapy in preventing recurrence of corticosteroid-resistant nephrotic syndrome with focal sclerosing glomerulosclerosis (FSGS) in the transplanted kidney when used in conjunction with cyclophosphamide

and pulse corticosteroids.[433,434] The mechanism of this therapeutic effect is thought to be removal of a protein permeability factor in plasma that mediates the renal injury in FSGS.

Hypercholesterolemia. Genetic absence of the low-density lipoprotein receptor results in extreme hypercholesterolemia and the development of severe atherosclerotic complications within the first several decades. Cholesterol-lowering drugs are largely ineffective in patients with completely absent of receptors or nonfunctional receptors. Hence, plasmapheresis is the treatment of first choice. It may be performed by simply removing plasma and replacing it with albumin or by selective lipid absorption columns. The reported advantages of the latter treatment are the greater volumes that may be processed with less depletion of coagulation factors, immunoglobulins, and high-density lipoproteins. Columns come in many varieties, and the most commonly used are disposable dextran sulfate columns. A dual-column method has been developed that cannot be saturated; the lipid collected is eluted from one column while the second is collecting. This system has been shown to be effective in pediatric patients.[435] Disadvantages of using columns include additional extracorporeal volume (150 to 400 mL) added to the system and some reports of adverse side effects.

Transplantation

ABO-incompatible bone marrow or solid organ transplantation is most problematic when the recipient has IgM antibodies against the donor ABO type.[436] Apheresis can be used to deplete isohemagglutinins (naturally occurring anti-A, anti-B antibodies).[437] Although this approach is effective in reducing IgM titers, the requirement for several daily procedures often results in a large number of donor exposures.[438] Most bone marrow transplant programs have switched to depleting the donor marrow of RBCs, a one-time procedure that has not been shown to compromise engraftment. For ABO-incompatible cardiac transplantation in neonates, however, plasmapheresis, either as a separate procedure or incorporated into cardiopulmonary bypass, may be used immediately before or after transplant surgery to remove isohemagglutinins.[142] Plasmapheresis has also been used to reduce HLA antibodies in patients who are candidates for renal transplantation but who have high degrees of HLA sensitization that restrict the availability of compatible organs and increase the risk of hyperacute rejection.[439]

Disseminated Intravascular Coagulation/Purpura Fulminans

Plasmapheresis may be used in desperate situations. Specifically, the dramatic coagulopathy of purpura fulminans associated with meningococcal sepsis can be treated by plasmapheresis. In trials using historical controls, improved survival and correction of coagulopathy have been documented, but because the trials had no concurrent controls, it is impossible to be sure that plasmapheresis contributed to the improvement.[440]

Special Applications and Selective Adsorption

Plasmapheresis allows the selective removal of components within plasma by additional processing of the separated plasma. Various devices such as immunoadsorbent columns may be incorporated in series into the plasma flow. For example, the plasma can be exposed to beads coated with antigen to remove a specific antibody or with staphylococcal protein A to remove IgG. Therapeutic protein A immunoadsorption has been applied to an array of hematologic disorders, including autoimmune thrombocytopenic purpura and alloimmune platelet transfusion refractoriness.[441] Coagulation factor VIII alloantibodies have also been treated extensively with this technique.

Types of Columns

Two general types of staphylococcal protein A columns for clinical use exist: disposable columns intended for single use and renewable columns that are part of a system to remove IgG continuously.[441] Both techniques use staphylococcal protein A attached to a solid matrix to permit selective removal of IgG antibodies, including subclasses IgG1, IgG2, and IgG4, either as free antibody or as immune complexes. IgG3 and immunoglobulins of other classes are less avidly bound to protein A and hence are less efficiently removed by these devices.[442]

An inherent limitation of this adsorption chromatography is saturation of the staphylococcal protein A binding sites. For example, the disposable column is saturated after 200 to 250 mL of plasma has passed over the column. A method to circumvent this problem of rapid saturation has been developed whereby two columns are used alternatively, collecting on one while eluting (flushing with a low pH solution) from the other column. Clinical studies using each of these systems have been performed, but only the disposable column is licensed for use in idiopathic thrombocytopenic purpura and the two-column system is available only for research protocols.[443]

Both types of staphylococcal protein A columns have been used to treat platelet refractoriness (platelet alloimmunization), but the clinical value of such intervention is not well established.

Use in Congenital Hemophilia with Inhibitors

The two-column immunoabsorption system has demonstrated efficacy for removal of coagulation factor inhibitors, either acquired or secondary to congenital deficiency (hemophilia A or B). One study of 22 patients used staphylococcal protein A adsorption to treat patients with a wide array of starting inhibitor titers. A majority achieved greater than 90% reduction in inhibitor titer;

however, a starting titer of greater than 200 Bethesda units (BU) typically resulted in postadsorption titers greater than 5.[444] Below this level one can overwhelm an inhibitor simply by giving larger doses of factor concentrate. For short-term removal of coagulation factor inhibitors, the technique has documented efficacy. In the Malmö protocol, staphylococcal protein A adsorption is used as the initial stage of inhibitor ablation therapy to reduce the initial titer to less than 10 BU, followed by the administration of IVIG, cyclophosphamide, and high doses of the missing coagulation factor (VIII or IX). In a published series, 8 of 11 inhibitor patients achieved durable responses to this inhibitor ablation protocol.[445] Limiting factors for generalized application of this protocol include both unavailability of the two-column system and the large quantities of factor concentrates used, issues that result in considerable expense when carrying out the protocol.

Other Autoimmune Diseases

Staphylococcal protein A columns have been applied to numerous different autoimmune disorders.[446] The common finding is that antibody can be removed with the system, but conclusions regarding whether staphylococcal protein A apheresis is warranted in each of these disorders must await prospective clinical trials.

Another selective-removal apheresis methodology has been developed to target the removal of some populations of granulocytes and monocytes based on their adherence to cellulose acetate beads. There are several reports from Japan of the efficacy and safety of this form of granulocytapheresis in the treatment of ulcerative colitis, but the device is not currently available in the United States.[447-449]

CONCLUSION

The addition of mechanical apheresis devices to the therapeutic armamentarium of transfusion medicine specialists has allowed dramatic interventions in both acute and chronic disorders. The complexity of the clinical settings in which apheresis is sometimes used often makes it difficult to assess the value of apheresis-based therapies. As economic constraints increasingly encroach on the application of medical technologies, it is imperative to design well-controlled studies to document the efficacy of the intervention. Consensus statements provide an opportunity to pose testable questions for interventions in multicenter trials. The involvement of pediatric transfusion medicine specialists early in the design of such trials is warranted because of the technical complexity of the procedures and the unique requirements of pediatric patients. Producers of apheresis devices must also be mindful of these unique requirements lest protocols designed for adults not be applicable for children. Reduction of extracorporeal volume, for example, may be beneficial to adults as well as pediatric patients.

Hematologic Manifestations of Systemic Diseases

R. Alan B. Ezekowitz

Evaluation of almost any patient who seeks medical attention, particularly in a hospital setting, includes the obligatory complete white blood cell count. In fact, the vast majority of patients do not have a primary hematologic problem. So the question is what information can be gleaned from this test and how can it inform the clinician about systemic diseases? There are many pathophysiologic paradigms that have secondary effects on hematopoiesis and many ways to approach the problem. The most satisfying is to dissect the mechanism whereby a systemic disease affects the complete blood count or results in a defect in coagulation. In this chapter an organ system approach is used, together with identification of certain diseases in which the diagnostic clue may lie in examination of the peripheral blood smear. In addition, some common infections, usually viral, that result in characteristic hematologic responses are discussed. Finally, the newly recognized application of a class of serum proteins as markers of systemic disease that play a role in host defense and serve as modulators of inflammation is addressed. A chapter on the hematologic manifestations of systemic diseases includes information that overlaps other sections of this book, and thus readers are encouraged to refer to other relevant chapters.

CARDIAC DISEASE

The focus of this section is on the three major hematologic complications of cardiac disease—hemolytic anemia, coagulopathy, and increased platelet turnover.

Hemolysis

A number of instances of continuing hemolysis and progressive anemia have been reported after the insertion of prosthetic valves, particularly in the aortic area.[1,2] These conditions may also occur postoperatively when intracardiac patches have been placed (the "Waring blender" syndrome). They are also being recognized as an increasing problem after endoluminal closure of the ductus arteriosus[3,4] and occasionally after repair of a ventriculoseptal defect.[5] The mechanism of such erythrocyte destruction has been related to failure of endothelialization of patches, thrombosis or perforation of prosthetic valves, and improper placement of prosthetic valves, especially when insufficiency develops at the suture lines. Erythrocyte destruction and ensuing hemolysis, however, have been described in the absence of these complications and been attributed to red blood cell mechanical trauma associated with apparently normal function of the prosthetic valve.[6,7]

Red cell survival studies have clearly shown that prosthetic valve and patch hemolysis is due to an extracorpuscular defect.[8] In general, hemolytic anemia results from fragmentation of the red cells as they are mechanically "battered" against a distorted vascular surface.[9] In some instances it has been postulated that the red cell fragmentation may be caused by contact with fibrin deposited in small blood vessels as a result of localized intravascular coagulation.[10] Most times, however, hemolysis is the result of direct mechanical trauma. Nevaril and associates[9] demonstrated that a shearing stress of 300 dynes/cm^2 causes hemolysis in vitro whereas less stress may result in deformed red cell morphologically similar in appearance to cells in cardiac hemolytic anemia and microangiopathic hemolytic anemia.[9]

The consequence of the process is hemolytic anemia of the intravascular type associated with hemoglobinemia and often hemoglobinuria. Iron deficiency develops quickly in patients with this disorder as a result of increased loss of body iron in the form of hemosiderin, which is shed within the renal tubular cells into urine.[11,12]

The onset of iron deficiency may be of clinical importance. The microcytic hypochromic cell in iron deficiency is more rigid, thereby leading to an accelerated rate of hemolysis from mechanical shearing in the microvasculature.[13] Plasma haptoglobin and hemopexin levels fall. Large quantities of red cell lactate dehydrogenase are released into serum, and a close correlation exists between the logarithm of serum lactate dehydrogenase and the half-life of chromium-labeled erythrocytes.[14] The rate of hemolysis may or may not result in anemia. If surgical correction of the defect causing hemolysis is not possible, the patient should be treated with both iron and folate, as well as red cell transfusion. The latter is intended to correct anemia, reduce stroke volume, and presumably reduce shear force. Sears and Crosby[15] observed that the severity of hemolysis is directly related to physical activity. This finding has been used as a test to determine whether the hemolysis is of cardiac origin because if it is, rest also diminishes the rate of hemolysis. If the source of the problem cannot be corrected surgically, propranolol, which reduces the shearing stress between red blood cells and the vascular wall by slowing the velocity of the circulation, may be given.[16]

Mechanical injury to red cells may result in loss of pieces of cell membrane, with or without loss of hemoglobin. Such loss will lead to the formation of spherocytes. Consequently, in many patients with heart valve hemolysis, results of the red cell osmotic fragility test may be abnormal.[16] Mechanical destruction of red blood cells on abnormal surfaces of the vasculature can result in hyperkalemia. This has been reported to cause ventricular arrhythmias.[17]

Occasionally, autoimmune hemolytic anemia is observed after cardiac surgery involving the placement of foreign material within the vascular system.[18] This condition may also occur in association with subacute bacterial endocarditis.

Erythrocyte disturbances in children with cardiac disease must be understood in the context of compensatory states or the context of iron deficiency as a complication. For example, infants with cyanotic congenital heart disease have erythropoietin-induced compensatory polycythemia. Aortic oxygen saturation higher than 80% is usually associated with low erythropoietin titers and hemoglobin levels that will not cause hyperviscosity. Even with moderate degrees of hypoxemia, elevated erythropoietin levels are not seen; presumably, the modest elevation in hemoglobin levels provides adequate tissue oxygenation.[19-21] Infants with cyanotic congenital heart disease have higher iron requirements because of the greater hemoglobin mass. Diminished iron stores in patients with cyanotic congenital heart disease are associated with a more right-shifted oxyhemoglobin dissociation curve.[22] Most children with cyanotic congenital heart disease have evidence of mild macrocytosis. A mean corpuscular volume greater than the 90th percentile for age and sex nearly eliminates the possibility of iron deficiency.[22]

Coagulation Abnormalities

Many investigations have suggested that a coagulopathy exists in some patients with cyanotic congenital heart disease. Newborns with protein C activity at or below the lower limit of the normal neonatal range may have a greater risk for either consumptive coagulopathy or major thrombosis.[23] Thrombocytopenia, low plasma fibrinogen levels, defective clot retraction, hypoprothrombinemia, factor V and VIII deficiency, and evidence of fibrin degradation products in serum have been reported.[24-28] Marked derangements in coagulation often accompany surgery involving cardiopulmonary bypass.[29] Management of the coagulation problems with heparin requires very careful and regular monitoring.[30]

Dennis and associates[31] were the first to report five patients with cyanotic congenital heart disease associated with coagulation abnormalities that were correctable by heparin.[31] Consumptive coagulopathy was thought to be responsible, but technical problems cast doubt on that interpretation.[32]

It is now generally thought that the presence of coagulation abnormalities correlates best with the extent of polycythemia.[33] The exact mechanism producing the coagulopathy, when present, is not known.

Hyperviscosity may lead to tissue hypoxemia, which then triggers a consumptive process.[34] Conflicting data suggest that the coagulation defects associated with cyanotic congenital heart disease must be multifactorial in origin. Therefore, each child should be studied individually. Data suggest that certain forms of heart disease may be associated with specific abnormalities. For example, subjects with mitral valve prolapse may experience factor VIII complex abnormalities.[35]

Platelet Abnormalities

Quantitative and qualitative platelet abnormalities are commonly associated with cardiac disease. In one series, the mean platelet count in cyanotic patients with an arterial oxygen saturation of less than 60% was 185,000 cells/mm^3 as compared with 315,000 cells/mm^3 in patients with an arterial oxygen saturation greater than 60%.[36,37] These abnormalities are readily noted on preoperative evaluation of the coagulation status of individuals about to undergo surgery.[38] Examination of bone marrow has failed to demonstrate any quantitative changes in megakaryocytes to account for these platelet differences.[36] This, together with the finding of shortened platelet survival in many patients, has suggested that the mechanism of the thrombocytopenia is destructive. Some patients, especially those with minimal cyanosis, may have elevated platelet counts. It should be noted that although iron deficiency is commonly associated with cyanotic congenital heart disease, the quantitative platelet abnormalities are not related to iron status.

Qualitative platelet defects associated with cyanotic congenital heart disease may include prolonged bleeding

times and abnormal aggregation in response to adenosine diphosphate, epinephrine, and collagen.[39] In as many as 70% of patients, either a delayed or no second wave of platelet aggregation and disaggregation is observed.[40] These platelet functional abnormalities appear to be due to a defective platelet release mechanism because diminished release of [^{14}C]serotonin occurs in response to adenosine diphosphate whereas uptake of [^{14}C]serotonin is normal.[41] Platelet release abnormalities are more common in patients older than 4 years, in those with a hematocrit greater than 60%, and in those with platelet counts less than 175,000 cells/mm^3. There is no correlation between abnormalities in platelet aggregation and release and the abnormal bleeding time.

Treatment

Management of these hemostatic defects is not settled. It is agreed that they may predispose patients to postoperative hemorrhage, but they are rarely associated with preoperative clinical bleeding tendencies. Suggested management procedures have included the use of heparin[31] to lower viscosity, erythrocytapheresis with plasma exchange,[34,42] and ε-aminocaproic acid to inhibit fibrinolysis.[43] Whether any of these modalities are indicated and, indeed, whether they might be uniformly effective is speculative. If erythrocytapheresis is chosen, the procedure should be done with great care in cyanotic patients. Withdrawal of red cells must be accompanied by infusion of an equal volume of fresh frozen plasma. Simple removal of red cells without volume replacement in polycythemic individuals may cause an acute increase in viscosity, vascular collapse, seizures, and even stroke.[44] Because of the high incidence of cerebrovascular accidents in children with cyanotic congenital heart disease, some workers have thought that a "hypercoagulable" state exists. Hyperviscosity alone may account for some ischemic infarctions. The clinician should be alert to the possibility of iron deficiency predisposing patients to stroke in the presence of polycythemia. Several children in whom neurologic deficits developed after the onset of iron deficiency in the presence of polycythemia have been described.[45,46] Card and Weintraub[47] showed that red blood cells from animals with iron deficiency have decreased deformability. Altered deformability in the presence of increased blood viscosity could theoretically result in vascular ischemia.

Shortening of platelet survival with or without thrombocytopenia has been observed in both children and adults with prosthetic heart valves.[48] The increased platelet turnover may result from a combination of mechanical damage to the platelet and adhesion to the foreign material. The use of anti–platelet-aggregating agents may correct this shortened survival, although clinical benefit of the use of this class of drug has not been established. Drugs such as acetylsalicylic acid, dipyridamole, and sulfinpyrazone have been used either singly or in combination.[49-51]

Miscellaneous Hematologic Manifestations of Heart Disease

Subacute bacterial endocarditis may be associated with a variety of hematologic manifestations. Anemia is often present and is usually the result of chronic infection. The white blood cell count is generally normal, although marked leukocytosis or leukopenia may occur. A 25-year review of the evolving pattern of pediatric endocarditis shows that anemia is present in 40% of children with endocarditis and leukocytosis in 30% of such patients.[52] Pancytopenia has been reported,[53] and thrombocytopenia has been noted in a few patients.[54,55]

Congestive heart failure may result in sufficient hypoxia to cause nucleated red blood cells to appear in the peripheral blood in association with mild reticulocytosis.[56] Thrombocytopenia may be present but is almost exclusively the result of hypersplenism.[57]

Cyanotic heart disease may result in poor perfusion of the spleen and subsequent functional hyposplenism manifested by Howell-Jolly bodies in peripheral blood.[58] This finding is likely to lead to the mistaken conclusion that a child may have the asplenia syndrome (absence of the spleen, cardiovascular malformations, abdominal situs inversus, and other anatomic malformations), which is associated with a poor prognosis.

GASTROINTESTINAL DISEASE

Hematologic complications of gastrointestinal disease appear in many disorders. This section does not include the wide range of situations in which blood loss from the gastrointestinal tract occurs but rather focuses on specific diseases and their hematologic complications.

Diseases of the Upper Gastrointestinal Tract

Esophagus

Plummer-Vinson syndrome (dysphagia, postcricoid webs, and iron deficiency)[59] occurs in older individuals. It is rarely seen in young adults. Iron deficiency anemia may be the only manifestation of gastroesophageal reflux; thus, endoscopy is important in the evaluation of unexplained iron deficiency anemia.[60] Chronic gastroesophageal reflux may cause Barrett's esophagus with its attendant risk for the development of adenocarcinoma.[61]

Stomach

The gastric mucosa is important in both vitamin B_{12} and iron absorption, and disorders of the gastric mucosa may cause defective absorption of either of these nutrients.

Chronic atrophic gastritis is usually a disorder of older adults but occasionally is seen in young adults. The

accompanying iron deficiency results from a combination of blood loss and iron malabsorption secondary to achlorhydria.[62] Vitamin B_{12} absorption defects may occur in association with chronic atrophic gastritis.[63]

Gastric resection may also result in iron or vitamin B_{12} deficiency—the former from bleeding at sites of anastomosis and the latter, years later, from lack of intrinsic factor. Vitamin B_{12} deficiency may develop in infants breast-fed by women who have undergone gastric or intestinal bypass procedures.[64] Macrocytic, megaloblastic anemia resulting from vitamin B_{12} deficiency has been reported in association with gastric trichobezoars.[65] This is presumed to be due to bacterial overgrowth of the upper gastrointestinal tract.

In congenital intrinsic factor deficiency, gastric biopsy results are normal, and no antibodies to parietal cells or intrinsic factor are present.[66]

Zollinger-Ellison syndrome is a disorder associated with increased parietal cell production of hydrochloric acid. This excess acid may cause iron deficiency as a result of mucosal ulceration. Carcinoid syndrome may cause a similar problem. In both conditions, vitamin B_{12} malabsorption may occur because of reduced pH in the ileum.

Small Bowel

Celiac disease may cause a panmalabsorption syndrome. Isolated iron deficiency results from blood loss secondary to ulcerations at the origins of the loop, and vitamin B_{12} deficiency may be due to consumption of this vitamin by stagnant intestinal bacteria.[67] Iron deficiency is quite common in patients with celiac disease.[68] It may be the sole initial manifestation of celiac disease.[69] The iron deficiency is generally mild and is readily corrected with a gluten-free diet.[70,71] Separate from iron deficiency, pica may be a symptom of childhood celiac disease.[72] Folate deficiency may also be seen.[73] Blind loops created surgically for the treatment of obesity have been reported to cause an unusual autoimmune disorder in young adults[74] characterized by immune intravascular hemolysis, neutropenia, and thrombocytopenia. Immune complex–mediated complement activation apparently accounts for the blood cell destruction, perhaps as a result of bacterial antigens that enter the blood and initiate immune complex formation. Hyposplenism is also associated with celiac disease.[75,76] The incidence of carcinoma and lymphoma is increased in adult patients with celiac disease.[77] Before the onset of lymphoma, elevations in placental ferritin, a tumor-associated antigen, may be found.[78]

Ileal resection may result in vitamin B_{12} deficiency if receptors for the vitamin B_{12}–intrinsic factor complex have been removed.

Regional enteritis may cause iron deficiency from blood loss, as well as vitamin B_{12} deficiency from inflammatory disease of the terminal ileum or from development of the blind loop syndrome as small bowel fistulas form. Low factor XIII levels have been observed in active disease associated with regional enteritis.[79] An abnormality in arachidonic acid metabolism may occur in patients with chronic inflammatory bowel disease, including regional enteritis. This may result in alterations in platelet function.[80] Diminished neutrophil function may be seen in both regional enteritis and other forms of inflammatory bowel disease. The condition may be identified by decreased oxidative metabolism and low superoxide dismutase content of neutrophils.[81] Perinuclear antineutrophil cytoplasmic antibodies are commonly found in patients with inflammatory bowel disease.[82,83]

Disorders such as tropical sprue, dermatitis herpetiformis, bowel lymphoma, amyloidosis, and connective tissue disturbances (including Ehlers-Danlos syndrome and pseudoxanthoma elasticum) may produce panselective or selective malabsorption. Certain disorders such as intestinal lymphangiectasia may cause protein loss of a magnitude sufficient to impair globin chain synthesis. Protein loss may also be associated with selective loss of thymic-dependent (T) lymphocytes into the bowel lumen, which causes lymphopenia and altered delayed-type hypersensitivity. This lymphopenia may be associated with hypogammaglobulinemia.[84]

Eosinophilic gastroenteritis is a disorder most often characterized by recurrent bouts of abdominal pain, nausea, vomiting, diarrhea, and an elevated peripheral blood eosinophil count for which there is no other explanation.[85] The gut wall may be infiltrated by eosinophils.[85]

Common diarrheal illnesses during infancy may result in life-threatening methemoglobinemia, especially if the diet has been high in nitrates.[86-89]

Diseases of the Lower Gastrointestinal Tract

Ulcerative colitis is often associated with iron deficiency anemia as a result of blood loss. Immune hemolytic anemia is also observed. Autoimmune hemolytic anemia identified by positive results on a Coombs test is a relatively rare complication of ulcerative colitis, however, and develops in less than 1% of patients.[90] Occasionally, vitamin B_{12} deficiency occurs after many years if a "backwash" ileitis is present. Polymorphonuclear leukocytosis is common. Occasionally, an increase in plasma fibrinolytic activity will be observed. A significant decrease in antithrombin III levels may be found.[91] Some clinicians have treated this complication with ε-aminocaproic acid.[92] Platelet functional abnormalities may exist and are discussed elsewhere. Alterations in T-cell subsets may also be seen in children with inflammatory bowel disease.[93]

Constipation has been reported to cause an increase in sulfmethemoglobin levels.[94] It has been suggested that excess nitrite absorption from the gut may be present in some patients as a result of abnormal bowel function.[95]

Symptoms of Peutz-Jeghers syndrome (gastrointestinal polyposis and mucocutaneous pigmentation) may occur in early childhood.[96] The increased risk for intestinal cancer associated with this syndrome may also be manifested in childhood.[97]

Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) may result in iron deficiency from gastrointestinal bleeding. Alterations in hemostasis (disseminated intravascular coagulation [DIC], platelet dysfunction, and factor XI deficiency) have been reported.[98] An association between this disorder and von Willebrand disease may exist.[99]

PANCREATIC DISEASE

Acute hemorrhagic pancreatitis may cause acute anemia during the first week of the illness as a result of hemodilution, intravascular coagulation, and blood loss.[100] Anemia may also be seen with pancreatic insufficiency in association with the Shwachman syndrome (congenital exocrine pancreatic insufficiency and neutropenia). Defects in neutrophil chemotaxis are likewise seen in the Shwachman syndrome,[101] as well as anemia and abnormalities of the ribs and metaphyses of long bones.[102] Leukocytosis with neutrophilia is a usual finding. Markedly elevated levels of fibrin split products usually suggest that a consumptive coagulopathy is present. A concomitant decrease in platelet count is also common.[103] High levels of methemalbumin are common in the ascitic fluid of individuals with hemorrhagic pancreatitis[104] and can be used to distinguish this disorder from nonhemorrhagic pancreatitis. Patients with ascitic fluid are the ones most likely to have evidence of consumptive coagulopathy. For example, fibrin degradation products are seen in 40% of subjects with fulminant pancreatitis without ascites but in 100% of patients with clinically apparent peritoneal fluid.[105]

Cystic fibrosis may cause malabsorption, which produces the expected hematologic abnormalities. A specific pattern of anemia in association with edema and hypoproteinemia may be observed in some children with cystic fibrosis. It is found most commonly in children who have low dietary intake of nitrogen, such as those who receive their protein primarily from breast milk or soybean formula.[106] The edema is caused by hypoalbuminemia. The anemia responds to adequate dietary protein enrichment and pancreatic enzyme supplementation but not to iron administration. Cystic fibrosis may also be associated with malabsorption of fat-soluble vitamins, and the consequent coagulopathy is related to vitamin K deficiency. Vitamin E deficiency may also occur and is manifested by mild hemolytic anemia and abnormal red cell peroxide hemolysis, as well as by hyperaggregation of platelets.[107]

In 1979, Pearson described a syndrome in which the main symptoms were severe sideroblastic anemia and exocrine pancreatic dysfunction.[108] Pearson's syndrome is not confined to the bone marrow and pancreas but is a multiorgan disorder associated with deletions in mitochondrial DNA.[109-111]

LIVER DISEASE

Red Blood Cell Disturbances

Anemia is common in acute and chronic liver disease and apparently has a diverse etiology.[112] Erythropoietin levels are elevated in the anemia associated with liver disease.[113]

The red blood cells in liver disease are often macrocytic, with mean corpuscular volumes in the range of 100 to 110/m³. Target cells and acanthocytes or spur cells are commonly observed.[114,115] Stomatocytosis has been reported in alcoholic liver disease.[116] These morphologic abnormalities appear to be in direct proportion to the increase in red cell membrane phospholipid and cholesterol that may accompany liver disease whenever any obstructive component is present.[117-119] Such membrane lipid alterations result in an increase in red cell membrane area, which accounts for the target and spur cells. Increased osmotic resistance is a consequence of this increased surface area.

Shortened red cell survival may be observed in some patients with no evidence of blood loss.[120,121] Acute hemolysis has also been observed in patients with acute liver disease who have glucose-6-phosphate dehydrogenase deficiency as well.

The exact mechanism by which red blood cell survival is shortened is unclear. Erythrocytes from patients with active liver disease have an increased tendency to form Heinz bodies after incubation with an oxidant chemical such as acetylphenylhydrazine or sodium ascorbate. This increase in Heinz body formation is associated with increased instability of red cell reduced glutathione, decreased hexose monophosphate shunt activity, and reduced glucose recycling through the hexose monophosphate shunt.[122] It has not been possible to demonstrate any decreased activity of red cell glutathione reductase, glutathione peroxidase, glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, or transketolase.[123] Activation of superoxide dismutase and glutathione reductase may be observed in the red blood cells of patients with profound liver disease. This may partially explain the alterations in the antioxidant system noted with these disorders.[124] The hemolytic anemia associated with liver disease secondary to Wilson's disease is especially severe.[125] The same is true of the hemolytic anemia related to protoporphyria.[126]

The exact significance of these metabolic alterations has not yet been determined. Red cell metabolism appears to return to normal within a few weeks after an insult to the liver. All of the metabolic consequences of liver disease can be reproduced in normal intact red cells by prolonged incubation in plasma from patients with active liver disease.

In patients with active liver disease, it may be wise to withhold any drug that has the potential to present an oxidant challenge to the red blood cell. Similar acquired abnormalities in hexose monophosphate shunt activity have been associated with drug-induced hemolysis in patients with uremia. Yawata and associates[127] have reported that primaquine therapy results in accelerated hemolysis in such patients.

Coagulation Abnormalities

Because the liver is involved to some extent in the synthesis of most of the coagulation factors, it is not unexpected that liver dysfunction would be associated with the presence of abnormal clotting studies. In most instances these abnormalities are a laboratory finding only. Less commonly, severe aberrations in clotting are seen and result in a serious risk of bleeding. The coagulation abnormalities common in patients with fulminant hepatic failure have been reviewed in detail.[128,129]

Factor I (Fibrinogen)

Fibrinogen levels are usually normal in liver disease. This may be accounted for by the fact that although fibrinogen synthesis has been demonstrated in liver cells, it is also produced in extrahepatic sites.[130]

Low levels of fibrinogen may be observed in fulminant acute liver failure. In these circumstances it has been speculated that intravascular coagulation contributes to the coagulation disturbance by depletion of some of the clotting factors.

An increased catabolic rate of labeled fibrinogen has been noted in acute and chronic active hepatitis despite normal levels of plasma fibrinogen.[131] In chronic active hepatitis, the rate of fibrinogen catabolism appears to correlate with the activity of the disease as assessed by variations in plasma aminotransferase levels.[131] This situation is less clear in acute hepatitis. Altered rates of fibrinogen catabolism may be the result of primary fibrinogenolysis or intravascular coagulation. In 1949, Ratnoff[132] documented primary fibrinolysis in cirrhosis of the liver, although more recent studies have failed to note this finding consistently. DIC in patients with liver disease is a complex and controversial area that is discussed later.

High levels of fibrinogen are occasionally observed in liver disease, mainly because fibrinogen is an acute phase reactant. Elevated levels of fibrinogen commonly accompany obstructive jaundice, biliary cirrhosis, and hepatoma.[133]

An abnormal fibrin monomer aggregate has been described in a number of patients with liver dysfunction.[134] The appearance of clotting defects involving prolongation of reptilase and thrombin clotting times, despite a normal fibrinogen concentration, should suggest that dysfibrinogenemia is present. Examination by sodium dodecyl sulfate–polyacrylamide gel electrophoresis of isolated fibrin from patients with liver disease failed to detect any molecular or structural defect associated with the polypeptide chains of fibrinogen.[135] An increase in sialic acid in the carbohydrate moiety of fibrinogen has been noted.[136]

Factors II, VII, IX, and X (Vitamin K–Dependent Factors)

Levels of vitamin K–dependent factors are often reduced in patients with liver disease.[137] This appears to result primarily from impaired synthesis. When hepatocellular damage is minimal (e.g., in mild acute or chronic hepatitis, obstructive jaundice, or biliary cirrhosis), these factors may be normal or increased.[138,139]

In acute and chronic liver disease, factor VII activity is generally reduced first and factor IX activity last.[140]

Of all the factors that may reflect hepatocellular damage, factor VII appears to be the most sensitive. Factor VII is synthesized almost exclusively in the liver and has the most rapid half-life (about 2 hours) of all the liver-dependent factors. In a study of patients with acute liver failure, it appeared that all those with factor VII activity exceeding 8% survived whereas the others died.[141] It is unfortunate that a direct factor VII assay is not available in many clinical laboratories, although some indication of factor VII activity is implied from the prothrombin time.

Factor V

Factor V activity usually parallels the activity of factors II and X in liver disease when the defect appears to be solely one of hepatic synthesis.[142] If DIC occurs in association with liver disease, the factor V level may be significantly depressed. Markedly elevated levels of factor V may be seen in obstructive liver disease, again as an acute phase reactant phenomenon.[138]

Factor VIII

Factor VIII procoagulant activity is generally normal or elevated in liver disease of all types.[143] Factor VIII antigen activity follows a similar pattern, except that antigenic activity will often exceed procoagulant activity by severalfold.[144] The explanation for this finding is not known.

Factors XI and XII

Factor XI activity is usually normal in hepatocellular disease but may be decreased.[145] The same is true of factor XII activity. The activity of both these factors may be elevated when the primary insult is obstructive.[138]

Factor XIII (Fibrin-Stabilizing Factor)

There are conflicting reports concerning factor XIII levels in liver disease. Reports of low activity have been based primarily on results of clot solubility tests[146]; however, when immunologic or radioisotopic techniques are used, more varied results are found.[147]

Plasminogen

Plasminogen levels are commonly decreased in liver disease. In one study, such levels were depressed in 45%

of patients with liver disease but without hepatic failure, whereas all patients with hepatic failure had diminished plasminogen levels.[142]

Antithrombin III

Antithrombin III levels are often decreased in patients with acute and chronic liver disease, whereas elevations may be observed in those with obstructive disease.[138,148]

α_2-Macroglobulin

Levels of this inhibitor of thrombin and plasmin have been found to be elevated in liver cirrhosis.

Tests for Coagulation Disturbances

Screening tests for coagulation disturbances often fail to give any indication that liver dysfunction exists. The sensitivity of both the prothrombin time and partial thromboplastin time for detecting mild to moderate depressions of factor levels varies markedly from laboratory to laboratory.

Although most studies have failed to show good correlation between clotting tests and cholesterol, transaminase, or γ-globulin levels, the prothrombin time still appears to be the most convenient clotting test for monitoring liver function.

As noted earlier, factor VIII antigen activity increases to very high levels with hepatocellular dysfunction. The level of factor VIII antigen can therefore be used to determine whether chronic active hepatitis is present because in uncomplicated acute hepatitis, antigen activity returns to normal within a few months.

Disseminated Intravascular Coagulation

Patients with liver disease commonly manifest a spectrum of coagulation abnormalities that are highly suggestive of DIC.[149,150] Findings consistent with DIC include hypofibrinogenemia, thrombocytopenia, increased fibrinogen catabolism, increased levels of fibrin degradation products, and depressed levels of other coagulation factors. This pattern of abnormalities is not specific for DIC and may simply reflect the severity of the hepatocellular disease process. For example, fibrinogen levels may be depressed on a synthetic basis alone. Increased catabolism of fibrinogen may reflect distribution in extravascular spaces, such as the formation of ascitic fluid or proteolysis by enzymes other than thrombin. Thrombocytopenia may occur for a variety of reasons and frequently is not present when other signs of DIC are seen. Changes in levels of factors V and VIII are varied and nonspecific. Because fibrin degradation products are cleared by the liver, severe liver dysfunction itself may cause elevations of these products without implicating DIC.[129] Studies reporting that heparin corrects DIC in liver disease are also open to some criticism because there is no evidence that the conditions of the patients studied were in a steady state at the time of heparin therapy.

Whether true DIC occurs in liver disease will probably remain a controversial subject for some time to come. As yet, no general recommendation for the use of heparin can be made. In the only controlled trial of heparin therapy in acute hepatic necrosis to date, no difference was found in recovery rates with or without heparin.[151] Fresh frozen plasma factor concentrates and platelet transfusions remain the treatment of choice. Care must be taken when factor concentrates are used because if contaminated by activated factor X, they may cause diffuse thrombosis.[152]

RENAL DISEASE

Renal disease may produce disturbances in red cells, white cells, platelets, and coagulation factors. In many instances the abnormalities that are found do not parallel the status of renal function but rather reflect the activity of the disease process that results in renal dysfunction. The hematologic aspects of renal insufficiency have been reviewed in detail.[153]

The Red Blood Cell

Anemia

Anemia is a common finding in renal disease. The erythrocytes of patients with renal disease are generally normochromic and normocytic without any distinguishing morphologic characteristics. Occasionally, scalloped or burr cells are observed, usually in association with uremia secondary to specific causes or related to specific syndrome complexes such as hemolytic-uremic syndrome.[154] In diseases associated with microangiopathic hemolytic anemia, red cell fragmentation is common. It may be observed in patients with malignant hypertension, renal cortical necrosis, polyarteritis nodosa, hemolytic-uremic syndrome, systemic lupus erythematosus, and thrombotic thrombocytopenic purpura.

The anemia of renal disease can have many causes, including a decreased rate of red blood cell production (the "anemia of chronic disorders"), shortened red blood cell survival, and nutritional factors.

