Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

The Publisher

Contributors

Nancy C. Andrews, MD, PhD

Professor of Pediatrics, Professor of Pharmacology and Cancer Biology, and Dean and Vice-Chancellor for Academic Affairs, Duke University School of Medicine, Durham, North Carolina

Disorders of Iron Metabolism and Sideroblastic Anemia

Ida Annunziata, PhD

Postdoctoral Fellow, Department of Genetics and Tumor Cell Biology, St. Jude Children's Research Hospital, Memphis, Tennessee

Storage Diseases of the Reticuloendothelial System

Alessandra d'Azzo, PhD

Affiliated Professor of Anatomy and Neurobiology, University of Tennessee Health Science Center; Member and Endowed Chair, Department of Genetics and Tumor Cell Biology, St. Jude Children's Research Hospital, Memphis, Tennessee

Storage Diseases of the Reticuloendothelial System

Kenneth A. Bauer, MD

Professor of Medicine, Harvard Medical School; Director, Thrombosis Clinical Research, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Rare Hereditary Coagulation Factor Abnormalities; Inherited Disorders of Thrombosis and Fibrinolysis

Mark J. Bergeron, MD

Fellow, Neonatal-Perinatal Medicine, Department of Pediatrics, University of Minnesota Medical School; University of Minnesota Children's Hospital, Fairview, Minneapolis, Minnesota

Disorders of Bilirubin Metabolism

Monica Bessler, MD, PhD

Professor of Internal Medicine, Division of Hematology, Professor of Molecular Biology and Pharmacology, Washington University School of Medicine, St. Louis, Missouri

Inherited Bone Marrow Failure Syndromes

Barbara Bierer, MD

Professor of Medicine (Pediatrics), Harvard Medical School; Senior Vice President, Research, and Director, Center for Faculty Development and Diversity, Brigham and Women's Hospital, Boston, Massachusetts

The Immune Response

Francisco A. Bonilla, MD, PhD

Assistant Professor of Pediatrics, Harvard Medical School; Director, Clinical Immunology Program, Children's Hospital Boston, Boston, Massachusetts

Primary Immunodeficiency Diseases

Erik Bonten, PhD

Associate Scientist, Department of Genetics and Tumor Cell Biology, St. Jude Children's Research Hospital, Memphis, Tennessee

Storage Diseases of the Reticuloendothelial System

Carlo Brugnara, MD

Professor of Pathology, Harvard Medical School; Director, Hematology Laboratory, Department of Laboratory Medicine, Children's Hospital Boston, Boston, Massachusetts

The Neonatal Erythrocyte and Its Disorders; Diagnostic Approach to the Anemic Patient; Reference Values in Infancy and Childhood

Kathleen Brummel-Ziedens, PhD

Associate Professor of Biochemistry, University of Vermont College of Medicine, Colchester, Vermont

Blood Coagulation

H. Franklin Bunn, MD

Professor of Medicine, Harvard Medical School; Physician, Brigham and Women's Hospital, Boston, Massachusetts

Hemoglobins: Normal and Abnormal

Alan B. Cantor, MD, PhD

Assistant Professor of Pediatrics, Harvard Medical School; Assistant in Medicine, Children's Hospital Boston, Dana-Farber Cancer Institute, Boston, Massachusetts

Developmental Hemostasis: Relevance to Newborns and Infants

Melody J. Cunningham, MD

Assistant Professor of Pediatrics, Harvard Medical School; Division of Hematology/Oncology, Children's Hospital Boston, Boston, Massachusetts

The Thalassemias

Mary C. Dinauer, MD, PhD

Nora Letzter Professor of Pediatrics and Professor of Microbiology/Immunology and Medical and Molecular Gentetics, Indiana University School of Medicine; Pediatric Hematology/Oncology, Riley Hospital for Children, Indianapolis, Indiana

The Phagocyte System and Disorders of Granulopoiesis and Granulocyte Function

Jorge Di Paola, MD

Associate Professor of Pediatrics, University of Iowa Carver College of Medicine; Director, Hemophilia Treatment Center, University of Iowa Children's Hospital, Iowa City, Iowa

Hemophilia and von Willebrand Disease

George J. Dover, MD

Professor and Director of Pediatrics, Johns Hopkins University School of Medicine; Pediatrician-in-Chief, Johns Hopkins Hospital, Baltimore, Maryland

Sickle Cell Disease

Christine Duncan, MD

Instructor, Harvard Medical School; Outpatient Clinical Director HSCT, Dana-Farber Cancer Institute, Boston, Massachusetts

Principles of Bone Marrow and Stem Cell Transplantation

R. Alan B. Ezekowitz, MBChB, DPhil

Department of Pediatrics, Harvard Medical School, Boston, Massachusetts; Merck Research Laboratories, Rahway, New Jersey

Hematologic Manifestations of Systemic Diseases

Mark D. Fleming, MD, DPhil

Associate Professor of Pathology, Harvard Medical School; Interim Pathologist-in-Chief, Department of Pathology, Children's Hospital Boston, Boston, Massachusetts

Disorders of Iron Metabolism and Sideroblastic Anemia

David F. Friedman, MD

Clinical Assistant Professor of Pediatrics, University of Pennsylvania College of Medicine; Associate Medical Director, Transfusion Service, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Transfusion Medicine

Raif S. Geha, MD

James L. Gamble Professor of Pediatrics, Harvard Medical School; Chief, Division of Immunology, Children's Hospital Boston, Boston, Massachusetts

Primary Immunodeficiency Diseases

Joan Cox Gill, MD

Professor of Pediatrics and Medicine, Medical College of Wisconsin; Director, Comprehensive Center for Bleeding Disorders, Blood Center of Wisconsin, Milwaukee, Wisconsin

Hemophilia and von Willebrand Disease

Neil A. Goldenberg, MD, PhD

Assistant Professor of Pediatrics and Medicine and Associate Director of Mountain States Regional Hemophilia and Thrombosis Center, University of Colorado at Denver; Co-Director, Thrombosis and Stroke Programs, The Children's Hospital, Colorado, Aurora, Colorado

Acquired Disorders of Hemostasis

Glenn R. Gourley, MD

Professor of Pediatrics and Research Director, Pediatric Gastroenterology, University of Minnesota Medical School; University of Minnesota Children's Hospital, Fairview, Minneapolis, Minnesota

Disorders of Bilirubin Metabolism

Rachael F. Grace, MD

Instructor in Pediatrics, Harvard Medical School; Pediatric Hematology/Oncology, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts

Disorders of the Red Cell Membrane

W. Nicholas Haining, BM, BCh

Assistant Professor of Pediatrics, Harvard Medical School; Staff Physician, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts

Principles of Bone Marrow and Stem Cell Transplantation

Katherine Amberson Hajjar, MD

Brine Family Professor of Cell and Developmental Biology and Professor of Pediatrics, Weill Cornell Medical College; Attending Pediatrician, New York-Presbyterian Hospital, New York, New York

The Molecular Basis of Fibrinolysis

Matthew Heeney, MD

Instructor in Pediatrics, Harvard Medical School; Director, Pediatric Sickle Cell Program, Children's Hospital Boston, Boston, Massachusetts

Sickle Cell Disease

Grace Kao, MD

Instructor in Pathology, Harvard Medical School; Assistant Medical Director, Connell & O'Reilly Families Cell Manipulation Core Facility, Dana-Farber Cancer Institute, Boston, Massachusetts

Transfusion Medicine

Richard M. Kaufman, MD

Assistant Professor of Pathology, Harvard Medical School; Medical Director, Adult Transfusion Service, Brigham and Women's Hospital, Boston, Massachusetts

Transfusion Medicine

Edwin H. Kolodny, MD

Bernard A. and Charlotte Marden Professor and Chair, Department of Neurology, New York University School of Medicine; Attending Neurologist, Langone Medical Center and The Bellevue Hospital Center, New York, New York

Storage Diseases of the Reticuloendothelial System

James P. Kushner, MD

M. M. Wintrobe Distinguished Professor of Medicine, Department of Internal Medicine, Division of Hematology, University of Utah School of Medicine; Chief, Division of Hematology, University Hospital, Salt Lake City, Utah

The Porphyrias

Dominic P. Kwiatkowski, FRCP, FRCPCH, FMedSci

Medical Research Council Professor, Wellcome Trust Centre for Human Genetics; University Department of Paediatrics, John Radcliffe Hospital, Oxford, United Kingdom

Hematologic Manifestations of Systemic Diseases in Children of the Developing World

Michele P. Lambert, MD

Assistant Professor of Pediatrics, University of Pennsylvania College of Medicine; Attending Physician, Division of Hematology, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Inherited Platelet Disorders

Leslie E. Lehmann, MD

Assistant Professor of Pediatrics, Harvard Medical School; Clinical Director, Pediatric Hematopoietic Stem Cell Transplant, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts

Principles of Bone Marrow and Stem Cell Transplantation

Helen G. Liley, MB, ChB

Senior Lecturer in Pediatrics and Child Health, University of Queensland School of Medicine; Senior Staff Specialist, Neonatology, Mater Mothers' Hospital, South Brisbane, Queensland, Australia

Immune Hemolytic Disease of the Newborn

Daniel C. Link, MD

Associate Professor of Internal Medicine, Division of Oncology, Washington University School of Medicine, St. Louis, Missouri

Inherited Bone Marrow Failure Syndromes

Jeanne M. Lusher, MD

Distinguished Professor of Pediatrics, Wayne State University School of Medicine; Director, Hemostasis Program, Co-Director, Division of Hematology-Oncology, Children's Hospital of Michigan, Detroit, Michigan

Clinical and Laboratory Approach to the Patient with Bleeding

Samuel E. Lux IV, MD

Robert A. Stranahan Professor of Pediatrics, Harvard Medical School; Chief Emeritus, Division of Hematology/Oncology, Children's Hospital Boston, Boston, Massachusetts

Disorders of the Red Cell Membrane

Lucio Luzzatto, MD, PhD

Professor of Hematology, University of Florence Medical School; Attending Physician, University Hospital, Careggi; Scientific Director, Istituto Toscano Tumori, Firenze, Italy

Glucose-6-Phosphate Dehydrogenase Deficiency

Kenneth G. Mann, PhD

Professor of Biochemistry and Medicine, University of Vermont College of Medicine, Colchester, Vermont

Blood Coagulation

Philip J. Mason, PhD

Professor of Internal Medicine, Division of Hematology, Professor of Genetics, Washington University School of Medicine, St. Louis, Missouri

Inherited Bone Marrow Failure Syndromes

William C. Mentzer, Jr., MD

Professor Emeritus, Department of Pediatrics, University of California, San Francisco, School of Medicine; Attending Hematologist, University of California Hospitals, San Francisco, California

Pyruvate Kinase Deficiency and Disorders of Glycolysis

Robert R. Montgomery, MD

Professor of Pediatric Hematology, Medical College of Wisconsin; Senior Investigator, Blood Research Institute of BloodCenter of Wisconsin; Staff Physician, Children's Hospital of Wisconsin, Children's Hospital Research Institute, Milwaukee, Wisconsin

Hemophilia and von Willebrand Disease

Ronald L. Nagel, MD

Irving D. Karpas Professor of Medicine, Professor of Physiology and Biophysics, and Head, Division of Hematology, Albert Einstein College of Medicine; Director, Bronx Comprehensive Sickle Cell Center, Montefiore Medical Center, Bronx, New York

Hemoglobins: Normal and Abnormal

David G. Nathan, MD

Robert A. Stranahan Distinguished Professor of Pediatrics and Professor of Medicine, Harvard Medical School; Physician-in-Chief Emeritus, Children's Hospital Boston; President Emeritus, Dana-Farber Cancer Institute, Boston, Massachusetts

Pediatric Hematology in Historical Perspective; Acquired Aplastic Anemia and Pure Red Cell Aplasia; Diagnostic Approach to the Anemic Patient; The Thalassemias

Peter E. Newburger, MD

Ali and John Pierce Professor of Pediatric Hematology/ Oncology, University of Massachusetts Medical School; Director, Pediatric Hematology/Oncology, UMass/ Memorial Medical Center, Worcester, Massachusetts

The Phagocyte System and Disorders of Granulopoiesis and Granulocyte Function

Debra K. Newman, PhD

Assistant Professor of Pharmacology and Microbiology, Medical College of Wisconsin; Associate Investigator, Blood Research Institute, Blood Center of Wisconsin, Milwaukee, Wisconsin

Platelets and the Vessel Wall

Peter J. Newman, PhD

Professor of Pharmacology and Cellular Biology, Medical College of Wisconsin; Vice President for Research, Blood Research Institute, Blood Center of Wisconsin, Milwaukee, Wisconsin

Platelets and the Vessel Wall

Stuart H. Orkin, MD

David G. Nathan Professor of Pediatrics, Harvard Medical School; Chief, Department of Pediatric Oncology, Dana-Farber Cancer Institute; Investigator, Howard Hughes Medical Institute, Boston, Massachusetts

The Thalassemias

Frank A. Oski, MD*

Distinguished Service Professor, Johns Hopkins University School of Medicine, Baltimore, Maryland

Diagnostic Approach to the Anemic Patient

Sung-Yun Pai, MD

Assistant Professor of Pediatrics, Harvard Medical School; Staff Physician, Dana-Farber Cancer Institute; Attending in Medicine, Children's Hospital Boston, Boston, Massachusetts

The Immune Response

John D. Phillips, PhD

Associate Professor of Medicine, Department of Internal Medicine, Division of Hematology, University of Utah School of Medicine, Salt Lake City, Utah

The Porphyrias

Steven W. Pipe, MD

Associate Professor of Pediatrics and Communicable Diseases, University of Michigan Medical School, Ann Arbor, Michigan

Acquired Disorders of Hemostasis

Orah S. Platt, MD

Professor of Pediatrics, Harvard Medical School; Director, Department of Laboratory Medicine, Children's Hospital Boston, Boston, Massachusetts

The Neonatal Erythrocyte and Its Disorders

Vincenzo Poggi, MD

Professor of Pediatric Hematology and Oncology, Federico II University; Chief, Division of Hematology-Oncology, Pediatric Oncology, Pausilipon Hospital, Naples, Italy

Glucose-6-Phosphate Dehydrogenase Deficiency

Mortimer Poncz, MD

Professor of Pediatrics, University of Pennsylvania College of Medicine; Chief, Division of Hematology, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Inherited Platelet Disorders

Madhvi Rajpurkar, MD

Assistant Professor of Pediatrics, Wayne State University School of Medicine; Associate Hematologist, Children's Hospital of Michigan, Detroit, Michigan

Clinical and Laboratory Approach to the Patient with Bleeding

Hematologic Manifestations of Systemic Diseases in Children of the Developing World

V. Michael Whitehead, MDCM

Cole Professor Emeritus, Department of Pediatrics, Faculty of Medicine, McGill University; Former Director of Hematology, Department of Pediatrics, Montreal Children's Hospital of the McGill University Health Centre, Quebec, Canada

Megaloblastic Anemia

David B. Wilson, MD, PhD

Associate Professor of Pediatrics and Molecular Biology and Pharmacology, Washington University School of Medicine; St. Louis Children's Hospital, St. Louis, Missouri

Inherited Bone Marrow Failure Syndromes; Acquired Platelet Defects

Leonard I. Zon, MD

Grousbeck Professor of Pediatrics, Harvard Medical School; Stem Cell Program and Division of Hematology/Oncology, Children's Hospital of Boston and Dana-Farber Cancer Institute; Investigator, Howard Hughes Medical Institute, Boston, Massachusetts

Anatomy and Physiology of Hematopoiesis

Wolf W. Zuelzer, MD*

Emeritus Professor of Pediatric Research, Wayne State University School of Medicine; Emeritus Director of Laboratories and Hematologist-in-Chief, Children's Hospital of Michigan, Detroit, Michigan; Emeritus Director, Division of Blood Diseases and Resources, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland

Pediatric Hematology in Historical Perspective

---

*Deceased.

Preface

On behalf of all the editors, I welcome you to the seventh edition of *Nathan and Oski's Hematology of Infancy and Childhood*. For more than 30 years this textbook has served as the premier resource for students, clinical fellows, investigators, and practitioners in the field of pediatric hematology. From its inception, David Nathan and Frank Oski sought to relate pathophysiology to the hematologic diseases afflicting children. Their goal was to stimulate bench-to-bedside and bedside-to-bench activities to understand and then treat pediatric hematological disorders. What was not envisioned in those early days was how rapidly the basic biology and genetics underlying the field would develop. With each new edition, the text and the roster of editors have grown. We take this as a healthy sign. So much has been learned in this timeframe that has contributed to improved care of children with hematologic disorders.

The seventh edition of *Hematology of Infancy and Childhood* represents a further evolution of the life of this organic textbook. We have recruited Sam Lux to join us as an editor in order to incorporate his remarkable insights and vision to the current edition. In prior editions we drew the boundary for the scope of the textbook to encompass hematology *per se*, both nonmalignant and malignant, despite the reality that we, and others, train clinical fellows in pediatric hematology *and* oncology. For several editions we provided superficial coverage of pediatric oncology with a single chapter on solid tumors. In the sixth edition, on the urging of Tom Look, an insightful investigator of childhood malignancies, we eliminated this chapter. Though beautifully done by Arnold Altman, it could never fully capture the increasing knowledge base and breadth of pediatric oncology. Reflecting on this history and the extraordinary progress in cancer biology and genetics, we chose to create an entirely new volume devoted to pediatric oncology. Going forward, we present our readers with parallel textbooks: *Hematology of Infancy and Childhood* and *Oncology of Infancy and Childhood.*

To meet the daunting challenge of bringing forward a new oncology volume, we invited David Fisher, an extraordinary cancer biologist, physician, and cellist, to join Tom Look as editors for this venture. The goal, as before, has been to join basic pathophysiology and clinical medicine at the hip. The creation of the Oncology volume necessitated moving the chapters on malignant hematology, including the leukemias, from *Hematology of Infancy and Childhood*. We hope that readers find the new volume as useful and perhaps as inspiring as prior editions of Nathan and Oski. Launching a new venture is never without some missteps. We welcome feedback from our readers on the extent to which these new developments meet the needs of students, investigators, and clinicians in the field. After all, the success of *Hematology of Infancy and Childhood* and *Oncology of Infancy and Childhood* cannot be measured in numbers of pages or volumes sold. We will be pleased only if these textbooks provide students, fellows, and faculty with the knowledge and inspiration to move the frontier of pediatric hematology and oncology forward and reduce the burden of disease on children.

This seventh edition of *Hematology of Infancy and Childhood* has truly been a team effort. I thank the other editors for their dedication to this project. We are grateful to the authors of each chapter for their contributions. Our efforts, however, would be futile if it were not for the hard work, patience, and guidance of our editors at Elsevier, Dolores Meloni and Ann Ruzycka Anderson, and our managing editor, Cathy Lantigua. We appreciate everything they have done.

Finally, we want to express our deep gratitude to those who trained us in academic medicine. This is a glorious field that we have mightily enjoyed. In many ways, this book is our expression of appreciation to them.

Stuart H. Orkin, MD

Acronyms

A2, annexin 2
AABB, American Association of Blood Banks
AAE, acquired angioedema
AAV, adeno-associated virus
ABC, ATP-binding cassette transporter superfamily
ABO, ABO(H) blood group system
ABP, actin-binding protein
ACS, acute chest syndrome
ACE, angiotensin-converting enzyme
ACTH, adrenocorticotropic hormone, adrenocorticotropin
AD, anauxetic dysplasia, autosomal dominant
ADA, adenosine deaminase
ADAD, ADA deficiency
ADC, apparent diffusion coefficient
ADCC, antibody-dependent cellular toxicity
AdoCbl, adenosylcobalamin, 5′-deoxyadenosylcobalamin
AdoHcy, S-adenosylhomocysteine
AdoMet, S-adenosylmethionine
ADP, adenosine diphosphate, ALA-D deficiency porphyria
ADPase, adenosine diphosphatase
AE1, anion exchange protein 1 (band 3 protein of the red cell membrane)
AFP, α-fetoprotein
AGLT, acidified glycerol lysis test
AGM, aorta-gonad-mesonephros
aGVHD, acute graft-versus-host disease
AHA, acute hemolytic anemia
AHSP, α-hemoglobin–stabilizing protein
AICAR, amino-4-imidazolecarboxamide ribonucleotide
AICD, activation-induced cell death
AID, activation-induced cytidine deaminase, activation-induced deaminase
AIDS, acquired immunodeficiency virus
AIHA, autoimmune hemolytic anemia
AIN, autoimmune neutropenia
AIP, acute intermittent porphyria
AIRE, autoimmune regulator
AK, adenylate kinase
ALA, δ-aminolevulinic acid
ALA-D, δ-aminolevulinic acid dehydratase
ALA-S, δ-aminolevulinic acid synthase
ALD, adrenoleukodystrophy
ALG, antilymphocyte globulin
ALL, acute lymphoblastic leukemia, acute lymphocytic leukemia
ALPS, autoimmune lymphoproliferative syndrome

AMKL, acute megakaryoblastic leukemia
AML, acute myelogenous leukemia, acute myeloid leukemia
AMT, amegakaryocytic thrombocytopenia
ANC, absolute neutrophil count
ANCA, antineutrophil cytoplasmic antibody
α_2-AP, α_2-antiplasmin
APA, antiphospholipid antibody
APC, activated protein C, adenomatous polyposis coli, antigen-presenting cell
APECED, autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy
APRCA, acquired pure red cell aplasia
APRIL, α-proliferation–inducing ligand
APS-1, autoimmune polyglandular syndrome type 1
APTT, activated partial thromboplastin time
AQP1, aquaporin-1
AR, autosomal recessive
Ara-C, cytosine arabinoside
ARSB, arylsulfatase B
ARTUS, amegakaryocytic thrombocytopenia with radioulnar synostosis
ASBMT, American Society for Blood and Marrow transplantation
ASCO, American Society of Clinical Oncology
ASH, American Society of Hematology
ASM, acid sphingomyelinase
AT, antithrombin, ataxia-telangiectasia
ATG, antithymocyte globulin
ATIII, antithrombin III
ATP, adenosine triphosphate
ATPase, adenosine triphosphatase
ATRUS, amegakaryocytic thrombocytopenia with radioulnar synostosis
AVN, avascular necrosis
AVWS, acquired von Willebrand's syndrome

BACT, BCNU (carmustine), Ara-C (cytarabine), cyclophosphamide, 6-thioguanine
BAEP, brainstem auditory evoked potential
BAFF, B-cell–activating factor
BAL, bronchoalveolar lavage
BCAM, basal cell adhesion molecule
BCG, bacille Calmette-Guérin
BCNU, carmustine
BCR, B-cell receptor
BEAM, BCNU (carmustine), etoposide, Ara-C (cytarabine), melphalan
BFU-E, burst-forming unit–erythrocyte
BFU-Meg, burst-forming unit–megakaryocyte
bHLH, basic helix-loop-helix

BLNK, B-cell linker protein
BM, bone marrow
BMD, bone mineral density
BMF, bone marrow failure
BMP, bone morphogenetic protein
BMT, bone marrow transplantation
BPGM, 2,3-bisphosphoglycerate mutase
BPI, bactericidal/permeability-increasing protein
BrdU, bromodeoxyuridine
BrOb, bronchiolitis obliterans
BSP, bromsulfophthalein
BSS, Bernard-Soulier syndrome
BT, bleeding time
Btk, Bruton's tyrosine kinase
BU, Bethesda units, busulfan
BUGT, bilirubin UDP-glucuronyltransferase
bZIP, basic region–leucine zipper domain

C

CADP, collagen/adenosine diphosphate
CAFC, cobblestone area–forming cell
CAIV, carbonic anhydrase IV
CaM, calmodulin
cAMP, cyclic adenosine monophosphate
CAMT, congenital amegakaryocytic thrombocytopenia
CAR, Central African Republic
CAT, calibrated automated thrombography
CBB, cord blood bank
C4bBP, C4b-binding protein
CBF, core-binding factor
CBP, cyclophosphamide, BCNU (carmustine), cisplatin
CBV, cyclophosphamide, BCNU (carmustine), VP-16 (etoposide)
CCG, Children's Cancer Study Group
CCI, corrected count increment
CDA, congenital dyserythropoietic anemia
CDP, CCAAT displacement protein, cytidine diphosphate
CDR3, complementarity-determining region 3
C/EBPα, CCAAT/enhancer-binding protein α
CEP, congenital erythropoietic porphyria
CEPI, collagen/epinephrine
CFC, colony-forming cell
CFC-Eo, eosinophil colony-forming cell
CFU-C, colony-forming unit in culture
CFU-E, colony-forming unit–erythrocyte
CFU-Eo, colony-forming unit–eosinophil
CFU-GEMM, colony-forming unit–multipotent (granulocyte, erythrocyte, macrophage, megakaryocyte)
CFU-GM, colony-forming unit–granulocyte-macrophage
CFU-Meg, colony-forming unit–megakaryocyte
CFU-S, colony-forming unit–spleen
CGD, chronic granulomatous disease
cGMP, current good manufacturing practice, cyclic guanosine monophosphate

CGP, circulatory granulocyte pool
cGVHD, chronic graft-versus-disease
CH, calponin homology domain
CHH, cartilage-hair hypoplasia
CHO, Chinese hamster ovary
CHr, reticulocyte hemoglobin content
CHS, Chédiak-Higashi syndrome
CIITA, class II *trans*-activator
C1-INH, C1 esterase inhibitor
CIS, cytokine-inducible SH2-containing protein
CLC, Charcot-Leyden crystal
CLIA, Clinical Laboratory Improvement Amendment
CLL, chronic lymphocytic leukemia
CLN-1, neuronal ceroid lipofuscinosis type 1
CLP, common lymphoid progenitor
CMC, chronic mucocutaneous candidiasis
CML, chronic myelocytic leukemia
cMOAT, canalicular multispecific organic anion transporter
CMP, common myeloid progenitor, cytidine monophosphate
CMV, cytomegalovirus
CN, Crigler-Najjar syndrome, type I (CNI) or type II (CNII)
CNCbl, cyanocobalamin
CNS, central nervous system
CNSHA, congenital nonspherocytic hemolytic anemia
CNTF, ciliary neurotrophic factor
CO, carbon monoxide
CoA, coenzyme A
COG, Children's Oncology Group
COX-2, cyclooxygenase-2
CPD, citrate-phosphate-dextrose
CPDA-1, citrate-phosphate-dextrose-adenosine
CPO, coproporphyrinogen oxidase
CR, complete remission
CR2, complement receptor 2
CRAC, calcium release–activated calcium
CREG, cross-reactive group
CRF, chronic renal failure
CRIg, complement receptor of the immunoglobulin superfamily
CRM, cross-reacting material
CRT, catheter-related thrombosis
CSF, cerebrospinal fluid, colony-stimulating factor
c-SMAC, central supramolecular activation cluster
CSSCD, Cooperative Study of Sickle Cell Disease
CSVT, cerebral sinovenous thrombosis
CT, closure time, computed tomography
CT-1, cardiotropin-1
CTD, C-terminal domain
CTLA-4, cytotoxic T-lymphocyte antigen 4
CTP, cytidine triphosphate
CVID, common variable immunodeficiency
CVS, chorionic villus sampling
CXCR4, CXC chemokine receptor 4
CY, cyclophosphamide

D

DAF, decay accelerating factor
DAG, diacylglycerol
DAT, direct antibody test, direct antiglobulin test
dATP, deoxyadenosine triphosphatase
DBA, Diamond-Blackfan anemia
DC, dyskeratosis congenita
DCE, downstream core element
DCLRE1C, DNA cross-link repair enzyme 1C
DDAVP, 1-deamino-8-D-arginine vasopressin
DEB, diepoxybutane
DFS, disease-free survival
DGS, DiGeorge's syndrome
dGTP, deoxyguanosine triphosphatase
DHAP, dihydroxyacetone phosphate
DHF, dengue hemorrhagic fever, 7,8-dihydrofolate
DHR 123, dihydroxyrhodamine 123
DIC, disseminated intravascular coagulation
DIDMOAD, diabetes insipidus, diabetes mellitus, optic atrophy, and deafness
DIDS, 4,4′-diisothiocyanostilbene-2,2′-disulfonate (anion channel inhibitor)
DJS, Dubin-Johnson syndrome
DLI, donor lymphocyte infusion
DMS, demarcation membrane system
DMSO, dimethyl sulfoxide
DMT1, divalent metal transporter 1
2,3-DPG, 2,3-diphosphoglycerate
DPT, diphtheria and tetanus toxoids and pertussis
DRESS, drug rash with eosinophilia and systemic symptoms (syndrome)
dRTA, distal renal tubular acidosis
DRVVT, dilute Russell viper venom time
DS, Down syndrome
DS-AMKL, Down syndrome–acute megakaryoblastic leukemia
DSS, dengue shock syndrome
DS-TMD, Down syndrome–transient myeloproliferative disorder
DTB, ditaurobilirubin
dTMP, thymidylate (deoxythymidine monophosphate)
DTS, dense tubular system
DVT, deep venous thrombosis
DWI, diffusion-weighted magnetic resonance (MR) imaging

E

EA, early antigen
EBA140, *Plasmodium falciparum* erythrocyte binding antigen 140
EBMT, European Group for Blood and Marrow Transplantation
EBP, elastin-binding protein
EBV, Epstein-Barr virus
EC, Enzyme Commission
ECLT, euglobulin clot lysis time
ECMO, extracorporeal membrane oxygenation

EDA-ID, anhidrotic ectodermal dysplasia with immunodeficiency
EDAMS, encephaloduroarteriomyosynangiosis
EDTA, ethylenediaminetetraacetic acid
EFS, event-free survival
EGA, estimated gestational age
EGF, epidermal growth factor
EGFR, epidermal growth factor receptor
EHEC, enterohemorrhagic *Escherichia coli*
EKLF, erythroid Krüppel-like factor
EM, extramedullary
eNOS, endothelial nitric oxide synthase
EPCR, endothelial cell protein C receptor
EPEC, enteropathogenic *Escherichia coli*
EPO, erythropoietin
EpoR, erythropoietin receptor
EPP, erythropoietic protoporphyria
ER, endoplasmic reticulum
ERGIC-53, endoplasmic reticulum–Golgi intermediate compartment, 53 kilodalton protein
ERT, enzyme replacement therapy
ES, embryonic stem
ESC, embryonic stem cell
ESL-1, E-selectin ligand-1

F

FA, Fanconi's anemia
FAAP, Fanconi's anemia–associated protein
FAB, French-American-British (staging)
FACS, fluorescence-activated cell sorting
FACT, Foundation for the Accreditation of Cell Therapy
FAD, flavin adenine dinucleotide
FAH, fumarylacetoacetate hydrolase
FAICAR, formamido-4-imidazolecarboxamide ribonucleotide
FBN, fibronectin
FCP, F-cell production (locus)
FcR, Fc receptor
FDA, Food and Drug Administration
FDC, follicular dendritic cell
FDP, familial platelet deficiency, fibrin(ogen) degradation product, fructose 6-diphosphate
FECH, ferrochelatase
FEIBA, factor eight inhibitor–bypassing activity
Fe-SIH, ferric salicylaldehyde-isonicotinyl-hydrazone
FFP, fresh frozen plasma
FGAR, formylglycinamide ribonucleotide
FGF, fibroblast growth factor
fH, factor H
fI, factor I
FIGlu, formiminoglutamic acid
FISH, fluorescence in situ hybridization
FL, ligand for the Flks/Flt3 receptor
FLAER, fluorescent aerolysin
FLAIR, fluid-attenuated inversion recovery
FOG-1, friend of GATA-1
FPA, fibrinopeptide A

FPB, fibrinopeptide A
F-PCT, familial porphyria cutanea tarda
FRAP, fluorescence recovery after photobleaching
FSGS, focal sclerosing glomerulosclerosis
FTCD, formiminotransferase-cyclodeaminase
5-FU, 5-fluorouracil

G

GABA, γ-aminobutyric acid
GAG, glycosaminoglycan
β-gal, β-D-galactosidase
GalNAc-T, *N*-acetylgalactosaminyltransferase
GALNS, *N*-acetylgalactosamine-6-sulfatase
GAP, GTPase-activating protein
GAR, glycinamide ribonucleotide
GAS, IFN-γ–activated sequence
GAT, granulocyte agglutination test
GBS, Guillain-Barré syndrome
GC, germinal center
G-CSF, granulocyte colony-stimulating factor
G-CSFR, granulocyte colony-stimulating factor
    receptor
GDF, growth and differentiation factor
GDP, guanosine diphosphate
GFR, glomerular filtration rate
GH, growth hormone
GI, gastrointestinal
GIF, gastric intrinsic factor
GIFT, granulocyte immunofluorescence test
GITMO, Gruppo Italiano Trapianti di Midollo
    Osseo
GlcNAc, *N*-acetylglucosamine
Glu-Plg, glutamic acid plasminogen
GluR1, glutamate receptor type 1
$G_{M2}A$, G_{M2} activator protein
GM-CSF, granulocyte-macrophage colony-stimulating
    factor
GMP, granulocyte/monocyte precursor, guanosine
    monophosphate
GNPT, UDP-*N*-acetylglucosamine:lysosomal-enzyme
    N-acetylglucosamine-1-phosphotransferase
GnRH, gonadotropin-releasing hormone
GPA, glycophorin A
GPB, glycophorin B
GPC, glycophorin C
GPCR, G protein–coupled receptor
GPD, glycophorin D
G3PD, glyceraldehyde-3-phosphate dehydrogenase
G6PD, glucose-6-phosphate dehydrogenase
GPE, glycophorin E
GPI, glucose phosphate isomerase,
    glycosylphosphatidylinositol
GPIb, glycoprotein Ib
GPS, gray platelet syndrome
GRF, guanine nucleotide–releasing factor
GS, Gilbert's syndrome, Griscelli's syndrome
GSCbl, glutathionylcobalamin
GSH, reduced glutathione

GSK3, glycogen synthase kinase 3
GSL, glycosphingolipid
GSSG, oxidized glutathione
GSHPX, glutathione peroxidase
GST, glutathione-*S*-transferase
GT, Glanzmann's thrombasthenia
GTP, guanosine triphosphate
GTPase, guanosine triphosphatase
GVHD, graft-versus-host disease
GVL, graft versus leukemia

H

HAART, highly active antiretroviral therapy
HABA, 2(4′-hydroxyazobenzene) benzoic acid
HAE, hereditary angioedema
Hb, hemoglobin
HB, Heinz body
HbF, fetal hemoglobin
HBV, hepatitis B virus
HC, homocysteine
4-HC, 4-hydroperoxycyclophosphamide
HCP, hereditary coproporphyria, hematopoietic cell
    phosphatase
HCV, hepatitis C virus
HD, Hodgkin's disease
HDN, hemolytic disease of the fetus and newborn,
    hemorrhagic disease of the newborn
HDW, hemoglobin distribution width
HE, hereditary elliptocytosis
HELLP, hemolytic anemia, elevated liver enzymes, low
    platelet count
HEMPAS, hereditary erythroblastic multinuclearity
    with a positive acidified serum lysis test
HEP, hepatoerythropoietic porphyria
HES, Hairy and Enhancer of Split, hypereosinophilic
    syndrome
HETE, 15(*S*)-hydroxyeicosatetraenoic acid
Hex-A, hexosaminidase A
Hex-B, hexosaminidase B
HGF, hematopoietic growth factor, hepatocyte growth
    factor
HGFR, hematopoietic growth factor receptor
HHS, Hoyeraal-Hreidarsson syndrome
HHV-6, human herpesvirus 6
HiB, *H. influenzae* type B
HIDA, hepatobiliary iminodiacetic acid
HIES, hyper-IgE syndrome, hyperimmunoglobulin E
    syndrome
HIF-1, hypoxia-inducible factor 1
HIT, heparin-induced thrombocytopenia
HITTS, HIT with thrombosis syndrome
HIV, human immunodeficiency virus
HK, hexokinase
HLA, human leukocyte antigen
HLH, hemophagocytic lymphohistiocytosis
HMB, hydroxymethylbilane
HMGB1, high–molecular group box 1 protein
HMP, hexose monophosphate

HMS, hyperreactive malarial splenomegaly
HMWK, high-molecular-weight kininogen
HNE, hydroxynonenal
hnRNA, heterogeneous nuclear RNA
HO, heme oxygenase
H₂O₂, hydrogen peroxide
H₂OCbl, aquocobalamin
holo-HC, holohaptocorrin
holo-TC, holotranscobalamin
HOX, homeobox transcription factor
HPA-1a, human platelet antigen 1a
HPC, hematopoietic progenitor cell
HPCHA, high-phosphatidylcholine hemolytic anemia
HPFH, hereditary persistence of fetal hemoglobin
HPLC, high-performance liquid chromatography, high-pressure liquid chromatography
HPP, hereditary pyropoikilocytosis
HPP-CFCs, high–proliferative potential colony-forming cells
HPRT, hypoxanthine phosphoribosyltransferase
HPS, Hermansky-Pudlak syndrome
HPV, human papillomavirus
HR, homologous recombination
HRE, hypoxia response element
HRI, heme-regulated inhibitor kinase
HRM, heme regulatory motif
HS, hereditary spherocytosis, hypersensitivity site
HSC, hematopoietic stem cell
HSCT, hematopoietic stem cell transplantation
HSP, heat shock protein, Henoch-Schönlein purpura
5-HT, 5′-hydroxytryptamine (serotonin)
HTLV, human T-cell leukemia/lymphoma virus, human T-cell lymphotropic virus
HUS, hemolytic-uremic syndrome
HUVEC, human umbilical vein endothelial cell

I

IAP, integrin-associated protein or CD47
IAS, ischemic arterial stroke
IBMFS, inherited bone marrow failure syndrome
IBMTR, International Bone Marrow Transplant Registry
ICAM, intercellular adhesion molecule
ICD-9, International Classification of Diseases, 9th revision
ICG, indocyanine green
ICH, intracranial hemorrhage
ICN, intracellular domain of Notch
ICOS, inducible costimulator, inducible T-cell costimulator
ICOSL, inducible costimulator ligand
IDO, indolamine 2,3-dioxygenase
IDS, iduronate 2-sulfatase
IDUA, α-ʟ-iduronidase
IFAR, International Fanconi Anemia Registry
IFN-γ, interferon-γ
IGAD, IgA deficiency

IGF-I, insulin-like growth factor I
IgG, immunoglobulin G
IκB, inhibitor of NF-κB
IKK, IκB kinase
IL-1RA, IL-1 receptor antagonist
IL-2, interleukin-2
IL-6R, interleukin-6 receptor
IMP, inosine 5′-monophosphate, intramembrane particle
iNOS, inducible nitric oxide synthase
INR, international normalized ratio
IP, isoprostenoid
IP₃, inositol 1,4,5-triphosphate
IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked (syndrome)
IPH, idiopathic pulmonary hemosiderosis
IPT, intraperitoneal fetal transfusion
IRAG, IP₃ receptor–associated cGMP
IRAK-4, interleukin-1 receptor–associated kinase 4
IRE, iron response element, iron responsive element
IRF, interferon regulatory factor
IRIDA, iron-refractory iron deficiency anemia
IRP, IRE-binding protein, iron regulatory protein
ISBT, International Society for Blood Transfusion
ISC, irreversibly sickled cell
ISHAGE, International Society for Hematotherapy and Graft Engineering
ISI, International Sensitivity Index
ISP, intermediate single positive
ISRE, interferon-stimulated response element
IST, immunosuppressive therapy
ISTH, International Society on Thrombosis and Hemostasis
ITAM, immunoreceptor tyrosine–based activation motif, immunoreceptor tyrosine activation motif
ITIM, immunoreceptor tyrosine–based inhibitory motif, immunoreceptor tyrosine activation motif
ITP, immune thrombocytopenia purpura
IVIG, intravenous immune serum globulin, intravenous immunoglobulin
IVS, intervening sequence (intron)
IVT, intravascular transfusion

J

JAK, Janus kinase
JAM-1, junctional adhesion molecule 1
JMML, juvenile myelomonocytic leukemia

K

KCC, K⁺-Cl⁻ cotransporter
K_d, dissociation constant
KD, Kostmann's disease, kyphomelic dysplasia
KEYY, lysine–glutamic acid–tyrosine-tyrosine
KIR, killer cell immunoglobulin-like receptor
KL, Klotho (gene)
K_m, Michaelis constant
KTLS, c-Kit⁺, Thy-1ˡᵒ, Lin⁻, Sca-1⁺ cell
KSS, Kearns-Sayre syndrome

L

LA, lupus anticoagulant
LAD I, leukocyte adhesion deficiency (type I)
LAMP-3, lysosome-associated membrane protein 3
LAT, linker for activation of T cells
LCAT, lecithin-cholesterol acyltransferase
LCL, large cell lymphoma
LCR, locus control region
LDH, lactate dehydrogenase
LDL, low-density lipoprotein
LEF-1, lymphoid enhancer–binding factor 1
LELY, low-expression allele Lyon
LEPRA, low-expression allele Prague
LFA-3, lymphocyte function antigen 3
LGL, large granular lymphocyte leukemia
LHRF, luteinizing hormone–releasing factor
LIF, leukemia inhibitory factor
LIFR, leukemia inhibitory factor receptor
LIR, leukocyte immunoglobulin-like receptor
LJP, localized juvenile periodontitis
LMWH, low-molecular-weight heparin
LMWK, low-molecular-weight kininogen
LPS, lipopolysaccharide
LRP, lipoprotein receptor–related protein
LRRC8, leucine-rich repeat–containing 8
LSD, lysosomal storage disease
LSP1, lymphocyte-specific protein 1
LTB$_4$, leukotriene B$_4$
LTC-IC, long-term culture–initiating cell
LTR-HSCs, long-term–reconstituting hematopoietic stem cells
LW, Landsteiner-Weiner glycoprotein
Lyso-PC, lysophosphatidylcholine
Lys-Plg, lysine plasminogen
LYST, lysosomal trafficking regulator

M

MAGUK, membrane-associated guanylate kinase
MAP, mitogen-activated protein
MAPK, mitogen-activated protein kinase
MARCKS, myristoylated alanine-rich C kinase substrate
MASP, MBL-associated serine protease
MBD, membrane binding domain
MBL, mannose-binding lectin
MBP, major basic protein
MCH, mean corpuscular hemoglobin
MCHC, mean corpuscular hemoglobin concentration
MCP, membrane cofactor protein
MCP-1, monocyte chemotactic protein 1
MCV, mean cell volume, mean corpuscular volume
MCV4, meningococcal conjugate vaccine
MDCK, Madin-Darby canine kidney (cells)
MDS, myelodysplastic syndrome
MDWH, metaphyseal dysplasia without hypotrichosis
MeCbl, methylcobalamin
MEK, MAPK kinase

MELAS, mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes
MEP, megakaryocyte, erythroid, and basophil (lineage); megakaryocyte/erythroid precursor
Met-Hb, methemoglobin
5-methyl-THF, 5-methyltetrahydrofolate
α_2-MG, α_2-macroglobulin
MGF, myelomonocytic growth factor
MGP, marginating granulocyte pool
MGSA, melanoma growth stimulatory activity
mHA, minor histocompatibility antigen
MHA, May-Hegglin anomaly
MHC, major histocompatibility complex
MIBG, metaiodobenzylguanidine
micro-PET, micro–positron emission tomography
MIDAS, metal ion–dependent adhesion site
MIM, Mendelian Inheritance in Man
MIP-1α, macrophage inflammatory protein 1α
MLASA, mitochondrial myopathy with lactic acidosis and sideroblastic anemia
MLL, mixed-lineage leukemia
MMC, mitomycin C
MMF, mycophenolate mofetil
MMP-25, the membrane-associated metalloproteinase leukolysin
MoAb, monoclonal antibody
M6P, mannose 6-phosphate
MPGM, monophosphoglycerate mutase
Mpl, ligand for the myeloproliferative ligand receptor
MPO, myeloperoxidase
MPS, Montreal platelet syndrome, mucopolysaccharidosis
MPSV4, meningococcal polysaccharide vaccine
MPV, mean platelet volume
M$_r$, molecular weight
MRA, magnetic resonance angiography
MRI, magnetic resonance imaging
MRC, Medical Research Council
mRNP, messenger ribonucleoprotein
MRP2, multidrug resistance–associated protein 2 (a.k.a. ABCC2, cMOAT)
MSCV, murine stem cell virus
MSMD, mendelian susceptibility to mycobacterial diseases
MSP1, *Plasmodium falciparum* merozoite surface protein 1
MTD, maximum tolerated dose
mtDNA, mitochondrial DNA
mTEC, medullary thymic epithelial cell
MTHFR, methylenetetrahydrofolate reductase, methylene-THF reductase
mTOR, mammalian target of rapamycin
MTP, microsomal triglyceride transfer protein
MVB, multivesicular body
MWC, Monod, Wyman, and Changeaux (model of cooperativity)
MYHIIA, myosin heavy chain IIA

N

NAD, nicotinamide adenine dinucleotide
NAD 47/89, neutrophil actin dysfunction with 47- and 89-kd protein abnormalities
NADH, reduced nicotinamide adenine dinucleotide
NADP, nicotinamide adenine dinucleotide phosphate
NADPH, reduced nicotinamide adenine dinucleotide phosphate
NAIT, neonatal alloimmune thrombocytopenia
NAT, nucleic acid testing
NATP, neonatal alloimmune thrombocytopenic purpura
NB-DGJ, *N*-butyldeoxygalactonojirimycin
NBS, Nijmegen's breakage syndrome
NBT, nitroblue tetrazolium
NDPase, nucleoside diphosphatase
NE, neutrophil elastase
NEMO, NF-κB essential modulator
NET, neutrophil extracellular trap
NF-1, neurofibromatosis type 1
NF-AT, nuclear factor of activated T cells
NF-κB, nuclear factor κB
NGAL, neutrophil gelatinase–associated lipocalin
NH, neonatal hemochromatosis
NHANES, National Health and Nutrition Examination Survey
NHEJ, nonhomologous end joining
NHL, non-Hodgkin's lymphoma
NHLBI, National Heart, Lung, and Blood Institute
NICU, neonatal intensive care unit
NIH, National Institutes of Health
NK, natural killer (cell)
NMDP, National Marrow Donor Program
NMR, nuclear magnetic resonance
NNJ, neonatal jaundice
NPD-C, Niemann-Pick disease type C
Nrf-1, nuclear regulatory factor 1
NRTI, nucleoside reverse transcriptase inhibitors
NS, Noonan's syndrome
NTD, neural tube defect
NO, nitric oxide
NOD, nonobese diabetic
NOS, nitric oxide synthase
NOX, NAD(P)H oxidase
NSAID, nonsteroidal anti-inflammatory drug
NuMA, nuclear mitotic apparatus (protein)

O

OATP, organic acid–transporting polypeptide
OCA, oral contraceptive agent
OCS, open canalicular system
OF, osmotic fragility
OHCbl, hydroxycobalamin
OMIM, Online Mendelian Inheritance in Man
OPSI, overwhelming postsplenectomy infection
OS, Omenn's syndrome
OSM, oncostatin M
OSMR, oncostatin M receptor