In renal disease, unlike many other chronic disease states, close correlation exists between erythrocyte mass and erythrocyte survival.[155] This implies that shortening of red cell survival has an important role in the development of anemia in these patients. About 70% of patients with renal disease have shortened red cell survival related to a host of potential alterations. These cells demonstrate increased mechanical fragility, autohemolysis, diminished deformability, and a variety of metabolic defects.[156,157]

Decreased red cell production is, however, the major cause of the anemia of chronic renal failure. A deficiency in erythropoietin production is probably the primary cause,[158,159] but toxic suppression of hematopoiesis is also a contributing factor. In patients with acute or

chronic renal failure as a result of nephrectomy, normal or even increased erythropoietin production can be maintained.[160]

The red cells of patients with uremia have either a normal or an increased rate of glucose utilization. The increased glycolytic rate appears to be primarily a result of the associated hyperphosphatemia because inorganic phosphorus is a well-recognized stimulant of red cell glucose utilization.[161]

In uremic states, the level of hemoglobin A_1 (HbA$_1$) is elevated.[162] The increased HbA$_1$ level in uremia correlates with the level of blood urea nitrogen and results from carbamylation of hemoglobin by urea-derived cyanate. Most interestingly, the carbamylated hemoglobin level integrates the average blood urea nitrogen levels—a situation analogous to that seen in glycosylation of hemoglobin in diabetes.[162]

A circulating inhibitor of red cell metabolism accumulates in some, but not all uremic patients. This inhibitor diminishes recycling of glucose through the hexose monophosphate shunt,[156] a defect that may be clinically important. There are several reports of severe hemolytic disease in uremic patients given sulfa drugs. In patients with renal disease who have undergone splenectomy, Heinz bodies are commonly observed. Because of this problem, caution in the use of oxidant drugs is advised in those with azotemia.[163] The decreased shunt activity may be secondary to a metabolic defect within the shunt itself or due to a block within the main glycolytic pathway. When erythrocytes from patients with renal insufficiency are stressed with oxidant compounds such as sodium ascorbate, glucose consumption and lactate formation are abnormally increased, whereas lactate-to-pyruvate ratios are abnormally diminished. Red cell glycolytic intermediates—including fructose 1,6-diphosphate, glyceraldehyde 3-phosphate, 3-phosphoglycerate, phosphoenolpyruvate, and pyruvate—markedly accumulate. No increase in 2-phosphoglycerate occurs, thus suggesting that inefficient phosphoglyceromutase activity may underlie this defective glucose reutilization.[156]

Adenosine triphosphate levels are significantly increased in uremic red blood cells. This increase may not result solely from elevated serum phosphorus levels because red cells from uremic patients incubated in medium with an artificially low phosphate concentration demonstrate increased adenosine triphosphate synthesis activity.[164] Pyruvate kinase activity is significantly increased in uremic as opposed to normal red cells, thus suggesting the presence of a younger red blood cell population.[164]

Red blood cell 2,3-diphosphoglycerate (2,3-DPG) levels are increased as well for similar reasons.[165] This increase results in a significant shift to the right in the hemoglobin-oxygen dissociation curve, which favors oxygen release. After dialysis with correction of acidosis and hyperphosphatemia, there is a sharp increase in arterial pH and a decrease in red cell 2,3-DPG levels. Both these changes result in an acute change in the oxygen dissociation characteristics of red cells. Whether this produces any physiologic impairment after dialysis is unclear.[164] Recombinant human erythropoietin administered two to three times weekly is extremely effective in eliminating the need for transfusion in subjects with chronic renal failure.[166] This has been shown in children as well as adults.[167]

Other incidental causes of hemolysis may be observed during hemodialysis. Contaminants such as copper, nitrate, and chloramines in hemodialysis baths may cause varying degrees of hemolysis.[168-170]

Anemia associated with megaloblastic changes in bone marrow is not uncommon in chronic renal failure. This anemia is usually due to folate deficiency[171] caused by poor dietary intake, hemodialysis, peritoneal dialysis, or the effects of immunosuppressive drugs. In addition, defective protein-mediated folate transport may be present.[172] Serum from uremic patients may contain an increased concentration of folic acid–binding protein.[172] Folate deficiency is usually suspected when large numbers of macro-ovalocytes are seen in association with hypersegmentation of polymorphonuclear leukocytes on the peripheral blood smear.

Treatment may be needed for the anemia associated with renal disease. In chronic renal disease, anemia is partially compensated for by improved oxygen unloading as a result of the high red cell content of 2,3-DPG. The treatment of choice for the anemia of chronic renal failure is the use of recombinant erythropoietin.[173,174] Recent studies, however, have challenged its efficacy in stage 3 and 4 chronic kidney disease. A randomized controlled trial enrolled 603 patients with chronic kidney disease and found that raising the hemoglobin to 14 g and higher did not improved cardiovascular outcomes.[175] In fact, a meta-analysis revealed that hemoglobin concentrations higher than 12 g/L place patients at increased risk for death, and thus the guidelines have been modified accordingly.[176] Iron therapy may be required as well.[177] The possible benefits of androgen therapy must be weighed against the side effects of this class of drugs.

Polycythemia

Erythrocytosis is a well-recognized complication of hydronephrosis[178] and has occasionally been noted in association with chronic glomerulonephritis, pyelonephritis, nephrosclerosis, and nephrotic syndrome in adults.[179] Erythrocytosis is a common finding after renal transplantation.[180] The cause of the elevated red cell mass in most patients appears to be mediated by erythropoietin.

The White Blood Cell

Azotemia and uremia per se appear to have relatively little effect on white blood cell function. Granulocytopenia is common during hemodialysis[181] and appears to be due to transient sequestration of granulocytes in the pulmonary vascular bed followed by later release back into

the circulation. After hemodialysis, a transient augmentation in granulocyte adherence coincides with the time of sequestration of the pulmonary vascular bed.[182] The adherence-augmenting factor in the plasma of patients undergoing dialysis is heat stable. Craddock and co-workers[183] believe that this factor is complement activated by contact with the dialysis coil. However, the use of 5-hydroxyindole-3-acetic acid, a complement inhibitor, fails to block the granulocytopenia associated with dialysis.[184]

Neutropenia as a result of folate deficiency may be present in patients with renal failure. The cause of the neutrophil nuclear hypersegmentation associated with uremia is unknown and should not be attributed to folate deficiency.

Coagulation Abnormalities

Patients with uremia may have varied changes in some coagulation factors. Among the most common abnormalities observed are mild to moderate depressions in factors V, VII, IX, and X.[185,186] These abnormalities are related to the high incidence of hepatic dysfunction in patients with uremia or vitamin K deficiency.[39] The level of fibrinogen is regularly elevated because it is an acute phase reactant.[187-189] Increased fibrinogen turnover has been demonstrated in experimental models,[190] and excessive fibrin degradation products have been found in the urine and serum of uremic patients.[191] When a decrease in one or more consumable clotting factors (factors I, II, V, or VIII) is also present, it may signify the existence of consumptive coagulopathy.[185,186,192] Because fibrin deposition may occur in the absence of such a coagulopathy, it is often helpful to determine whether high-molecular-weight fibrin degradation products are present in the urine and serum. If found only in the urine, such products are probably derived from the dissolution of fibrin deposits in the kidneys. If demonstrable simultaneously in urine and serum, their presence indicates renal injury because such degradation products cannot be demonstrated in the urine of patients with streptokinase-induced fibrinolysis who have no renal disease.[193,194] Fibrin degradation products in the urine and serum usually indicate active renal disease, although other reasons for this finding may be seen in patients with renal disease. Fibrin degradation products may also result from concomitant liver disease or from an external shunt used for hemodialysis.[47] Urinary fibrinolytic activity is either diminished or absent in renal failure, and inhibitors of urokinase-induced plasminogen activation are demonstrable.[193]

Nephrotic syndrome is often accompanied by changes in a number of coagulation factors.[195] Increased levels of fibrinogen, factor VIII, and the factor VII-X complex are commonly present.[196] A prolonged partial thromboplastin time is often observed and is usually due to a decrease in the plasma level of factor IX.[197] Factor IX is consistently found in urine containing more than 10 g of protein per 24 hours in patients with nephrotic syndrome.[198] Plasma

levels of factor IX rarely decrease to less than 10%, and clinical bleeding episodes are unusual. With resolution of the proteinuria in patients receiving corticosteroid therapy, levels of factor IX increase. Factors II and VII have also been identified in considerable quantity in the urine of patients with nephrotic syndrome despite normal levels of these factors in plasma.[199] This finding suggests that loss of some coagulation factors into urine can be fully compensated for by an increased rate of synthesis. A prolonged partial thromboplastin time may also be due to a low level of Hageman factor (factor XII).[200] Hageman factor has a molecular mass of approximately 75,000 kd, similar to that of albumin, and losses in urine are to be expected.[201] Although factor XII levels may decrease to less than 10%, as with congenital deficiency of this factor, bleeding is not a problem. Patients with nephrotic syndrome appear to have a substantially higher risk for thromboembolic complications,[193] although the exact reasons are still mainly unknown. Enhanced platelet function characterized by hyperaggregability has been observed.[202] An identical defect is seen in diabetics[203] and many patients with advanced cirrhosis of the liver.[204] Such changes may relate to alterations in plasma lipid fractions and are discussed in detail in Chapter 29. The coagulation defects associated with nephrotic syndrome have been reviewed by Kaufmann and colleagues.[205]

The hypercoagulable state seen in many forms of renal disease may be compounded by the occurrence of lupus-like anticoagulants. This is common in a variety of end-stage renal diseases, with a rate of occurrence as high as 22%.[206] Whether therapy focused on prevention of fibrin deposition within the kidney is of benefit to patients with certain forms of glomerulonephritis remains uncertain. Kincaid-Smith[207,208] used a combination of an anticoagulant, dipyridamole, and cyclophosphamide in a series of patients with membranoproliferative glomerulonephritis. A similar approach was reported by Robson and associates,[209] but with azathioprine substituted for cyclophosphamide. In both studies it was suggested that these therapies produced improvement in the patients' clinical course. The concept of anticoagulation therapy for these disorders has been reviewed.[210] The pathophysiology and management of hemolytic-uremic syndrome are discussed in Chapter 29.

Platelet Abnormalities

Mild thrombocytopenia occurs in approximately 25% of patients with acute renal failure and 10% of those with chronic renal disease.[211] The thrombocytopenia is most likely due to impaired production because platelet life span in uremia is generally normal.[188] Platelet function is abnormal in patients with renal failure. The standardized Ivy bleeding time is usually prolonged and generally correlates with the clinical tendency for bleeding in these patients.[212] Platelet adhesion and platelet factor 3 availability are diminished in acute and chronic uremia.[213] Impaired aggregation of platelet-rich plasma in the pres-

ence of adenosine diphosphate,[214] epinephrine,[215] thrombin,[215] and collagen[215] has been observed by various workers. Clinical bleeding episodes related to these platelet abnormalities can usually be managed with 1-deamino-8-D-arginine vasopressin given intravenously.[216] Long-term administration of recombinant erythropoietin also improves the biochemical and functional changes in the platelets of uremic patients.[217]

Platelet functional abnormalities are not due to an intrinsic platelet defect because dialysis quickly reverses these changes and incubation of normal platelets in plasma from uremic patients promptly induces functional aberrations. Rather, platelet dysfunction appears to be due to the interaction of intrinsically normal platelets with various abnormal dialyzable metabolites found in the plasma of uremic patients.[218] If urea and creatinine levels are elevated, some of these findings can be reproduced.[218] Phenols[187] and guanidinosuccinic acid,[219] which accumulate in the plasma of uremic patients, can also account for platelet functional abnormalities. These findings are discussed in detail in Chapter 29.

Several hereditary disorders have been reported in which quantitative or qualitative platelet abnormalities occur in association with nephritis. In 1972, Epstein and associates[220] described a family with hereditary macro-thrombopathia, nephritis, and deafness. The renal pathologic findings are identical to those described in patients with classic hereditary nephritis and nerve deafness (Alport's syndrome) and consist of sclerosing and proliferative glomerulonephritis and interstitial nephritis with fibrosis. Members of these families have large platelets, prolonged bleeding times, defective platelet factor 3 activity, and defective platelet aggregation in the presence of adenosine diphosphate, collagen, and epinephrine. Coexpression of May-Hegglin anomaly and hereditary nephritis has been described in several families.[221] Thrombocytopenia is also present in this autosomal dominant disorder.[222] A similar disorder, but with normal platelet function, has been described by Eckstein and associates.[223] In these families, platelet survival studies have been normal.

Vascular occlusion of the kidney may result in eosinophilia. Approximately 80% of adult subjects with embolic renal disease have eosinophil counts ranging from 540 to 2000 cells/mm³.[224]

ENDOCRINE DISORDERS

Disturbances in endocrine balance tend to produce real, but relatively mild hematologic abnormalities. The most thoroughly evaluated of these abnormalities are those caused by thyroid disorders.

Thyroid Gland

Thyroid hormone appears to have many hematologic effects (Table 36-1), with the most impressive being its

TABLE 36-1	Hematologic Effects of Thyroid Hormone	
↑ **Thyroid Hormone**	↓ **Thyroid Hormone**
↑ PRBC volume	↓ PRBC volume
Variable effect on RBCs	↑ Or normal MCV; spiculated RBCs
↑ Glucose utilization and hexose monophosphate shunt activity	↑ O_2 affinity
↓ RBC glutathione, reduced	↓ 2,3-Diphosphoglycerate
↑ Red cell 2,3-diphosphoglycerate	↓ RBC Na^+
↓ O_2 affinity	↓ Platelet adhesion
↑ Diphosphoglycerate mutase activity	↓ (Slight) platelet aggregability
↑ Glyceraldehyde-3-phosphate dehydrogenase	↓ Factor VIII activity
↑ Glucose 6-phosphate activity	↑ Fibrinolytic activity
↓ RBC carbonic anhydrase	↑ Plasminogen
↓ RBC zinc	↑ Plasminogen activation
↑ RBC Na^{2+}	↓ Plasminogen activation
↑ (Slight) platelet turnover	↓ Capillary fragility
↑ Platelet adhesion	↑ Factors VIII, VII, IX, XI activity
↑ Platelet aggregability	
↑ Factor VIII activity	
↓ Plasminogen activation	
↑ Capillary fragility	

MCV, mean corpuscular volume; PRBC, packed red blood cell; RBC, red blood cell.

effect on erythropoiesis. Although thyroid hormone slightly stimulates erythropoiesis in vitro,[225] the anemia caused by thyroid hormone deficiency is a secondary finding. Autoimmune hemolytic anemia may be seen in association with Graves' disease.[226] Most workers have correlated the erythropoietic effects of thyroid hormones with their calorigenic properties. Thyroid hormone increases oxygen consumption, which results in increased renal production of erythropoietin and stimulation of erythropoiesis. However, the erythropoietic stimulatory effect may, in fact, occur independently of erythropoietin. Administration of triiodothyronine and thyroxine to nephrectomized rats produces an increase in bone marrow erythroid precursors.[227]

The anemia of hypothyroidism is usually normochromic and normocytic and occasionally mildly macrocytic.[228] Small numbers of irregularly contracted red blood cells may be noted on the peripheral blood smear (Fig. 36-1).[229] Red cell survival is normal, and ferrokinetic studies demonstrate a decreased rate of iron clearance. In adults with hypothyroidism, an unusually high incidence of iron deficiency[230] and pernicious anemia is found.[231] A single confounding occurrence of erythrocytosis in association with hypothyroidism has been described.[232] Subsequent to this case report, a series of 23 patients with congenital hypothyroidism have been
FIGURE 36-1. Red blood cell morphologic features in hypothyroidism. *(From Wardrop C, Hutchinson HE. Red cell shape in hypothyroidism. Lancet. 1969;2:1243.)*

evaluated for the presence of anemia. Of these infants, 26% had elevated hemoglobin levels, some of which were marked.[233]

Somewhat opposite findings are noted in uncomplicated hyperthyroidism. Anemia is rare, and red blood cell indices are normal. There is usually an increase in red blood cell mass that does not result in significant increases in hemoglobin concentration because a similar elevation in plasma volume also occurs.[234] Erythrocyte survival is normal or mildly diminished, especially in thyrotoxic children.[235] Peripheral blood and bone marrow lymphocyte counts may be increased.

Thyroid hormone may play a role in the regulation of red cell metabolism. Thyroxine has been reported to increase red cell glycolysis.[236] It helps regulate red cell carbonic anhydrase I concentrations.[237] Hexose monophosphate shunt activity may increase in the presence of triiodothyronine.[238] The activity of glucose-6-phosphate dehydrogenase is consistently elevated in thyrotoxicosis, whereas normal levels are found in most patients with mild hyperthyroidism.[239] Glutathione levels are usually depressed in hyperthyroidism. Thyroid hormone may affect the activities of several other red cell enzymes. This hormone stimulates diphosphoglycerate mutase and glyceraldehyde-3-phosphate dehydrogenase.[240] These effects may be the cause of the elevated levels of red cell 2,3-DPG that are seen in patients with hyperthyroidism and that result in decreased whole blood oxygen affinity and a shift to the right in the hemoglobin-oxygen dissociation curve.[241] Opposite effects are seen in hypothyroidism. The carbonic anhydrase activity of erythrocytes is diminished in hyperthyroidism and increased in hypothyroidism. Because red cell zinc is almost exclusively con-

tained in carbonic anhydrase, hyperthyroidism will result in a decrease in total red cell zinc levels.[242]

The red blood cells of patients with hyperthyroidism may have increased osmotic resistance.[243] The red cell sodium concentration is significantly increased in hyperthyroidism, and decreased sodium pump activity may be present.[244]

Neutropenia may occur in approximately 5% of children with hyperthyroidism.[245] The mechanism of this abnormality is unclear, although some patients will have antineutrophil antibodies.[246]

Multiple effects on platelets and blood coagulation factors may occur in thyroid disease states. Marked hyperthyroidism may reduce platelet survival.[247] Egeberg[248] reported on a patient with hypothyroidism who had a prolonged bleeding time and low factor VIII activity, similar to findings in von Willebrand's disease. Autoimmune thrombocytopenia has been observed in association with hyperthyroidism[249] and is related to increases in mean platelet volume.[250]

Simone and associates[251] reported on patients with hypothyroidism who had multiple coagulation factor deficiencies. Diminished platelet responsiveness to epinephrine and low platelet adhesiveness may be present as well.[252] Impressively low levels of factor VIII occur occasionally, with milder depression of factors VII, IX, and XI being found either alone or in combination.[253] In hypothyroidism, increased plasma fibrinolytic activity may result from an elevation in plasma plasminogen and a decrease in an inhibitor of plasminogen activation.[253,254] This may account for the mild to moderate increase in levels of fibrinogen and fibrin split products occasionally found in patients with hypothyroidism.[253] Menorrhagia secondary to acquired hypothyroidism-related von Willebrand's disease has been reported.[255]

Adrenal Gland

Adrenal cortical steroid hormones appear to have a stimulatory effect on erythropoiesis. In Addison's disease, the adrenal insufficiency may cause mild to moderate anemia, probably as a result of reduced basal metabolism. In most patients, a decrease in plasma volume masks the decreased red cell mass. After treatment of adrenal insufficiency, the plasma volume corrects quickly, whereas the red cell mass responds over a period of several weeks. The usual effect of treatment is therefore a prompt decrease in hemoglobin concentration followed by a gradual increase.[256]

Erythrocytosis may occur in Cushing's syndrome, but in most patients the reported increase has been slight.

A variety of effects on leukocytes occur after steroid administration or endogenous overproduction of a steroid, including granulocytosis, a reduced lymphocyte count, involution of lymphatic tissue, and a decrease in peripheral blood eosinophils and monocytes. In Addison's disease, neutropenia, eosinophilia, and lymphocy-

tosis appear.[257] Coagulation abnormalities suggesting a hypercoagulable state may be seen in patients with Cushing's syndrome.[258]

Glucocorticosteroids affect lymphoid cells in many ways. The effects, however, are species specific. The mouse, rat, hamster, and rabbit are steroid sensitive; many of their lymphoid cells are easily lysed by steroids, and in these species, steroids inhibit antibody production. Human, simian, and guinea pig lymphoid cells are not easily lysed by steroids; in these species, it is difficult to demonstrate profound steroid inhibition of antibody production.[259] Cellular metabolism, including nucleic acid synthesis and glucose uptake, is inhibited.

The mechanism by which endogenous or exogenous steroids lower the number of circulating eosinophils is unknown.

Testes and Ovaries

Hematologic abnormalities are rare in association with gonadal dysfunction. This does not mean that the gonadal hormones play no role in hematopoiesis. Androgens stimulate erythropoiesis, whereas estrogens, in general, depress red cell production. Castration of the adult male results in a definite decrease in red cell mass.[260] In disorders associated with androgen excess, such as Cushing's syndrome and congenital adrenal hyperplasia, the hemoglobin concentration may exceed normal values. Exogenous androgen administration may cause polycythemia and may also increase red cell 2,3-DPG.[261] Androgens appear to stimulate erythropoiesis by increasing erythropoietin production, as well as by having a direct effect on bone marrow stem cells.

The normal menstrual cycle is associated with hematologic variations. Delivoria-Papadopoulos and colleagues[262] described cyclic variations in endogenous carbon monoxide production during the menstrual cycle of fertile women and suggested that heme catabolism was increased during the progesterone phase. It has been known for some time that reticulocyte counts are increased during the progesterone phase.[263] A cyclic variation in erythrocyte deformability also occurs during the menstrual cycle.[264] The relationship between decreased red cell deformability, reticulocytosis, and increased heme catabolism is speculative. A similar decrease in deformability occurs during the last trimester of pregnancy and with the use of oral contraceptives.[265,266]

Pregnancy causes increases in levels of several coagulation factors, including factors I, VII, VIII, IX, and X.[267] Carriers of genes for classic hemophilia and von Willebrand's disease may have significantly increased factor VIII activity during pregnancy.[267] Plasma fibrinolytic activity diminishes during pregnancy.

Pituitary Gland

The hematologic effects of pituitary disease are usually a consequence of the action of trophic hormone on target endocrine organ function. For example, anemia is common in patients with hypopituitarism.[268] This normochromic, normocytic anemia is associated with findings of lymphocytosis and eosinophilia, which indicate that this effect of hypopituitarism results from adrenal insufficiency. Erythropoietin production may be diminished as a consequence of a lower metabolic rate.

Growth hormone may play an important role in erythropoiesis.[269] This hormone stimulates erythropoiesis directly and indirectly by increased production of erythropoietin. The red blood cell count may decrease with isolated growth hormone deficiency.[270] Erythrocyte glucose-6-phosphate dehydrogenase activity is low in hypopituitarism and increases with growth hormone administration.[271] Growth hormone depresses erythrocyte glycolysis.[272]

Megaloblastic and sideroblastic anemia, neutropenia, and thrombocytopenia have been reported in children with the DIDMOAD syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness). It is thought to be an inherited abnormality of thiamine metabolism.[273]

PULMONARY DISEASE

Hypoxia may be caused by a wide variety of pulmonary disorders and, in turn, results in a form of secondary polycythemia and compensatory shifts in the hemoglobin-oxygen dissociation curve that can be attributed to an increase in the red cell content of 2,3-DPG. Rarely, the polycythemia results in a state of extreme hyperviscosity and decreased tissue blood flow. Other than polycythemia, the hematologic findings of specific pulmonary disorders tend to be unique to those disorders.

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis (IPH) is an uncommon chronic disease that usually affects children and young adults. However, the age at onset may be as early as the newborn period.[274] IPH is characterized by recurrent intrapulmonary hemorrhage and may result in hemoptysis and pulmonary insufficiency. The hematologic manifestation of this disorder is iron deficiency anemia.

The etiology of IPH is not known. A hereditary or familial tendency has been suggested. An immunologic cause seems likely because other occasional findings include positive Coombs' test results, the presence of cold agglutinins, and an increased number of mast and plasma cells in the lungs. Various etiologic hypotheses such as congenital weakness or fragility of the capillaries, milk allergy, and abnormal growth and function of alveolar epithelial cells have all been suggested.[275] Cow's milk pulmonary vasculitis as the

cause of pulmonary hemosiderosis remains a popular theory.[276]

The most helpful clinical signs for identifying IPH are iron deficiency anemia and recurrent or chronic cough, hemoptysis, dyspnea, wheezing, and frequently cyanosis. Any single feature may be present without the others. For example, occasionally the only clinical sign is iron deficiency anemia.[277] Pulmonary symptoms may be present without radiologic findings and vice versa. When pulmonary symptoms are predominant, there may be associated fever, tachycardia, tachypnea, leukocytosis, an elevated sedimentation rate, and occasionally, abdominal pain.[278] Roentgenographic abnormalities vary from minimal transient infiltrates to massive parenchymal involvement with atelectasis, emphysema, and hilar adenopathy.[279,280]

The anemia reflects an iron deficiency state resulting from excessive accumulation of iron in the lungs. This iron is usually sequestered in alveolar macrophages and is largely unavailable for new red cell formation. With time, however, the iron is eventually lost from the lungs.[281] In some patients, iron administration fails to correct the anemia. This is usually a reflection of inadequate heme synthesis resulting from the anemia of chronic disorders. Immune hemolytic anemia may occur, and cold agglutinins are often present. Eosinophilia is found in 15% to 20% of children with IPH.

A diagnosis of IPH may be made by the finding of siderophages in the gastric aspirate. Siderophages will stain positive with Prussian blue dye. If the diagnosis of IPH is seriously being considered, it may be necessary to perform a lung biopsy. Typical findings include alveolar epithelial hyperplasia, degeneration with excessive shedding of cells, large numbers of siderocytes, varying amounts of interstitial fibrosis and mast cell accumulation, elastic fiber degeneration, and sclerotic vascular changes.[282] Electron microscopic examination shows no evidence of subendothelial deposits or basement membrane lesions.[283] No evidence for localization of immunoglobulin G (IgG), IgM, B$_{1c}$, C1q, or fibrinogen has been found.[281] The results of needle aspiration or needle biopsy may also provide a diagnosis,[284] although some workers have considered these procedures to be hazardous.

Treatment of IPH continues to be a controversial subject. Corticosteroid therapy will sometimes produce a remission of disease activity.[285,286] Immunosuppressive therapy may be useful, but the results of such treatment are unpredictable.[287,288] In 1962, Heiner and associates[289] reported the presence of precipitating antibodies to a small number of cow's milk antigens in the sera of several children with IPH. Reversal of symptoms followed withdrawal of cow's milk, and recurrence was noted with reinstitution of cow's milk in the diet. Although many, if not most children with IPH fail to show these responses, a trial of removal of cow's milk from the diet is appropriate in most instances.[290] Abstinence should be continued for 2 to 3 months.

Pulmonary Hemosiderosis from Other Causes

Clinical findings of hypochromic and microcytic anemia and pulmonary infiltrates may be seen in association with glomerulonephritis (Goodpasture's syndrome), collagen vascular disease (especially periarteritis nodosa), Wegener's granulomatosis, and occasionally, systemic lupus erythematosus.[291-294] Similar findings in association with anaphylactoid purpura have been noted. Episodes of pulmonary hemosiderosis have been described in subjects with cystic fibrosis and celiac disease.[295,296]

Hematologic Findings in Other Pulmonary Disorders

Sarcoidosis does not usually cause specific hematologic disturbances, although a higher than average incidence of blood group antigen A has been reported in this disorder.[297,298] Anemia and leukopenia have been reported in sarcoidosis. One study has suggested that 87% of affected patients will have hematologic abnormalities, the most common of which is anemia (28%). Bone marrow granulomas are noted occasionally.[299] The significance of this finding is not known, but the altered immune response of these patients[300] and an association of sarcoidosis with hemolytic anemia[301] and immune thrombocytopenia[302-304] suggest that sarcoidosis represents a generalized autoimmune disorder and that it may be related to abnormal balance of T-cell subset production. Severe thrombocytopenia may occur in subjects with sarcoidosis.[305]

Eosinophilia may be observed in a variety of pulmonary disorders, including asthma, Löffler's syndrome, tropical pulmonary eosinophilia, polyarteritis nodosa, and sarcoidosis.

Patients with cystic fibrosis demonstrate a significant impairment in erythropoietic response to hypoxemia.[306] There is neither an appropriate increase in hemoglobin level nor an adequate shift in the red cell–oxygen affinity curve. Failure of the hemoglobin-oxygen dissociation curve to compensate means that such patients may be more symptomatic at any given hemoglobin level than patients who have anemia and other disorders. Disturbances in erythropoietin regulation, as seen in the anemia of chronic disorders and iron deficiency, appear to be the principal cause of the relative anemia in children with cystic fibrosis.[307] If a severe hemolytic anemia is observed in a subject with cystic fibrosis, it may be related to vitamin E deficiency.[308]

COLLAGEN VASCULAR DISEASES AND THE ANEMIA OF CHRONIC DISORDERS

The anemia of chronic disorders and its concomitant reticuloendothelial siderosis are associated with a wide

TABLE 36-2	Findings in the Anemia of Chronic Disorders and Iron Deficiency

variety of illnesses, including cancer, lymphoma, collagen vascular disease, severe tissue injuries, renal failure, and infectious processes.[309] Unfortunately, each of these disorders may be associated with multiple sources of anemia, including blood loss, hemolysis, and drug suppression. A diagnosis of anemia of chronic disorders should not be made without consideration of other potential causes.

The anemia of chronic disorders is usually mild. It is characterized by decreased plasma iron levels, decreased total iron-binding capacity of plasma, decreased saturation of transferrin by iron, reduced numbers of bone marrow sideroblasts, and normal or increased levels of reticuloendothelial iron (Table 36-2).[310]

The anemia, when it occurs, develops slowly over a period of a month or longer until a plateau is reached. The hematocrit rarely decreases to less than 30% in adults and the low 20% range in children. The anemia is most often normochromic and normocytic with a low or normal percentage of reticulocytes. Occasionally, hypochromic and normocytic anemia is observed; less often, hypochromia and microcytosis are found.[309] In contrast to the situation in iron deficiency anemia, the uncommon microcytosis of chronic disorders is rarely proportional to the degree of anemia associated with these conditions.

The pathophysiologic processes that cause the anemia of chronic disorders are complex. At least three factors are commonly operating: shortened red cell survival, impaired marrow response to anemia, and impaired flow of iron from reticuloendothelial cells to the bone marrow.

The shortening of red cell survival is not seen in the anemia of all chronic disorders.[311] Autologous survival may be mildly shortened, but when the red blood cells of an affected individual are transfused into normal recipients, survival is normal.[312] The nature of the extracorpuscular defect has not been defined.

Bone marrow fails to develop an erythropoietic response to the anemia. Although normal bone marrow can increase red blood cell production sixfold to eightfold, the maximum response in the anemia of chronic disorders is one to two times normal.

Studies of the release of erythropoietin have produced conflicting results. In some cases there appears to be defective production or release of erythropoietin.[313]

Response to erythropoietin has been noted in rats with chronic inflammatory reactions.[314] Cobalt, which acts by means of the production of cellular hypoxia and release of erythropoietin, improves the anemia of infection in dogs and humans.[315,316] However, some resistance to the effects of erythropoietin is seen that probably relates to the block of iron release to transferrin.[317]

An impairment in iron release from the reticuloendothelial system accounts for the iron-deficient type of erythropoiesis seen in these disorders. This block in iron utilization is most easily demonstrated by iron kinetic studies in which plasma iron clearance is normal but the presence of iron in circulating red blood cells (utilization) is markedly diminished.[318,319] The consequences of this blockage are a decrease in plasma iron levels, a decrease in marrow sideroblasts, and an increase in red cell protoporphyrin concentration, all in the presence of normal or increased reticuloendothelial iron.

Iron absorption in the anemia of chronic disorders may be either normal or diminished. Diminished absorption is not due to defective uptake of iron into intestinal cells but rather results from an inability to release intracellular iron.[320] In any event, sufficient iron is absorbed to maintain adequate reticuloendothelial stores.

The reduced levels of plasma transferrin so commonly noted may be due to diminished production or to increased binding to iron-overloaded reticuloendothelial cells.[309] The latter cause may, in fact, be more important because transferrin levels tend to increase in the anemia of chronic disorders if iron deficiency develops.

There has been a common clinical impression that the degree of anemia associated with inflammation may vary with the specific cause of the inflammation. If the cause of the inflammation is infectious, this impression may not be true. Subjects with meningitis, cellulitis, mastoiditis, septic arthritis, osteomyelitis, bacterial endocarditis, and streptococcal pharyngitis all experience a mean decrease in hemoglobin concentration of 1.8 g/dL during active inflammation over a 6-day period.[321] The anemia of mild viral infection is associated with a decrease in hemoglobin of 1.0 g/dL in 9% of individuals and greater than 0.6 g/dL in 24%. After the administration of live attenuated measles vaccine, 22% of infants overall are expected to be anemic. This anemia persists for 14 to 31 days.[322]

Diagnosis of the anemia of chronic disorders is based on the typical findings of a low plasma iron level, low plasma transferrin concentration, and a low percentage of marrow sideroblasts despite normal or increased reticuloendothelial iron levels (see Table 36-2). Bone marrow examination is not critical in establishing the diagnosis if a serum ferritin determination is obtained because the serum ferritin level is normal or increased in the anemia of chronic disorders,[323] even in the presence of hypoferremia. Plasma copper levels are usually increased.

No specific therapy is available for this anemia other than treatment of the basic disease. Iron therapy is of no value because when given either orally or by intramuscular injection, the iron is first cleared in the reticuloendothelial system. Intravenous iron infusions would most probably improve marrow iron delivery but are neither practical nor therapeutically indicated for this problem. Occasionally, a patient with the anemia of chronic disorders is also iron deficient, particularly one with rheumatoid arthritis,[324] in whom gastrointestinal bleeding caused by aspirin therapy is common. Such a patient may respond partially to iron therapy.

Readers interested in a comprehensive review of the anemia of chronic disorders are referred to Hansen's 1983 report[325] and Chapter 12.

Hematologic Aspects of Collagen Vascular Disease

Many of the hematologic manifestations of the various collagen vascular diseases are similar. However, the characteristics that are unique to each syndrome are emphasized in this section.

Rheumatoid Arthritis

The most common causes of anemia in rheumatoid arthritis are the anemia of chronic disorders and iron deficiency. These two causes can be difficult to distinguish because of overlap in many of the laboratory findings. In both instances, the serum iron level is depressed, and free erythrocyte protoporphyrin levels are elevated. The serum ferritin level may be normal in the iron deficiency associated with rheumatoid arthritis.[324] In the absence of iron deficiency, the anemia of rheumatoid arthritis can be corrected with recombinant erythropoietin therapy.[326]

A high incidence of iron deficiency is seen in children with rheumatoid arthritis, possibly secondary to the ingestion of large quantities of aspirin or in part to defective iron absorption. Koerper and co-workers[324] found that a serum ferritin concentration less than 25 ng/mL was useful in predicting a response to oral iron, but a value greater than 25 ng/mL does not preclude a response.[325] Laboratory tests often fail to distinguish between iron deficiency and the anemia of chronic disorders, so a clinical trial of iron therapy may be necessary. Because medicinal iron may be absorbed poorly in subjects with chronic inflammatory states, low-dose intravenous iron may be used effectively.[327]

Microcytosis is very common in juvenile chronic forms of arthritis, with a rate of occurrence of about 40%. The degree of microcytosis relates directly to disease activity.[328] Occasionally, macrocytic anemia develops in patients with juvenile rheumatoid arthritis.[329] Although abnormal vitamin B_{12} metabolism has been suggested as a cause, this is not seen in children. Folate metabolism may, however, be abnormal. Some children with rheumatoid arthritis have diminished plasma and red cell folate levels.[330] Increased folic acid plasma clearance and reduced protein binding have also been observed.[331]

A few patients have had mild shortening of red cell survival as a result of an extracorpuscular defect.[332] More severe hemolytic anemia is much less common than in other collagen vascular diseases. Erythroid aplasia responsive to corticosteroid therapy has been reported in a child with juvenile rheumatoid arthritis.[333] Circulating inhibitors of erythropoiesis have also been noted.[334]

Leukocytosis and neutrophilia are common during acute flare-ups of juvenile rheumatoid arthritis; however, this is uncommon in the adult form of the disorder. Neutrophil chemotaxis may be mildly diminished.[335] Phagocytosis is normal or mildly impaired.[336] Nitroblue tetrazolium dye reduction may be increased during active phases of this disease.[337] These minimal alterations in white cell function do not produce any clinical disturbances. Wound healing, for example, is normal even after surgery in patients who have not been receiving high-dose corticosteroid therapy.[338] A peripheral blood eosinophil count greater than 5% has been noted in slightly more than 50% of children with juvenile rheumatoid arthritis.[339] Some will also demonstrate basophilia and plasmacytoid lymphocytes.[340,341]

A consumptive coagulopathy may be seen in association with systemic juvenile rheumatoid arthritis.[342-344] Acquired circulating inhibitor to factor VIII has been described in juvenile rheumatoid arthritis and may cause bleeding.[343] Clinical problems related to coagulation abnormalities in this disorder are rare, however.[344]

Transient thrombocytopenia may be observed in systemic-onset juvenile rheumatoid arthritis. It need not be an autoimmune form of thrombocytopenia.[345]

The symptoms and signs of rheumatoid arthritis can be very similar to those of acute lymphatic leukemia and include fever, joint pain, and anemia. Therefore, the diagnosis of acute lymphatic leukemia should be excluded before treatment of rheumatoid arthritis is instituted.

Elevated platelet counts occur in many patients with juvenile rheumatoid arthritis. No consistent functional defects have been described.

Felty's Syndrome

Felty[346] originally described the triad of rheumatoid arthritis, splenomegaly, and neutropenia in 1924. Whether Felty's syndrome occurs with juvenile rheumatoid arthritis is unclear. Splenomegaly is seen in about 20% of all children with rheumatoid arthritis and especially in those with the acute extra-articular exacerbations of this disease. However, splenomegaly alone does not suggest Felty's syndrome.

The neutropenia of Felty's syndrome is not a consequence of hypersplenism per se because only 60% of adults who undergo splenectomy experience resolution of their neutropenia.[347] In some patients, bone marrow demonstrates granulocyte arrest. Neutropenia in association with cytotoxic lymphocytes directed against granu-

locyte progenitors has also been reported.[348] Lower than normal levels of granulocyte colony-stimulating activity have been reported rarely.[349] The neutropenia of Felty's syndrome may represent, in part, an immunologic phenomenon because IgG antibodies directed against neutrophils have been observed in the sera of patients with rheumatoid arthritis.[350,351]

The neutropenia may be associated with serious infections. Splenectomy may be indicated in these circumstances because a favorable response may be observed, but the response is variable. The most consistent result is a reduction in serum granulocyte-binding immunoglobulin.[352] An alternative to splenectomy is the use of granulocyte colony-stimulating factor, which has been effective in some patients.[353-355]

Systemic Lupus Erythematosus

Anemia is the most common hematologic abnormality in systemic lupus erythematosus.[356,357] There are multiple causes of anemia in this disease, although the anemia of chronic disorders is probably the most common.

Acquired immune hemolytic anemia may precede the onset of active lupus. Although positive results on an antiglobulin test are common (either to γ-globulin, complement, or both), true hemolysis is seen in less than 10% of patients.[358]

Aplastic anemia has been reported in association with lupus but appears to be more common in scleroderma.[359]

A reduction in the total white blood cell count is seen in most patients but is more common in adults than children. The leukopenia is usually caused by a combination of decreased numbers of granulocytes and lymphocytes.[360] Antibodies to granulocytes have been proposed as one mechanism for the granulocytopenia. Granulocyte antibodies and peripheral granulocyte destruction have been observed.[361] Bone marrow depression of granulocyte formation may also occur. Sera from patients with systemic lupus erythematosus can inhibit mouse bone marrow colony-forming units.[362] Qualitative abnormalities in granulocyte function have also been noted. Although several investigators have found no abnormalities in chemotaxis,[335,363] others have observed abnormal migration by the skin window technique and diminished in vitro phagocytosis.[364,365] These defects parallel the observed depressions in complement. The qualitative defects in granulocyte function may be the result of altered humoral factors rather than defects in the phagocytic cells themselves.

Lymphopenia may be severe in lupus[366] and is sometimes due to IgG or IgM antilymphocyte antibodies.[367-369] In contrast to the depression of T and B cells, the percentage and absolute number of null cells increase.[370] The magnitude of the reduction in T cells parallels disease activity and is associated with defects in cellular immunity as measured by skin tests of delayed hypersensitivity, blast transformation in response to mitogen (phytohemagglutinin and concanavalin A), and macrophage-

inhibiting factor production.[366,371] Unlike T-cell function, B-cell function is increased despite the decrease in the absolute number of B cells.[372,373] There is actually an increase in IgG-synthesizing peripheral blood lymphocytes, as well as elevated numbers of cells capable of binding native DNA and elevated numbers of IgM- and IgG-producing cells with antibody specificity against DNA antigen.[374,375] These changes in peripheral blood lymphocytes are associated with certain morphologic alterations. A strongly basophilic cytoplasm and a high nuclear-to-cytoplasmic ratio are noted in many lymphocytes thought to be "immunoblasts."[376] On electron microscopic examination, inclusions are identified within lymphocytes that appear as undulating tubules characteristically associated with the endoplasmic reticulum.

Platelet survival is shortened, and there are increased numbers of bone marrow megakaryocytes. The platelet antibody is an IgG with a molecular mass of 150,000 to 330,000 daltons, and it binds complement.[377] The latter feature distinguishes the immune thrombocytopenia of systemic lupus erythematosus from that of idiopathic thrombocytopenic purpura.[378,379] Danazol may have several serologic effects in patients with systemic lupus erythematosus, including a decrease in DNA antibodies and antiplatelet antibodies. This drug has shown some therapeutic effectiveness in patients with this disease who have immune complex–mediated thrombocytopenia.[380] A qualitative defect in platelet function may also be present.[381] Patients with systemic lupus erythematosus may have a serum inhibitor of platelet aggregation.[382] Thrombocytopenia may be seen in association with systemic lupus erythematosus and the lupus anticoagulant.[383]

Patients with systemic lupus erythematosus may also have a circulating anticoagulant in their plasma.[384,385] The incidence of this anticoagulant in children is unknown, but it is seen in 5% to 10% of adults with this disease.[386] The prevalence of thrombosis in children with lupus anticoagulant is not known. In adults, the prevalence of thrombosis is about 30%, with the predominant site being the legs in 66%, followed by the peripheral arteries in 10% and the cerebral arteries in 2%.[387] The anticoagulant inhibits the interaction between the prothrombin activator (factor V, factor Xa, phospholipid, and calcium complex) and prothrombin, but the exact molecular substrate against which it is directed is not known.[388] Most investigators have reported that lupus anticoagulant is an immunoglobulin that may be of the IgG, IgM, or mixed IgG-IgM class.[389-392] In addition to the inhibitor itself, a cofactor in normal plasma is necessary for maximal action of the lupus anticoagulant. This cofactor, which may be a γ-globulin, potentiates the inhibitory action of lupus anticoagulant.[393]

The partial thromboplastin time is invariably prolonged in patients with the lupus anticoagulant and is considered to be the most sensitive screening test.[386] The inhibitor is suspected when the addition of normal plasma to the patient's plasma fails to correct the defect.[389]

The prothrombin time in patients with the lupus anticoagulant is often normal or minimally prolonged because of the influence of the inhibitor. True prothrombin deficiency may occur in patients with the inhibitor, but it is rare.[394,395]

Prolonged thrombin times in the absence of elevated levels of fibrin split products may occasionally be seen.[396] The exact significance of this finding is unclear.

Lupus anticoagulant is usually found coincidentally on routine coagulation screening.[397] Bleeding is a rare manifestation, and patients have undergone surgery without unusual postoperative bleeding.[398] In fact, some patients with lupus anticoagulant may manifest thrombotic events, a situation observed with other inhibitors,[399] particularly if the inhibitor has activity against antithrombin III.

Renal involvement with some types of microangiopathy has been associated with the presence of antiphospholipid antibodies in patients with systemic lupus erythematosus and in those with other types of connective tissue disorders.[400]

Because bleeding is rarely a problem as a consequence of the presence of the inhibitor, specific therapy is not generally indicated.

Polyarteritis Nodosa

Anemia resulting from a chronic disease state is seen occasionally in patients with polyarteritis nodosa. A more common occurrence is microangiopathic hemolytic anemia in association with renal disease or hypertensive crises. The hemolytic process in these circumstances parallels disease activity. Neutropenia occurs and is associated with the presence of antineutrophil cytoplasmic antibodies.[401]

Neutrophilia and eosinophilia are also common. The eosinophilia may be extensive, with levels suggesting eosinophilic leukemia or Löffler's endocarditis often being reached. Marked eosinophilia is generally restricted to patients with clinically apparent pulmonary involvement.

Wegener's Granulomatosis

Wegener's granulomatosis, characterized by necrotizing vasculitis (particularly in the lungs and kidneys), is rare but can affect children.[402,403] The disease can also occur in the newborn period.[404] The course of the disease is marked by fever, cough, hemoptysis, epistaxis, nasal discharge, obliteration of the nasal sinuses, and nodular pulmonary infiltrates. Renal failure may occur. As with most chronic disease states, normochromic, normocytic anemia develops.[405] The peripheral blood smear may demonstrate anisocytosis, poikilocytosis, and marked fragmentation reflective of a microangiopathic process associated with vasculitis.[406] Hemolytic anemia with splenomegaly that gives negative Coombs' test results may be present.[405] The white blood cell count is elevated, and eosinophilia can occur.[407] The disease is characterized by marked thrombocytosis.[405] Various immunosuppressive

therapies have been attempted. Cyclophosphamide is occasionally effective in the management of children with Wegener's granulomatosis.[408] Autoantibodies directed against cytoplasmic components of neutrophil granulocytes and monocytes have been described as a disease-specific marker for Wegener's granulomatosis.[409,410]

The hematologic manifestations of these disorders are relatively nonspecific. No consistent hematologic abnormalities are recorded in polymyositis and dermatomyositis. Scleroderma may result in malabsorption of vitamin B_{12}, but this disease is rare in children. Coagulation abnormalities may be seen with scleroderma. Elevations in levels of factor VIII–related antigen and β-thromboglobulin are often noted. Additionally, about half of subjects with active disease show elevations in levels of fibrin degradation products.[411] Autoimmune hemolytic anemia and thrombocytopenia may also be seen in patients with scleroderma,[412] and some will have autoimmune neutropenia.[413] The hematologic manifestations of scleroderma, particularly the magnitude of elevated factor VIII–related antigen levels, may be used as a marker for disease activity.[414]

INFECTIONS

General Hematologic Signs of Infection

Red Blood Cell Disturbances

The pathophysiologic findings of the anemia of chronic infection are similar to those of the anemia of chronic disorders. Although some infections, particularly viral ones, cause transient bone marrow aplasia or selective erythroid aplasia, anemia from this cause is rare because of the long life span of red blood cells. In contrast, patients with hemolytic anemia may experience a rapid decrease in hemoglobin concentration during viral and some bacterial infections. This is especially common in association with infectious episodes caused by parvovirus. Such infections should be considered in any child with a congenital hemolytic anemia who experiences an "aplastic" crisis.

Even common childhood infections, especially those associated with inflammation, will cause a decline in hemoglobin concentration. During active inflammation, the hemoglobin concentration declines about 13%, usually within 1 week, followed by an increase of nearly 25% during resolution of the active inflammation.[321]

Severe hemolytic anemia may be observed in certain types of infections. Clostridial infections may result in a high titer of hemolysins and cause severe anemia with hemoglobinemia and hemoglobinuria.[415] A similar severe anemia may result from sepsis related to other bacterial organisms, including staphylococci, streptococci, pneumococci, and *Haemophilus influenzae*.[416] Immune hemolytic anemia mediated by a cold agglutinin may be observed with *Listeria* and *Mycoplasma* infections[417] and

occasionally with infections by other organisms such as Epstein-Barr virus (EBV).

Many viral illnesses may be associated with what appears to be a mild hemolytic anemia for which no pathologic mechanism has been defined. The most common morphologic finding in these circumstances is poikilocytosis. Certain viruses, such as most strains of influenza virus, contain neuraminidase activity, which is, at least theoretically, capable of affecting the sialic acid content of the red cell membrane. Whether this plays any significant role in the hemolysis associated with some viral diseases is not known.

Many congenital infections, including cytomegalovirus, herpes simplex, rubella, toxoplasmosis, and syphilis, produce profound hemolytic anemia in the newborn period, even though these same agents may not significantly alter red cell survival at other times of life. The explanation for this finding is also unclear.

Finally, anemia may result from blood loss associated with intestinal parasitic infestation.

White Blood Cell Disturbances

The white blood cell count may be normal, low, or high with infection. Viral illnesses may be associated with leukocyte counts lower than 5000 cells/mm³, although bacterial diseases of certain types or overwhelming sepsis of any type may also cause leukopenia. The most common viral illnesses associated with leukopenia are infectious hepatitis, infectious mononucleosis, rubella, measles, and occasionally, influenza. Of the bacterial infections, shigellosis may produce leukopenia with a marked increase in band cell forms. Sepsis caused by meningococci, pneumococci, staphylococci, and a few other bacterial pathogens may also cause leukopenia.

Neutrophilia, with or without an increase in band cell count, is a common result of bacterial infection. White blood cell counts do not differ between white and black children with bacteremia, and the total white blood cell count and neutrophil counts may be interpreted without regard to race.[418] Occasionally, viral illness will also initially be manifested as neutrophilia. A variety of morphologic changes may appear in the neutrophils of patients with infection. Döhle bodies, pale blue cyst-like inclusion bodies usually located in the periphery of the cytoplasm of neutrophils, may appear in bacterial infections.[419] They are occasionally associated with viral illness but are also commonly seen in patients with burns, massive trauma, and cancer, as well as in pregnancy and after the use of cyclophosphamide.[419] In addition, Döhle bodies are seen in the May-Hegglin anomaly.[420] Increased size of neutrophil granules ("toxic granulation") may be seen in both bacterial and viral illnesses, as well as in many of the other disorders associated with the presence of Döhle bodies. Vacuolization of the cytoplasm of neutrophils is the next most common morphologic abnormality of neutrophils in patients with significant bacteremia. In a study of the neutrophils of patients with bacteremia, Zipursky and associates[421] found toxic granulation, Döhle bodies,

and vacuolization in 75%, 29%, and 24%, respectively, of the patients studied.

Increased neutrophil alkaline phosphatase activity and nitroblue tetrazolium dye reduction may also occur,[422,423] but neither of these characteristics is specific for bacterial infection. Infections may be associated with development of the Pelger-Huët anomaly, in which granulocytes and eosinophils have one or two lobes per nucleus and assume a round, dumbbell, or peanut shape.[424] This is most commonly observed with tuberculosis. The Pelger-Huët anomaly is seen in 1 in 6000 people as an autosomal disorder and is also occasionally observed in patients with preleukemia, leukemia, and other cancers and in those taking colchicine and sulfonamide medications.[424]

In newborns, especially those born prematurely, an increase in total white cell or mature neutrophil counts may not be seen in the presence of infection. In fact, a decrease in the neutrophil count often occurs. The most helpful signs of septicemia in this age group are an increase in the band cell count and the presence of toxic granulations and Döhle bodies.[421,425]

Leukocytosis may result from lymphocytosis. The most common infections producing the greatest increases in lymphocyte counts are infectious mononucleosis, cat-scratch disease, "acute infectious lymphocytosis of childhood," and pertussis. Many other viral illnesses such as cytomegalovirus, rubella, mumps, and hepatitis may also cause an increase in the lymphocyte count. T lymphopenia is a common finding after measles infection. It is predominantly due to suppression of OKT4⁺ lymphocytes.[426]

Eosinophilia may reflect the presence of parasitic infections. In the United States, the most common cause of marked elevations in eosinophil counts is *Toxocara* infestation, which is often accompanied by high titers of isohemagglutinins. Other parasites commonly causing eosinophilia include organisms belonging to *Trichinella*, *Echinococcus*, *Filaria*, *Strongyloides*, *Schistosoma*, *Enterobius*, and *Ancylostoma* and tapeworms other than *Echinococcus*. Allergic sensitization to mites may cause eosinophilia, as well as fungal infections, especially aspergillosis.[427] Eosinophilia is, of course, not specific for infestation. Marked degrees of eosinophilia may occur in association with prematurity. An absolute eosinophilia may be expected in about 75% of low-birth-weight infants.[428] In some, the eosinophilia is marked (>3000 cells/mm³), and the maximal increase seems to occur at about the time that birth weight is regained, although this is not true in all infants.[429]

Monocytosis is occasionally seen with specific infections, especially tuberculosis, syphilis, and subacute bacterial endocarditis. Monocytosis is often noted early in the course of many infections and again on recovery, particularly if it is associated with granulocytopenia.

Basophilia is rarely seen in infection but has been reported with tuberculosis, influenza, and hookworm infestation.[430]

Clotting Abnormalities and Thrombocytopenia

DIC may be triggered by infectious processes. Of the infectious causes, gram-negative septicemia is probably most common. *Meningococcus*, *Escherichia coli*, *Proteus*, *Pseudomonas*, *Aerobacter*, and *Klebsiella* are among the most common etiologic agents recovered from the bloodstream.[431,432] Gram-positive septicemia can cause a similar picture. The most common offender is *Diplococcus pneumoniae*, especially in asplenic individuals. Other gram-positive agents causing DIC include *Staphylococcus aureus*, *Streptococcus*, and *Clostridium*. A wide range of viral infections may cause a consumptive coagulopathy that often leads to purpura fulminans. Among the most common agents are those that cause infectious hepatitis, measles, rubella, varicella, and infectious mononucleosis. Less common causes of DIC are severe mycoplasmal, rickettsial, and malarial infections.

Thrombocytopenia occurring separately from a true disseminated consumptive process is quite common in many infectious processes, especially in association with infectious mononucleosis, cytomegalovirus infection, rubella, measles, gram-negative bacteria, and rickettsial diseases. Congenital viral infections and congenital syphilis and toxoplasmosis, if clinically apparent, are almost invariably associated with increased platelet turnover with or without thrombocytopenia. Thrombocytopenia may occur after immunization with live viral vaccines, particularly measles vaccines.[433] Corrigan[434] found that thrombocytopenia without consumptive coagulopathy is an extremely common finding in infants and children with septicemia. In contrast, thrombocytosis is often present during the active phases of infectious processes. The platelet distribution width and mean platelet volume may be helpful in predicting whether the thrombocytopenia is due to infection. In the late neonatal period, thrombocytopenia associated with an infection dramatically increases the mean platelet volume and platelet distribution width as determined by electronic counting equipment.[435]

Immune complex–mediated thrombocytopenia is commonly associated with a variety of infectious agents.[436]

Hematologic Aspects of Selected Specific Infections

Certain infectious processes are associated with specific or unique hematologic findings distinct from those described in the preceding section. Such infections include *Bordetella pertussis* (pertussis or whooping cough), *Salmonella typhi* (typhoid fever), *Mycobacterium tuberculosis* (tuberculosis), *Plasmodium falciparum* (malaria), *Clostridium perfringens*, and *Bartonella bacilliformis* (bartonellosis or Carrión's disease).

Typhoid fever produces remarkable leukopenia and neutropenia early in the course of the illness. The number of bone marrow precursor cells is increased. A high white blood cell count in this disease usually suggests a secondary bacterial infection. The leukopenia of typhoid fever is often associated with thrombocytopenia. Shigellosis may also be associated with leukopenia. The hallmark of *Shigella* infection, however, is a sharp increase in the band cell count.

In the pediatric age group, *C. perfringens* infections are most common in adolescent girls who have undergone septic abortion. This organism has a potent exotoxin, a lecithinase, that disrupts cell membranes and liberates hemolytic material such as lysolecithins. Such disruption may result in fatal intravascular hemolytic anemia with spherocytosis.[415]

Pertussis may cause a marked increase in the white blood cell count, with elevations to 40,000 cells/mm^3 or higher, most of which is due to an increase in the lymphocyte count.

Tuberculosis produces a variety of hematologic abnormalities. Leukemoid reactions mimicking myeloproliferative disorders are common.[437] Bone marrow involvement in miliary tuberculosis may result in a leukoerythroblastic pattern with teardrop-shaped red cells, nucleated red cells, and myeloblasts apparent on the peripheral blood smear.[438] In this respect, the manifestation of tuberculosis is similar to some occurrences of sarcoidosis. Bone marrow biopsy may show evidence of granulomas. Monocytosis is common, and thrombocytopenia and pancytopenia have been reported.[439]

Bartonellosis is a disease transmitted by the sandfly and is associated with potentially severe hemolytic anemia. It was first recognized in 1885 when a medical student inoculated himself with the *Bartonella* organism. The student, Daniel Carrión, died of severe hemolytic anemia. For this reason, human bartonellosis caused by *B. bacilliformis* is still called Carrión's disease.[440] This organism infects red blood cells, coats them (Fig. 36-2), and causes them to be rapidly removed from the circula-

tion. Unlike malarial organisms, *Bartonella* organisms do not invade the red blood cell.[441]

Hemolysis is common in malaria, especially with infection by *P. falciparum*.[442] This disease, transmitted by *Anopheles* mosquitoes, results in parasitization with organisms at the merozoite stage within the red cell. The parasitization causes altered permeability and increased osmotic fragility.[443] The presence of the organism within the cell is also reflected in a defect in red cell membrane shape. Hemolysis in malaria has been attributed to direct damage to the red cell by the parasite, to autoimmune destruction, to hypersplenism, to splenic pitting with the formation of microspherocytes, and to loss of the cell surface negative charge resulting from alteration of the cell's metabolic function by the parasite.[444-446] In addition to destroying infected cells, the spleen may merely remove the offending organisms and leave membrane pits or cavities that may be seen on scanning electron microscopic examination.[447] A particularly severe form of hemolysis called blackwater fever may occur with *P. falciparum* infection. The basis of the massive hemolysis is unknown. *Babesia* and *Babesia*-like infections produce intraerythrocytic merozoite forms similar to those seen in malaria. These infections may also cause hemolytic anemia and DIC.[448]

Infectious Mononucleosis

There is unequivocal evidence that links infectious mononucleosis to EBV. Before etiologic evidence was established, the diagnosis of infectious mononucleosis was based on the triad of (1) a classic clinical picture, (2) atypical lymphocytosis, and (3) positive results on a heterophil antibody test.[449] It was maintained that absence of any one of these three would negate the diagnosis. Serologic testing for EBV has helped explain certain puzzling diagnostic features. For example, it was previously not recognized that children younger than 5 years often contract infectious mononucleosis. The results of a heterophil antibody test are usually negative in this age group, but antibody to EBV is seen. This specific serologic test also explains some occurrences in adults who seem to have a typical clinical picture of infectious mononucleosis and demonstrate atypical lymphocytosis but whose heterophil test results are negative. The masquerading disease is cytomegalovirus infection in most instances.

History

The major landmarks in the diagnosis of infectious mononucleosis have occurred in three areas. The first was the emergence of this disease as a separate clinical entity. The second was establishment of a diagnostic test, the heterophil antibody test, and the third was identification of EBV as an etiologic agent.

The history spans about 100 years. The earliest clinical descriptions are found in writings of Filatov[450] in 1885 and Pfeiffer[451] in 1889. The disease was initially termed

glandular fever until 1920, when Sprunt and Evans,[452] appreciating the presence of the now well-known atypical lymphocytosis, coined the name infectious mononucleosis.

The serendipitous discovery of the heterophil antibody was surpassed only by that of EBV as an etiologic agent. By the 1920s, the occurrence of sheep cell antibodies in serum sickness was well known. Because of similarities in the symptomatology of serum sickness and rheumatic fever, Paul[453] began to look for these antibodies in patients with rheumatic fever. Little came of the primary purpose of this study, but one day, as part of this investigation, Paul and Bunnell[454] found that a control serum sample had an extraordinarily high titer of heterophil antibody. This control serum was from a medical student who had typical infectious mononucleosis. Davidsohn and Lee[455] completed this phase of the story in 1937 when they organized the differential absorption procedures.

The etiologic agent of infectious mononucleosis eluded investigators for half a century. In 1958, Burkitt[456] described African children with the lymphoma now bearing his name. Because the distribution pattern of the disease coincided with the African mosquito belt, many investigators believed that a viral agent might be the cause of this lymphoma. After successful culturing of this tumor tissue in 1964, Epstein and associates[457] noted herpes-like virus particles in the tissues of patients with this lymphoma. By 1966, the Henles and their associates[458,459] had developed an indirect immunofluorescence test to detect this viral particle, which was already called the Epstein-Barr virus. With this test, EBV antibody was found to be present in many healthy American children. A fortunate chance occurrence was observed when infectious mononucleosis developed in a technician in the Henles' laboratory. Her white cells, which previously could not be grown in culture, now grew in continuous culture, and demonstrable EBV antibody was noted. With sera that had been obtained previously from Yale University students, a clear correlation linking EBV with the clinical appearance of infectious mononucleosis was found.[460]

Epidemiology

EBV infection is acquired at an early age in lower socioeconomic groups. In economically privileged children, infection is often delayed until adolescence and young adulthood. About 40% of American children are seropositive for EBV by 5 years of age.[461-463] In a report from the U.S. Military Academy at West Point, 63.5% of entering cadets had EBV antibody, indicative of previous infection.[464] During the college years, the infection rate among susceptible individuals is 12% to 15% per year. The pattern of infection in different groups of susceptible persons is probably best explained by transmission of this virus in throat secretions. Low titers of infectious virus in throat specimens account for the moderate contagiousness of this infection and the requirement of

intimate contact for transmission. Thus, infection might be more common at younger ages in lower socioeconomic groups because of a greater opportunity for oral or oral/fecal transmission.

Another possible route of transmission of EBV is transfusion. EBV is carried in circulating white blood cells. In 1942, Wising[465] suggested that infectious mononucleosis could be transferred by blood transfusions. Subsequently, it was demonstrated that in approximately 8% of individuals undergoing cardiopulmonary bypass, EBV antibody developed in the postoperative period.[466] EBV does not appear, however, to be the cause of post-perfusion syndrome, which is most likely due to cytomegalovirus. Except for a rare instance in which a clinical manifestation of infectious mononucleosis appeared after transfusion of blood from a donor with this disorder, clinical disease from transfusion-transmitted EBV is largely unknown.

EBV is present in the saliva of most patients with infectious mononucleosis, in up to 20% of healthy persons with EBV antibodies, and in 50% or more of seropositive patients receiving immunosuppressive drugs. The ease with which EBV is recovered from the oral secretions of persons with primary or reactivated EBV infection suggests that a cell type that freely permits EBV replication exists in the oropharynx. The oropharyngeal epithelial cell may be the target cell type that is productively infected in infectious mononucleosis.[467] Transmission requires intimate contact, so there is no significant spread of EBV in the school setting. Intrafamilial spread, however, does occur frequently, and in this setting an incubation period of 4 to 6 weeks has been demonstrated.[468]

It has been suggested that EBV infection may be transmitted congenitally.[469,470] A fatal illness in a 2-week-old infant in whom EBV genomes were detected in a lymph node biopsy specimen has been described.[471] Such occurrences, if representative of true congenital EBV infection, must be rare. A study of 4063 pregnant women showed that only 1.1% were susceptible to infection early in gestation and less than 0.1% showed seroconversion. Two of three infants born of women who seroconverted were normal, but one had tricuspid atresia. None of the infants could be demonstrated to be actively infected.[472,473] Similar findings have been found by others.[474]

The relationship of infectious mononucleosis to other disorders known to be associated with EBV infection or virus isolation is unclear. Such disorders include nasopharyngeal carcinoma, in addition to Burkitt's African lymphoma.[475] A higher than anticipated association of EBV with sarcoidosis,[476] leprosy,[477] and systemic lupus erythematosus[478] has been observed, although any specific relationship to these disorders remains speculative.[479]

In patients who undergo renal transplantation, a spectrum of lymphoproliferative diseases may occur as a result of activation of EBV. These diseases may vary from an infectious mononucleosis–like polyclonal B-cell proliferation to a monoclonal B-cell lymphoma. Therapeutic approaches to this problem usually fail.[480] Acyclovir therapy may be helpful early in the course of illness. When frank malignancy has developed, chemotherapy is suggested.

Clinical Features

The classic clinical manifestation of infectious mononucleosis is generally seen only in adolescents and young adults. Younger children rarely exhibit the typical findings of this disease, and most generally have only a mild viral respiratory illness.[461-463]

The onset of typical illness is usually a subtle prodrome consisting of fatigue, malaise, sweating, feverishness, and anorexia. As with infectious hepatitis, a distaste for cigarettes is common. Headache, nausea, and vomiting are seen frequently. The most common symptom during this period is a sore throat, which begins slowly and increases in intensity over a 1-week period. The usual findings of infectious mononucleosis then follow (Table 36-3). The course of fever often follows a specific pattern, with no temperature elevation in the morning but daily

TABLE 36-3	Infectious Mononucleosis—Approximate Rate of Occurrence of Various Signs and Symptoms in Young Adults
Symptom or Sign	**%**
Adenopathy	100
Malaise and fatigue	90-100
Fever	80-95
Sweats	80-95
Sore throat, dysphagia	80-95
Pharyngitis	65-85
Anorexia	50-80
Nausea	50-70
Splenomegaly	50-60
Headache	40-70
Chills	40-60
Bradycardia	35-50
Cough	30-50
Periorbital edema	25-40
Palatal enanthema	25-35
Liver or splenic tenderness	15-30
Myalgia	12-30
Hepatomegaly	15-25
Rhinitis	10-25
Ocular muscle pain	10-20
Chest pain	5-20
Jaundice	5-10
Arthralgia	5-10
Diarrhea or soft stools	5-10
Photophobia	5-10
Rash	3-6
Conjunctivitis	5
Abdominal pain	5
Gingivitis	3
Pneumonitis	3
Epistaxis	3

afternoon or evening peaks of 38.3° C to 39.4° C (101° F to 103° F). Occasionally, higher temperatures are observed. The fever usually lasts about 2 weeks.

Lymphadenopathy is seen in all patients. Symmetrical, moderately enlarged, discrete, slightly tender nodes, especially in the posterior cervical region, are most characteristic. Adenopathy is common in the axillary, epitrochlear, and inguinal areas. The nodes are not matted and do not show signs of heat, redness, or fluctuation. Rarely, enlargement of the mediastinal glands constitutes the only evidence of adenopathy and may be confused with a lymphomatous process.

Splenomegaly occurs in more than 50% of patients with infectious mononucleosis. The spleen is usually just barely palpable but on rare occasion may be quite large. It is smooth, soft to firm, and sometimes slightly tender. In a few patients, splenomegaly persists for months, but the most common situation is resolution by 2 to 3 weeks after onset of the illness.

Hepatomegaly occurs in about 20% of patients, and clinical jaundice is seen in 10%. The jaundice is invariably mild. Despite the low rate of occurrence of apparent hepatic dysfunction, virtually all patients with infectious mononucleosis demonstrate abnormal liver enzyme levels. Except in rare patients with acute liver failure, the hepatitis associated with this illness is self-limited. There is no evidence that chronic liver disease or cirrhosis results from infectious mononucleosis. Reye's syndrome has been reported in a child with infectious mononucleosis.[481]

Rashes occur occasionally, and their manifestation follows no particular pattern. The rash may be a diffuse, faint, erythematous or maculopapular eruption, or it may be urticarial, scarlatiniform, petechial, or herpetiform. In general, the rashes of infectious mononucleosis have no unique features and are of little or no help for diagnosis. Circulating immune complexes and complement sequence activation occur only when rashes are present.[482] If ampicillin is administered to patients with infectious mononucleosis, a rash will develop in 69% to 100%.[483] Other penicillins may cause this response, but less often. This rash is not a reagin-mediated allergic reaction, and these antibiotics may be administered subsequently without ill effect.

Only a few patients with infectious mononucleosis have no pharyngitis. Almost all demonstrate hyperplasia of the pharyngeal lymphoid follicles. The presence of an exudate is common, and membrane formation occurs frequently. The inflammation may be severe enough to cause respiratory obstruction. Peritonsillar abscesses may complicate the course of the illness.[484] A palatal enanthema is seen in about a third of patients and consists of crops of sharply circumscribed petechiae, symmetrically distributed at the junction of the soft palate. Unfortunately, such petechiae are not specific for infectious mononucleosis and have been described in rubella and other viral disorders. In fact, the entire pharyngeal manifestation of infectious mononucleosis is clinically indistinguishable from that of streptococcal disease.

Periorbital edema is not rare and occasionally leads to the erroneous suspicion that renal disease or hypoproteinemia is present. The edema is self-limited and lasts only a few days.

Complications

Much attention is paid to the complications associated with infectious mononucleosis, although their overall occurrence is low (Table 36-4).

The incidence of the neurologic complications reported varies from 0.37% to 7.3%, depending on the

TABLE 36-4	Infectious Mononucleosis—Reported Complications
Type of Complication	**Diagnosis or Description of Abnormalities**
Neurologic	Bell's palsy, cerebellar syndrome, encephalitis, encephalomyelitis, encephalomyelopathy, Guillain-Barré syndrome, meningitis, meningoencephalitis, myelitis, optic neuritis, peripheral neuritis, psychosis, radiculoneuritis
	Ataxia, positive Babinski's sign, coma, convulsions, diplopia, extraocular palsy, facial diplegia, hemiplegia, hyperesthesia, meningismus, mental confusion, nystagmus, papilledema, psychotic reaction, ptosis, respiratory paralysis, positive Romberg's sign, seizure, status epilepticus, scotomas
Cardiac	Electrocardiographic changes, myocarditis, pericarditis
Ocular	Conjunctivitis, diplopia, cyclic edema, hemianopia, lacrimal pericyclitis, nystagmus, optic neuritis, ptosis, retinal edema, retinal hemorrhage, retro-orbital pain, scotomas, uveitis
Respiratory	Laryngeal obstruction, peritonsillar abscess, pharyngeal edema, pleural effusion, pleuritis, pneumonitis
Hematologic	Acquired hemolytic anemia, agranulocytosis, eosinophilia, fibrinolysis, pancytopenia, splenic rupture, thrombocytopenia
Digestive	Esophageal varices, gingivitis, hepatic dysfunction, hepatic necrosis, jaundice, melena
Renal	Hematuria, hemoglobinuria, nephritis, nephrotic syndrome, porphyrinuria, proteinuria
Other	Bullous myringitis, endocervicitis, orchitis, otitis media, pancreatitis, porphyria, rashes

From Finch SC. Clinical symptoms and signs of infectious mononucleosis. In Carter RL, Penman HG (eds). Infectious Mononucleosis. Oxford, Blackwell Scientific, 1969, p 35.

series.[485] A not rare occurrence in adolescence is the "Alice in Wonderland" phenomenon in which objects are visualized in a very distorted fashion, with exaggerations in size, being either too large or too small.[486,487] A transverse myelopathy characterized by a sudden onset of profound weakness of the lower extremities and urinary retention may complicate the clinical course of infectious mononucleosis.[488] A list of the neurologic complications appears in Table 36-4.

Cardiac complications are rare and occur in 1% to 6% of reported series. They usually consist of only nonspecific T-wave changes or minor conduction abnormalities. Myocarditis and pericarditis are also rare.

Liver function abnormalities are rarely severe, although enzyme changes are common. Primary EBV infection has been associated with a Reye syndrome–like illness.[489] Severe liver dysfunction causing death is a common complication of EBV infection in the X-linked lymphoproliferative syndrome. Hepatic dysfunction is uniformly present with this disorder at the time of death and is the cause of death in about a third of such patients.[490] An unusual manifestation of infectious mononucleosis may be intense jaundice. It generally results from a combination of hemolysis and mild hepatitis.[491] Spontaneous rupture of the spleen may occur.[492] Respiratory difficulties usually consist of upper airway obstruction. Transient interstitial infiltrations, some with effusions, have been recorded. Infectious mononucleosis should be considered in the differential diagnosis of any child with pleural effusions.[493] Renal complications of infectious mononucleosis generally consist of hematuria associated with a mild nephritis. Not all occurrences have been clearly separated from poststreptococcal glomerulonephritis. Severe rhabdomyolysis can be associated on rare occasion with EBV infection.[494] Eye findings in infectious mononucleosis are unusual but may be significant when they do occur. Severe retinochoroiditis is such an ocular complication.[495] In some patients with infectious mononucleosis, a chronic fatigue syndrome will develop in which lethargy, particularly daytime lethargy, is seen for prolonged periods, often longer than a year.[496] The mechanism is not known, but the lethargy is often associated with serologic evidence of persistent infection.[497,498] Hematologic complications of infectious mononucleosis include disturbances resulting in anemia, granulocytopenia, thrombocytopenia, and occasional coagulation defects.

Anemia is rare. In approximately 3% of West Point cadets with infectious mononucleosis, anemia of the immune hemolytic type developed.[464] When hemolysis does occur, it usually begins 1 to 2 weeks into the course of the illness. The majority of occurrences terminate in less than 1 month, and chronic hemolysis is rare. Though usually mild, hemolysis occasionally occurs rapidly and can then result in severe anemia. Jenkins and associates in 1965[499] reported the first instance of hemolytic anemia in infectious mononucleosis that was mediated by the temporary induction of a high–thermal amplitude cold

agglutinin of anti-i specificity.[500] Since then, several series have verified the high incidence of anti-i antibody as the cause of hemolysis in infectious mononucleosis. It should be noted that although hemolysis is not common in infectious mononucleosis, the presence of anti-i in serum is seen in as many as 50% of all patients. Not all instances of immune hemolysis in infectious mononucleosis are caused by anti-i antibodies. Anti-N antibodies have also been reported, and in some patients the nature of the antibody has not been identified.[501]

Aplastic anemia has been reported to follow the onset of infectious mononucleosis.[502] Aplastic anemia caused by EBV infection has also been reported after bone marrow transplantation.[503] Localization of EBV in the bone marrow of some patients with aplastic anemia supports a causative role of the virus in this disorder.[504]

Granulocytopenia is common during the acute phase of infectious mononucleosis. It is rarely severe but on occasion is a cause of secondary bacterial infection.[505] Bone marrow myeloid hyperplasia with myeloid arrest is the most typical finding.[506] Spontaneous resolution is the rule.

Immune thrombocytopenia occurs rarely in infectious mononucleosis.[507] The peak age at incidence is between 10 and 30 years with a male preponderance. Most occurrences of thrombocytopenia are mild.[508] The signs and symptoms of severe occurrences are similar to those of idiopathic thrombocytopenic purpura, except that in infectious mononucleosis hemorrhagic bullae may develop in the mouth. Platelet counts as low as 3000/L have been reported in association with EBV infection.[509] This is a rare finding in idiopathic thrombocytopenic purpura. The usual duration of thrombocytopenia is 4 to 8 weeks. Severe hemorrhagic complications are rare.[510]

The thrombocytopenia of infectious mononucleosis appears to be immune in nature and has been associated with the presence of antiplatelet antibodies in several patients.

Treatment of the thrombocytopenia of infectious mononucleosis should be expectant. Severe occurrences may be treated with corticosteroid therapy, which generally increases the platelet count promptly.[511] The rate of occurrence of these hematologic abnormalities is shown in Table 36-5.

The total spectrum of the rare complications and unusual syndromes associated with EBV infection have been reviewed by Timár and colleagues.[512]

Laboratory Diagnosis

Atypical lymphocytosis is the hallmark of infectious mononucleosis (Fig. 36-3). Several attempts have been made to classify these abnormal cells on morphologic grounds, the best known method being that of Downey and McKinlay.[513] However, it is clear that atypical lymphocytes cannot be easily classified into separate categories and that a spectrum of cell types exists. Undue emphasis on minor morphologic detail in stained films is not very rewarding. In general, the atypical lymphocytes

of infectious mononucleosis are large, but they vary in size considerably. Their outlines are irregular, and many cells show a characteristic tendency to flow around adjacent erythrocytes. Nuclei are large and usually eccentrically located and pleomorphic, with abundant coarse chromatin and occasional nucleoli. The cytoplasm is generally abundant and typically basophilic. Cytoplasmic vacuoles may be seen. These types of cells are not morphologically specific for infectious mononucleosis. Morphologic characteristics similar to these are associated with infections such as cytomegalovirus, infectious hepatitis, rubella, rubeola, and herpes simplex; after the administration of certain drugs such as phenytoin and *p*-aminosalicylic acid; and after a number of chemical intoxications.[514]

The vast majority of atypical lymphocytes from patients with infectious mononucleosis are thymus derived.[515,516] These atypical cells possess human T-lymphocyte–specific antigens, as well as sheep erythrocyte receptors.[515] T lymphocytes appear to lack receptors for EBV, and it would appear that only B lymphocytes are infected by this virus.[516,517] A possible unifying interpretation of the role of T lymphocytes is that these cells represent an immune reaction that protects against this potentially oncogenic virus. Increased numbers of B cells are found during the first week of illness and decline to normal levels in 3 weeks. T lymphocytes reach their peak later, usually 10 to 14 days after the onset of symptoms, and remain elevated for 5 weeks.[518] There may be an early reversal of the ratio of T to B lymphocytes, with a subsequent increase in the percentage of T cells during the second through fifth weeks of illness. It is possible that both T and B cells may be "transformed" into atypical lymphocytes—B cells by infection with EBV and T cells by an immunologic response to viral antigen itself—or the B cells may respond to altered antigens on their surface. EBV-infected B lymphocytes account for only a minority of the atypical lymphocytes found in peripheral blood. In the very early stages of symptomatic illness, however, nearly 20% of all B cells in the circulation may be infected with the virus. The majority of atypical lymphocytes are T lymphocytes. Natural killer (NK) cell activity has been shown to be present during the acute phase of infectious mononucleosis. Interferons, which are inducers of NK cell activity, may have an inhibitory effect on the outgrowth of EBV-infected B lymphocytes in vitro. Significant anergy and diminished lymphocyte responsiveness in vitro to mitogens and antigens exist during the first week of illness. These lymphocyte changes are reflected in a great increase in uric acid turnover, with 55% of infected patients having serum uric acid levels of 8 mg/dL or higher.[519]

Patients with infectious mononucleosis have lymph node pathologic findings that are easily confused with

TABLE 36-5	Infectious Mononucleosis— Laboratory Features	
Findings	**% Positive**
Lymphocytosis, relative and absolute	100
Atypical lymphocytes, definite*	100
Epstein-Barr virus antibody in serum	100
Heterophile antibody	80-100
Liver enzyme abnormalities	80-100
Leukocytosis	60-80
Neutropenia	60-80
Hyperbilirubinemia	30-50
Bone marrow granulomas	50
Slight thrombocytopenia	25-50
Increased cold agglutinins	10-50
Occult hemolysis	20-40
Hyperuricemia	15-20
Leukopenia	10-20
Severe thrombocytopenia with bleeding	Rare
Positive direct Coombs' test results	Rare
Significant anemia (usually caused by hemolysis)	Rare

*Twenty percent or more of white blood cells in peripheral blood.

lymphoma. The nodal architecture is distorted by large, dark lymphoid cells, and the capsule may be infiltrated. Reed-Sternberg cells have been reported on several occasions.[520,521] Pathologic changes are not confined to lymphoid tissue, however. Perivascular cuffing of the brain vasculature, inflammation of the liver, and inflammatory infiltration of the kidney and bone marrow have been repeatedly observed.