P

PA, phosphatidic acid
PAF, platelet-activating factor
PAGE, polyacrylamide gel electrophoresis
PAI-1, plasminogen activator inhibitor 1
PAIgG, platelet-associated IgG
PALS, periarterial (or periarteriolar) lymphoid sheath
PAMP, pathogen-associated molecular pattern
PANDAS, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections
PAR, protease-activated receptor
PAS, periodic acid–Schiff
PBG, porphobilinogen
PBG-D, porphobilinogen deaminase
PBREM, phenobarbital-responsive enhancer module
PBSC, peripheral blood stem cell
PC, phosphatidylcholine
PCC, prothrombin complex concentrate
PCFT, proton-coupled folate transporter
PCH, paroxysmal cold hemoglobinuria
PCP, *Pneumocystis carinii* pneumonia
PCR, polymerase chain reaction
PCT, porphyria cutanea tarda
PCV, polycythemia vera
PCV7, 7-valent pneumococcal polysaccharide vaccine
PCV23, 23-valent pneumococcal polysaccharide vaccine
PD-1, programmed death 1
PDGF, platelet-derived growth factor
PE, phosphatidylethanolamine, pulmonary embolism
PEBP2, polyomavirus enhancer–binding protein 2
PECAM-1, platelet–endothelial cell adhesion molecule 1
PEG, polyethylene glycol
PEG-MGDF, pegylated megakaryocyte growth and development factor
PF4, platelet factor 4
PFA-100, Platelet Functional Analyzer 100
PFK, phosphofructokinase
PFT, pulmonary function test
PGC-1α, peroxisomal proliferator–activated cofactor 1α
PGD, preimplantation genetic diagnosis
6-PGD, 6-phosphogluconate dehydrogenase
PGI$_2$, prostaglandin I$_2$ (prostacyclin)
PGK, phosphoglycerate kinase
PH, Pleckstrin homology
PHA, phytohemagglutinin
PHT, primary hypertension
P$_i$, inorganic phosphate
PI, phosphatidylinositol
PIG-A, phosphatidylinositol glycan class A (gene: *PIGA*)
PI3K, phosphatidylinositol 3′-kinase
PIP, phosphatidylinositol 4-phosphate
PIP$_2$, phosphatidylinositol 4,5-bisphosphate
PIP$_3$, phosphatidylinositol 3,4,5-triphosphate

PIT, plasma iron turnover

PIVKA, protein induced by vitamin K antagonists

PK, pyruvate kinase

PKA, protein kinase A

PKB, protein kinase B

PKC, protein kinase C

PKG, protein kinase G

PKR, protein kinase regulated by RNA

PLCγ2, phospholipase Cγ2

PLP, pyridoxal 5-phosphate

PLTP, phospholipid transfer protein

PMN, polymorphonuclear neutrophil

PMPS, Pearson's marrow-pancreas syndrome

PN, parenteral nutrition

P-5′-N, pyrimidine-5′-nucleotidase

PN2/APP, protease nexin-2/amyloid β-protein precursor

PNET, primary neuroectodermal tumor

PNH, paroxysmal nocturnal hemoglobinuria

PNP, purine nucleoside phosphorylase

PNPD, purine nucleoside phosphorylase deficiency

PPCA, protective protein cathepsin A

PPO, protoporphyrinogen oxidase

PPP, platelet-poor plasma

PR, partial remission

PRCA, pure red cell aplasia

PROWESS, Protein C Worldwide Evaluation in Severe Sepsis (trial)

PRP, platelet-rich plasma

PRPP, 5-phosphoribosylpyrophosphate

PRR, pattern recognition receptor

PS, Pearson's marrow-pancreas syndrome, phosphatidylserine

PSD95, postsynaptic density protein of 95 kd

PSGL-1, P-selectin glycoprotein ligand-1

p-SMAC, peripheral central supramolecular activation cluster

PT, prothrombin time

PTH, parathyroid hormone

PTK, phosphotyrosine kinase

PTP, post-transfusion purpura

PTS, post-thrombotic syndrome

PTT, partial thromboplastin time

R

RA, refractory anemia

RAD, recombinase-activating gene

RAEB, refractory anemia with an excess of blasts

RAEBIT (RAEB-T), RAEB in transformation

RAG, recombination-activating gene

RANTES, regulated on activation, normal T cell expressed and secreted

RARS, refractory anemia with ringed sideroblasts

RBC, red blood cell

RDA, recommended dietary allowance

RDS, respiratory distress syndrome

RDW, red cell distribution width, red cell volume distribution width

RFC, reduced folate carrier

RFLP, restriction fragment length polymorphism

rFVIIa, recombinant activated factor VII

RGD, arginine, glycine, aspartic acid

Rh, rhesus

RhAG, Rh-associated glycoprotein

rhG-CSF, recombinant human granulocyte colony-stimulating factor

r-HuEPO, rhEPO, rHuEPO, recombinant human erythropoietin

RIAM, Rap1$_{GTP}$-interacting adaptor molecule

RMRP, RNase mitochondrial RNA processing

rNAPc2, recombinant nematode anticoagulant protein c2

RNP, ribonucleoprotein

RPA, replication protein A

RPL, ribosomal protein of the large ribosomal subunit

RPS, ribosomal protein of the small ribosomal subunit

RPS19, ribosomal protein S19

rRNA, ribosomal RNA

RS, Rotor's syndrome

RSC, reversibly sickled cell

RSP-2, ring surface protein 2

RTA, renal tubular acidosis

RTK, receptor tyrosine kinase

rVIIa, recombinant factor VIIa

RVT, renal vein thrombosis

S

SAA, severe aplastic anemia

SABD, spectrin-actin binding domain

SAGE, serial analysis of gene expression

SAO, Southeast Asian ovalocytosis

SAP, SLAM-associated protein

SBDS, Shwachman-Bodian-Diamond syndrome

Sca-1, stem cell antigen 1

SCD, sickle cell disease

SCDSC, subacute combined degeneration of the spinal cord

SCF, stem cell factor

SCID, severe combined immunodeficiency

SCN, severe congenital neutropenia

SCNIR, Severe Chronic Neutropenia International Registry

SCT, stem cell transplantation

SDF-1, stromal cell–derived factor 1

SDS, Shwachman-Diamond syndrome, sodium dodecyl sulfate

SDS-PAGE, sodium dodecyl sulfate–polyacrylamide gel electrophoresis

SERCA, sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase

SGD, specific (secondary) granule deficiency

SH2, Src homology domain 2

SHD, sex hormone–binding domain

SH2D1A, SH2-containing protein 1A, Src homology 2 domain–containing protein

Shh, Sonic hedgehog

SHIP1, SH2 domain–containing inositol 5′-phosphatase 1

SHP-2, SH2 domain–containing protein tyrosine phosphatase-2

sIgM, surface IgM

SIV, simian immunodeficiency virus

SLAM, signaling lymphocyte activation molecule

SLC4A, solute carrier family 4A

SLE, systemic lupus erythematosus

SLP3, stomatin-like protein 3

SLP76, SH2 domain–containing leukocyte protein of 76 kd

SM, sphingomyelin

SMD, spondylometaphyseal dysplasia

Smo, Smoothened receptor

SNARE, soluble N-ethylmaleimide–sensitive attachment protein receptor

snoRNA, small nucleolar RNA

SNP, single nucleotide polymorphism

SOCbl, sulfitocobalamin

SOCS, suppressor of cytokine signaling

SOS, sinusoidal obstruction syndrome, son of sevenless (protein)

S-PCT, sporadic porphyria cutanea tarda

SPD, storage pool deficiency

sPLA2, secretory phospholipase A_2

SQUID, superconducting quantum interference device

SRC, SCID-reconstituting cell

SRT, substrate reduction therapy

SSCP, single-strand conformation polymorphism

SSP, stage-selector protein

STAT, signal transducer and activator of transcription

sTfR, serum transferrin receptor

STOP, Stroke Prevention Trial in Sickle Cell Anemia

STR-HSC, short-term–reconstituting hematopoietic stem cell

Stx, Shiga-like toxin

SUMF1, sulfatase-modifying factor

SVC, superior vena cava

T

TACI, transmembrane activator and calcium modulator and cyclophilin ligand interactor

TAFI, thrombin-activatable fibrinolysis inhibitor

T-ALL, T-cell acute lymphoblastic leukemia

T antigen, Thomsen-Friedenreich cryptoantigen

TAP1 or TAP2, transporter associated with antigen processing 1 or 2

TAR, thrombocytopenia with absent radii

TAT, thrombin-antithrombin complex

TBI, total body irradiation

TBP, TATA-binding protein

TCD, transcranial Doppler

TCDD, 2,3,7,8-tetrachlorodibenzo-p-dioxin

TCR, T-cell antigen receptor, T-cell receptor

TCT, thrombin clotting time

TD, thymus dependent (antigen)

TdT, terminal deoxyribonucleotidyl transferase

TE, thromboembolism

TEC, transient erythroblastopenia of childhood

TEG, thromboelastography

TERT, telomerase reverse transcriptase

TF, tissue factor

TFPI, tissue factor pathway inhibitor

TGA, thrombin generation assay

TGF-β, transforming growth factor β

THF, 5,6,7,8-tetrahydrofolate

THI, transient hypogammaglobulinemia of infancy

TI, thymus independent (antigen)

TIA, transient ischemic attack

TIBC, total iron-binding capacity

TIPS, intrahepatic portosystemic shunting

TKI, tyrosine kinase inhibitor

TLR2, Toll-like receptor 2

TLS, translesion synthesis

TLT-1, TREM cells–like transcript-1

TM, tropomyosin

TM8, transmembrane domain 8

TMD, transient myeloproliferative disorder

TOF, time-of-flight (imaging)

TMod, tropomodulin

7-TMS, seven-transmembrane–spanning domain

TNF-α, tumor necrosis factor-α

tPA, tissue plasminogen activator

TPH, transplacental hemorrhage

TPI, triose phosphate isomerase

TPN, total parenteral nutrition

TPO, thrombopoietin

TPOR, thrombopoietin receptor

TPR, tetratricopeptide repeat

TQM, total quality management

TRAF, TNF receptor–associated factor

TRALI, transfusion-related acute lung injury

TRAP, Trial to Reduce Alloimmunization to Platelets

TREC, T-cell receptor excision circle, T-cell receptor gene excision circle

TREM, triggering receptor expressed on myeloid cells

TfR, transferrin receptor

TRMA, thiamine-responsive megaloblastic anemia

tRNA, transfer RNA

TSB, total serum bilirubin

TSH, thyroid-stimulating hormone

TSLP, thymic stromal thymopoietin

TT, thrombin time

TTP, thrombotic thrombocytopenic purpura

TTTS, twin-to-twin transfusion syndrome

TXA₂, thromboxane A_2

U

UCB, umbilical cord blood

UDP, uridine diphosphate

UDPG, uridine diphosphate glucose

UDPGA, uridine diphosphate glucuronic acid

UDPNAG, uridine diphosphate N-acetylglucosamine

UGT1A1, UDP glucuronosyltransferase 1A1 gene

ULVWF, unusually large VWF

UMP, uridine monophosphate
UNG, uracil nucleoside glycosylase
uPA, urokinase plasminogen activator
uPAR, uPA receptor
UPR, unfolded protein response
URO-D, uroporphyrinogen decarboxylase
URO3-S, uroporphyrinogen III synthase
UTP, uridine triphosphate
UV, ultraviolet

V

VACTERL, vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, and/or esophageal atresia, renal agenesis and dysplasia, and limb defects
VASP, vasodilator-stimulated phosphoprotein
VATER, vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia
VCA, viral capsid antigen
VCAM-1, vascular cell adhesion molecule 1
VDRL, Venereal Disease Research Laboratory
VEGF, vascular endothelial growth factor
VHL, von Hippel-Lindau (protein)
VK, vitamin K
VK1, phylloquinone
VK2, menaquinone
VKDB, vitamin K–dependent bleeding
VKDP, vitamin K–dependent protein
VKOR, vitamin K 2,3-epoxide reductase
VLA-4, very late antigen 4
VLDL, very-low-density lipoproteins
VOD, veno-occlusive disease
VP, variegate porphyria
VP-16, etoposide
VTE, venous thromboembolism
V/Q, ventilation-perfusion

VWD, von Willebrand disease
VWF, von Willebrand factor
VWF:Ag, von Willebrand factor antigen
VWF:CB, collagen-binding assay for von Willebrand factor
VWFpp, von Willebrand factor propeptide
VWF:RCo, VWF activity by ristocetin cofactor assay

W

WAS, Wiskott-Aldrich syndrome
WASP, Wiskott-Aldrich syndrome protein
WBC, white blood cell
WHIM, warts, hypogammaglobulinemia, infections, myelokathexis (syndrome)
WIP, WASP-interacting protein
WNV, West Nile virus
WRK, Woodward's reagent K
WSXWS, Trp-Ser-Xaa-Trp-Ser

X

X-CGD, X-linked chronic granulomatous disease
XHIM, X-linked immunodeficiency with normal or elevated IgM
XLA, X-linked agammaglobulinemia
XLPD, X-linked lymphoproliferative disease
XLSA, X-linked sideroblastic anemia
XLSA/A, X-linked sideroblastic anemia with ataxia
XPD, xeroderma pigmentosum disease
XRT, x-ray therapy
XSCID, X-linked severe combined immunodeficiency

Y

YTRF, tyrosine-threonine-arginine-phenylalanine (sequence)

Z

ZAP-70, TCR{zeta}–associated protein of 70 kd
ZPI, protein Z–dependent protease inhibitor

1 Pediatric Hematology in Historical Perspective

Wolf W. Zuelzer and David G. Nathan

Wolf W. Zuelzer, who died on March 19, 1987, at the age of 77, wrote the history of pediatric hematology for the first edition of this book. We reprint it here in his memory.

As a subspecialty of pediatrics and a sine qua non of the modern teaching institution, pediatric hematology is a latecomer, naturally enough, for diseases of the blood were a minor problem—one is tempted to say a mere hobby of a few inquisitive and farseeing minds—compared with the great challenges of infectious and nutritional disorders that faced the pioneers of pediatrics. As a serious concern of investigators, however, pediatric hematology is as old as scientific pediatrics as a whole, though its early history is too closely interwoven with that of general hematology to be traced separately. Its tools as well as its basic concepts came largely from internal medicine and from the experimental sciences, and one needs only to mention such names as Ehrlich, Metchnikoff, Landsteiner, Chauffard, Downey, Minot, Castle, Whipple, and Wintrobe to appreciate the magnitude of this debt.

The discoveries of these and many other men were applied to the special problems of infancy and childhood by investigators who, with few exceptions, were pediatricians with diverse interests rather than hematologists with a specialized background. This is true even of those whose names are familiar through eponymic usage, such as von Jaksch, Lederer, Cooley, Blackfan, and Fanconi. Those who labored patiently in the vineyards without stumbling on a buried syndrome are mostly forgotten, though it is among them that one finds the first true pediatric hematologists. A case in point is that of Heinrich Lehndorff, who grew up in the Vienna of von Pirquet and Escherich and devoted his life to the study of both normal and abnormal hematologic conditions in childhood, publishing his first paper at the age of 29 in 1906 and his last at the age of 86 in 1963. His interest was in the blood of the newborn, in the anemias of infancy, and in leukemia. Like that of most of his contemporaries, his work was almost entirely descriptive, but he was a good morphologist and clinical observer. Lehndorff was forced to leave Vienna in 1939 at the age of 63, found temporary shelter in Birmingham with Leonard Parsons (then the leading figure in pediatric hematology in England), came to the United States during World War II, and ended his career as an octogenarian with an honorary appointment at the New York Medical College. *Sic transit gloria mundi.*

From the very beginning, the unique blood picture of the newborn received special attention. In one of the oldest hematologic texts, *Du Sang et de ses Altérations Anatomiques*, published in Paris in 1889, Hayem—known to this day as the inventor of Hayem's solution but deserving to be remembered for more important contributions—discussed the blood at birth in great detail, giving the number of red and white corpuscles and platelets on the basis of his own counts; describing macrocytosis, anisocytosis, and a tendency toward spherocytosis; and attributing the high hemoglobin level of the newborn to hyperactivity of the bone marrow. The title of a paper by E. Schiff in the *Jahrbuch für Kinderheilkunde* in 1892, "Newer contributions to the hematology of the neonate, with special reference to the time of ligation of the umbilical cord," implies the existence of earlier studies and anticipates those of Windle and his associates some 50 years later.

The hematology of the neonate remained a cardinal concern of investigators for many decades. Progress was slow, perhaps in part because of the tediousness of the methods used and in part because of variables in obstetric and pediatric practice and differences in the timing of observations. Schiff himself, working successively in Prague and Budapest, found hemoglobin levels on the

first day after birth to average 104 per cent in one city and 144 per cent in the other. Much controversy arose over normal values because the early workers did not come to grips with the problems of individual variation and frequency distribution. A German author, H. Flesch,[1] wrote despairingly in 1909, "The differences in the hemoglobin values of different observers according to the ages of the children are so considerable that one is really in no position to give definite normal figures." It was difficult, moreover, to draw a line between normal and abnormal conditions. ABO hemolytic disease, for example, was unknown until 1944, when Halbrecht[2] in Hadera recognized the relationship between "icterus praecox" and incompatibility of the major blood groups of mother and child. Prior to the studies of Lippman[3] in 1924, on the other hand, the transient normoblastemia of normal full-term infants was considered pathologic, although Neumann[4] had observed it in 1871 and König[5] had written about it in 1910. Supravital staining, introduced by Ehrlich in 1880, was not used until 1925, when Friedländer and Wiedemer,[6] writing in the *American Journal of Diseases of Children*—then the only major pediatric journal in the United States—reported reticulocytosis as a regular feature of neonatal blood. Although it was known by then that reticulocytes were young cell forms, the belief still prevailed that the high hemoglobin level at birth was due solely to hemoconcentration rather than to active erythropoiesis, as postulated by Hayem.

Conversely, the postnatal drop in hemoglobin concentration was taken as evidence of accelerated hemolysis, which in turn was held by some to be the cause of physiologic jaundice. That puzzling phenomenon was long thought to signify the entry of bile into the blood as a result of temporary mechanical obstruction by a mucous plug in the common bile duct or a "desquamative catarrh" of the small radicles, or liver damage from bacterial toxins from the recently colonized intestine of the newborn. The noted Finnish neonatologist Ylppö,[7] however, had demonstrated increased bilirubin levels in the cord blood as early as 1913 and had concluded that icterus neonatorum was due to a "functional inferiority" of the liver. All theories involving the regurgitation of bile became untenable in 1922, when Erwin Schiff and E. Färber,[8] pupils of the renowned Adalbert Czerny, showed that "during the period of bilirubinemia only the indirect van den Bergh reaction is positive." The alternative that the jaundice was due to increased blood destruction, however, could not be proved. Summarizing the argument in 1928, the Viennese pediatric hematologist Eugene Stransky[9] wrote, "Although the morphologic stigmata of a hemolytic icterus (i.e., spherocytosis) are lacking and the red blood counts do not permit a firm explanation, a hematogenous origin of icterus neonatorum nevertheless seems likely. Why destruction of red corpuscles takes place is still an unsolved question."

One must sympathize with these early investigators who formulated the alternatives clearly enough but could not solve the riddle of neonatal jaundice with the means at their disposal. To them icterus meant either regurgitation of bile or increased destruction of blood. Hemolysis seemed indeed a plausible explanation for the combination of bilirubinemia of the indirect variety with a falling hemoglobin level and a regenerative blood picture, all the more because mild forms of hemolytic disease were undoubtedly included in studies of infants presumed to be normal. The life span of fetal—or, for that matter, adult—red cells remained an unknown quantity, even after Winifred Ashby in 1919 had measured it in adults, using the differential agglutination technique, as the range of 30 to 100 days reported by her was too great to be of practical value. This was also true of the blood volume of the newborn, which William Palmer Lucas and B. F. Dearing[10] of San Francisco had actually attempted to measure in the same year, using the brilliant vital red dilution method. They obtained a range of values from 107 to 195 mL per kg of body weight, almost twice that found in 1950 by Mollison and his associates[11] with a method combining isotope and dye dilution. The mere fact that they concerned themselves with such questions in 1919 puts them ahead of their pediatric contemporaries. Neither of the first two books devoted specifically to pediatric hematology, that of Ferruccio Zibordi of Modena, *Ematologia Infantile Normale e Patologica*,[12] which appeared in 1925, and that of Baar and Stransky of Vienna, *Die Klinische Hämatologie des Kindesalters*,[1] published in 1928, mentioned blood volume or red cell survival. The name of Lucas deserves recognition in any survey of pediatric hematology, for, apart from looking after patients with blood diseases in the Children's Department of the University of California before such specialization had become accepted elsewhere, he was an enterprising and thoughtful investigator. His chapters on blood in *Abt's Pediatrics* of 1924, written with E. C. Fleischner,[13] are outstanding in their emphasis on physiologic processes, clarity of thought, and absence of semantic claptrap, and in these respects are superior to the two works just cited.

As for the solution to the puzzle of neonatal jaundice, the functional inferiority of the liver postulated so long ago by Ylppö could not be defined, of course, until Hijmans van den Bergh's two pigments had been identified as free and glucuronide-conjugated bilirubin by the independent studies of Billing and Lathe,[14] Schmid,[15] and Talafant[16] in 1956. The results of the preceding demonstration of the role of uridine diphosphate glucuronic acid (UDPGA) as a glucuronide donor by Dutton[17] and others could be applied to bilirubin, and the enzymatic reactions involved in the conjugation process could be investigated as a function of hepatic maturation by Brown and co-workers.[18]

Traditionally, the history of pediatric hematology begins in 1889 with von Jaksch's report[19] on the condition that bears his name, which he designated *anemia pseudoleucaemica infantum*. By an irony of fate, not only the term but the very syndrome has long since vanished

from the horizon, although in its day it had an enormous vogue and was considered by some to be the anemia of infancy *par excellence*. In 1891, the condition was described independently by Hayem[20] and his compatriot Luzet,[21] so that their names were also attached to it. The clinical picture was overshadowed by severe nutritional disturbances, wasting, diarrhea, rickets, and, as a rule, chronic infections of the respiratory tract, otitis media, pyoderma, and the like. The findings suggestive of leukemia were marked splenomegaly, anemia, and that which later hematologists would call a leukemoid reaction, characterized by leukocytosis and immature granulocytes. It was Luzet who noted the normoblastemia that led to the use of the term "erythroblastic anemia," until that term was temporarily pre-empted by Cooley for the anemia that he described. At that time, the combination of splenomegaly and leukocytosis meant leukemia, and von Jaksch's paper was therefore a distinct step forward, though its essence was the simple observation that some of the patients survived, a remarkable fact in itself given their general condition and the paucity of therapeutic means then available.

Von Jaksch was not a hematologist, and except for a follow-up report in 1890, he made no further contributions to the understanding of the disease that made him famous. He practiced pediatrics in Prague, then the capital of the Austrian province of Bohemia, and held an appointment at the Charles University, where, as a legendary octogenarian, he was pointed out to this writer in 1934, a tall aristocratic figure with a massive white head who bore his fame with a casual elegance reminiscent of the old Hapsburg Empire. The riddle of von Jaksch's anemia was never properly solved. It was at one time common in central Europe and in France, less so in England, and still less so in the United States. Its disappearance paralleled the gradual improvement in child health and care. As Lehndorff[22] wrote many years afterward in an almost nostalgic epitaph on the extinct entity, it had been "a poor people's disease." In truth, it was not an entity at all but a convenient diagnostic wastebasket, though an interesting one. The contemporaries finally agreed that it was a nonspecific response of the infantile organism to the horrendous combinations of infectious and nutritional insults that were so common at the time and so difficult to sort out.

More lasting and far more important, of course, was the contribution made to pediatric hematology—and indeed to medical science as a whole—by Thomas B. Cooley of Detroit in 1925,[23] when he salvaged from this wastebasket the distinct entity now known as thalassemia. He soon abandoned his original designation of "erythroblastic anemia," for he realized that the conspicuous normoblastemia that had first attracted his attention was neither a specific nor a central feature of the disorder, and in his later publications he emphasized the fragmentation and shape anomalies of the red cells and the paucity and uneven distribution of the hemoglobin. He did not know, of course, that the ultimate disturbance was one of hemoglobin, let alone β chain synthesis, but he came to conceive of the disease as a fundamental disorder of hematopoiesis and was fully aware of its genetic nature from the beginning. He himself had originally proposed a recessive mode of inheritance, anticipating the classic study of Valentine and Neel of 1944.[24] Strangely enough, he failed to investigate the seemingly normal parents and siblings of the propositi. Later, unverified reports of hereditary transmission of the disorder by a single affected parent seemed to militate against a recessive mode and left him uncertain.

Cooley was, in any case, profoundly interested in the genetic aspects of the anemias and was in this respect far ahead of most contemporary hematologists. He corresponded with geneticists, used such terms as "heterozygote" for humans at a time when their use was still largely restricted to plants and *Drosophila*, and for years pondered the then wholly puzzling relationship between "sicklemia" and sickle cell anemia. He reported the first instance of sickle cell disease (which this writer later had occasion to identify as a case of sickle-thalassemia) in a Greek family.[25] He also proposed an X-linked mode of inheritance, backed by pedigree studies over five generations, for a familial hypochromic anemia in a kindred first described by him[26] and later restudied by Rundles and Falls[27] at Ann Arbor, Michigan. In accepting the term "Mediterranean anemia," which Whipple had suggested at a time when the known cases were restricted to Italian and Greek families, Cooley[28] made an interesting and prophetic reservation: "We are not inclined," he wrote in 1932, "to lay great stress on the limitation of this or any similar disease to a particular race. We have found that sickle cell anemia, formerly supposed to be peculiar to Negroes, occurs in Greeks, and it seems likely to us that any disease in which there is a hereditary element, as presumably there is in this disease, is limited more by locality and association than by race."

The style is as characteristic of the man as the thought. Cooley was articulate, well educated—he spoke or at least read four languages and maintained a global correspondence—and highly intelligent. He came from a family of distinguished jurists, the only one to eschew the law and enter the medical profession. Born in Ann Arbor, the son of a future justice of the Michigan Supreme Court, he obtained his degree in medicine at the University of Michigan, worked for 3 years in "clinical chemistry," interned at Boston City Hospital, spent a year visiting clinics in Germany, returned to Boston for prolonged training in contagious diseases, and then was appointed Assistant Professor of Hygiene at his alma mater. Except for a stint with the Children's Bureau of the American Red Cross during World War I, he remained in Michigan for the rest of his life, first as a practicing pediatrician and, after the death of Raymond Hoobler in 1936, as a professor of pediatrics in Detroit. Throughout these years he was closely associated with The Children's Hospital of Michigan, whose pediatrician-in-chief he ultimately became.

As mentioned, Cooley had no formal training in hematology and very little technical help. He and his faithful associate of many years, Pearl Lee, examined blood smears, roentgenograms, and, of course, the patients themselves, making sketchy notes on index cards and keeping the bulk of their observations in their heads. His equipment consisted of a monocular microscope of ancient vintage, a staining rack, a rather small card file, and—in an otherwise vacant room upstairs intended for the affairs of the Child Research Council of the American Academy of Pediatrics—a couch on which he took siestas and did much of his thinking. His daughter Emily, a gifted and artistic young woman, made the beautiful camera lucida and freehand drawings with which he illustrated his papers. She also chauffeured him about town, went to the library for him, and accompanied him to meetings. His home in Detroit's "Indian Village" and his garden, professionally landscaped by Emily, were oases of good taste. He owned a cottage on the coast of Maine where he spent his summers. He loved music, knew his wines, enjoyed good food, and was an excellent conversationalist. He knew how to live.

At times, his penchant for conversation got him into trouble. Old-time Detroiters recall the story of his house call to a well-to-do family whose child had contracted an undiagnosed illness. As a social acquaintance Dr. Cooley was led into the living room, offered refreshments, and asked his opinion on some topic of current interest. A lively discussion ensued, at the end of which the doctor, having forgotten the original purpose of his visit, grabbed his hat and coat and was out of the house before the astonished parents could remind him of the patient upstairs.

Cooley's influence extended well beyond the field of hematology. His was the conception behind a series of studies on the chemical composition of the red cell stroma carried out in the 1930s by Erickson and associates in the laboratories of Icie Macy Hoobler of the Children's Fund of Michigan, which earned high praise from Eric Ponder. He was one of the founders of the Academy of Pediatrics and, long before the time was ripe, saw the role of pediatrics in terms of preventive medicine. Politically he was a liberal, scientifically a radical, personally a patrician. Combined with a rather haughty expression, an irrepressible wit, and an utter lack of reverence for established authority, these traits were bound to earn him enmities on the part of town and gown alike, but his enemies respected and his friends admired him. He was well ahead of his time, a lucid thinker and a giant in the history of pediatric hematology.

An entirely different personality was George Guest, for many years one of the mainstays of the Children's Hospital Research Foundation in Cincinnati, whose contributions were equally important, if less spectacular. Guest was as much a physiologist as a hematologist, interested in the basic aspects of blood during growth, a stickler for precise measurements, a patient investigator who set himself longterm goals and took a systematic approach to reaching them. The meticulous studies he conducted between 1932 and 1942 on the hemoglobin levels, red blood counts, and packed cell volumes of a large group of infants and young children of widely different social and economic backgrounds are a model of intelligent and purposeful data-gathering, the purpose being both physiologic and clinical. In the face of the rather arbitrary definitions and therapeutic practices then prevailing, Guest set out to ascertain the range of normal variation and to delineate optimal values against hypoferric states. Such data were badly needed then and have remained valid to this day. In serial studies[29] involving, among other things, intrafamily and twin comparisons, he showed convincingly that a fall of the mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH) in the presence of seemingly adequate hemoglobin levels could be reversed or altogether prevented by the administration of iron and is therefore a sensitive indicator of an incipient deficiency state rather than a physiologic phenomenon. He concluded that iron deficiency anemia was far more common among infants than had been previously thought, and advocated the general use of prophylactic measures. His earlier observations on glycolysis and the rise of inorganic phosphorus levels in stored blood[30] and his joint observations with Sam Rapoport[31] on the role of the pH in the breakdown of diphosphoglycerate were milestones in the understanding of red cell metabolism. He also made significant contributions to the knowledge of the osmometric properties of erythrocytes,[32] both normal and abnormal, devising a method that was, typically, both practical and precise and permitted simultaneous determinations of hemolysis and red cell volume at each stage of the procedure.

Apart from these accomplishments, George Guest was a delightful friend and, with the help of his wife, a perfect host, so that the house on Dana Avenue in Cincinnati became a kind of unofficial headquarters for the entertainment of the many visitors to the Children's Hospital. Here they were offered the vin d'honneur from a well-stocked wine cellar decorated with frescoes by an artist friend—the owners' pride and the first and last stop for the visitor—and here they would find good conversation, interesting people, and exquisite cuisine. The Guests were passionate Francophiles, and the cooking was French, unless a keg of oysters had just arrived from the East to be prepared in endless variations, or unless Jesse, the houseman, more friend than butler, just happened to have shot—illegally, of course—a fat squirrel from one of the magnificent old trees in the garden. George, a short, stocky, quiet-spoken man, understood the art of good fellowship, but the soul of the house and its social genius was his wife "M.L.," a handsome woman with red hair who had a passion for poetry and a gift for conversation. They had met in Europe after World War I as young and idealistic members of the Hoover Relief team, were drawn together by their love for all things French, and remained deeply devoted to one another. A large part of every

summer was spent in France visiting friends, traveling through the countryside, and sampling wines. George Guest was the only American member of the French Pediatric Society, a fact in which he took greater pride than in all his other achievements, and though his French accent left much to be desired, he liked to attend meetings and even present papers in such delightful places as Bordeaux, Lyon, and Paris. When M.L. died about 1964, the house was sold and an era passed.

It would be instructive to trace in detail the thinking of earlier observers concerning the iron deficiency anemia of infancy, to whose definition Guest made such a solid contribution, but which remained an object of controversy, confusion, and neglect for generations of pediatricians. Although Bunge had proposed an essentially correct explanation as early as 1889, the nature of the most common anemia of infancy eluded investigators for many years. The reasons for this paradox are enlightening. One was the belief that not only mild anemia but also hypochromasia was a physiologic phenomenon. "That the hemoglobin content suffers more than the red blood count," Heinrich Baar wrote in 1928,[33] "is surely a purposeful mechanism, for the same quantity of hemoglobin can serve its function better when it is distributed over a larger number of red corpuscles." More important, no doubt, is the fact that among the clinic patients on whom most studies were conducted, pure iron deficiency anemia was rare. In the face of the multiple ailments to which such patients were prone, failure to respond to iron alone was common, and it was easy to draw erroneous conclusions from therapeutic trials. Conversely, of course, a rise of the hemoglobin level following the administration of iron was just as uncritically taken as proof of its efficacy on the principle of *post hoc propter hoc,* though it was believed that iron was a bone marrow "stimulant" rather than a specific substance effective only when correcting or preventing a deficiency.

Much of the problem was semantic in nature. Whereas French pediatricians described iron-responsive hypochromic anemia in infants as "chlorose du jeune âge" or "chlorose alimentaire," most German and Austrian authors rejected this concept, if only because "chlorosis occurs only during puberty and only in females." The highly influential Czerny, in particular, set the clock back by stating categorically that an entire group of alimentary anemias existed that could be influenced by diet but in which iron was utterly ineffective. Baar wrote: "If it appears, a priori, unjustified to group together, and attribute to direct or indirect lack of iron, anemias of the most diverse origin solely because they are all hypochromic, fail to show nucleated red cells in the peripheral blood and lack splenomegaly, the notion of chlorosis of alimentary origin was definitely refuted by Czerny's findings." If this was to pour the baby out with the bathwater, Baar retreated from his a prioristic position to the extent of recognizing a "pseudochlorosis infantum," or infantile iron deficiency anemia, as an "etiologically uniform type to be separated from the rest of the alimentary anemias

of infancy." This was rare, however, he asserted, in comparison with "the overwhelming majority [which] remains uninfluenced by iron administration, though nevertheless improved or cured by appropriate changes in diet." In reading such statements, one must remember that even fresh air and sunshine were still considered essential adjuncts to the treatment of anemia. Moreover, no less an authority than Haldane[34] had asserted earlier that "recovery affords no ground for assuming that iron is built up into hemoglobin," and that "in typical cases [of chlorosis] the curative factor of iron salts must be exercised otherwise than simply in building up the hemoglobin." Haldane went on to say that "The essential process in the cure of chlorosis is the reduction in the volume of the plasma [sic]." In addition, the notion of toxic hemolysis due to the fatty acids in cow's milk and especially in goat's milk had a prolonged vogue on the Continent, where "cow's milk anemia" and "goat's milk anemia" were accepted entities.

Related to the semantic difficulties was the problem of classification. Ever since Hayem had introduced the color index in 1877, hypochromasia had been used to characterize certain anemias. It was soon apparent that most anemias of older infants were of this type, but the difficulty of relating morphologic criteria to pathogenetic mechanisms and of recognizing in turn that different etiologic factors could operate through identical pathways proved too much. Not until the work of Minot and Castle established the characteristic response of hemoglobin and reticulocytes to specific hematinics, and Wintrobe put the morphologic classification on the firm basis of red cell measurements, did pediatric hematologists gradually abandon terms such as "alimentary-infectious" anemia. In 1936, Hugh Josephs[35] still used this term as a common denominator that, to him, included deficient hemoglobin formation, deficient erythropoiesis and deficient stimulation of erythropoiesis, deficient maturation (the "erythroblastoses"), and blood destruction. Such usage, apart from the vagueness of the etiologic concept, was bound to delay both the understanding of the pathogenesis and the development of a workable classification of the anemias. It was an internist who said that "the infant bleeds into its own increasing blood volume," and the importance of the hemoglobin mass at birth was not appreciated until later. When Blackfan and Diamond's *Atlas of the Blood in Children* finally appeared in 1944,[36] it used Wintrobe's classification and described the principal anemia of infancy under the title "iron deficiency anemia."

One cannot leave the subject of iron deficiency without reference to Hugh Josephs, a strange figure, and in his day an authority in the field of American pediatric hematology. It is remarkable that this should have been the case, for he published little and confined his work primarily to the relationship between iron metabolism and anemia in infancy. His chapters on diseases of the blood in Holt and McIntosh's textbook were excellent, but his mind had a somewhat pedantic cast and a ten-

dency to look for profound meanings underneath simple facts. His forte was a thorough knowledge of the literature, which he analyzed in erudite but unconscionably lengthy reviews, complete with foreword, statement of scope and purpose, introduction, presentation of fundamental concepts, summary, table of contents, and a bibliography that in one instance exceeded 750 titles. He was Associate Professor of Pediatrics in Dr. Park's department at Johns Hopkins University and published mostly in the *Johns Hopkins Bulletin*. His manner and appearance were those of a college professor or a don—mild, pleasant, serious, single-minded, a slight, gray-haired man who smoked a pipe, wore soft collars and a velvet jacket with elbow patches, and received his visitors in a drab office in the old Harriet Lane Home cluttered with books, magazines, and reprints.

By means of a curious logic, Josephs came to the unshakable conclusion that the hypochromic iron deficiency anemia of infants was not due to depletion of iron but to its diversion to unknown sites by unknown mechanisms.[37] He based this hypothesis on theoretical calculations that proved that an anemic baby of 18 months should have an excess of 200 mg of unused iron—other than the necessary tissue iron—somewhere in his body; ergo the baby suffered from "iron deficiency without depletion." This hypothetical baby, Josephs said, "is starving in the midst of plenty. Give this baby a small amount of iron by mouth and he will utilize it avidly for hemoglobin formation, and may as a result use even more than he was given." In the absence of infection, the unavailability of iron might be due, he thought, to hormonal, histotrophic, or even emotional factors. But in 1956, 3 years after these speculations, Philip Sturgeon[38] calculated on the basis of the same data that had been available to Josephs that a seemingly normal newborn could easily have a hemoglobin mass low enough to account for severe anemia in later infancy, reflecting the expansion of the blood volume with growth. Earlier, Bruce Chown[39] of Winnipeg had documented the occurrence of massive transplacental hemorrhage. Soon afterward, Kleihauer and Betke[40] devised their ingenious method for demonstrating fetal cells in maternal blood by the acid elution technique. Subsequent studies by Cohen, Zuelzer, and associates[41] and others showed that moderate and repeated fetal bleeds were not at all rare. A mechanism for depriving the fetus of hemoglobin iron without necessarily causing overt anemia at birth but capable of explaining the later development of iron deficiency in the absence of further blood loss seemed to offer a simpler solution than the tortuous hypothesis of "iron deficiency without depletion." The modern age had arrived.

Their semantic difficulties did not keep the earlier pediatricians from devising eminently practical methods of treatment, as exemplified by the story of pediatric transfusion therapy. The technical problems of transfusing infants were overcome in various ways. In 1915, Helmholz of the Mayo Clinic advocated the use of the superior sagittal sinus, and in 1925 Hart of the Sick Children's Hospital of Toronto used this route for the first exchange transfusion ever given for "icterus gravis."[42] Though his patient recovered, exchange transfusion was not again used for this indication until Wallerstein revived it in 1946 on the grounds that "the removal of most of the Rh-positive cells and of the circulating antibody shortly after birth prevents the incidence of the more severe pathological and physiological changes." Wallerstein,[43] then Director of the Erythroblastosis Fetalis Clinic of the Jewish Memorial Hospital in New York, had used the sagittal sinus for most of his cases, but stated that "the umbilical vessels should be an excellent route for both the withdrawal and replacement procedures," with the strange proviso that they could be used "only if the decision to perform the substitution is made before birth. . . ." J. B. Sidbury,[44] a pediatrician at the Babies' Hospital in Wrightsville, North Carolina, in a little-noticed report had described a simple transfusion via the umbilical vein in the case of a bleeding newborn in 1923. It was Diamond[45] who later established the umbilical route as the safest and simplest for exchange transfusion in hemolytic disease and who, with Allen and Vaughan,[46] was the first to recognize that the prevention of kernicterus was the main rationale of the procedure. It is interesting to recall that exsanguination transfusion through the fontanelle or the femoral vein was used on a large scale at the Sick Children's Hospital in Toronto for the treatment of burns, erysipelas, and other conditions since 1921. This procedure was introduced by Bruce Robertson, who in 1916 during the campaign in France had observed two soldiers recover from severe carbon monoxide poisoning after venesections followed by transfusions. By March of 1924, when Robertson was already dead, 501 exsanguination transfusions had been performed at the Sick Children's Hospital.[47]

In the late 1950s there was a small flurry of papers reporting successful transfusions by the intraperitoneal route. This subject had been thoroughly explored in two studies, one experimental,[48] the other clinical,[49] in 1923 by a young pediatric resident in Minneapolis, David Siperstein, whose concise and accurate summary read as follows: "1. The intraperitoneal transfusion of citrated blood is a therapeutic procedure of possible merit. 2. It can apparently be utilized in cases in which transfusion is indicated, when other routes are unavailable." The author documented the effective reabsorption of the transfused cells not only with serial red counts and hemoglobin determinations but also with photomicrographs showing the dual population of hypochromic recipient and normochromic donor cells. In his review of the literature, he found that intraperitoneal transfusion was first used by Ponfick of Berlin in 1875, and that Hayem in 1884 had performed ingenious experiments involving cross transfusions of dog and rabbit blood in order to prove absorption from the peritoneal cavity. Although technical progress has since made the procedure obsolete, Siperstein's work deserves to be rescued from oblivion, if only to show that there is nothing new under the

sun. He recognized a potential need, defined the problem, and solved it with an enviable economy of means (and words).

Passing mention should also be made of the use of bone marrow transfusions as a means of side-stepping technical difficulties in transfusing infants, especially for the general pediatrician with little practice in "needle-work." The method had its day in England and particularly in Denmark, where Heinild[50] in 1947 described the experience of 4 years, during which 686 blood transfusions were given via the bone marrow without a single mishap. He stated that the risk of osteomyelitis was limited to patients receiving continuous infusions. One hesitates to argue with success and realizes that, in places and under conditions in which the required skills or supplies are lacking, it is better to apply unorthodox methods than to let a baby die for lack of blood.

A less desirable development that took place in the late 1920s and continued until the early 1940s was the practice of giving newborn infants intramuscular injections of adult blood as a prophylactic measure against hemorrhagic disease of the newborn. During those years, according to recollections provided by James L. Wilson, who for many years was Dr. Blackfan's right arm at The Children's Hospital in Boston, hemorrhagic disease was becoming so great a problem that this practice seemed justified. The blood was given without typing or cross-matching, and the procedure undoubtedly was responsible for a significant number of sensitizations against the Rh factor that did not come to light until these infants had grown up (and the Rh factor had meanwhile been discovered). The subsequent decline in hemorrhagic disease of the newborn coincided with both the introduction of vitamin K and a significant improvement in obstetric practices. Since the condition has now become rare and its definition was always vague and without clear distinction between traumatic hemorrhages and those primarily attributable to a coagulation difficulty, the mystery of its upsurge and the reasons for its virtual disappearance have never become quite clear.

If pediatricians proved resourceful in the matter of blood transfusions, it must be said that they showed little innovative spirit in certain other respects. It is a curious fact that the study of the bone marrow in children was neglected, especially in the United States, long after its usefulness had been amply demonstrated in adults. Thus Cooley, for example, never looked at anything but the peripheral blood, and Blackfan and Diamond's otherwise exhaustive *Atlas* of 1944 appeared without a single illustration of bone marrow. This writer remembers visiting a major pediatric center on the East Coast about 1946 and being shown half a dozen patients on the wards suspected of having leukemia and awaiting surgical biopsies—to be performed when and if they stopped bleeding. His own interest in the cytology of the bone marrow, which led to the recognition of megaloblastic anemia of infancy and its reversal by folic acid,[51] had been stimulated by many "curb-stone" discussions with Lawrence Berman, a

student of Downey and himself an outstanding morphologist. It should be noted that Amato of Naples, Italy,[52] gave an excellent description of infantile megaloblastic anemia independently in the same year as Zuelzer and Ogden,[51] though he did not have folic acid at his disposal and concluded from the response to potent liver extract that he was dealing with true pernicious anemia or at least with a temporary deficiency of intrinsic factor. An even earlier report by Veeneklaas of Holland[53] had the misfortune of being prevented from reaching readers abroad because of World War II.

This is the place to pay tribute to the memory of Katsuji Kato, pupil and associate of Downey, a superb morphologist and illustrator, who was the first student of the infantile bone marrow in the United States. In 1937, Kato[54] published a definitive study based on bone marrow aspirations in 51 normal infants and children. He commented on the lymphocytosis in the younger subjects and gave the myeloid-erythroid ratios for the various ages. He also illustrated the diagnostic value of the procedure by citing a case of leukemia and one of Niemann-Pick disease. Kato was on the staff of Bobs Roberts Memorial Hospital in Chicago and often made the long trek to the North Side to participate in Dr. Brennemann's grand rounds at the Children's Memorial Hospital. One remembers him, a jolly, round-faced, smiling figure reminiscent of the Hotei-Sama statuettes of his native Japan, a rapid speaker with an atrocious accent but interesting ideas, showing off his delicate colored drawings with as much aesthetic pleasure as scientific pride and at the same time implying by his self-deprecating manner that it was all quite simple and hardly worth the honorable listener's attention. World War II put an end to his career. He returned to Japan and was lost from sight.

Perhaps it was Kato's unfortunate choice of the sternum as the site for diagnostic punctures, making the procedure unnecessarily difficult and unpleasant in pediatric practice, that kept others from emulating him. American authors virtually ignored Kato's work, except for the enterprising Peter Vogel at Mount Sinai Hospital in New York, whose study with Frank Bassen[55] in 1939 covered 113 examples of diverse conditions, including leukemia, Gaucher's disease, and metastatic neuroblastoma, illustrated with excellent photomicrographs. In Europe, and especially in Switzerland under the influence of Rohr and Moeschlin, pediatric hematologists were more curious. Zürich, where Naegeli had created a strong tradition, had already become a mecca of Continental hematology. Writing in 1937, Guido Fanconi[56] declared: "The painstaking exploration of every case [of unexplained anemia] with old and new methods, which include bone marrow puncture, handled at the Zürich [Children's] Clinic with consummate skill by my Oberarzt, Dozent Willi, promises to uncover new, sharply defined entities." In the short span between 1935 and 1938, H. Willi[57] published four excellent studies on the bone marrow in thrombocytopenic purpura, leukemia, and various anemias of childhood. Fanconi had the sat-

isfaction of seeing his prophecy fulfilled, in part by his next Oberarzt, Conrad Gasser. In addition to megaloblastic anemia of infancy, a whole series of conditions came to light or were clarified by bone marrow studies, among them the acute erythroblastopenia described in 1949 by Gasser[58]; chronic benign neutropenia, also studied by Gasser[59] and later by Zuelzer and Bajoghli[60]; Kostmann's infantile genetic agranulocytosis[61]; "myelokathexis"[62] or "ineffective granulopoiesis"[63]; and the aplastic and hypoplastic anemias.