The heterophil antibody is so named because the antigen to which the antibody reacts is found in more than one species. The antibody, like anti-i, is an IgM macroglobulin. It agglutinates sheep red cells and can be removed completely from serum by preincubation with beef red cells but not with guinea pig kidney. Heterophil antibody titers usually increase after the third day of illness, peak at 2 weeks, and may remain positive for several months before ultimately becoming negative (unlike the antibody specific for EBV).[522] This traditional Paul-Bunnell serologic agglutination method has been largely replaced for screening purposes by the spot test, in which finely ground guinea pig kidney or beef red cell stroma is added to serum on a slide, followed by a drop of horse cells.[523] Results of the test are considered positive if agglutination occurs in the presence of guinea pig kidney (which absorbs out Forssman antibody but not heterophil antibody) but are negative with beef red cell stroma. The spot test requires only 2 minutes and is 96% to 99% accurate. Results of both the Paul-Bunnell test and the spot test are usually negative in preschool-aged children, in whom heterophil antibody production is limited.[524] This age group does produce diagnostic levels of EBV-specific antibody.

EBV is a herpes-like DNA virus. It is a relatively complex virus, and a variety of virus-associated antigens have been described.[525] Antibodies to viral capsid antigen (VCA) and early antigen (EA) are detected early after the onset of EBV-associated infectious mononucleosis.[526] Levels of antibodies to VCA reach their peak at about 3 weeks after the onset of clinical illness. Their levels decline somewhat thereafter, but they remain for life.[527] Antibodies to EA usually last 2 to 4 months. EA has two components that are differentiated by their immunofluorescent staining: "D" for diffuse and "R" for restricted staining. A technique for determining EBV-specific IgM has been described.[528] EBV-specific IgM almost always occurs in the acute phase of infectious mononucleosis. It rarely persists more than 2 to 3 months. During this period, virus shedding from the oropharynx is easily demonstrable.[529]

Figure 36-4 shows the characteristic antibody patterns observed in young adults with EBV-induced infectious mononucleosis.[530] Before infection, no antibodies are present. During the acute phase of illness, high titers of IgM and IgG antibodies to VCA are seen. IgM antibodies are transient and disappear after 1 to 2 months. Antibodies appearing against EA disappear after a few weeks to months. Antibodies against Epstein-Barr nuclear antigen are the last to appear and are seen 1 to 2 months after the illness. In young infants, VCA IgM is found in only 60% of patients, and EA antibody is identified in
FIGURE 36-4. Characteristic Epstein-Barr virus (EBV)-specific antibody responses observed in young adults with acute infectious mononucleosis. *(Adapted from Henle W, Henle GE, Howwitz CA. Epstein-Barr virus specific diagnostic tests in infectious mononucleosis. Hum Pathol. 1974; 5:551-565; and Sullivan JL. Epstein-Barr virus and the X-linked lymphoproliferative syndrome. Adv Pediatr. 1984;30: 365-399.)*

only 50%. The only persistent antibody response should be VCA IgG and antibodies to Epstein-Barr nuclear antigen. Polymerase chain reaction (PCR) analysis for the EBV genome in peripheral blood is a more sensitive test than heterophile antibody in children, but it is more costly and it is wise to perform the serologic erythropoietin tests as a screen.[531]

Association with Malignancy

In 1974 and 1975, three families were described in whom fatal infectious mononucleosis caused by EBV occurred in young male members of these kindreds.[532-534] Subsequently, many families have been described. Acquired immunodeficiency and lymphoproliferative disorders occur at a higher than expected incidence in susceptible males. Of males who become affected, approximately 70% die of fatal infectious mononucleosis. Of those who survive the initial infection, a lymphoproliferative disorder will develop in up to 40%. Virtually all patients who survive are immunocompromised. Sullivan and colleagues[535] have found that those with common variable immunodeficiency demonstrate hypogammaglobulinemia and abnormal immune responses to in vivo immunization with various phage types of *Staphylococcus*.[535] NK cell activity is diminished and unresponsive to interferon therapy. This presumably leaves affected individuals with little defense against lymphoproliferative disorders characterized by multiplication of malignant cells containing the EBV genome. Of males who survive the initial infection, 80% have absent or abnormal humoral immune responses to EBV.[536] Before EBV infection, susceptible males usually had no history of recurrent infections or difficulty in limiting infections.

Recognition of X-linked lymphoproliferative syndrome has led to wider understanding of the effect of EBV infection and its immunologic consequences in other states. Transient immunodeficiency during asymptomatic EBV infection may occur in otherwise healthy children.[537] A non–X-linked susceptibility to severe EBV infection has now been described.[538-540] X-linked lymphoproliferative syndrome was first described in 1975. Fatal or severe infectious mononucleosis, acquired hypogammaglobulinemia, and malignant lymphoma are the three major phenotypes in X-linked lymphoproliferative syndrome. Fatal infectious mononucleosis occurs in two thirds of these individuals, with an overall mortality rate of 85%.

Recently, three different groups independently identified mutations in a novel gene in families with X-linked lymphoproliferative syndrome. The gene encodes for a cytoplasmic protein that has a 128–amino acid intracytoplasmic domain termed Src homology 2 domain–containing protein (SH2D1A) or signaling lymphocyte activation molecule (SLAM)-associated molecule.[541-543] It appears that this molecule acts as a regulator of at least two CD2-like lymphocyte receptors, in particular, 2B4. The 2B4 receptor is expressed primarily on NK cells and a subset of CD8+ T cells. Ligation of 2B4 in NK cells by its natural ligand CD48 on target cells results in selective activation of NK cells. SH2D1A seems to be required for activation of 2B4. It appears that NK cells from patients with X-linked lymphoproliferative syndrome have abnormal 2B4 activation and are unable to lyse EBV-infected targets.[544]

As noted, the outcome in susceptible individuals with the infection is extremely guarded.[545] Acyclovir treatment of two subjects with life-threatening EBV infection (one of whom had X-linked lymphoproliferative syndrome) produced no apparent improvement.[546] There may be a role for acyclovir very early in the course of serious complications of infectious mononucleosis when EBV induces polyclonal B-cell activation. Treatment subsequently is not likely to be effective.[547] Trials with interferon are under way. Bone marrow transplantation has been used successfully in the management of X-linked lymphoproliferative syndrome.[548]

A variety of other malignancies have been linked to EBV, including clonal T-cell proliferations.[549] EBV infection can also result in a hemophagocytic syndrome.[550] The interaction between EBV and human immunodeficiency virus (HIV) is discussed elsewhere in this chapter.

Management

There is no evidence that bed rest or rest in general shortens the clinical course of infectious mononucleosis. Patients will determine their own level of activity. The most significant risk during acute illness is splenic rupture, but its incidence is extremely low.

Corticosteroid therapy is often used for infectious mononucleosis. Although these agents may produce improvement of symptoms, enhancement of general well-being, and reduction of fever, their use for these purposes should be restricted.[532] Less controversial is the use of corticosteroid therapy for patients with airway obstruction secondary to tonsillar hypertrophy, severe hemolytic anemia, and hemorrhagic thrombocytopenia.[551]*

The hematologic and oncologic consequences of EBV-host interactions have been reviewed.[552]

METABOLIC DISEASES

Discussion in this section is restricted to the hematologic consequences of diabetes mellitus, some of the lipid

---

Editor's comment: Young adolescents with persistent but non–life-threatening viral infections may be seen with symptoms and signs suggesting serious systemic diseases, such as tuberculosis or lymphoma. The symptoms may persist for weeks and include sweating, weight loss, fatigue, anorexia, low-grade fever, lymphadenopathy, and splenomegaly. There may be mild microcytic anemia, particularly in young women. Thrombocytosis with an elevated sedimentation rate and rare lymphoblasts with basophilic cytoplasm may be detected in peripheral blood, particularly in smokers.

disorders of metabolic origin, and methylmalonic and orotic aciduria.

Diabetes Mellitus

That diabetic patients are prone to anemia,[553] infection,[554] and thrombotic episodes with macrovascular and microvascular sequelae[555] has long been recognized.

An unusual hemoglobin component in hemolysates prepared from the blood of some diabetic patients was first noted by Rahbar.[556] A component that migrated near the position of fetal hemoglobin was described on agar gel electrophoresis at pH 6.2 in citrate buffers. This hemoglobin is present in normal individuals; it constitutes 5% to 7% of total hemoglobin[557] and is called HbA_{1c}. Rahbar's group observed a twofold increase in this hemoglobin fraction in some diabetic patients.[558] Structurally, HbA_{1c} is a condensation product, by means of a Schiff base, between 1 molecule of HbA and 1 molecule of an aldehyde or ketone, linked at the N-terminals of β chains. The aldehyde or ketone group appears to be one or more hexoses, thus making HbA_{1c} a glycohemoglobin. Bunn and Briehl[559] have shown that the oxygen affinity of HbA_{1c} is little affected by the addition of 2,3-DPG, which leads to decreased oxygen affinity when added to HbA. Although an early study failed to demonstrate any correlation between the degree of elevation in HbA_{1c} and clinical parameters of disease activity,[557] other investigations have shown highly significant relationships between the percentage of HbA_{1c} and the response to an oral glucose tolerance test and overall diabetic control, as reflected in quantitative urinary glucose determinations.[560,561] In this sense, measurement of the glycohemoglobin provides an insight into diabetic control over many days. Although HbA_{1c} is a glycohemoglobin and an unusual glycoprotein has been found in the basement membrane material of kidneys of diabetic patients, correlation between these findings has yet to be found.[560]

Red blood cell survival, as measured by chromium (^{51}Cr) labeling, may be mildly impaired during periods of poor diabetic control (mean erythrocyte half-life of 27 days). With improvement of diabetic control, red cell survival will increase (mean half-life of 31 days).[562] During episodes of ketoacidosis, rapid shifts in the oxygen affinity of hemoglobin may also occur. A decrease in pH causes a shift to the right with an increase in oxygen unloading. Very rapid correction of pH may impede oxygen delivery. A prompt decrease in red cell 2,3-DPG levels occurs at these times.[563] This decrease is probably compensatory—an attempt to correct the oxygen affinity disturbances caused by the acidosis. A decrease in red cell 2,3-DPG levels may also result from hypophosphatemia, if it occurs during insulin treatment.

Other red cell abnormalities have been found in diabetic subjects. The red blood cells of such individuals show evidence of lipid peroxidation and antiperoxidative enzyme changes when compared with those of healthy subjects.[564] An increase in the glycosylated form of erythrocyte superoxide dismutase has been found in diabetic subjects and is related to nonenzymatic glycosylation of this enzyme.[565] Erythrocytes from diabetic subjects also show sodium influx.[566] Red blood cell sorbitol concentrations will increase in subject with poorly controlled diabetes; the amount of red blood cell sorbitol is related to the degree of diabetic control.[567] Finally, if electronic counting equipment is used to determine the mean corpuscular volume of red cells, artifactual elevations in mean corpuscular volume may be seen in subjects with hyperglycemia.[568]

Anemia in diabetes is usually an example of the anemia of chronic disorders (discussed earlier). Adult diabetic patients have a higher incidence of pernicious anemia than normal individuals do. A thiamine-responsive anemia, neutropenia, and thrombocytopenia have been reported in the DIDMOAD syndrome.[569]

Polymorphonuclear cell function may be disturbed in diabetic patients. Leukocyte adherence is diminished in individuals with poor control of diabetes, as is phagocytic capacity.[570] Chemotaxis may also be abnormal, but this does not correlate with the status of diabetic control.[571] Impaired cellular metabolism and DNA synthesis have been reported in the lymphocytes of some patients with diabetes.[572] Increased superoxide production by mononuclear cells is observed in patients with diabetes and hypertriglyceridemia.[573]

A variety of coagulation and platelet abnormalities have been described in diabetic patients. A state of hypercoagulability associated with changes in clotting factors and platelet function has been postulated to be important in the increased thrombotic complications in diabetic patients. Approximately a third of patients with diabetes will show abnormally increased factor VIII coagulant activity and diminished antithrombin III levels. Abnormalities in fibrinolysis do not appear to be common.[574] In addition to this, factor XI and factor XII levels are higher in some diabetic patients with evidence that the kallikrein-prekallikrein system has been activated.[575] Ketoacidosis may be associated with DIC.[576] Altered levels of factors V and VIII and diminished fibrinolytic activity have been reported in a few patients.[577]

Many studies have emphasized the abnormalities in platelet adhesion and aggregation in patients with diabetes. The finding that enhanced platelet aggregation occurs before clinical evidence of diabetic vascular disease suggested that this defect may be acquired early in the natural history of diabetes and could underlie the vascular disease.[578] Platelet aggregation in diabetic subjects is characterized by a shortened adenosine diphosphate–induced aggregation time.[579] Increased platelet adhesiveness and platelet factor 3 and 4 activity also occur.[562,580] Normal platelets incubated in the plasma of diabetic patients will become abnormal. This aggregation-enhancing activity is present in both plasma and serum and is nondialyzable and heat resistant.[579] In patients with this plasma factor, von Willebrand factor

activity is also increased, thus suggesting that the two are related.[581] The enhanced in vitro responsiveness of platelets from diabetic patients can be decreased by prostaglandin synthetase inhibitors.[578,582] Platelets from diabetic patients demonstrate increased activity of the prostaglandin synthetase system, which results in increased synthesis of prostaglandin endoperoxides and, therefore, of prostaglandin E_2.[583] When induced to aggregate with arachidonic acid, the platelets of diabetic patients with vascular disease tend to produce more thromboxane A_2 than those of normal subjects do.[584] A lower prevalence and severity of diabetic retinopathy have been observed in a group of diabetic patients with concurrent rheumatoid arthritis who were taking high doses of aspirin. This finding suggests that inhibition of platelet aggregation and prostaglandin synthesis may be desirable in the management of diabetic patients.[585] The increased glycosylation of connective tissue proteins in diabetic patients has been suggested to increase their aggregation potency.[586]

The hematologic consequences of diabetes also extend to infants born of diabetic mothers. An increased incidence of thrombosis or thromboembolic phenomena is well recognized in these infants.[587] Complications such as renal vein thrombosis, peripheral gangrene secondary to vascular occlusion, and cerebral thrombosis may occur.[588]

It may be difficult to resist the urge to perform lymph node biopsy or abdominal exploration in such patients. However, most of them should be treated expectantly with simple home remedies, such as white meat of chicken or chicken soup.[589]

Abnormalities in Lipid Metabolism

Abetalipoproteinemia is an autosomal recessive disorder that results in abnormalities in plasma lipids. Plasma levels of triglycerides, cholesterol, and phospholipids are diminished.[590] These findings are associated with the presence of acanthocytic red blood cells. The cholesterol content of the red cell is normal or slightly increased, whereas the phospholipid content reflects that of serum.[590] Autohemolysis[591] and peroxidative hemolysis[592] may be increased, but osmotic fragility[591] and rates of glycolysis[591] are normal. Anemia, if present, is mild.

Patients with familial hyperbetalipoproteinemia (type II hyperlipoproteinemia) have abnormal platelet function[593] characterized by increased sensitivity to aggregating agents and release of increased amounts of nucleotides in response to aggregating agents. These changes are associated with platelet plasma membrane ultrastructural changes, particularly in type IIa hypercholesterolemia.[594] Such subjects may truly demonstrate a "hypercoagulable state." The latter has been demonstrated in severely hypertriglyceridemic conditions.[595] These findings suggest the possibility that platelet function may be involved in the thrombotic complications of familial hyperbetalipoproteinemia. Erythrocytes from patients with various disorders in lipoprotein metabolism have abnormal red blood cell morphologic characteristics, including acanthocytes, stomatocytes, and crenated cells.[596,597]

Essential fatty acid deficiency will result in a variety of characteristic changes in plasma lipids. Decreased prostaglandin formation in in vitro platelet studies involving animals with essential fatty acid deficiency has been reported.[598] This results in a thrombocytopathy with impaired platelet aggregation and may reflect a deficiency of arachidonic acid necessary for the formation of thromboxane A_2.[598] Clinically, essential fatty acid deficiency is being recognized more often as a result of prolonged fat-free parenteral nutrition.[599] Several infants have been described with hemorrhagic complications from this disorder.[598]

Other Metabolic Disorders

A single infant with methylmalonic aciduria was found to have neutropenia.[600] The mechanism of neutropenia in this child is unclear. More commonly, excessive urinary excretion of methylmalonic acid occurs as a result of vitamin B_{12} deficiency.[601]

A child has been described with altered vitamin B_{12} metabolism in association with megaloblastic anemia and homocystinuria secondary to a defect in methionine biosynthesis.[602] Homocystinuria and megaloblastic anemia responsive to vitamin B_{12} therapy have also been reported as an inborn error of metabolism caused by a defect in cobalamin metabolism.[603] Infants and children with orotic aciduria, hyperglycinemia, and hyperglycinuria may have neutropenia.[604] Patients with orotic aciduria may exhibit megaloblastic changes in bone marrow and have macrocytic indices.

NEUROLOGIC AND PSYCHIATRIC DISORDERS

Muscular Dystrophy

Roses and Appel[605] reported decreased levels of red cell membrane protein phosphorylation in patients with myotonic muscular dystrophy. As a further example of the usefulness of red cells as biopsy tissue and also as possible additional evidence for the clinical importance of membrane protein phosphorylation, increased phosphorylation of red cell spectrin has been reported to occur in patients with Duchenne's muscular dystrophy.[606] These observations have prompted the hypothesis that the muscular defects in dystrophic patients may represent specific manifestations of a generalized membrane disorder.[607] In addition, the red cells of patients with muscular dystrophy may demonstrate decreased deformability.[608,609] Increased osmotic fragility is seen in almost 85% of patients.[610] It has been suggested that analysis of intramembrane particles in freeze-fractured

erythrocyte plasma membranes will show the same abnormalities in carriers of human Duchenne's muscular dystrophy as in affected subjects and may be used as a rapid, simple, and highly accurate diagnostic tool for such carrier detection.[611] The Pelger-Huët anomaly has been associated with the autosomal dominant form of muscular dystrophy in one family,[612] as has the Jordan anomaly.[613] All these findings are subtle and require careful evaluation and confirmation. Structural platelet membrane abnormalities have also been described in subjects with muscular dystrophy, although this finding is not universal.[614,615]

Myasthenia Gravis

Because both myasthenia gravis and acquired pure red cell aplasia have been associated with the presence of thymoma, occasional reports of patients with myasthenia gravis and concomitant pure red cell aplasia have appeared.[616] Pancytopenia may also occur. Such occurrences in children are rare. In addition, there is a higher than average incidence of autoimmune hemolytic anemia in patients with myasthenia gravis.[617] Antibody-mediated pure neutrophil aplasia may result from recurrent myasthenia gravis and thymoma.[618]

Lesch-Nyhan Syndrome

The Lesch-Nyhan syndrome is an X-linked recessive disorder characterized by mental retardation, choreoathetosis, hyperuricemia, and self-mutilation. Cells from affected individuals are unable to convert hypoxanthine and guanine to the corresponding nucleotides because of an inactive phosphoribosyltransferase. A patient with this syndrome has been described in whom megaloblastic anemia developed, presumably as a result of deficient nucleic acid synthesis because the administration of large amounts of adenine reversed the process.[619] The enzyme is present in red cells, but its deficiency does not generally alter the function or survival of mature red cells.[620] On an experimental basis, erythrocyte transfusions have been used as a source of enzyme replacement in Lesch-Nyhan syndrome.[621]

Rivard and associates[622] have shown that in patients with Lesch-Nyhan syndrome, radioactive hypoxanthine cannot be incorporated into platelet nucleotides. This results in a significantly lower adenosine triphosphate platelet content. Nonetheless, platelet function and number are normal in Lesch-Nyhan syndrome.

Brain Trauma

Brain tissue from all mammalian species is rich in thromboplastin activity. Severe injury to the brain that disrupts the brain architecture may release this material into the circulation. This most commonly occurs after gunshot wounds or crush injury to the head and has resulted in acute DIC.

Anorexia Nervosa

Patients with anorexia nervosa may demonstrate many of the hematologic manifestations of severe malnutrition. In one patient with anorexia nervosa, the total amount of red cell lipids was normal, but there was an increased proportion of the long-chain polyunsaturated fatty acids associated with starvation.[623] Small numbers of irregularly shaped red blood cells are often seen.[624] The sedimentation rate is low. About a third of subjects will have a normochromic, normocytic anemia.[625] Slight to moderate leukopenia and neutropenia develop in about half of the patients who are severely malnourished. This may be associated with an increased risk for infection.[626] The bone marrow may become hypoplastic and filled with gelatinous material and fat.[627] Leukocyte response to bacterial infection may be suboptimal. Several months may be needed for the white cell abnormalities in anorexia nervosa to resolve after adequate caloric intake. Platelet counts are generally normal, but mild depressions and occasionally severe depressions are observed.[628] A marked increase in platelet hyperaggregability may be found.[629]

SKIN DISEASES

Skin diseases are only rarely a direct cause of hematologic disturbances. More often than not, the hematologic alterations reflect a simultaneous disturbance in more than one developmental system, such as the skin and blood. Certain disorders that affect the hematologic system in a major way, such as Wiskott-Aldrich syndrome, are described in Chapter 23.

Eczema and Psoriasis

Patients with extensive eczema or psoriasis commonly have a mild anemia.[630] The anemia is usually normochromic and normocytic, although microcytosis may occur. Typically, this anemia is associated with a low serum iron level and normal or decreased iron-binding capacity. Because the level of iron in bone marrow is not diminished, the anemia is best classified as an anemia of chronic disorders.[630] A defect in red blood cell deformability resulting in decreased deformability in eczematous patients has been reported.[631] Some individuals with extensive rash will have greatly expanded whole blood and plasma volumes, which may result in a dilutional anemia.[621,633] In rare patients with eczema or psoriasis, long-standing steatorrhea may develop and cause folate malabsorption and macrocytic anemia.[634] Psoriasis may be a widespread membrane disorder. Alterations in red blood cell sodium and potassium fluxes are seen, as well as alterations in membrane lipid composition (an increase in arachidonic acid and unsaturated fatty acid content).[635,636] The increased erythrocyte membrane arachidonate and platelet malondialdehyde production

noted in patients with psoriasis may normalize after treatment with fish oil.[637]

Dermatitis Herpetiformis

Anemia may result from the malabsorption syndrome found in many individuals with dermatitis herpetiformis. It usually causes a megaloblastic anemia.[638] Splenic hypofunction and atrophy may also occur[639] and are detectable by the presence of Howell-Jolly bodies on the peripheral blood smear. This lymphoreticular dysfunction probably relates to the high incidence of celiac disease found in association with dermatitis herpetiformis. Hyposplenism is also common in children and adults with celiac disease.[640] In any event, it is generally held that the hematologic consequences of dermatitis herpetiformis are simply a result of the nutritional problems produced by this disease.[641]

Dyskeratosis Congenita

An illness resembling Fanconi's aplastic anemia may occur in patients with dyskeratosis congenita.[642] Before onset of the skin problem, thrombocytopenia, macrocytosis, and elevations in fetal hemoglobin may be seen.[643] These abnormalities, which result in hypoplastic anemia, appear to be a stem cell defect because they are preceded by a prolonged period characterized by a decrease in the number of precursor cells in both the bone marrow and peripheral blood of such patients.[644] Interested readers are referred to Chapter 8 for recent findings in this disorder.

Hereditary Hemorrhagic Telangiectasia

This inherited structural abnormality of the vasculature is characterized by mucocutaneous telangiectases caused by localized dilation and convolution of venules and capillaries. It is an autosomal dominant disorder that results in a bleeding tendency because of the friable blood vessels. Telangiectases predominate on the lips, buccal mucosa, gingivae, palate, tongue, and skin of the face and upper parts of the body and may be present in visceral organs as well. Pulmonary arteriovenous fistulas are not rare but tend to appear later in life. Easy bruisability, epistaxis, and respiratory and gastrointestinal bleeding may be caused by these telangiectases.

Ehlers-Danlos Syndrome and Other Connective Tissue Disorders

The elastic tissue defects seen in Ehlers-Danlos syndrome may result in an increased bleeding tendency. A somewhat similar problem occurs in association with pseudoxanthoma elasticum and Marfan's syndrome. Platelet dysfunction in the form of reduced aggregation in the presence of adenosine diphosphate, collagen, and norepinephrine has been described in both Ehlers-Danlos and Marfan's syndrome. A defective fibronectin has been proposed as the cause of the hypermobility and platelet dysfunction.[645] An unusual sensitivity to aspirin has been noted in one family with Ehlers-Danlos type IV syndrome.[646]

Mast Cell Disease

In this disorder, large numbers of mast cells are found, often diffusely located in the skin or the gastrointestinal tract.[647] These cells periodically release histamine and heparin-like substances.[647,648] Trauma to involved areas may trigger release of these substances and may also cause urticaria and blistering of affected parts of the body. A coagulation defect is the hematologic manifestation of mast cell disease. Laboratory testing demonstrates a heparin-like effect. Because fatal hemorrhage may result from this excessive anticoagulant effect, treatment with protamine sulfate may be necessary.

Urticaria pigmentosa is one form of mast cell disease. On rare occasion, mast cell disease and urticaria pigmentosa precede the onset of mast cell leukemia.[649]

LEUKOCYTE VARIATIONS IN DISEASE STATES

Since the recognition by Huët[650] in 1931 that a nuclear segmentation defect, now called the Pelger-Huët anomaly, was inherited, a wide variety of morphologic variations in leukocytes have been found. Many of these alterations are discussed in detail in other chapters.

Nuclear Changes

Pelger-Huët Anomaly

In this anomaly, segmentation of lobes in neutrophilic leukocytes is limited (Fig. 36-5). The anomaly was described first by Pelger in 1928, who thought that the finding was a manifestation of tuberculosis.[651] Huët[650] recognized that it appeared to be inherited as an autosomal dominant trait. Individuals with this disorder rarely have neutrophils or eosinophils with more than two lobes. In heterozygotes, the neutrophils are unsegmented, dumbbell shaped, or bilobed in the nuclei. In homozygotes, the vast majority of neutrophils have round nuclei.

This anomaly affects 1 in 6000 individuals. Although neutrophil migration may be minimally impaired, granulocyte function is otherwise normal, and individuals with this inherited anomaly suffer no adverse effects. The Pelger-Huët anomaly is inherited in an autosomal dominant fashion and is due to mutations within the lamin B receptor, a member of the sterol reductase family.[652] Expression of the lamin B receptor affects neutrophil nuclear shape and chromatin distribution.
FIGURE 36-5. Pelger-Huët anomaly.

FIGURE 36-6. Increased nuclear appendages in a neutrophil of a patient with trisomy 13-15. *(From Huehns ER, Lutzner M, Hechte F. Nuclear abnormalities of the neutrophils in D-(13-15)-trisomy syndrome. Lancet. 1964;1:589-590.)*

A Pelger-Huët–like change in granulocyte morphologic characteristics may occur as an acquired condition in several disease states, such as chronic infections of the bowel, glandular fever, malaria, leukemia, and diffuse metastatic disease.[653,654] This same finding may be produced by toxins and certain drugs such as colchicine.[655] A reversible Pelger-Huët anomaly has been seen with acute gastroenteritis caused by *Salmonella* group D.[656] Not only does leukemia potentially result in a Pelger-Huët anomaly, but non-Hodgkin's lymphoma may as well.[657] Pelger-Huët anomaly has been reported in association with Sjögren's syndrome.[658] It has also been found in some patients with trisomy 18 syndrome.[659] A transient acquired Pelger-Huët anomaly may be observed with *Mycoplasma pneumoniae* infection.[660] Valproic acid toxicity may be associated with the anomaly.[661] Bilobed nuclei are common in many other animal species, most notably in the rabbit.

Hereditary Constitutional Hypersegmentation of Neutrophils

In this autosomal dominant condition, the mean number of neutrophil nuclear lobes is approximately four as compared with the approximately three lobes found in normal neutrophils.[662] This hereditary form of neutrophil hypersegmentation is not associated with any adverse effects and appears to be more common than previously thought. It must be distinguished from more significant disorders such as vitamin B_{12} and folate deficiency and myeloproliferative states.

Hereditary Constitutional Hypersegmentation of Eosinophils

This is probably an autosomal disorder in which the mean lobe count of eosinophils is between 3 and 4, unlike the mean lobe count of normal eosinophils, which is 2.3. Affected individuals are otherwise normal.[663]

Hereditary Giant Neutrophils

Normal neutrophils have an average cell size of 12.7 μm. In this hereditary autosomal dominant disorder, neutrophil diameter is about 17 μm, which represents an approximate doubling of white cell size.[664] There are usually 6 to 10 nuclear lobes. In actuality, only relatively few neutrophils demonstrate these morphologic abnormalities in affected individuals, but they are clearly distinguished from the normal population because these findings never occur otherwise.

Hereditary Prevalence of Nuclear Appendages

In general, thread-like and other small projections from the nucleus of neutrophils are relatively nonspecific. Excessive numbers of projections may be seen in various forms of carcinoma, in trisomy 13-15, and as a hereditary phenomenon (Fig. 36-6).[665]

These disorders must be distinguished from those that increase the number of neutrophil drumsticks, which are female-specific nuclear appendages. In normal women, drumsticks are present in 2% to 10% of mature neutrophils.[666] At least six drumsticks per 500 neutrophils must be present for the sex to be determined as female. Pseudodrumsticks in males generally occur, if at

all, in fewer than 6 of 500 neutrophils. Drumstick number is increased in any condition with an increased average number of lobes per cell—for example, in the hypersegmentation anomaly, when there are multiple X chromosomes in the karyotype, and when there is an isochromosome of the long arms of an X chromosome (X-iso X). The presence of a Y chromosome reduces the drumstick number when there are supernumerary X chromosomes (XXY, XXXY, or XXXXY). The normal drumstick head is 1.5 μm in diameter. The diameter is increased in females with a long-arm isochromosome.

Cytoplasmic Abnormalities

Granulation Disturbances

Alder-Reilly Anomaly

This anomaly, described independently by Alder and Reilly, is discussed in detail in Chapter 24.[667] It is a hematologic manifestation of Hurler's syndrome in which prominent granules (often called Reilly bodies) are found in neutrophils that stain positively with metachromatic stains (Fig. 36-7). Increased numbers of dense cytoplasmic granules may also be seen in other mucopolysaccharidoses. Lymphocytes, monocytes, and plasma cells may also be affected.

May-Hegglin Anomaly

In this rare autosomal dominant disorder, large (up to 5 μm) pale blue–staining inclusions are found in the cytoplasm of neutrophils, eosinophils, basophils, and monocytes.[668] Thrombocytopenia and giant platelets are also observed. The inclusions consist of material derived from the endoplasmic reticulum, and their gross appearance is similar to that of Döhle bodies. Ultrastructural and functional abnormalities of platelets may be observed in patients with the May-Hegglin anomaly.[669]

The May-Hegglin anomaly is only one of three forms of hereditary thrombocytopenia seen in association with giant platelets and inclusion bodies in leukocytes. Fechtner's syndrome is a variant of Alport's syndrome with inclusion bodies consisting of dispersed filaments, ribosomes, and a few segments of rough and smooth endoplasmic reticulum. The Sebastian platelet syndrome shows the same platelet and leukocyte morphologic characteristics observed in Fechtner's syndrome, but the anomalies of Alport's syndrome are lacking.[670]

Chédiak-Higashi Syndrome

This disorder is discussed in detail in Chapter 21. Giant granules give the cytoplasm of the neutrophil a bizarre appearance. The granules seen in the neutrophils of patients with Chédiak-Higashi syndrome are not specifically isolated to the neutrophil. The granule abnormality is due to a defect in the *LYST1* gene, which predisposes these patients to hemophagocytosis.[671] Giant membrane-bound cytoplasmic granules have been observed in the epidermal Langerhans cells of a patient with Chédiak-Higashi syndrome.[672]

Batten-Spielmeyer-Vogt Disease

This degenerative neurologic disease was noted by Strouth and colleagues[673] in 1966 to be associated with coarse azurophilic granulation in neutrophils. Because these granules do not exhibit metachromasia, they can be easily differentiated from those observed in the mucopolysaccharidoses.

FIGURE 36-7. Reilly bodies in the cytoplasm of neutrophils (**A**) and lymphocytes (**B**) in a patient with Hurler's syndrome. Vacuoles are also present in the cytoplasm of the neutrophil.
Hereditary Dense Granulation of Neutrophils

It should be emphasized that several normal individuals have been described who demonstrate dense granulation of neutrophils.

Hermansky-Pudlak Syndrome

Hermansky-Pudlak syndrome (HPS) is a rare familial disorder characterized by albinism, a bleeding problem related to platelet dysfunction and accumulation of ceroid-like pigment in bone marrow macrophages, and the presence of lipopigment bodies, as well as other dense inclusions.[674,675] Similar ceroid deposition may be found within dermal macrophages.[676] The bleeding time abnormality seen in HPS may be correctable by the administration of 1-desamino-8-D-arginine vasopressin. HPS is a heterogeneous group of disorders that result from defective lysosome-related organelle formation. Lysosome-related organelles are found in melanosomes, platelets, and cytotoxic T cells, and defects in seven genes in humans disrupt the function of protein complexes such as BLOC-1, BLOC-2, BLOC-3, and AP3. This disorder has been important in defining key components of intracellular organelle trafficking.[677]

Vacuolization

Small vacuoles are not uncommonly associated with granules in the cytoplasm of normal lymphocytes. Large vacuoles in both lymphocytes and neutrophils develop rapidly in specimens collected in anticoagulants, especially ethylenediaminetetraacetic acid. Cytoplasmic vacuolization may occur in response to certain stresses, such as burns and infections. Vacuolization of lymphocytes is noted in a variety of inherited disorders, including Tay-Sachs disease, Niemann-Pick disease, and some instances of Hurler's syndrome, possibly after the disappearance of specific granules.[678-680] Some patients with type II glycogen storage disease (Pompe's disease) have vacuolated lymphocytes. In this disease, a high percentage of the vacuoles stain with the periodic acid–Schiff reaction.

A familial vacuolization of leukocytes (Jordan's anomaly) has been described in which vacuoles are present in the cytoplasm of granulocytes, monocytes, and occasionally lymphocytes and plasma cells.[681] These vacuoles contain lipids and range in size from 2 to 5 μm. Members of some affected families have had ichthyosis, whereas others have had a progressive form of muscular dystrophy.[682]

Eosinopenia and Eosinophilia

The lowest normal eosinophil counts are found in the immediate newborn period, after which such values in infants, children, and adults are remarkably similar.[683] The mean absolute eosinophil count of children and adults is 150 cells/mm³, with values of up to 700 cells/mm³.[684] A diurnal variation in the eosinophil count exists, and the highest value is seen in the evening. These changes

Box 36-1	Causes of Eosinophilia

Allergic disorders: Asthma, urticaria, hay fever, angioneurotic edema, occasional drug sensitivity, or simple exposure

Parasitic infections: Usual in invasive helminthic infections such as *Toxocara* infections, trichinosis, echinococcal infections, and ascariasis and less common in intestinal parasitism; rare in protozoal infection except for malaria

Skin disorders: Pemphigus, dermatitis herpetiformis

Hematologic and oncologic disorders: Hodgkin's disease, acute lymphatic leukemia, chronic myelogenous leukemia, pernicious anemia, postsplenectomy effects, immunodeficiency syndromes, polycythemia vera and other chronic myeloproliferative states, some solid tumors

Infectious disorders other than parasitism: Scarlet fever, chorea, erythema multiforme, chlamydial infections

Inherited eosinophilia

Miscellaneous disorders: Rheumatoid arthritis, periarteritis nodosa, sarcoidosis, radiation therapy, peritoneal dialysis, cirrhosis, Löffler's syndrome (including pulmonary infiltration with eosinophilia syndrome)

probably reflect varying activity in the production of adrenal corticosteroids. Premature infants commonly demonstrate eosinophilia.[428,429] Infection with falciparum malaria can result in eosinopenia.[685]

Eosinopenia may occur as a result of adrenocortical hyperfunction or after the administration of pharmacologic doses of corticosteroids.[686] Some children with Down syndrome also have eosinopenia.

There are many causes of eosinophilia (Box 36-1). In the United States, allergy is the single most common cause of this finding. All types of allergy may result in eosinophilia, including asthma, hay fever, urticaria, eczema, serum sickness, and angioneurotic edema.

Drug exposure is frequently a cause of eosinophilia. In most instances, no specific signs of drug allergy are present, and eosinophilia is noted coincidentally. Although some drugs are associated with a higher incidence of associated eosinophilia, any drug may potentially cause this finding.

Parasitic infections are the most common causes of eosinophilia on a worldwide basis. A general rule is that whereas helminthic infections often cause eosinophilia, protozoal infections (with the exception of malaria) do not. Of the helminthic infections, those associated with tissue invasion rather than those remaining within the bowel lumen cause the greatest degree of eosinophilia. Among the infectious causes of eosinophilia, visceral larva migrans produces the most profound elevations in eosinophil counts, with white blood cell counts greater than 100,000 cells/mm³ not being uncommon. Parasitic infection as a cause of eosinophilia cannot be excluded because of failure to demonstrate larvae or eggs in feces. In children with blood groups other than type AB, a

marked increase in isohemagglutinin titer is highly suggestive of infection with *Toxocara* organisms.

Hypereosinophilic syndrome, which is characterized by pulmonary infiltrates, cardiomegaly, congestive heart failure, and an elevated eosinophil count, is a well-described but poorly understood entity.[687] The eosinophilia in this disorder is marked. Hypereosinophilic syndrome is a term that encompasses disorders such as Löffler's syndrome, eosinophilic leukemoid reaction, endocarditis parietalis fibroplastica, pulmonary infiltrates with eosinophilia, disseminated eosinophilic collagen disease, and eosinophilic leukemia. The etiology of these syndromes is controversial, and the possibility exists that these disorders represent a spectrum of a similar pathologic process. Eosinophilia has been noted in association with acute lymphoblastic leukemia.[688] In several of the patients described, an illness similar to Löffler's syndrome preceded the onset of leukemia.[689] The eosinophilia in these patients is an interesting finding because it is thought to be mediated by interleukin-5 (IL-5) released by thymus-dependent lymphocytes, which in turn stimulates eosinophil proliferation.[690,691] In the last 5 years great progress has been made in recognizing that fusion of tyrosine kinases FIPIL1-PDGFRA leads to the proliferation of T cells that secrete IL-5. This understanding has opened the way for targeted therapy with anti–IL-5 antibody or kinase inhibitors.[692]

There are many other causes of eosinophilia, including collagen vascular disease, malignancy, cirrhosis, and certain skin disorders. Eosinophilia may also be observed as an autosomal dominant familial trait in some families.[693]

Basophilia

Basophilia is usually said to occur when the basophil count exceeds 100 to 150 cells/mm³.[694] Adrenocorticosteroids, infection, hyperthyroidism, and irradiation will decrease the basophil count. A wide variety of disorders may increase the basophil count, including ulcerative colitis, smallpox, varicella, and some occurrences of nephrosis.[695] Basophilia is extremely common in association with myeloproliferative disorders such as chronic myelogenous leukemia, polycythemia vera, and myeloid metaplasia.[696] Basophilia is occasionally seen in Hodgkin's disease and some hemolytic anemias (Box 36-2).[697]

Although increased numbers of basophils in the bone marrow and certain other tissues are found in urticaria pigmentosa and mast cell disease, numbers of blood basophils are not usually increased.

Monocytosis

Monocytosis is common in many protozoal and rickettsial infections and is one of the hematologic hallmarks of certain bacterial infections, especially tuberculosis, subacute bacterial endocarditis, and syphilis.[698] In any process

---

Box 36-2   Causes of Basophilia

Hematologic and oncologic disorders: Some hemolytic anemias, Hodgkin's disease, many chronic myeloproliferative disorders, including chronic myelogenous leukemia and polycythemia vera
Infections: Chronic sinusitis, smallpox, varicella
Endocrine disorders: Hypothyroidism, ovulation, pregnancy
Drugs: Estrogens, antithyroid medications
Miscellaneous: Stress, nephrosis, radiation (may also decrease the basophil count)

Box 36-3   Causes of Monocytosis

Bacterial infections: Syphilis, tuberculosis, subacute bacterial endocarditis, brucellosis
Nonbacterial infections: Rocky Mountain spotted fever, typhus, malaria, kala-azar, trypanosomiasis
Hematologic and oncologic disorders: Hodgkin's disease, preleukemia, leukemia, non-Hodgkin's lymphomas, myeloproliferative disorders, congenital and acquired neutropenia, some hemolytic anemias, metastatic solid tumors, splenectomy
Collagen vascular diseases: Systemic lupus erythematosus, rheumatoid arthritis, polyarteritis nodosa
Miscellaneous: Ulcerative colitis, regional enteritis, sarcoidosis, tetrachlorethane poisoning, Hand-Schüller-Christian syndrome

---

that is associated with granulocytopenia, monocytosis will usually precede and herald recovery. Monocytosis parallels disease activity in some patients with systemic lupus erythematosus and rheumatoid arthritis.[699] Several hematologic malignancies may be associated with peripheral blood monocytosis (Box 36-3).

Lymphocytosis

Except for pertussis, acute bacterial infections are rarely associated with lymphocytosis. Lymphocytosis should not be expected to be uniformly present in infants younger than 6 months who have pertussis.[700] Only 25% of these infants will have an elevated lymphocyte count suggestive of pertussis. Chronic bacterial infections such as tuberculosis and brucellosis may cause a sustained lymphocytosis. Although many nonspecific viral infections may cause a mild lymphocytosis with the presence of transient atypical lymphocytes, infectious mononucleosis and cytomegalovirus infection are the only probable causes of persistent atypical lymphocytosis. Markedly increased lymphocyte counts are sometimes seen in association with a disorder known as "acute infectious lymphocytosis." Marker analysis of the blood of such individuals has shown that the increased lymphocytes are predominantly T cells associated with a rise in the helper-inducer

Box 36-4	Causes of Lymphocytosis

Infection: Pertussis, infectious mononucleosis, infectious lymphocytosis, infectious hepatitis, cytomegalovirus (including postperfusion syndrome), toxoplasmosis, syphilis, brucellosis, many common viral illnesses
Hematologic disorders: Lymphocytic leukemias, neutropenia (a relative lymphocytosis)
Miscellaneous: Thyrotoxicosis, Addison's disease (a relative lymphocytosis)

Box 36-5	Causes of Lymphocytopenia

Infection: Active tuberculosis, malaria (sometimes)
Collagen vascular disease: Systemic lupus erythematosus, regional enteritis
Certain immunodeficiency syndromes
Endocrine disorders: Hyperadrenalism and adrenal corticosteroid administration
Hematologic and oncologic disorders: Hodgkin's disease, solid tumors (some), aplastic anemia
Excessive loss: Thoracic duct drainage, intestinal lymphangiectasia

phenotype ($CD4^+$) population of lymphocytes.[701] Thyrotoxicosis in both children and adults will also cause lymphocytosis (Box 36-4).[702]

Causes of lymphocytopenia are summarized in Box 36-5.

ACQUIRED IMMUNODEFICIENCY SYNDROME

In the early 1980s a newly described constellation of symptoms that resulted from immune compromise and led to death from opportunistic infections and unusual malignancies was recognized in a cluster of homosexual males.[703-705] These early descriptions of what is now known as acquired immunodeficiency syndrome (AIDS) heralded the beginning of what has become one of the major medical, public health, and social issues of our time. Identification of the retrovirus HIV as the etiologic agent that transmits the disease[706,707] has led to major advances in understanding the pathogenesis of AIDS. At least two types of HIV, HIV-1[706,707] and HIV-2,[708] exist; both are considered lentiviruses based on similarities in genetic composition, mechanisms of replication, and interaction with their hosts.[709] A characteristic of lentivirus infections is that they cause slowly progressive disease with an incubation period of months to years before clinical symptoms appear. Although this concept is new with respect to human viral diseases, it is well established in lentivirus infections of domestic animals such as sheep, in which maedi-visna develops, or in goats infected with caprine-arthritis-encephalitis virus.[710] The worldwide spread of AIDS has led to a plethora of information

about the biology of the virus and its epidemiology and incidence projections in different countries, as well as a concerted search for effective means of prevention and treatment. Increasing numbers of infected adults, in particular women of childbearing age, have highlighted a rapidly growing pediatric population with AIDS. A discussion of the hematologic complications and manifestations of this disorder must include comments about the epidemiology, biology, and transmission of HIV infection because all are germane to the clinical findings, diagnosis, and treatment in children.

Epidemiology

The first occurrences of AIDS in the pediatric population in the United States took place in children born to mothers infected with HIV or in children, especially neonates, who had received blood products contaminated with HIV.[711] The actual number of children infected with HIV in the United States is unknown, but increasing spread into the pediatric population reflects a change in the demographics of the adult infection. Greater numbers of women of childbearing age are at risk of being infected, either from illicit drug use and direct contact from contaminated needles or from sexual relations with an infected person.[712,713] A 1988 study examining HIV infection in the United States reported 737 occurrences of AIDS in children younger than 13 years, a 64% increase over the number found in the previous year. In 75% of these patients the disease was acquired perinatally, in 13% it was associated with transfusions, and in 5% it occurred in children with hemophilia.[714] More than 70% of cases of AIDS acquired perinatally were related to intravenous drug use by the child's mother or the mother's sexual partner.[714] In July 1989, 1600 cases of perinatal AIDS in the United States had been reported to the Centers for Disease Control and Prevention, and a rise to 10,000 to 20,000 cases was predicted for the next few years.[715] The findings of the HIV Survey in Childbearing Women[716] estimated that 7000 HIV-infected women gave birth to infants in the United States in 1993. If a perinatal transmission rate of 15% to 30% is assumed, approximately 1000 to 2000 infants were infected with HIV perinatally in 1993.[717] HIV infection is increasing in urban women throughout Europe and is having a dramatic impact in central and eastern Africa and Haiti. In Zaire, 5% to 10% of women of childbearing age are seropositive for HIV, and heterosexual transmission unrelated to drug abuse accounts for nearly all of the reported cases.[718] Of interest is the fact that initially the western Africa population seemed to be relatively free of AIDS until reports of patients with typical symptoms started to appear.[719-721] Unexpectedly, these patients were seronegative for HIV-1 antigens but were found to be infected with a related virus termed HIV-2. The sequence of HIV-2 differs significantly from that of HIV-1 and is remarkably similar to that of a virus isolated from captive macaques, termed simian immunodeficiency virus (SIV)

mac.[722,723] This noted similarity has led to an interesting discourse on the origins of HIV, and debate still continues on whether HIV-1 and HIV-2 could indeed have a common ancestor that resided in the genome of nonhuman primates or whether the related viruses evolved from two separate horizontal infections in humans.[724] Although the origins of HIV are not known, certain routes of transmission are understood, and it is anticipated that with control of the blood supply in most developed countries, vertical transmission from mother to child will be the sole route of pediatric HIV infection in the future.

The AIDS pandemic in Africa and, in particular, southern Africa has reached catastrophic proportions. The rising incidence of the disease in eastern Europe, India, and Thailand and throughout most of the Third World poses many political, social, and medical challenges that are beyond the scope of this chapter.

Transmission

Transmitted primarily through contact with infected lymphocytes and monocytes, HIV may be found in blood, semen, and vaginal secretions.[725,726] Isolation of the virus from 13- and 15-week abortuses, placenta, and cord blood provides strong support for intrauterine infection.[711,727-729] AIDS has developed in children born by cesarean section who were never again in contact with their mothers,[730] and the fact that life-threatening illness is often manifested within the first few months of life favors vertical transmission in utero. Maternal-fetal transfusion at delivery remains another possible route of infection.[731] Postpartum transmission via breast milk, though possible, appears to be rare. Accordingly, in countries in which safe feeding substitutes are not readily available, breast-feeding should not be curtailed; however, in developed countries where alternatives exist, breast-feeding by HIV-infected women is discouraged.

The rate of transmission from mother to child is estimated to be about 25% based on several studies from the United States and Europe.[732-735] Factors that influence transmission are related to maternal health, with asymptomatic mothers experiencing a lower rate of infected children. Transmission from mother to child can be reduced from 25% to 2% by the use of antiretroviral therapy during pregnancy, labor, and the neonatal period. Although it is clear that breast milk may be a source of maternal transfer of virus from mother to child, the risk-benefit ratio is dependent on the socioeconomic status of the mother and child.[731]

Major advances in screening and testing of the blood supply in the United States after 1985 led to a reduction in the risk of receiving a contaminated single transfusion in 1988 to 1 in 250,000.[736] The first screening test is a questionnaire to exclude people who engage in high-risk activities. The next step is an enzyme-linked immunosorbent assay for detection of antibodies to HIV antigens. In rare individuals who are infected but seronegative, HIV can escape detection, but newer, sensitive screening tests detect the viral genome by PCR.[737] In addition, routine screening for cytomegalovirus antibody serves as a surrogate screening test for HIV because it is also present in 95% of HIV-infected donors.[738]

Tragically, individuals with bleeding disorders such as hemophilia A and B who received clotting factors from a large donor pool for a single infusion have had an increased likelihood of acquiring AIDS. In large metropolitan areas, the number of these patients who are affected approaches 90%. Recognition of the problem and the availability of heat-pasteurized preparations of factor concentrates and recombinant factor preparations should eliminate the risk in patients with newly diagnosed AIDS.

Sexually active adolescents are at risk to the same degree as adults, and younger children have been infected as a result of sexual abuse.[711]

Biology

The genome of HIV encodes the structural proteins GAG, POL, and ENV, which are common to all replication-competent retroviruses.[738] The life cycle of the virus begins with entry into a susceptible cell. Infection by HIV appears to be initiated by binding of gp120 of the viral envelope protein (encoded by the *ENV* gene) to the CD4 antigen.[739-741] Cell surface expression of CD4 is necessary and sufficient for viral infection of human cells in vitro.[742] Interaction between CD4 and HIV envelope proteins mediates the formation of syncytia, which are multinucleate collections of fused infected and uninfected cells.[743] The interaction between gp120 and CD4 triggers a conformational change in gp120 that promotes engagement of the HIV coreceptors CCR5 or CXCR4. These events result in gp41 envelope protein–mediated fusion of viral and cellular membranes. Fusion then allows the HIV capsid component to be inserted into the cell. Viral entry appears to occur through coated pit–dependent and coated pit–independent pathways; however, the precise subcellular compartments of viral uncoating remain unresolved. After uncoating is complete, the HIV preintegration complex is formed with the loss of some viral core proteins. The preintegration complex components include the double-stranded DNA version of the viral genome, as well as the reverse transcriptase, matrix, integrase, and Vpr proteins.[744] It was initially thought that G_0 cells lacked the cellular factors necessary for complete synthesis of the DNA provirus and were probably unable to support effective DNA provirus integration into the host genome.[745,746] Recent work has shown that both nondividing macrophages and naïve T cells serve as important targets for HIV infection in vivo. It now appears that nuclear import signals in the viral integrase, matrix, and Vpr proteins, as well as a DNA flap produced during reverse transcription, play a key role in allowing the HIV preintegration complex to enter the nucleus. It also appears that activation of HIV-1 provirus in dividing cells is influenced by the action of constitutively expressed

host transcription factors, such as Sp1, TDFII, CTF/NFI, and LBP-1,[747] and inducible cellular transcription factors, such as NFκB and NFAT-1.[748] The HIV-1 long terminal repeat (LTR) contains *cis*-acting motifs that act as signatures to which these *trans*-acting proteins can bind. In particular, the LTR has a duplicated NFκB site to which NFκB, which is induced by T-cell activation, is able to *trans*-activate the expression of viral genes. In this way, the HIV LTR acts like a T-cell activation gene.[748]

The HIV genome also codes for two different proteins required for viral morphogenesis and maturation (VF and VPU) and three nonstructural regulatory proteins (TAT, REV, and NEF).[749] The TAT protein is a very effective *trans*-activator of all genes linked to the LTR, including the *TAT* gene itself.[750,751] The target sequence for TAT recognition coincides with a predicted RNA secondary structure,[7525] and the so-called *trans*-activation response element appears to be present within all HIV transcripts. The *REV* gene product is a 19-kd phosphorylated protein[753] that appears to regulate nuclear export of the incompletely spliced viral RNA that is normally excluded from the cell cytoplasm.[754] During the initial course of infection only spliced viral RNA is transported to the cytoplasm for the translation of TAT, REV, and NEF proteins. The TAT protein induces a positive feedback on transcription, whereas the REV protein recognizes a REV response element that enhances the transport of singly spliced or unspliced RNA to the cytoplasm. These latter transcripts encode structural proteins, and it has been proposed that the action of REV restricts the expression of viral structural protein to a relatively short period, thereby diminishing the host's ability to recognize infected cells.[748] The critical roles of these regulatory proteins in the HIV life cycle may provide targets for future antiviral agents, and in this regard, *trans*-dominant mutants of REV have been shown to be effective in vitro.[755]

Mononuclear phagocytes harbor HIV-1, and it has been suggested that their tropism contributes to the latency of the infection.[756] Megakaryocytes also harbor the virus.[757,758] Indeed, tropism of macrophages is via CCR5 tropic strains, and CXCR4 tropic virus predominately infects nondividing T cells. Direct in vitro infection of microglia cells[759] and epithelial cells, especially in the gut, may partly explain some of the clinical manifestations of HIV infection, which are most likely a result of a direct cytopathic effect of the virus and the consequences of immune suppression.

Work has focused on the biologic and immunologic characterization of long-term survivors of patients infected with HIV-1.[760,7661] These studies have to be viewed in the context of a new understanding that has modified thought pertaining to the dynamics of HIV replication and host responses during the early phases of the disease.[762] It was previously assumed that the latent phase of HIV infection involved less extensive viral turnover. Two articles have indicated that HIV viremia is a balance between continuous rounds of de novo viral infection and replication and vigorous induction of CD4+ and CD8+ lymphocytes that attempt to induce sterilizing immunity.[763,764] Mathematical modeling has allowed a projection that billions of virions escape; however, when they do, they rapidly acquire resistance to single-drug therapy. These studies raise the hope for combination antiviral therapy and the possibility that sterilization immunity may occur. In fact, Bryson and colleagues[765] described an infant who was infected with HIV perinatally, but the infection subsequently resolved. HIV infection was not detectable in this child 5 years later. The authors of this study convincingly demonstrated that the child was indeed infected, but it is not clear how the infection was resolved.[766] The question of effective immunity to HIV infection has also been studied in a subgroup of patients who remain asymptomatic despite HIV infection. In one study it appeared that asymptomatic long-term survivors have a decreased viral load in their plasma and low levels of HIV in their lymphoid tissue.[761] Furthermore, lymphoid architecture and immune function appeared to be intact in 15 subjects with nonprogressive HIV infection as compared with 18 subjects who had progressive disease. The implication of these findings is that therapies focused on induction of some degree of viral attenuation in combination with stimulation of immune responses may offer the best hope for curtailing HIV infection.

The idea that a reduction in viral load is an important hallmark of therapy is further bolstered by a study that showed a reduction in maternal-infant transmission of HIV with zidovudine treatment.[767] In a study of 363 HIV-positive pregnant women, 180 were randomly assigned to receive zidovudine and 183 to receive placebo; 13 infants in the zidovudine group and 40 in the placebo group were infected with HIV. The results strongly suggest that a regimen of antepartum zidovudine treatment reduces the risk of maternal-infant HIV transmission by approximately two thirds.[767] More recent studies involving protease inhibitors used with other agents strongly suggest that combination therapy is the appropriate approach to the treatment of this pernicious disease.[768] The latest study revealed that combination therapy with protease inhibitors has reduced the mortality from 5.3% in 1996 to 0.7% in 1999 in a cohort of HIV-infected children from 0 to 20 years of age in the United States. Furthermore, the combination of HIV screening in pregnancy and the use of antiviral therapy has reduced the risk of vertical transmission in the United States from 25% to 1.4% such that the incidence of HIV infection in infants is 300 per year.[768] This should be contrasted to the situation in Third World countries, where it is estimated that 1700 new pediatric infections occur per day.[770]

Clinical Features

General

Infection with HIV results in a spectrum of disease from an asymptomatic state to severe immunodeficiency

involving multiple organ systems. The heterogeneity of symptoms is explained by the underlying pathophysiologic course in that (1) the incubation period may be weeks, months, or years; (2) the direct cytopathic effect on target cells, predominantly $CD4^+$ lymphocytes, monocytes, and accessory cells, results in dysregulation of the immune system; and (3) the viral elimination phase that is accompanied by a host response to infection varies with the immune competence of the host. Because many children are infected congenitally, they show signs early in life and often have constitutional symptoms such as unexplained diarrhea, fever, night sweats, generalized lymphadenopathy, and hepatosplenomegaly. Failure to thrive and developmental delay are often prominent early manifestations of HIV infection in children. Susceptibility to recurrent infections by common bacterial and viral pathogens, as well as to opportunistic infections, increases the index of suspicion that the underlying disorder is in fact AIDS. These and other manifestations of HIV infection are summarized in Box 36-6.

Hematologic Findings

The hematopoietic dysfunction that is invariably associated with HIV infection results from global dysregulation of the physiologic cascades of antibody formation, coagulation and complement, and direct infection of key regulatory cells. Acute and chronic infections and therapies for the underlying disorder also affect hematopoiesis. Although for the purposes of discussion it is simpler to view these changes according to cell lineage, it should be stressed that these events rarely occur in isolation. Examination of the peripheral blood smear from the majority of AIDS patients reveals anemia and granulocytopenia and, in a third of patients, associated thrombocytopenia.[771]

Box 36-6	**Clinical Manifestations**

PRIMARY MANIFESTATIONS OF HIV INFECTION

Hematologic and Immune Abnormalities

Hypergammaglobulinemia
Lymphopenia ($CD4^+$ cells decrease)
Decreased CD4/CD8 ratio
Thrombocytopenia
Anemia
Neutropenia
Drug allergies (e.g., trimethoprim in 40% to 60% of
    patients)

Nonspecific Findings (includes children with two or more unexplained findings for more than 2 months)

Failure to thrive
Hepatosplenomegaly
Generalized lymphadenopathy
Parotitis
Diarrhea (three or more loose stools per day)

Neurologic Disease

Loss of intellectual ability or developmental milestones
Impaired brain growth (acquired microcephaly, brain
    atrophy, or both)
Progressive systemic motor defects
    Paresis
    Abnormal tone
    Pathologic reflexes
    Ataxia or gait disturbance

Cardiovascular Disease

Cardiomyopathy
Arrhythmias

Other Diseases

Hepatitis
Nephropathy (sclerosing glomerulonephritis)
Dermatologic diseases (most commonly seborrheic
    dermatitis)

SECONDARY MANIFESTATIONS OF HIV INFECTION

Secondary Infections

Pneumocystis carinii pneumonia
Chronic cryptosporidiosis
Disseminated toxoplasmosis (onset after 1 month of age)
Extraintestinal strongyloidiasis
Chronic isosporiasis
Candidiasis (esophageal, bronchial, and pulmonary)
Extrapulmonary cryptococcosis
Disseminated histoplasmosis
Mycobacterial infection
Cytomegalovirus infection (onset after 1 month of age)
Coccidioidomycosis
Nocardiosis
Progressive multifocal leukoencephalopathy
Lymphocytic interstitial pneumonitis

Secondary Cancers

Kaposi's sarcoma
B-cell non-Hodgkin's lymphoma
Primary lymphoma of the brain

HIV, human immunodeficiency virus.
From Centers for Disease Control and Prevention (CDC). Classification systems for human immunodeficiency virus (HIV) in children
    under 13 years of age. MMWR Morbid Mortal Wkly Rep. 1987;36(15):225-230, 235-236.

Bone Marrow Findings

In several studies, the bone marrow morphologic changes in patients with AIDS were reported.[772] The most common findings were hypercellularity, lymphoid aggregates, plasmacytosis, and dysplasia. When thrombocytopenia is present, the marrow often contains adequate megakaryocytes, thus suggesting an immune mechanism of platelet destruction (see later). The anemia and granulocytopenia appear to be related to the dysplastic bone marrow and result from ineffective hematopoiesis. Increases in reticulum and fibrosis have been reported in association with *Mycobacterium avium* infection.

Thrombocytopenia

The underlying mechanism of thrombocytopenia, which can be the initial finding of HIV infection in children, appears to be immune destruction of platelets. Several studies have identified a high incidence of cytophilic antibodies[773,774] and have highlighted concomitant complement deposition on the platelet.[775] In addition, a 25-kd platelet-associated antigen has been detected in thrombocytopenic adults and children with AIDS[776]; however, the presence of the antibody in serum does not invariably lead to thrombocytopenia because 15 of 16 nonthrombocytopenic patients with AIDS and generalized adenopathy also had this antibody. Purified platelet eluates from homosexuals and narcotic addicts with AIDS and thrombocytopenia contain anti-HIV antibodies; however, no viral antigens were detected on the platelet surface, and PCR failed to detect provirus.[777] In 1983, an idiopathic thrombocytopenic purpura syndrome in patients with hemophilia was reported,[778] and it was subsequently recognized that these patients, like many older patients with hemophilia, had AIDS. The mechanisms of platelet destruction in hemophilia, as with that in other AIDS populations, remain an open question and as such pose a challenge in the design of rational treatment regimens. Spontaneous recovery from thrombocytopenia does occur; for instance, in one study, 8 of 25 patients with thrombocytopenia recovered.[779] Treatment is often considered when the platelet count decreases to less than 20,000/mL or a clinical bleeding episode is encountered. The question whether prednisone therapy worsens the underlying disease remains unanswered, but prednisone has been used as the initial therapy for thrombocytopenia in homosexual men. In 16 of 17 patients with a mean platelet count of 21,000/mL who were treated with 60 to 100 mg/day of prednisone, platelet counts increased to greater than 50,000/mL. However, platelet counts decreased to pretreatment levels with a reduction of the prednisone dose.[780] Similar findings were observed in another study in which 19 of 24 patients responded initially to prednisone treatment, but the improvement was sustained in only 2 when prednisone therapy was stopped.[781] Several studies have indicated that splenectomy is effective in most patients whose platelet counts decline after prednisone therapy, and it is often considered in patients with hemophilia and thrombocytopenia.[775]

High-dose intravenous immunoglobulin, 1 g/kg on days 1, 2, and 15 and every 3 weeks, resulted in a transient increase in platelet count.[781] However, all patients experienced relapse during the 3-week maintenance therapy period. Other modalities include danazol anti-Rh immunoglobulin[782] and zidovudine, which has been used in patients who are asymptomatic and have mild thrombocytopenia (50,000/mL),[783-785] as well as in patients with lower platelet counts who are asymptomatic.

Some consensus can be drawn from these studies. Immediate treatment of patients with platelet counts below 20,000/mL or clinical bleeding appears to be prednisone, 30 to 40 mg daily, and possibly high-dose intravenous gamma globulin, with splenectomy being a good option for long-term control. Zidovudine and other new treatment modalities should also be considered as maintenance therapy.

Anemia and Granulocytopenia

Anemia and granulocytopenia are found in most patients with AIDS and reflect, in large part, ineffective hematopoiesis. The anemia is typically normochromic and normocytic, with a low reticulocyte count and mild to severe anisocytosis and poikilocytosis. Up to 40% of patients with AIDS may have positive findings on a direct Coombs test as a result of absorbed immunoglobulin. Although antibodies have been detected on the surface of granulocytes,[786,787] the mechanism for granulocytopenia appears to be suppression of bone marrow progenitors. Bone marrow from patients with HIV infection exhibits colony formation (colony-forming units–granulocyte-macrophage and burst forming units–erythroid) similar to that in HIV-seronegative control subjects when cultivated in serum from an HIV-seronegative donor. However, there is selective suppression of colony formation in bone marrow derived from a patient with HIV infection versus bone marrow from seronegative donors when cultivated in seropositive sera. This suggests that progenitor cells and progeny are able to be infected with HIV and express HIV antigens on their surface that are recognized by HIV antibodies, thus accounting for the suppression. Further support for this hypothesis comes from the demonstration of provirus in megakaryocytes from the bone marrow of patients with AIDS.[788,789]

Alloantibodies are detected in 30% to 60% of patients with AIDS in different series, with anti-i and anti-I being the most common.[786] Anti-i has also been associated with EBV and cytomegalovirus infections, both of which often coexist with HIV infection and may account for the presence of specific red cell antibodies. Antibodies to Le, PL, E, K, Lu, and Sd all have been found, although their relationship to the pathophysiologic course of the anemia in HIV, which in large part does not appear to be hemolytic, remains an open question.

Zidovudine is now widely used in pediatric patients with AIDS,[790] and therefore treatment often causes

anemia and neutropenia. Macrocytosis with 25- to 40-unit increases in mean corpuscular volume is observed in 74% of patients receiving zidovudine. The macrocytosis is not usually accompanied by anemia, but when it does occur, the anemia is usually mild and dose related. In a subgroup of patients, anemia caused by bone marrow suppression is observed. A depressed reticulocyte count is an early sign of toxicity and is accompanied by normal to elevated serum folate and vitamin B_{12} levels. In patients with advanced disease, maintenance of zidovudine therapy requires regular blood transfusions.[791]

Neutropenia (absolute neutrophil count of 750 to 1000) is seen early in zidovudine treatment and is often dose limiting. More severe neutropenia is observed in patients with advanced disease and can be reversed by cessation of therapy. Pancytopenia has also been described but does not seem to resolve after withdrawal of treatment.[791]

Mitochondrial myopathy may result from long-term treatment.[792]

Coagulation Defects

In 1984, four homosexual patients with AIDS were reported to have prolonged partial thromboplastin times in the absence of any factor deficiency.[793] Because these defects were not correctable with kaolin or normal serum and were accompanied by a prolonged Russell viper venom time, they appeared to be due to the presence of lupus anticoagulant. Although one of these patients had documented deep venous thrombosis and pulmonary embolism, no other sequelae related to lupus anticoagulant have been reported. The lupus anticoagulant is a member of a family of antiphospholipid antibodies that includes anticardiolipin antibody and the Venereal Disease Research Laboratory (VDRL) test for syphilis. The antibody may be an IgG or an IgM and may be directed against the phospholipid components of the prothrombin activator complex and hence is capable of prolonging the lipid-dependent coagulation tests. Although it has been proposed that the presence of antiphospholipid antibodies is strongly associated with *Pneumocystis* infection, the significance of this claim remains open to doubt.[772] In short, therefore, coagulopathies do not appear to be of great clinical importance in AIDS, but they can be part of DIC in an associated superinfection.

Diagnosis in Infants and Children

Detection of antibodies to HIV antigens is a standard approach to the diagnosis of HIV infection. The first screen is an enzyme-linked immunosorbent assay; positive results may be confirmed by a specific immunoblot. However, the presence of anti-HIV immunoglobulin of the IgG subclass in an infant does not necessarily indicate that the infant is infected with HIV because maternal IgG crosses the placenta and has a half-life of 28 days. In fact, persistence of maternal IgG has been detected beyond 15 months of age.[733] In contrast, several seronegative HIV-infected children have been reported.[794-796] Although IgM or IgA anti-HIV antibodies are better indicators of active infection in children because these subclasses of antibody do not cross the placenta, the sensitivity and specificity of the enzyme-linked immunosorbent assays for these antibody isotypes are much lower than those for IgG anti-HIV. Definitive proof of HIV infection rests with viral culture and demonstration of the provirus via the very sensitive PCR.[796] The importance of early diagnosis, which combines laboratory tests and clinical findings, lies in the possibility and hope that early antiviral therapy may alter the natural history of the disease in children. Thus, the search for novel therapies is being actively pursued, and it appears that the newer nucleoside analogues may be associated with less bone marrow toxicity than seen with zidovudine. Current U.S. treatment guidelines for pediatric HIV infection advocate aggressive therapy with a combination of antiretroviral regimens. The goal is durable suppression of viral replication with preservation of immune function. A combination of a protease inhibitor and dual nucleoside reverse transcriptase inhibitors (NRTIs) is the most commonly used form of highly active antiretroviral therapy (HAART) in children.[797] The expense and difficulty of adhering to this regimen limit access to the vast majority of infected children in the world. Prevention and education remain the most effective short-term modes of limiting the spread of AIDS.[798]

37 Hematologic Manifestations of Systemic Diseases in Children of the Developing World

David J. Weatherall, Dominic P. Kwiatkowski, and David J. Roberts

Diagnosis and management of hematologic disorders in children in developing countries pose a number of problems that are not encountered in advanced Western societies.[1,2] Although all the conditions that have been described in this book are seen in these populations, their clinical features may be modified to a varying degree by the coexistence of malnutrition, chronic bacterial infection, or parasitic illness. Furthermore, many of the common killers, particularly in tropical climates, produce their own complicated hematologic manifestations.

It therefore follows that the study of hematologic disease in these populations presents a particular challenge to hematologists. It is often very difficult to define the clinical features and pathophysiology of a single hematologic disorder in this setting. Sickle cell anemia is a good example. This disorder, as described in Chapter 19, usually produces a well-defined clinical and hematologic picture in North American or European children. However, the disease may be different in the rural populations of Africa, where its course is generally complicated by diarrheal illness, malnutrition, endemic malaria, and as yet ill-defined climatic effects on the clinical phenotype. It is very difficult to separate the environmental and genetic factors that must underlie the extraordinarily varied severity of this condition in different parts of the world.

The same problems are posed when attempts are made to define the hematologic manifestations of disorders that are peculiar to tropical climates. For example, despite many years of intensive investigation it is still not possible to provide a clear picture of the pathophysiologic cause of the anemia of malaria caused by *Plasmodium falciparum* infection. Although there are many reasons, the major one for those who wish to study this important problem is finding patients with malaria who do not have other diseases that may cloud the clinical picture, such as chronic bacterial infection, human immunodeficiency virus (HIV) infection, malnutrition, hemoglobinopathies, or red cell glucose-6-phosphate dehydrogenase (G6PD) deficiency (see Chapter 17).

Despite these difficulties, in recent years it has been possible to start to understand the pathogenesis of some of the hematologic manifestations of systemic disease in children in the Third World. In this chapter some of the progress that has been made in this extremely important area of childhood hematology is reviewed.

PREVALENCE AND MULTIPLE CAUSES OF ANEMIA IN THE THIRD WORLD

Numerous surveys have been conducted to determine the prevalence of anemia in tropical populations.[3-6] However, because of differences in methodology and demographic design, it is very difficult to interpret the results and compare one study with another. Representative data from several countries, using the World Health Organization definition of anemia (Table 37-1),[7] are shown in Table 37-2. It is clear that in many populations the prevalence of anemia in preschool children is extremely high, and in some locations almost 100% of the population is affected. Although the data shown in Table 37-2 were compiled more than 20 years ago, the situation does not seem to have improved. In 2002, the World Health Organization reported that 0.8 million (1.5%) deaths worldwide are attributable to iron deficiency, 1.3% of male deaths and 1.8% of female deaths. Attributable disability-adjusted life years (DALYs), the current measure of health burden, is even greater and amounts to the loss of about 35 million healthy life years.[8]

It is equally difficult to determine the relative importance of different causes of anemia in the tropics. Most

FIGURE 37-1. Admissions to the children's ward of a hospital in Gambia, where malaria transmission is confined to the rainy season. The incidence of severe malarial anemia corresponds to seasonal epidemics of malaria fever and cerebral malaria. Gastroenteritis and malnutrition also reach a peak incidence in the early part of the rainy season and thus contribute to the multifactorial etiology of the anemia. *(Data from Brewster DR, Greenwood BM. Seasonal variation of paediatric diseases in The Gambia, West Africa. Ann Trop Paediatr. 1993;13:133-146.)*

surveys have concentrated on only one mechanism, such as iron or folate deficiency. However, to get a true picture of the cause of anemia in a particular population it is necessary to obtain consecutive data over a substantial period. For example, studies in Gambia have shown that mean hemoglobin levels in children vary significantly at different times of the year; anemia is much more common in the wet season when malaria transmission it at its highest (Fig. 37-1).[5] This is also the time when diarrhea and malnutrition are most common because heavy rains after many dry months have profound effects on the community, sanitation measures are disrupted, and food stores are at a low point in the annual cycle.[9] Although these observations emphasize the multifactorial etiology of anemia, it is clear that iron deficiency, which affects at least 20% of the world's population, is the major factor and that the numerous other diseases that may exacerbate anemia are often operating in the setting of low body iron stores.

Iron deficiency and anemia are less common in groups that have persisted as hunter-gatherers, for example, the Hadza in Tanzania and the pastoralists who eat blood and meat, such as the Masai in Kenya.[2] On the other hand, absorption of nonheme iron, except from breast milk, is comparatively restricted, and the content of iron in breast milk is very low. Therefore, iron deficiency is common in communities whose food is predominantly of vegetable origin.[10] The three great staples in these populations are rice, wheat, and maize. Sorghum and millet are also important in some areas of Africa and Asia. Soy and similar legumes are major sources of protein

in many countries. The iron content of these diets is generally low and absorption is inhibited by fiber, phytates, phosphates, and polyphenols, which are all found at high levels in these largely vegetarian diets.[10] Loss of iron from chronic hemorrhage secondary to hookworm infection or schistosomiasis further contributes to the high incidence of iron deficiency anemia in the developing world.

The infants of mothers with iron deficiency have low iron stores, their folate status at birth reflects that of their mother, and the folate content of breast milk is diminished by maternal deficiency and maternal malaria.[11-13]

In many populations anemia may be associated with folate deficiency.[3,4,13] Again, the reasons are complex and multifactorial. Although intake of folate varies widely among different populations, depending on the way in which food is prepared and the temperature at which it is cooked, it is clear that low intake is not necessarily the result of lack of folate in the diet. Work in Africa suggests that the continuous anorexia associated with recurrent infections such as malaria or tuberculosis is the most important cause of folate deficiency in children.[2] As discussed later, postinfective malabsorption is a particularly common cause of folate deficiency, especially in the Indian subcontinent. Folate deficiency may be exacerbated by erythroid hyperplasia associated with chronic malarial infection or hemoglobinopathy.[14]

Although nutritional vitamin B_{12} deficiency is uncommon, Indian infants born to mothers with sprue (see later) who are fed breast milk or goat milk containing insufficient vitamin B_{12} may be susceptible to megaloblastic anemia with locomotor complications during the early months of life.[2] This syndrome, which is often fatal, appears to be complicated by a marked predisposition to infection.

Although many of the population surveys on the prevalence of anemia in tropical countries have concentrated on one particular cause and intercurrent illness has not been assessed, studies in Africa, in which attempts have been made to assess body iron stores, folate levels, and the presence of intercurrent infection, indicate that chronic recurrent malaria, without other important complicating factors, is the major cause of anemia in these populations.

A major issue is whether iron supplementation is the most effective way to prevent anemia in regions where malaria is highly endemic. For example, a study in Tanzania showed that either iron supplementation or malaria chemoprophylaxis could be used to reduce the incidence of anemia in the first year of life but that the benefits of malaria prophylaxis were outweighed by increased risk for both malaria and anemia after the prophylaxis was stopped, thus suggesting that iron supplementation is the better option.[15] Then again, a reduction in iron levels is part of natural host defense against infection, and there is long-standing debate about whether supplementation has adverse consequences, particularly on mortality from infectious diseases.