Hematology occupied a special place among Fanconi's far-flung interests, and in giving encouragement and support to his associates—in this respect not unlike Blackfan—he contributed as much to progress in this field as he had done earlier with the recognition of the anemia that bears his name.[64] A tall, handsome man, every inch the professor yet gracious and outgoing, capable of charming an audience in six languages, a lively and eclectic spirit, Fanconi was a superb clinician and an excellent organizer to whom pediatric hematology owes much. With Fanconi one must rank his colleague in Bern, Glanzmann,[65] whose report in 1918 on "hereditary hemorrhagic thrombasthenia" as a condition characterized by prolonged bleeding time and poor clot retraction in the presence of a normal platelet count opened the era of platelet function studies. Glanzmann postulated the existence of a platelet factor specifically involved in clot retraction. He contributed greatly to the knowledge of the various purpuras. The term "anaphylactoid purpura" stems from his studies[66] and was based partly on clinical observations and similarities with human serum sickness and partly on his interpretation of Hayem's findings in dogs injected intravenously with bovine serum.

Conrad Gasser, one of the ablest and most productive pediatric hematologists in Europe, deserves more than passing mention in this narrative. Apart from his discovery of acute erythroblastopenia—known until then only from the report of Owren[67] as a complication of congenital spherocytosis—and his study of chronic neutropenia, he added greatly to our knowledge of hemolytic anemias in childhood. His monograph *Die Hämolytischen Syndrome des Kindesalters*,[68] which appeared in 1951, ranks in quality if not in scope with Dacie's well-known book. In 1948, in a paper with Grumbach,[69] Gasser described spherocytosis as a feature of ABO hemolytic disease. In the same year he gave a detailed report of anemia with spontaneous Heinz body formation in a premature infant,[70] a condition then unknown except for a brief note by Willi. In his book, and in subsequent publications, he added a large compilation of case material, described the detailed morphologic picture of the abnormal red cells—which were identical with the "pyknocytes" later observed in full-term infants by Tuffy, Brown, and Zuelzer,[71] but which he called more graphically "ruptured eggshells"—and determined their incidence in the blood of normal premature infants. He coined the term "hemolytic-uremic syndrome," being among the first to recognize that condition.

One reports with regret that so fruitful a career was disrupted by the exigencies of an academic system that, at the time at least, provided insufficient "room at the top" and effectively eliminated key people upon the retirement of their chief (unless they happened to be chosen to succeed him). Such a system was, and to a large extent still is, in force in Switzerland and elsewhere on the Continent. Fanconi's retirement from the Kinderspital in Zürich almost automatically entailed that of his Oberarzt Gasser. The latter, a modest man with a quiet sense of humor and a gemütlich Alemannic temperament, maintained his interest in hematology, which came to include the treatment of childhood leukemia, but he did so as a practicing pediatrician in a private office. Similar reasons prematurely ended the academic career of Sansone in Genoa, author of a book on favism and one of the most promising pediatric hematologists in Italy.

It is manifestly impossible in the allotted space to do justice to, or even name, all those who contributed to the evolution of pediatric hematology. Among European workers one would like to dwell on the achievements of Sir Leonard Parsons of Birmingham, England, the Grand Old Man of British pediatric hematology, founder of a veritable school that attracted students from many countries, including the United States. Parsons was an original thinker who refused to accept the confused semantics of childhood anemias and created his own system along pathophysiologic lines. He was the first to recognize, in 1933, the hemolytic nature of erythroblastosis fetalis and to defend that concept[72] even against the authority of Castle and Minot. These men, along with Diamond, Blackfan and Baty, Josephs, and others, regarded erythroblastosis fetalis as a defect of hematopoiesis in a class with Cooley's anemia and other "erythroblastoses." One would like to describe the achievements of Parson's associates, Hawksley and Lightwood; of Cathie, Gairdner, Walker, Hardisty, and so many other British colleagues of Lichtenstein in Sweden—an early student of the anemia of prematurity, which he was the first to call physiologic and to separate from the later phase of iron deficiency; of his compatriots Wallgren and Vahlquist; of Plum in Copenhagen, the discoverer of vitamin K and originator of the thesis of a temporary deficiency of this substance as the cause of hemorrhagic disease of the newborn; of van Crefeld of Amsterdam, a pioneer in the study of coagulation factors in the newborn; of Betke, then in Tübingen, who with Kleihauer developed the acid elution technique for the demonstration of fetal hemoglobin in individual cells and who later, in Munich, made his department into a strong base of pediatric hematology; of Jonxis in Leyden, an imaginative investigator, who among other things organized a comparative study of the incidence of sickling in Curaçao and Dutch Guiana (now Surinam) to test Allison's hypothesis of the selective effect of malaria on two genetically similar populations exposed for centuries to different risks of the infection.

To return closer to home, credit must be given to James M. Baty as a member, with Blackfan and Diamond, of the triumvirate at Children's Hospital, Boston, that set the pattern for the development of pediatric hematology in the United States. Their collaborative effort resulted in, among other things, the recognition that hydrops fetalis, icterus gravis, and hemolytic anemia of the newborn, in spite of the differences in their clinical manifestations, were etiologically related conditions.[73] This was truly a breakthrough in the understanding of hemolytic disease. After Baty moved to the Floating Hospital and Blackfan died an untimely death, Diamond emerged as the American pediatric hematologist *par excellence*. His role cannot be described solely in terms of his publications, which are too numerous to be listed here. He became the mentor of a whole generation of pediatric hematologists who later held, and in most instances still hold, key positions in teaching institutions throughout the United States. Directly or indirectly we all owe him a debt of gratitude, even those of us who from time to time disagreed with some of his ideas. This writer vividly remembers his first meeting with Dr. Diamond, when as a lowly intern in 1935 he consulted him in connection with a case of Cooley's anemia, then an unheard-of rarity in the small New England hospital where he served. This writer made the pilgrimage to Children's Hospital—which under Blackfan was forbidden territory to those who were not graduates of Harvard, Yale, Columbia, or Johns Hopkins—with some trepidation. His fears were not allayed when he laid eyes on Dr. Diamond, rather fierce-looking in a dark, Assyrian sort of way. But Diamond proved to be a gracious consultant, willing to discuss the case at hand without condescension or conceit with an insignificant beginner, to listen to the history and examine the blood films, and above all to confirm the beginner's diagnosis. Over the years, hundreds of colleagues and young would-be hematologists came to appreciate "L.K.'s" kindness and unfailing courtesy. Of his numerous contributions one need mention here only the "Diamond-Blackfan" syndrome of hypoplastic anemia[74]; the studies on the nature, diagnostics, and treatment of hemolytic disease; and the *Atlas*, an outstanding achievement for its day, which was his work rather than Blackfan's. But perhaps even more important was the guidance and encouragement he provided for pediatric hematologists of the next generation, of whom—at the risk of being selective—we can name here only a few: Fred ("Hal") Allen, Park Gerald, Frank Oski, N. T. Shahidi, Victor Vaughan, and William Zinkham.

Less influential, though no less respected, was the late Carl Smith of New York. His book, *Blood Diseases of Infancy and Childhood*,[75] was the first of its kind in the United States and for many years served as the major reference work in the field. Smith's most important contribution was the description of infectious lymphocytosis, an essentially asymptomatic condition associated with a blood picture reminiscent of that of whooping cough (or chronic lymphocytic leukemia), endemic and probably of viral origin. He took a great interest in thalassemia and established a model outpatient transfusion service at The New York Hospital. Carl Smith was a modest and generous man, always willing to praise and give credit, even when credit was not due. Through his untiring efforts, Cornell became one of the important centers of pediatric hematology on the East Coast.

The prime mover in the field on the West Coast was Philip Sturgeon, who created the hematology service at the Children's Hospital of Los Angeles. He emerged about 1950 as an independent investigator interested in the study of the infantile bone marrow. His research provided quantitative measurements, then badly needed,[76] and stimulated the diagnostic use of bone marrow aspiration. A great traveller and sportsman in private life, Sturgeon combined in his work the elements of common sense and scientific curiosity, establishing the outstanding hematology clinic that was later carried on by his successor, Dennis Hammond. In the midst of a productive career, Sturgeon surprised his friends and colleagues by retiring to Zermatt in Switzerland, but skiing and hiking even in the most glorious of landscapes was not enough to fill his existence, and after a few years he returned to his work, and California.

The fact that a major pediatric teaching institution in the United States (or in many European countries, for that matter) today is almost unthinkable without a pediatric hematologist reflects the influence of a few model institutions in the post–World War II era. We have noted the importance of a Diamond "school" of pediatric hematology. During this same critical era, the only other center of comparable importance was the Hematology Service at the Children's Hospital of Michigan in Detroit, which this writer was privileged to direct, and which over a quarter of a century turned out well over 100 fellows, many of them today directing services of their own in the United States and abroad, among them Audrey Brown, Flossie Cohen, Eugene Kaplan, Sanford Leikin, Jeanne Lusher, and William A. Newton. The work of this group includes contributions to the knowledge of ABO hemolytic disease, fetal-maternal hemorrhage, immune hemolytic anemia, the hemoglobinopathies, purpura and other bleeding disorders, and the therapy of childhood leukemia. The creation some time ago of a subspecialty board in pediatric hematology, whether or not it serves a practical purpose, is a sure indication that among Boston, Detroit, Los Angeles and San Francisco, New York, and more recently New Haven, Cincinnati and Syracuse, Minneapolis and Memphis, and Seattle and Houston, a sufficiency of man- (and woman-) power exists to provide service, teaching, and research at a high level of excellence today and in the future.

Throughout its history, pediatric hematology has benefited from the advances of adult hematology, and in fact some of its major achievements rest on contributions made by scientists in other fields (e.g., immunology, chemistry, genetics, and physiology). A striking example is the history of hemolytic disease of the newborn. In

1938, Ruth Darrow, a pathologist who had a deep personal interest in the subject, having experienced a series of stillbirths, reflected on the pathogenesis of what was then called erythroblastosis fetalis.[77] Assembling all of the then known facts, notably the sparing of the first child, the involvement of all or most children born after the first afflicted baby, and the range of clinical and hematologic manifestations, she discarded all the current theories and concluded that the disease could be explained only as the result of maternal sensitization to an as yet unknown fetal antigen—a splendid example of the value of intelligent speculation.

Within 3 years Darrow's hypothesis was confirmed, and the Rh factor, described in a brief communication by Landsteiner and Wiener[78] in 1940, was identified as the offending antigen. Wiener,[79] and independently Levine,[80] observed transfusion reactions after administration of ABO-compatible blood that could be attributed to Rh antibodies. It was Levine, observing such a reaction in a woman who had received no prior transfusions[81] but had received blood from her husband after delivering a stillborn fetus, who recognized the relationship between the Rh factor and hemolytic disease of the newborn.[82] He showed that mothers of affected infants possessed antibodies that reacted with most random blood samples and with blood samples of their husbands and children but not with each other's. Gentle, unassertive, and scholarly, Levine characteristically sought the opinions of those experienced in neonatal pathology before publishing his revolutionary conclusion. This writer remembers Levine's visit to his laboratory in Detroit in this connection, which took place sometime in 1941. Bubbling with excitement yet reluctant to overturn established dogma and aware that he was venturing into uncharted seas, Levine was visibly reassured when his attention was called to Ruth Darrow's paper in the *Archives of Pathology*. But the serologic evidence was conclusive in itself, and the paper Levine and his associates published the same year bore the title "The role of isoimmunization in the pathogenesis of erythroblastosis." Levine had been an associate of Landsteiner at the Rockefeller Institute, but by this time he had withdrawn from that prestigious institution and was working at a hospital in Elizabeth, New Jersey, a modest, unpretentious man, content to pursue his research in any setting. When this writer first knew him, he was a devoted paterfamilias, amateur pianist, and bridge player. After the death of his wife he moved to New York City and continued his work at the Sloan-Kettering Institute, where he remains active to this day. The scope and the fruitfulness of his investigations, which extend from fetal-maternal isoimmunization to the relationship between blood group and cancer antibodies, have made him one of the most creative scientists of our time.

The names of Levine and Alexander Wiener were antithetically linked for the generation that witnessed their ascent, largely because both had been associates of Landsteiner and both contributed enormously to the knowledge of immunohematology and of human genetics, but above all because their views often clashed. This was confusing for the bystanders but in no way detracts from the achievements of each man. Wiener's role in the technical and conceptual understanding of hemolytic disease, both Rh and ABO, cannot be underestimated, but his obsession with nomenclature, his tendency to pile hypothesis upon hypothesis, usually without bothering to inform the reader that he was discarding pieces from the bottom without toppling the edifice, and most of all his imperviousness to the needs of clinicians unfamiliar with the mysteries of blood group immunology isolated him from the mainstream of clinical investigation. Of Wiener's enormous output—by 1954, when the theory of Rh isoimmunization was essentially complete, he had published more than 333 papers, and a typical Wiener bibliography might contain 60 references by A. S. Wiener (with or without et al.)—the contributions relevant to pediatric and obstetric practice were above all those dealing with the "blocking" Rh antibodies,[83] which he discovered and named "univalent," recognizing that they alone could pass the placental barrier and cause disease in the fetus.[84] He was one of the pioneers of exchange transfusion[85] and personally performed the procedure countless times at the Brooklyn Jewish Hospital, but his technique involving transection of the radial artery and the use of heparinized blood did not gain general acceptance. Less reticent to invade the domain of the clinician and the clinical pathologist than his rival Levine, he proposed ingenious but purely speculative theories of the pathophysiology of hemolytic disease that did not stand the test of time and tended to detract from his brilliant achievements in his proper field of blood group immunology. Personally a likable, friendly, unassuming man, he was always in the thick of a battle in which he was his own worst enemy.

Rh hemolytic disease has become a rarity. Within the life span of one generation the condition was defined, its etiology and pathogenesis identified, effective treatment devised, and a program of prophylaxis instituted that prevents maternal sensitization and has virtually eliminated the disease. This crowning achievement rests on the work of two teams of investigators working independently in Britain and the United States: Clarke and Finn in Liverpool,[86] and Freda, Gorman, Pollack, and their associates in New York.[87] Starting from different theoretical premises, both groups, by 1967, had demonstrated the effectiveness of passive isoimmunization of previously unsensitized mothers by means of a potent anti-Rh gamma globulin. The story of the conquest of hemolytic disease of the newborn is matched by few other chapters in the history of medicine.

The modern era of leukemia therapy begins in the 1940s with the work of Sidney Farber,[88] then pathologist at Children's Hospital of Boston and the leading pediatric pathologist in the United States and indeed the world, who in 1948 developed the concept of cancer chemotherapy. Farber had the good fortune of finding, in Subarov of Lederle Laboratories, a chemist able to give

him the "antifol" compounds he needed, but the idea of disrupting the growth of malignant cells with antimetabolites was his, and he pursued and promoted it with single-minded energy. It led him to the creation of the Children's Cancer Research Foundation and to the organization of a vast program of clinical and fundamental research that in turn gave rise to the nationwide collaborative studies sponsored by the National Cancer Institute and to the efforts of countless institutions and individuals the world over. Although married to a charming woman of great artistic talent, and the father of gifted and lively children, Farber was a man of almost monastic dedication to his work, a magnificent hermit who spent day and night in his rather resplendent cell in the Jimmy Fund building planning new approaches, an indefatigable optimist who was convinced from the beginning that a cure for leukemia would come forth and who did much to bring it nearer.

It is a little known irony of fate that Farber's concept of antimetabolite therapy evolved as the result of a faulty—or at least doubtful—observation, namely the impression that the administration of folic acid accelerated the growth of leukemic cells in the bone marrow. This writer became privy to this information because it was he who, during a visit to Boston in 1946, showed his former chief slides of aspirated bone marrow from leukemic children. Farber, hitherto strictly a "tissue pathologist," became very interested in the cytologic method and switched from surgical biopsies to needle aspirations. At that time folic acid had just become available, and in view of its striking effects on the bone marrow in megaloblastic anemia, Farber decided to investigate its effects on leukemia. From sequential examinations he gained the—probably erroneous—impression that the administration of folic acid per os led to more rapid growth of the leukemic cell population. It seems unlikely that the difference, if any, between treated and untreated patients was real, given the pitfalls of quantitating the cellular elements of aspirated bone marrow, but correct or not, the observation gave rise to the idea of using folic acid antagonists, of which aminopterin was the first, and the era of cancer chemotherapy had begun.

Shortly afterward, in 1949, new ground was broken in another field. In that year, by coincidence, two papers bearing on the same subject from different angles appeared within a few months of each other; they were destined to revolutionize the study of what became known as the "hemoglobinopathies." One was the report of Linus Pauling, Harvey Itano, and their co-workers[89] identifying sickle hemoglobin as a discrete protein separable by electrophoresis from normal hemoglobin, and characterizing sickle cell anemia as a "molecular disease." The other was James V. Neel's study of the genetics of sickle cell anemia and the sickle trait, establishing the former as the homozygous and the latter as the heterozygous state for the sickling gene.[90] The findings of the two reports meshed and became the fountainhead of a veritable flood of investigations leading to the discovery

of other hemoglobinopathies and enormously widening the scope of human genetics. The next major achievement was Vernon Ingram's demonstration, by means of the "fingerprinting" of hemoglobin fragments obtained by tryptic digestion, that sickle hemoglobin differs from normal adult hemoglobin (HbA) only in the replacement of a single amino acid among the more than 300 components of the half-molecule, and his subsequent identification of the abnormality as the substitution of a valine for a glutamic acid residue.[91,92] Since then, abnormalities in the amino acid sequence of the hemoglobin molecule (for the most part involving β chain mutations) have been found in hundreds of variants, and amino acid sequencing has become a basic tool of molecular genetics.

Following the identification of point mutations affecting the amino acid skeleton of globin molecules as the basis of sickling and other hemoglobinopathies, it seemed logical to search for similar structural anomalies of hemoglobin in thalassemia and, when none were found, to postulate "silent" mutations (i.e., amino acid substitutions that did not alter the electrophoretic behavior of the hemoglobin, but inhibited the rate of its synthesis).[93] While this hypothesis proved to be incorrect, it implied the valid assumption that, in analogy to the known structural mutants, the abnormality would be specific for either the α or β chain synthesis. This assumption was made explicit in 1959 by Ingram and Stretton,[94] when they postulated two classes of thalassemia, α- and β-thalassemias, corresponding to the α and β chain variants, respectively, of the hemoglobinopathies proper. This concept proved to be extraordinarily fruitful. It soon became apparent that the thalassemias constitute a highly heterogeneous group of disorders, and that these disorders generally can be classified as either α- or β-thalassemias. Following the development of a method for separating α and β (as well as γ and δ) chains by Weatherall and co-workers,[95] it became possible—by means of incorporating radioactive amino acids into the hemoglobin of reticulocytes in vitro—to determine the rate of synthesis of these chains directly and to identify α- and β-thalassemias as disorders of globin chain production of one or the other type. A new explosion of knowledge began with the demonstrations by Nienhuis and Anderson,[96] and Benz and Forget[97] of reduced β chain synthesis by β messenger RNA from β-thalassemic patients, measured in a cell-free heterologous system. The emphasis now shifted to the investigation of quantitative and qualitative defects of mRNA. As additional new techniques became available—e.g., the use of DNA polymerase (reverse transcriptase) to make complementary DNA from mRNA templates, the mapping of DNA sequences by means of restriction endonucleases, and the cloning of DNA fragments—it was possible to identify coding, transcription, translation, and many other defects in the genetic machinery of both α- and β-thalassemic cells. This writer cannot trace the ramifications of this work, which is still ongoing and is discussed elsewhere in this book, nor would I presume to select the names of

the investigators from among the many—in the United States, Great Britain, Greece, Thailand, and many other countries—who deserve special recognition. Suffice it to say that the elucidation of the defects in the various forms of thalassemia constitutes one of the great triumphs of biomedical and genetic research. The hoped-for conquest of these disorders surely will come from the application of this knowledge.

In yet another field, that of the enzymopathies, the red cell proved to be an almost inexhaustible source of information of equal interest to the hematologist and the geneticist. The point of departure was the 1956 report of Carson and associates[98] of a deficiency of glucose-6-phosphate dehydrogenase (G-6-PD) in primaquine-sensitive erythrocytes. Not only did this prove to be the explanation for the acute severe hemolytic anemia seen in certain adults who had received the antimalarial drug but, as shown within 2 years by Zinkham and Childs,[99] it also accounted for the then common hemolytic anemia associated with naphthalene poisoning in infants and young children (described in 1949 by this writer and Leonard Apt[100]), as well as for the previously mysterious hemolysis associated with favism, elucidated by Sansone in Genoa.[101] Through the investigations of Kirkman and co-workers[102] and those of Marks and associates,[103] it was soon apparent that G-6-PD deficiency is genetically as heterogeneous (and geographically as widespread) as are the thalassemias. Of special interest to the pediatric hematologist and to the neonatologist are the numerous reports of an association of G-6-PD deficiency and neonatal hyperbilirubinemia in certain Mediterranean and African countries, as well as in China. In addition to the many mutants of G-6-PD, all under the control of genes located on the X chromosome, other defects of the pentose pathway inherited as autosomal recessives were found, but these proved to be rare and chiefly of theoretical interest. Of greater importance for the understanding of the hereditary nonspherocytic hemolytic anemias was the discovery of a whole series of defects in the glycolytic pathway, beginning with pyruvate kinase deficiency, by Tanaka and Valentine and their co-workers.[104] Here too, an association with severe neonatal hyperbilirubinemia was observed. Here too, a high degree of genetic polymorphism soon became apparent. Today, when the well-equipped pediatric hematology laboratory must be able to perform a whole range of red cell enzyme studies as a matter of course, it seems strange that less than a generation ago the entire field of the enzymopathies was *terra incognita*.

The same can be said for several other areas of hematology that are today considered essential, but that were hardly dreamed of a few decades ago. One example is cellular immunity. During much of this writer's early career the thymus was a wholly mysterious organ, "status thymico-lymphaticus" was a widely accepted entity (and an indication for the ill-founded practice of "prophylactic" irradiation), and the different classes and functions of lymphocytes, T and B cells, and helper, suppressor,

and killer cells were unknown. Similarly, immunologic tolerance, self-recognition and graft-versus-host disease, the HLA system, and the importance of these observations for bone marrow transplantation (and transplantation in general) are now such well-established concepts that it is easy to forget how recently they were elaborated. Still another example involves the origin of the various lines of blood cells. The existence of a common ancestral cell in the bone marrow, which earlier generations of hematologists so heatedly debated for so many years, was not established until the 1960s, when morphologic arguments suddenly became irrelevant in the face of Till and McCulloch's[105] demonstration of pluripotential colony-forming cells, and the subsequent studies of these and many other workers elucidating the conditions of amplification and differentiation of these precursors. A comparable quantum jump occurred in the field of blood coagulation. Only those who had to deal with the horrendous problems of hemophiliacs in the days before cryoprecipitates and factor VIII (and IX) concentrates made replacement therapy and home care possible can truly appreciate the magnitude of this progress.

It cannot be our purpose here to give a complete overview of our subject. To do so would require a book of its own and duplicate much of the information contained in the following chapters. From what has been said it is clear that pediatric hematology has come into its own. After a prolonged infancy beset by semantic and morphologic woes, it has moved out of the descriptive and empirical phase into an era of functional and physiologic concepts well beyond the fondest dreams of the pioneers. In the process, it has again become part of the mainstream of hematology, yet preserved its identity and its impetus. It seems fitting that this text, which represents the sum of current knowledge, should begin with an account of this evolution and a tribute to those who brought it about, the men and women who did the best they could with the tools available to them and on whose work the new generation is building.

ADDENDUM

Wolf Zeulzer's history of pediatric hematology has graced the pages of this textbook since its inception, and the editors of this, the seventh edition, see no reason to alter it in any way. Zeulzer knew many of the individuals who began our field, and he described them and their contributions with consummate skill. Since Zeulzer's exposition, Howard Pearson, who also knew many of the main actors, has provided a more up-to-date history from the perspective of an active clinical investigator and teacher of the discipline.[106]

However, neither Zeulzer nor Pearson were given enough space to describe the impact of the genetics revolution of the 1960s and 1970s on all of pediatrics and particularly on pediatric hematology and oncology. The tools that made the enormous recent advances in our

field possible were fashioned 40 years ago by basic scientists and first applied in globin genetics. Our burgeoning field has its present roots in the remarkable tumor virus program at Indiana University, where Luria, Dulbecco, and students such as Watson and Temin probed the human genome. The discovery of reverse transcriptase by Temin and Baltimore and of restriction enzymes by Nathans and Smith gave clinical investigators their first ability to attack the globin genes, discover the molecular basis of the disorders of hemoglobin, and develop prenatal diagnostics that could reduce disease incidence. Shortly thereafter and particularly after the discovery of polymerase chain reaction by Kary Mullis in the mid-1980s, the mysteries of the leukemias and the sarcomas began to be resolved and the complexities of the coagulopathies and disorders of immunity clarified. Pediatric hematology/oncology is now a discipline in full spate. However, its depth measurements have largely been made possible by basic molecular genetics laboratories.

All of this discovery and application through the science of clinical trial and outcome analysis has been of huge benefit to pediatrics and to patients and families, but the rate of change in our field has necessitated a marked alteration in our approach to training. In Pearson's history, attention is paid to the development of clinical board examinations, which are new creations of the past 25 years, but training programs that have as their primary goal achievement of a passing score on a long quiz make very little contribution to the growth and development of pediatric hematology and oncology. The real task is to create a clinically strong physician who has equally strong skills in biology, epidemiology, behavioral science, or biostatistics. These multiple demands strain trainees and trainers alike. The stress on trainees has been the subject of in-depth analysis by the National Institutes of Health (NIH), the agency most responsible for biomedical research training in the United States.[107] Although the NIH has made inroads on the problem,[108] the fact remains that the length of time necessary to train a fully qualified pediatric hematologist/oncologist who can make an intellectual contribution to the field is dauntingly long, and the training can never stop because the biologic rules of the road are ever changing. As Pearson emphasizes the complexity forces specialists to become sub-specialists and even sub-sub-specialists.

All this growth of knowledge demands that pediatric hematologists/oncologists learn to work in teams and value each others' contributions. Training programs must instill a cooperative attitude while still retaining that necessary drive on the part of investigators and full-time clinicians to be considered the very best in their fields. That competitive spirit drives any intellectual effort, but it must be tempered with the realization that the skills of others may be sorely needed in the clinic or in wet and dry laboratories.

Zeulzer and Pearson give us reason to be very proud of the history of pediatric hematology and oncology. This textbook is written to help others to contribute to that fascinating history. The editors take satisfaction from knowing that some of the readers of this edition will do exactly that.

The Neonatal Erythrocyte and Its Disorders

Carlo Brugnara and Orah S. Platt

THE NEONATAL ERYTHROCYTE

At no other time in the life of a patient is the physician confronted with as many diagnostic considerations in the interpretation of apparent disturbances in the erythrocyte as during the neonatal period.

The erythrocytes produced by the human fetus are fundamentally different from those produced by older infants and children. These cells possess different membrane properties, different hemoglobins, a unique metabolic profile, and a much shorter red cell life span. In a variety of pathologic conditions, erythrocytes bearing some of the properties of fetal erythrocytes again appear in the circulation. A better understanding of the factors that regulate fetal erythropoiesis and a precise definition of the fetal erythrocyte may eventually result in the development of a unifying hypothesis that explains these acquired disorders of erythropoiesis. Interpretation of hematologic abnormalities in neonates is confounded by the interactions of genetics, acquired disease in the neonate, and maternal factors with the gestationally related peculiarities of the fetal erythrocyte.

Development of Erythropoiesis

Hematopoiesis in the embryo and fetus can be divided into three periods conceptually: mesoblastic, hepatic, and myeloid (see also Chapter 6).[1-3] All blood cells are derived from embryonic connective tissue—the mesenchyme—and blood formation can first be detected by the 14th day of gestation. Isolated foci of erythropoiesis can be observed throughout the extraembryonic mesoblastic tissue in the area vasculosa of the yolk sac at 3 to 4 weeks after conception. Blood islands in the yolk sac differentiate in two directions. Peripheral cells in the islands form the walls of the first blood vessels, whereas the centrally located cells become the primitive blood cells, or hematocytoblasts.[4,5] The hemangioblast has been shown to be a common precursor for both blood and endothelial cells.[6,7] This three-stage migration of hematopoietic precursors from an initial vascular-mesoblastic area to a definitive erythropoietic organ via an intermediate stage seems to be conserved ontogenically, even between mammals and zebra fish.[8]

The first blood cells produced by the embryo belong to the red cell series. Two distinct generations of erythrocytes can be observed in the developing embryo. Red cells arise as a result of either primitive megaloblastic erythropoiesis or definitive normoblastic erythropoiesis. Both megaloblasts and normoblasts apparently derive from similar-appearing hematocytoblasts and develop through roughly similar but morphologically distinct series of erythroblasts. In the very early embryo, red cells arise from primitive erythroblasts. These cells were termed "megaloblasts" by Ehrlich because of their resemblance to the erythroid precursors found in patients with pernicious anemia.[9] Megaloblasts are large cells with abundant polychromatophilic cytoplasm, and they possess a nucleus in which fine chromatin is widely dispersed. Megaloblasts give rise to large, irregularly shaped, somewhat hypochromic erythrocytes that can be seen in circulating blood 4 to 5 weeks after conception. The primitive erythroblasts arise primarily from intravascular sites; as development continues, these cells are gradually replaced by smaller cells of the definitive or normoblastic series.

Normoblastic erythropoiesis begins at about the 6th gestational week, and enucleated macrocytes enter the circulation by the 8th week; by the 10th week of development, normoblastic erythropoiesis accounts for more than 90% of the circulating erythrocytic cells. Maturation of normoblastic erythroid cells resembles that seen in postnatal life, and these cells give rise to enucleated erythrocytes and are primarily extravascular.

By about the fifth to sixth week of gestation, blood formation begins in the liver. In the period between the 5th and 10th weeks, the liver undergoes a substantial increase in size, with an associated increase in the total nucleated cell count from 2.3×10^6 to 1.7×10^8 cells.[10] The fetal liver appears to be a site of pure erythropoiesis, and during the third to fifth months of gestation, erythroid precursors represent approximately 50% of the total nucleated cells of this organ.[11] Migration of pluripotent cells and early progenitors via the bloodstream is probably responsible for the transition from yolk sac to liver.[10] However, more recently it has been proposed that circulating stem cells and progenitors do not derive from the yolk sac but from an intraembryonic site, the so-called aorta-gonad-mesonephros (AGM) region.[12,13] This is supported by the fact that stem cells derived from the yolk sac can produce transient primitive hematopoiesis but cannot reconstitute definitive hematopoiesis[14,15] (Fig. 2-1).

The liver is the chief organ of hematopoiesis from the third to the sixth fetal month and continues to produce formed elements into the first postnatal week (Fig. 2-2). During the third fetal month, hematopoiesis can also be detected in the spleen and thymus and, shortly afterward, in the lymph nodes. Blood cell formation can still be observed in the spleen during the first week of postnatal life.

Fukuda used electron microscopy to examine the characteristics of hepatic hematopoiesis in 26 human embryos and fetuses from 26 days after conception to 30 weeks of gestation.[16] The development of hepatic hematopoiesis appeared to correlate closely with histologic development of the liver. In the earliest stages of hepatic hematopoiesis, undifferentiated mononuclear cells, presumably stem cells, were present in the intercellular spaces of hepatocytes. With maturation of the fetus, the number of erythroid cells in the hepatic parenchyma increased, and stem cells diminished in number and eventually disappeared. These stem cells were exclusively observed in the extravascular spaces and were thought to derive from the septum transversum.

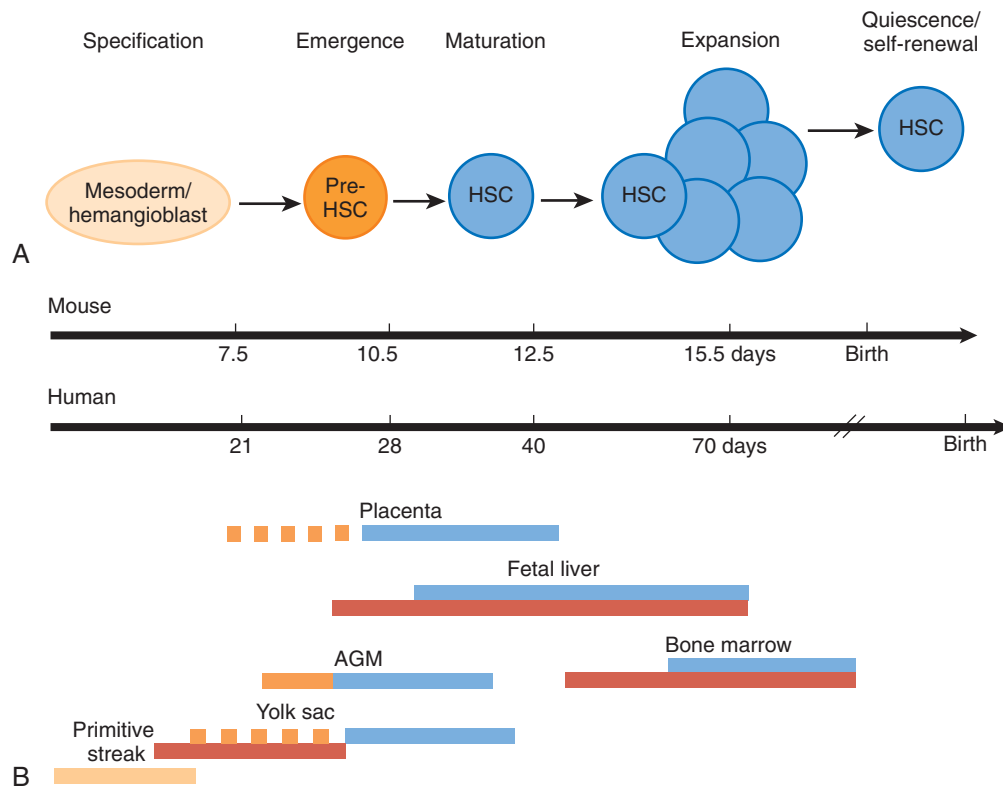
Erythropoietic progenitors from the livers of fetuses studied between 13 and 23 weeks of gestation appear to


FIGURE 2-1. Establishment of definitive hematopoietic stem cell (HSC) pools in mouse and human embryos. **A,** Hematopoietic development starts as specification of primitive streak mesoderm (yellow) into hematopoietic and vascular fates. Nascent HSCs undergo a maturation process (blue) that allows them to engraft, survive, and self-renew in future hematopoietic niches. Subsequently, fetal HSCs expand rapidly, after which a steady state is established in which HSCs reside in a relatively quiescent state in the bone marrow. **B,** Ages at which mouse and human hematopoietic sites are active. *Yellow bars*, mesoderm; *red bars*, active hematopoietic differentiation; *orange bars*, HSC genesis; *blue bars*, presence of functional adult-type HSCs. *Broken orange bars* for the yolk sac and placenta indicate that de novo HSC genesis has not been experimentally proven. AGM, aorta-gonad-mesonephros. *(Redrawn from Mikkola HKA, Orkin SH. The journey of developing hematopoietic stem cells. Development. 2006; 133:3733-3744.)*

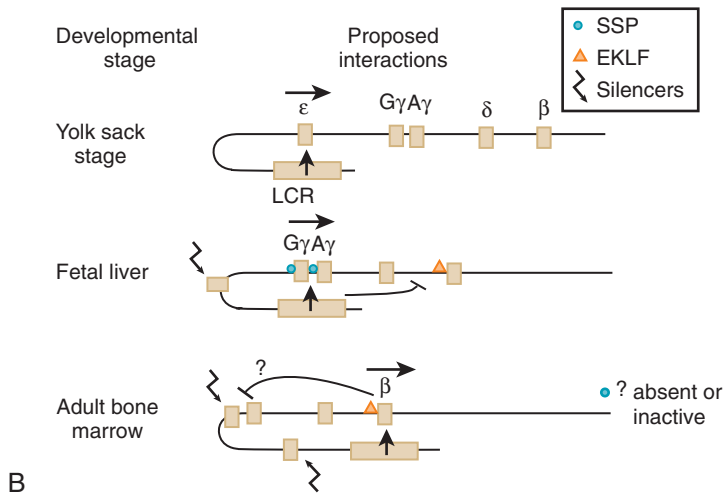
be more sensitive to humoral stimuli—colony-forming units–erythrocyte (CFU-E) for erythropoietin (EPO) and burst-forming units–erythrocyte (BFU-E) for burst-promoting activity—than progenitors from adult bone marrow do.[17] Large numbers of multipotent and committed (erythroid and granulocytic-monocytic) progenitor cells have been found in blood obtained by fetoscopy at 12 to 19 weeks of gestation.[12,18] These fetal progenitor cells are more sensitive than adult progenitor cells grown under the same conditions to appropriate stimuli, presumably as a consequence of intrinsic differences in the progenitor cells of fetal origin.[19,20] Functional and genetic differences between fetal and adult stem cells indicate that the hematopoietic stem cell is not an invariable cell type.[21]

The myeloid period of hematopoiesis commences during the fourth to fifth fetal month and becomes quantitatively important by the sixth fetal month. During the last 3 months of gestation, the bone marrow is the chief site of blood cell formation. Marrow cellularity becomes maximal at about the 30th gestational week, although the volume of marrow occupied by hematopoietic tissue continues to increase until term.[21] A summary of the time of

first appearance of the different blood cells in the various fetal hematopoietic organs, based on the observations of Kelemen and associates from an analysis of 190 fetuses and embryos, is provided in Table 2-1.[22]

Cord blood is rich in bone marrow progenitor cells and contains multipotential cell lines: granulocyte-erythroid-monocyte-macrophage (CFU-GEMM), erythroid (BFU-E), and granulocyte-macrophage (CFU-GM).[23] The frequency of circulating CFU-GM from the 23rd week of gestation to full term is consistently high and provides evidence that CFU-GM is produced in the yolk sac, as well as at other hematopoietic sites.[24] The frequency of BFU-E is highest at midgestation, with values being 3-fold greater than those for cord blood and 10-fold greater than those for adult bone marrow.[25] CD34+ circulating progenitors also peak at the second trimester and fall thereafter, with an inverse relationship with gestational age noted between 24 and 40 weeks.[26,27] Table 2-2 shows a comparison of circulating hematopoietic progenitors at different gestational ages.[18]

The in vitro behavior of progenitor cells obtained from umbilical cord blood is substantially different from that of progenitor cells in the bone marrow of adults. In


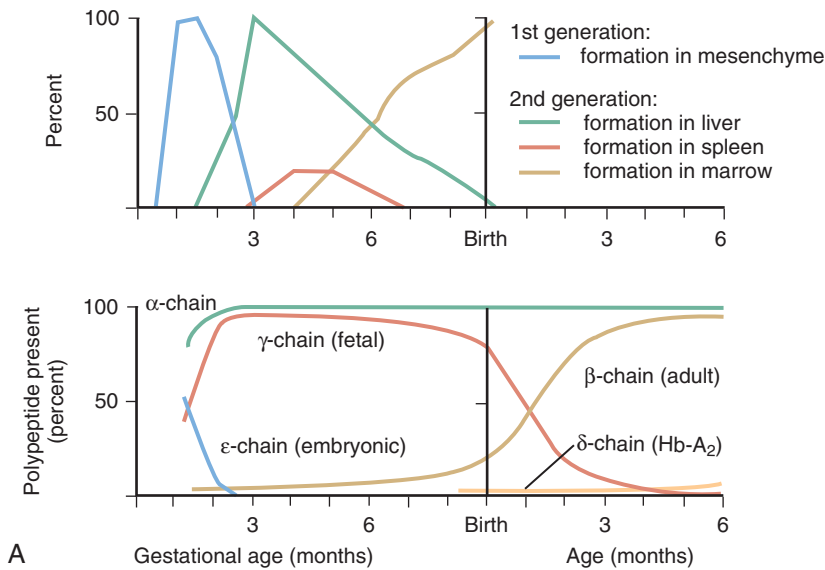


FIGURE 2-2. **A,** Hematopoietic sites and development of different globin chains during fetal life and early infancy. **B,** Globin gene switching in the human β-globin gene cluster. Some of the postulated interactions at each developmental stage of the human are indicated. *Arcs ending in oblique lines* are meant to depict competitive interactions. In the fetal liver stage, interaction of the β-globin genes with the locus control region (LCR) prevents β-globin expression despite the presence of EKLF, a β-globin gene–specific activator. In adult bone marrow erythroid cells, interaction of the β-globin gene with the LCR may facilitate shutoff of the β-globin gene (as indicated by ?). Though not established, EKLF is shown bound to the β-globin promoter at the fetal stage to emphasize that transcription of β-globin genes prevails even in its presence. The status of the stage-selector protein (SSP) complex, as well as the postulated embryonic/fetal-specific subunit in adult cells, is unknown (as shown at the *bottom*). It is likely that SSP is present at the yolk sac stage. If such is the case, interactions between the β-globin gene and the LCR presumably are dominant for β-globin expression. (*A, After Knoll W, Pingel E. Der Gang der Erythropoese beim menschlichen Embryo. Acta Haematol. 1949;2:369-380, with permission of Karger, Basel; and Huehns ER, Dance N, Beaven GH, et al. Human embryonic hemoglobins. Symp Quant Biol. 1964;29: 327-331. B, Redrawn from Orkin SH. Regulation of globin gene expression in erythroid cells. Eur J Biochem. 1995;231:271-281.*)

TABLE 2-2	Hematopoietic Progenitors Circulating in Fetal Blood

Rights were not granted to include this table in electronic media.
Please refer to the printed publication.

From Campagnoli C, Fisk NM, Overton T, et al. Circulating hematopoietic progenitor cells in first trimester fetal blood. Blood. 2000;95:1967-1972.

contrast to adult progenitors, which require the presence of multiple growth factors, fetal progenitors can mature in vitro with no growth factors present or with the addition of only one. Recombinant human erythropoietin (r-HuEPO),[28,29] interleukin-6,[30] interleukin-9,[31] and interleukin-11[32] are active as single agents in fetal but not adult progenitors. It has been shown that in vitro cultures of CD34+ fetal hematopoietic progenitors produce hematopoietic factors such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukin-3, which can sustain their growth factor–independent proliferation.[33] Exit from the G_0/G_1 phase of the cell cycle in response to stem cell factor is also accelerated in umbilical cord blood CD34+ cells.[34]

Adult hematopoietic stem cells are mostly quiescent, whereas fetal ones cycle at a higher rate.[35] An intrinsically regulated master switch takes place 3 to 4 weeks after birth (in mice) and facilitates the change from "fetal" to the "adult" type of hematopoietic stem cells.[36-38]

The number of hematopoietic progenitors in cord blood is in the range of the requirements for successful engraftment by bone marrow cells.[23] Although the average cord blood collection contains only 14% of the nucleated cells present in an autologous bone marrow collection, it contains 91.6% of the CFU-GM colonies, 24% of the CFU-GEMM colonies, and 29% of the BFU-E colonies.[23] Studies of long-term culture–initiating cells have indicated that the number of putative stem cells in cord blood is comparable to that of allogeneic bone marrow or peripheral stem cell collections.[39]

Human umbilical cord blood has been used successfully for hematopoietic reconstitution in patients with Fanconi's anemia,[40] aplastic anemia, X-linked lymphoproliferative disease, sickle cell anemia, leukemia, immune deficiency, genetic and metabolic diseases (e.g., Hunter's syndrome),[41,42] and severe hemoglobin E–β-thalassemia disease.[43-46] For recent reviews, see Ballen and Symthe and colleagues.[47,48] The clinical use of umbilical cord blood may be expanded based on evidence of the presence of vascular/endothelial progenitor cells.[49]

After birth, the amount of marrow tissue continues to grow, with no apparent increase in cellular concentration. The only way for an infant to increase cell production is to effect a more rapid turnover of cells or to increase the volume of hematopoietic tissue. This increase in tissue produces the marrow expansion that is most readily observed in the calvaria.

An increasing role for EPO is observed during the hepatic and myeloid phases of erythropoiesis. EPO is detectable in the cord blood of nonanemic premature infants in quantities that are comparable to or greater than those in the blood of normal adults.[50] Fetal erythropoiesis is only partially influenced by maternal factors and is primarily under control of the fetus. In the mouse, suppression of maternal erythropoiesis by hypertransfusion does not suppress fetal erythropoiesis,[51] nor does stimulation of maternal EPO production result in stimulation of fetal red cell production; these findings indicate that EPO is incapable of crossing the placenta.[52] The exact site of EPO production in the fetus is unknown, but the liver is a probable candidate. In other animal species, nephrectomy of the fetus does not influence EPO production or the erythropoietic response to stress such as bleeding.[53]

The development of hematopoiesis is controlled by the effect of growth factors on cell proliferation and activation of lineage-specific genes by transcription factors (nuclear regulators).[2,54] Some genes, such as *Scl/Tal1* (stem cell leukemia protein) and *Klf6*, are crucial for the embryonal development of both endothelial and hematopoietic cells.[55-57] The divergence of hematopoietic stem cells from their hemangioblastic precursor is accompanied first by the expression of CD41 (GBIIb, a megakaryocytic/platelet marker in adult hematopoiesis) and c-kit and then by the panhematopoietic marker CD45.[58] Some other genes, such as *Notch1*, and growth factors, such as hepatocyte growth factor (HGF) and bone morphogenic protein (BMP), are essential for early hematopoietic development but may not be required for definitive hematopoiesis.[59-63] Others, such as *Runx1*, *AML1/EVI1*, and other members of the AML1-CBFβ transcription factor complex, and genes crucial for the erythropoietic microenvironment, such as *paladin*, are essential for the establishment of definitive erythropoiesis.[64-66]

For each cell lineage, cell-specific transcription depends on critical DNA-binding motifs in promoters or enhancers. Differentiation in the erythroid series depends on the presence of GATA- and AP-1/NFE2-binding

proteins, as well as the transcription factors TAL1/SCL, EKLF, RBTN2, GATA-1, and GATA-2.[54,67-70]

A *GATA1* mutation has been shown to be responsible for a form of familial dyserythropoietic anemia and thrombocytopenia.[71] Other mutations have been described in newborns with Down syndrome and in a case of congenital erythropoietic porphyria.[72,73]

STAT5 is a latent cytoplasmic transcription factor, which after activation of the EPO receptor, binds to phosphorylated tyrosines on the receptor and itself becomes tyrosine-phosphorylated.[74,75] This process results in STAT5 dimerization and translocation to the nucleus, where it initiates transcription of target genes. STAT5 is critical during fetal erythropoiesis.[75] Mice mutant for both isoforms of STAT5 (STAT5A and STAT5B) show a profound alteration in fetal (definitive) erythropoiesis.[76] Fetal liver cells give rise to fewer erythroid colonies, and a marked increase in apoptosis is seen in vitro.[76] The fetal anemia of STAT5a$^{-/-}$5b$^{-/-}$ mice seems to resolve in 50% of adults, but adult mice are deficient in generating high erythropoietic rates in response to stress.[77] STAT5a$^{-/-}$5b$^{-/-}$ hematopoietic tissue shows a dramatic increase in early erythroblast numbers, but these cells fail to progress in differentiation.[77] The effects seen in the STAT5a$^{-/-}$5b$^{-/-}$ mice are mostly mediated by decreased expression of bcl-x$_L$, which is a crucial determinant of early erythroblast survival and plays a major role in fetal erythroid development and response to stress.[78] Thus, both STAT5 and bcl-x$_L$ seem to be crucial not only for fetal hematopoietic development but also for response to erythropoietic stress in adulthood.

Erythroid progenitors found in the liver, bone marrow, or peripheral blood of the fetus appear to produce identical quantities of fetal hemoglobin (HbF).[79] Fetal erythropoiesis results in the orderly evolution of a series of different hemoglobins. Developmentally, there is embryonic, fetal, and adult hemoglobin (Table 2-3). Globin genes are arranged in order of expression in the α- and β-globin clusters and are selectively activated and silenced at the various stages of erythroid development. Distal, *cis*-regulatory elements in the β-globin–like cluster are contained in the locus control region (LCR), which consists of four hypersensitivity sites[80]; additional *cis*-

regulatory downstream core elements (DCEs) have also been described.[81] Figure 2-1 presents some of the postulated interactions involved in gene switching for the human β-globin gene cluster.

The first globin chains to be produced are the ε chains, which appear to be similar to β chains in certain aspects of their structural sequences.[82] Before other chains begin to form, these unpaired globin chains may form tetramers (ε$_4$) that result in the presence of hemoglobin Gower-1 (Hb Gower-1). Almost immediately thereafter, α- and ζ-chain production begins, and Hb Gower-2 (α$_2$ε$_2$) and Hb Portland (ζ$_2$γ$_2$) are formed. Early γ-chain formation also results in the presence of HbF (α$_2$γ$_2$). By the time that the fetus has a crown-rump length of about 16 mm (about 37 days of gestation), Hb Gower-1 and Gower-2 constitute 42% and 24% of the total hemoglobin, respectively, with HbF accounting for the remainder.[83] At a crown-rump length of about 30 mm, HbF represents 50% of the total hemoglobin, and at a length of 50 mm it is responsible for more than 90% of the hemoglobin. Very small quantities of HbA begin to be found at 6 to 8 weeks of gestation.

Although Hb Portland may constitute as much as 20% of the hemoglobin at 10 weeks of gestation, only trace amounts are normally present at birth. The ζ chain is quite similar to the α chain in its amino acid sequences.[84] Studies of steady-state liver messenger ribonucleic acid (mRNA) globin levels in human embryos (gestational age, 10 to 25 weeks) indicate that levels of globin proteins are regulated by the relative amount of each globin mRNA.[85] Studies on the physiologic properties of embryonal hemoglobin will be facilitated by their recent expression in a transgenic mouse model.[86]

The absolute rate of synthesis of hemoglobin or formation of red cells during fetal life is difficult to estimate because neither the absolute increase in circulating hemoglobin or red cells nor the absolute rate of destruction is known. The absolute rate of production of red cells at birth, however, can be estimated fairly well. A value of 2.5% to 3.0% per day of the circulating red cell mass, or about 4.5 mL/day in a 3.5-kg infant, can be calculated by determining the relative number of circulating reticulocytes and the in vitro mean life span of reticulocytes obtained from cord blood.[87] A very similar figure was obtained by analysis of the distribution kinetics of radio-iron in plasma and red cells (Fig. 2-3).[88]

The intrinsic stability of embryonic, fetal, and adult hemoglobin differs by 3 orders of magnitude, with subunit interface strength increasing from the embryonic to the fetal to the adult types. These differences may play a role in determining the life span of the three cell types.[89]

Measurement of circulating red cell volume in newborn infants at various gestational ages, as shown in Figure 2-4, demonstrated an increase in red cell mass of about 1.5% per day.[90] Assuming a mean life span of these cells of 45 to 70 days (discussed later in this chapter), these data show a production rate of 3.6% to 4.2% per

Erythropoiesis after Birth

The rate of hemoglobin synthesis and red cell production decreases dramatically during the first few days after delivery. Production of red cells (or hemoglobin) decreases by a factor of 2 to 3 during the first few days after birth and by a factor of about 10 during the first week of life. This sudden and marked decrease in red cell production is undoubtedly initiated by the equally sudden increase in tissue oxygen level that takes place at birth, as reflected by the virtual disappearance of EPO in plasma.[95] At the time of birth, between 55% and 65% of total hemoglobin synthesis consists of HbF.[96] Thereafter, synthesis of HbF decreases much more rapidly than that of HbA; the time course is shown in Figure 2-5. The switch from HbF to HbA is delayed in infants of diabetic mothers,[97] in those with metabolic diseases characterized by an inability to metabolize propionic acid,[98] and in infants with chronic bronchopulmonary dysplasia.[99] Synthesis of HbF can also be "reactivated" in severe cases of anemia of prematurity.[100] The rate of production of red cells (and of hemoglobin), which reaches a minimum during the second week of life, increases during the following months and reaches a maximum, at about 3 months of age, of approximately 2 mL of packed red cells per day, or about 2% of the circulating red cell mass per day.

Life Span of the Erythrocyte

The life span of erythrocytes obtained from term infants is somewhat shorter than that of red cells from adults,

day of red cell volume 2 months before term and a rate of 2.5% to 3.5% per day of red cell volume at term. The combined data therefore indicate very strongly that the rate of red cell production during the latter part of fetal life is quite high—about threefold to fivefold that of a normal adult subject. This finding is in agreement with the well-established facts that at the same period of development, all the bones are filled with red marrow, the concentration of red cell precursors per unit volume of marrow is markedly increased,[91-93] and the number of erythroid and granulocyte-monocyte progenitors in cord blood is greater than that in normal adult blood.[94]

whereas the life span of red cells obtained from premature infants is considerably shorter. The more immature the infant, the greater the degree of reduction in life span.

Because of their relative simplicity, studies using ^{51}Cr have been performed most extensively. The results of numerous investigators are summarized in Table 2-4.[101] These data indicate that the mean ^{51}Cr half-life of erythrocytes from term infants is 23.3 days (range, 13 to 35 days), whereas the mean value for red cells from premature infants is 16.6 days (range, 9 to 26 days). Conversion of these fetal red cell life spans for term infants from ^{51}Cr half-life to true red cell survival indicates an actual life span of approximately 60 to 70 days. Similar calculations for the red cells of premature infants yield values of 35 to 50 days.

Wranne, using the carbon monoxide technique, found that 1.5% of term infants' red cell mass was broken down daily during the first week of life.[96] Wranne concluded that the life span of most erythrocytes formed during the late fetal and early neonatal period is only 90 days. Equations derived from accumulated data led Bratteby and Garby to the conclusion that the mean life span of cells produced during the last 60 days of fetal life was between 45 and 70 days and that the life span frequency was skewed, with a majority of the cells dying before the mean life span was achieved.[102]

No unifying hypothesis has been presented to explain why the red cells produced in fetal life have a shortened life span. Landaw and Guancial demonstrated a similar shortening of the life span of erythrocytes obtained from the fetal rat.[103] In their studies, the decrease in life span correlated with red cell rigidity, as reflected by red cell filtration studies.[104] These observations suggest that alterations in membrane function and increased susceptibility to mechanical damage may ultimately be responsible for the decreased life span of fetal erythrocytes.[105]

Unique Characteristics of the Neonatal Erythrocyte

The Red Cell Membrane

Simple clinical laboratory studies, as well as sophisticated biochemical procedures, have provided evidence that the red cell membrane of fetal erythrocytes differs from that of its adult counterpart.

The red cells from normal newborns are slightly more resistant to osmotic lysis than those of adults are.[106] A minor population of cells with increased osmotic fragility is also present; however, these cells appear to be selectively destroyed within the first several days after birth.[101] The mechanical fragility of cord blood red cells is likewise increased. Neonatal reticulocytes are composed of mostly motile R1 reticulocytes,[107] which have been shown to be capable of performing receptor-mediated endocytosis.[108] Neonatal red cells have greater total and membrane-associated myosin content than adult red cells do[109]; possibly, this increased content is a remnant of these cells' motile machinery.

Figure 2-6 presents flow cytometric measurements of cell volume and hemoglobin concentration in neonatal red cells versus adult red cells. Measurements of reticulocyte indices in neonatal and adult blood are also presented. Neonatal red cells have a larger volume and lower hemoglobin concentration than adult cells do.[110] Neonatal reticulocytes also have a larger volume and lower hemoglobin concentration than adult reticulocytes do. Macrocytosis is more prominent in premature newborns and appears to decrease with gestational age, probably as spleen function matures and assumes a greater role in red cell membrane remodeling. Spleen function and remodeling are major determinants of the decrease in cell volume observed when reticulocytes become mature erythrocytes. The difference in volume between reticulo-

cytes and erythrocytes is greatly reduced in blood from premature newborns, another indication of reduced spleen function.[110]

The red cells of normal newborns also appear different by conventional light microscopy, interference phase microscopy, and electron microscopy. Zipursky and coworkers, via careful analysis of wet preparations suspended in 0.2% glutaraldehyde, observed that 78% of erythrocytes from adults appeared as biconcave discs and 18% as "bowl" forms; in contrast, only 43% of cells from term infants appeared as discs and 40% as bowl forms.[111] In addition, only up to 3% of cells from normal adults

appeared as assorted spherocytes and poikilocytes of various types, whereas up to 14% of cells from term infants showed these morphologic distortions.

In premature infants, the departure from normal adult cells was even more marked. In these infants, 40% of the cells were discs, 30% were bowls, and 27% displayed a variety of morphologic disturbances (Fig. 2-7). The high frequency of dysmorphology in hematologically normal neonates creates great difficulty in diagnosing specific disorders of the red cell at birth. When the dysmorphology is severe, the condition is sometimes called "infantile pyknocytosis." In this usually transient disor-

der, red cell life span is even shorter than normal,[112] and the disorder may represent a neonatal form of hereditary ovalocytosis (see Chapter 15). Using interference phase microscopy, Holroyde and associates[113] observed that the red cells from both premature and term infants displayed the "pocked" appearance that was first noted by Nathan and Gunn in splenectomized patients with thalassemia.[114] These surface alterations are believed to reflect the presence of vacuoles and internal structures just below the red cell membrane. They were observed in greatest number among the most immature infants. Similar surface abnormalities are seen in patients without spleens and in those with sickle cell hemoglobinopathies with reduced splenic function.[113,115] The presence of these red cell "pocks" is presumed to reflect impaired splenic function in the immature infant but may also be a reflection of the tendency of fetal erythrocytes for increased vesicle formation, which overwhelms the clearance capacity of the spleen.[116,117]

Examination of fetal red cells by electron microscopy also reveals the presence of vacuoles and internal structures just below the cell membrane.[118,119] Freeze-etching and transmission electron microscopy of fetal erythrocyte membranes indicate that the protoplasmic fracture faces have 24% more intramembrane particles than do those of adult cells and that the number of particles on

exoplasmic fracture faces exceeds that of the adult by 45%.[120]

The membrane of fetal erythrocytes also appears to be more fluid than that of adult cells. Both ferritin-labeled anti-A antibodies[119] and concanavalin A[121] are taken up by endocytosis in the mature erythrocytes of newborn infants but not by cells from normal adults. This unique phenomenon does not appear to be the result of differences in lipid viscosity of the membrane.[122]

When compared with adult cells, the erythrocyte membrane of the newborn has more binding sites for insulin,[123] more insulin-like growth factor,[124] and more prolactin[125]; however, it has fewer digoxin receptor sites[126] and reduced membrane acetylcholinesterase.[127,128] Membrane proteins from both premature and term infants are indistinguishable from those of normal adults when solubilized in sodium dodecyl sulfate and analyzed with polyacrylamide gel electrophoresis.[121,126]

The red cells of the cord blood of full-term infants contain increased quantities of total lipid, lipid phosphorus, and cholesterol per cell, although the percentage of total lipid composed of lipid phosphorus and cholesterol is similar to that found in adults.[129] These erythrocytes have a greater percentage of their phospholipid as sphingomyelin and a lesser proportion as lecithin. Phospholipid fatty acid patterns in cord blood erythrocytes show a greater percentage of palmitic, stearic, arachidonic, and combined 22- and 24-carbon fatty acids and a lesser proportion of oleic and linoleic acid. The cells are much more prone to lipid peroxidation on oxidant challenge,[130,131] which may contribute to their removal from the circulation after birth. It is likely that the relative hyposplenism of the neonate contributes to these membrane alterations. Erythrocytes of babies born to mothers with gestational diabetes have reduced choline phosphoglycerides and reduced total ω-6 and ω-3 fatty acids.[132]

From an immunologic perspective, the erythrocyte membrane of the newborn is also different from that of the adult. At birth, the Lewis system of absorbed serum antigens is incompletely expressed, partly because the receptor sites of the membrane are weak or absent. In the ABO system, the A antigen, particularly the A_1 antigen, and the B antigen sites are weakly expressed, and in the Ii system, the I antigen is either weak or absent. Other weakly expressed antigens are Sd^a, P1, Lu^a, Lu^b, Yt^a, Xg, and Vel.[133]

The cells are less permeable to the nonelectrolytes glycerol and thiourea[134]; they display reduced potassium influx via the Na^+,K^+-adenosine triphosphatase (ATPase) and Na^+,K^+,Cl^- cotransport systems[135] and altered kinetics of glucose transfer[136]; and they are prone to acid lysis.[137] The number of Na^+-K^+ pumps, estimated from ouabain binding, is greater in premature infants than in term infants.[138] The chloride and bicarbonate transport systems of fetal and adult red cells are similar.[139]

The filtration rate of red blood cells from preterm and term infants is lower than that of adults.[140-142] This decreased filterability may be a manifestation of the larger size of erythrocytes from newborns rather than their different lipid composition.

Metabolism of Erythrocytes of the Newborn Infant (Box 2-1)

Enzymes of the Embden-Meyerhof Pathway

Numerous investigators are in agreement that the activity of the enzymes phosphoglycerate kinase and enolase in the red cells of newborn infants is much more intense than would be anticipated from their young cell age.[128,143-147] The activity of the enzymes glyceraldehyde-3-phosphate dehydrogenase and glucose phosphate isomerase is also probably significantly greater than would be anticipated from cell age.[145]

The activity of phosphofructokinase (PFK), a rate-controlling enzyme in glycolysis, has repeatedly been found to be lower than normal in the red cells of newborn infants.[144,145,148] The decreased PFK activity may reflect the accelerated decay of an unstable enzyme. Travis and Garvin fractionated cord blood red cells into cohorts of varying cell age and compared them with adult red cells fractionated in similar fashion.[149] The rate of decline in pyruvate kinase activity was essentially the same in neonates and adults, whereas PFK activity in cord erythrocytes decreased at a significantly greater rate than it did in adult erythrocytes.

Studies of Vora and Piomelli have provided a clear understanding of the nature of PFK in fetal erythrocytes.[150] They found that human muscle PFK and liver PFK are homotetramers, each of which is composed of identical subunits, which they termed "M_4" and "L_4." Study of adult erythrocytes revealed the presence of three heterotetramers—M_3L, M_2L_2, and ML_3. Analysis of cord blood erythrocytes revealed the presence of the three heterotetramers in adult erythrocytes; the L_4 isoenzyme was also identified. The presence of the liver homotetramer in fetal erythrocytes may be responsible for the decreased PFK stability observed by Travis and Garvin.[149]

Differences in the distribution of other red cell isoenzymes have also been described. Hemolysates normally contain two isoenzymes of hexokinase, types I and III. Holmes and co-workers found that in the cells of a newborn infant, type II hexokinase was the predominant isoenzyme.[151] Schröter and Tillman, in contrast, observed that type I predominated, although the predominance of type I was not characteristic of young cells in general but was a unique feature of the red cells of newborn infants.[152] Chen and associates also observed differences in the distribution of hexokinase isoenzymes obtained from first-trimester and midtrimester fetuses.[153]

Enolase exists as multiple isoenzymes in erythrocytes as well, and the distribution of enolase isoenzymes appears to be a unique characteristic of fetal erythrocytes.[154]

Chen and associates studied a total of 26 enzyme patterns in hemolysates prepared from 11 fetuses ranging

Box 2-1	Metabolic Characteristics of the Erythrocytes of Newborns

CARBOHYDRATE METABOLISM

Glucose consumption increased
Galactose more completely used as substrate both under normal circumstances and for reduction of methemoglobin*
Decreased activity of the sorbitol pathway*
Decreased triokinase activity*

GLYCOLYTIC ENZYMES

Increased activity of hexokinase, phosphoglucose isomerase,* aldolase, glyceraldehyde 3-phosphate,* phosphoglycerate kinase,* phosphoglycerate mutase, enolase,* pyruvate kinase, lactate dehydrogenase, glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, galactokinase, and galactose 1-phosphate uridyltransferase
Decreased activity of phosphofructokinase*
Different distribution of hexokinase isoenzymes*

NONGLYCOLYTIC ENZYMES

Increased activity of aspartate transaminase and glutathione reductase
Decreased activity of NADP-dependent methemoglobin reductase,* catalase,* glutathione peroxidase, superoxide dismutase, carbonic anhydrase,* adenylate kinase,* and glutathione synthetase*
Presence of α-glycerol-3-phosphate dehydrogenase*

ATP AND PHOSPHATE METABOLISM

Decreased phosphate uptake,* slower incorporation into ATP and 2,3-diphosphoglycerate*
Accelerated decline of 2,3-diphosphoglycerate on red blood cell incubation*

Increased ATP and 2,3-diphosphoglycerate levels
Accelerated decline of ATP during brief incubation

STORAGE CHARACTERISTICS

Increased potassium efflux and greater degrees of hemolysis during short periods of storage
More rapid assumption of altered morphologic forms on storage or incubation*

MEMBRANE

Decreased ouabain-sensitive Na^+,K^+-ATPase*; decreased ouabain-resistant potassium influx*
Decreased permeability to glycerol and thiourea*
Decreased membrane deformability*
Increased sphingomyelin, decreased lecithin content of stromal phospholipids
Decreased content of linoleic acid*
Increased lipid phosphorus and cholesterol per cell
Greater affinity for glucose*
Increased number of insulin, insulin-like growth factor, and prolactin binding sites
Increased membrane-associated myosin
Reduced membrane acetylcholinesterase activity

OTHER

Increased methemoglobin content*
Increased affinity of hemoglobin for oxygen*
Glutathione instability*
Increased tendency for Heinz body formation in the presence of oxidant compounds*

---

*Appears to be a unique characteristic of the newborn's erythrocytes and not merely a function of the presence of young red blood cells.

in gestational age from 65 to 138 days.[153] Six enzymes—enolase, guanylate kinase, lactate dehydrogenase, nucleoside phosphorylase, PFK, and the previously mentioned hexokinase—showed differences in the staining intensity of certain isoenzyme zones as compared with adult controls. The fetal red cell zymograms contained the mitochondrial forms of isocitric dehydrogenase and aspartate transaminase, as well as more definite zones of phosphoglucomutase type 3.

Glucose Consumption

Glucose consumption by the erythrocytes of both term and premature infants has generally been found to be greater than that observed in the cells of normal adults.[155,156] This would be anticipated in view of the fact that young red cells consume more glucose. However, when the cells from infants are compared with adult cell populations of similar young age, their rate of glucose consumption appears to be less than would be expected.[155]

Circumstantial evidence suggests that the relative deficiency of PFK may be responsible for this relative impairment in glycolysis. All strategies designed to maximize PFK activity produce far greater augmentation of glucose consumption in the cells of neonates. Incubation of cells at high phosphate concentration causes the cells of both premature and term infants to consume glucose at rates commensurate with their age.[157] Increasing the pH of the incubation medium produces a much greater increase in red cell glucose consumption in cells from newborn infants.[155] Analysis of glycolytic intermediates reveals that as pH increases, there is a decrease in levels of glucose 6-phosphate and fructose 6-phosphate and an increase in the concentration of fructose 1,6-diphosphate, glyceraldehyde 3-phosphate, dihydroxyacetone phosphate, and 2,3-diphosphoglycerate (2,3,-DPG). All these

changes are consistent with activation of PFK. It would appear that this pH-induced augmentation of PFK obscures the relative deficiency that is manifested as lower than expected glucose consumption at pH 7.4.

Further evidence that the relative deficiency of PFK may play the major role in depressing glucose consumption in the newborn comes from the incubation of neonatal red cells with methylene blue, 10^{-6} mol. At this concentration of methylene blue, 90% of glucose consumption proceeds via the pentose phosphate pathway, which bypasses the PFK step. Incubation of red cells from newborn infants in the presence of methylene blue produces a far greater acceleration of glycolysis than observed either in the red cells of normal adults or in those of subjects with reticulocytosis.[158]

Finally, when one examines the oldest cells from the cord blood of newborn infants, the profound PFK deficiency that was previously described is found to be associated with a marked decrease in glucose consumption and a pattern of glycolytic intermediates that suggests a relative block in glycolysis at this step.

2,3-Diphosphoglycerate Metabolism

When the red cells of infants and adults are incubated under identical conditions, the concentration of 2,3-DPG declines far more rapidly in the erythrocytes of newborns than in those of adults.[133-134] Various postulates have been advanced to explain this 2,3-DPG instability. Zipursky and co-workers presented evidence to suggest that a relative block in glycolysis, proximal to the formation of glyceraldehyde 3-phosphate, was responsible for the failure to maintain 2,3-DPG levels.[159] Trueworthy and Lowman proposed that the instability of 2,3-DPG was the result of an accelerated rate of hydrolysis as a consequence of increased 2,3-DPG phosphatase activity.[160] The 2,3-DPG content of normal fetal red cells is greater than that of adult cells and is further increased in anemic fetuses, possibly as a consequence of the relative preponderance of PFK activity over pyruvate kinase activity.[161]

The Pentose Phosphate Pathway and Response to Oxidant-Induced Injury

Oxidative stress induced by the formation of O_2, H_2O_2, or related species is handled within the red cell by the combined activities of the hexose monophosphate shunt (in which reduced nicotinamide adenine dinucleotide phosphate [NADPH] is generated), glutathione peroxidase, catalase, and superoxide dismutase. There is general agreement that the red cells from newborn infants are more susceptible to oxidant-induced injury than adult cells are and that this susceptibility is greater in very-low-birth-weight infants [128,162-164]

Fetal hemoglobin is more prone than adult hemoglobin to denaturation; however, there is no relationship between the fetal hemoglobin content of the cell and the tendency to form Heinz bodies. The pentose phosphate pathway in the cells of both term and premature infants is intact and responds appropriately to oxidant-induced stimulation.[158,165] The cell content of glutathione is normal in neonatal erythrocytes.[166] The activity of glutathione peroxidase is decreased in comparison to that of adult cells[167,168]; however, metabolic studies have failed to demonstrate a convincing direct relationship between this relative deficiency and vulnerability to oxidant.[140,144] Decreased levels of reduced glutathione and increased levels of oxidized glutathione have been found in patients with retinopathy of prematurity.[169] Erythrocytes from extremely-low-birth-weight infants exhibit a marked reduction in the 6-phosphogluconate dehydrogenase (6PGD)/glucose-6-phosphate dehydrogenase (G6PD) ratio, glutathione peroxidase, methemoglobin (Met-Hb) reductase, and catalase.[128] A slight decrease in superoxide dismutase activity has been observed in fetal red cells.[170] The relative deficiencies of glutathione peroxidase and catalase may act in concert with plasma factors to produce this metabolic handicap.[171,172] Vitamin E plays a crucial role in limiting membrane lipid auto-oxidation. Vitamin E deficiency has been observed in the plasma of full-term and premature newborns.[173]

G6PD activity is increased in cord/neonatal blood,[144,148,158,174] whereas 6PGD activity is similar in neonatal and adult blood.[144,175] In fetal and extremely-low-birth-weight infant cells, 6PGD activity is markedly reduced[128,176]; the associated reduction in the 6PGD/G6PD ratio has been proposed as a marker of developmental immaturity of erythrocytes.[128,147]

Suggestions that other factors are implicated come from observations that the red cells of newborn infants, when compared with those of adults, have a decreased number of membrane SH groups,[177] that the membranes isolated from them contain more residual hemoglobin and form Heinz bodies faster,[178] and that after the transfusion of adult cells into newborn infants, these cells also appear to be more prone to the development of Heinz bodies.[179,180]

The red cells from newborn infants, like other young red cells, consume more oxygen and produce more hydrogen peroxide than the red cells of adults do.[181,182]

HEMATOLOGIC VALUES AT BIRTH

Several variables influence the interpretation of what might be considered normal values for hemoglobin, hematocrit, red cell indices, and reticulocyte count at the time of birth and during the early weeks of life. These variables include the gestational age of the infant, the conduct of labor and treatment of the umbilical vessels, the site of sampling, and the time of sampling. The Appendix of this text contains a series of tables describing representative norms that have appeared in the literature. A few of these norms are highlighted in the following discussion to illustrate pertinent points.

Site of Sampling

Capillary samples obtained by skin prick, generally from the heel or toe, have a higher hemoglobin concentration than simultaneously collected venous samples do. During the first hours of life, this difference averages approximately 3.5 g/dL, as is illustrated in Figure 2-8.[183] In some instances the capillary hemoglobin–venous hemoglobin difference may exceed 10 g/dL.[184]

The clinical importance of the site of sampling was illustrated by Moe in a study of 54 infants with erythroblastosis fetalis.[184] Simultaneously obtained cord blood and capillary samples were compared. In this study, 41 infants eventually required exchange transfusion for hyperbilirubinemia. Of these 41 infants, 25 were found to be anemic based on determinations performed on cord blood samples, whereas only 14 could be considered anemic on the basis of the results of capillary sample analysis.

In virtually all infants, the capillary-to-venous hematocrit ratio is greater than 1.00. The greatest ratios, often in excess of 1.20, are observed in infants born before 30 weeks of gestation, infants with arterial blood pH values below 7.20, infants with hypotension, and infants with a red cell mass of less than 35 mL/kg.[185] In other words, capillary hemoglobin values are falsely elevated in the sickest infants. These are the same infants in whom accurate determination of the hemoglobin concentration is most important for clinical management. The capillary-to-venous hematocrit ratio gradually decreases with increasing gestational age.[185] Infants born between 26 and 30 weeks of gestation have a mean ratio of 1.21; infants born at 31 to 32 weeks, 1.12; infants born at 33 to 35 weeks, 1.16; and infants born between 36 and 41 weeks, 1.12. By the fifth day of life, the capillary-to-venous difference has decreased in healthy infants, and capillary samples may have a hematocrit that is only 2.5% higher when blood is obtained by deep stick from a well-warmed heel.

Several studies have shown that venipuncture is as effective and less painful than heel blood collections.[186]

The use of automated incision devices for heel sticks should be encouraged because they reduce the number of sticks needed and induce less bruising and inflammation.[187] Pain and stress are associated with the heel prick procedure,[188,189] as well as some rare but severe permanent sequelae.[190] The use of topical anesthetics reduces the pain associated with drawing blood in infants,[191,192] although Met-Hb levels may be transiently increased if prilocaine is used.[193]

Treatment of the Umbilical Vessels

At birth, the volume of blood of the infant may be increased by as much as 61% if the placental vessels are allowed to empty completely before the cord is clamped.[194,195] It has been estimated that the placental vessels contain 75 to 125 mL of blood at birth—or a quarter to a third of the fetal blood volume. Under normal circumstances, about a quarter of placental transfusion takes place within 15 seconds of birth and half by the end of the first minute. The ratio of blood in the neonatal and placental circulations has been found to average 67:33 at birth, 80:20 at 1 minute, and 87:13 at the end of placental transfusion.[195]

The umbilical arteries generally constrict shortly after birth, so no blood flows from the infant to the mother; however, the umbilical vein remains dilated and permits blood to flow in the direction of gravity. Infants held below the level of the placenta continue to gain blood; infants held above the placenta may bleed into it.[196] Yao and co-workers demonstrated that hydrostatic pressure, produced by placing the infant 40 cm below the mother's introitus, hastened placental transfusion to virtual completion in 30 seconds.[195] In infants delivered at term by cesarean section, maximal placental transfusion is achieved within 40 seconds after birth; however, net blood flow reverses, with blood traveling from the infant back to the placenta, if clamping is delayed for longer than 40 seconds.[197] A recent controlled study has shown that delayed cord clamping significantly increases
FIGURE 2-8. Simultaneous capillary and venous hemoglobin determinations in 24 newborn infants. Av, average. *(Redrawn from Oettinger L, Mills WB. Simultaneous capillary and venous hemoglobin determinations in newborn infants. J Pediatr. 1949;35:362-365.)*

the hematocrit and reduces the incidence of neonatal anemia with no harmful effects.[198]

The effects of placental transfusion on the total blood volume of the infant show wide variability, partially because of the techniques used and the time at which the samples were taken. During the first hours after birth, plasma apparently leaves the circulation. It seems that the greater the placental transfusion, the greater the plasma loss. Thus, by the third day of life, there are only small differences in total blood volume, regardless of the method of cord clamping. Usher and associates found that infants with delayed cord clamping had an average blood volume of 93 mL/kg at an age of 72 hours; infants with immediate cord clamping had a blood volume of 82 mL/kg.[194] Although the total blood volume may be only slightly altered by the timing of cord clamping, more significant differences can be observed in red cell mass or hemoglobin concentration. In the study of Usher and colleagues, infants with delayed cord clamping had an average red cell mass of 49 mL/kg at 72 hours of age as compared with only 31 mL/kg in infants with immediate cord clamping.[194] The results of other investigators are listed in Table 2-5.[199-201]

Infants with delayed cord clamping tend to have higher hemoglobin values during the first week of life than do those whose clamping was not delayed. A reduced volume of red blood cells is associated with increased mortality in premature infants with respiratory distress syndrome.[202] Thus, delayed cord clamping could be particularly indicated for premature births. Studies have shown that delayed cord clamping in premature infants is associated with a significant reduction in transfusion requirements and improved outcome, but not with a reduced incidence of periventricular/intraventricular hemorrhage.[201,203-205]

There have been reports of circulatory overload and congestive cardiac failure in the setting of delayed cord clamping. "Symptomatic neonatal plethora" was observed in eight premature and three full-term infants.[206] Radiologic findings of volume overload and reduced left ventricular performance have been reported in infants with delayed cord clamping.[207,208] For cesarean section, a delay of 3 minutes in cord clamping has been associated with signs of respiratory and metabolic acidosis (reduced oxygen tension and pH and elevated plasma lactate levels), thus indicating that earlier clamping may be preferable in this setting.[209]

Blood Volume

Both blood volume and red cell mass are influenced by the treatment of the cord vessels and by the clinical condition of the infant. Shortly after birth, the blood volume of term infants may range from 50 to 100 mL/kg, with the mean value being 85 mL/kg.[194,210,211] As previously discussed, blood volume in infants with early cord clamping averages 78 mL/kg at 30 minutes of age, in contrast to a value of 98.6 mL/kg in infants with cords that were clamped late. By 72 hours of age, these differences are not as great; infants with early clamping have an average blood volume of 82 mL/kg, whereas those with late clamping have an average of 93 mL/kg.

The blood volume of premature infants ranges from 89 to 105 mL/kg during the first few days of life.[212,213] This increased blood volume is primarily the result of an increase in plasma volume, with the total red cell volume per kilogram of body weight being quite similar to that of term infants. Plasma volume decreases with increasing gestational age, except in infants with intrauterine growth retardation.[214]

For infants born at term, blood volumes are approximately 73 to 77 mL/kg by 1 month of life.[215,216]

Reduced blood volume and decreased red cell mass are frequently observed in infants with hyaline mem-

brane disease and in newborns delivered with a tight nuchal cord.[217,218] Approximately 16% of infants born with a nuchal cord are anemic in the neonatal period.[219] Infants born after late intrauterine asphyxia tend to have a greater blood volume and red cell mass.[218]

Hemoglobin, Hematocrit, Red Cell Count, and Red Cell and Reticulocyte Indices

Representative values for these hematologic measurements are presented in Tables 2-6 to 2-9. Hemoglobin

TABLE 2-6	Hematologic Values for Normal Cord Blood		
Parameter	Mean	SD	n
Hb (g/dL)	15.9	1.86	28

Values obtained with an ADVIA 120 hematology analyzer (Bayer Diagnostics, Tarrytown, NY) in neonates delivered at term with weight greater than 2500 g. These data were kindly provided by Drs. Gil Tchernia and Therese Cynober, Laboratoire d'Hematologie, Centre Hospitalier de Bicetre, Bicetre, France.

values increase gradually until approximately 32 to 33 weeks of gestation and remain relatively constant until term. Mean corpuscular volume (MCV) and the mean reticulocyte count decline continuously during the course of gestation. Hematologic values from normal fetuses with gestational ages between 18 to 30 weeks reflect this trend.[220]

In healthy term infants, no measurable decrease in hemoglobin values occurs during the first week of life (see Fig. 2-9); in contrast, in infants born weighing less than 1500 g but of appropriate weight for gestational age, the hemoglobin concentration may decrease by as much as 1.0 to 1.5 g/dL during this interval (Fig. 2-10).

Considerable differences are seen in the peripheral blood cell counts and indices of infants born in developing countries. A study carried out by Tchernia's group in 199 newborns in Bamako (Mali) indicated that 32% were anemic (hemoglobin level <13 g/dL).[221] When compared with a control group of French newborns, the Bamako group had lower hemoglobin levels (13.9 ± 2.0 g/dL versus 15.1 ± 1.4 g/dL), lower mean corpuscular hemoglobin (MCH) levels (32.9 ± 3.0 pg versus 35 ± 1.9 pg), lower serum ferritin levels (97.5 μg/L versus 135 μg/L, geometric means), and lower erythrocyte ferritin levels (244.7 attogram [ag] per cell versus 348 ag per cell, geometric means). These differences cannot be explained by hemoglobinopathies, malaria, or folate deficiency, and they are probably due to iron deficiency. However, in developed countries, there seems to be very little difference in neonatal hemoglobin, erythrocyte zinc protoporphyrin, and cord blood serum ferritin levels between neonates born to iron-deficient and iron-replete mothers.[222]

FETAL ANEMIA

Improved diagnostic and therapeutic techniques have made early identification and treatment of anemia in the fetus possible. The experience gained in the in utero treatment of hemolytic diseases of the fetus has been applied to a wide spectrum of pathologic conditions.[223] Normal fetal hematologic values are also available

as a consequence of the development of percutaneous umbilical blood sampling and prenatal diagnosis (see Table 2-10).[220] There is evidence that intravascular transfusion to treat anemia in fetuses with immune hydrops results in high survival rates and favorable long-term neuropsychological outcomes.[224]

A substantial proportion of cases of nonimmune fetal hydrops are due to chromosomal abnormalities and thus are not treatable presently.[225,226] Fetuses with hydrops fetalis and anemia have characteristic sonographic abnormalities (thickened placenta, less pleural effusion, less marked edema); these abnormalities aid in the distinction of infants with hydrops fetalis but without anemia from those with anemia.[227] In growth-restricted fetuses,

Doppler studies of the middle cerebral artery and umbilical artery showed significant anemia-related changes, although their predictive accuracy was not high enough to justify clinical use.[228-230] In Rh-alloimmunized pregnancies, Doppler ultrasonography is more sensitive and accurate than amniocentesis in predicting severe fetal anemia.[231,232]

The major causes of treatable fetal anemia are listed in Box 2-2. Most of them are related to hemolytic disease of the fetus, hemoglobinopathies, or severe red cell enzyme defects.[233]

Cases of severe fetal anemia caused by acquired maternal chronic pure red cell aplasia[234] or congenital type I dyserythropoietic anemia[235] have been described.

Box 2-2	**Fetal Anemia Treatable by Intrauterine Transfusion**

IMMUNE

Hemolytic disease of the fetus

NONIMMUNE

Hemolytic: hemoglobinopathies (e.g., α-thalassemia [four-gene deletion]), G6PD deficiency
Nonhemolytic: acquired chronic pure red cell aplasia

OTHER

Severe antepartum fetomaternal hemorrhage
Twin-to-twin transfusion syndrome
Cystic hygroma with hydrops fetalis
Placenta chorioangioma
Intrauterine parvovirus B19 infection
Malaria

G6PD, glucose-6-phosphate dehydrogenase.

However, other pathologic conditions have been associated with anemia during the fetal period, such as hydrops fetalis in combination with either cystic hygroma[236] or placental chorioangioma,[237] parvovirus B19 infection,[238-243] cytomegalovirus infection,[244] and malaria.[245] Rarely, congenital mesoblastic nephroma can induce marked prenatal hematuria and hemorrhagic shock.[246] For a more comprehensive list of causes, management, and outcome of nonimmune hydrops fetalis, see elsewhere.[247-250]

Drug-induced cases of fetal anemia have also been described, such as after antiretroviral therapy during pregnancy[251,252] and in association with mycophenolate therapy.[253]

Severe chronic anemia in the prenatal period may result in cutaneous manifestations called "blueberry muffin baby"[254]; these expressions of cutaneous hematopoiesis need to be distinguished from neoplastic diseases and from the angioedema seen in neonates with parvovirus B19 maternal infection.[255,256]

ANEMIA IN THE NEONATE

Anemia present at birth or appearing during the first week of life can be broadly classified into three major categories: anemia as a result of blood loss, anemia as a result of a hemolytic process, or anemia secondary to less than normal red cell production. Many of the disorders producing a hemolytic process are discussed in greater detail in other sections of this text (see Chapters 3, 15, 16, and 17 and Section VI).

Anemias that are unique to the newborn and not the result of isoimmunization are the focus of the following discussion. The reader is encouraged to consult other monographs in which the primary focus is anemia in the newborn period.[257-268]

BLOOD LOSS AS A CAUSE OF ANEMIA

Blood loss resulting in anemia may occur prenatally, at the time of delivery, or in the first few days of life. Blood loss may be the result of occult hemorrhage before birth, obstetric accidents, internal hemorrhage, or excessive blood sampling by physicians.

The multiple causes of blood loss in the newborn period are listed in Box 2-3. Faxelius and associates estimated the red cell volume in 259 infants admitted to a high-risk unit in an attempt to determine which clinical events were frequently associated with a reduction in red cell mass.[218] Low red cell volume was frequently associated with a maternal history of vaginal bleeding, with placenta previa or abruptio placentae, with nonelective cesarean section, and with deliveries complicated by cord compression. Asphyxiated infants (Apgar score of 6 or less at 1 minute) often had low red cell volume. An early central venous hematocrit below 45% correlated with low red cell volume, but a normal or even high early hematocrit did not exclude the possibility that the infant was hypovolemic. Infants with a mean arterial pressure of less than 30 mm Hg and infants in whom the hematocrit fell by more than 10% during the first 6 hours of life were also frequently found to have reduced red cell mass. These findings serve to underscore the fact that much of the anemia in early life is the result of obstetric factors that produce blood loss in the infant.

Occult Hemorrhage before Birth

Occult hemorrhage before birth may be caused by bleeding of the fetus into the maternal circulation or by bleeding of one fetus into another when multiple fetuses are present.

Fetal-to-Maternal Hemorrhage

In approximately 50% of all pregnancies, some fetal cells can be demonstrated in the maternal circulation.[269] Nucleated fetal erythrocytes can be detected in the maternal circulation as early as the fifth gestational

Box 2-3	Types of Hemorrhage in the Newborn

OCCULT HEMORRHAGE BEFORE BIRTH

Fetomaternal

Abdominal or multiple trauma
Amniocentesis in the third trimester
After external cephalic version
Placental tumors
Spontaneous

Twin to Twin

Velamentous cord insertion
"Stuck twin" phenomenon

OBSTETRIC ACCIDENTS, MALFORMATION OF THE PLACENTA AND CORD

Rupture of a normal umbilical cord (precipitous delivery, entanglement)
Hematoma of the cord or placenta
Rupture of an abnormal umbilical cord (varices, aneurysm)
Rupture of anomalous vessels (aberrant vessels, velamentous insertion; communicating vessels in a multilobed placenta)
Intrauterine manipulation*
Manual removal of the placenta*
Cesarean section*
Incision of the placenta during cesarean section
Placenta previa*
Abruptio placentae*

INTERNAL HEMORRHAGE

Intracranial
Giant cephalohematoma, caput succedaneum
Retroperitoneal
Ruptured liver
Ruptured spleen

---

*Defined by the American College of Obstetrics and Gynecology as conditions associated with high risk for the development of fetomaternal hemorrhage of 30 mL or greater. Additional high-risk conditions are antepartum fetal death and antepartum bleeding.

week,[270] and substantial progress has been made in recent years to isolate these cells for prenatal diagnosis of genetic disease.[271-273] Fetal DNA is also present in maternal plasma and is another possible source of fetal genetic material for diagnostic testing.[274-276]

The estimated volume of fetal blood present in the maternal circulation is less than 2 mL in 98% of pregnancies.[277] Fetal-to-maternal hemorrhage of 30 mL or greater is observed in 3 in 1000 women, and it is most common after traumatic diagnostic amniocentesis or external cephalic version before delivery. A study of 30,944 Rh-negative mothers showed that 1 in 1146 had fetal bleeding of at least 80 mL whereas 1 in 2813 had bleeding of 150 mL or greater.[278] Risk factors for fetal-to-maternal bleeding are summarized in Box 2-3. Trau-

TABLE 2-11	Characteristics of Acute and Chronic Blood Loss in the Newborn	
Characteristics	**Acute Blood Loss**	**Chronic Blood Loss**
Clinical	Acute distress; pallor; shallow, rapid, and often irregular respiration; tachycardia; weak or absent peripheral pulses; low or absent blood pressure; no hepatosplenomegaly	Marked pallor disproportionate to evidence of distress; on occasion, signs of congestive heart failure may be present, including hepatomegaly
Venous pressure	Low	Normal or elevated
LABORATORY VALUES		
Hb concentration	May be normal initially, then drops quickly during first 24 hr of life	Low at birth
RBC morphology	Normochromic and macrocytic	Hypochromic and microcytic; anisocytosis and poikilocytosis
Serum iron level	Normal at birth	Low at birth
Course	Prompt treatment of anemia and shock necessary to prevent death	Generally uneventful
Treatment	Intravenous fluids and whole blood; iron therapy later	Iron therapy; packed RBCs may be necessary on occasion

Hb, hemoglobin; RBC, red blood cell.

matic injury to the mother during pregnancy (e.g., injury secondary to motor vehicle accidents, falls, abdominal trauma),[279] third-trimester amniocentesis, placental abnormalities (abruptio placentae and placental tumors),[280] and manual removal of the placenta have also been associated with fetal-to-maternal hemorrhage.[277]

The clinical manifestations of fetal-to-maternal hemorrhage depend on the volume of hemorrhage and the rapidity with which it has occurred. If the hemorrhage has been prolonged or repeated during the course of the pregnancy, the anemia develops slowly and the fetus has an opportunity for hemodynamic compensation. Such an infant may manifest only pallor at birth. After acute hemorrhage, just before delivery, the infant may be pale and sluggish, have gasping respirations, and exhibit signs of circulatory shock. The typical physical findings and laboratory data that are useful in distinguishing the acute and chronic forms of fetal-to-maternal blood loss are described in Table 2-11.

The degree of anemia is quite variable. Usually, the hemoglobin value is less than 12 g/dL before signs and symptoms of anemia can be recognized by the physician. Hemoglobin values as low as 3 to 4 g/dL have been recorded in infants who were born alive and survived. If the hemorrhage has been acute, particularly when hypovolemic shock is present, the hemoglobin value may not reflect the magnitude of the blood loss. In such instances, several hours may elapse before hemodilution occurs and the magnitude of the hemorrhage is appreciated. In general, acute loss of 20% of blood volume is sufficient to produce signs of shock and is reflected in a decrease in hemoglobin levels within 3 hours of the event.

Examination of a peripheral blood smear provides useful diagnostic information. In acute hemorrhage, the red cells appear normochromic and normocytic, whereas in chronic hemorrhage, the cells are generally hypochromic and microcytic.

In anemia that is a direct result of fetal-to-maternal hemorrhage, the Coombs test yields a negative result, and the infants are not jaundiced. Infants with anemia secondary to blood loss generally have much lower bilirubin values throughout the neonatal period as a consequence of their reduced red cell mass.

The diagnosis of fetomaternal hemorrhage of sufficient magnitude to result in anemia at birth can be made with certainty only through demonstration of the presence of fetal cells in the maternal circulation. Techniques for demonstrating these cells include differential agglutination, mixed agglutination, fluorescent antibody techniques, and the acid elution method of staining for cells containing fetal hemoglobin.

The Kleihauer-Betke technique of acid elution is the simplest of these methods and the one most commonly used for detection of fetal cells,[281,282] although its value in monitoring patients at risk has been questioned.[283] The test is based on the resistance of fetal hemoglobin to elution from the intact cell in an acid medium. The acid elution technique can be relied on with certainty for diagnosis only when other conditions capable of producing elevations in maternal fetal hemoglobin levels are absent. Interpretation of this visual test shows considerable interobserver and interhospital variation, with up to 500% differences[284] for certain conditions, including maternal thalassemia minor, sickle cell anemia, hereditary persistence of fetal hemoglobin, and in some normal women, pregnancy-induced increase in fetal hemoglobin production. In such circumstances, other techniques based on differential agglutination should be used.[285] In addition, flow cytometry has been shown to be an acceptable alternative to the acid elution test for detection of fetomaternal hemorrhage.[286] However, most of the flow cytometry tests are designed to quantify D-positive fetal cells in D-negative mothers and are not applicable to D-positive mothers.[287,288]

The diagnosis of fetomaternal hemorrhage may be missed in situations in which the mother and infant are incompatible for the ABO blood group system. In such instances, the infant's A or B cells are rapidly cleared from the maternal circulation by maternal anti-A or anti-B antibodies and are not available for staining. A presumptive diagnosis may be made by demonstration of either marked erythrophagocytosis in smears of the maternal buffy coat or an increase in maternal immune anti-A or anti-B titer in the weeks after delivery.