Studies with a large sample size are needed to address this issue, and two have recently been published. On Pemba Island, Zanzibar, where malaria is endemic, an initial study found that iron supplementation improved motor and language development,[16] but a subsequent larger study involving 24,000 children found that deaths and hospital admissions were significantly higher in those who received iron and folate supplementation than in those who did not.[17] Although the cause of increased deaths in those receiving supplementation was not precisely defined, malaria appeared to play a major role. In contrast, a study of 25,000 preschool children in southern Nepal found that children who received iron and folic acid had no significant difference in mortality from those who did not, but there was a suggestion of modest protective effects against diarrhea, dysentery, and acute respiratory illness.[18]

Iannotti and colleagues[19] reviewed 26 randomized controlled trials of preventive oral iron supplementation in children younger than 5 years. Their general conclusion is that iron-deficient children may need to be identified to ensure that iron supplementation programs are effectively targeted to improve hemoglobin levels and cognitive and motor development. Although most studies found no effect on morbidity, few had adequate sample size or study design to resolve this issue. The outcome of a supplementation program may depend greatly on the pattern of endemic disease in the population.

HEMATOLOGIC CHANGES ASSOCIATED WITH SPECIFIC INFECTIONS IN THE TROPICS

Malaria

Malaria is the most important parasitic illness of humans.[20] The total burden of disease has recently been estimated to be 515 million episodes annually, and malaria is responsible for 18% of all childhood deaths in sub-Saharan Africa, equivalent to 800,000 deaths each year.[21,22] With increasing drug resistance of the malarial parasite, the problems of both treatment and control are becoming more complex, and this disease remains one of the major unsolved world health problems, although the widespread use of insecticide and bed nets appears to be reducing the incidence of severe malaria in many parts of Africa.

Life Cycle and Species

Because of its peculiar life cycle (Fig. 37-2), the malarial parasite is particularly prone to cause hematologic manifestations. Female anopheline mosquitos, during a blood meal, inject sporozoites that disappear from the circulation after about 1 hour and enter liver parenchymal cells, where they proliferate into thousands of merozoites. The period of development in liver cells varies between species. Merozoites rupture from liver cells, pour into the blood-
FIGURE 37-2. The life cycle of malarial parasites. The duration of the erythrocyte cycle is 48 hours for all human malaria parasites except *Plasmodium malariae*, which has a 72-hour cycle.

stream, and invade erythrocytes. Further development of the intraerythrocytic parasite follows one of two pathways: asexual differentiation or differentiation into sexual parasites called gametocytes. The latter continue their development within anopheline mosquitos. Asexual para-

sites develop from young ring forms through trophozoites to dividing forms called schizonts. On rupture of infected erythrocytes, forms called merozoites are released, invade other erythrocytes, and thus continue the erythrocyte cycle. When billions of schizonts rupture simultaneously and release cytokine-inducing toxins, they cause paroxysms of malarial fever.

When a child is infected with malaria for the first time, the result is usually an intermittent febrile illness lasting a few weeks, but complete eradication of malarial parasites from the bloodstream may take months or years. In the phase between cessation of the fever and final resolution of the infection, the child may appear well, but the destruction of red cells continues. From a hematologic viewpoint, the major question is how soon will the child be reinfected, for in some communities reinfection occurs almost every day, and immunity to malaria is slowly acquired and never complete. In regions of high transmission, children eventually acquire the ability to maintain a parasite density below the level that causes fever, but chronic or repeated infections cause a state of chronic anemia.

Four species of *Plasmodium* infect humans—*P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*—and a fifth species, *P. knowlesi*, normally restricted to macaque monkeys, has recently been discovered in the human population in Borneo.[23] Each has particular morphologic and biologic properties and clinical manifestations. *P. falciparum* is the predominant cause of clinical malaria in Africa and much of Southeast Asia, whereas *P. vivax* tends to predominate in Central America and the Indian subcontinent, but their distribution overlaps considerably and multiple infections are not uncommon. *P. vivax* is essentially absent in populations of Central and West Africa because their erythrocytes fail to express the Duffy antigen or interleukin-8 (IL-8) receptor, to which the merozoites of this species attach during invasion.[24,25]

Another peculiarity of *P. vivax*, shared also with *P. ovale*, is the ability to form hypnozoites, which can remain dormant in cells for months or years. This ability results in relapsing infections that are often associated with mild chronic anemia. However, profound anemia and other grave complications are almost always seen with *P. falciparum* malaria, and the following sections apply mainly to this particular species.

Severe Malaria

Life-threatening complications are estimated to occur in about 1% of episodes of *P. falciparum* infection in African children, and it has been estimated that a child in rural Africa has a 15% lifetime risk of a malaria infection requiring hospital admission as a result of complications.[26] Such complications include profound anemia, cerebral malaria (a syndrome of unrousable coma, often accompanied by severe convulsions), hypoglycemia, jaundice, renal failure, pulmonary edema, and coagulation abnormalities. There are important and as yet largely unexplained differences in the clinical spectrum of severe *P. falciparum* malaria in different parts of the world.[27] In Southeast Asia, all the aforementioned complications are commonly seen, whereas in Africa, where cerebral malaria and severe malarial anemia together account for about 1 million deaths per year and hypoglycemia is also common, the other complications of *P. falciparum* malaria are surprisingly rare. Malarial illness affects mostly children in Africa, whereas adults are more commonly affected in some other parts of the world; it has been suggested that much of the variation in clinical symptomatology is related to age. However, this does not provide a full explanation. Even among African children there are regional differences, and there is a growing impression that higher rates of malarial transmission lead to a greater prevalence of anemia but, paradoxically, a low incidence of cerebral malaria.[28]

The lethality of *P. falciparum* as compared with other species of *Plasmodium* probably stems from two biologic properties. First, the parasite density that it achieves is typically a hundred times higher than that of other species before its growth is curtailed by host defense mechanisms.[29] Second, mature intraerythrocytic forms of *P. falciparum* adhere to the endothelium of postcapillary venules and thus sequester in tissues. Because these properties are common to all strains of *P. falciparum*, the greater puzzle is why lethal complications arise in only a minority of infected individuals. Some important clues have emerged recently. Parasite sequestration is mediated by a parasite-derived molecule known as PfEMP1 that is expressed on the surface of a mature infected erythrocyte and binds to a variety of endothelial adhesion molecules, including CD36, intracellular adhesion molecule 1, E-selectin, and vascular cell adhesion molecule.[30] Whether a parasite will bind to a specific endothelial adhesion molecule is determined by its PfEMP1 type, and this shows an extraordinary degree of phenotypic variability.[31] Expression of endothelial adhesion molecules varies between organs and is regulated by cytokines released by the host in response to the infection, such as tumor necrosis factor (TNF). There is evidence that genetic variation in the host TNF response influences susceptibility to cerebral malaria.[32] Another potentially important pathophysiologic mechanism is vascular sludging, which results from the clumping of parasitized erythrocytes, either with platelets ("autoagglutination" or "clumps") or with unparasitized erythrocytes ("rosettes"). Both phenomena are strain specific and have been associated with the severity of malaria. As usual, the parasite uses diverse adhesive mechanisms; complement receptor-1 is a key binding target for some rosetting parasites,[33] whereas the platelet glycoprotein CD36 and other as yet unknown proteins are used in the formation of autoagglutinates or clumps.[34]

There is an association between salmonellosis and malarial infection.[35] This association goes beyond the growing recognition that a significant proportion of cases of severe malaria in the tropics are bacteremic[36] in that salmonellosis in Africa seems to be specifically associated

with malarial anemia.[37] It remains open to speculation whether *Salmonella* infection aggravates malarial anemia, anemia is a marker of chronic malarial infections that favor salmonellosis, or there is some other explanation for this curious and striking relationship.[38]

Malarial Anemia

The pattern of hematologic changes in malaria varies considerably, depending on the type of patient. During an acute attack of *P. falciparum* malaria in a nonimmune person, the hematocrit starts to decrease after 1 or 2 days and continues to decrease for about 1 week after antimalarial treatment.[39,40] Subsequently, there is usually a steady increase in the hematocrit, although it may take several weeks before the hematologic picture is back to normal. The anemia, which is not usually life threatening, is characterized by both hemolysis and an ineffective marrow response,[39,40] features that have also been documented in acute *P. vivax* infection. When profound anemia occurs with acute *P. falciparum* malaria, it is often associated with multiorgan failure, although it can also occur as an isolated complication.

From the perspective of tropical child health, the most important hematologic problem is seen in a child chronically infected with *P. falciparum*, whose anemia is debilitating and sometimes fatal. Although this problem most commonly occurs in areas of high malarial transmission, it is a growing problem in regions of lower transmission because of the increase in resistance to antimalarial drugs, which has served to prolong the average duration of infection. Attempts to investigate the problem of chronic malarial anemia are often hampered by the coexistence of iron or folate deficiency and hemoglobinopathies. In a study in which patients with these conditions were carefully excluded, the most striking pathophysiologic findings were hemolysis, hypersplenism, and a suboptimal bone marrow response.[40] In the sections that follow, some of the mechanisms for these components of the anemia of malaria are discussed in more detail.

Role of Hemolysis

Normal children living in rural Africa typically have extremely low levels of haptoglobin that increase significantly after malaria prevention programs,[40,41] thus providing some indication of the burden of chronic hemolysis that malaria causes in many tropical communities. The mechanisms of red cell destruction in *P. falciparum* malaria are complex and not fully understood.[42] Clearly, erythrocytes are destroyed when schizonts rupture and release their progeny, and depending on the state of immunity, a proportion of the parasitized erythrocytes are destroyed by the host before schizont rupture can take place. Both mechanisms can have devastating consequences if the patient is hyperparasitemic (sometimes more than 50% of erythrocytes are infected), but such patients are rare. In most infections, less than 1% of erythrocytes are infected, a loss that is important in the context of chronic

infection but would not account for the severity of anemia that is commonly observed. Both mathematical modeling and clinical observation suggest that 10 times as many uninfected erythrocytes are removed from the circulation for each infected erythrocyte.[43] Indeed, cross-transfusion experiments clearly indicate that erythrocyte survival is shortened both in the acute phase of malaria and during convalescence.[44,45]

Role of the Spleen

Some degree of splenomegaly is a normal feature of malarial infection, and the prevalence of splenomegaly in regions of malarial transmission is used as a major indicator of the level of malarial endemicity. The importance of the spleen in host defense against malaria has been demonstrated in experimental systems, and individuals whose spleens have been surgically removed are thought to be more susceptible to severe infection (see later). The phenomenon of parasitic sequestration, discussed earlier, is thought to have evolved primarily as an immune evasion strategy whereby the mature parasite can avoid passing through the spleen.[46]

Several studies have attempted to define the pathophysiologic changes in the spleen during acute malaria. In animal models, malaria is accompanied by increased intravascular clearance of infected or rigid heat-treated cells by the spleen,[47] alterations in the splenic microcirculation,[48] and recruitment of myelomonocytes to the spleen and liver.[49] In studies of human malaria it has been found that increased splenic clearance of heated red cells occurs during acute attacks.[50] Reduced deformability of uninfected red cells is observed in *P. falciparum* malaria and is a significant predictor of the severity of anemia, consistent with the notion that these cells are being removed by the spleen[51] (see later). It has also been found that immunoglobulin G (IgG)-sensitized red cells are rapidly removed from the circulation by the spleen and that unusually rapid clearance persists well into the convalescent phase.[52] Undoubtedly, the activity and number of macrophages are increased during human malarial infection, and this may therefore contribute to the increased removal of uninfected cells.[53-55]

In rodent malaria, a model of chronic anemia has been developed in which *Plasmodium berghei*–infected semi-immune mice show a 5- to 10-fold increase in the clearance of uninfected erythrocytes, although the extent of parasitemia remains below 1%.[56] In this study, clearance of uninfected red cells was delayed in mice depleted of macrophages, thus supporting the view that removal of uninfected erythrocytes is an important factor in anemia.

All the available evidence, therefore, points to increased reticuloendothelial clearance in *P. falciparum* malaria that persists long after recovery. These changes are presumably a host defense mechanism to maximize the clearance of parasitized erythrocytes. Clinical studies have also uncovered a curious phenomenon whereby some erythrocytes appear to be returned to the circula-

tion after having had their parasites removed,[57] but killing parasites usually means destroying erythrocytes, and it appears that the survival of uninfected red cells is reduced in the process.

These observations in patients are consistent with findings at the cellular level. Active erythrophagocytosis is a conspicuous feature within the bone marrow during *P. vivax* and *P. falciparum* malaria,[58,59] and it is highly probable that it also occurs within the spleen. Children with acute *P. falciparum* malaria have high circulating levels of interferon-γ and TNF,[60] a synergistic combination of cytokines that activate macrophages.[61] Transgenic mice that constitutively overexpress human TNF are anemic and show enhanced clearance of autologous erythrocytes, which is presumed (though not proved) to be due to erythrophagocytosis.[62] When infected with *Plasmodium yoelii* or *P. berghei*, transgenic mice suppress parasite density much more effectively than their littermates do. This finding supports the notion that with relatively nonspecific effector mechanisms such as erythrophagocytosis within the spleen, anemia is part of the price that the host has to pay for protection against overwhelming parasitemia.

Massive Intravascular Hemolysis

A peculiar example of malaria-associated hemolysis is blackwater fever.[42,63] The classic form of this syndrome, often reported in colonial times among Europeans living in Africa, was characterized by fever and massive intravascular hemolysis associated with low or no parasitemia; it led to renal failure and was associated with high mortality. It was suspected that intermittent quinine ingestion might have led to a drug-induced immune hemolysis, although this mechanism was never proved and recent reports have implicated newer antimalarial drugs such as halofantrine and mefloquine/artemisinin combinations.[64,65] Classic blackwater fever is now much less common, but it is important to remember that massive intravascular hemolysis with hemoglobinuria remains an important complication of *P. falciparum* malaria in Southeast Asia in both children and adults.[39] Blackwater fever is sometimes associated with high parasitemia or destruction of G6PD-deficient red cells by oxidant antimalarial drugs. A survey of cases in Vietnam found considerable overlap of quinine ingestion, G6PD deficiency, and concurrent malaria, thus suggesting that these different factors may interact but certainly do not all have to be present for blackwater fever to occur.[66] It is conceivable that hemolysis is caused by the rupture of a large number of sequestered parasites, but the possibility of another hemolytic process has yet to be ruled out.

Decreased Erythrocyte Deformability

The increased clearance of uninfected erythrocytes is due not only to the activation of splenic macrophages but also to extrinsic and intrinsic factors that enhance their recognition and phagocytosis. Uninfected erythrocytes have reduced deformability, which leads to enhanced clear-

ance in the spleen. The mechanism responsible for the loss of deformability is not completely understood, however. Increased oxidation of membranes in uninfected erythrocytes has been demonstrated in children with severe *P. falciparum* malaria, and the ongoing inflammatory insults associated with acute malaria (proinflammatory cytokines) or the direct effects of parasite products have been shown to cause loss of red cell deformability.[54,67,68] Intriguingly, a severe reduction in red cell deformability measured on admission is also a strong predictor not just for anemia but also for mortality, both in adults and children with severe malaria.[51,69]

Immune Complex–Mediated Hemolysis

It is also possible that at least part of the hemolysis in *P. falciparum* malaria might have an immune basis. A positive direct Coombs antiglobulin test (DAT) is seen in some patients with malaria.[40,70-76] Like all studies on malaria, there seem to be considerable differences in the incidence of positive DAT results in malarial infection in different populations and at different ages. For example, in Thai children or adults during their first attack or with subsequent attacks in those who live in areas where a degree of immunity has not developed, DAT results are invariably negative.[75] Furthermore, studies using labeled immunoglobulin have shown that the number of antibodies bound to the red cells of patients with malaria of this type is no different from that in uninfected control patients of the same age and in the same location.[75]

The position is different in African children who have suffered repeated attacks of malaria. Positive DAT results have been found in up to 50% of these children, and the incidence is significantly higher in children with active malarial infection than in those who are not infected.[71-74,76] The phenomenon is age related and is more common in young children. DAT results may remain positive for several weeks after an acute infection. With specific antisera it has been found that the most common type of red cell sensitization occurs with C3; other specificities include IgG alone, IgG plus C3, IgG plus C3 and C4, and various other combinations of IgG with complement components.[71-75] The IgG that can be eluted from these cells has specific activity against *P. falciparum* schizont antigen.[71] This suggests that the erythrocyte coating results from passive attachment of circulating complement-fixing malarial antigen-antibody complexes. It is therefore likely that the development of positive DAT results is part of the immune response to *P. falciparum*.

Recent studies have suggested that the *P. falciparum* ring surface protein 2 (RSP-2) may be one component of the immunoglobulin-antigen complexes deposited on uninfected erythrocytes. This protein is expressed on infected erythrocytes shortly after merozoite invasion and may mediate some adhesion of infected erythrocytes to endothelial cells. RSP-2 is also deposited on uninfected erythrocytes and forms immune complexes that contribute to the phagocytosis of uninfected erythrocytes. Limited clinical studies have shown that high levels of

anti–RSP-2 antibodies are found in the sera of immune adults and children with severe anemia.[77] This antigen is also present on the surface of erythroblasts in the bone marrow of *P. falciparum*–infected patients, thus indicating that clearance or damage to developing erythroid cells by RSP-2 and anti–RSP-2 could contribute to the development of anemia.

However, it is far from clear whether the presence of positive DAT results indicates that immune destruction of red cells occurs in African children with malaria. Several studies have shown that there is no correlation between the degree of anemia and positive DAT results,[75,76] and other measured parameters of hemolysis have not correlated with coating of red cells. Nonetheless, immune destruction may occasionally be of importance. A small number of patients have been described with severe anemia and positive DAT results who had active C3 components on their red cells.[72] In these patients, striking monocyte erythrophagocytosis of nonparasitized erythrocytes was seen.

In some patients with *P. falciparum* infection, IgM antibodies have been reported to develop against triose-phosphate isomerase, and disappearance of the antibodies coincides with disappearance of the hemolysis. Because these antibodies can induce erythrocyte lysis and complement activation in vitro, it has been postulated that they may contribute to a hemolytic process in vivo.[78]

In short, there is little evidence for immune destruction of red cells in *P. falciparum* malarial infections in nonimmune adults. Although a varying proportion of children with chronic malaria in Africa have positive DAT results, only occasionally is evidence of genuine immune destruction of red cells seen. It is possible, of course, that a sensitized red cell population is very rapidly destroyed and subsequent serologic studies have missed this event. However, the persistence of shortened red cell survival of nonparasitized cells in the absence of any consistent serologic abnormalities suggests that there must be another factor involved in the shortened red cell survival in malaria. This factor appears to be nonspecific "overactivity" of the monocyte/macrophage populations of the spleen and liver, as discussed earlier.

Defective Marrow Response

In addition to the hemolytic components of the anemia of *P. falciparum* malaria, there is undoubtedly an inappropriate marrow response.[39,40,42,79,80] That the reticulocytosis in response to the decrease in hematocrit is often inappropriately low and delayed has been noted for many years (Fig. 37-3). It remains unclear whether defective erythropoietin production is a significant cause, with some studies suggesting an appropriate rise[81] or even enhanced response[80] and others observing a blunted response,[82,83] but there is no question that significant dysfunction of marrow takes place and appears to have a complex multifactorial basis.

Some of the features of iron metabolism and bone marrow morphology and function in acute malaria resemble those of other acute infections. Thus, the serum iron level rapidly decreases and iron appears to be sequestrated into the storage compartments of the marrow.[39,40] Serum ferritin levels are extremely high during the acute phase, although studies of isoferritins suggest a complex source; in many instances it appears that much of the ferritin is released as a consequence of liver damage.[39]

During acute malarial infections there may be marked dyserythropoietic changes in the bone marrow.[39,40] Although changes are most marked in African children with chronic relapsing malaria,[40] they have also been observed in nonimmune Thais[39] and in travelers returning to the United Kingdom.[42] These morphologic abnor-
FIGURE 37-3. Hemoglobin level and reticulocyte response in a nonimmune patient with *Plasmodium falciparum* malaria.

FIGURE 37-4. Bone marrow in *Plasmodium falciparum* malaria. **A**, Multinucleate red cell precursors. **B**, Intercytoplasmic bridging (Leishman stain, magnification ×500).
malities, which have been studied by both light and electron microscopy, consist of erythroblast multinuclearity, karyorrhexis, incomplete and unequal amitotic nuclear divisions, and cytoplasmic bridging (Fig. 37-4).[40] On electron microscopic examination, binucleate or multinucleate erythroblasts, bizarre myelination with loss of parts of the nuclear membrane, and widening of the space between the two layers of the nuclear membrane have been observed.[40,59] There appears to be some degree of iron loading of the mitochondria and a reduction in electron density of the cytoplasmic matrix, together with a paucity of ribosomes. In addition, in acute infection there is widespread sequestration of erythrocytes in the sinuses of the bone marrow.[59]

With [³H]thymidine autoradiography and Feulgen microspectrophotometry it is clear that a significant abnormality of red cell proliferation in the bone marrow occurs in acute malaria. Changes include an increased proportion of red cell precursors in the G_2 phase and arrest in progress of cells in the S phase. These findings are nonspecific and have been observed in other conditions associated with ineffective erythropoiesis.[79]

In addition to these dyserythropoietic changes, erythrophagocytosis is particularly common in the bone marrow in *P. falciparum* malaria.[40] This phenomenon is not restricted to the marrow and may be seen in the spleen and other organs and, as mentioned earlier, may play a role in the hemolytic component of the disease.

Although the mechanism of these dyserythropoietic changes is unknown, it is possible that they are an exaggerated example of the bone marrow suppression that occurs in other situations of chronic infection. An important factor may be the high levels of TNF production that occur during malarial infection because this cytokine has been strongly implicated in the anemia of chronic infection and severe malarial anemia has been associated with certain TNF promoter polymorphisms.[84] TNF suppresses the proliferation of erythroid progenitor cells in human marrow culture, although the effect declines as the cells differentiate.[85] On the other hand, TNF stimulates fibroblasts to secrete growth factors for colony-forming unit (CFU)–granulocyte-erythrocyte-monocyte-macrophage and burst-forming unit–erythrocyte (BFU-E).[86] In nude mice implanted with transfected Chinese hamster ovary cells that can constitutively express the human TNF gene, erythropoiesis is preferentially suppressed, with a marked reduction of CFU-E and BFU-E in the marrow and spleen.[87] Chronic malaria has specific features that might augment these effects because huge numbers of pigment particles are ingested by the resident macrophages of the spleen and marrow, thereby providing a sustained stimulus for TNF production at the site of erythropoiesis.[88] Furthermore, experimental findings in mice are consistent with a role for TNF in the dyserythropoietic changes of malaria.[89]

Other cytokines have also been implicated. IL-10 is an anti-inflammatory cytokine that inhibits TNF, and two clinical studies in African children with severe malarial anemia have found a low ratio of IL-10 to TNF in plasma, thus leading the investigators to propose that defective IL-10 production may pave the way to marrow suppression by TNF.[90,91] IL-12 protects against severe anemia in experimental murine malaria,[92] which might reflect both its antiparasitic actions and effects on erythropoiesis.[93]

Several studies have suggested that a parasite byproduct of hemoglobin digestion, hemozoin, may have an indirect or direct role in impaired erythroid development.[80] Hemozoin stimulates the secretion of biologically active endoperoxides from monocytes, such as 15(S)-hydroxyeicosatetraenoic acid (HETE) and hydroxynonenal (HNE), via oxidation of membrane lipids,[94,95] which may affect erythroid growth.[96]

Hemozoin and TNF-α also have additive effects on erythropoiesis in vitro, and in a clinical study hemozoin-containing macrophages and plasma hemozoin were associated with anemia and reticulocyte suppression.[80] Moreover, bone marrow sections from children who died with severe malaria show a significant association between the quantity of hemozoin (located in erythroid precursors and macrophages) and the proportion of erythroid cells that were abnormal. These findings are consistent with a direct inhibitory effect of hemozoin on erythropoiesis.

Coagulation Abnormalities

Modest thrombocytopenia is not uncommon during acute *P. falciparum* attacks, and occasionally the platelet count decreases to as low as 10,000 to 20,000/mL.[39] The mechanisms have not been determined but probably involve platelet activation and adhesion of infected eryth-

rocytes to platelets, and experimental studies in mice suggest that platelets sequester in venules during malarial infection.[97] Adherence of platelets to epithelium appears to be mediated through a specific receptor-ligand interaction involving lymphocyte function antigen-1. There is also evidence to indicate reduced thrombopoiesis during acute infection.

In some patients with severe *P. falciparum* malaria, a severe bleeding diathesis may develop during the acute phase of the illness. Although it has been suggested that the diathesis results from disseminated intravascular coagulation, studies in Thailand have not substantiated this supposition.[39] Rather, the bleeding appears to reflect gross thrombocytopenia together with liver damage. However, it is becoming apparent that approximately 10% of African children with severe malaria also have bacteremia,[36] so when disseminated intravascular coagulation occurs, the etiology may be complex.

Malaria in Pregnancy

In endemic regions, malaria in pregnancy is extremely common. The placenta provides a favorable environment for parasite replication, and specific pathways of adhesion of infected erythrocytes to the surface of syncytiotrophoblasts have now been unraveled. A specific variant antigen, PfEMP1, expressed on the surface of infected erythrocytes (varCSA-2), mediates adhesion of infected erythrocytes to chondroitin sulfate. Primigravidae are particularly susceptible to malarial infection and may become systemically unwell, but immunity to this variant antigen modulates the duration and severity of infection in subsequent confinements. These observations suggest that varCSA-2 may be an excellent candidate antigen for a pregnancy-specific malaria vaccine. Apart from effects on the mother, it is an important cause of low birth weight and increased perinatal mortality. Studies of cord hemoglobin levels indicate that it is also a significant cause of fetal anemia. Because the severity of the fetal anemia is out of proportion to the degree of maternal anemia, it has been suggested that intrauterine hemolysis may be involved.[98] Malaria in pregnancy is a preventable illness, although it has become more difficult to control with the rise of resistance to antimalarial drugs. Studies in different parts of Africa have found placental malaria to be an important risk factor for anemia in the first 6 months of life.[99,100]

Given the high prevalence of malaria in pregnancy and the strong association of placental malaria with infantile anemia, it is surprising how few infants have overt symptoms of congenital malaria in the tropics. On the rare occasions when it does occur, it can result in a perplexing hematologic disorder. The manifestations of malaria may not be seen until several months after birth, presumably because of passive immunization from the mother and possibly the fact that *P. falciparum* tends to grow less effectively in cells containing relatively large amounts of fetal hemoglobin. The disease is characterized by a febrile illness associated with anemia that may

often be profound.[98] As in conventionally acquired malaria, the pathophysiologic course of the anemia is a complex combination of hemolysis and marrow suppression. Thus, it is important to obtain a careful travel history from the parents of any infant with unexplained hemolysis. This condition is commonly misdiagnosed because it is not considered.

Malaria in Splenectomized Patients

Although it is generally believed that malaria may be associated with particularly severe infections in individuals who have been splenectomized, in a review[101] of this important question no clear evidence was found. Until this problem is resolved, it is wise to advise visitors to the tropics who have had their spleens removed and splenectomized patients who live in regions where malaria is endemic to be particularly careful about continuing to maintain malaria prophylaxis.

Hyperreactive Malarial Splenomegaly Syndrome

Although splenomegaly is a feature of many tropical disorders, there is increasing evidence, particularly from work in East and West Africa and Papua New Guinea, that a specific entity, formerly known as tropical splenomegaly syndrome, occurs widely throughout Africa, India, and Southeast Asia.[1,102,103] This condition is characterized by gross splenomegaly, high malarial antibody titer, and serum IgM levels at least 2 SD above the local mean. The classic syndrome regresses after prolonged antimalarial prophylaxis with proguanil, a dihydrofolate reductase inhibitor marketed outside the United States as Paludrine.

Etiology and Pathophysiology

Evidence that malaria plays an important role in this syndrome is increasing. Epidemiologic studies indicate that its prevalence is related to patterns of malarial transmission and that affected individuals have higher malarial antibody titer than do those who live in the same environment and are unaffected; this seems to involve IgM rather than IgG. These observations, together with the partial clinical response to treatment with antimalarial drugs and the fact that individuals with sickle cell trait seem to be partially protected, suggest that the condition probably results from an unusual form of immune response to chronic malarial infection. For this reason it is now commonly referred to as hyperreactive malarial splenomegaly (HMS).

With progressive splenomegaly, there is pooling of the formed elements of blood; in patients with particularly large spleens, a third to half of the total circulating red cell mass may be sequestered. Such sequestration produces a dilutional anemia that is made worse by an absolute increase in plasma volume. There is also pooling of neutrophils and platelets, so the hematologic picture is characterized by pancytopenia. No characteristic changes in bone marrow are seen.

Some evidence of a genetic predisposition to HMS exists.[104] A recent study in Ghana found that splenomegaly, high IgM levels, and anemia were more common in relatives of HMS patients than in the general population, but there was no clear pattern of mendelian segregation, thus suggesting that the etiology in this population is likely to be complex and involve multiple genetic and environmental factors.[105] For some years researchers have debated about whether HMS is premalignant because it sometimes becomes refractory to antimalarial treatment, and it can also be associated with a lymphocytosis resembling chronic lymphocytic leukemia (CLL). Clonal rearrangements of the J_H region of the immunoglobulin gene have been noted in some patients whose clinical syndrome appears to be intermediate between HMS and CLL, thus suggesting that HMS has premalignant potential.[106]

Clinical Features

The clinical picture of HMS is typical and consists of massive splenomegaly, weight loss, and a variable degree of anemia.[102,103] Serum IgM levels are high, and a relative increase in T lymphocytes in peripheral blood may be seen. Serum may also show increased cold agglutinin titers and an increase in rheumatoid factor, antibodies to thyroglobulin and antinuclear factor, and circulating immune complexes.

The prognosis for patients with this condition is remarkably poor in parts of Africa, with up to 50% mortality in some populations. It is managed by long-term antimalarial prophylaxis, most commonly with proguanil.

Visceral Leishmaniasis (Kala-azar)

Leishmaniasis is an infection caused by intracellular protozoan parasites transmitted by various species of sandflies.[107,108] Human infections can result in three main forms of disease: cutaneous, mucocutaneous, and visceral (kala-azar). The important hematologic manifestations of leishmanial infection are found in the visceral forms.

The generalized form of leishmanial disease involves the liver, spleen, bone marrow, and lymph nodes and is caused by organisms belonging to the *Leishmania donovani* complex. The parent species, *L. donovani*, is found throughout Asia and Africa and can affect individuals of all ages. However, the parasite that causes kala-azar in countries bordering the Mediterranean, in southern Europe, and in North Africa affects primarily young children and infants. It differs from *L. donovani* to such an extent that it warrants the designation of a special species and is called *Leishmania infantum*. Similarly, in the Western Hemisphere, kala-azar is also a disease of very young children; the causative organism is *Leishmania chagasi*.

Although visceral leishmaniasis is primarily a disease of indigenous populations, it may be contracted on short-term visits. For example, in the United Kingdom it is being recognized increasingly after return from Mediterranean holidays, and particularly in young children, it can cause considerable diagnostic difficulty; occurrences have been mislabeled as leukemia when the diagnosis of leishmaniasis was not considered. The risk for leishmaniasis is greatly increased in individuals infected with HIV.[109]

Although the incubation period is usually 1 to 3 months, it can be as short as a few weeks. The onset is usually insidious and consists of fever, sweating, malaise, and anorexia, although a much more acute onset may be seen. As the disease progresses, the acute symptoms abate, but there is gradual enlargement of the spleen and liver for several months. By this time there may be marked splenomegaly, cachexia, and anorexia. Generalized lymphadenopathy is also present.

Hematologic findings in later stages of the illness include anemia, neutropenia, and thrombocytopenia, manifestations characteristic of hypersplenism. The bone marrow is hyperplastic with dyserythropoietic changes, and the diagnosis can usually be made by finding Leishman-Donovan bodies—macrophages containing intracellular organisms with characteristic staining properties. The diagnosis can also be made by splenic or lymph node puncture.

Red cell survival studies and ferrokinetic analyses have suggested that hemolysis is the major cause of anemia in leishmaniasis[110-112] but that there may also be plasma volume expansion associated with the massively enlarged spleen.[112] Surprisingly, ferrokinetic studies have shown very little evidence of ineffective erythropoiesis, but a reduced plasma iron level in the presence of greatly increased iron stores suggests that the reticuloendothelial hyperplasia is accompanied by abnormal iron retention by macrophages, typical of the anemia of chronic disorders.[112] This may limit the marrow response to hemolysis.

In babies or young children with acute visceral leishmaniasis, the clinical and hematologic findings may differ from those described earlier. For example, in Mediterranean populations a very rapid onset of anemia with severe hemolysis is commonly observed.[113] Occasionally, both IgG and complement components are found on the red cells, but this finding is not consistent and its significance remains to be determined. In most instances there is no evidence of immune hemolysis, and it appears that nonsensitized red cells are destroyed by macrophages recruited to the spleen and liver as part of the inflammatory response to the parasite. Severe neutropenia may also occur in young children, and this, together with dyserythropoietic changes in the marrow, marked erythrophagocytosis, and bizarre mononuclear infiltrates, may cause confusion with leukemia.

Schistosomiasis

The schistosomes are a group of trematodes that cause major health problems in many parts of the developing

world.[114] The major human parasites include *Schistosoma haematobium*, *Schistosoma mansoni*, and *Schistosoma japonicum*. Schistosomiasis affects mainly children and young adults. Two hundred million people worldwide are estimated to have schistosomiasis, 80% in sub-Saharan Africa.[115]

The location of adult worms in the human host varies with the parasite species: *S. hematobium* in the veins of the bladder, *S. mansoni* in the superior mesenteric veins, and *S. japonicum* in the inferior mesenteric veins. Sexual maturity of female schistosomes depends on their interaction with living male worms. Egg deposition occurs in the small venules of the bladder or portal venous system. When freshly deposited, the ova are partially developed. Hatching of the eggs leads to the liberation of miracidia. Further development occurs when miracidia penetrate a snail intermediate host. After two generations, cercariae are released that are capable of penetrating intact skin and migrating through tissues to reach their final home.

S. haematobium infections occur in Africa and the Middle East, whereas *S. mansoni* is found in Africa, the Middle East, and parts of South America. *S. japonicum* occurs in Japan, the Philippines, and together with the related species *Schistosoma mekongi*, in mainland Indochina.

The most consistent hematologic changes are found in association with *S. mansoni* infection. The acute phase is characterized by fever, myalgia, and progressive hepatosplenomegaly. At this time the most common finding in peripheral blood is eosinophilia. As the disease progresses, there may be massive hepatosplenomegaly associated with anemia, neutropenia, and thrombocytopenia.[116] Good descriptions of the appearance of bone marrow in this condition are few, and the data available suggest that the anemia is predominantly due to hypersplenism and hemodilution from the massive splenomegaly.

S. haematobium infection leads to urinary tract symptoms, in particular, hematuria and dysuria. The hematuria may be gross and persistent and lead to iron deficiency anemia. In addition, affected children have typical features of the anemia of chronic disorders.

A major advance in control of schistosomiasis is the availability of a highly effective drug, praziquantel, which is safe in both children and pregnant women. The cost of control programs may be reduced by combination therapy for schistosomiasis, gastrointestinal helminths, and filariasis; in 2001 the World Health Assembly resolved that at least 75% of school-aged children in high-burden areas should be treated for schistosomiasis and soil-transmitted helminth infections by 2010 to reduce morbidity.[115]

Trypanosomiasis

Trypanosomal infections are a major cause of ill health throughout the world. The disease syndromes produced by these infections vary widely but, in general, are divided into the American and African forms.[117-119]

American Trypanosomiasis (Chagas' Disease)

American trypanosomiasis is a zoonosis caused by *Trypanosoma cruzi*, which is transmitted to humans by blood-sucking insects. It was first described by Carlos Chagas in 1909.

In its invertebrate host, *T. cruzi* grows extracellularly. Epimastigotes divide in the insect gut and differentiate into metacyclic trypomastigotes, which are the infective form for mammalian hosts. They are released close to the site of a bite and enter the host via the skin or mucous membranes. After invasion they enter cells, where they replicate as rounded amastigote forms that differentiate into trypomastigotes, which are released into the circulation and tissues. A variety of organs are involved, but the most important pathophysiologic result is a chronic cardiomyopathy.

There are characteristic clinical findings at each of these different stages of infection. After penetration of the skin, a local cutaneous lesion called an inoculation chagoma develops and is accompanied by swelling of the local lymph glands. Occasionally, the route of inoculation is through the eye, where the initial lesion is characterized by unilateral conjunctivitis with edema of the eyelids. Invasion may or may not be followed by an acute phase consisting of fever, generalized lymphadenopathy, hepatosplenomegaly, and acute myocarditis.

The chronic phase of Chagas' disease takes several forms. If cardiac involvement is predominant, a slowly progressive cardiomyopathy with heart failure, arrhythmias, and embolic complications is seen. In other patients, gastrointestinal symptoms predominate as a result of denervation and destruction of the myenteric plexus, which may give rise to megaesophagus or megacolon.

A congenital form of Chagas' disease may occur. The organism can traverse the placental villi and from there be released into the fetal circulation. The most common findings include growth retardation; hepatosplenomegaly; acute myocarditis; neurologic lesions, including a meningoencephalitic picture with tremors and convulsions; and occasionally, a generalized hemorrhagic tendency with purpura or more widespread bleeding. The prognosis for patients with congenital Chagas' disease is poor, and most infants die during the first week of life.

The hematologic changes in Chagas' disease are non-specific. In the acute phase, mild anemia and lymphocytosis may occur. At this stage the parasite can be found in the blood or in leukocyte concentrates. Parasites may be concentrated by sedimentation of heparinized blood cells with the addition of phytohemagglutinin. Similarly, it is possible to find amastigote forms of *T. cruzi* in muscle or lymph node biopsy samples. The results of serologic tests for anti–*T. cruzi* IgM antibodies typically become positive about 20 to 40 days after the onset of symptoms.

African Trypanosomiasis

In Africa these conditions are caused by subspecies of the hemoflagellate *Trypanosoma brucei* known as *T. brucei*

gambiense, which causes a chronic illness called sleeping sickness, and *T. brucei rhodesiense*, which is associated with a more acute illness. *T. brucei* is transmitted by the tsetse fly *Glossina*, in which it undergoes a variety of developmental changes.

At the site of the tsetse bite a small nodule called a trypanosomal chancre forms from which organisms may be isolated. After this self-limited lesion subsides, the parasite invades and multiplies extracellularly in the blood, which leads to the systemic phase of the illness characterized by fever, lymphadenopathy, and splenomegaly. In the later phase of African trypanosomiasis, invasion of the central nervous system takes place and results in meningoencephalitis.