Twin-to-Twin Transfusion Syndrome

This form of hemorrhage is observed only in monozygotic multiple births with monochorial placentas. In approximately 70% of monozygotic twin pregnancies, a monochorial placenta exists.[289] The incidence of twin-to-twin transfusion syndrome (TTTS) in pregnancies in which a monochorial placenta is present has been estimated to be 13% to 33% in one study[290] and 6.2% in another.[291] Velamentous cord insertion is associated with an increased risk for TTTS, possibly as a result of compression force, which reduces blood flow to one twin.[292] This blood exchange can produce anemia in the donor and polycythemia in the recipient and is associated with a characteristic twin oligohydramnios-polyhydramnios sequence except in rare cases.[293] When significant transfer of blood has occurred, the difference in hemoglobin concentration between the twins exceeds 5.0 g/dL. This is in contrast to a maximal discrepancy of 3.3 g/dL in cord blood hemoglobin in dizygotic twins. The survival rate of fetuses with TTTS diagnosed before the 28th week of gestation varies between 21% and 50%.[290,294,295] Clinical characteristics, diagnostic modalities, and the possible therapeutic role of amniocentesis and cordocentesis with fetal transfusion in reducing the high perinatal mortality associated with this syndrome have been reviewed.[291,295-298] Laser ablation of the chorionic plate vessels at the intertwin membrane has been shown to improve the survival of at least one of the two fetuses and reduce neurologic complication when compared with serial removal of a large volume of amniotic fluid.[299-301]

Congestive heart failure may develop in the anemic infant, whereas the plethoric twin may have symptoms and signs of hyperviscosity syndrome, disseminated intravascular coagulation, and hyperbilirubinemia.[302] Rarely, hydrops fetalis may develop if TTTS occurs early in the pregnancy.[303]

The hemorrhage may be acute or chronic. In a review of 482 twin pairs by Tan and associates, 35 pairs were found to have TTTS.[304] They pointed out how the difference in weight of the twins could be used to establish the timing of the hemorrhage. When the weight difference exceeded 20% of the weight of the larger twin, the transfusion was chronic and the smaller infant was invariably the donor. The anemic smaller twin displayed reticulocytosis. When the difference in the weight of the twins did not exceed 20% of the weight of the larger twin, the larger twin was the donor in almost 50% of all instances. In these presumably acute transfusions, significant reticulocytosis was not observed in the anemic donor. Although hemoglobin values of the recipient were increased equally with both acute and chronic transfusion, the donor twin in the chronic transfusion group was found to be more anemic than the donor in the acute transfusion group. These findings support and extend the original proposal of Klebe and Ingomar, who suggested these two types of transfusion on the basis of a review of previously documented cases.[305]

Obstetric Accidents and Malformations of the Placenta and Cord

The normal umbilical cord may rupture during precipitous deliveries. The cord may also rupture during a normal delivery when it is unusually short or entangled around the fetus or when traction is applied to the infant with forceps.[306]

Other abnormalities of the umbilical cord that predispose to hemorrhage and the development of anemia in the infant include vascular abnormalities such as umbilical venous tortuosity and arterial aneurysm. Inflammation of the cord can weaken vessels and predispose them to rupture.

Velamentous insertion of the umbilical cord is observed in approximately 1% of all pregnancies. It appears to be most common in twin pregnancies and in pregnancies accompanied by low-lying placentas. It is estimated that 1% to 2% of pregnancies associated with velamentous insertion of the cord result in fetal blood loss.[306] The perinatal death rate in such circumstances ranges from 58% to 80%, with many of the infants being stillborn. Approximately 12% of these infants who are born alive will be anemic.

The placenta may be inadvertently incised during cesarean section, with the incision producing fetal hemorrhage.[307] As previously mentioned, placenta previa or abruptio placentae often results in fetal hemorrhage.[308] In women with late third-trimester bleeding, the physician may anticipate the birth of an anemic infant by examining vaginal blood for the presence of fetal erythrocytes with the acid elution technique of Kleihauer and Betke.[309]

Internal Hemorrhage

When internal hemorrhage takes place in the newborn, it may not be recognized until shock has occurred.

Anemia that appears in the first 24 to 72 hours after birth and is not associated with jaundice is commonly due to internal hemorrhage. It is well recognized that traumatic deliveries may result in subdural or subarachnoid hemorrhage of sufficient magnitude to result in anemia. Cephalohematomas may be of giant size and result in anemia.[310]

Blood loss into the subaponeurotic area of the scalp tends to be greater than that observed with cephalohematomas. The bleeding is not confined by periosteal attachments and thus is not limited to an area overlying a single skull bone. A subaponeurotic hemorrhage usually extends through the soft tissue of the scalp and covers the entire calvaria. Blood loss in this area can result in exsanguination.[311] Pachman observed a hemoglobin value of 2.2 g/dL in an infant 48 hours of age in whom massive hemorrhage into the scalp had occurred.[312] This form of hemorrhage most commonly occurs after difficult deliveries or vacuum extraction.[313] It also appears with vitamin K deficiency and may be more frequent in African American infants than in those of other ethnicity. Examination of the infant reveals a boggy edema of the head extending into the frontal region and to the nape of the neck. The edema, which may have bluish coloration, obscures the fontanelles and swells the eyelids. The infant may be in shock. Robinson and Rossiter have developed a formula for predicting the volume of blood loss in this condition.[311] For each centimeter of increase in head circumference above that expected, a 38-mL loss of blood has occurred. When the products of red cell breakdown are absorbed from these entrapped hemorrhages, hyperbilirubinemia may develop.[314]

Breech deliveries may be associated with hemorrhage into the adrenal glands, kidneys, spleen, or retroperitoneal area. Blood loss of this type should be suspected in infants found to be anemic during the first few days of life after a traumatic delivery. Hemorrhage into the adrenal glands may also be observed after any difficult delivery or after the birth of a large infant. In adrenal hemorrhage, the clinical picture may include sudden collapse, cyanosis, limpness, jaundice, irregular respirations, elevated or subnormal temperatures, and the presence of a flank mass accompanied by bluish discoloration of the overlying skin.

Rupture of the liver, with resultant anemia, appears to occur more frequently than clinically appreciated. In stillbirths and neonatal deaths, the incidence of hepatic hemorrhage found at autopsy ranges from 1.2% to 5.6%.[315] In approximately half of the cases reviewed by Henderson, the hemorrhage was subcapsular only; in the remainder, the capsule had ruptured, and free blood was present in the peritoneal cavity.[316]

An infant with a ruptured liver generally appears to be well for 24 to 48 hours and then suddenly goes into shock. The moment of onset of shock appears to coincide with the time when the gradually increasing hematoma finally ruptures the hepatic capsule and causes hemoperitoneum. At this time the upper part of the abdomen may appear distended, and often a mass contiguous with the liver is palpable. Shifting dullness can be demonstrated on abdominal percussion. Flat films of the abdomen taken with the patient in both the erect and supine positions frequently confirm the presence of free fluid in the abdomen. Paracentesis, performed with the infant in the lateral position, reveals free blood in the abdomen.

The prognosis is poor, but infants have been saved after multiple blood transfusions and prompt surgical repair of the laceration.

Splenic rupture may also occur after a difficult delivery or as a result of the extreme distention of the spleen that often accompanies severe erythroblastosis fetalis.[317,318] The physician should always suspect rupture of the spleen with associated hemorrhage when at the time of exchange transfusion, an anemic and hydropic infant with erythroblastosis fetalis is found to have decreased rather than increased venous pressure. Rupture of the spleen may also occur during the exchange transfusion.

Splenic rupture occurs, though uncommonly, in healthy infants born after seemingly normal deliveries.[319] Many of these infants are of large size. Pallor, abdominal distention, scrotal swelling, and radiographic evidence of peritoneal effusion without free air should alert the physician to the presence of splenic rupture.

Other less common causes of neonatal bleeding include maternal treatment with antiepileptic drugs during pregnancy associated with vitamin K deficiency,[320] neonatal adenovirus infection,[321] fetal cytomegalovirus infection,[322] hemangiomas of the gastrointestinal tract, and hemangioendotheliomas of the skin.[323,324]

Bleeding into the ventricles and subarachnoid space can also produce significant anemia. Intraventricular hemorrhage may occur in half of all infants with birth weights of less than 1500 g and with even greater frequency when the mother has ingested aspirin in the week before birth of the infant.[325] In many of these infants, no neurologic symptoms are present, and the hemorrhage is recognized on computed tomography of the head.[326]

Anemia Caused by Drawing Blood for Laboratory Analysis

A major cause of anemia in critically ill neonates treated in neonatal intensive care units (NICUs) is frequent blood drawing for laboratory analysis. In very-low-birth-weight infants (<1500 g), a 1-mL blood draw represents 1% or more of the total blood volume (Fig. 2-11). In neonates weighing less than 1500 g, blood drawings during the first 4 weeks of hospitalization may range from 5% to 45% of the calculated total blood volume.[327] A study of 60 very-low-birth-weight infants (560 to 1450 g) showed an average of 4.8 punctures per day per infant, with a mean blood loss for diagnostic sampling of 50.3 mL/kg per 28-day period (range, 7 to 142 mL).[328] Increased blood loss was associated with increased number of transfusions. There is also evidence that the volume of blood drawn for laboratory tests may exceed the actual laboratory requirement for the tests ordered by almost 20%.[329] Another study showed lower blood loss (13.6 mL/kg), with the most frequently ordered tests being glucose, sodium, and potassium.[330]

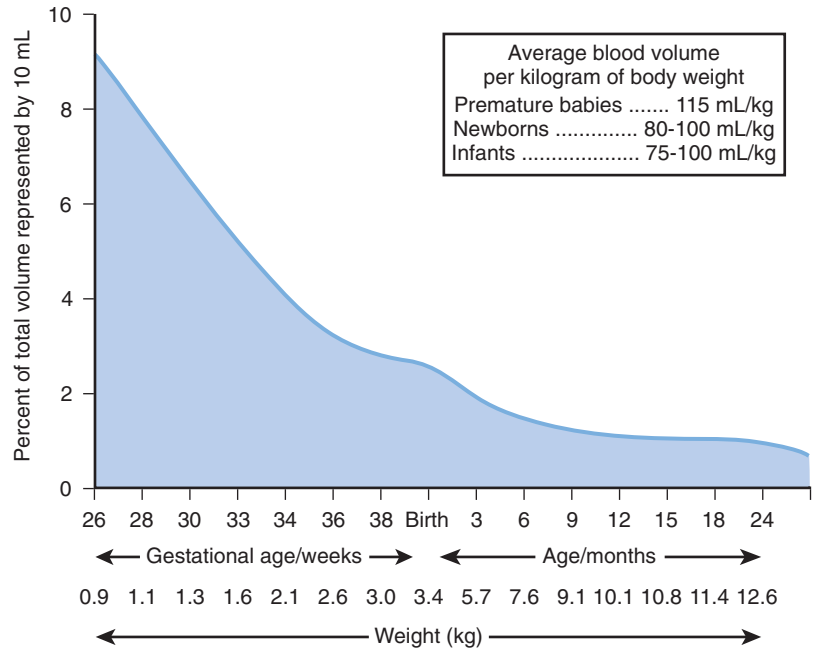
Various approaches for limiting the amount of blood drawn for laboratory tests include the following:


FIGURE 2-11. Average blood volume per kilogram of body weight. *(Redrawn from Werner M. Microtechniques for the Clinical Laboratory. New York, John Wiley & Sons, 1976, p 2. Reprinted by permission of John Wiley & Sons, Inc.)*

1. Reducing the amount of blood discarded from central venous lines before blood is obtained for culture. It has been shown that discarding only 0.3 mL in infants and 1.0 mL in children does not affect the accuracy of central venous line cultures.[331]
2. Use of micromethods that reduce blood loss from peripheral arterial catheters during sampling.[332]
3. Use of a closed method that allows return of the initial sample drawn to clear a line to the patient. This technique has been shown to reduce blood loss as a result of diagnostic sampling, even in adult patients.[333,334]
4. Reducing the amount of blood drawn in excess of that needed for the analytic procedure (25% of the blood removed in NICU settings is in excess of the analytic need).[327] Phlebotomy overdraw is more prominent in the most critically ill infants and is greater when syringes are used.[329]
5. Reducing the need for blood drawing through the use of transcutaneous monitoring techniques (40% of the blood drawn in an NICU setting is for analysis of blood gases and electrolytes).[327]

Recognition of Infants with Blood Loss

The clinical manifestations of hemorrhage are dependent on the site of bleeding, the extent of the hemorrhage, and whether the blood loss is acute or chronic. Features useful in distinguishing infants with acute and chronic blood loss at the time of delivery are described in Table 2-11. Asphyxiated infants may also display pallor. Features that aid in distinguishing an infant with asphyxia from an infant with acute blood loss are presented in Box 2-4. In all circumstances associated with late third-trimester bleeding, multiple births, cesarean section, a nuchal cord, any form of cord compression, or a difficult delivery, a hemoglobin determination should be obtained promptly

Box 2-4 Differential Diagnosis of Pallor in the Newborn

ASPHYXIA

Respiratory findings: retractions, response to oxygen, cyanosis
Moribund appearance
Bradycardia
Stable hemoglobin

ACUTE SEVERE BLOOD LOSS

Decrease in venous and arterial pressure
Rapid shallow respirations
Acyanotic
Tachycardia
Drop in hemoglobin

HEMOLYTIC DISEASE

Hepatosplenomegaly, jaundice
Positive result on the Coombs test
Anemia

in the infant. Even when the first value is normal, a repeat hemoglobin determination should be performed 6 to 12 hours after birth.

ANEMIA AS A RESULT OF A HEMOLYTIC PROCESS

A *hemolytic process* is generally defined as a pathologic process that results in shortening of the normal red cell

life span of 120 days. For neonates, a different definition that recognizes that the normal red cell life span of term infants is only 60 to 80 days (and may be as short as 20 to 30 days in infants born at 30 to 32 weeks of gestation) must be used. A hemolytic process during the neonatal period is usually manifested by one of the following combinations of clinical and laboratory findings:

1. A persistent increase in the reticulocyte count, with or without an abnormally low hemoglobin concentration in the absence of current or previous hemorrhage
2. A rapidly declining hemoglobin concentration without an increase in the reticulocyte count in the absence of hemorrhage

Most infants with hemolytic anemia have accompanying hyperbilirubinemia; however, in the majority of infants in whom the bilirubin level exceeds 12 mg/dL, an increase in red cell destruction, as reflected by an increase in blood carboxyhemoglobin levels, cannot be demonstrated.[335] Approximately 30% of infants with an increase in carboxyhemoglobin levels have maximum bilirubin values of less than 8 mg/dL. The major causes of a shortened red cell life span in the neonatal period are listed in Box 2-5. Only the most salient features of the hereditary hemolytic anemias that are manifested in the neonatal period are discussed in this section. Extensive descriptions of these disorders appear in other portions of the text.

Hemoglobinopathies

Clinically significant hemoglobinopathies in the newborn may be categorized, as in older children, as defects in structure or defects in synthesis (thalassemic syndromes). Because of the rapid evolutionary changes that occur in the fetus and newborn with respect to globin chain synthesis, a unique situation exists. Certain hereditary defects of hemoglobin may be seen at this age; some of these defects spontaneously resolve (e.g., γ-chain defects), whereas other defects, clinically inapparent at birth, produce problems at a later age (e.g., β-chain disorders). Other defects that might be thought to be similar in their clinical manifestations throughout life, such as α-chain defects, may in fact act differently in the newborn period when paired with a γ chain rather than with a β chain.

Defects in Hemoglobin Structure

α-Chain Structural Defects

When α-chain variants of hemoglobin occur, they are present in significant concentration at birth because the α chain is common to all forms of hemoglobin present at birth. In contrast, β-chain variants such as HbS become quantitatively significant only as β-chain synthesis replaces γ-chain production during the first months after birth. When the amino acid alteration is in the α chain, the concentration of abnormal hemoglobin will remain

γ-Chain structural abnormalities

G6PD, glucose-6-phosphate dehydrogenase.

fairly constant during infancy and adulthood; however, during infancy, the abnormal hemoglobin will be present primarily in a fetal form ($\alpha_2^x\gamma_2$), with a lesser amount in the adult form ($\alpha_2^x\beta_2$). An example of this is the HbD St. Louis trait ($\alpha_2^{Asn68\to Lys}\beta_2$), in which the total concentration of abnormal hemoglobin ($\alpha_2^x\gamma_2 + \alpha_2^x\beta_2$) was found to be 27% in neonates, as opposed to an average of 28% HbD in the heterozygous state in adults.[336]

Fortunately, most α-chain mutations do not cause clinically significant disorders in adults, and the same situation appears to exist in newborns. Most infants with α-chain mutations are detected only as part of routine neonatal screening programs. Occasionally, the fetal form of an α-chain mutation is clinically more significant than

the adult form of the mutation. Neonates with Hb Hasharon ($\alpha_2^{Asp14 \rightarrow His}\beta_2$) are an example of this phenomenon. Hb Hasharon is mildly unstable; unstable mutant hemoglobins have a greater tendency to dissociate into subunits, and this increased dissociation leads to hemolysis. HbF is less stable than HbA, presumably as a result of a 10-fold greater affinity between α and β chains than between α and γ chains. As a mildly unstable hemoglobin, the interaction between Hasharon α chains and normal β chains must be minimally decreased, but the interaction between Hasharon α chains and γ chains in the fetal form of Hb Hasharon would be expected to be considerably less and result in an even more unstable form of the α-chain variant. Levine and co-workers described a 965-g newborn who was heterozygous for Hb Hasharon.[337] This infant manifested a hemolytic anemia that resolved coincidentally with the transition from the fetal to the adult form of Hb Hasharon trait at several months of age.

β-Chain Structural Defects

β-Chain mutations generally produce no clinical symptomatology in the newborn period. This does not mean that chain variants are never a problem in the neonate, nor does it mean that these variants cannot be easily detected in the laboratory.

Although HbA usually constitutes less than 30% of the normal hemoglobin at birth, it is possible that the amount may, under certain circumstances, be far greater. Because the γ- to β-chain switchover begins at about 32 weeks' gestation, any disorder that causes the fetus to destroy its existing red cell population will result in replacement with red cells that have a markedly different HbF/HbA ratio at the time of delivery. Fetomaternal blood group incompatibility and intrauterine blood loss may, for example, unmask a β-chain defect earlier than it might otherwise be detected.

Sickle cell hemoglobinopathies are the most commonly encountered β-chain variants in the newborn period. Several cases of homozygous sickle cell disease have been seen clinically in neonates. In patients with homozygous sickle cell disease, the HbS concentration at birth is usually about 20%.

In infants in whom sickle cell anemia has been diagnosed in the first 30 days of life because of some specific symptomatology, the most frequent findings are jaundice, fever, pallor, respiratory distress, and abdominal distention. Hyperbilirubinemia appears to be more common in newborns with sickle cell anemia.[338] Hegyi and co-workers described a full-term newborn in whom abdominal distention developed during the first day of life.[339] The cord bilirubin value was 3.1 mg/dL, the hemoglobin level was 12.7 g/dL, and the reticulocyte count was 13.3%. No evidence of G6PD deficiency or blood group incompatibility was found, but hemoglobin electrophoresis demonstrated 20% HbS and 80% HbF. The child rapidly improved but was later found dead in her crib on the fifth day of life. Postmortem examination revealed sickle cells in multiple organs and histopathologic findings consistent with widespread vaso-occlusion, including multifocal enterocolitis.

Of special concern is the problem of "iatrogenic" sickle cell crisis—exchange transfusion of neonates with respiratory distress syndrome with the use of blood from apparently healthy donors who happen to have sickle cell trait.[340] Such transfusions can produce death in hypoxic infants.

γ-Chain Structural Defects

Table 2-12 lists the most commonly observed γ-chain structural hemoglobinopathies. These variants are quite interesting because they represent disorders that spontaneously resolve as γ-chain production diminishes. Concentrations of these hemoglobin variants in cord blood average 10% to 20% of the total hemoglobin and appear to represent the heterozygous state of these γ-chain hemoglobinopathies.[336] The structural γ-chain defects are not generally associated with any hematologic disturbances and are usually found during newborn screening programs. HbF Poole is an exception to this rule. HbF Poole is an unstable hemoglobin that is manifested as a Heinz body hemolytic anemia during the first weeks of life.[341]

Defects in Hemoglobin Synthesis

In newborn infants, defects in hemoglobin synthesis create a greater variety of thalassemia syndromes than may occur at any other time of life. Newborns may demonstrate all varieties of α-thalassemia, β-thalassemia, γ-thalassemia, or δ-thalassemia, or any combination of these types.

α-Thalassemia Syndromes in the Neonate

In the newborn period, hemolytic disease secondary to thalassemia has invariably been associated with homozygous α-thalassemia. A large spectrum of α-thalassemia syndromes may be observed in the newborn period.

Silent Carrier (One-Gene Defect). Thus far, no observations have been made of this disorder in the neonatal period. This entity would be suspected only if a parent were known to be a silent carrier.

α-Thalassemia Trait (Two-Gene Defect). Although the α-thalassemia syndromes have been described for more than 20 years, the heterozygous state (trait) has been difficult to identify because of the mild hematologic changes that accompany this disorder. Older children and adults may demonstrate a very mild anemia and microcytosis in the presence of normal hemoglobin electrophoresis. The diagnosis is more easily made in the neonatal period than at any other time of life because of two unique occurrences. First, microcytosis is observed in the cord blood of newborns with α-thalassemia trait. Because other causes of microcytosis are rare at this age, infants who are born with a low MCV are more likely to

have α-thalassemia trait than any other disease. Second, α-thalassemia in newborns is associated with the presence of Hb Bart's (γ_4), which is easily identified.

Hemoglobin values in neonates with thalassemia trait are no different from those of normal neonates (range, 15.2 to 18.5 g/dL).[342] MCV is significantly lower (≈94 μm^3) than that in normal term infants (106.4 ± 5.7 μm^3). In addition, patients with the trait syndrome usually have an MCH of less than 29.3 pg. Determination of MCV and MCH appears to be an adequate screening test. The presence of Hb Bart's is the confirmatory finding.

Hemoglobin H Disease. This disorder appears to caused by the inheritance of a three-gene deletion that results in sufficient α/β + γ-chain imbalance to result in

the presence of large quantities of Hb Bart's (γ_4) and some HbH (β_4) in the newborn period. After the first few months of life, the Hb Bart's disappears, and the only remaining abnormal hemoglobin is HbH.

Infants born with HbH disease have higher levels of Hb Bart's in their cord blood than do normal infants or individuals with α-thalassemia trait; however, they have lower levels than homozygous infants with hydrops fetalis do. Unlike infants with α-thalassemia trait, infants with HbH disease are born with significant anemia. Microcytosis is present.[343] The hemolytic process may contribute to a somewhat increased incidence of neonatal jaundice.

Hydrops Fetalis. This four-gene deletion disease results in death of the affected fetus. Because of the

virtual absence of α-chain synthesis, affected infants are born with Hb Bart's only (occasionally, however, some Hb Portland may be found). The peripheral blood smear demonstrates marked hypochromia, poikilocytosis, and target cells. This disorder must be distinguished from other causes of hydrops fetalis with severe anemia. A negative result on the Coombs test and the demonstration of intracellular crystals of Hb Bart's with supravital staining rapidly confirm the high probability of the homozygous state as the correct diagnosis. If death does not occur in utero, it occurs within minutes after birth. Although infants with hydrops fetalis have been reported to have cord hemoglobin values as high as 11 g/dL, the usual levels are much lower.[344] Oxygen delivery is severely impaired even when hemoglobin levels are greater because of the profound leftward shift of the oxyhemoglobin dissociation curve for Hb Bart's. There is a possible association between homozygous α-thalassemia and hypospadias.[345,346] When this disorder is detected in utero, the fetus may be salvaged with intrauterine transfusion and maintained by a postdelivery transfusion program.[347,348] Prevention of severe forms of α-thalassemia and hydrops fetalis can be achieved with prenatal testing and counseling.[349]

β-Thalassemias

In the β-thalassemia syndromes (both trait and homozygous states), the disorders become apparent only after 2 or 3 months of age. In β-thalassemia minor, hematologic findings at birth are entirely normal, with microcytosis being noted later in the first 6 months of life. Similarly, in β-thalassemia major, no clinical findings are present initially; the first sign of any abnormality is the presence of nucleated red cells on smears or maintenance of high HbF concentrations. Any disorder that significantly alters the survival of fetal red cells (e.g., intrauterine blood loss or blood group incompatibility) could make the β-thalassemia syndromes clinically obvious at an earlier age.

Erlandson and Hilgartner recorded their observations of infants in whom thalassemia major was diagnosed during the first 3 months of life.[350] In four infants in whom the disease was diagnosed between 1 and 2 months of age, hemoglobin concentrations were abnormally low. Morphologic erythrocyte abnormalities were already present at 3 days of age in one infant who was also mildly anemic (hemoglobin level, 12.7 g/dL). The earliest morphologic abnormalities were similar to those found in the heterozygous state; however, by 2 months of age, the presence of marked numbers of normoblasts, consistent with homozygous thalassemia, was noted in all infants. Splenomegaly was not present in the one infant who was examined at birth but was apparent in all infants between 1 and 3 months of age. Fetal hemoglobin levels were elevated at 1 to 2 months of age. It would seem then that at least some manifestations of thalassemia major may be present at birth.

γ-Thalassemias

Theoretically, a decrease in γ-chain synthesis (γ-thalassemia) would produce symptoms in utero. Because there are multiple structural genes for γ-chain synthesis, the severity of γ-thalassemia would depend on the extent to which these genes are involved. The condition would be lethal if no γ chains were formed; if only one or two genes were involved, only slight hypochromia or, at most, a mild anemia would ensue. If the diagnosis were not established in the neonatal period, it would be missed because as β-chain synthesis replaces γ-chain synthesis, the red cell changes would disappear.[351]

Combinations of Thalassemia Syndromes

Kan and co-workers described a full-term infant who had hemolytic hypochromic anemia at birth associated with microcytosis and nucleated red cells on smear.[352] Neither HbH nor Hb Bart's was detected. Studies of globin chain synthesis in peripheral blood revealed a deficiency in the synthesis of γ and β chains. As the infant matured, the peripheral smear morphology improved and became identical to that of the subject's father, who had β-thalassemia trait. Since then, several such cases have been reported (see Chapter 20).

Methemoglobinemia in Neonates Treated with Nitric Oxide

Methemoglobinemia is discussed in detail in Chapter 18. A new form of drug-induced Met-Hb has special relevance for oxygen transport in neonates. Pulmonary vasoconstriction is characteristic of persistent pulmonary hypertension of the newborn and is frequently seen in neonatal respiratory distress syndromes. Inhaled nitric oxide (NO) acts as a potent vasodilator on the pulmonary vasculature, improves oxygenation, and lowers pulmonary vascular resistance.[353-358] A potentially serious side effect of the administration of NO is the oxidation of Fe^{2+} of hemoglobin to form Fe^{3+} and Met-Hb. This is usually transient but has been reported to be as high as 40%.[359] Detection of Met-Hb formation is particularly problematic in neonates because of the interference of HbF on determination of Met-Hb. Multiwavelength hemoglobin co-oximeters can provide reliable estimates of Met-Hb in samples with high HbF, although their reliability differs in different models.[360-362] It is advisable to monitor Met-Hb levels in all neonates treated with NO.

Methemoglobinemia in Neonates with Diarrhea

Diarrhea in neonates can be associated with methemoglobinemia, in some cases requiring infusion of methylene blue. Affected patients are usually seen in the first 1 to 3 months of life, frequently with failure to thrive,

weight on admission below the 10th percentile, and formula-feeding.[363-365]

Hereditary Disorders of the Red Cell Membrane

Hereditary spherocytosis, hereditary elliptocytosis, hereditary stomatocytosis, and hereditary xerocytosis all may be manifested in the newborn period.[366] If hemolytic anemia is detected during evaluation for hyperbilirubinemia, a precise diagnosis is not generally established in most patients until they are older. It should also be kept in mind that genetic defects in bilirubin metabolism may be associated with hereditary disorders of the red cell membrane and lead to marked neonatal hyperbilirubinemia.[367]

In hereditary spherocytosis, the condition is diagnosed in only a third of patients during the first year of life. Neonates with hereditary spherocytosis have dehydrated erythrocytes with decreased membrane surface area and exhibit a sharp fall in hemoglobin (near-normal at birth) and reticulocyte counts during the first 20 days of life, with transfusion required in 75% of cases.[368] The reticulocyte response to the anemia is also blunted in the first year of life.[368] Two cases of severe neonatal anemia caused by hereditary spherocytosis and absence of the anion exchange protein band 3 have been reported.[369,370]

The classic morphologic abnormalities of patients with hereditary elliptocytosis may not be present during the first few weeks of life. Patients with the hemolytic form of hereditary elliptocytosis may display pyknocytes rather than elliptocytes early in life, and only after several months are the typical elliptocytes observed. These membrane disorders are described in detail in Chapter 15.

Hereditary xerocytosis (or dehydrated hereditary spherocytosis) is associated in some families with perinatal edema that resolves in a few weeks after birth. In other families it is associated with pseudohyperkalemia. Erythrocyte MCV and MCH are both increased, and the defect has been localized to 16q23-q24.[371,372]

Red Cell Enzyme Deficiencies

Inherited disorders of red cell metabolism may also be anticipated to produce hemolytic anemia early in life. The most common of these abnormalities are G6PD deficiency and pyruvate kinase deficiency.[266,373] These and other disorders of red cell metabolism are described in Chapters 16 and 17. G6PD deficiency may be associated with Gilbert's syndrome and lead to marked hyperbilirubinemia and jaundice.[374,375] Severe transfusion-dependent neonatal anemia accompanied at birth by jaundice, by pyropoikilocytosis, and in the first 3 to 4 years of life by rhabdomyolysis and hyperkalemia has been described in a patient with compound mutations for the erythrocyte/muscle enzyme aldolase A.[376]

Malaria

Although the pathophysiology of malaria-associated anemia is not fully understood,[377] it has been shown that congenital malaria and the presence of parasitemia at birth are strongly associated with neonatal anemia (hemoglobin <14 g/dL).[378-381]

Infantile Pyknocytosis

Infantile pyknocytosis, with pyknocytes defined as "distorted, irregular, densely stained erythrocytes, presenting with several to many spiny projections," has been shown to account for up to 10% of cases of otherwise unexplained neonatal hemolytic anemia and jaundice.[382] The proportion of pyknocytes varied from 4% to 23% in this series, whereas lower numbers have been described in full-term or premature infants.

Neonatal Cobalamin and Folate Deficiency

Both severe maternal dietary deficiency of cobalamin and folate and inherited errors in the absorption, transport, and metabolism of these two key metabolites have been associated with neonatal anemia.[383] In a normal pregnancy, plasma and red cell folate decrease and total plasma homocysteine levels increase without producing folate deficiency in the newborn.[384]

IMPAIRED RED BLOOD CELL PRODUCTION

Diamond-Blackfan syndrome (pure red cell anemia, erythrogenesis imperfecta, or chronic aregenerative anemia) is an uncommon condition characterized by failure of erythropoiesis but normal production of white blood cells and platelets (see Chapter 8).[385] The disease may affect more than red cell production because it is associated with pancytopenia, hypoplasia of the bone marrow, and reduced in vitro clonogenic potential.[386]

Two reviews of the subject suggest that as many as 25% of affected patients may be anemic at birth.[387,388] Hemoglobin values as low as 9.4 g/dL, accompanied by reticulocytopenia, have been observed during the first days of life.[389] There is no correlation between the various types of gene mutations described in this disease and clinical expression and severity.[390,391] However, the severity of the disease is greater in patients affected at a young age and born prematurely.[392] Congenital Diamond-Blackfan anemia may be missed if associated with other more common causes of fetal anemia, such as hemorrhage.[393]

Low birth weight occurs in approximately 10% of all affected patients, with about half of this group being small for gestational age. There appears to be a slight increase in the incidence of miscarriage, stillbirth, and complications of pregnancy in mothers who have given birth to infants with this syndrome.

Abnormalities that have been described include microcephaly, cleft palate, anomalies of the eye, web neck, and thumb deformity. A triphalangeal thumb, duplications of the thumb, and a bifid thumb have been reported in association with this syndrome.[394-396]

Another cause of impaired red cell production in the neonatal period is Pearson's syndrome.[397] This syndrome is characterized by vacuolization of bone marrow precursors, sideroblastic anemia, and exocrine pancreatic dysfunction.[398] It may be associated with Leigh's disease (subacute necrotizing encephalopathy)[399] or with Kearns-Sayre syndrome (bilateral ptosis and atypical retinitis pigmentosa).[400] A deletion in mitochondrial DNA has been found in Pearson's syndrome.[401-403] A case of pyridoxine-refractory congenital sideroblastic anemia with autosomal recessive inheritance has also been described.[404] Neonatal anemia with macrocytosis has been reported in some cases of cartilage-hair hypoplasia.[405]

Cases of congenital dyserythropoietic anemia (CDA) resulting in severe fetal and neonatal anemia have been described.[235,406] Anemia and early jaundice, with or without splenomegaly/hepatomegaly, accompany the bone abnormalities in almost all cases described thus far.[407,408] The reticulocyte count is characteristically lower than expected based on the degree of anemia. Pulmonary hypertension of the newborn has been shown to accompany CDA in neonates.[409]

Association with Gilbert's syndrome increases neonatal hyperbilirubinemia in CDA type II.[410]

Impaired red cell production resulting in anemia during the neonatal period may also be observed as a result of congenital infections such as rubella, cytomegalovirus, adenovirus, and human parvovirus.[411-413] Congenital leukemia, Down syndrome, and osteoporosis may likewise produce anemia during the early days of life as a result of inadequate erythropoiesis.

A DIAGNOSTIC APPROACH TO THE ANEMIC NEWBORN

In view of the great number of entities that may be responsible for anemia in the newborn period, a disciplined approach to diagnosis is essential. A detailed family and obstetric history should be obtained. The placenta should be examined whenever possible.

During physical examination of the infant, particular attention should be devoted to detection of congenital anomalies, stigmata of intrauterine infection, internal hemorrhage, and the presence of hepatosplenomegaly.

Initial laboratory studies should include a complete blood count, red cell indices, reticulocyte count, direct Coombs test, and examination of a well-prepared peripheral blood smear. Other useful simple procedures include a Heinz body preparation and performance of a "wet prep" of the infant's erythrocytes.

One approach that relies on the reticulocyte count and cellular indices in arriving at a diagnosis is illustrated in Figure 2-12. This approach can be supplemented with specific diagnostic tests as indicated.

PHYSIOLOGIC ANEMIA OF PREMATURITY

The hemoglobin concentration of term infants normally decreases over the first weeks of life, and this is known as the "physiologic anemia of infancy." Infants who are born prematurely but are otherwise healthy experience a more exaggerated decrease in hemoglobin concentration (see the following paragraph), which has been termed the "physiologic anemia of prematurity."[414] Factors that influence the magnitude of this physiologic anemia include the nutritional status of the infant and a variety of complex adaptations to changes in oxygen availability.[415]

Cord hemoglobin values do not change significantly during the last trimester of pregnancy. After birth, the rapidity with which the hemoglobin level declines and the magnitude of the actual decrease vary directly with the degree of immaturity of the newborn. Although the nadir in hemoglobin concentration for normal full-term infants may be as low as 11.4 ± 0.9 g/dL by the age of 8 to 12 weeks, the average hemoglobin value observed by Schulman in premature infants weighing less than 1500 g was 8.0 g/dL at the age of 4 to 8 weeks.[414] These data are consistent with the normal data found by others.[416]

It is generally agreed that this fall in hemoglobin concentration results in greatest part from a decrease in red cell mass rather than a hemodilutional effect of an expanding plasma volume.[90] These changes occur at a time when the red cell survival of both term and premature infants is known to be shortened and when a striking decrease occurs in hematopoietic activity, as evidenced by a fall in the reticulocyte count and a decrease in marrow erythroid elements.

Cord blood analysis generally demonstrates elevated levels of EPO; these elevated levels are increased further in infants who experience transient hypoxemia at the time of delivery.[417,418] One notable exception is seen in neonates with severe isoimmunization treated by intrauterine transfusion, in whom severe anemia typically develops postnatally. The anemia is due to a combination of continued immune-mediated hemolysis and suppressed erythropoiesis. Serum EPO in these neonates surged transiently at birth but did not reach "appropriate" levels until the hemoglobin level decreased to below 5 g/dL.[419] Otherwise, infants born anemic demonstrate reticulocytosis. Increased erythropoiesis is generally seen in small-for-gestational-age infants who have experienced intrauterine hypoxia.[420] The anemia of prematurity rarely occurs in association with cyanotic congenital heart disease or respiratory insufficiency, which indicates that infants in the first few weeks of life can maintain higher oxygen-carrying capacity if the need arises. In premature infants, early neonatal anemia is an important predictor of mortality and neurologic sequelae.[421]

An important insight into the ability of preterm infants to adjust the hemoglobin level adequately to their own specific requirements may be noted if the hematologic status of infants who are born with widely varying hemoglobin concentrations is compared in the first few months of life. Differences in initial hemoglobin levels greatly affect the hemoglobin concentration in the weeks after birth. Infants with lower hemoglobin levels at birth achieve minimum hemoglobin values more rapidly, and their recovery phase occurs earlier than in infants born with higher hemoglobin levels.[415] It is interesting to note, however, that the minimum hemoglobin levels achieved are similar in infants born with widely discrepant hemoglobin values, thus suggesting that the signal for return of active erythropoiesis is roughly equivalent among infants.

Until recently it was not clear how infants, particularly premature infants, could tolerate large declines in hemoglobin concentration while at the same time provide sufficient supplies of oxygen to tissues. Adequate tissue oxygenation in the face of diminished oxygen-carrying capacity (lower hemoglobin concentration) can be accomplished only if oxygen demands are reduced or if one or more compensatory changes that are known to accompany anemia are observed. These responses include, in part, higher cardiac output, improved oxygen-unloading capacity, redistribution of blood flow, and greater oxygen extraction (a decrease in oxygen tension in mixed central venous blood). Apparently, only some of these responses occur.

Cardiac output does not change significantly between the end of the first week of life and 3 months of age. Although the oxygen content of blood (milliliters of oxygen carried per 100 mL of blood) decreases to its lowest level in the first 2 to 3 months of life, this reflects nothing more than the overall decline in hemoglobin concentration. The oxygen-unloading capacity of blood—that is, the actual quantity of oxygen that is theoretically capable of being delivered to tissues—is constantly increasing from the moment of birth, even as the hemoglobin level falls.[422] This increase in oxygen unloading results from a gradual rightward shift in the oxyhemoglobin dissociation curve as fetal hemoglobin levels decrease and the red cell 2,3-DPG level increases. The magnitude

of this shift may have profound physiologic significance for both term and premature infants.

Recombinant Human Erythropoietin and the Anemia of Prematurity

In 1977, Stockman and associates observed EPO concentrations within or below the normal adult range in infants with the anemia of prematurity.[423] Very low levels for the degree of anemia have subsequently been observed and reported by others.[424,425] EPO levels in neonates of different weight at birth vary over a wide range, but they seem to reach a nadir between days 7 and 50 independent of weight at birth; this is followed by the nadir in hemoglobin concentration (between day 51 and 150).[426] These and other data indicate that the increase in EPO levels is insufficient for the degree of anemia when the neonates are compared with matched adults.[50,427]

Investigation of in vitro erythroid colony growth has demonstrated normal numbers of both circulating BFU-E[428] and bone marrow CFU-E[429] in the anemia of prematurity. Both classes of erythroid progenitors show normal EPO dose-response curves. Taken together, the findings of low serum EPO concentrations, relative bone marrow erythroid hypoplasia, and a normal EPO dose-response curve suggest that inadequate EPO production is a major factor in the genesis of anemia of prematurity.

The blunted EPO response to decreasing hemoglobin levels[312] may be a consequence of the incomplete switch from liver to kidney as the major source of EPO production in premature infants and the relative insensitivity of liver-controlled EPO production to hypoxia.[424] An additional factor may be related to a different clearance and volume of distribution of EPO in neonates that results in lower EPO levels.[430,431] The anemia of prematurity is also due to blood loss related to the shorter life span of neonatal erythrocytes and to the rapid growth observed in the first weeks of life, which is not accompanied by a parallel increase in red cell mass. Detailed reviews of the pathophysiology and treatment of anemia of prematurity have been published.[262-264,431,432]

The use of r-HuEPO reduces the need for transfusions in premature infants weighing more than 1000 g, a group that rarely undergoes transfusion.[432] r-HuEPO may not be as effective in reducing transfusion requirements when it is used in infants weighing less than 1000 g or in neonates requiring artificial ventilation.[433-435] In a large, double-blind, placebo-controlled trial, r-HuEPO was shown to reduce blood transfusion requirements in preterm infants (weight at birth, 924 ± 183 g).[436] Although the reduction in blood transfusions was statistically significant, use of r-HuEPO resulted in only a small increase in the number of untransfused infants (from 31% to 43%). This disappointing result could have been due to poor EPO responsiveness, variability in the r-HuEPO

dosages used, or inconsistency in providing supplemental iron for sustaining the enhanced erythropoiesis induced by r-HuEPO. A detailed cost analysis of the use of r-HuEPO for the anemia of prematurity has been published.[437] A meta-analysis of 21 clinical trials in which r-HuEPO was administered to premature neonates showed an average reduction of 11 mL/kg in red cell transfusion in neonates weighing less than 1000 g.[438] However, the large variability in published results does not permit r-HuEPO to be recommended as standard of care in this setting.[438] Early (first 2 weeks of life) use of r-HuEPO does not seem to reduce the number of transfusion in infants with birth weight less than 1250 g.[439] However, it lowers transfusion requirements in infants with birth weight lower than 800 g and phlebotomy losses of greater than 30 mL/kg.[439]

A potential advantage of the use of r-HuEPO in the anemia of prematurity is the associated right shift in the oxyhemoglobin dissociation curve, most likely secondary to the increased erythrocyte 2,3-DPG content.[440] The incidence of necrotizing enterocolitis is lower in very-low-birth-weight infants treated with r-HuEPO,[441] whereas neurodevelopmental outcomes are unaffected by r-HuEPO therapy.[442]

Studies in adult subjects have identified a functional iron deficiency in normal iron-replete subjects treated with r-HuEPO and oral iron.[443] Oral iron administration is insufficient for sustaining the increased marrow activity in the presence of r-HuEPO, and intravenous iron supplementation should always be considered for premature infants, possibly in association with vitamin E supplementation. In very-low-birth-weight premature infants, no measurable detriment in antioxidant defense could be shown in conjunction with oral iron supplementation therapy.[444] Use of intravenous iron together with r-HuEPO was associated with a greater hemoglobin and reticulocyte response in premature infants.[445]

Studies in adult patients have indicated that autologous donation is not cost-effective when compared with allogeneic blood transfusion, mostly as a consequence of the high cost of collecting and discarding units that are not used.[446] However, reduction of allogeneic blood use by means of autologous blood donation (and the use of r-HuEPO) may be a prudent practice to follow despite the associated additional cost.[447] Cost-benefit analysis does not indicate cost-effectiveness for the use of EPO in the neonatal setting,[448] but this conclusion is based on the high cost of the product (to reach a break-even point would require a 54% reduction in product cost) and the way it is currently packaged: a 2000-unit vial cannot be used more than once for the same patient, although it can be used for multiple patients on the same day. However, any vial-sharing practice should be carefully scrutinized, given the reports of *Serratia liquefaciens* sepsis from multiple use of single-use vials in adult dialysis centers.[449] Changes in r-HuEPO price and packaging could make r-HuEPO therapy more similar in cost to

allogeneic blood transfusion. r-HuEPO is a remarkably safe drug. No significant side effects have been reported with its use, with the exception of the occurrence of seizures and blood pressure elevation when the circulating red cell mass is increased too rapidly. r-HuEPO has been shown to increase total bilirubin production in premature infants without inducing clinically significant jaundice.[450] Use of r-HuEPO in preterm infants does not affect the ratio of HbF to HbA.[451]

NEONATAL HYPERVISCOSITY

Neonates with hematocrit values in excess of 65% are at some risk for *hyperviscosity syndrome*, a condition that consists of hypoglycemia, central nervous system injury,[452] and hypocalcemia with elevated plasma calcitonin gene–related peptide levels.[453] Infants with polycythemic hyperviscosity should undergo careful isovolumic partial plasma exchange transfusion, especially when abnormal results are obtained on cerebral blood flow velocity studies.[454] Although there is good correlation between polycythemia and hyperviscosity, several infants with hyperviscosity syndrome have normal hematocrit values and can be identified only with the use of viscosity measurements.[455] Several risk factors for neonatal polycythemia and hyperviscosity have been identified, such as maternal insulin-dependent diabetes,[456,457] intrauterine growth retardation, perinatal asphyxia, twin-to-twin transfusion (recipient), delayed cord clamping, and Beckwith's syndrome.[458]

TRANSFUSIONS IN PREMATURE INFANTS

Red cell transfusion is discussed in Chapter 35; however, some of the problems unique to the neonatal setting are discussed in this section. For a more detailed discussion of issues related to neonatal red cell transfusion, consult recent publications.[263,459-463]

Decisions regarding the need for transfusion in low-birth-weight infants cannot be based on hemoglobin concentration or hematocrit alone. Wardrop and co-workers have demonstrated that "available oxygen" and not the absolute hemoglobin level most closely correlates with the presence of symptoms and signs of hypoxemia such as tachycardia, tachypnea, easy fatigability, and poor feeding in low-birth-weight infants.[464] Available oxygen is a reflection of the position of the oxyhemoglobin dissociation curve, the hemoglobin concentration, and arterial oxygen saturation. Nomograms that illustrate the importance of these factors in making decisions regarding transfusion have been prepared.[465] These nomograms are based on assumptions regarding cardiac output and oxygen consumption that have been derived from serial measurements in low-birth-weight infants.[466] An example of the importance of P_{50} and arterial oxygen saturation in making decisions regarding the hemoglobin required

TABLE 2-13	Hemoglobin Levels Required in Low-Birth-Weight Infants* to Maintain Central Venous Oxygen Tension of 30 mm Hg			
	ARTERIAL OXYGEN SATURATION (%)			
P_{50} (mm Hg)	**95**	**90**	**85**	**80**
20	10.0	13.0	20.0	>25.0
23	7.3	9.0	11.0	15.5
25	6.2	7.3	8.8	11.0
27	5.3	6.3	7.3	8.9

*Assumes a cardiac output of 250 mL/kg/min and an oxygen consumption of 6.5 mL/kg/min.

for maintaining central venous oxygen tension at 30 mm Hg is illustrated in Table 2-13.

As a general rule, hemoglobin values in otherwise healthy low-birth-weight infants should be maintained above 12 g/dL during the first 2 weeks of life. After that period, decisions regarding transfusion when determinations of "available oxygen" cannot be performed should be based on the infant's clinical condition. Factors to evaluate include the infant's weight gain, evidence of fatigue during feeding, tachycardia, tachypnea, and evidence of hypoxemia as reflected by an increase in blood lactic acid concentrations.[467] Although a study in premature infants has shown no relationship between hematocrit (values from 19% to 64%) and either heart or respiratory rates or the occurrence of bradycardia,[468] hematocrit still seems to be the best indicator of red cell mass in low-birth-weight infants.[469] Capillary whole blood lactate has been shown to have little value in transfusion decisions,[440,470] although plasma lactate levels decrease after transfusion.[440] In a study comparing "liberal" and "restrictive" hematocrit transfusion thresholds (46% versus 34% for tracheal incubation, 38% versus 28% for nasal continuous positive airway pressure or supplemental oxygen, and 30% versus 22% for neither), the "liberal" group received more transfusions without being exposed to more donors, whereas infants in the "restrictive" groups experienced more frequent major neurologic adverse events.[462] However, a recent study comparing two hemoglobin thresholds for transfusion (7 versus 9.5 g/dL, with target ranges of 8.5 to 9.5 g/dL versus 11 to 12 g/dL, respectively) showed that the 7.0-g/dL threshold was associated with decreased transfusion requirements and no worse adverse outcomes.[471,472]

Infants with cardiac or pulmonary disease that reduces arterial oxygen saturation may require hemoglobin concentrations of at least 16 to 17 g/dL for their oxygen requirements to be met adequately. No guidelines for neonatal transfusion have been clearly defined. It is common practice to transfuse neonates for the following reasons[473]:

1. Replacement of blood drawn for testing when cumulative blood loss reaches 5% or 10% of total blood volume
2. Maintenance of hematocrit greater than 40% in patients with severe respiratory distress or symptomatic heart disease
3. Maintenance of hematocrit greater than 30% in neonates with cardiopulmonary problems or growth failure

It has been estimated that more than 300,000 red blood cell transfusions are given annually to 38,000 premature neonates in the United States.[473] Most infants who weigh more than 1000 g do not receive transfusions in this country.[474] There has been a significant reduction in the prevalence of transfusions because of improved treatment and prevention of neonatal lung disease with surfactants, better ventilation, inhalation of NO, reduction in blood loss for analytic purposes, and less aggressive transfusion regimens. Neonatal transfusion practices in the United States have been studied in a national survey,[475,476] which indicated that a large number of institutions in the United States still perform unnecessary major antiglobulin crossmatches for neonatal transfusions. This practice leads to a greater amount of blood being drawn and thus more transfusions.

Standards issued by the American Association of Blood Banks require testing for ABO group and Rh type, as well as red cell antibody screening before the first transfusion. If the red cell antibody screen is negative, it is unnecessary to crossmatch red cells for the initial or subsequent transfusions. Repeat testing may be omitted for the remainder of the neonate's hospital admission. If a non–group O neonate is to receive non–group O red blood cells that are not compatible with the maternal ABO group, the initial sample should also be tested for passively acquired anti-A or anti-B immunoglobulin.[477]

Infants do not usually produce red cell–specific antibodies. Production of antibodies against white cells has been described, but its clinical significance is unclear.[478,479]

Traditionally, blood used for neonatal transfusion is less than 7 to 10 days old and is collected in anticoagulant citrate-phosphate-dextrose-adenine (CPDA) rather than in additive solutions, even though there is no good scientific evidence to support this practice with small-volume (10 mL/kg) red cell transfusions.[475,480,481] When transfused in small volumes (15 mL/kg), up to 42-day-old red cells in additive solutions are equivalent to fresh red cells in CPDA.[482] Use of specifically assigned units less than 14 days old and sterile connecting devices allows a reduction in donor exposure and has no adverse effects.[483] Exposure to different donors can be drastically reduced by the multiple use of a single unit of blood for a patient over a period of 35 to 42 days without affecting cost.[484-486]

Blood products with a low risk for cytomegalovirus (cytomegalovirus negative or leukodepleted red cells) should be used only for neonates with weight at birth of less than 1200 g who are cytomegalovirus negative or of unknown cytomegalovirus status.[487,488] Universal leukodepletion is now applied to all red cells collected in the United States.[489] Early immunostimulatory (increase in lymphocyte count) and late (day 14) immunosuppressive effects (increase in lymphocytes expressing CD45RA, CD3$^-$/CD16$^+$CD56, CD80, and CD3$^-$/DR) have been described in transfused very-low-birth-weight infants.[490]

Packed red cells should be adjusted to the desired hematocrit (60% to 79%) with normal saline or 5% albumin solution. However, a significant number of institutions still use fresh frozen plasma from the same donor or from a different donor for this purpose.[475] This practice is particularly widespread for exchange transfusions in which red cells reconstituted in fresh frozen plasma from different donors are used—that is, each neonate is exposed to two different donors. In some settings, partial exchange transfusion may be preferable to simple transfusion.[491] Use of a small-bore central venous line (1.90-French NeoPICC) may not be associated with significant hemolysis, at least based on in vitro data.[492]

A significant factor in determining different blood use in the neonatal setting is related to existing institutional practice. Comparison of blood use in two NICUs has revealed major differences in the percentage of patients transfused and the number of transfusions that cannot be accounted for by differences in disease severity.[493-495] Because no differences can be demonstrated in clinical outcome between high-transfusion and low-transfusion NICUs, implementation of guidelines on blood drawing, use of arterial catheters, and transfusion should result in a reduction in transfusion rates and associated complications and cost.

3 | Immune Hemolytic Disease of the Newborn

Helen G. Liley

HISTORICAL ASPECTS

Whereas many serious complications of pregnancy were well known in antiquity, maternofetal blood group incompatibility was recognized more recently. Much of the understanding of the disease developed between the 1930s and 1970s, although since the late 1980s, the molecular basis of both Rh and other blood group genotypes and phenotypes has been revealed. Despite the spectacular appearance of a hydropic fetus and placenta and the drastic effect of recurrent perinatal death on family size and structure, only about 1 in 200 pregnancies in Occidental societies is vulnerable to complication by antibodies. Even without any effective treatment only about half the babies would die. Against the high perinatal mortality prevailing until the mid-20th century, deaths from hemolytic disease were of little statistical significance. Louyse Bourgeois, midwife to Marie de Medici, may have been the first (in 1609) to give an account of hemolytic disease of the fetus and newborn (HDN).[1] She described twins: the first was hydropic and died shortly after birth; the second initially appeared well but rapidly became jaundiced, then opisthotonic, and subsequently died.

The connection between "congenital anemia," icterus gravis, and hydrops fetalis was not recognized until 1932 despite detailed descriptions of each condition by pathologists. Diamond and co-workers[2] deduced that these conditions were variations on a common theme and coined the term *erythroblastosis fetalis* for disease characterized by hemolytic anemia, intramedullary and extramedullary erythropoiesis, and hepatosplenomegaly. Darrow, who had lost a baby of her own to kernicterus, correctly speculated in 1938 that the disease was caused by maternal antibodies to fetal antigens developed as a result of transplacental fetomaternal hemorrhage.[3] However, because she incorrectly concluded that the antibody was to fetal hemoglobin (HbF), much of the recognition for this remarkable insight was given to those who provided the evidence.

In 1939, Levine and Stetson linked a woman's severe transfusion reaction to her husband's blood with her recent delivery of a hydropic stillborn infant.[4] She was found to have an antibody that agglutinated her husband's red blood cells (RBCs). Levine postulated that she had become sensitized to an antigen that the fetus had inherited from its father.

In 1940, Landsteiner and Wiener[5] proposed the identity of the antigen by generating antibodies to rhesus monkey RBCs in guinea pigs and rabbits. The antisera agglutinated RBCs from 85% of whites. These people were designated rhesus (Rh) positive. The 15% whose RBCs did not agglutinate were Rh negative.

Levine and associates then used Landsteiner and Wiener's antiserum to show that Levine and Stetson's patient was Rh negative and her husband was Rh positive. Furthermore, her serum agglutinated the RBCs from Wiener and Landsteiner's Rh-positive but not their

Rh-negative individuals.[6] The monkey RBC antigen and antibody (LW and anti-LW) are not the same as the human RhD antigen and antibody, but reactivity was linked to Rh status because LW is more strongly expressed on Rh-positive RBCs. Subsequent years saw rapid and dramatic progress, including recognition that immunoglobulin G (IgG) crossed the placenta and development of the Coombs test.[7] This test uses anti-human IgG antibodies to agglutinate IgG-labeled RBCs and remains important in the detection and management of HDN. Chown reported in 1954 that mothers could be sensitized by transplacental hemorrhage of fetal blood,[8] although until crossmatching for Rh groups became routine, transfusion for postpartum hemorrhage and other indications also contributed to the incidence of the disease. Chown's observation plus subsequent recognition that most sensitizing fetomaternal hemorrhages occurred at delivery, thus explaining why Rh HDN was mainly a disease of multipara, paved the way for the development of immunoprophylaxis. Since the late 1960s, RhD immunoglobulin has been available to treat Rh-negative mothers of Rh-positive infants at delivery to prevent Rh HDN.

These discoveries all contributed to understanding of the delicate balance in the immunology of pregnancy; the maternal immune system generally remains in a state of armed neutrality toward the fetus and its foreign antigens, which remain shielded by the trophoblast. Meanwhile, the advantages of maternal immunologic memory are conferred on the fetus and newborn via active transplacental passage of antibodies, thereby creating optimal conditions for awakening of the newborn's own adaptive immune system. However, if a maternal antibody develops to a self-antigen or a fetal antigen, fetal disease can result. Thus, when an Rh-negative woman exposed to Rh-positive RBCs develops anti-D IgG, the antibody traverses the placenta and can bind fetal D-positive RBCs and lead to their destruction. The subsequent fetal hemolysis can lead to icterus gravis, kernicterus, and hydrops fetalis.

For many problems of pregnancy, obscurity of the pathophysiology until recently often led to management that at best was symptomatic. In contrast, with hemolytic disease the genetic predilection, molecular mechanism, and rationale for treatment were rapidly deduced, which led to remarkable success in preventing the disease and mitigating its effects. Indeed, the history of prevention and management of Rh HDN includes a number of pivotal discoveries that have influenced the management of other diseases. These breakthroughs include exchange transfusion for neonatal treatment, development of screening programs for maternal blood group antibodies, strategies for managing early delivery to optimize neonatal outcomes, the use of amniocentesis for fetal diagnosis, the first example of intrauterine fetal treatment, and the development of one of the earliest and most successful forms of immunoprophylaxis using human antibodies. Subsequently, many of the successes of fetal and neonatal

TABLE 3-1	Incidence of Rh Allelic Combinations Expressed by the Fisher-Race and Wiener Nomenclature

†Rh negativity is more common in Indo-Asians.

treatment of Rh HDN have been extrapolated to HDN caused by other blood group antibodies and other problems of pregnancy.

Advances in molecular biology and biochemistry allowed identification of the Rh polypeptides in 1982 and Rh genes in 1991. Until these discoveries, controversy existed between two models to explain Rh genotype and phenotype relationships. Wiener and Wexler[9] proposed the existence of a single gene with multiple epitopic sites, whereas Fisher and Race[10,11] postulated that there were two closely linked genes encoding three pairs of Rh antigens: Dd, Cc, and Ee inherited in two sets of three (one set from each parent) (Table 3-1).[12] Both models have been shown to be partly correct, although like many disorders that were once thought to have been genetically simple and phenotypically diverse, the diversity of Rh genotype/phenotype relationships is much greater than previously envisaged.

THE Rh BLOOD GROUP SYSTEM

Biochemistry and Molecular Genetics

Although the incidence of Rh HDN has declined and the incidence of HDN secondary to other alloantibodies has increased, the Rh blood group system remains the most common cause of HDN (particularly severe HDN), especially in whites, for whom about one in seven conceptions involves an Rh-negative mother and an Rh-positive father. Individuals are classed as Rh positive or negative based on expression of the major D antigen on their RBCs; however, more than 50 other Rh antigens have been identified, the most commonly recognized of which in clinical practice are those designated D, C, c, E, and e. The Rh blood group system is the most complex blood group system in humans.[13,14]

After the landmark descriptions of the RhD protein in 1982,[15,16] non-D[17,18] and D complementary DNA

(cDNA) and genes were cloned in the early 1990s.[19,20] In most individuals the Rh blood group loci are the products of two very similar genes, one of which encodes CD240CE, the polypeptide that carries the Cc/Ee epitopes in combinations (Ce, ce, cE, or CE), and the other of which encodes CD240D, the D antigen polypeptide[14,21,22] (Table 3-2).[23] The two genes are separated by only 30 kilobases (kb) and are organized in opposite orientation on chromosome bands 1p36.2-p34. The small *SMP1* gene (a "small membrane protein" family member) lies between them. They share a very similar 10-exon structure, and their intronic sequences are also highly conserved. Their sequence identity strongly suggests that they evolved by duplication of an ancestral gene about 8 million years ago.[24] Worldwide, the Rh blood group system displays considerable polymorphism. A wide variety of both small and large mutations (including gene deletion and recombination to form hybrid *RHD-RHCE* products) and the effects of other modifying genes account for the diverse common and rare Rh phenotypes[25,26] (Table 3-3). Although some genotypic and phenotypic variants are confined to a single family, for others the incidence in various gene pools is much higher or unknown. This diversity mandates caution in the use of DNA-based clinical diagnostic approaches, especially when these approaches are applied to populations other than the ones in which they were piloted, but it may open the door for future individualization of prevention and therapy.[27,28]

The predicted product of the RhD messenger RNA is a 417–amino acid polypeptide with a molecular mass of 45,100. The D and Cc/Ee polypeptides have greater than 90% amino acid identity. Of the 32 to 37 amino acid substitutions that usually differ between the D and CE polypeptides, about a quarter are located in extracellular domains of the protein. Within RhCE, E/e specificity is conferred by a single amino acid substitution (P226A) encoded by exon 5 of the *RHCE* gene and found in the fourth extracellular loop. C/c specificity is

TABLE 3-3	Examples of Variant Rh Phenotypes for Which a Corresponding Genotype Has Been Described to Illustrate the Diversity of the *RHD* Genotype	
Category	**Phenotype**	**Typical Mutations**
Partial D	D^{II} to D^{VII} and others	Variety of point mutations and *RHD-RHCE* hybrids
Weak D	Weak D (D^u) types 1-16	Variety of point mutations leading to amino acid substitutions in the transmembrane or cytoplasmic domains
D negative (silent D or d)	D negative	Variety of mechanisms: *RHD* complete or partial deletion, *CE* hybrids, point mutations; some prevent transcription, but all prevent expression at the cell surface
CE variants	RN, E^{I-III}, VN, CX, C^W, etc.	Variety of hybrids and point mutations
CE silent	D.., D– and various others	Mostly *RHD-RHCE* hybrids
Rh deficiency states (no D or CE expression)	Rh_{null} amorph	*RHCE* silent genes plus *RHD* deletion
	Rh_{null} reg, Rh_{null}mod	*RHAG* mutations that prevent expression

associated with four amino acid differences: C16W encoded by exon 1 and I60L, S68N, and S103P all encoded by exon 2 of the *RHCE* gene.[29] Of these, the S103P substitution is the only extracellular substitution and is most important in determining antigenic reactivity.[14,29,30]

It has been well established for decades that no d antigen exists. RhD negativity is defined as the absence of RhD antigen, and its incidence is highest in the Basque population.[31] It has been suggested that peripatetic Basque traders and fishermen (or their ancestors) may have spread this genotype to other populations. In these European-descended populations in which Rh negativity is relatively common, most RhD-negative individuals are homozygous for an *RHD* gene deletion.[19,20] This mutation appears to have arisen because two highly homologous sequences (1463-bp "rhesus boxes") flank the *RHD* gene and provide the opportunity for unequal crossing over.[32] However, although Rh negativity is less common among them, other mechanisms for D negativity appear more commonly in other populations, such as individuals of African, Chinese, or Japanese ancestry.[33-35] These alternative mechanisms include partial deletion, recombination between *RHD* and *RHCE* genes, and point mutation. An Rh allele that comprises a pseudogene (*RHDΨ*) is prevalent among RhD-negative people of African ances-

try, including approximately 66% in South Africa and about one in five RhD-seronegative African Americans.[35,36] *RHDΨ* is not expressed because of two inactivating mutations, a 37-bp duplication in exon 4 that causes a premature stop codon and a nonsense mutation (Y269X) in exon 6. Four characteristic single-nucleotide polymorphisms also occur in exons 4 and 5. Singleton and colleagues found that 15% of RhD-negative black South Africans carry a hybrid *RHD-CE-D* that also encodes an altered C antigen.[35]

The molecular basis of the D-positive phenotype is also intricate. Studies using site-directed mutagenesis, naturally occurring variants of *RHD*, and monoclonal antibodies or molecular modeling indicate that the D antigen is composed of at least 37 different, but overlapping epitopes,[25,37-41] some of which are missing in individuals who express partial D antigenicity. Most of the epitope clusters are located in exofacial loops 3, 4, and 6 of the D protein. RhD variants are discussed in more detail later.

The *RHD* and *RHCE* gene products are unique among blood group antigens in being nonglycosylated, palmitoylated integral membrane proteins (Fig. 3-1). Their 12 predicted helical transmembrane domains are connected by small extracellular and cytoplasmic loops. Their expression is confined to erythroid cells, whereas
FIGURE 3-1. Diagram of the Rh peptides RhD (*top*) and RhCE (*bottom*) inserted in the cell membrane (*parallel horizontal lines*). The amino acid sequence of both proteins predicts 12 transmembrane domains. Neither is glycosylated, but RhD has two sites of palmitoylation (*zigzag lines*) and RhCE has three. D-specific amino acids are marked with *open circles*. The predicted position of most is in the transmembrane and cytoplasmic domains. E/e specificity appears to be conferred by a single proline-to-alanine amino acid substitution at residue 226 (P226A) encoded by exon 5 of the *RHCE* gene and C/c specificity by the S103P (serine 103 to proline) substitution encoded by exon 2. Four other amino acid differences are also associated with C/c polymorphism but do not appear to affect antigen characteristics: C16W encoded by exon 1 and I60L, S68N, and S103P all encoded by exon 2 of the *RHCE* gene.[29]

many other blood group antigens are present in many tissues. They are found in hetero-oligomeric complexes, the structure and function of which are still under investigation. In these oligomers, Rh antigens are found in association with a glycosylated membrane component that migrates diffusely on sodium dodecyl sulfate–polyacrylamide gel electrophoresis at approximately 45 to 75 kd.[15,16] This 409–amino acid glycoprotein, formerly known as Rh50 glycoprotein, is now designated Rh-associated glycoprotein (RhAG). It is about a third identical to RhD and RhCE and, putatively, has a similar configuration involving 12 helical membrane-spanning domains. Its gene has an exon-intron organization similar to that of *RHD* and *CE*; however, it maps to chromosome bands 6p21.1-p11. Its expression is also confined to erythroid cells.[42] Nonerythroid homologues (RhBG and RhCG) have been found in other tissues.[43] The Rh

complex was thought to comprise a tetramer of two RhD and/or CE subunits and two RhAG subunits[44]; however, more recently a model consisting of trimers of two RhAG subunits and either an RhD or CE or possibly two RhD or CE subunits with one RhAG has been supported by hydrophobic cluster analysis.[45]

Cartron[13] and Cartron and Colin[22] have reviewed the Rh deficiency states. Rare individuals with the Rh deficiency syndrome (Rh$_{null}$) lack expression of all or virtually all RhD, C/c, and E/e antigens. This recessive condition can result (in RhD-negative individuals) from homozygous silent mutations in the *RHCE* gene that appear to reduce cell surface expression of RhAG ("amorph type"). Homozygotes for mutations that prevent expression of RhAG have the more common "regulator type" or the Rh$_{null}$mod phenotype. Despite normal transcription of Rh genes, the proteins are not found at the cell surface.[46]

The functional significance of the Rh complex is indicated by the fact that Rh-deficient individuals have spherocytosis, stomatocytosis, and chronic hemolysis of varying severity. Their RBCs have altered ion transport and membrane composition and are partly or completely deficient in certain other membrane proteins, including RhAG, CD47, LW (Landsteiner-Wiener glycoprotein, or intercellular adhesion molecule 4 [ICAM-4]), GPB (glycophorin B, which confers the Ss blood group), and Duffy Fy5 (Duffy antigen receptor for chemokines). These deficiencies suggest that Rh proteins form complexes with RhAG and other proteins and that the complexes fail to form if components are missing.[13,47] There is also strong evidence for an interaction with the anion exchange protein (band 3) and linkage of the Rh complex to the spectrin-based RBC membrane skeleton, thus indicating a role in maintaining the biconcave disc shape of RBCs (Fig. 3-2).[47] Failure of this association may explain some of the dysfunction of Rh-deficient cells. However, many details of when, how, and why the Rh complexes form remain to be explained.

An additional functional role for components of the Rh complex is also suggested by their evolutionary conservation, particularly in regard to molecules similar to RhAG.[13,24,43] The probable function of these glycoproteins was suspected because of sequence identity between them and the yeast Mep proteins. This led to the discovery that RhAG and a second Rh-related glycoprotein, RhGK (normally expressed in kidney cells), rescue Mep-deficient mutant cells grown on media with low ammonium. These and related experiments suggested a role for Rh glycoproteins in ammonia or ammonium ion import and export across cell membranes.[48-51] However, more recent studies indicate that RhCE and RhD proteins lack the key residues essential for ammonium transport, and it has been proposed instead that Rh complexes in RBCs form CO_2 channels.[25,52,53] The diversity of abnormalities in Rh-deficient RBCs raises the possibility of ancillary functions.

In contrast to the common Rh-negative and very rare Rh deficiency states, weak and partial D phenotypes are
FIGURE 3-2. Diagram of the proposed Rh complex and its interactions. The trimer, composed of RhAG molecules and either RhCE molecules or RhD, interacts with other membrane proteins and with the cytoskeleton.

fairly common (e.g., 0.2% to 1% of populations of European ancestry) and are caused by *RHD* coding region alterations that affect the number and antibody-binding characteristics of RhD sites per cell. The term "partial D" has been used to describe RBCs that react with some monoclonal anti-D antibodies and not others, and their RhD proteins typically have one or more amino acid substitutions on or near the RBC surface or consist of RhD-RhCE hybrids. In contrast, "weak D" has been used for RBCs with a markedly reduced number of antigenic sites and in which one or more amino acid substitutions are found in regions that are presumed to be in or below the membrane and may interfere with the assembly of Rh complexes.[25,54] Most weak D individuals, especially those with types 1, 2, and 3, do not make anti-D. However, it has been recognized that there is overlap and some imprecision in allocation of these phenotypes, and the terms "aberrant D" or "D variant" have been proposed as collective terms for these plus the (very weak) D-elute phenotype[26,54-56] (see Table 3-3).

Because of variable antigenic potential and the potential to form antibodies to RhD, certain weak and partial D phenotypes are significant in transfusion therapy and pregnancy. Some individuals need to be regarded as RhD negative in pregnancy and as transfusion recipients (eligible for anti-D immunoprophylaxis and Rh-negative blood) but Rh positive as blood donors.[54,56,57] For example, if some blood donors with aberrant/variant D are regarded as D negative, their blood can cause alloimmunization of D-negative recipients. On some occasions, women with partial D (especially partial D[IV]) form anti-D antibodies capable of causing severe HDN if they carry a D-positive child,[58] or D-negative women can form antibodies if their babies have some types of aberrant/variant D. Some partial D phenotypes are also associated with distinct antigens.

The C antigen is most common in Southeast Asia, parts of South America, and the southern tip of Greenland, whereas the E antigen occurs most often in populations indigenous to parts of South America and Alaska.[31]

The genetics underlying the RhCc/Ee phenotypes also display more subtle variation than was once envisaged, and weak, partial, and variant antigen phenotypes have also been recognized. Internet databases are a good source of up-to-date information about the phenotype-genotype relationships for RhD and RhCE.[23,59]

RhD ALLOIMMUNIZATION

HDN is a disease of the fetus caused by a maternal response to pregnancy. As such, the pathogenesis can be considered in three stages: maternal alloimmunization, antibody transfer to the fetus, and fetal response.

Maternal Rh Sensitization

Maternal sensitization to Rh antigens can occur as a result of exposure to antigenically dissimilar fetal RBCs during pregnancy, as a result of therapeutic transfusion, or occasionally as a result of needle sharing.[60,61] Transfusion has become a rare cause of RhD sensitization because compatibility testing for RhD antigen has been routine practice for several decades. However, it accounts for a high proportion of sensitization to other blood group antigens, including RhCE, and among those with RhD and RhCE variants. Furthermore, the need for emergency transfusion of Rh-positive blood to Rh-negative women is likely to remain an occasional cause of sensitization to RhD in locations where the Rh-negative phenotype is rare and Rh-negative blood is scarce.

Exposure to fetal antigens remains the most common cause of maternal antibodies to RhD. Although Chown first described maternal Rh immunization occurring as a result of fetal transplacental hemorrhage (TPH), the test of Kleihauer and associates[62] in 1957 was needed to show the incidence, size, and timing of these events and to show that most maternal Rh sensitization occurs this way.[63] The test depends on the resistance of HbF to acid elution (Fig. 3-3) and can detect 1 fetal RBC in 200,000

FIGURE 3-3. Acid elution technique of Kleihauer. Fetal red blood cells (RBCs) stain with eosin and appear dark. Adult RBCs do not stain and appear as ghosts. This maternal blood smear contained 11.2% fetal RBCs and represents transplacental hemorrhage of about 450 mL of blood. *(From Bowman JM. Hemolytic disease of the newborn. In Conn HF, Conn RB [eds]. Current Diagnosis 5. Philadelphia, WB Saunders, 1977, p 1103.)*
adult RBCs, which corresponds to a fraction of a milliliter in the circulating maternal blood volume. Bowman and colleagues[64] used this technique for two weekly tests in a group of 33 women and concluded that 76% had had experienced TPH. The incidence increased as pregnancy progressed: 3% had TPH in the first trimester, 12% in the second trimester, 45% in the third trimester, and 64% immediately after birth. However, acid elution studies must be interpreted with some caution because of rapid destruction of fetal cells when ABO incompatibility exists and because of natural variation and pregnancy-induced increases in expression of HbF among adults. Subsequently, using flow cytometric techniques and DNA amplification of fetal sequences, researchers have confirmed that some fetal cells can be detected in maternal blood during all trimesters of most pregnancies.[65,66] Because strategies for detection vary among studies and because of uncertainties about the persistence of various types of fetal cells in the maternal circulation, the volume and timing of this transplacental passage of fetal cells remain unclear. However, most of these "hemorrhages" are likely to be tiny. Delivery is the time of greatest risk for fetomaternal hemorrhage and for larger hemorrhages, especially when complications of delivery of the fetus or placenta occur.[66]

Larger TPHs are uncommon; the amount of fetal blood exceeds 2.5 mL in less than 1% of gestations and is greater than 30 mL in less than 0.25%.[66] However, certain obstetric situations increase the risk for significant TPH, including antepartum hemorrhage, pre-eclampsia, external version,[67] cesarean section,[68,69] and manual removal of the placenta.[70] Abdominal trauma and placental vascular malformations are additional, but uncommon causes. TPH occurs in about 2.5% to 8.4% of patients after amniocentesis,[71,72] but the risk after early-gestation chorionic villus sampling (CVS) is uncertain.[73]

The level of risk for sensitization as a result of first-trimester pregnancy loss is also uncertain and, in the case of spontaneous miscarriage, will depend on whether an embryo with circulating blood ever formed, but surgical evacuation of the uterus is thought to present a greater risk for TPH than medically induced or spontaneous evacuation is.[74] The Rh antigen may be expressed by about 38 days after conception,[75] early enough in gestation for early CVS or pregnancy loss to present a risk.

All studies have focused on fetal cells in the maternal bloodstream, which may have gained access across the placenta but in some situations could have been absorbed from the maternal peritoneum, but the responses to submucosal, subcutaneous, or intramuscular antigen presentation differ from those to intravascular presentation. Therefore, deposition of fetal RBCs in these sites could be more immunogenic than deposition via the intravascular route and could account for some of the propensity for Rh sensitization after invasive procedures. If this is the case, techniques such as those recommended to minimize exposure of the fetus to maternal blood[76] might be effective in reducing the risk for blood group sensitization.

The Nature of Rh Sensitization

Primary and Secondary Immune Responses

In most Rh-negative individuals, the primary immune response develops slowly. In experimental Rh immunization of male volunteers, antibody responses are typically detected at 8 to 9 weeks, although they can occur at any time from 4 weeks to 6 months. Hemolytic anemia caused by anti-D has been detected as early as 10 days after a massive Rh-incompatible transfusion in a previously unsensitized patient.[77] A primary, often weak IgM response will not affect the fetus, even if it occurs before

delivery in a sensitizing pregnancy, because IgM anti-D does not cross the placenta. However, IgG anti-D production usually ensues, and if sensitization occurs early in pregnancy, there is the potential for continued antigenic challenge, which can account for the rare occurrence of HDN in the progeny of women during their first Rh-positive pregnancy.

After a primary response has been invoked, subsequent exposure to Rh-positive RBCs induces a rapid increase in anti-D IgG, which can cross the placenta and affect the fetus. Repeated exposure can progressively increase the titer and change the characteristics (including IgG subclass distribution) of the Rh antibody, thus increasing the severity of Rh hemolytic disease in successive pregnancies.

Dose of Rh Antigen Necessary to Produce Rh Sensitization

Experiments involving injection of Rh-positive blood into Rh-negative males show, not unexpectedly, that the likelihood of Rh sensitization depends on both the dose and repetition of exposure to the antigen.[78,79] A proportion of individuals are anergic to RhD, regardless of the dose and repetition of exposure ("nonresponders").[80] Secondary immune responses may occur after exposure to very small amounts of RhD-positive RBCs (as little as 0.03 mL).

Studies performed during and immediately after pregnancy using the Kleihauer technique indicated that if the volume of TPH was always less than 0.1 mL of RBCs, the prevalence of Rh sensitization detectable up to 6 months after delivery was 3%, whereas when volumes exceeded 0.4 mL, the prevalence was 22%.[78,79] Nevertheless, because in 75% to 80% of pregnancies the amount of TPH is always less than 0.1 mL, it is likely that either small or undetectable TPH or fetal cells deposited in other sites account for the majority of sensitization.

Incidence of Rh Sensitization

Rh sensitization has decreased markedly with the introduction of Rh immunoprophylaxis. In its absence, about 16% of Rh-negative women become sensitized in their first ABO-compatible Rh-positive pregnancy. Of these, about half have detectable anti-D 6 months after delivery, and in half a rapid secondary response is seen in the next susceptible pregnancy, thus indicating that primary sensitization had occurred previously.[78,81] If sensitization does not occur, the risk in a second D-positive, ABO-compatible pregnancy is similar. By the time that an Rh-negative woman has completed her fifth ABO-compatible, Rh-positive pregnancy, the probability that she will be Rh sensitized is about 50%.

As parity increases and the number of women capable of an Rh immune response diminishes because they have already become immunized, the proportion of the remainder whose systems mount a primary immune response decreases because of a greater residual number of "nonresponders." About 25% to 30% of D-negative women are nonresponders in that they do not become Rh sensitized despite having many D-positive pregnancies; however, some may yet become Rh sensitized if they are exposed to a very large amount of Rh-positive blood. Immunologic tolerance can be induced by several different mechanisms and can depend on the context of antigen presentation to the immune system. It is not known which mechanisms of tolerance predominate in nonresponding Rh-negative women.

ABO incompatibility provides partial protection against Rh sensitization. Without anti-D immunoprophylaxis, it has been estimated that in whites, blood group A incompatibility between the mother and fetus reduces the risk for Rh sensitization by 90% and group B incompatibility by 55%.[82] Bowman[81] suggested that this partial protection is due to rapid intravascular hemolysis of the ABO-incompatible, D-positive RBCs, with sequestration of D-positive cells in the stroma of the liver (an organ with poor antibody-forming potential) rather than the spleen (the site of RBC sequestration when extravascular RBC destruction occurs). However, it is not clear whether the immune system remains naïve with respect to the Rh antigens or whether tolerance is induced in these instances. Although ABO incompatibility provides substantial protection against the primary Rh immune response, it provides no protection against the secondary Rh immune response[83,84] and should not influence the management of an already affected pregnancy. Maternal HLA type does not have any consistent effect on the risk for sensitization, although it may affect antibody titer and the severity of HDN.[85,86]

Other factors that influence the likelihood and severity of sensitization include fetal gender and fetal red cell phenotype, which affects the number and antigenicity of D antigen sites on fetal RBCs. For example, R1r (CDe/cde) cells, with only 9900 to 14,400 D antigen sites per cell, are less immunogenic than R2r (cDE/cde) cells, which have 14,000 to 16,000 sites.[87,88] The possibility that Rh-negative women were exposed to RhD during their own fetal life (the so-called "grandmother theory") has been considered, but the evidence from a case-control study is against it.[89] Nevertheless, convincing evidence of maternal-to-fetal hemorrhage has been found in other circumstances, and these events could explain the occasional presence of Rh antibodies in Rh-negative men and nulliparous women who have never had a transfusion.

Rh sensitization during pregnancy, once considered to be rare, occurred in about 1.8% of susceptible pregnancies in one study.[90] The proportion of all occurrences of Rh sensitization that are attributable to antenatal sensitization now varies among studies, depending on the application of antenatal immunoprophylaxis.

In summary, some general rules apply to Rh HDN. The probability of incompatible pregnancies is predictable from the Hardy-Weinberg genetic principles, but the impact of HDN on a population will also depend on

typical family size and on careful management of obstetric complications.[91] The risk should be low when good blood bank procedures, parsimonious approaches to blood transfusion, effective screening of pregnant women, and evidence-based administration of Rh immunoprophylaxis are applied. The disease should be uncommon or mild in a woman's first incompatible pregnancy, and 50% of the infants of heterozygous fathers and sensitized mothers should be safe. However, as pointed out by Kinnock and Liley,[84] the striking feature of pregnancies in severely isoimmunized women is their clinical variability. Because these women have often become sensitized despite the predictions of conventional wisdom, their care requires astute and conscientiousness management to ensure satisfactory outcomes.

Prevention of Rh Sensitization

The background to prevention of Rh sensitization lies in the experiments of Von Dungern at the beginning of the 20th century.[92] He showed that serum from rabbits that had previously been injected with ox cells prevented the development of antibodies to ox cells in a second group of rabbits. The partial protective effect of ABO incompatibility also suggested that antibody-mediated destruction of fetal RBCs could prevent maternal Rh sensitization. Finn and co-workers[93] suggested a strategy of administering anti-D immunoprophylaxis, and it was put to the test almost simultaneously in New York[94] and Liverpool[95] and shortly thereafter in Winnipeg.[96] Because anti-RhD immunoglobulin was strikingly successful in preventing sensitization in males, clinical trials were then undertaken in which Rh-negative, unsensitized women were given anti-D intramuscularly after delivery of an Rh-positive infant.[96-98] The licensing of Rh immune globulin in 1968 profoundly influenced the prevalence of Rh sensitization. Despite its success, the exact mechanism of action of anti-D remains elusive.[99,100]

The level of evidence for the postpartum use of anti-D immunoprophylaxis is high. A recent systematic review collated data from six eligible trials involving more than 10,000 women in which postpartum anti-D prophylaxis was compared with no treatment or placebo.[101] The conclusion was that anti-D prophylaxis strikingly lowered the incidence of RhD alloimmunization 6 months after birth (relative risk, 0.04; 95% confidence interval, 0.02 to 0.06) and in a subsequent pregnancy (relative risk, 0.12; 95% confidence interval, 0.07 to 0.23). These benefits were seen regardless of the ABO status of the mother and baby when anti-D was given within 72 hours of birth. Higher doses (up to 200 μg) were more effective than lower doses (up to 50 μg) in preventing RhD alloimmunization in a subsequent pregnancy. The usual dose after full-term delivery in the United States and Canada is 300 μg (1500 IU), which will effectively suppress the immunizing potential of approximately 17 mL of RhD RBCs,[102] although lower doses are administered elsewhere with almost equivalent effectiveness. Postpartum prophylaxis is recommended whenever a D-positive

infant is born to an unsensitized D-negative mother.[103] Some guidelines also recommend anti-D if the infant is weak D positive.[57,103]

After postnatal immunoprophylaxis, the risk for RhD alloimmunization is between 1% and 2%. Administration of 100 μg (500 IU) of anti-D at 28 and 34 weeks' gestation to women in their first pregnancy can reduce this risk to about 0.2%.[104,105] Most current guidelines[57,106-109] therefore recommend routine administration of Rh immunoglobulin to all D-negative pregnant women in the early and mid third trimester unless the father of the fetus is known and can be shown conclusively to be Rh negative. This combined antenatal and postnatal prophylaxis will prevent 96% of cases of RhD isoimmunization.[103] Most guidelines are silent on the issue, but many transfusion services also recommend prophylaxis for weak D-positive women,[110] although more extensive serologic or genetic characterization can obviate the need for such prophylaxis in many cases.[54] Additional or earlier doses (depending on the timing and circumstances) for D-negative women who are not already sensitized and who abort, experience abdominal trauma, or are undergoing amniocentesis, CVS, or other relevant procedures may further reduce the risk for sensitization.[107,111,112] Small amounts of anti-D cross the placenta and cause a weakly positive antiglobulin test, but there are no apparent adverse effects on the infant.[113] It is important to note that the results of maternal antibody screening tests performed near term may be positive (albeit usually at low titer) after anti-D administration during pregnancy, but under the current guidelines these results should not preclude the postnatal administration of anti-D.

About 1 in 400 woman will have fetal-to-maternal TPH of greater than 30 mL of fetal blood at the time of delivery. Prevention of Rh sensitization in the presence of such a large dose of antigen requires prompt assessment (by the Kleihauer-Betke test or flow cytometry) and administration of a titrated dose of anti-D.[109] Pediatricians must be aware of this possibility and promptly notify their obstetric colleagues of any suspected anemia or blood loss in the newborn infant of an Rh-negative mother. Assessment of the magnitude of TPH is also recommended after pregnancy complications such as abdominal trauma.

Certain knowledge of Rh negativity in the biologic father of the fetus can obviate the need for antenatal immunoprophylaxis. However, this information should be established with a very high degree of certainty because of the potential for severe consequences in a future pregnancy in case of error.[109]

Reports from numerous countries have documented a reduction in RhD HDN as a result of anti-D immunoglobulin. Nevertheless, there is no room for complacency because 30% to 40% of the reduction in incidence of HDN over recent decades has been attributed to decreased family size rather than administration of anti-D.[114] Chavez and colleagues[115] noted that the incidence of Rh sensitization in the United States is three times the

rate predicted if anti-D were always applied according to guidelines issued by the American College of Obstetricians and Gynecologists. Failure of the anti-D program to completely abolish RhD HDN can be partly attributed to noncompliance with guidelines. In addition, recommendations for additional doses during pregnancy have led to a scarcity of anti-D in some locations. These problems are even greater in poorer countries.[116] Giving donors booster doses consisting of carefully screened RhD-positive RBCs has been a necessity as the number of suitable sensitized donors decreases, but this practice requires extreme care to protect both the donor and eventual recipients. Distribution of the Rh-negative phenotype may increase as a result of migration. As with the use of any blood product, issues of safety cannot be disregarded.[117] All these forces threaten the supply of anti-D. Recombinant monoclonal or polyclonal preparations, which could in principle replace the current polyclonal anti-D and thereby resolve problems of availability and safety, have been under development in recent years. However, although monoclonal antibodies have significant diagnostic and research applications, they are not yet available for prophylaxis against sensitization.[118,119]

Overall, it is unlikely that the incidence of Rh HDN will ever return to the levels seen in previous generations, but it is also not likely to be abolished altogether.

Pathogenesis of Rh Hemolytic Disease

Erythropoiesis begins in the yolk sac by the third week of gestation, and Rh antigen is expressed by the sixth week. By 6 to 8 weeks' gestation, the liver replaces the yolk sac as the main site of RBC production. Normally, erythropoiesis then diminishes in the liver and takes place nearly entirely in the bone marrow by the late third trimester of pregnancy.[120]

Erythroblastosis is caused by coating of fetal RBCs with maternal IgG, which leads to their destruction. The subsequent fetal anemia stimulates erythropoiesis via the production of erythropoietin and other erythroid growth factors. When fetal marrow RBC production cannot keep up with RBC destruction, marked extramedullary erythropoiesis can be found in other organs, including the liver and in more severe cases also in the spleen, kidneys, skin, intestine, and adrenal glands. Hepatosplenomegaly is a hallmark of erythroblastosis fetalis. In the presence of erythroblastosis, immature nucleated RBCs, from normoblasts to early erythroblasts (Fig. 3-4), are poured into the circulation.

SEVERITY OF Rh HEMOLYTIC DISEASE

Degrees of Severity

For purposes of audit, research, and planning of treatment, degrees of severity of HDN have been used since the 1950s.

In general, fetuses and infants with mild HDN have had antibody-coated RBCs that yield positive results on a direct antiglobulin (Coombs) test, but they have no anemia or anemia that is well compensated for in utero and after birth and do not require exchange transfusion to prevent bilirubin toxicity. This group historically accounted for about half of affected fetuses. Nearly all survive and do well without invasive treatment.

Moderately affected fetuses are at risk for neural toxicity from bilirubin if they do not receive treatment. Historically, they are a group who routinely underwent exchange transfusion after birth. They are likely to have some signs of anemia in utero and ex utero but are not significantly acidotic or hydropic. Their peripheral blood typically shows polychromasia, anisocytosis, and reticulocytosis, although these conditions can be suppressed by intrauterine treatment. Maternal clearance copes with the products of hemolysis, and the fetus is usually born
FIGURE 3-4. Cord blood from a baby with severe Rh erythroblastosis fetalis who required multiple fetal transfusions and exchange transfusions. The smear was treated by Kleihauer's technique with Wright staining. Note the adult donor ghost red blood cells (RBCs), dark fetal RBCs, and early fetal erythroid series consisting of erythroblasts through normoblasts. *(From Bowman JM. The management of Rh-isoimmunization. Obstet Gynecol. 1978;52:1. Reprinted with permission from The American College of Obstetricians and Gynecologists.)*

in good condition at or near term. This category historically represented about a third of fetuses. Moderately affected neonates do require vigilant neonatal management, including intensive phototherapy or exchange transfusion, to manage jaundice.

Severely affected fetuses have hydrops or hydrops is impending, and they would die before, during, or after birth unless managed intensively. Untreated, hydrops develops in half between 18 and 34 weeks' gestation and in the other half between 34 and 40 weeks' gestation. Polyhydramnios usually occurs early in the course or precedes the development of hydrops. Ascites and pleural and pericardial effusions develop. In infants with the most extreme conditions, compression hypoplasia of the lungs makes gas exchange after birth precarious.

When these categories of disease were first devised, severe fetal disease predicted severe neonatal disease. However, as fetal and neonatal management has been refined, the predictions must be updated, and the proportion of mildly and moderately affected neonates has risen. For example, some mildly anemic but not hydropic neonates who met previous criteria for exchange transfusion are now managed effectively with intensive phototherapy and would therefore be regarded as having mild rather than moderate disease. Similarly, a fetus with the early development of hydrops (severe fetal HDN) may respond well to one or more intrauterine transfusions and would therefore be born with mild neonatal disease and yet still have severe late anemia that is as much a consequence of hematopoietic suppression caused by effective intrauterine treatment as of hemolysis caused by the underlying disease. A suggested update to the working definitions that separates the criteria into epochs and includes a summary of implications for practice is given in Table 3-4.[121]

Pathogenesis of Hydrops

Hydrops in HDN was originally attributed to fetal heart failure, but other factors probably play a role (Fig. 3-5).[122] With severe hemolysis and progressively greater extra-medullary erythropoiesis, the hepatic architecture and circulation are distorted by the islets of erythropoiesis. It has been suggested that this alteration results in portal and umbilical venous obstruction and portal hypertension. Impairment of umbilical venous return would exacerbate the fetal tissue hypoxia caused by anemia and explain the placental edema that is usually seen in severe hydrops. The placental edema, by increasing the placental barrier to gas exchange, could then impair oxygen delivery even more. The theory that liver distortion and dysfunction are at least as important as heart failure in the pathogenesis of hydrops fetalis could explain why hydrops is not always accompanied by hypervolemia or even anemia.[122] Support for the suggestion that portal hypertension is present is provided by ultrasound assessment of waveforms in the portal venous system.[123]

Hypoalbuminemia is a common feature, but the mechanism has not been explained. It could be caused by a greater volume of distribution for albumin or reversion to α-fetoprotein expression rather than failure of hepatic synthesis.

The mechanisms that lead to hydrops remain poorly understood, both in anemic fetuses and in nonanemic fetuses with "nonimmune" hydrops. Various inflammatory mediators could play a role but have not been examined. Genes that are regulated by hypoxia include those for vascular endothelial growth factor and other molecules involved in capillary morphogenesis. Depending on the pattern of expression, these molecules can markedly affect capillary permeability and could also play a role.

Factors Affecting the Severity of Fetal/Neonatal Hemolytic Disease

If a sensitized mother is pregnant with an Rh-incompatible fetus, a number of factors influence the severity of disease in the fetus, including placental transfer of antibody, antibody characteristics, antigen characteristics, state of maturation of the fetal spleen, and resilience of fetal erythropoiesis.

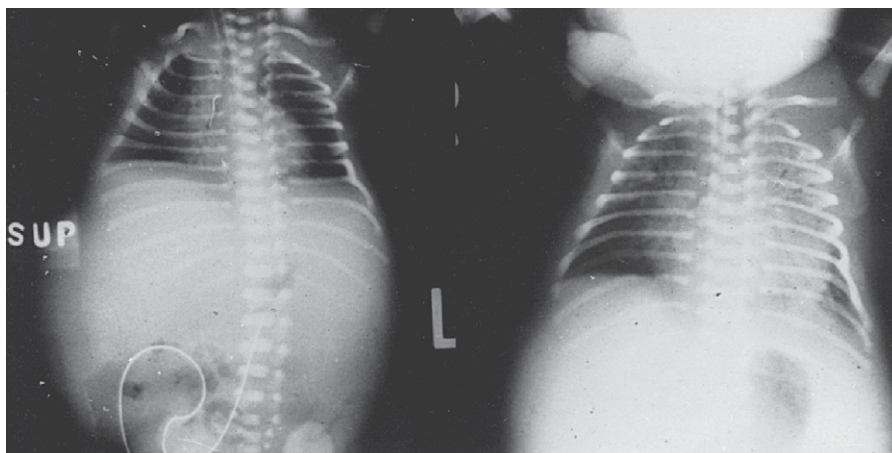
FIGURE 3-5. Radiograph of a hydropic newborn at birth and 6 hours later after exchange transfusion. Note the small size of the heart at the time of birth and the very marked increase in heart size and evidence of pulmonary congestion denoting heart failure 6 hours later. The fetus has extreme ascites. *(From Bowman JM. Blood-group incompatibilities. In Iffy L, Kaminetzky HA [eds]. Principles and Practice of Obstetrics and Perinatology. New York, John Wiley & Sons, 1981, p 1203. © Leslie Iffy, MD, Newark, NJ.)*


TABLE 3-4 Degrees of Severity of Rh Hemolytic Disease of the Fetus and Newborn			
	Mild	**Moderate**	**Severe**
IN THE FETUS			
Historical proportion of Rh HDN before intrauterine therapy was available	≈50%	25-30%	20-25%
Probable history in previous siblings	No exchange	Exchange unless in utero treatment performed	Severe unless in utero treatment performed
Probable maternal anti-D titer	<1:64	>1:64	>1:64
Ultrasound abnormalities	None	Altered patterns of flow in fetal vessels	Signs of severe anemia (see Table 3-5), hydrops, portal hypertension, ascites and other effusions, polyhydramnios
IN THE NEONATE			
Clinical condition at birth	Normal	Mildly or moderately ill	Hydrops
Hemoglobin at birth	No anemia	Mild or moderate anemia; HgB >0.6 MoM for gestation	Severe, symptomatic anemia, HgB <0.6 MoM
Hemoglobin nadir	Transfusion not needed	At risk for symptomatic anemia	Risk of death unless transfusion performed
Bilirubin cord	<3.5 mg/dL (≈70 µmol/L)	>3.5 mg/dL (≈70 µmol/L)	>3.5 mg/dL (≈70 µmol/L)
Bilirubin peak	Term: <20 mg/dL (≈380 µmol/L) Premature: lower levels, depending on prematurity	Term: >20 mg/dL (≈380 µmol/L) Premature: lower levels, depending on prematurity	Rate of RBC destruction depends on (low) HgB; peak bilirubin is variable, toxicity increased
Phototherapy	If bilirubin increases faster than 0.4-0.5 mg/dL/hr; lower threshold for premature infants	If bilirubin increases faster than 0.4-0.5 mg/dL/hr; lower threshold for premature infants	Immediate, intensive, pending measurement of bilirubin increase
"Early" exchange	No	If rate of increase in bilirubin >0.8-1 mg/dL/hr; lower threshold for premature infants	Yes
"Late" exchange	If bilirubin > exchange level	If bilirubin ≥ exchange level	If bilirubin approaches exchange level
Heme oxygenase inhibition	Unnecessary—number needed to treat to avoid exchange will be high	In the context of well-designed clinical trials	In clinical trial to avert late exchange; unlikely to allow avoidance of early exchange
Intravenous immunoglobulin	Unnecessary—number needed to treat to avoid exchange will be high	In the context of well-designed clinical trials	In clinical trial to avert late exchange; unlikely to allow avoidance of early exchange
Phenobarbital	No	No	No clear benefit if optimal phototherapy performed
Erythropoietin for late anemia	No	In the context of well-designed clinical trials	In the context of well-designed clinical trials

HDN, hemolytic disease of the fetus and newborn; MoM, multiples of mean; RBC, red blood cell.
Modified from Peterec SM. Management of neonatal Rh disease. Clin Perinatol. 1995;22:561-592.