During the acute phase, normochromic normocytic anemia associated with hypoalbuminemia may be present. Occasionally, patients have hemorrhagic manifestations and evidence of disseminated intravascular coagulation. The total white blood cell count is either normal or elevated with relative lymphocytosis. The sedimentation rate is markedly elevated, and circulating immune complexes may be present together with rheumatoid factor.

The parasite can often be demonstrated in thin or thick blood films stained with Giemsa or Field stain. Several concentration techniques have been developed to increase the likelihood of finding the parasite. A variety of immunodiagnostic tests are available, notably indirect immunofluorescence and enzyme-linked immunosorbent assay, but visualization of the parasite is necessary for a confident diagnosis. In the more chronic stage, it is important to examine cerebrospinal fluid, which often shows lymphocytosis, an elevated protein level, and the presence of morular cells of Mott or motile trypanosomes. High levels of IgM in cerebrospinal fluid may suggest the diagnosis in advanced disease if trypanosomes have not been found.

A novel test for African trypanosomiasis involves analysis of serum samples by mass spectrometry to detect distinct proteomic signatures; this test appears to provide more sensitive and specific detection than other diagnostic tests.[120]

Hookworm

It has been estimated that more than 900 million people are infected with hookworms.[121] There are two main species, *Ancylostoma duodenale* and *Necator americanus*, sometimes called the Old World and the New World hookworms, respectively. Both species are widely distributed in tropical and subtropical Asia and Africa. The prevalence of infection ranges from 80% to 90% in rural areas in the moist parts of the tropics, such as west Bengal, to 10% to 20% in relatively dry countries, such as those of the Middle East and Pakistan.

Both species of hookworm produce enormous numbers of eggs—approximately 20,000 per day per female. The eggs are discharged into the intestinal lumen, where they undergo a number of cell divisions before being passed in stool. Given appropriate conditions, the eggs develop further and hatch, with liberation of larvae. These free-living stages go through a series of developments designated L1 to L3, after which they penetrate the skin and the infective filarial larval forms migrate to the intestinal tract via the circulation, lungs, and respiratory tract. The final larval stage, L4, and the adult worms are found in the small intestine.

Hookworms attach to the mucosa of the upper intestine by their buccal capsules. Although they are found mainly in the jejunum, in very heavy infections they may be distributed as low as the ileum. Attachment of the worm results in bleeding into the gastrointestinal tract.

The worms change their attachment site every few hours. Continuous or intermittent suction causes tissue and blood to be drawn into the worm's intestinal tract.[122] Only about 50% of the iron lost as hemoglobin into the gut may be reabsorbed. Therefore, there is a marked increase in fecal iron concentration that is related directly to the worm load, which can be assessed by the fecal egg count. Direct recordings of blood loss have given values on the order of 0.03 mL/day per worm for *N. americanus* and up to 0.26 mL/day per worm for *A. duodenale*,[122] and the latter species tends to cause more profound levels of iron deficiency in the community.[123]

The hematologic findings in children or adults with heavy hookworm infections are characteristic. Because the condition is usually chronic, anemia is the major clinical feature. In severe cases, hemoglobin values of 2 to 5 g/dL are common.[124] The blood film shows the typical changes of iron deficiency anemia, such as microcytosis, hypochromia, and a normal reticulocyte count. The serum iron level is low, and iron is absent from bone marrow stores. Because of associated protein loss, these children often have hypoalbuminemia.[124-127] Mild eosinophilia may be present[124] in patients with established illness, although very high eosinophil counts may occur during the phase of the illness in which the worms are migrating from the skin to the gastrointestinal tract (see later).

The diagnosis is made by analysis of stool for eggs. In heavy infections, a fecal film can be examined directly after the sample is mounted in saline or iodine solution. In lighter infections, concentration by zinc sulfate flotation is required.

Affected children require oral iron treatment to restore the iron stores, as well as treatment with anthelmintic drugs. Although many of these children are severely anemic, they have had chronic anemia for many years, and rapid restoration of the hemoglobin level is not usually required. However, in profoundly anemic children with high-output failure and associated hypoalbuminemia, it may be necessary to administer red cells slowly, together with appropriate diuretics. These children may have greatly increased blood volume, and it is easy to precipitate circulatory overload and cardiac failure. For patients with severe heart failure, an exchange transfusion consisting of removal of blood from one arm

while infusing red cells into the other may be helpful. Whatever method is chosen, monitoring of the patient's central venous pressure is essential.

In recent years a growing number of tropical countries have made concerted efforts to reduce the effects of hookworm infection by anthelmintic strategies in the community. For example, mass administration of mebendazole to 30,000 schoolchildren in Zanzibar was estimated to prevent 1260 cases of moderate to severe anemia and 276 cases of severe anemia in 1 year, although it appeared that at least two doses per year would be necessary to maintain this level of protection, thus raising the issue of long-term sustainability.[128]

Bartonellosis

Bartonellosis (Carrión's disease, Oroya fever) is an infectious disease that is endemic in the western Andes of Peru and is seen occasionally in Colombia and Ecuador.[129] It results from infection by an aerobic, gram-negative bacillus, *Bartonella bacilliformis*. It is usually transmitted through a sandfly bite. After inoculation, the organism multiplies in endothelial and red blood cells. In severe disease, almost 100% of red cells are infected with numerous bacteria. Hence the major feature of the disease is profound anemia resulting from the infection and subsequent phagocytosis of red cells. Although the precise mechanisms of the anemia are not fully understood, it seems to have many of the features of anemia of acute malarial infection. Survival of infected and noninfected red cells is shortened, and a limited response to the hemolysis associated with dyserythropoietic changes in the bone marrow is seen.

The disease has two stages, anemic and eruptive, with an asymptomatic period between the stages. After an incubation period of approximately 60 days, the onset of the condition is acute and consists of malaise, chills, fever, and headache. The clinical picture is then dominated by severe hemolytic anemia associated with hepatosplenomegaly, lymphadenopathy, and occasionally a fine petechial rash. In the later eruptive stage, nodule lesions of varying size appear on the face, trunk, and limbs. Arthralgia and fever may also be present. The lesions, which are widespread on the arms and legs, may be confused with leprosy, yaws, or even Kaposi's sarcoma. Although the infection is often present for a prolonged period, the eruptive phase tends to regress spontaneously.

During the anemic stage, moderate to severe hemolytic anemia is seen with reticulocyte counts in the 5% to 10% range. The organisms can be seen on thick and thin blood films stained with Giemsa, Wright, or related stains. The bone marrow is hyperactive with dyserythropoietic changes. The white blood cell count is not usually elevated, but thrombocytopenia is common.

The principal complication of this disease, apart from profound anemia, is superinfection with other organisms, particularly *Salmonella typhi* and *Mycobacte-*

rium tuberculosis. Fortunately, *B. bacilliformis* is extremely sensitive to chloramphenicol, penicillin, and tetracyclines. Supportive treatment includes regular transfusion through the anemic phase of the illness.

Complex Hematology of Childhood Human Immunodeficiency Virus Infection in the Developing Countries

The devastating impact of perinatally acquired HIV infection in an increasing number of developing countries is mirrored by the complexity of the hematologic complications of this disease in these populations. In some central African countries, seroprevalence rates in pregnant mothers in 1990 ranged from 20% to 30%, and in several others they exceeded 10%.[130] In India and Southeast Asia, the figures are presently much lower than this but are rapidly rising. Perinatal transmission rates have been difficult to establish with certainty but seem to be considerably higher than in the West. In 1989, an estimated figure in Zaire was 39%.[131] Although some children are infected through breast-feeding, the current consensus is that the benefits of breast-feeding probably outweigh the risk in countries where infectious diseases are the major cause of infant mortality.

The clinical picture of childhood HIV infection in the tropics does not differ greatly from that seen elsewhere, except that protein-energy malnutrition occurs much earlier. Tuberculosis and measles, both major causes of mortality by themselves, are more severe in HIV-infected children, but surprisingly, the severity of malaria does not seem to be affected. In Malawi, it is estimated that approximately half of perinatally infected infants die in the first year of life,[132] a considerably earlier mortality than seen in the West.[133]

HIV infection provides yet another example of the complex pathogenesis of hematologic problems in the tropics. The virus can infect hematopoietic precursors,[134,135] as well as bone marrow macrophages and stromal fibroblasts, an observation that may explain the marked dyserythropoiesis that is commonly observed in the bone marrow of affected children, but these changes may also be complicated by opportunistic infection, malnutrition, and drug toxicity. Anemia with a low reticulocyte count and a microcytic hypochromic blood picture is common and may reflect both coexistent iron deficiency and the anemia of chronic disorders.[133,136,137] HIV may cause immune thrombocytopenia early in the course of the disease, but this is not regarded as an adverse prognostic feature. Thrombocytopenia may also be accompanied by microangiopathic hemolytic anemia as part of thrombotic thrombocytopenic purpura, which in the context of HIV infection responds well to plasma infusion. Later, in addition to the progressive lymphopenia that characterizes acquired immunodeficiency syndrome, both reduced production and increased cellular

clearance may contribute to neutropenia and thrombocytopenia.[137,138] Finally, advancing immunodeficiency contributes to a greatly increased risk for lymphoid neoplasms, particularly lymphoma.

The wide spectrum of hematologic complications associated with HIV and the high prevalence of infection make HIV testing an essential part of the investigation of cytopenia in most tropical areas. One of the most difficult dilemmas that HIV infection poses for pediatricians in the tropics is management of a child with life-threatening anemia. The conventional approach would be blood transfusion, but in many regions this is now a major risk factor for HIV infection that is not adequately prevented by the available screening programs.[139,140] This problem is discussed further in a later section.

TROPICAL EOSINOPHILIA

The structure and function of eosinophils are described in Chapter 21. Here the importance of eosinophilia in the tropics is discussed.

After anemia, eosinophilia is probably the next most common hematologic abnormality in children in the tropics.[141] An increase in eosinophils in bone marrow and peripheral blood, as well as in tissues, is a major feature of infections caused by worms that migrate through extraintestinal organs. There is a strong association between eosinophilia and infection with tissue nematodes, trematodes, or cestodes. In contrast, however, there is no well-documented evidence that worms that do not invade tissues or protozoal infections are associated with elevated eosinophil counts.

Some common causes of eosinophilia in the tropics are summarized in Box 37-1. A functional role for eosinophils in host protection against some invasive helminths has been demonstrated. For example, incubation of human eosinophils with the larval forms of *S. mansoni* or *Trichinella spiralis*, together with specific antibodies or complement, causes the destruction of these organisms. These in vitro studies have been confirmed by in vivo experiments in mice depleted of eosinophils; animals treated in this manner lose resistance to these helminths. It appears that killing of these organisms is initiated by attachment of eosinophils to the parasite surface, followed by extracellular degranulation and deposition of electron-dense material.

An absolute elevation in the peripheral blood reticulocyte count may occur in any of the conditions listed in Box 37-1. However, the term *tropical eosinophilic syndrome* was first used in the 1940s to describe patients with a paroxysmal cough and wheezing, particularly at night, scanty sputum production, weight loss, low-grade fever, lymphadenopathy, and extreme blood eosinophilia (>3000/μL). Later, this syndrome was discovered to be due to filarial infection.

Hypereosinophilic syndrome is seen in children or young adults and is found most commonly in India,

Box 37-1	Causes of Eosinophilia in Tropical Populations

Indonesia, Sri Lanka, Pakistan, and Southeast Asia, although it may occur in any area where human filariasis is common.[142-145] In addition to typical clinical and hematologic findings, these patients have very high levels of serum IgE together with increased levels of specific antifilarial antibodies. Although it is usually easy to make this diagnosis in a tropical setting, if patients with these symptoms return to nontropical countries, other conditions that cause eosinophilia have to be considered, including chronic eosinophilic pneumonia, allergic aspergillosis, vasculitic syndromes, and idiopathic hypereosinophilic syndrome. The major distinguishing features of tropical hypereosinophilic syndrome are a marked elevation in antifilarial antibody and very high IgE levels. It may be possible to identify filaria on blood films. Traditionally, better results have been obtained with films prepared from blood samples taken at night, although some studies suggest that this may not be necessary.[145]

What is the best approach to determine a diagnosis in a child who has spent time in the tropics and who has persistent eosinophilia? It is important to determine which parts of the tropics have been visited. A careful respiratory history should be taken. Detailed studies of stool for cysts and ova should be performed several times by an experienced observer. Serologic studies for *Filaria*, *Toxocara*, and *Trichinella* infection should be carried out, and immunoglobulin levels should be determined. If a diagnosis has not been determined after these investigations, it is important to exclude nontropical causes of eosinophilia, including collagen vascular disease, allergy, drug reactions, lymphoma, and leukemia associated with an eosinophil response. It may be necessary to initiate a trial of the antifilarial drug diethylcarbamazine under careful medical supervision as part of the diagnostic workup.

HEMATOLOGIC ASPECTS OF MALABSORPTION IN THE TROPICS

One of the major difficulties in discussing the problem of malabsorption in the tropics is definition.[146] A large proportion of people in tropical climates, both indigenous populations and expatriates who have lived and worked in rural areas, have mild abnormalities of the intestinal mucosa, often associated with impairment of absorption. These structural and functional alterations of the gut have been called tropical enteropathy.[147-149] It is likely that they reflect an adaptation to life in the contaminated environment of the tropics with its recurrent enteric infections and peculiarities of diet. Interestingly, similar morphologic lesions have been demonstrated in the colon of otherwise healthy residents of southern India. After expatriates return to temperate climates, these changes in the gut revert to normal.[150]

The more severe malabsorption syndromes, sprue and postinfective malabsorption, are associated with chronic diarrhea, wasting, and a variety of hematologic changes.

The term *sprue* was first coined by the English physician Manson while working in China; it is an Anglicization of the Dutch term *indische sprouw*. During the 19th and 20th centuries, tropical sprue was thought to be a disease of expatriates, but during World War II it became apparent that similar syndromes commonly occur in indigenous populations. The occurrence of severe malabsorption syndromes is not distributed evenly in the tropical world.[150-152] They are particularly common in the Indian subcontinent, Burma, Malaysia, Vietnam, Borneo, Indonesia, and the Philippines. They are also seen in the West Indies, in parts of Central America (particularly Puerto Rico, Cuba, and the Dominican Republic), and in northern parts of South America. There are a few reports from the Middle East and temperate areas. Tropical Africa seems to be spared.

These syndromes are believed to originate from an infection.[153,154] They usually start as an acute attack of diarrhea, which then becomes chronic. Many well-documented epidemics of sprue have been reported both in southern India and in the Philippines among American military personnel. However, despite a vast amount of work and the establishment of units specifically assigned to study the problem, no organism has been isolated that could even approach meeting Koch's postulates. It may be that these disorders can follow infection with a variety of agents, but the reason for the peculiar geographic distribution remains unexplained. Remarkably, genetic factors have been almost totally ignored in the investigation of this disease.

Tropical malabsorption syndromes can occur in individuals of any age. They are characterized by intermittent diarrhea, weight loss, and anemia. Varying degrees of mucosal damage are found on biopsy of the small intestine, although an absolutely flat mucosa, as seen in gluten-induced enteropathy, is rare. Hematologic findings in patients with tropical malabsorption syndromes vary considerably. In more advanced disease, megaloblastic anemia is common. It is usually caused by folate deficiency but may also be complicated by vitamin B_{12} deficiency. Frequently, bizarre mixed pictures of iron and folic acid deficiency are found.

Interestingly, although much of the data derive from uncontrolled studies, many of the symptoms and hematologic changes associated with these syndromes can be reversed by a course of oral tetracycline. However, recovery is much more rapid if folate or vitamin B_{12} treatment is given as well.

In a tropical setting, malabsorption can also result from colonization of the small bowel by specific parasites, including *Giardia lamblia*, *Strongyloides stercoralis*, *Cryptosporidium*, and others. Furthermore, abdominal tuberculosis with malabsorption is particularly common, and in Africa, HIV infection may be an important cause of malabsorption.[155,156] The local name "slim disease" acknowledges the severe wasting that can occur with HIV infection.[155]

Hematologists without experience in the tropics should be aware that the clinical and hematologic findings of tropical malabsorption syndromes can be extreme. In young children particularly, a good history of diarrheal illness may not always be available, and in many tropical populations recurrent diarrheal illness is the norm anyway. Folate deficiency, as well as producing anemia, may give rise to severe neutropenia and thrombocytopenia with associated infection or bleeding. If intercurrent infection is present, as is often seen in severely affected children, the bone marrow appearance may be deceiving, although there is nearly always some megaloblastic change even if overall the bone marrow is much less hyperplastic than usually observed with folate or B_{12} deficiency in Western settings.

A major diagnostic problem that is often encountered in children returning from the tropics with persistent diarrhea and malabsorption is determining whether they have postinfective malabsorption or celiac disease. If symptoms do not resolve, it may be necessary to initiate a trial of a gluten-free diet and then reintroduce gluten at a later date while monitoring progress with repeated small bowel biopsies.

HEMOSTATIC FAILURE AS A MANIFESTATION OF SYSTEMIC DISEASE IN THE TROPICS

Many tropical infections or other hazards produce serious bleeding disorders. Malaria was considered in an earlier section. Here, a few other causes of bleeding disorders that are seen in the tropics are discussed.

Dengue

The dengue viruses are four antigenically related but distinct organisms that are transmitted to humans by

mosquitos of the species *Aedes aegypti*.[157] The clinical manifestations of this very common infection vary in different parts of the world. In American, African, and Indian populations the disease is characterized by classic dengue fever, but in Southeast Asia a much more serious condition develops in many children, dengue hemorrhagic fever (DHF)/dengue shock syndrome (DSS). The latter develops in infants born to dengue-immune mothers during initial infections or in children older than 1 year during secondary infections. It appears that this curious paradox reflects enhancement of dengue viral infection in mononuclear phagocytes mediated by subneutralizing concentrations of dengue antibody.

The pathophysiologic course of DHF/DSS is quite remarkable.[157,158] Dengue viruses appear to be parasites of mononuclear phagocytes. Furthermore, they use antibody as a specific receptor for gaining entry to these cells. Such antibodies are known as infection-enhancing antibodies. Epidemiologic studies have shown that children 1 year or older always have detectable dengue antibody before acquiring a subsequent infection that results in DHF/DSS. Infants who acquire dengue antibody passively from their mothers are also at risk for development of the syndrome. DHF/DSS is characterized by simultaneous activation of the complement and hemostatic systems, together with a marked increase in vascular permeability.[158-160] It appears that complement activation follows both the classical and alternative pathways. The hemostatic abnormalities include gross thrombocytopenia, prolonged bleeding time, elevated prothrombin time, and a reduction in the levels of factors II, V, VII, and IX, together with marked hypofibrinogenemia and an increase in fibrin degradation products. The abnormalities in vascular permeability are characterized by an elevated hematocrit, normal or low serum protein levels because of selective loss of albumin, and variable serous effusions.

Precisely what triggers these remarkable events is not clear. However, it seems likely that the mediators are the product of dengue virus–infected mononuclear phagocytes. Studies in Thailand have suggested that low levels of heterotypic neutralizing antibody from a single previous infection prevent the illness in those who acquire dengue 2 infections.[157,160] On the other hand, children with circulating dengue-enhancing antibodies but no neutralizing antibodies are at high risk.

Once DHF has been triggered, however, the immune disturbance is not confined to antibodies. Both the CD4[+] and CD8[+] subpopulations of T lymphocytes are more intensively activated in DHF than in uncomplicated dengue fever.[161] High levels of TNF and other procoagulant cytokines may also contribute to the pathologic changes.[162] A further factor might be antibodies to plasminogen, which are found in a significant proportion of dengue infections, particularly if hemorrhage is present.[163] These antibodies are thought to arise because of structural homology between plasminogen and the dengue envelope glycoprotein.[164] Findings in Vietnamese children with DSS suggest that rather than causing true

disseminated intravascular coagulation, the virus may act to directly degrade fibrinogen and thereby result in secondary activation of procoagulant homeostatic mechanisms.[165]

The clinical findings of DHF/DSS consist of fever, malaise, and anorexia, and about 2 to 5 days later a second phase occurs in which there are widespread hemorrhagic phenomena, including purpura, large spontaneous ecchymoses, and bleeding from previous venipuncture sites. These children then enter a phase of profound shock. The hematologic findings are characterized by a normal or even high hematocrit associated with gross thrombocytopenia and evidence of disseminated intravascular coagulation.

The fact that the most serious pathophysiologic mechanism in this disease is fluid loss rather than hemorrhage has focused attention on the development of treatment regimens similar to those used for the management of severe diarrheal illnesses in children in the tropics. A study in Vietnamese children concluded that initial resuscitation with lactated Ringer's solution was appropriate for moderately severe DSS whereas hydroxyethyl starch had fewer adverse reactions than dextran for colloid treatment of severe DSS.[166] Clinical trials of heparin treatment to counteract disseminated intravascular coagulation have not produced impressive results.

Other Viral Hemorrhagic Fevers

Severe hemorrhagic fevers caused by viruses occur throughout the tropical world and are encountered on every continent except Australia and North America.[167] They are the result of RNA viruses of four distinct families, each of which is a zoonosis with typical epidemiologic features. They are transmitted by a variety of agents, including tics and mosquitos. In many instances the reservoirs and vectors are unknown. These diseases are associated with specific clinical entities in different parts of the world, such are Rift Valley fever, Lassa fever, Argentine hemorrhagic fever, Bolivian hemorrhagic fever, and others.

Many of these conditions are accompanied by hemorrhagic diatheses of varying severity ranging from mild purpura to severe hemostatic failure.[168] As with dengue, shock is a major feature and is often associated with an elevated hematocrit. The bleeding manifestations reflect both increased vascular permeability and consumptive coagulopathy. There have been few extensive coagulation studies performed in patients with these disorders, although disseminated intravascular coagulation has been implicated as the basis for the hemostatic failure.

Snake Bite

Snake bite is an important and neglected problem in the rural tropics; its incidence is underestimated because of the lack of reliable epidemiologic data.[169] In northern Ghana, the carpet viper (*Echis* complex of species) is

responsible for some 86 bites per 100,000 population per year, with 28% mortality. This particular snake, whose geographic range extends throughout the northern half of Africa and the Middle East to India, probably bites and kills more people than any other species. In the Indian subcontinent, the most important species are the cobra (*Naja naja*), the common krait (*Bungarus caeruleus*), Russell's viper (*Vipera russelli*), and *Echis* species. In Sri Lanka there are about 60,000 bites and 900 deaths (6 per 10,000 population) each year. In Southeast Asia, the Malayan pit viper (*Calloselasma rhodostoma*), *D. russelli*, and green pit vipers cause most bites and deaths. In Burma, Russell's viper bite has been the fifth major cause of death, with an annual mortality of about 15 per 100,000 population. Snake bite is also a common public health problem in Central and South America.

The hematologic complications of snake bite are a reflection of the complex chemistry of venoms.[170-172] Although much work remains to be done, at least some components of snake venom have been well defined. Venom may contain 20 or more different components. More than 90% of the dry weight of venom is protein in the form of enzymes, nonenzymatic polypeptide toxins, and nontoxic proteins. The mechanisms of envenomation have been most clearly defined for some of the venom procoagulants. For example, *V. russelli* venom contains a glycoprotein that activates factor X and an arginine ester hydrolase that activates factor V. *Echis* venom contains a zinc metalloprotein called ecarin that activates prothrombin. Many crotaline venoms contain proteases that cleave fibrinogen (e.g., arvin and reptilase). Some venoms contain phospholipase A_2 (lecithinase), which probably contributes to their neurotoxicity, cardiotoxicity, and hemolysis and is also responsible for increasing vascular permeability.

After a snake bite, swelling and bruising of the limb result from increased permeability induced by proteases, phospholipase, polypeptide toxins, and hyaluronidase, as well as by endogenous activators released by the venom such as histamine, 5-hydroxytryptamine, and kinins. The acute hemostatic failure that may follow envenomation is mediated in several ways.[173,174] Bites from snakes that produce procoagulants that activate factors V or X or prothrombin are associated with a rapid consumptive coagulopathy. In other instances there may be rapid defibrinogenation that is due to either direct attack on fibrinogen or activation of the endogenous fibrinolytic system. Thrombocytopenia results from either aggregation or consumption. The bleeding is potentiated by damage to vascular endothelium. The combination of defibrination, thrombocytopenia, and increased vessel wall permeability leads to massive bleeding, which is a common cause of death.

Although as mentioned earlier, many venoms are hemolytic in vitro, massive intravascular hemolysis is seen rarely and usually in association with bites by *V. russelli*.

Management of snake bite includes supportive treatment, careful correction of the coagulation abnormali-

ties, appropriate respiratory support if the venom is associated with neurotoxins, and judicious use of appropriate antivenin. Hemostatic disturbances usually respond well to antivenin treatment, and replacement therapy with fresh whole blood, fresh frozen plasma, specific factors, or platelet concentrates is not generally required. Even though a theoretical case can be made for the use of heparin in patients bitten by Russell's viper, particularly if there is definite evidence of disseminated intravascular coagulation, thus far clinical trials have not shown any benefit.

Although the long-term prognosis for those who recover from a snake bite is good, work in Burma has shown that chronic pituitary failure and renal failure may develop later. These conditions are believed to be caused by infarction of the pituitary gland during the phase of intravascular coagulation, similar in pathophysiology to that observed after childbirth and called, in this setting, Sheehan's syndrome.[175] It may be accompanied by a mild normochromic anemia.

GEOGRAPHIC VARIABILITY IN THE DISTRIBUTION AND EXPRESSION OF HEMATOLOGIC DISEASE

In addition to the unique hematologic problems caused by disorders that are specific to the tropics or other parts of the developing world, the pattern of distribution of primary disorders of the blood varies considerably among different populations. Furthermore, there are some hematologic syndromes, as yet ill defined, that are unique to certain parts of the developing world.

Lymphoma and Leukemia

The pathophysiologic and clinical features of the lymphomas and childhood leukemias[176,177] are described elsewhere in this book. Burkitt's lymphoma is endemic throughout large regions of sub-Saharan Africa and in Papua New Guinea. In Burkitt's classic descriptions of the tumor, he pointed out that its occurrence is related closely to altitude, temperature, and rainfall, features that are similar in sub-Saharan Africa and Papua New Guinea. Although this distribution, together with work relating this B-cell tumor to infection with Epstein-Barr virus and evidence for loss of immunologic control of Epstein-Barr virus during acute attacks of malaria,[168,178] relates the prevalence of the tumor to malaria, this is certainly not the whole story. For example, it is not found in Zanzibar, although it is very common in the coastal regions of neighboring Tanzania.

The T-cell leukemia/lymphoma syndrome, first recognized in southern Japan and now known to be due to infection with human T-cell leukemia/lymphoma virus type 1 (HTLV-1), has a very restricted distribution in southern Japan and the Caribbean.[177] It is not yet clear which particular lymphocyte populations are involved in

the very common histiocytic lymphomas that occur throughout the Middle East and across parts of Central and South America.

The curious syndrome of primary upper intestinal lymphoma (Mediterranean lymphoma) and immunoproliferative disease of the small intestine has to be distinguished from the rare primary intestinal lymphomas that occur sporadically throughout the world, usually in elderly patients.[179,180] In endemic regions, primary upper intestinal lymphoma and immunoproliferative disease of the small intestine occur in much younger age groups, usually of poor socioeconomic background. The pathologic lesions are found predominantly in the upper part of the small intestine and are associated with a clinical picture characterized by malabsorption, which often precedes development of the tumor.

Although this condition is still known as Mediterranean lymphoma, it was first described in Peru. However, the largest epidemic area is the region of the Mediterranean and the Middle East, and many cases have now been reported from Israel, Lebanon, Iraq, Syria, and Iran, as well as Greece.

Studies of the population distribution of classic Hodgkin's disease have also shown some discrepancies.[176,181] High rates are found in most affluent westernized countries and lower rates in poorer countries and the tropics; this does not seem to be due entirely to ascertainment bias. Interestingly, particularly low rates are seen in Japan and also in China, India, and Malaysia. In addition, there are considerable variations in age distribution and histologic subtype in different parts of the world. In poorer or lesser developed countries, Hodgkin's disease occurs at a younger age and is usually the histologic type with a poorer prognosis.

Some interesting differences in rate of occurrence and type of acute leukemia throughout the world are also seen.[176,182] In North America and Europe and in all other westernized populations, acute lymphoblastic leukemia (ALL) accounts for a high proportion of acute leukemia in children between the ages of 2 and 5. In contrast, ALL is uncommon in the tropics, particularly in sub-Saharan Africa, where Burkitt's lymphoma is the predominant childhood tumor. On the other hand, in older children the incidence of acute myeloid leukemia and various subtypes of ALL is similar to that in Western societies.

Hereditary Blood Disorders

The distribution of hemoglobin disorders in the world is described elsewhere in this book. Particularly as developing countries pass through the epidemiologic transition toward a reduction in childhood mortality secondary to malnutrition and infection, children with these conditions tend to survive long enough to be evaluated for treatment. Hence they are producing an increasingly serious burden on health care resources in many of the developing countries. For environmental and cultural reasons, their diagnosis, management, and control raise

problems in many developing countries completely different from those encountered in developed countries. A full description of these complex issues is beyond the scope of this chapter; they have been covered in detail in two recent monographs.[183,184]

The manifestations of G6PD deficiency in some developing countries also differ from those seen in the West. The problems of drug-induced hemolysis and favism are discussed elsewhere in this book. It is important to point out, however, that in parts of Southeast Asia, Greece, and Africa, G6PD deficiency appears to be associated with neonatal jaundice.[185-187] This is not a common problem in G6PD deficiency in advanced Western societies. Although this observation was first made more than 30 years ago, the precise mechanism of the neonatal jaundice is not clear. In Singapore it is enough of a public health problem to have led to routine screening of all newborn babies for G6PD levels.

The high frequency of the hemoglobin disorders and G6PD deficiency reflects relative protection of carriers against malaria. This mechanism is also responsible for the unusually high frequency of ovalocytosis in Melanesia, a condition that is relatively rare in Western populations. Melanesian ovalocytosis is asymptomatic in heterozygotes, although the absence of reported homozygotes suggests that it may have a much more severe phenotype. There is clear evidence that it has reached high frequencies in Melanesia by protection against malaria, particularly cerebral malaria.[188]

Aplastic Anemia

Although more data are needed for confirmation, there is growing evidence that aplastic anemia, particularly in childhood, is much more common in parts of Southeast Asia and South America than in developed Western countries.[189] The ease of availability of potentially toxic agents such as chloramphenicol may be reflected by this finding, but this is probably not the whole story. The possibility exists that that it reflects the action of an as yet unidentified infectious agent. This challenging question certainly requires further detailed prospective studies because a full hematologic workup, including bone marrow trephine biopsy, is rarely available in many parts of the world, even at tertiary referral hospitals.

Hematologic Disorders Unique to Certain Countries

A number of ill-defined hematologic disorders appear to be common to particular countries. In Thailand, for example, there is a well-recognized disorder called acquired prothrombin complex deficiency, a condition seen mainly in infants who have been breast-fed.[190] Despite a great deal of work, the etiology is not yet known, although it is suspected that mothers may have ingested substances antagonistic to prothrombin.

Also in Thailand, a very curious condition called acquired platelet dysfunction with eosinophilia is seen.[191] It is a pediatric disorder characterized by bleeding and ecchymoses. There is associated eosinophilia and abnormal platelet function test results. The etiology is unknown, and current efforts are focused on trying to define a parasitic cause.

In India an increase has been seen in hemolytic disease of the newborn, which appears to be due to fetomaternal ABO incompatibility.[192] Evidence showing that this may be related to the administration of tetanus toxoids to pregnant women to prevent the major problem of tetanus neonatorum in that population is increasing; there is a marked increase in the maternal titer of anti-A/anti-B antibodies after the injection of tetanus toxoid.

ASPECTS OF CLINICAL MANAGEMENT

Treatment of Severe Anemia in the Tropics

The definition of severe anemia depends on the clinical context, and the normal level of hemoglobin in the community has to be considered. In an African child with malaria, a hemoglobin level of approximately 5 g/dL is commonly used as the criterion for transfusion, although a transfusion would normally be given sooner if the parasitemia were extremely high. The fatality rate for severe malarial anemia varies widely between clinics, but a typical figure is approximately 7%.[193] Until recently, most tropical pediatricians have endeavored to improve survival by improving the availability of transfusion.

The situation has altered dramatically as a result of the significant risk of HIV infection that now accompanies blood transfusion in many tropical regions.[139,194] Apart from the logistic and financial difficulties of screening blood donations, these screening procedures are an unreliable means of preventing transfusion-associated HIV infection in the developing world[140] (see later). There are also other problems with blood transfusion that tend to be ignored. Cross-matching can be erratic in a clinic with inadequate resources, and the infusion is often unsupervised. Occasionally, the consciousness level of a child with malaria deteriorates dramatically after the transfusion. Such occurrences are rare, but there are theoretical reasons why transfusion might worsen sequestration, such as the blood group favoring the formation of erythrocyte rosettes.[195]

An urgent need exists to define the clinical criteria that make transfusion absolutely essential. Decision trees have been devised,[196] but the underlying risk-benefit equation may vary from place to place, and a meta-analysis found no clear evidence of benefit for transfusion in anemic children whose conditions are clinically stable.[197] One issue that has become clear is the prognostic importance of respiratory distress. For example, in Kenyan children, malarial anemia rarely causes death unless respiratory distress is present,[198] and the only clear evidence that blood transfusion is beneficial is seen in the group of children who have both anemia and respiratory distress.[199]

Investigations into the clinical physiologic course of severe malarial anemia in African children have yielded important insight into the management of this condition. Lactic acidosis appears to be the main cause of the relationship between anemia and respiratory distress,[200] and there is a substantial oxygen debt.[201] Rapid transfusion may be lifesaving, not only because it increases hemoglobin but also because volume repletion reduces acidosis,[200] and a careful study in Kenya showed no evidence that it was likely to cause fluid overload. This is contrary to the notion that a severely anemic child is likely to be in high-output failure and should therefore be depleted of fluids or undergo diuresis before transfusion. However, before rewriting the textbook on the management of severe anemia, we need data from other parts of the tropics, where different pathophysiologic factors may be operative.[202]

With the steady increase in levels of resistance to antimalarial drugs worldwide, the incidence of severe childhood anemia in the tropics is expected to increase. As the criteria for transfusion become stricter, there is a need for more data on optimal hematinic therapy for children with malarial anemia. The practices of pediatricians vary, but many prescribe both iron and folic acid in addition to antimalarial therapy. One concern has been that iron deficiency may help suppress parasite growth, and in some studies[203,204] but not others,[15] iron repletion has been found to increase the risk for subsequent infection. Another concern has been that folic acid supplements might reduce the efficacy of the antifolate drugs that are increasingly being used to treat chloroquine-resistant malaria in the community.[205] These issues were addressed in a study of moderately anemic Gambian children with *P. falciparum* infection.[206] Supplementary iron therapy was found to result in a small, but significant improvement in hemoglobin levels after 1 month and did not increase the risk for reinfection within this period. Folic acid supplements failed to improve hemoglobin levels and increased the risk for parasite recrudescence if sulfadoxine-pyrimethamine was used to treat the infection. However, it cannot be assumed that these findings would necessarily apply to regions with different rates of malarial transmission and different nutritional problems, and the need for locally based research into this type of problem cannot be overemphasized.

Problems with Blood-Borne Infection and Blood Transfusion

The risk of contracting an infection after blood transfusion is increasing and becoming a major economic burden for developing countries. Whereas the most important infections are those resulting from blood-borne HIV and hepatitis B and C viruses, the incidence of other infec-

tions is increasing. As mentioned earlier, although donor screening has had a major effect in reducing the occurrence of HIV infection in patients who are receiving regular blood transfusions, such as those with thalassemia, even if blood is screened adequately, the risk for infection remains. Hepatitis C is becoming a major problem throughout the southern Mediterranean region, the Indian subcontinent, and Southeast Asia, whereas hepatitis B remains a problem in many of the poorer countries. With the reappearance of malaria as a major problem in parts of the Indian subcontinent and Southeast Asia, post-transfusion malarial infection is increasing. Indeed, in many clinics it is becoming standard practice to treat recipients of transfusions with antimalarial drugs prophylactically.

In addition to these common viral and parasitic infections, the risk of blood-borne disease caused by other bacteria and parasites must always be considered, particularly in places where these infectious diseases are endemic. For example, Chagas' disease is often transmitted through blood transfusion, although remarkably, pretreatment of blood with gentian violet seems to result in a major reduction of this complication. In parts of South America, transfusion-borne infections with *Bartonella* may occur. Diseases associated with HTLV-1 and HTLV-2, notably tropical spastic paraparesis and adult T-cell leukemia, which seem to be restricted mainly to the Caribbean and certain Japanese populations, can also be transmitted by blood transfusion.

Clearly, screening programs must be tailored to the particular infections that are common in individual communities, and blood should be administered only when absolutely necessary in these populations.

Management of Imported Malaria

The most important part of the management of malaria is to be constantly aware of the possibility of the diagnosis.[207] Obtaining an accurate travel history is critical. Children who have flown from one nonmalarious region to another may have had a brief stopover during which they could have been infected. It is vital to obtain a detailed account of all countries visited and the use of malaria prophylaxis. Clinical symptoms are usually seen within a month of infection, but they can occasionally appear after several months if the infection has been partially suppressed by a prophylactic drug with a long half-life such as mefloquine. In a child who has previously been infected with *P. vivax* or *P. malariae* and parasites in the dormant stage in the liver have not been eradicated, symptoms may recur years after the initial infection. If malaria is suspected, it is important to not discard the diagnosis if parasites are not found at first, and thick blood film stains may have to be repeated several times, ideally during episodes of fever. Results with thin films are unreliable for diagnostic screening, but they can be useful for determining the species of parasite when infection has been confirmed. Dipstick assays based on detection of *P. falciparum* antigens in serum are now available. The most commonly used is based on *P. falciparum* lactate dehydrogenase, which is present in blood at the time of infection but is cleared rapidly.[208] An alternative is based on *P. falciparum* histidine-rich protein 2, which persists for some time after infection.[209] A positive result with this test may be helpful in a medical emergency, but the thick blood film remains the diagnostic "gold standard."