Transfer of Antibody to the Fetus

All four IgG subclasses are transported across the placenta via FcRn-mediated endocytosis and then exocytosis.[124-126] The fetal-to-maternal ratio for total IgG is approximately 0.4 at 28 weeks' gestation and increases to 1.4 at term,[127] but fetal levels of IgG1 are close to maternal levels by 17 to 20 weeks' gestation.[128] The efficiency of placental transport of antibody may be an important factor in the severity of Rh HDN, and reduced IgG transport can result in unexpectedly mild disease.[129]

Mechanism of Red Blood Cell Hemolysis

When anti-RBC antibodies bind complement and are present in high concentration (as with transfusion reactions to ABO-incompatible blood in adults), extravascular RBC destruction occurs and may cause a clinically severe reaction that includes hemoglobinemia, shock, and disseminated intravascular coagulopathy. Products of

RBC destruction are cleared predominantly by the liver.

When antibodies do not fix complement, as is typical with anti-D in the fetus and neonate,[130,131] the mechanisms of hemolysis are more subtle but, in the end, equally destructive. Three Fc receptor–mediated pathways have been implicated in the destruction of opsonized RBCs: direct phagocytosis, phagocytic damage leading to later lysis, and killer cell–mediated damage. When anti-D becomes concentrated on the membrane of RhD-positive RBCs, the RBCs adhere to macrophages and form rosettes, particularly in the red pulp of the spleen, where RBCs and macrophages come into close apposition. The phagocytic cell can then destroy the RBC or damage and deplete the membrane, thereby causing loss of RBC deformability. If the RBC escapes being consumed by the macrophage, its membrane is damaged and its osmotic fragility and likelihood of lysis are greater (Fig. 3-6).

Antibody-dependent cellular cytotoxicity (ADCC) probably also accounts for the destruction of some RBCs.[132] Large granular "K cells" (natural killer lymphocytes) or myeloid cells (polymorphonuclear leukocytes and monocytes) bind antibody-labeled cells and release lysosomal enzymes and perforin, which causes lysis.

Hemolysis also requires a competent system of phagocytic cells in the fetus. The clinical manifestations of the disease suggest that maturation is sufficient as early as the mid second trimester.

Antibody Specificity and Severity of Hemolytic Disease

Antigen characteristics, including details of antibody distribution, density, and structure, all affect the risk for HDN and have been reviewed by Hadley.[133] Antibodies with the potential to cause HDN generally recognize antigens restricted to erythroid cells (such as Rh antigens) rather than those with wider tissue distribution (such as A and B antigens, found on many cell types). The antigens must be expressed in the fetus and neonate. Thus, antibodies to Kell and Rh antigens, which are expressed early in fetal life, cause severe HDN, whereas antibodies to Lewis antigens, which are not synthesized in erythrocyte progenitors, never cause HDN. The circulating glycosphingolipids carrying the antigenic Le^a or Le^b epitopes generally adsorb to the erythrocyte membrane only during postnatal life. Lewis antibodies are also usually IgM. Lewis is the only human blood group system that has never been reported to cause HDN of any severity.

Antigen density is also an important factor. Within the Rh system, even in the presence of high maternal anti-D titer, fetuses with aberrant D phenotypes are unlikely to be severely affected. As might be expected, homozygotes for *RHD* appear to have higher D antigen density than heterozygotes do,[88] although this is not usually clinically relevant in Rh HDN because RhD-positive infants of RhD-negative mothers are obligate heterozygotes. The *RHCE* genotype also affects RhD antigen density, and in particular there seems to be higher expression of D when CE is deleted or underexpressed.[134,135] The density of several other antigens, including A and B and the Lutheran antigens,[136] is developmentally regulated, and antigen density on immature RBCs limits the severity of hemolysis.

Antigen structure may also play a role, with some antigens being more capable of promoting recognition of RBCs by phagocytic cells.

FIGURE 3-6. A Rebuck skin window preparation in which anti-D–sensitized erythrocytes have been ingested by macrophages. Note that neutrophil erythrophagocytosis is not seen. *(From Zipursky A, Bowman JM. Isoimmune hemolytic disease. In Nathan DG, Oski FA [eds]. Hematology of Infancy and Childhood, 4th ed. Philadelphia, WB Saunders, 1993, p 53.)*
Antibody characteristics likewise play a role in determining the severity of HDN. IgG subclasses bind different classes of Fc receptors, although it has not yet been established conclusively which receptors are involved in RBC destruction in vivo. Fc receptor polymorphisms (analogous to an FcRII allele found in whites, which binds IgG2 very avidly and may play a role in ABO HDN) may yet be found to account for some of the heterogeneity of Rh HDN.[133]

Whereas anti-A and anti-B antibodies are predominantly IgG2, IgG1 and IgG3 anti-D antibodies tend to predominate in Rh-sensitized women.[137-140] They are often present in combination.

The capacity of RBC-bound IgG3 antibodies to bind to the Fc receptors of monocytes is greater than that of IgG1 antibodies. Threshold levels of antibody binding for rosette formation in vitro are approximately 1000 IgG3 or 2000 IgG1 molecules per RBC.[141] Both can promote phagocytosis, but their relative potencies depend on circumstances. IgG3 usually causes more efficient lysis by monocytes than IgG1 does.[142-144] Clearance of Rh-positive RBCs is caused by fewer molecules of IgG3 anti-D than of IgG1 anti-D.[145] However, the relationship of these factors to HDN is still unclear. Studies of maternal IgG subclasses do not indicate a clear relationship between subclass distribution and disease severity.[146]

HLA antibodies have been found in the sera of some women who have infants with mild HDN despite high anti-D antibody levels. The HLA antibodies may block antibody-antigen interactions on the macrophage membrane.[133]

ANTIBODY DETECTION

ABO and RhD typing plus antibody screening is recommended at the first prenatal visit in all pregnancies, including visits for elective abortion. A history of previous pregnancies and blood transfusions should also be elicited. If the blood group is D negative or weak D, another antibody screening is recommended at 24 to 28 weeks' gestation, before the administration of anti-D immunoprophylaxis. If an alloantibody is detected at low titer, screening is usually repeated at regular intervals to detect any increase. There are a variety of methods for assessing maternal antibodies, some that are better suited for screening methods and some that are more useful for predicting the severity of disease.[133]

Manual Methods

Rh-positive RBCs suspended in isotonic saline are agglutinated only by IgM anti-D because although IgG anti-D can bind to antigen, it cannot bridge the gap between RBCs suspended in saline. Therefore, a maternal serum sample containing only IgG anti-D does not agglutinate Rh-positive RBCs suspended in saline. The addition of albumin lowers the negative electrical potential of the

RBC membrane, and IgG anti-D can then bridge the smaller gaps between the RBCs.[147] Because IgM anti-D also agglutinates Rh-positive RBCs suspended in albumin, if saline and albumin titers are similar, the albumin titer does not accurately assess IgG anti-D. Addition of dithiothreitol disrupts IgM sulfhydryl bonds and reveals the true IgG anti-D titer. Albumin methods have been surpassed but are described to clarify the earlier literature that refers to them.

Coombs' serum is an anti-human globulin produced by immunizing another species.[7] Rh-positive RBCs are incubated with the serum sample that is being tested for the presence of anti-D. If anti-D is present in the sample, it adheres to the Rh-positive RBC membrane. The RBCs are then washed to remove nonadherent human protein and suspended in Coombs' serum. If the RBCs are coated with anti-D, they are agglutinated by the antibodies to human immunoglobulin (positive test result). The reciprocal of the highest dilution of maternal serum that produces agglutination is the indirect antiglobulin titer.

Incubation of RBCs with enzymes such as papain, trypsin, and bromelin reduces the electrical potential of the RBC membrane and thus allows agglutination of Rh-positive cells by IgG anti-D, even in saline. Enzyme screening methods are the most sensitive manual techniques available for detecting Rh sensitization, but they detect many antibodies that have no clinical significance.[148]

These manual methods have the advantages of sensitivity and flexibility, but the correlation between antibody titer and disease severity is poor.

Automated Analysis

Autoanalyzer methods have been developed and refined for more efficient and reproducible detection and quantitation of Rh and other antibodies.[149-151] Autoanalyzer techniques are very sensitive, and the finding of an Rh antibody detected only by an autoanalyzer method does not necessarily indicate the presence of HDN or even true sensitization, especially if the titer is very low and stable. Gel and solid-phase assays have also been developed.[152-156] Rising titers indicate worsening disease and suggest the need for assessment of the fetus.

PREDICTION OF FETAL HEMOLYTIC DISEASE

Once sensitization is detected, subsequent investigative measures are required. To refine the estimation of risk, one or more of the following may need to be considered.

Determination of fetal blood type by

- Paternal blood typing
- Fetal blood typing

Prediction of the severity of disease by

- A history indicating the severity of HDN in previous infants
- Maternal antibody titers
- Cell-mediated maternal antibody functional assays
- Fetal ultrasound
- Amniotic fluid spectrophotometry
- Percutaneous fetal blood sampling

Determination of Fetal Blood Type

Paternal Blood Typing

In some instances, paternal blood typing can indicate that the baby has no risk for HDN. This situation occurs if the father is Rh negative and the mother was sensitized not by his offspring but by those of a previous partner or by transfusion. If the father is predicted to be Rh negative or heterozygous, the fetus may be completely unaffected regardless of the maternal antibody titer. In predominantly white populations, about 56% of Rh-positive individuals are heterozygous. It is important, however, to not place too much weight on heterozygosity when it is present. Half the offspring of a heterozygous father should be Rh negative, but to come reliably ($P=.95$) within 20% of this ideal state, it can be deduced statistically that each mother would have to have about 30 pregnancies.[84]

Historically, paternal genotype was estimated by determination of the father's RhCE type, in combination with information about the distribution of Rh phenotypes in different racial groups. Molecular genetic techniques now allow more direct determination of genotype and correlation with phenotype.

Fetal Blood Typing

Fetal Rh typing, either by traditional antigen typing or by genotyping via DNA amplification techniques, is becoming increasingly feasible and widespread. Although the need for it can be obviated if paternal homozygosity is certain, it can be an especially important technique if paternity is uncertain or the father is heterozygous.

Molecular methods are now used routinely and with high accuracy in many locations to detect fetal *RHD*, *RHCE*, *KEL*, *FY*, and *JK* genes in fetal DNA obtained by amniocentesis or from fetal cells or free DNA in maternal blood.[157-164] Cell-free fetal DNA, presumed to be from apoptotic syncytiotrophoblasts, is now most commonly used for amplification because unlike some fetal cells, it is cleared rapidly after delivery and therefore reflects only the current pregnancy.[165] These tests have the potential to reduce the need for assessment throughout the pregnancy, including the need for invasive tests, and to avert the need for administration of anti-D during some pregnancies. Single-cell preimplantation diagnosis has also been described.[166]

The genetic diversity of the Rh blood group system outlined in an earlier section of this chapter provides an important reminder to use caution in choosing primers that minimize false-positive and false-negative test results and to keep in mind the fact that genotype does not always obviously predict phenotype. The prevalence of *RHD-RHCE* hybrids and partially intact but functionally inert *RH* genes in certain populations can invalidate some tests designed for application in whites. The use of appropriate controls, amplification of several diagnostic sites, preferably checking the correlation between the parents' genotype and phenotype in parallel, and using the tests with a good understanding of the typical genotypes in the populations for which they were developed and to which they are being applied should minimize errors.[167,168] The need to have a good positive control for fetal DNA to identify false-negative results is critical. The *SRY* sequence can be used if the fetus is male, but more complicated comparison of multiple fetal and parental polymorphisms in other genes may be necessary if the fetus is female. Differential methylation of the maspin gene in fetal and maternal tissues recommends it as a universal positive control.[164,169]

Because *RHD* genotyping of amniotic and chorionic cells agrees with serologic and tissue typing,[157] CVS or amniocentesis can be used for typing of the fetus. However, the need to use these procedures should diminish as procedures involving fetal DNA from maternal blood become more widely available. If maternal blood samples are used for diagnosis, advantages include the fact that typing can be done early in pregnancy and that sample acquisition neither risks harming the fetus nor increases maternal exposure to fetal antigens.

Prediction of Severity of Disease

The relative roles of methods for assessing the severity of hemolytic disease in the fetus have changed in recent years.

Pregnancy History

Although it is usually true that the severity of HDN remains the same or increases during subsequent affected pregnancies, the disease sometimes becomes less severe. If a previous baby was hydropic, a subsequent affected fetus has a 90%, not a 100% chance of the development of hydrops. If hydrops is going to develop, it usually does so at the same gestation or earlier, but occasionally it develops later. In a first D-sensitized pregnancy with no previous history of HDN, there is an 8% to 10% probability that hydrops will develop. If a mother has had a previous fetus with hydrops and the father is heterozygous for the offending antigen, the fetus may be negative and completely unaffected or be positive and very severely affected, a dilemma that requires resolution, usually by fetal typing. Thus, though worth noting, there are a variety of situations in which a history of previous pregnancies is unreliable.

Maternal Antibody Titers

Although antibody titrations carried out in the same laboratory by the same experienced personnel using the same methods and test cells are reproducible and do give

the physician some indication of risk, their predictive value is inadequate to guide invasive fetal treatment. The autoanalyzer technique provides somewhat better prediction of the severity of HDN than manual methods do, but the two approaches have not been compared rigorously. Hadley[133] has stated that although many laboratories can and should undertake screening for alloantibodies, antibody quantitation is best limited to regional centers with proven reliability. Ideally, these laboratories will also have programs auditing the outcomes of pregnancies in which antibodies have been detected. This can lead over time to the recognition of a critical titer, below which no cases of severe disease have occurred, and allow targeting of more extensive and invasive tests to those with titers above the threshold. However, the follow-up needed is laborious, is prone to ascertainment bias, and can threaten patient privacy. Generally, if the obstetric history is good, low titers ($\leq 1:16$ by manual methods or <5 IU/mL [1 µg/mL] by autoanalyzer) that increase slowly or not at all are reassuring and an indication for continued surveillance with antibody titers and ultrasound.

Although rising titers suggest increasing risk to the fetus, it has not been possible, even with autoanalyzer methods, to establish a titer above which the fetus must be sensitized,[170,171] and sometimes antibody levels increase significantly (but presumably nonspecifically) despite the presence of a compatible and therefore unaffected fetus. Nevertheless, in the presence of very high or rising titers, fetal assessment becomes urgent.

Maternal Antibody Functional Assays

Various functional assays that measure the ability of maternal antibody to promote interactions between RBCs and monocytes or K cells have been developed.[172] These assays include the monocyte monolayer assay,[173,174] the ADCC assay using lymphocytes[175] or monocytes,[176] and monocyte chemiluminescence.[141]

Each assay has its proponents, and their advantages and limitations have been reviewed.[133,174] Hadley and associates[153] compared monocyte chemiluminescence, K-cell lymphocyte ADCC, monocyte-macrophage ADCC, and a rosette assay using U937 cells. They found that monocyte chemiluminescence and monocyte ADCC functional assays predicted severity of disease better than rosette assay with U937 cells and K-lymphocyte ADCC did. Similarly, Zupanska and colleagues[140] found that the results of a monocyte-based assay (monocyte monolayer assay) correlated better with the clinical severity of hemolytic disease than did the results of rosette assays with lymphocytes. A survey of nine European laboratories that carried out functional assays on sera from mothers delivering babies with varying degrees of HDN revealed correct results as follows: ADCC (monocytes), 60%; ADCC (lymphocytes), 57%; chemiluminescence, 51%; and rosetting and phagocytosis with peripheral monocytes, 41% (with U937 cells or cultured macrophages, 32%).[177] However, a more recent report has cast doubt

on the ability of the monocyte-macrophage assay to predict the severity of HDN.[178]

Overall, when taken in conjunction with ultrasonography, consideration of the outcomes of previous pregnancies, and antibody quantitation, bioassays are somewhat useful in helping weigh the risks associated with invasive procedures in women with borderline levels of alloantibodies because they seem to be better in predicting mild rather than severe disease. However, there is no consensus that bioassays reduce the need for other forms of fetal assessment, and most published reports involve relatively small numbers of participants. These tests should be carried out in reference laboratories that perform them regularly and validate them carefully. Because they are measuring characteristics of the antibody, not the fetal antigen, bioassays are of no use in excluding an antigen-negative, unaffected fetus.

Amniotic Fluid Spectrophotometry

Bevis[179] showed that bilirubin could be found in the amniotic fluid of infants with HDN, and in 1961, Liley[180] plotted fetal outcomes by gestation and the results of amniotic fluid spectrophotometry, thus devising a prenatal test of the severity of fetal hemolytic disease that has only recently been surpassed as the standard method of assessing fetuses with hemolytic disease. Liley used the ΔOD_{450} reading (the deviation from linearity at 450 nm caused by the absorption spectrum of bilirubin) as a measurement of the amniotic fluid bilirubin level. Three zones of predicted severity of disease were defined (Fig 3-7). Readings in zone I indicated either no disease or no anemia at the time of testing but reflected a 10% chance that exchange transfusion would be needed. Readings in zone II indicated moderate disease that becomes more severe as readings approach the zone III boundary. Readings falling into very high zone II or zone III indicated severe disease. Hydrops was present or would develop within 7 to 10 days. When serial ΔOD_{450} measurements are taken, the overall accuracy of prediction of hemolytic disease with the amniotic fluid technique is 95%. Accuracy is higher in the third trimester than in the second trimester. Because the graphs were developed before intervention at earlier than 27 weeks' gestation was contemplated, zone boundaries in the second trimester were not defined. The Liley zone boundaries were subsequently modified by inclining them downward before 24 weeks' gestation because of the observation that ΔOD_{450} readings peak at 23 to 24 weeks' gestation in pregnancies unaffected by HDN.[181] The division lines for Queenan's chart are lower at all gestations than those of Liley's system. Although it was suggested that Queenan's modification could overestimate severity and lead to too many interventions,[182] others concluded that a more conservative approach was appropriate as safer and more effective intervention became available.[183] Monitoring with ultrasound and selective direct fetal blood sampling has markedly reduced the need for assessment by amniocentesis. Amniocentesis may be useful as

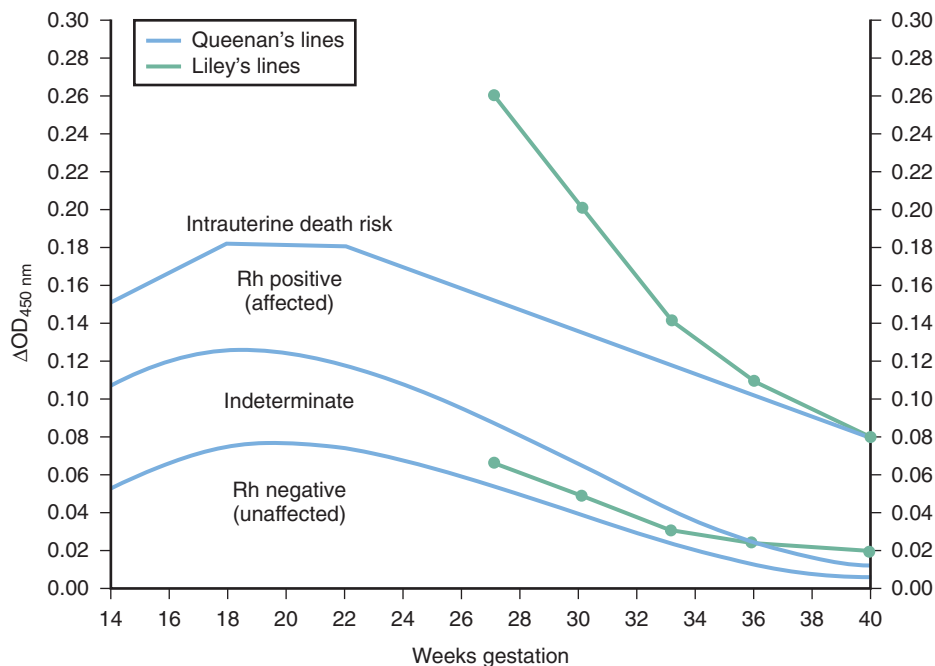
FIGURE 3-7. Superimposed Queenan and Liley charts of the deviation of absorbance at a wavelength of 450 nm (ΔOD_{450}) versus gestation. Liley's lines began at 27 weeks, and they were rectilinear when shown on a log-linear plot.[150] They were subsequently extrapolated back to 20 weeks.[151] Queenan's chart demonstrates that the lines should deflect downward in the early second trimester.[154] However, the division lines for Queenan's chart are lower at all gestations and may overestimate the risk in some fetuses. Current practice is to use fetal cerebral velicometry instead of or sometimes in addition to amniotic fluid results in determining the need and timing for intrauterine treatment. *(Redrawn from Scott F, Chan FY. Assessment of the clinical usefulness of the 'Queenan' chart versus the 'Liley' chart in predicting severity of rhesus iso-immunization. Prenat Diagn. 1998;18:1143-1148.)*


TABLE 3-5	**Comparison of Test Characteristics for Peak Systolic Velocity in the MCA Measured via Doppler Ultrasonography and Amniotic Fluid ΔOD_{450} in Predicting Severe Fetal Anemia***		
Test	**Sensitivity[†]**	**Specificity[†]**	**Accuracy[†]**
MCA blood flow >1.5 MoM[189]	88 (78-94)	82 (73-89)	85 (79-90)
Amniotic fluid ΔOD_{450}

MCA, middle cerebral artery; MoM, multiples of the median.

an adjunct to ultrasound to assess severity when factors such as fetal and placental position complicate fetal umbilical blood sampling.

Amniocentesis has risks, although ultrasound guidance has improved its safety and reliability considerably. Blood in amniotic fluid can obscure the 450-nm peak and thus make the fluid worthless for predicting the severity of hemolytic disease and complicate the determination of fetal genotype. Ultrasound guidance has reduced this risk from about 10% to 2.5%. Increases in antibody titer occur after some amniocenteses, although the risk is reported to be lower than that after umbilical blood sampling.[71,184]

Ultrasound Assessment

The development of obstetric ultrasonography in the late 1970s was a major advance in the management of maternal blood group isoimmunization. Ultrasound allows estimation of placental and hepatic size and determination of the presence or absence of polyhydramnios, edema, ascites, and other effusions. It has increased the safety of amniocentesis and intraperitoneal transfusion

and is essential for umbilical blood sampling and intravascular fetal transfusions.

Although ultrasound was previously said to be of little use in assessing the severity of disease until hydrops had developed, assessment of flow velocity in major fetal vessels has now been shown by several groups to be very reliable in detecting significant fetal anemia. Middle cerebral artery velocimetry is the most extensively used assessment.[185-191] As with any critical test, responsible practitioners should audit outcomes and refine their judgments according to them, but when skills to perform it are available, ultrasound velocimetry has become the method of choice for monitoring women with blood group–sensitized pregnancies and for planning and timing invasive fetal sampling, fetal treatment, and delivery (Table 3-5).[192]

Percutaneous Fetal Blood Sampling

With the development of sophisticated ultrasound equipment and the availability of perinatologists skilled in its use, percutaneous fetal umbilical blood sampling became feasible in the mid-1980s.[193] This procedure allows direct

diagnosis of fetal blood type, anemia, and acidosis and therefore provided the "gold standard" for diagnosis of fetal anemia against which the accuracy of other assessment techniques has been assessed. The procedure does carry with it a likelihood of fetal-to-maternal hemorrhage and a small risk of mortality.[193,194] Generally, it should be reserved for use when ultrasound (or amniocentesis) indicates moderately severe or severe disease with a probable need for intrauterine treatment. It is not usually indicated unless fetal treatment of severe anemia appears to be justified for continuation of the pregnancy and safe delivery. Fetal blood sampling may be possible as early as 18 weeks' gestation; it is generally feasible by 20 to 21 weeks' gestation. The preferred sampling site is the umbilical vein at its insertion into the placenta. For this reason, the procedure is technically easier to perform if the placenta is implanted on the anterior uterine wall.

MANAGEMENT OF MATERNAL ALLOIMMUNIZATION

Suppression of Alloimmunization

Since the mid-1940s, efforts have been made to suppress the strength of already developed maternal immune responses against fetal RBCs. Administration of Rh immune globulin, of great value in preventing Rh sensitization, has been shown to be ineffective in suppressing an established antibody response, no matter how weak, once it has begun.[195,196]

Two measures that have potential to reduce maternal antibody levels and ameliorate hemolytic disease are (1) intensive plasma exchange[197,198] and (2) the administration of nonspecific intravenous immune serum globulin (IVIG).[199-201] With intensive plasma exchange, alloantibody levels can be lowered by as much as 75% but tend to rebound, at times to levels higher than they were before.[202] Vascular access becomes difficult and IgG and albumin administration is needed. Plasma exchange is tedious, costly, and uncomfortable.[203] It may have a role in a mother with a fetus known to be susceptible to the antigen to which she is immunized and who has a previous history of hydrops at or before 24 to 26 weeks' gestation. However, the risk-to-benefit ratio remains insufficiently high to recommend it for routine management.

High-dose IVIG administration can also be effective in a severely alloimmunized pregnant woman, but its use should likewise be the subject of clinical audit and research. The mechanism of action has not been defined, but it could include inhibition of antibody synthesis or competitive blockade of receptor-mediated transfer across the placenta or binding sites on fetal immune cells. If IVIG therapy is considered, it should be used in the same situation as intensive plasma exchange, beginning at 10 to 12 weeks' gestation. Ongoing assessment of fetal disease remains essential because not all fetuses respond adequately. As a result of its cost, inconvenience, and side effects,[204] its use, like that of plasmapheresis, is reserved for fetal disease that is expected to be refractory to other therapy.[205]

Fetal Treatment

Induced Early Delivery

Premature delivery of fetuses with Rh HDN has been important in prevention of mortality since the late 1940s. With the introduction of amniotic fluid assessment in 1961, it became possible for the first time to predict which fetuses should be considered candidates for early delivery. Subsequent advances in perinatal and neonatal management of premature infants have had a major impact on survival. However, HDN is different from many other pregnancy complications in that intrauterine treatment has been effective in prolonging many gestations. As the effectiveness of fetal treatment has improved, particularly after the introduction of intravascular intrauterine transfusion, the need for premature delivery of infants with HDN has diminished. If premature delivery is required, antenatal betamethasone therapy should be given to the mother according to consensus guidelines. It is probable that infants with HDN have as much or more to gain from the use of this important preparation for extrauterine life than their gestation-matched peers with other fetal conditions do. A possible role for antenatal phenobarbital treatment to reduce the need for exchange transfusion of the neonate may warrant investigation in randomized controlled trials.[206]

Intrauterine Transfusion for Fetal Hemolytic Disease

In 1961, induced early delivery could not be undertaken before 31 to 32 weeks' gestation without the risk of prohibitive mortality from prematurity and severe Rh disease. Hydrops develops in 8% of fetuses before 32 weeks' gestation. In 1963, the introduction of intraperitoneal fetal transfusion (IPT) by Liley[207] completely altered the prognosis for these most severely affected of all fetuses (Fig. 3-8).

Since the beginning of the 20th century it was known that RBCs placed in the peritoneal cavity are absorbed and function normally. At one time, IPT was a preferred method for giving transfusions to children with thalassemia. It was abandoned in favor of vascular transfusions because of the severe discomfort that it caused. Absorption is via the subdiaphragmatic lymphatic lacunae, up the right lymphatic duct, and into the venous circulation. In the fetus, breathing movements are necessary for absorption to occur.[208] In the absence of hydrops, 10% to 12% of infused RBCs are absorbed daily. Ascites does not prevent absorption per se, although the rate of absorption in its presence is less predictable and the procedure is more risky. Rupture of membranes and spontaneous labor after IPT are also risks.

FIGURE 3-8. Hydrops fetalis at intraperitoneal fetal transfusion (IPT). Note the gross ascites at both the first and second IPTs. The fetus, hydropic at birth with a cord hemoglobin level of 9 g/100 mL (all donor RBCs), survived. *(From Bowman JM. Maternal blood group immunization. In Creasy RK, Resnik R [eds]. Maternal-Fetal Medicine: Principles and Practice, 2nd ed. Philadelphia, WB Saunders, 1989, p 636.)*
Although IPT was a major advance in the management of severe erythroblastosis fetalis, intravascular transfusion (IVT) has proved to be even more successful for most fetuses. The earliest attempts at direct IVT, either into a fetal or into a placental blood vessel approached via a hysterotomy incision, were made in the mid-1960s, but outcomes were poor because complications, including premature labor, almost invariably ensued.[209,210]

In 1981, Rodeck and co-workers[211] reported direct fetal transfusions through a fetoscope. Intracardiac transfusion has also been described,[212] but this method was soon superseded by percutaneous transfusion into umbilical vessels.[213-217] Under ultrasound guidance and local anesthesia, the tip of a 22- or 20-gauge spinal needle is introduced into an umbilical blood vessel, preferably the vein at its insertion into the placenta (Fig. 3-9). Fetal blood sampling usually precedes and follows the transfusion, and confirmation that the needle tip remains in the correct position can be obtained throughout the procedure by observing altered echoes in the vessel via ultrasonography.

There are a number of advantages of IVT over IPT. IVT allows direct diagnostic sampling at the onset and completion of the procedure. For skilled practitioners, the failure rate and procedure-related mortality are lower, especially in hydropic fetuses.[218,219] IVT allows larger transfusions and administration of platelets if needed.[216,220] It is effective in correcting anemia and its immediate physiologic consequences[221,222] and in reversing hydrops.[215] Survival and the neonatal condition were improved so rapidly by the introduction of IVT that just as with IPT before it, its merits have been determined by comparison with historical control data rather than prospective randomized studies. Comparison with historical control data may fail to take into account numerous other improvements in perinatal and neonatal care since the 1970s. However, babies with more severe disease respond to IVT, and they need less invasive and intensive neonatal care afterward. Undoubtedly, if an intrauterine procedure is necessary and IVT is feasible, it is the procedure of choice. Because of the rarity of severe disease, follow-up studies are limited, but they indicate that most survivors of both IPT and IVT have a good prognosis for neurologic development and general health.[223-228] Umbilical and inguinal hernias are reported to occur often after IPT.[227]

Despite the great advantages of IVT, there remain some situations in which IPT is necessary, including a fetus that is severely afflicted early in pregnancy, at a time when the cord vein is too small for successful venipuncture. In late pregnancy or with twin gestation, fetal size and position may preclude access to the umbilical vessels. IPT may also be necessary to "top up" an incomplete IVT if needle dislodgement or other immediate complications occur.

IVT and IPT can expose the mother to fetal cells, thereby raising her antibody titer and potentially worsening disease. As stated earlier, there is no benefit to giving anti-D antibody to already sensitized mothers. In the future, other methods of immunomodulation might prove beneficial to improve the safety of this aspect of treatment.

It has been recommended that both IPT and IVT be done in centers that perform at least 20 to 30 cordocenteses and 10 to 15 transfusions annually to maintain competence and allow adequate surveillance of outcomes.[229,230] Some perinatologists advocate the use of pancuronium before IVT to prevent fetal movement,[218] but others use it selectively or rarely. Transfusion volume should be optimized.[231,232] Complications include fetal bradycardia, cord hematoma, thrombosis or bleeding, rupture of membranes, infection, and premature labor.

Blood for Intrauterine Transfusion

No general guidelines have been published recently for many aspects of intrauterine transfusion. Although there
FIGURE 3-9. Real-time ultrasound view of intravascular transfusion via insertion of the umbilicus into the anterior surface of the placenta. The *bottom* panel shows a needle inserted (in this case through the placenta) into the umbilical vein. The intravascular transfusion in progress is shown by the echogenicity of the transfused blood in the umbilical vein.

have undoubtedly been advances in equipment design and blood banking techniques, reports of their application to intrauterine transfusion have not been published in peer-reviewed literature. By extrapolation from the results of neonatal transfusion therapy, it seems reasonable to propose that cytomegalovirus-negative packed RBCs be used for intrauterine transfusion. Cells should be as fresh as is compatible with careful screening and crossmatch against maternal blood and should be leukocyte depleted and irradiated. The risk for graft-versus-host disease is very low but not zero.[233,234] The use of Kell antigen–negative blood is optimal, if it is available.

Treatment of Neonates with Hemolytic Disease

General Measures

As a result of advances in antenatal assessment and treatment, the pediatrician often has the benefit of treating an infant with HDN whose condition is better and whose disease course is more predictable than those of infants with HDN in previous decades. Management of an infant with severe hydrops fetalis remains difficult, and because the disease is now very uncommon, there is little opportunity for well-designed trials to test various approaches to management. Uncertainties include the role of antenatal drainage of pleural effusions and ascites, which resuscitation fluids and drugs to use, and when to perform top-up or exchange transfusion. Surfactant therapy may be necessary because of prematurity or surfactant inactivation.[235,236] Top-up transfusion may be useful for stabilization[122,237] because nearly all hydropic infants are severely anemic and some have low central venous pressure.

Even in a mildly affected infant, careful assessment and anticipatory management are required. A fetus that has coped well in the intrauterine environment and has not needed or has responded well to intrauterine treatment can still have significant problems with the transition to independent extrauterine life. Problems attributable to HDN, such as hyperinsulinemic hypoglycemia,[238] may be compounded by the problems of prematurity. The baby should be assessed promptly at birth and resuscitated if necessary. Physical examination may reveal

hepatic and splenic enlargement and signs of anemia. Occasionally, stigmata resulting from accidents of intrauterine therapy are found.

Laboratory assessment should include a complete blood count, assessment of blood group and relevant antibodies, and baseline measurement of the bilirubin level so that the rate of increase in bilirubin can be calculated. In severely affected infants, liver function, acid-base balance, and coagulation profile should also be assessed. Cord blood can be useful for these tests but may provide misleading results unless the sample is obtained promptly. Many blood banks will not accept cord blood for crossmatch. In infants who have received multiple transfusions, assessment of iron status should be considered, especially if there is evidence of liver dysfunction.[239-241]

In regard to general care, breast-feeding should commence early in infants who are not deemed to be in imminent need of exchange transfusion. If mature and in good condition, the infant can be breast-fed while receiving phototherapy via a suitable fiberoptic blanket or spotlight. Although Rh antibodies are present in breast milk, particularly in colostrum, very little antibody is absorbed.[242] There is no evidence that forced fluid administration (beyond requirements for nutrition and compensation for any increased insensible loss) improves the outcome of the disease, and it is hazardous in premature infants and those with heart failure.

Folate is normally stored in the liver in late gestation, but reserves may be deficient in premature infants and depleted by ineffective erythropoiesis or by exchange transfusion, which replaces the infant's blood with adult blood that has a lower folate level.[243,244] Supplemental folic acid at a dose of 100 to 200 μg/day is recommended for several weeks. Vitamin B_{12} will usually be supplied in adequate amounts in breast milk (unless the mother has a deficiency), and supplemental iron is not only unnecessary but potentially hazardous.[239] Drugs that interfere with binding of bilirubin to albumin or with bilirubin metabolism should be avoided.

The use of phototherapy and other measures for hyperbilirubinemia is discussed in Chapter 4 and has been reviewed elsewhere.[245,246] The principles that we now apply in deciding when to begin and end phototherapy are little more than traditional rules of thumb. However, it seems clear that phototherapy is effective in preventing many exchange transfusions in infants with hemolysis.[247,248] Most guidelines still recommend lower thresholds for beginning phototherapy for HDN than for nonhemolytic jaundice, despite the improved condition of most of the infants with HDN whom we now treat. Intensive phototherapy is justified for infants with high or rapidly rising bilirubin levels. The risks and resource implications of phototherapy are low in comparison to those of exchange transfusion.

Phototherapy can be discontinued when serum bilirubin levels decrease or if the conjugated fraction of bilirubin increases substantially. Commonly, well near-term infants who have received intrauterine transfusions can be discharged at about a week of age. Conversely, many weeks of tertiary-level neonatal intensive care may be needed for premature, very anemic prehydropic or hydropic infants.

Administration of IVIG to prevent the need for exchange transfusion in HDN has been the subject of limited investigation.[249-252] These small studies used different IVIG preparations for different thresholds.[253] IVIG therapy deserves further investigation in selected infants, but there is not sufficient published evidence to recommend it outside of carefully conducted clinical trials.

Exchange Transfusion

Exchange transfusion originated in the 1920s in a procedure done via the anterior fontanelle. Refinements to the technique of "exsanguination transfusion" were introduced by Wallerstein and Wiener in 1946.[254,255] Generations of infants and pediatric residents should be grateful that Diamond pioneered the use of umbilical catheters[256] because Wiener's technique involved infusion of blood through a saphenous vein cutdown and drainage (after heparinization of the baby) via an incision in the radial artery at the wrist. A randomized controlled trial in 1952 confirmed that the technique could save lives and prevent kernicterus.[257]

During exchange transfusion, RBCs coated with antibody are replaced with RBCs negative for the antigen to which the mother is alloimmunized. Exchange transfusion corrects the anemia of a severely affected newborn, mitigates hyperbilirubinemia by removing the infant's hemolyzing erythrocytes and suppressing erythropoiesis, removes some of the already formed bilirubin, and depletes unbound anti-D antibody. Only modest amounts of the offending antibody are removed by exchange transfusion because unbound antibody is widely distributed in extracellular fluid, both within and outside the vascular compartment.

Exchange transfusion produces a significant drop in neutrophil levels, the functional significance of which is uncertain, but the initial neutropenia and subsequent "left shift" during rebound from it can certainly complicate the diagnosis of sepsis in the hours and days after exchange. A similar decrease in platelets is generally well tolerated, provided that the baby does not have thrombocytopenia or other coagulopathy before the exchange transfusion. Because a variety of coagulation defects increase the risk for intraventricular hemorrhage,[258] platelet therapy should be considered in sick and premature infants with thrombocytopenia.

Indications for Exchange Transfusion

Exchange transfusion is generally performed early for severe anemia or later when phototherapy and other conservative measures fail to control the bilirubin level. However, the exact thresholds at which it should be applied are controversial and warrant the development of

contemporary guidelines. Traditional criteria for early exchange transfusion included a cord hemoglobin level less than 13 to 15 g/dL (130 to 150 g/L) and a cord serum bilirubin level greater than 60 to 130 µmol/L (3 to 7 mg/dL). However, Wennberg and colleagues[259] showed in 1978 that neither cord hematocrit nor bilirubin level had much value in predicting a postnatal increase in bilirubin level. They suggested using the criterion of rate of increase in bilirubin. Rates of increase of 8 to 13 µmol/L/hr, despite intensive phototherapy, indicate that exchange transfusion is likely to be needed. Improved antenatal treatment, phototherapy, and other supportive care has cast even these guidelines into doubt. Many neonatal intensive care units that have prompt blood bank support and the ability to perform exchange transfusion at short notice will delay exchange transfusion in babies who do not have symptomatic anemia until the risk associated with exchange transfusion is thought to approximate that of kernicterus. The decision process is clearly hampered by imprecise knowledge of where these risk boundaries lie. Jackson[260] recently estimated the risk of serious complications of exchange transfusion to be less than 1% in previously well infants and about 12% in ill infants. In a recent audit of 141 exchange transfusions over a period of 21 years in one center (69% of which were for immune hemolytic disease), there were no exchange transfusion–related deaths and only 14% had any transfusion-related complication.[261] In severely anemic hydropic babies, early exchange transfusion still seems warranted to improve oxygen transport. Peterec has suggested working guidelines.[121]

Free Bilirubin and Reserve Albumin Binding Studies

It appears that the level of free unconjugated bilirubin is the determining factor in the pathogenesis of bilirubin encephalopathy (kernicterus; see Chapter 4). Measurements of free bilirubin have not routinely influenced clinical practice in most centers, but some take the bilirubin-to-albumin ratio into account.[262]

Technique of Exchange Transfusion

The specific technical details of exchange transfusion are clearly set out elsewhere[263] and are discussed only briefly here. The safest location for catheter tips and whether it is better to use a single-catheter "push-pull" technique or a double-catheter continuous technique have not been determined conclusively. In practice, these decisions are often based on local tradition and on the number and type of catheters that can be inserted easily. The procedure should be conducted precisely and with meticulous attention to precautions against infection.

The blood should be ABO compatible and, for anti-D HDN, Rh negative. If the mother is alloimmunized to an antigen other than D, the blood should be missing that antigen. It should be crossmatch compatible with the mother's serum. Ideally, the blood should also be negative for Kell antigen (to avoid sensitizing the infant) and hemoglobin S (to avoid problems with filtration). If the initial exchange transfusion is carried out with group O blood, any further exchange transfusions should use group O blood. Otherwise, brisk hemolysis and jaundice secondary to ABO incompatibility may become a further complication. Graft-versus-host disease occurs rarely after exchange transfusion, but blood should be irradiated if possible, especially for premature infants. The question of whether to use whole blood or packed RBCs partially reconstituted with plasma or saline plus or minus platelets has not been subjected to rigorous study, but component therapy is widely used. Component therapy potentially exposes the infant to more donors and more risk of handling errors, but less risk of white blood cell–related complications. For very unusual antibodies or combinations of antibodies, RBCs may need to be transported over long distances. Occasionally, stored washed maternal RBCs must be used. In these circumstances, whole blood is unlikely to be available.

Depending on the local strategy for neonatal screening for metabolic and other diseases, it is strongly recommended that some of the blood from the first drawback be applied to a neonatal screening card. Otherwise, the diagnosis of some disorders such as galactosemia may be masked for some time to come. If any blood for serologic analysis or a DNA sample is needed for other diagnostic purposes such as congenital infection, it should also be collected at this time.

Aliquots of the infant's blood are removed and replaced with antigen-negative donor blood. In choosing a technique for transfusion, the practitioner should take into account the following considerations: the infant's tolerance of the metabolic, hemodynamic, and hematologic demands; the effectiveness of the procedure in treating anemia and preventing an increase in bilirubin level; and safe handling of the blood for transfusion. The size of aliquot should be chosen to take into account the tolerance of the infant and, if a single catheter is used, its dead space. Principles of calculus make it clear that the largest aliquots that the infant can tolerate will correct anemia most rapidly, but very rapid correction of anemia is not usually the prime objective. Allowing sufficient time for equilibration of bilirubin and antibody between the vascular and extravascular compartments is another concern, but with very long procedures there is the risk of clotted catheters and degradation of the donor blood. Generally, between 1.5 and 2 infant blood volumes are exchanged (130 to 170 mL/kg of body weight) over a 1- to 2-hour period.[264] A two–blood volume exchange transfusion removes approximately 90% of the affected RBCs of the infant, but the response is asymptotic rather than linear, and 70% removal occurs after the first blood volume has been exchanged. Only about 25% to 30% of total bilirubin is removed because it is sequestered in the extravascular and cellular compartments. A decrease of

about 50% in the serum bilirubin level can be expected, but rapid rebound to about 75% of the pre-exchange level is typically seen.

Administration of albumin, 1 g/kg of body weight, before the exchange transfusion or addition of albumin, 4 to 6 g, to the blood used for exchange transfusion modestly increases the amount of bilirubin removed to about 35% of the total body bilirubin by drawing bilirubin into the vascular compartment. Caution is advised in administering albumin to a severely anemic infant because it may precipitate heart failure.

Many previous guidelines suggested routine administration of calcium gluconate. However, contemporary anticoagulants affect ionized calcium much less than the citrate-phosphate-dextrose used in years gone by does. Furthermore, most neonatal units now have immediate access to blood gas analyzers that also measure ionized calcium, electrolytes, and glucose in tiny samples. Periodic measurement of ionized calcium, electrolytes, glucose, and blood gas is therefore a reasonable alternative (e.g., every 30 minutes or earlier if the infant manifests any instability).

Complications of Exchange Transfusion

Complications of exchange transfusion include all those of simple transfusion plus a variety of others related to the large size of the transfusion, the catheters, and the technique.[260,261] As fewer procedures are being performed, experience with the procedure among neonatal and pediatric medical and nursing staff is declining. Furthermore, well infants who were previously given exchange transfusions are now being managed conservatively, whereas the sickest and most premature infants still require exchange transfusion. Thus, paradoxically, at a time when most transfusion therapy has never been safer, exchange transfusion has the potential become more hazardous, although improved monitoring and supervision may be compensating for these trends.[261]

Necrotizing enterocolitis is a potentially life-threatening hazard. The occurrence of necrotizing enterocolitis may be related to the technique. In the absence of evidence-based guidelines, effort should be made to prevent wide pressure and volume variations during exchange transfusion. Blood injection and withdrawal should be carried out smoothly, without undue haste. The use of blood products that are anti–T cryptantigen negative, prolongation of the interval until oral feeding is restarted, and the use of prophylactic antibiotics might also influence the risk for necrotizing enterocolitis, but there is no clear evidence for any of these practices in relation to exchange transfusion.

As discussed earlier for intrauterine transfusions, performance of exchange transfusions in neonatal intensive care units with experienced staff and with blood banks familiar with supplying neonates is likely to yield the best results for infants and the best hope of accumulating evidence to guide practice.