A child with malaria may lack the classic symptoms of paroxysmal fever and body pain. The presence of vomiting, diarrhea, cough, or tachypnea can be particularly misleading. Febrile convulsions are common and need to be distinguished from the seizures that accompany cerebral malaria, the defining feature of which is coma secondary to *P. falciparum* from which patients cannot be aroused. Hypoglycemia sometimes contributes to the coma and must be immediately excluded. Other potential problems include severe anemia, jaundice, circulatory collapse, pulmonary edema, renal failure, and coagulation abnormalities. Vigilance is needed because although these potentially lethal complications occur in only a minority of infections, they can arise after treatment has commenced.

The choice of antimalarial treatment depends on the species of parasite, the geographic source of infection, the age of child, and the severity of infection. Here it is only possible to outline the general principles involved, and specific recommendations should be sought from an up-to-date formulary or reference center. Oral chloroquine is generally the drug of choice for all species other than *P. falciparum*, although it is important to be aware of the increasing prevalence of chloroquine-resistant *P. vivax* in Papua New Guinea and Indonesia.[210] With *P. vivax* or *P. ovale* infection, it is also necessary to destroy the dormant liver forms with primaquine. The child's G6PD activity should be checked before giving this drug; if it is deficient, a lower dose of primaquine may be given over a longer period. If the infective species is not known, treatment should initially be the same as for falciparum malaria because this is the most dangerous form.

The presence of chloroquine-resistant forms of *P. falciparum* is now so widespread that chloroquine can no longer be recommended for imported infections with this species. For uncomplicated infection, several alternative treatments are available. The most convenient are combination therapies: proguanil with atovaquone (Malarone) or artemether with lumefantrine (Riamet). The alternative and classic method is a course of oral quinine, but this needs to be followed by a course of either pyrimethamine-sulfadoxine (Fansidar) if from an area where the parasites are likely to be sensitive, doxycycline if older than 12 years, or clindamycin.

For severe malaria, the standard therapy is quinine or quinidine given by carefully controlled intravenous infusion. The use of intravenous infusion is impractical for many pediatric wards in the tropics because of nursing shortages and inadequate infusion equipment. In this situation, quinine is commonly given intramuscularly

(diluted to reduce the likelihood of abscess formation),[211] and there is increasing use of artemisinin (qinqhaosu) derivatives because of their rapid antimalarial action.[212,213]

The principles of intensive management for complications of *P. falciparum* infection are the same as those for any other serious systemic infection. Dextrose infusion is often required to maintain blood glucose levels, which may be suppressed by quinine or by the infection.[214] Renal function and hemoglobin levels need to be closely monitored. In a child with cerebral malaria, overt seizures are usually controlled by diazepam and phenobarbital, but subclinical seizures are common and may be highly refractory to treatment. If high doses of anticonvulsant are necessary, it is important to recognize that the child's system is often trying to compensate for metabolic acidosis and that respiratory arrest is the most common mode of death[215]; indeed, high doses of phenobarbital have been shown to increase mortality.[216]

Fluid management of a child with severe malaria has been the focus of considerable recent debate. Studies in Kenyan children with severe malaria have concluded that overall volume status is generally low and that relatively aggressive fluid replacement may be beneficial,[200] with preliminary evidence that volume replacement with albumin results in lower fatality rates than replacement with saline does.[217] In contrast, studies of Gabonese children with severe malaria found no evidence of significant hypovolemia,[218] and these authors recommend that fluid replacement regimens be relatively conservative because intracranial pressure tends to be moderately elevated.[219] Use of steroids does not improve the outcome for adult cerebral malaria; whether this is true for children remains unknown. There is no conclusive evidence that any other form of adjunctive therapy is beneficial in childhood cerebral malaria. Exchange transfusion is sometimes used in patients with very high parasitemia, although its efficacy has not been evaluated in a controlled trial. More effective forms of treatment of severe malaria are badly needed.

Leishmaniasis

Leishmaniasis may be contracted on short visits to countries where the condition is endemic. It is a disease that may cause considerable diagnostic difficulty when seen in the setting of a hospital in the developed world. In children with this disorder, a primary hematologic disorder such as leukemia may be misdiagnosed if the diagnosis of visceral leishmaniasis is not considered. It may be manifested as an acute disorder with fever, hepatosplenomegaly, and hemolysis or as a more chronic condition characterized by increasing hepatosplenomegaly, lymphadenopathy, and pancytopenia. The hematologic and diagnostic features were mentioned earlier in this chapter.

Treatment remains difficult, with several different drugs to chose from, all of which have potential toxic effects, so expert advice should be sought.[220-222] For many years pentavalent antimony has been the drug of choice; the preparation that is available in the United States, stibogluconate (Pentostam), is classified as an investigational drug and is obtained from the Centers for Disease Control and Prevention in Atlanta, Georgia, which provides advice on dosage schedules for particular preparations. However, significant resistance is emerging, particularly in patients with kala-azar in India, and even in patients who show a good response to treatment, relapses may occur. Pentamidine has long been used as alternative for antimonial-resistant visceral leishmaniasis, but it is relatively toxic.

The past decade has seen the introduction of new therapies, including liposomal amphotericin, oral miltefosine, and paromomycin.[222] Although these are significant advances, they are not ideal drugs, and cheaper and less toxic therapies are still needed. Liposomal amphotericin has been shown to be is at least as effective and less toxic than antimony-containing compounds for the treatment of visceral leishmaniasis, and it is now licensed in the United States for that purpose, although its high cost is a significant impediment to use in the developing world. It has been used successfully for the treatment of visceral leishmaniasis in children.[223] Miltefosine, an alkyl phospholipid developed for use in cancer treatment, has been demonstrated to be an effective oral treatment of visceral leishmaniasis, including antimony-resistant infection.[224] A recent comparison of the different regimens for visceral leishmaniasis concluded that sodium stibogluconate is the most cost-effective option in areas with high response rates to antimonials; in other areas, miltefosine is most cost-effective, but its use as a first-line drug is limited by teratogenicity and the rapid development of resistance; and liposomal amphotericin remains an expensive option for poor countries where the disease is endemic.[225]

Please refer to the printed publication.

From Forestier F, Daffos F, Catherine N, et al: Developmental hematopoiesis in normal human fetal blood. Blood 1991; 77:2360.

APPENDIX 2   White Cell Manual Differential Counts in Normal Fetuses at Different Gestational Ages

Rights were not granted to include this table in electronic media.
Please refer to the printed publication.

From Forestier F, Daffos F, Catherine N, et al: Developmental hematopoiesis in normal human fetal blood. Blood 1991; 77:2360.

APPENDIX 3   Hematologic Parameters in Normal, Full-Term Cord Blood

	Paterakis et al. (1993)*	Diagne et al. (1995)[†]	Boulot et al. (1993)[‡]
Hemoglobin (g/dL)	15.6 ± 1.2	15.3 ± 1.3	13.9 ± 1.6
RBCs (×10⁶/μL)	4.42 ± 0.35	4.30 ± 0.4	—
Hematocrit (%)	51.0 ± 4.5	49 ± 5	41.3 ± 4.9
Mean Corpuscular Volume (fL)	119.1 ± 4.8	112 ± 6	109 ± 9.8
Mean Corpuscular Hemoglobin (pg)	36.4 ± 1.6	36.2 ± 2.2	38.7 ± 4.0
Mean Corpuscular Hemoglobin Concentration (g/dL)	30.6 ± 1.3	30.9 ± 1.3	33.3 ± 1.4

Data are expressed as mean ± SD.
*Paterakis GS, Lykopoulou L, Papassotiriou J, et al: Flow-cytometric analysis of reticulocytes in normal cord blood. Acta Haematol 1993; 90:182. Data obtained in 35 specimens with H*1 Technicon analyzer.
[†]Diagne I, Archambeaud MP, Diallo D, et al: Parametres erythrocytaires et reservés en fer dans le sang du cordon. Arch Fr Pediatr 1995; 2:208. Data obtained in 142 specimens with H*2 Technicon analyzer.
[‡]Boulot P, Cattaneo A, Taib J, et al: Hematologic values of fetal blood obtained by means of cordocentesis. Fetal Diagn Ther 1993; 8:309.

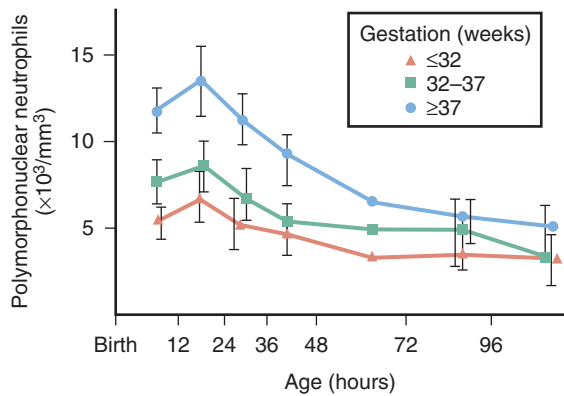
APPENDIX 4   Erythroblast and Leukocyte Counts in Umbilical Cord Blood

Type of Delivery	Erythroblast Count (×10⁹/L)	Leukocyte Count (×10⁹/L)
Spontaneous, vaginal (n = 55)	0.75 (0.0-5.3)	13.8 (7.25-48.0)
Elective cesarean section (n = 39)	0.30 (0.0-0.49)	10.6 (6.2-17.7)
Emergency cesarean section (n = 55)	1.10 (0.0-15.9)	13.5 (4.2-40.3)

Values are expressed as mean (range). Erythroblast counts were significantly higher in the spontaneous vaginal and emergency cesarean section groups compared with the elective cesarean delivery group.
From Thilaganathan B, Athanasiou S, Ozmen S, et al: Umbilical cord blood erythroblast count as an index of intrauterine hypoxia. Arch Dis Child 1994; 70: F192.

APPENDIX 5 Hematologic Values for Normal Cord Blood	
	Mean ± SD
RED BLOOD CELLS	
Hb (g/dL)	15.3 ± 1.3
Hct (%)	49 ± 5
RBC (×10⁶/µL)	4.3 ± 0.4
MCV (fL)	112 ± 6
MCH (pg)	36.2 ± 2.2
MCHC (g/dL)	30.9 ± 1.3
CHCM (g/dL)	30.4 ± 1.2
% HYPO (MCHC < 28 g/dL)	17.3 ± 11.9
% HYPER (MCHC > 41 g/dL)	0.6 ± 0.3
% MICRO (MCV < 61 fL)	0.8 ± 0.3
% MACRO (MCV > 120 fL)	31.8 ± 9.7
RETICULOCYTES	
%	3.63 ± 1.11
Absolute reticulocytes (×10⁹/L)	156.1 ± 47.7
MCVr (fL)	125.8 ± 7.3
CHCMr (g/dL)	25.6 ± 1.2
CHr (pg)	31.3 ± 1.4

MCV = mean corpuscular volume; MCHC = mean corpuscular hemoglobin concentration; MCH = mean corpuscular hemoglobin; CHCM = cell hemoglobin concentration mean; % HYPO = % hypochromic red cells; % HYPER = % hyperchromic red cells; % MICRO = % microcytic red cells; % MACRO = % macrocytic red cells; MCVr = reticulocyte mean corpuscular volume; CHCMr = reticulocyte cell hemoglobin concentration mean; CHr = reticulocyte hemoglobin content. Values obtained with Technicon H*2 and H*3 Hematology analyzers (Bayer Diagnostics) in neonates delivered at term with weight ≥ 2500 g.

Adapted from Diagne I, Archambeaud MP, Diallo D, et al: Parametres erythrocytaires et reservés en fer dans le sang du cordon. Arch Fr Pediatr 1995; 2:208, and from G Tchernia, personal communication. Data obtained in 142 specimens with H*2 Technicon analyzer.
APPENDIX 6. **Reference range for circulating neutrophil counts in healthy very-low-birth-weight neonates.** Based on 160 neutrophil counts obtained in 63 infants without perinatal complications at 0 to 60 hours of age. Birth weight was 1220 ± 203 g, gestational age 29.9 ± 2.3 weeks (± SD). **A,** Neutrophil count at birth to 60 hours of life. **B,** Neutrophil count at 61 hours to 28 days of life. Bold (*A*) and dotted (*B*) lines represent the envelopes bounding these data, respectively. (Redrawn from Mouzinho A, Rosenfeld CR, Sanchez PJ, et al: Revised reference ranges for circulating neutrophils in very-low-birth-weight neonates. Pediatrics 1994; 94:76. Reproduced by permission of Pediatrics, Copyright 1994.)


APPENDIX 7.   Changes in polymorphonuclear neutrophils after birth in three groups with different gestational ages. Total WBC counts were obtained with a Coulter S analyzer; manual differential counts were performed on 200 nucleated cells. (Redrawn from Coulombel L, Dehan M, Tchernia G, et al: The number of polymorphonuclear leukocytes in relation to gestational age in the newborn. Acta Paediatr Scand 1979; 68:709.)

APPENDIX 8	Normal Hematologic Values During the First 2 Weeks of Life in the Term Infant*				
Value	Cord Blood	Day 1	Day 3	Day 7	Day 14
Hemoglobin (g/dL)	16.8	18.4	17.8	17.0	16.8
Hematocrit (%)	53.0	58.0	55.0	54.0	52.0
Red cells (mm^3)	5.25	5.8	5.6	5.2	5.1
MCV (fL)	107	108	99.0	98.0	96.0
MCH (pg)	34	35	33	32.5	31.5
MCHC (g/dL)	31.7	32.5	33	33	33
Reticulocytes (%)	3-7	3-7	1-3	0-1	0-1
Nucleated RBCs (/mm^3)	500	200	0-5	0	0
Platelets (1000's/mm^3)	290	192	213	248	252

MCV = mean corpuscular volume; MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration.
*During the first 2 weeks of life a venous hemoglobin value below 13.0 g/dL or a capillary hemoglobin value below 14.5 g/dL should be regarded as anemic.
From Oski FA, Naiman JL: Hematologic Problems in the Newborn. 2nd ed. Philadelphia, W.B. Saunders Co., 1972, p 13.

APPENDIX 9	Normal Hematologic Values During the First Year of Life in Healthy Term Infants*						
	AGE (mo)						
n	0.5 (n = 232)	1 (n = 240)	2 (n = 241)	4 (n = 52)	6 (n = 52)	9 (n = 56)	12 (n = 56)
Hemoglobin (mean ± SE)	16.6 ± 0.11	13.9 ± 0.10	11.2 ± 0.06	12.2 ± 0.14	12.6 ± 0.10	12.7 ± 0.09	12.7 ± 0.09
−2 SD	13.4	10.7	9.4	10.3	11.1	11.4	11.3
Hematocrit (mean ± SE)	53 ± 0.4	44 ± 0.3	35 ± 0.2	38 ± 0.4	36 ± 0.3	36 ± 0.3	37 ± 0.3
−2 SD	41	33	28	32	31	32	33
RBC count (mean ± SE)	4.9 ± 0.03	4.3 ± 0.03	3.7 ± 0.02	4.3 ± 0.06	4.7 ± 0.05	4.7 ± 0.04	4.7 ± 0.04
−2 SD +2 SD	3.9-5.9	3.3-5.3	3.1-4.3	3.5-5.1	3.9-5.5	4.0-5.3	4.1-5.3
MCH (mean ± SE)	33.6 ± 0.1	32.5 ± 0.1	30.4 ± 0.1	28.6 ± 0.2	26.8 ± 0.2	27.3 ± 0.2	26.8 ± 0.2
−2 SD	30	29	27	25	24	25	24
MCV (mean ± SE)	105.3 ± 0.6	101.3 ± 0.3	94.8 ± 0.3	86.7 ± 0.8	76.3 ± 0.6	77.7 ± 0.5	77.7 ± 0.5
−2 SD	88	91	84	76	68	70	71
MCHC (mean ± SE)	314 ± 1.1	318 ± 1.2	318 ± 1.1	327 ± 2.7	350 ± 1.7	349 ± 1.6	343 ± 1.5
−2 SD	281	281	283	288	327	324	321

MCH = mean corpuscular hemoglobin; MCV = mean corpuscular volume; MCHC = mean corpuscular hemoglobin concentration.
*These values were obtained from a selected group of 256 healthy term infants followed at the Helsinki University Central Hospital who were receiving continuous iron supplementation and who had normal values for transferrin saturation and serum ferritin.
Values at the ages of 0.5, 1, and 2 months were obtained from the entire group, and those at the later ages were obtained from the iron-supplemented infant group after exclusion of iron deficiency.
From Saarinen UM, Siimes MA: Developmental changes in red blood cell counts and indices of infants after exclusion of iron deficiency by laboratory criteria and continuous iron supplementation. J Pediatr 1978; 92:414.

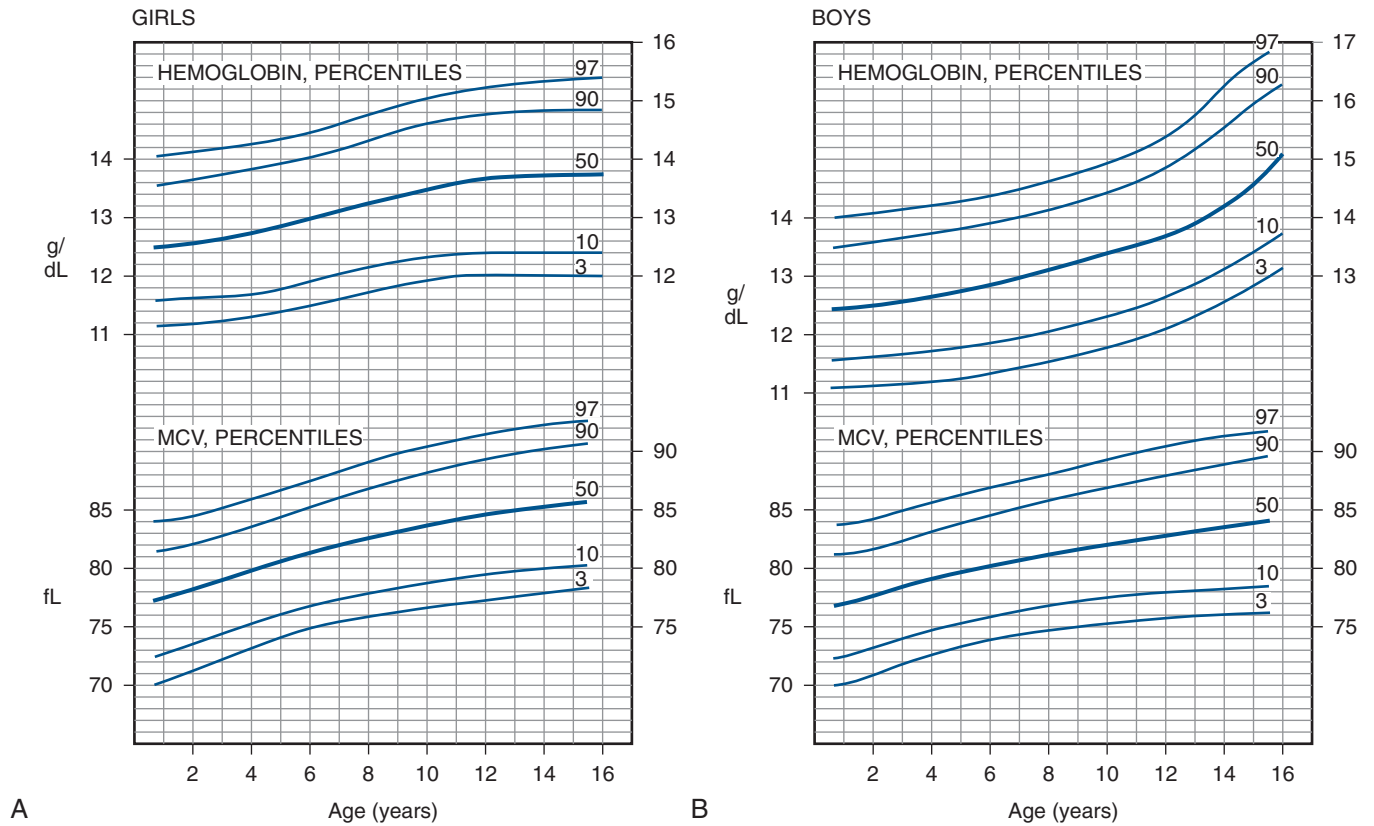
		BIRTH WEIGHT	
APPENDIX 10	**Hemoglobin Concentration During the First 6 Months of Life in Iron-Sufficient Preterm Infants***		
Age	**No.**	**1000-1500 g**	**1501-2000 g**
2 wk	17, 39	16.3 (11.7-18.4)	14.8 (11.8-19.6)
1 mo	15, 42	10.9 (8.7-15.2)	11.5 (8.2-15.0)
2 mo	17, 47	8.8 (7.1-11.5)	9.4 (8.0-11.4)
3 mo	16, 41	9.8 (8.9-11.2)	10.2 (9.3-11.8)
4 mo	13, 37	11.3 (9.1-13.1)	11.3 (9.1-13.1)
5 mo	8, 21	11.6 (10.2-14.3)	11.8 (10.4-13.0)
6 mo	9, 21	12.0 (9.4-13.8)	11.8 (10.7-12.6)

*These infants were admitted to the Helsinki Children's Hospital during a 15-month period. None had a complicated course during the first 2 weeks of life or had undergone an exchange transfusion. All infants were iron sufficient, as indicated by a serum ferritin ≥ 10 ng/mL.

From Lundstrom U, Siimes MA, Dallman PR: At what age does iron supplementation become necessary in low birth weight infants? J Pediatr 1977; 91:882.

APPENDIX 11 **Normal Hematologic Values in Children***

Rights were not granted to include this table in electronic media.
Please refer to the printed publication.

From Dallman PR: In Rudolph A (ed): Pediatrics, 16th ed. New York, Appleton-Century-Crofts, 1977, p 1111.


APPENDIX 12. **Hemoglobin and mean conpuscular volume (MCV) percentile curves for girls and boys. A,** Hemoglobin and MCV percentile curves for girls. **B,** Hemoglobin and MCV percentile curves for boys. These figures were obtained from populations of nonindigent white children residing in either northern California or Finland. Hemoglobin values were derived from a total of 9946 children and MCV values from 2314 children. The reference population excluded subjects with laboratory evidence of iron deficiency, thalassemia minor, and hemoglobinopathy. (Redrawn from Dallman PR, Siimes MA: Percentile curves for hemoglobin and red cell volume in infancy and childhood. J Pediatr 1979; 94:28.)

APPENDIX 13 **Hemoglobin Concentration in White, Black, and East Asian Children***

Rights were not granted to include this table in electronic media.
Please refer to the printed publication.

From Dallman PR, Barr GD, Allen CM, et al: Hemoglobin concentration in white, black, and Oriental children: is there a need for separate criteria in screening for anemia? Am J Clin Nutr 1978; 31:379. © Am J Clin Nutr, American Society for Clinical Nutrition.

APPENDIX 14 Activities of Red Cell Enzymes

Enzyme	Activity at 37° C (mean ± SD)
Acetylcholinesterase	36.93 ± 3.83
Adenosine deaminase	1.11 ± 0.23
Adenylate kinase	258 ± 29.3
Aldolase	3.19 ± 0.86
Bisphosphoglyceromutase (2,3-diphosphoglyceromutase)	4.78 ± 0.65
Catalase	$15.3 ± 2.4 \times 10^4$
Enolase	5.39 ± 0.83
Epimerase	0.23 ± 0.06
Galactokinase	0.029 ± 0.004
Galactose-1-phosphate uridyl transferase	28.4 ± 6.94
Glucose phosphate isomerase	60.8 ± 11.0
Glucose-6-phosphate dehydrogenase	8.34 ± 1.59
WHO method	12.1 ± 2.09
Glutamic oxaloacetic transaminase without PLP	3.02 ± 0.67
Glutamic oxaloacetic transaminase with PLP	5.04 ± 0.90
γ-Glutamyl-cysteine synthetase	0.43 ± 0.04
Glutathione peroxidase*	30.82 ± 4.65
Glutathione reductase without FAD	7.18 ± 1.09
Glutathione reductase with FAD	10.4 ± 1.50
Glutathione-S-transferase	6.66 ± 1.81
Glyceraldehyde phosphate dehydrogenase	226 ± 41.9
Hexokinase	1.78 ± 0.38
Hypoxanthine phosphoribosyl-transferase	1.72 ± 0.30
Lactate dehydrogenase	200 ± 26.5
Methemoglobin reductase	2.60 ± 0.71
Monophosphoglyceromutase	37.71 ± 5.56
NADH-methemoglobin reductase	19.2 ± 3.85 (30°)
NADPH diaphorase	2.26 ± 0.16
Phosphofructokinase	11.01 ± 2.33
Phosphoglucomutase	5.50 ± 0.62
Phosphoglycerate kinase	320 ± 36.1
Phosphoglycolate phosphatase	1.23 ± 0.10
Pyrimidine 5′ nucleotidase	0.11 ± 0.03
Pyruvate kinase	15.0 ± 1.99
6-Phosphogluconate dehydrogenase	8.78 ± 0.78
Triose phosphate isomerase	2111 ± 397

*From Beutler E, Blum KG: In Altman PL, Dittmer DS (eds): Human Health and Disease. Bethesda, MD, Federation of American Societies for Experimental Biology, 1977, p 156; and Beutler E. Red cell metabolism: a manual of biochemical methods. 3rd ed. Orlando, FL, Grune & Stratton, 1984.

APPENDIX 15 Levels of Intermediate Metabolites in Normal Adult Erythrocytes

Metabolite	Abbreviation	CONCENTRATION (mean ± 1 SD)		
		nmol/g Hb	nmol/mL Red Cells	μmol/L in Whole Blood
Adenosine-5′-diphosphate	ADP	6635 ± 105	216 ± 36	—
Adenosine-5′-monophosphate	AMP	62 ± 10	21.1 ± 3.4	—
Adenosine-5′-triphosphate	ATP	4230 ± 290 (whites)	1438 ± 99	—

APPENDIX 16 Red Cell Enzyme Activity in Adults and Term Infants*		
Enzyme	**Adults (20)**	**Infants (10)**
Hexokinase	12.9 ± 2.1	34.0 ± 6.0
Phosphoglucose isomerase	406 ± 37	560 ± 112
Phosphofructokinase	148 ± 24.5	84.5 ± 24
Aldolase	24.5 ± 3.7	42.0 ± 10.0
Glyceraldehyde-3-phosphate dehydrogenase	885 ± 127	884 ± 245
Triosephosphate isomerase	26,323 ± 3240	29,111 ± 4100
Phosphoglycerate kinase	2795 ± 144	3926 ± 528
Phosphoglycerate mutase	751 ± 99	1049 ± 160
Enolase	252 ± 54	517 ± 121
Pyruvate kinase	179 ± 16	256 ± 50
Lactic dehydrogenase	2033 ± 287	2756 ± 425
Glucose-6-phosphate dehydrogenase	215 ± 18	328 ± 40

*Infant samples were obtained from newborns weighing more than 2800 g whose gestational age was 39 weeks or greater. Blood was drawn within 24 hours of birth. All the newborns were clinically healthy. Adult samples were obtained from healthy, normal volunteers.

APPENDIX 17 Red Cell Glycolytic Intermediate Metabolites in Normal Adults, Term Infants, and Premature Infants*				
Metabolite	**Normal Adults (10)**	**Term Infants (10)**	**Premature Infants (11)**	**Normals (5)**
Glucose-6-phosphate	24.8 ± 9.8	45.2 ± 8.7	66.8 ± 34.8	27 ± 2.4
Fructose-6-phosphate	5.4 ± 1.0	9.9 ± 2.3	20.5 ± 8.9	11 ± 2.5
Fructose, 1,6-diphosphate	4.6 ± 1.0	3.8 ± 0.7	3.6 ± 0.8	5 ± 0.9
Dihydroxyacetone phosphate	4.9 ± 3.5	11.9 ± 5.0	18.6 ± 10.7	12 ± 3.7
Glyceraldehyde-3-phosphate	2.6 ± 0.7	1.9 ± 1.6	6.5 ± 3.2	4 ± 1.5
3-Phosphoglycerate	61.6 ± 12.4	58.2 ± 14.4	47.5 ± 14.2	48 ± 16.1
2-Phosphoglycerate	4.3 ± 1.8	4.9 ± 1.6	4.4 ± 2.5	7 ± 1.7
Phosphoenolpyruvate	8.8 ± 2.6	7.6 ± 2.9	7.4 ± 3.0	12 ± 0.9
Pyruvate	73.5 ± 33.1	70.4 ± 32.3	78.4 ± 4.15	71 ± 17.7
2,3-Diphosphoglycerate	4423 ± 1907	3609 ± 800	3152 ± 2133	4000

*Samples from normal adults and term infants were identical to those described in Appendix 18. Premature infants had birth weights below 2200 g and gestational age less than 37 weeks. These premature infants were healthy at the time of investigation.
From Oski FA: Red cell metabolism in the newborn infant: V. Glycolytic intermediates and glycolytic enzymes. Pediatrics 1969; 44:87. Reproduced with permission of Pediatrics, Copyright 1969.

APPENDIX 18 Red Cell Enzyme Activity Levels in Cord Blood and 4th-Day Blood			
	Cord	**4th Day**	**P**
Glucose-6-phosphate dehydrogenase	8.51 ± 1.20	6.23 ± 1.45	.005
Glutathione peroxidase	12.73 ± 1.32	14.01 ± 1.10	.001
Glutathione reductase	5.27 ± 1.21	6.49 ± 1.15	.004
Catalase	11.36 ± 1.28	12.73 ± 1.12	.025
Superoxide dismutase	1.21 ± 0.09	1.20 ± 0.08	NS

Data expressed in IU/g Hb as mean ± SD; n = 36.

| APPENDIX 22 | Methemoglobin Levels in Normal Children* | | | | | | | | | |

			METHEMOGLOBIN (g/dL)					METHEMOGLOBIN AS PERCENTAGE OF TOTAL HEMOGLOBIN		
	No. Cases	No. Det.	Mean	Range	Standard Dev.	No. Cases	No. Det.	Mean	Range	Standard Dev.
Prematures (birth-7 days)	29	34	0.43	(0.02-0.83)	±0.07	24	28	2.3	(0.08-4.4)	±1.26
Prematures (7-72 days)	21	29	0.31	(0.02-0.78)	±0.19	18	23	2.2	(0.02-4.7)	±1.07
Prematures (total)	50	63	0.38	(0.02-0.83)	±0.10	42	51	2.2	(0.08-4.7)	±1.10
Cook County Hospital, prematures (1-14 days)	8	8	0.52	(0.18-0.83)	±0.08	—	—	—	—	—
Newborns (1-10 days)	39	39	0.22	(0.00-0.58)	±0.17	25	30	1.5	(0.00-2.8)	±0.81
Infants (1 month-1 year)	8	8	0.14	(0.02-0.29)	±0.09	8	8	1.2	(0.17-2.4)	±0.78
Children (1-14 years)	35	35	0.11	(0.00-0.33)	±0.09	35	35	0.79	(0.00-2.4)	±0.62
Adults (14-78 years)	30	30	0.11	(0.00-0.28)	±0.09	27	27	0.82	(0.00-1.9)	±0.63

*The premature and full-term infants were free of known disease. None had respiratory distress or cyanosis. Analysis of milk and water ingested by these infants revealed a nitrate level less than 0.027 ppm. The premature infants routinely received vitamin C orally each day from the seventh day of life.

*Percentages of cell types (means ± standard deviation) in tibial bone marrow of infants from birth to 18 months of age. Data were obtained from normal American infants of black, white, and Asian racial origin. The changes in the marrow during the first 18 months of postnatal life are based on differential counts of 1000 cells classified on stained smears on each of 10 serial marrow samples aspirated from the same population of infants. Criteria for including bone marrow data in this study consisted of absence of any clinical evidence of disease, normal rate of growth, and normal serum proteins and transferrin saturations.

†n = number of infants studied at each stage.

‡Expressed in round figures for facilitating comparison. Means ± SD were calculated from values obtained in individual infants, and statistical comparisons were performed.

From Rosse C, Kraemer MJ, Dillon TL, et al: Bone marrow cell populations of normal infants: the predominance of lymphocytes. J Lab Clin Med 1977; 89:1228.
APPENDIX 30.   Platelet counts as a function of gestational age. Reference range (mean ± 2SD) for fetal platelet counts as a function of gestational age in 229 pregnancies. (Redrawn from Van den Hof MC, Nicolaides KH: Platelet count in normal, small and anemic fetuses. Am J Obstet Gynecol 1990; 162:735.)

APPENDIX 31	Circulating Platelet Counts and Serum Thrombopoietin (TPO) Levels at Different Ages	
Age Categories	**Platelet Count (10⁹/L)**	**Serum TPO (fmol/L)**
Cord blood	288 ± 53	3.73 ± 1.48 (1.44-6.74)
2 days	303 ± 48	5.92 ± 1.4 (4.33-9.18)
5 days	338 ± 59	4.32 ± 0.94 (2.38-5.76)
1 month	343 ± 72	3.77 ± 1.45 (2.25-7.60)
2-11 months	365 ± 49	2.10 ± 0.69 (1.04-4.24)
1-2 years	314 ± 78	2.23 ± 0.89 (0.43-4.54)
3-4 years	304 ± 66	1.97 ± 0.67 (0.98-3.73)
5-6 years	303 ± 65	1.67 ± 0.66 (0.58-3.14)
7-10 years	295 ± 58	1.39 ± 0.63 (0.53-2.94)
11-15 years	251 ± 40	1.24 ± 0.40 (0.49-1.99)
Adult	234 ± 48	0.83 ± 0.36 (0.25-1.72)

Data are expressed as mean ± SD. The range of values for TPO is reported in ( ).
All children values are significantly different ($P < 0.001$, Mann-Whitney U test) from adult values.
From Ishiguro, A, Nakahata T, Matsubara K, et al. (1999). Age-related changes in thrombopoietin in children: reference interval for serum thrombopoietin levels. Br J Haematol 106(4):884-888.

APPENDIX 43	Values of Serum Iron (SI), Total Iron-Binding Capacity (TIBC), and Transferrin Saturation (S%) from Infants During the First Year of Life*

			AGE (mo)						
			0.5	1	2	4	6	9	12
SI	Median	μmol/L	22	22	16	15	14	15	14
	95% range		11-36	10-31	3-29	3-29	5-24	6-24	6-28
		μg/dL	120	125	87	84	77	84	78
			63-201	58-172	15-159	18-164	28-135	34-135	35-155
TIBC	(mean ± SD)	μmol/L	34 ± 8	36 ± 8	44 ± 10	54 ± 7	58 ± 9	61 ± 7	64 ± 7
		μg/dL	191 ± 43	199 ± 43	246 ± 55	300 ± 39	321 ± 51	341 ± 42	358 ± 38
S%	Median		68	63	34	27	23	25	23
	95% range		30-99	35-94	21-63	7-53	10-43	10-39	10-47

*These data were obtained from a group of healthy, full-term infants who were born at the Helsinki University Central Hospital. Infants received iron supplementation in formula and cereal throughout the 12-month period. Infants with hemoglobin below 110 g/dL, mean corpuscular volume of red blood cells below 71 μ³, or serum ferritin below 10 ng/mL, were excluded from the study. The 95% range of the transferrin saturation values indicates that the lower limit of normal is about 10% after 4 months of age.

From Saarinen UM, Siimes MA: Serum iron and transferrin in iron deficiency. J Pediatr 1977; 91:876.

APPENDIX 48   Serum Erythropoietin Levels During the First Year of Life

Days After Birth	Erythropoietin (mU/mL)	Hemoglobin (g/dL)	RBC (×10⁶/μL)
0-6	33.0 ± 31.4 (11)	15.6 ± 2.2 (11)	4.51 ± 0.74 (11)
7-50	11.7 ± 3.6 (7)	12.8 ± 1.1 (5)	3.92 ± 0.35 (5)
51-100	21.1 ± 5.5 (13)	11.4 ± 1.0 (10)	4.09 ± 0.51 (10)
101-150	15.1 ± 3.9 (5)	11.2 ± 1.1 (3)	4.21 ± 0.31 (3)
151-200	17.8 ± 6.3 (6)	—	—
>201	23.1 ± 9.7 (10)	11.8 ± 0.8 (9)	4.57 ± 0.24 (9)

Values are expressed as mean ± SD; ( ), number of specimens.
From Yamashita H, Kukita J, Ohga S. Serum erythropoietin levels in term and preterm infants during the first year of life. Am J Pediatr Hematol Oncol 1994; 16:213.

APPENDIX 49   Plasma Erythropoietin Reference Ranges in Children

| | MALE SUBJECTS | | FEMALE SUBJECTS | |
Age (y)	2.5%	97.5%	2.5%	97.5%
1-3	1.7	17.9	2.1	15.9
4-6	3.5	21.9	2.9	8.5
7-9	1.0	13.5	2.1	8.2
10-12	1.0	14.0	1.1	9.1
13-15	2.2	14.4	3.8	20.5
16-18	1.5	15.2	2.0	14.2

Values expressed in mIU/mL. Data obtained from a total of 1122 hospitalized and outpatient children age 1-18 years.

Levels found in anemic patients cannot be compared with normal values. In fact, as long as the erythropoietin-generating apparatus in the kidney is efficient, serum levels increase exponentially as the hematocrit decreases. Serum erythropoietin must therefore be evaluated in relation to the degree of anemia, and every single laboratory should determine the exponential regression of serum erythropoietin versus hematocrit (or hemoglobin) in a home-made reference population of anemic subjects and define the 95% confidence limits. The patients gathered to calculate a reference regression equation should have an anemia with a single simple mechanism and no evidence of either renal failure or excessive cytokine production (i.e., normal values for C-reactive protein and α$_2$-globulins). Chronic iron deficiency anemia patients due to non-neoplastic and noninflammatory chronic blood loss have the advantages of being easily found, unequivocally defined, and homogeneous. They could become the universal reference population, although patients with hemolytic anemia or thalassemia intermedia also may be studied as reference subjects. Serum erythropoietin levels are also much higher for hemoglobin concentration in hypoplastic than in hyperplastic states. Thus, for the same hemoglobin concentration, serum erythropoietin levels are lower in thalassemia intermedia than in Diamond-Blackfan anemia.

APPENDIX 65. Sedimentation rate in the newborn period. The erythrocyte sedimentation rate was measured in capillary blood in healthy full-term and low-birth-weight newborns. Normal values ranged from 1 mm/h at 12 hours of age to 17 mm/h at 14 days of age. All values of neonates with hematocrit values less than 40% were corrected to 40%. (Redrawn from Adler SM, Denton RL: The erythrocyte sedimentation rate in the newborn period. J Pediatr 1975; 86:942.)