OTHER MATERNAL ALLOANTIBODIES CAUSING FETAL/NEONATAL HEMOLYTIC DISEASE

Alloantibodies Other Than A and B

Although reports from numerous geographic areas demonstrate the effectiveness of administration of anti-D IgG to prevent RhD alloimmunization, most find that Rh is still the blood group system causing most cases of HDN and that anti-D is still the most common single antibody causing severe HDN. Of non-D Rh antigens, anti-c is the next most important in causing clinically significant HDN. About half of anti-c antibodies are attributable to transfusion, and they are often present at low titer or the fetus is c negative. However, because anti-c can cause severe HDN or fetal death, careful assessment is warranted.[66] Anti-E is relatively common but seldom causes HDN. A variety of other non-D Rh antigens, such as anti-C, anti-e, and anti-Rh17, have also been reported to very occasionally cause moderate or severe HDN.[66] Rh antigens are not infrequently found in combination, such as anti-D plus -C, anti-D plus -E, or anti-c plus -ce. Often, one of the antibodies (e.g., anti-c) is present in higher titer and has the predominant influence on disease severity, but the combination adds to the complexity of finding suitable donors for intrauterine exchange or top-up transfusion.

There are at least 26 blood group systems with more than 900 alleles of 39 genes, and the molecules carrying these antigens are very diverse in structure, function, and tendency to cause HDN. The molecules include transporters and channels (e.g., Diego, Kidd, Colton, and Rh), receptors for pathogens (Duffy, P, and others) and for adhesion to other cells (e.g., Landsteiner-Wiener), enzymes (ABO, H, Lewis, P, and Kell), structural proteins (Ge), and complement receptors (Ch/Rg).[22]

As the incidence of RhD HDN has been decreasing, other blood group antibodies have assumed greater importance. Bowman[265] found that in Manitoba (population, 1 million), the mean annual occurrence of D alloimmunization in pregnant women dropped from 194 in 1962 through 1967 to 23 in 1989 through 1994. In the same two periods, the mean annual occurrence of detected non-D alloimmunization in pregnant women, excluding ABO alloimmunization, increased from 14 to 108. This rise was partially the result of increased screening of pregnant D-positive women. It also reflected a real increase in the occurrence of non-D alloimmunization because of the increased incidence of blood transfusion (transfused blood is generally crossmatched only for ABO and D). A summary of results of seven studies from the 1960s to 2000 is presented in Table 3-6.

There is marked international variation in the frequency and distribution of alloantibodies. For example, in Asian countries where RhD negativity is rare, so is anti-D. Lee and associates identified one case in 28,303 women in Hong Kong over a 5-year period, and Rh

antibodies accounted for only 27.3% overall. Anti-Mi, which recognizes an antigen in the MNS blood group system, was about twice as common, and although it caused no cases of severe HDN in this series, its potential to do so has been reported.[271]

The alloantibodies listed by Mollison and co-workers and Bowman as having been reported to cause HDN are listed in Table 3-7.[66,272] Of the multitude of antibodies implicated as causes of HDN, most are fortunately rare or rarely cause severe disease (Table 3-8). Some are the subject of single case reports.

There are various reasons why the incidence and severity of HDN differ from one blood group antigen system to another. In some cases it is because of the rarity of the offending antigen or the lack of it and the likelihood of incompatibility between parents being low. An example is the Colton blood group system, which comprises the high-incidence antigens Co$_a$ and Co$_3$ found on aquaporin-1. Rare individuals lacking this aquaporin can produce antibodies that lead to severe HDN. In others, it is because of low levels of expression on the RBC surface. For this reason, maternal anti-I and anti-Lutheran

antibodies, even when present at high titer, usually do not cause HDN because of low cell surface expression of these antigens on fetal RBCs. Lutheran antigens are also widely distributed in endothelial cells.

Disease attributable to anti-Kell antibodies can be very severe. Maternal antibodies to KEL1 causing neonatal anemia were first described in 1945,[7] and the blood group system was named for the woman in whom the antibodies were found. Kell glycoprotein is an endopeptidase involved in the activation of endothelin,[273] and it is more properly regarded as a subunit of a larger protein because it is linked via a disulfide bond to the XK protein. Absence of XK can cause weak Kell expression and dysfunction of other organs (McLeod's syndrome). Null Kell alleles also occur. Redman and associates[273,274] reviewed the Kell blood group and summarized the low- and high-incidence antigens, about 25 of which have been described. They occur as variants of several epitopes. The most immunogenic antigen, KEL1, is second to RhD in its immunizing potential and occurs in about 9% of whites and 2% of blacks. It results from a point mutation causing a Thr193 (KEL2) to Met193 (KEL1)

substitution, which in turn leads to loss of a glycosylation site. The other Kell phenotypes are also generally due to single-base substitutions, so genotyping is more straightforward than that in the Rh system.

Sensitization occurs most commonly as a result of unmatched blood transfusion but can arise during pregnancy. Although the number of incompatible pregnancies is lower for Kell than for RhD, the proportion of anti-KEL1–affected fetuses that are severely affected is thought to be 20% or greater.[275-278]

Kell antibodies, which recognize antigens expressed in early erythroid progenitors and at an early stage of erythropoiesis in fetal liver, appear to be capable of suppressing erythropoiesis.[279] This is the putative reason for the tendency for hydrops early in pregnancy seen in anti-Kell HDN. It has also been proposed as the reason why amniotic fluid spectrophotometry is not as reliable as in Rh hemolytic disease, although not all studies agree on this point.[275,280,281] Paternal typing followed, when necessary, by fetal genotyping and early, close monitoring by ultrasound is recommended in pregnancies complicated by anti-Kell antibodies.

Rarely, anti-Kp^a, -k, -Fy^a, -s, -S, -U, and occasionally other antibodies (see Table 3-8) have caused hemolytic disease severe enough to require intrauterine or postnatal treatment.[66,265] Bowman also reported that 34 pregnant non–D-alloimmunized women referred from outside Manitoba (a highly selected group with very severely affected fetuses drawn from a much greater population base) showed the following distribution of antibodies that produced HDN so severe that intrauterine treatment was required: anti-K (18 fetuses), -c (9 fetuses), -cE (2 fetuses), -k[34] (1 fetus), -Jk^a (1 fetus), -Fy^a (1 fetus), -CC^W (1 fetus), and -E (1 fetus). There are rare instances of other alloantibodies, usually benign ones, causing severe hemolytic disease (e.g., anti-Kp^b, anti-Di, and anti-M).

ABO Hemolytic Disease

ABO HDN behaves differently from HDN caused by either anti-D or other blood group antibodies. Anti-A and anti-B, which bind complement in adults, cause violent, life-threatening intravascular hemolysis after the transfusion of ABO-incompatible blood. Fetal ABO

HDN is usually much milder than HDN caused by D, c, K, and E. Although kernicterus may develop if a baby with ABO HDN is left untreated, hydrops rarely occurs, anemia is usually absent or moderate at birth, and late anemia is rare. There are rare reports of hydrops fetalis being due to ABO erythroblastosis.[282] It is possible that some of these involve other causes of increased ineffective erythropoiesis (such as RBC enzyme deficiency or α-thalassemia trait) or nonimmune hydrops superimposed on ABO HDN. Some but not all series have found that ABO antibodies are a more common cause of HDN (and severe HDN) in Southeast Asia, Africa, and Latin America for reasons that have yet to be determined.[66]

Several reasons have been proposed for the mildness of ABO HDN in comparison to HDN caused by other antibodies and to adult ABO hemolysis.[283] First, there are fewer A and B antigenic sites on the fetal RBC membrane,[284] and anti-A and anti-B do not bind complement on the fetal RBC membrane.[285] Second, anti-A and anti-B are often IgM, which does not cross the placenta, or IgG2, which plays a minor role in HDN.[286] Third, the small amounts of IgG anti-A and anti-B that do traverse the placenta have myriad antigenic sites both on tissues other than on RBCs and on secretions to which they may bind. Because there is very little antibody on the RBC, the result of the cord blood direct antiglobulin test in ABO hemolytic disease is usually only weakly positive and may be negative unless a sensitive test is used. Capillary blood taken at 2 or 3 days of age often yields a negative direct antiglobulin test result regardless of test sensitivity. In at least 25% of ABO-incompatible babies, cord blood RBCs give weakly positive results on the direct antiglobulin test at delivery, and an excess of babies with blood types A and B from mothers with blood type O become severely jaundiced.[287,288] The A- or B-incompatible infants of mothers with blood type A or B do not appear to be at increased risk for hemolysis or jaundice.[289]

In only a small fraction of A- or B-incompatible infants of O mothers does clinical evidence of HDN develop (early and severe jaundice).[288,290,291] One study found that only 0.07% of more than 88,000 infants required exchange transfusion for anti-A or -B HDN.[290] Nevertheless, ABO HDN continues to account for a significant proportion of infants with troublesome jaundice that necessitates prolongation of the hospital stay, readmission to the hospital, or home therapy. The same large study found that ABO incompatibility accounted for 5.5% of infants with jaundice.

Although anemia is rarely severe, mild hemolysis appears to be common. In a series of 1704 infants of blood group O mothers, infants with blood group A or B had significantly higher cord bilirubin and lower cord hemoglobin concentrations than did the babies with blood group O.[292] Blood films may show polychromasia, reticulocytosis, and prominent spherocytosis, which can be difficult at times to differentiate from hereditary spherocytosis.

Control of hyperbilirubinemia is usually the major issue in infants with ABO HDN, and thresholds for phototherapy and exchange transfusion are generally regarded as similar to those for Rh HDN. The risk for symptomatic late anemia in ABO HDN is very low. The risk for recurrence of jaundice attributable to anti-A or -B in future incompatible siblings is high, and mothers should be counseled accordingly.[293]

MANAGEMENT OF SPECIAL PROBLEMS

Syndrome of Hepatocellular Damage

Most infants with severe anemia and erythroblastosis, particularly those who are hydropic or prehydropic, show signs of obstructive jaundice. They have extreme hepatomegaly and evidence of biliary canalicular obstruction. Extreme or prolonged jaundice may develop in these infants, but with half or more of the total bilirubin being direct-acting conjugated bilirubin. The threshold for exchange transfusion in such infants is unclear and should be individualized. If hepatic damage is so severe that symptomatic coagulopathy has ensued, exchange transfusion (with appropriate components) may be necessary to remove activated clotting factors and degradation products and to replenish clotting factor levels.

Infants Who Have Undergone Fetal Transfusions

Assessment of infants who have undergone IVT or IPT does not differ from that of other babies with HDN. Because these infants are often delivered with few residual Rh-positive hemolyzing RBCs, their postdelivery management may be simple. Nevertheless, some require one or more exchange transfusions. When compared with those who received IPT, relatively few babies born after undergoing IVT require exchange transfusion. However, careful individual assessment is still required, and delivery in or near a center that can perform exchange transfusion is still advisable.

Follow-up Care of Infants with Hemolytic Disease

Regardless of whether an affected infant has required fetal transfusions or exchange transfusions, anemia is commonly seen in the first few weeks of life.[294] Hemoglobin levels should be checked at 7- to 14-day intervals until the infant is 8 to 12 weeks of age. The anemia is due to gradual loss of transfused Rh-negative RBCs and to failure of the infant's Rh-positive RBCs to replace them. This failure is initially due to hemolysis of any RBCs produced and to transient erythroblastopenia,

which usually resolves spontaneously at about 6 to 8 weeks of age.

In the interim, if symptomatic anemia develops or if hemoglobin levels are falling rapidly toward symptomatic levels, a simple transfusion of 20 mL/kg of body weight of crossmatched, packed RBCs compatible with the infant's serum is administered. Iron supplementation is not indicated, but folic acid and, in some circumstances, vitamin B_{12} should be given.

Recombinant erythropoietin has been used with some success in the treatment of anemia of prematurity. Erythropoietin treatment for prevention of "late" anemia in infants with HDN has been tested in small trials.[295-297] A larger trial is needed to evaluate the role of erythropoietin in preventing the late anemia of HDN.

CONCLUSIONS

Advances in prevention of Rh sensitization and the management of immune HDN in the past 30 years have been dramatic. Statistics from all over the developed world have indicated that the prevalence of Rh sensitization in pregnant women has been reduced by more than 90%. The number of exchange transfusions has also decreased by more than 100-fold. In addition, the number of perinatal deaths caused by HDN has plummeted. However, for those still affected by anti-D or other significant antibodies, the disease burden remains significant.

Despite a recent explosion in knowledge about antigen presentation and provocation of the immune response in general, little detail at the molecular and cellular level is known about maternal sensitization to RhD. Better understanding of these events, together with the recent elucidation of the molecular genetics of RhD and other blood groups, is likely to provide new tools for prevention, diagnosis, and treatment.

4 Disorders of Bilirubin Metabolism

Mark J. Bergeron and Glenn R. Gourley

Elevation of serum bilirubin level is a common, if not universal finding during the first week of life and has been reviewed elsewhere.[1-3] It can be a transient phenomenon that will resolve spontaneously or can signify a serious or even potentially life-threatening condition. There are many causes of hyperbilirubinemia and related therapeutic and prognostic implications. Independent of the cause, elevated serum bilirubin levels can potentially be toxic to newborn infants. This chapter reviews perinatal bilirubin metabolism and addresses assessment, etiology, toxicity, and treatment of neonatal jaundice. Diseases in which there is a primary disorder in the metabolism of bilirubin are reviewed with regard to their clinical findings, pathophysiology, diagnosis, and treatment.

BILIRUBIN METABOLISM

Bilirubin Production and Transport

In 1864 Städeler used the term "bilirubin," derived from Latin (*bilis*, bile; *ruber*, red), for the red-colored bile pigment.[4] Bilirubin is formed from the degradation of heme-containing compounds (Fig. 4-1). The largest source for the production of bilirubin is hemoglobin. However, other heme-containing proteins are also degraded to bilirubin, including the cytochromes, catalases, tryptophan pyrrolase, and muscle myoglobin.[5]

Formation of bilirubin is initiated by cleavage of the tetrapyrrole ring of protoheme (protoporphyrin IX), which results in a linear tetrapyrrole (biliverdin). The first enzyme system and rate-limiting step in bilirubin synthesis is microsomal heme oxygenase (HO).[6] HO can be up-regulated threefold to fivefold in response to hemolysis. Two major forms of HO have been identified. HO1, the inducible form, is located in the spleen, liver, and bone marrow. HO2, the constitutive form, is located in the testes, central nervous system (CNS), vasculature, liver, kidney, and gut. HO results in the reduction of porphyrin iron (Fe^{III} to Fe^{II}) and hydroxylation of the α-methine ($=C-$) carbon. This α carbon is then oxidatively excised from the tetrapyrrole ring to yield carbon monoxide (CO). Such excision opens the ring structure and is associated with oxygenation of the two carbons adjacent to the site of cleavage. The cleaved α carbon is excreted as CO, which has numerous biologic effects, including neurotransmission, vasodilation, and mediation of apoptosis and anti-inflammatory processes. The iron released by HO can be reused by the body. The stereospecificity of the enzyme produces cleavage almost exclusively at the α carbon of the tetrapyrrole. This is unlike in vitro chemical oxidation, which results in cleavage at any of the four carbons (α, β, γ, and δ; see Fig. 4-1, structure 1) linking the four pyrrole rings and produces equimolar amount of the α, β, γ, and δ isomers.[7] HO produces a linear tetrapyrrole, biliverdin IXα. The IX designation is a result of Fischer and Orth's grouping of the protoporphyrin isomers, with group IX being the

physiologic source of bilirubin.[8] In utero, bilirubin IXβ is the first bile pigment seen and can be found in bile or meconium by 15 weeks' gestation.[9] Small amounts of bilirubin IXβ are also found in adult human bile.[10] The central (C-10) carbon on biliverdin IXα is then reduced from a methine to a methylene group ($-CH_2-$), thereby forming bilirubin IXα. This reaction is accomplished by the cytosolic enzyme biliverdin reductase.[11] The proximity of this enzyme results in very little biliverdin ever being present in the circulation. Bilirubin formation can be assessed by measurement of CO production.[12] Such assessments indicate that the daily rate of production of bilirubin is 6 to 8 mg/kg/24 hr in healthy term infants and 3 to 4 mg/kg/24 hr in healthy adults.[13,14] In mammals, 80% to 85% of the bilirubin produced daily originates from hemoglobin.[15] Degradation of hepatic and renal heme appears to account for most of the remainder and reflects the very rapid turnover of certain of these heme proteins. Although the precise fate of myoglobin heme is unknown, its turnover appears to be so slow that it is relatively insignificant.[16] Catabolism of hemoglobin occurs largely from the sequestration of erythrocytes at the end of their life span (120 days in adult humans, 90 days in newborns, 50 to 60 days in rats). A small fraction of newly synthesized hemoglobin is degraded in bone marrow. This process, termed "ineffective erythropoiesis," normally represents less than 3% of daily bilirubin production but may be substantially increased in persons with hemoglobinopathies, vitamin deficiencies, and heavy metal intoxication.[17-19] Infants produce more bilirubin per unit body weight because of their greater red blood cell (RBC) mass and shorter RBC life span. Additionally, hepatic heme proteins represent a larger fraction of total body weight in infants.

Although bilirubin has long been thought of solely as a waste product, data suggest that some mild degree of hyperbilirubinemia may be helpful because of the antioxidant capacity of bilirubin and its potential role as a free radical scavenger and cytoprotectant.[20] Although bilirubin crosses the placenta more easily than biliverdin does,[21] it is not clear what biologic advantage this offers.

Bilirubin is poorly soluble in aqueous solvents and thus requires biotransformation to more water-soluble derivatives for excretion from the body. This poor solubility is related to the structure of bilirubin.[22] Rather than being linear (structure 5, Fig. 4-1), bilirubin undergoes extensive internal hydrogen bonding (structure 4, Fig. 4-1). This extensive bonding occurs because the saturated middle carbon (C-10) permits the two halves of the bilirubin molecule to rotate such that the pyrrole nitrogens and lactam oxygen of one half form hydrogen bonds with the carboxyl groups of the propionic acid side chain on the other half. This shields the polar propionic acid side chains and makes bilirubin very nonpolar and lipophilic. The carbon-carbon double bonds at positions 4-5 and 15-16 can assume two different configurations (similar to "*cis*" and "*trans*"), depending on whether the
FIGURE 4-1. Chemical structures depicting the conversion of heme to bilirubin. Bilirubin is frequently represented by any of the three structures (3 to 5) shown at the bottom. *(Redrawn from Gourley GR. Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF [eds]. Liver Disease in Children, 3rd ed. New York, Cambridge University Press, 2007. Used with permission.)*

higher-priority atoms or groups (based on atomic number) are on the same (German: Z, *zusammen*, "together") or opposite (E, *entgegen*, "opposite") sides of the double bond. The naturally occurring form of bilirubin, 4Z,15Z-bilirubin IXα, can be represented by any of the three structures (3-5) depicted at the bottom of Figure 4-1. Knowledge of this stereochemistry is important in understanding phototherapy, which is discussed later.

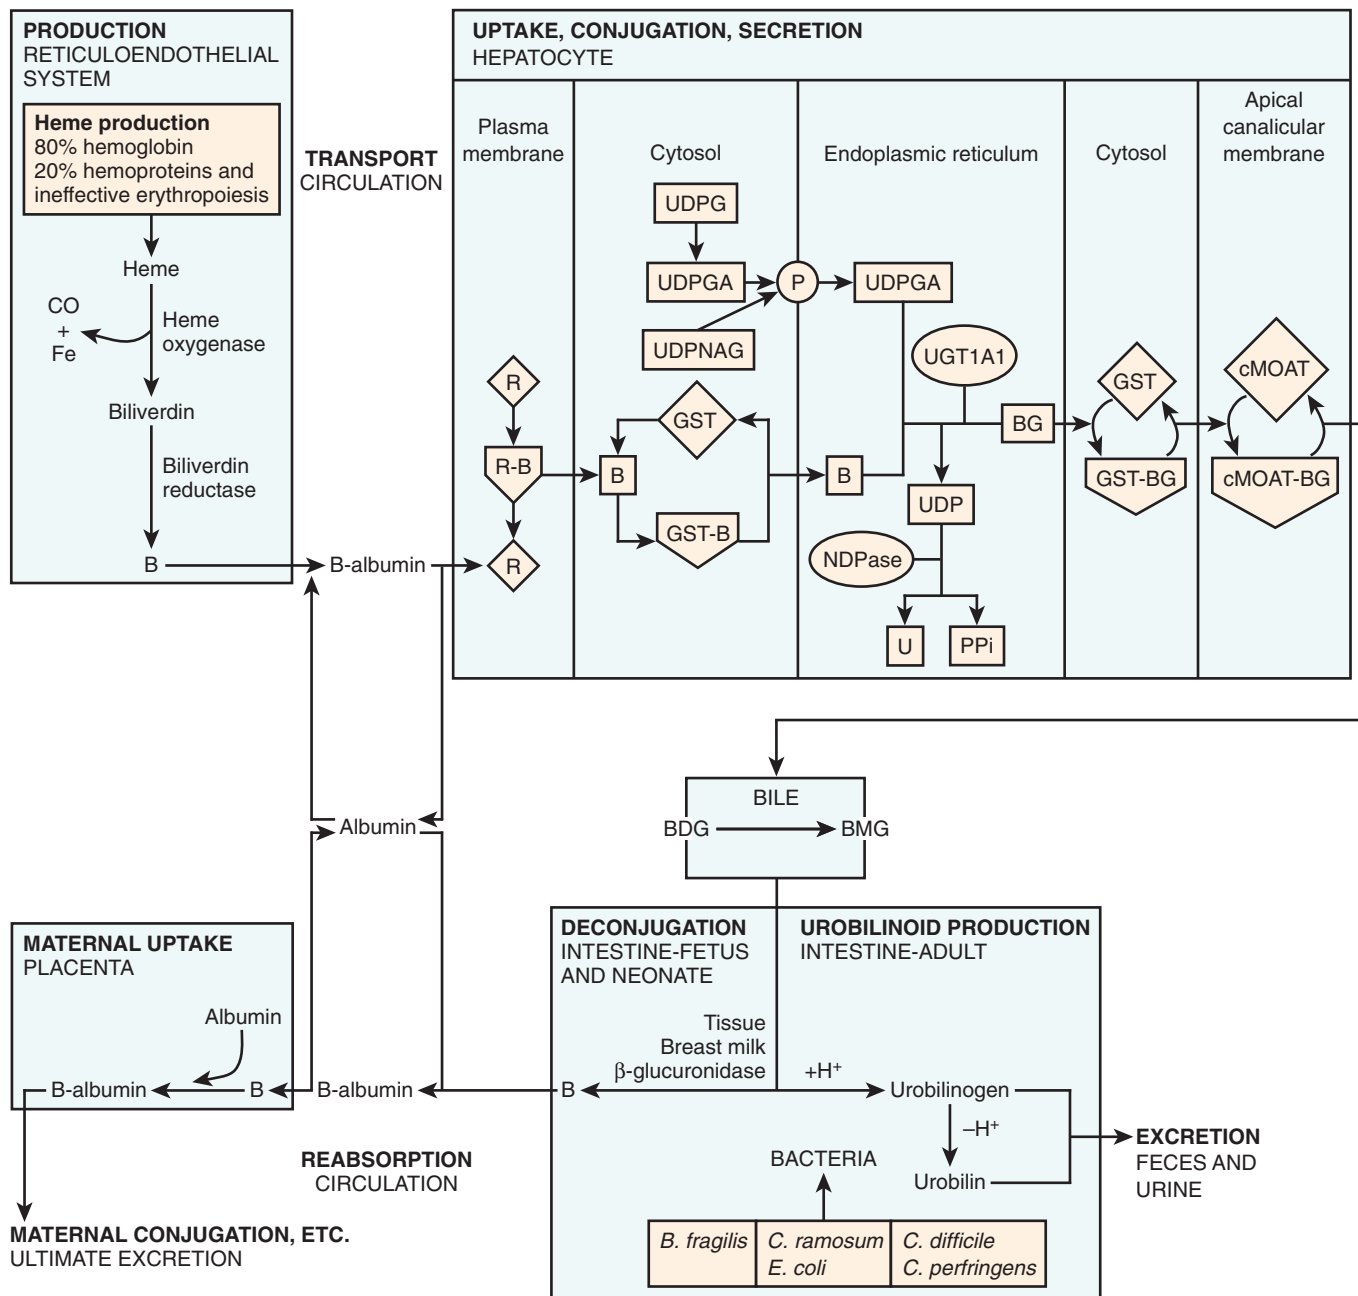
Bilirubin's poor aqueous solubility necessitates a carrier molecule, albumin, for transport from sites of production in the reticuloendothelial system to the liver for excretion (Fig. 4-2).[23] Each albumin molecule possesses a single high-affinity ($K_a = 7 \times 10^7 \, M^{-1}$) binding site for one molecule of bilirubin.[24] A binding affinity of this magnitude implies that at normal serum bilirubin levels, all bilirubin will be transported to the liver bound to albumin, with negligible amounts free to diffuse into


FIGURE 4-2. Schematic overview of bilirubin (B) metabolism in the fetus, neonate, and adult. BDG/BMG, bilirubin diglucuronide/monoglucuronide; BG, bilirubin glucuronide; cMOAT, canalicular multispecific organic anion transporter (also known as MRP2 or ABCC2); GST, glutathione-S-transferase (ligandin); NDPase, nucleoside diphosphatase; P, permease; PPi, inorganic pyrophosphate; R, membrane carrier; UDPG, uridine diphosphate glucose; UDPGA, uridine diphosphate glucuronic acid; UDPNAG, uridine diphosphate *N*-acetylglucosamine; UGT1A1, bilirubin glucuronosyltransferase. New York, Cambridge University Press, 2007. Used with permission.*)

other tissues. Secondary binding sites of lesser affinity also exist on albumin. Albumin additionally serves as a carrier for other compounds such as xenobiotics and fatty acids. It is important to remember that albumin from each animal species has different binding characteristics for various ligands.[25]

Hepatic Uptake of Bilirubin

The structure of the liver is well suited for uptake of bilirubin by individual hepatocytes. Cords of hepatocytes are arranged radially such that adjacent sinusoids border all hepatocytes. Flow of blood through the sinusoids is slower than that through other capillary beds because it is generated by portal venous pressure rather than arterial pressure. Albumin-bound bilirubin easily passes from plasma into the tissue fluid space (space of Disse) between the endothelium and the hepatocyte because the sinusoidal endothelium of the liver lacks the basal laminae found in other organ capillary systems.[26] The pores of the endothelium allow direct contact with the plasma membrane of the hepatocyte.

A hepatocyte with a schematic illustration of bilirubin metabolism is shown in Figure 4-2. In the first step, bilirubin dissociates from its albumin carrier[27] and enters the hepatocyte via a membrane receptor-carrier that facilitates entry into the hepatocyte. Carrier-mediated transport into the hepatocyte has been demonstrated for several organic anions, including bilirubin, bromsulfophthalein (BSP), and indocyanine green (ICG),[28] although bilirubin has been shown to be able to pass through membranes by simple passive diffusion.[29] Evidence suggests that bilirubin, BSP, and ICG share the same hepatocyte receptor-carrier because they exhibit competitive inhibition when injected simultaneously. This finding cannot be explained by subsequent intrahepatic metabolism inasmuch as these anions are handled differently by the hepatocyte: bilirubin is conjugated with glucuronic acid in the endoplasmic reticulum (ER), BSP is conjugated with glutathione in the cytosol, and ICG is excreted directly without biotransformation. Data from rat hepatocytes suggest that the anion-binding receptor-carrier is a dimeric protein with a subunit molecular weight of 55,000.[30-32] Antibody studies confirm the expected location in the plasma membrane[31] and demonstrate blockage of uptake.[32] Organic anion–transporting polypeptide 2 (OATP2, recently named OATP1B1 under new nomenclature[33]) has shown high-affinity uptake of bilirubin in the presence of albumin and is a member of the OATP family, transporter symbol SLC21A.

Carrier-mediated transport of bilirubin into the hepatocyte is necessary because of differences in protein binding inside and outside the hepatocyte. Outside the hepatocyte, bilirubin is bound to albumin (affinity constant, $\approx 10^8$; concentration, 0.6 mM).[24] Inside the hepatocyte, bilirubin is bound to glutathione-S-transferase B (GST), historically known as ligandin or Y protein (affinity constant, $\approx 10^6$; concentration, 0.04 mM).[34,35] GST
FIGURE 4-3. Bilirubin diglucuronide. In bilirubin monoglucuronide, only one propionic acid side chain (C-8 or C-12) is glucuronidated. *(Redrawn from Gourley GR. Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF [eds]. Liver Disease in Children, 3rd ed. New York, Cambridge University Press, 2007. Used with permission.)*

constitutes a family of proteins that exhibit important functions both as enzymes and as intracellular binding proteins for nonsubstrate ligands such as bilirubin.[36] Carrier-mediated uptake helps generate a concentration gradient for bilirubin uptake despite the difference in affinity between albumin and GST. GST is important in the intracellular storage of bilirubin and bilirubin conjugates and reduces efflux from the hepatocyte back into plasma.[35]

Bilirubin Conjugation

Inside the hepatocyte, bilirubin is conjugated with glucuronic acid[37] within the ER (microsomes). The glucuronic acid donor is uridine diphosphate glucuronic acid (UDPGA). Conjugation results in an ester linkage formed with either or both of the propionic acid side chains on the B and C pyrrole rings of bilirubin (Fig. 4-3). The enzyme responsible for this esterification is bilirubin UDP-glucuronosyltransferase (BUGT; Online Mendelian Inheritance in Man* [OMIM] 191740). BUGT is distinct from the other glucuronosyltransferase isoforms that catalyze the conjugation of thyroxine, steroids, bile acids, and xenobiotics.[38] BUGT is embedded in the lipid environment of the microsomal membrane, and perturbations of this environment greatly affect in vitro measurements of BUGT activity. Because BUGT

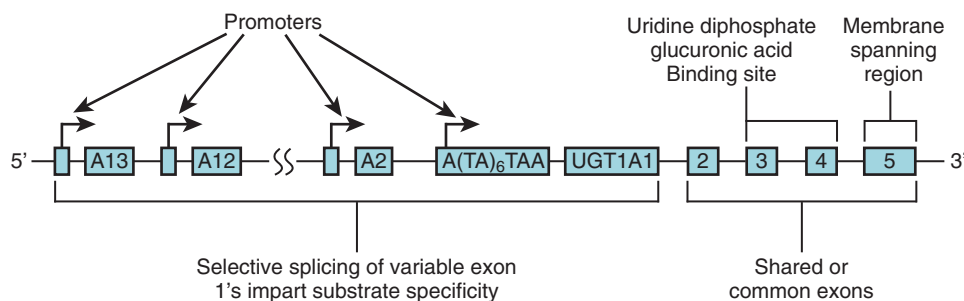

FIGURE 4-4. Human uridine diphosphate glucuronosyltransferase-1 gene (*UGT1*). UDPGA, uridine diphosphate glucuronic acid. *(Redrawn from Gourley GR. Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF [eds]. Liver Disease in Children, 3rd ed. New York, Cambridge University Press, 2007. Used with permission.)*

is located on the interior of the ER, the existence of a permease has been hypothesized to facilitate transport of UDPGA from the cytosol across the lipid layers of the ER. The permease has been proposed because uridine diphosphate glucose (UDPG) is present in the cytosol in higher concentrations yet UDPGA serves as the preferred donor for bilirubin conjugation.[39] Uridine diphosphate *N*-acetylglucosamine (UDPNAG) is considered to be a natural regulator of BUGT[40] because UDPNAG increases in vitro BUGT activity threefold. The mechanism for such regulation is unknown and could possibly involve facilitation of the permease UDPGA transporter.[41] After providing glucuronic acid for conjugation, UDP is converted to uridine and inorganic pyrophosphate by a nucleoside diphosphatase that is also located on the interior of the ER[42] and prevents the reverse reaction.

The specific isoform responsible for bilirubin conjugation is UGT1A1 (trivial name, HUG-Br1, EC 2.4.1.17).[38] It is part of the UDP-glycosyltransferase superfamily of enzymes encoded by the *UGT* gene complex on chromosome 2 that is involved in the metabolism of many xenobiotic and endogenous substances. The *UGT1* gene encodes several isoforms and has a complex structure consisting of four common exons (2 to 5) and 13 variable exons encoding different isoforms (Fig. 4-4).[43,44] At least 30 different *UGT1* mutant alleles have been described that cause Gilbert's syndrome and Crigler-Najjar syndromes I and II.[45] UGT1A1 catalyzes the formation of both bilirubin monoglucuronides and diglucuronides[46] but also metabolizes other hormones and drugs, so mutations could be involved in carcinogenesis and adverse drug reactions.[47] In normal adult humans the majority of bilirubin conjugates are excreted in bile as bilirubin diglucuronides ($\approx$80%)[48-53] (Fig. 4-5, middle panel). Lesser amounts of bilirubin monoglucuronides ($\approx$15%) are also excreted along with very small amounts of unconjugated bilirubin and other bilirubin conjugates (e.g., glucose, xylose, and mixed diesters). Because UGT1A1 activity is lower in infants than adults, the bile of infants contains less bilirubin diglucuronide and more bilirubin monoglucuronide (Fig. 4-6, middle panel).

Bilirubin Excretion

After conjugation, bilirubin conjugates are excreted against a concentration gradient from the hepatocyte through the canalicular membrane into bile. Data from purified canalicular membrane vesicles of rat liver suggest that transport of bilirubin diglucuronide through the canalicular membrane is carrier mediated, electrogenic, and stimulated by HCO_3^-.[54] Similar data also suggest that bilirubin glucuronides are transported across the canalicular membrane by both adenosine triphosphate (ATP)-dependent and membrane potential–dependent transport systems and that these systems are additive in normal rats.[55] The ATP-dependent transporter responsible for passage of bilirubin glucuronide from the hepatocyte through the canalicular membrane is the canalicular multispecific organic anion transporter (cMOAT). cMOAT is a member of the ATP-binding cassette (ABC) transporter superfamily; it is homologous to the multidrug resistance–associated protein (MRP2)[56,57] and is also known as ABCC2 because it is encoded by the *ABCC2* gene.[58] cMOAT/MRP2/ABCC2 is involved in ATP-dependent transport across the apical canalicular membrane of a variety of endogenous compounds and xenobiotics,[59] including both bilirubin monoglucuronide and diglucuronide.[60] cMOAT has previously been described as the non–bile acid organic anion transporter, the glutathione S-conjugate export pump, and the leukotriene export pump.[61] Genetic mutations in which these ABC transporters are altered cause diseases that include cystic fibrosis, hyperinsulinemia, adrenoleukodystrophy, multidrug resistance,[62] and as discussed later in this chapter, Dubin-Johnson syndrome. This mechanism can be saturated with increasing amounts of bilirubin or bilirubin conjugates.[63-65] Many other organic anions (e.g., BSP, ICG) share this same canalicular membrane excretion mechanism.[66] Simultaneous infusion of BSP and ICG will decrease the maximal canalicular excretion of bilirubin and vice versa.[67,68] The canalicular excretion mechanism for bilirubin and BSP is different from that for bile salts. Biliary excretion of conjugated bilirubin and BSP is decreased in individuals with Dubin-Johnson syndrome,[69] although bile salt excretion is not
FIGURE 4-5. Bile pigment excretion in an adult human as assessed by high-performance liquid chromatography. Chromatograms represent analysis of serum (20 μL, *top*), duodenal bile (20 μL, *middle*), and stool extract (equivalent to 50 mg of wet stool, *bottom*) from a normal man. The scale of the y-axes varies. Serum bile pigments are almost all bilirubin. The bilirubin diglucuronide and monoglucuronide (BDG, BMG) that predominate over bilirubin (B) in adult bile are not present in adult feces because of metabolism by intestinal bacteria. *(Redrawn from Gourley GR. Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF [eds]. Liver Disease in Children, 3rd ed. New York, Cambridge University Press, 2007. FIGURE 4-6. Bile pigment excretion in a newborn human as assessed by high-performance liquid chromatography. Chromatograms represent analysis of serum (20 μL, *top*) from an infant receiving phototherapy in the first week of life and duodenal bile (20 μL, *middle*) and stool extract (equivalent to 50 mg of wet stool, *bottom*) from a normal full-term, formula-fed female infant on day 3 of life. Serum bile pigments include lumirubin (L). The scale of the y-axes varies. Neonates lack intestinal bacterial flora, and hence large quantities of bilirubin diglucuronide and monoglucuronide (BDG, BMG) and bilirubin (B) are present in feces. *(Redrawn from Gourley GR. Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF [eds]. Liver Disease in Children, 3rd ed. New York, Cambridge University Press, 2007. Used with permission.)*

impaired. However, excretion of bile salts and bilirubin conjugates by the canalicular membrane is not completely independent because infusion of bile salts does increase the maximal excretion of bilirubin conjugates.[70] A similar effect in seen with phenobarbital.[71] Conversely, the maximal excretion of bilirubin conjugates can be decreased by cholestatic agents such as estrogens and anabolic steroids.[72,73]

Under normal conditions, there is evidence that bilirubin conjugates equilibrate across the sinusoidal membrane of hepatocytes, thereby resulting in small amounts of bilirubin conjugates being present in the systemic circulation.[74-76] If hepatic glucuronidation of bilirubin is diminished (e.g., in the neonate), a decreased amount of bilirubin conjugates will be present in serum.[74,75,77] Data show that in full-term newborns there is an increase in the serum level of bilirubin diconjugates ($0.55\% \pm 0.25\%$ on days 2 to 4 increasing to $1.62\% \pm 0.99\%$ on days 9 to 13), consistent with the maturation of bilirubin

glucuronidation.[78] In contrast, in premature infants younger than 33 weeks' gestation, bilirubin diconjugates were very low and remained so, thus suggesting more severe immaturity of the glucuronidation process.

In many pathologic circumstances, bilirubin mono-glucuronides and diglucuronides are not excreted from the hepatocyte fast enough to prevent significant reflux back into the circulation. The ensuing elevation in serum bilirubin conjugate levels results in transesterification of bilirubin glucuronide with an amino group on albumin and creation of a covalent bond between albumin and bilirubin.[79] This product is formed spontaneously and is known as delta bilirubin or bilirubin-albumin.[80] Similar nonenzymatic reactions have been demonstrated between albumin and various drugs.[79,81-83] Delta bilirubin is not formed in hyperbilirubinemic conditions unless the conjugated bilirubin fraction is elevated. Both delta bilirubin and bilirubin conjugates are direct reacting, which explains a situation that has long confounded clinicians. Direct bilirubin may continue to be elevated in patients who are otherwise recovering from a hepatic insult because the delta bilirubin formed lingers as a result of the long ($\approx$20 days[84]) half-life of albumin.

Enterohepatic Circulation of Bilirubin

When bilirubin conjugates enter the intestinal lumen (see Fig. 4-2), several possibilities for further metabolism arise. In adults, the normal bacterial flora hydrogenate various carbon double bonds in bilirubin to produce assorted urobilinogens (Fig. 4-7). Subsequent oxidation of the middle (C-10) carbon produces the related urobilins. Because there are a large number of unsaturated bonds in bilirubin, many compounds are formed by reduction and oxidation of these bonds. This large family of related reduction-oxidation products of bilirubin is known as urobilinoids,[85] and they are excreted in feces and urine. Bacteria capable of producing urobilinoids include *Clostridium ramosum*,[86] *Escherichia coli*, *Bacteroides fragilis*,[87] *Clostridium perfringens*, and *Clostridium difficile*.[88] Conversion of bilirubin conjugates to urobilinoids is important because it blocks the intestinal absorption of bilirubin known as the enterohepatic circulation.[89,90] Neonates lack intestinal bacterial flora and are more likely to absorb bilirubin from the intestine. This difference in bile pigment excretion between adults and neonates is demonstrated by comparing Figures 4-5 and 4-6 (lower panels).

Bilirubin conjugates in the intestine can also act as substrate for either bacterial[91-93] or endogenous tissue[94] β-glucuronidase. This enzyme hydrolyzes glucuronic acid from bilirubin glucuronides. The unconjugated bilirubin produced is more rapidly absorbed from the intestine.[95] In the fetus, tissue β-glucuronidase is detectable by 12 weeks' gestation and is believed to play an important role in facilitating the intestinal absorption of bilirubin that enables it to be cleared via the placenta. After birth, increased intestinal β-glucuronidase can increase the neonate's likelihood of experiencing higher serum bilirubin levels.[96] The ability of endogenous tissue β-glucuronidase to deconjugate bilirubin glucuronides has been demonstrated in germ-free animals.[97] Breast milk can contain high levels of β-glucuronidase, and it has been suggested that this is one factor related to the higher jaundice levels seen in breast-fed infants.[98] Feeding specific nutritional ingredients that inhibit β-glucuronidase, such as hydrolyzed casein or L-aspartic acid,[99] has been shown to result in increased fecal bilirubin excretion and lower levels of jaundice.[100]

DIAGNOSIS OF HYPERBILIRUBINEMIA

Jaundice and icterus both refer to the yellow discoloration of tissues (skin, sclerae, etc.) caused by the deposition of bilirubin. "Jaundice," from the French *jaune*, means yellow. "Icterus" is derived from the Greek word for jaundice (*ikteros*). Jaundice is a sign that hyperbilirubinemia exists (i.e., total serum bilirubin greater than $\approx$1.4 mg/dL after 6 months of age; 1 mg/dL = 17 μmol/L). The degree of jaundice is directly related to the level of serum bilirubin and the amount of bilirubin deposited in extravascular tissues. Hypercarotenemia, occasionally mistaken for jaundice, can impart a yellow hue to the skin, but the sclerae remain white. There are many conditions associated with neonatal jaundice, some of which are so commonly recognized that they are termed "physiologic." Alternatively, jaundice can be a sign of severe disease.

Total Serum Bilirubin Measurements

Measurement of the total serum bilirubin concentration allows quantitation of jaundice. Such measurements are very common in the newborn nursery and in one study were made at least once in 61% of term newborn infants.[101] Two components of total serum bilirubin can be routinely measured in the clinical laboratory: conjugated bilirubin ("direct" reacting because in the Van den Bergh test, color development takes place directly without adding methanol) and unconjugated bilirubin ("indirect" fraction). Although the terms "direct" and "indirect" are often used equivalently with conjugated and unconjugated bilirubin, this is not quantitatively correct because the direct fraction includes both conjugated bilirubin and albumin-bound delta bilirubin.[102] Elevation of either of these fractions can result in jaundice. There is a long history of undesirable variability in the measurement of serum bilirubin fractions.[103,104] One problem is the ditaurobilirubin (DTB) content of standards sent by the College of American Pathologists.[104] DTB influences the result variably because of protein matrix differences related to the specific bilirubin measurement used. This has prompted the suggestion that standards should consist of human serum enriched solely with unconjugated bilirubin rather than bovine serum containing a mixture of unconjugated bilirubin and DTB.[105] The auto-
FIGURE 4-7. Reduction and oxidation of bilirubin to a family of related compounds known collectively as urobilinoids. Only several examples are given of this much larger family. *(Redrawn from Gourley GR. Neonatal jaundice and disorders of bilirubin metabolism. In Suchy FJ, Sokol RJ, Balistreri WF [eds]. Liver Disease in Children, 3rd ed. New York, Cambridge University Press, 2007. Used with permission.)*

mated laboratory methods now used to measure serum bilirubin have been reviewed elsewhere.[102,106-108] The Jendrassik-Grof procedure is the method of choice for measurement of total bilirubin, although this method also has problems.[109] When the total serum bilirubin level is high, factitious elevation of the direct fraction has been reported.[110] Three newer methods have been developed that can more accurately determine the various bilirubin

fractions (unconjugated, monoconjugated, diconjugated, and albumin bound or delta): high-pressure liquid chromatography (HPLC),[111] multilayered slides,[112,113] and use of bilirubin oxidase.[114] HPLC analysis is superior and is used as the "gold standard,"[115,116] but it is too expensive and time consuming for the clinical laboratory.[102] HPLC analysis of serum from normal human neonates in the first 4 days of life[117] showed that unconjugated and con-

jugated bilirubin levels rose in parallel, with the conjugated fraction making up only 1.2% to 1.6% of the total pigment (3.6% in adults). Although the absolute concentration of conjugates was two to six times higher in neonates, only 20% were diconjugates (54% in adults). These sensitive HPLC data are consistent with the increased bilirubin production and relatively deficient glucuronidation seen in neonates. Analysis with automated multilayered slide technology (Johnson & Johnson—Vitros), used in many clinical laboratories, allows measurement of specific conjugated and unconjugated bilirubin fractions without the inclusion of delta bilirubin. Measurement of conjugated bilirubin provides an earlier indicator of relief from biliary cholestasis than measurement of direct bilirubin does because of the long half-life of delta bilirubin.[118] In a comparison of the bilirubin oxidase method it was concluded that determinations of total bilirubin in neonatal serum were not advanced by this method.[119]

Newer methods of total bilirubin measurement (Twin Beam, Ginevri, Rome; ABL 735, Radiometer, Copenhagen; Roche OMNI S, Roche Diagnostics, Graz, Austria) using nonenzymatic photochemical analysis offer the convenience of bilirubin quantitation outside a core laboratory setting (i.e., blood gas analyzer in the nursery) with a smaller blood sample than needed for traditional serum analysis. However, these measurements must be interpreted with caution because the instruments tend to underestimate the total bilirubin concentration when greater than 15 mg/dL.[120]

There are conflicting data regarding the accuracy of capillary versus venous serum bilirubin levels.[121,122] However, as Maisels has pointed out, the literature regarding kernicterus, phototherapy, and exchange transfusion is based on bilirubin measurements in capillary samples.[123]

Transcutaneous Bilirubinometry

Noninvasive methods of measuring jaundice levels have been shown to be useful in neonates. Current commercially available methods include the BiliCheck (Respironics, Pittsburgh)[115] and the Minolta/Hill-Rom Air-Shields Transcutaneous Jaundice Meter 103 (Air-Shields, Hatboro, PA).[124] The technique uses principles of reflectance spectrophotometry, has been validated against both HPLC and clinical laboratory measures,[115,116] and is advocated by the American Academy of Pediatrics.[125] Touching the skin with the device in a painless manner results immediately in point-of-care measurement of transcutaneous bilirubin. Significant transcutaneous bilirubin levels (e.g., >13 mg/dL) should prompt measurement of a serum or plasma bilirubin level. Some suggest that the yellow color of the skin is a better indicator of the risk for bilirubin-dependent brain damage than the serum bilirubin level is.[126] A less expensive[127] method useful in assessing jaundice[128,129] involves pressing a Plexiglas color chart against the baby's nose (Ingram icterometer, Thos. A. Ingram and Co., Ltd, Birmingham, England).

TOXICITY OF UNCONJUGATED HYPERBILIRUBINEMIA

Kernicterus

Reviews of neonatal bilirubin toxicity have been published elsewhere.[1,130,131] Kernicterus (German: *kern* = nucleus; Latin: *icterus* = yellow) is the neuropathologic finding associated with severe unconjugated hyperbilirubinemia and is named for the yellow staining of certain regions of the brain, particularly the basal ganglia, hippocampus, cerebellum, and nuclei of the floor of the fourth ventricle.[130,132] Acute clinical findings associated with kernicterus, termed acute bilirubin encephalopathy, include a sluggish Moro reflex, opisthotonos, retrocollis, hypotonia, vomiting, high-pitched cry, hyperpyrexia, seizures, gaze paresis ("setting sun sign"), oculogyric crisis, and death. Long-term findings (chronic bilirubin encephalopathy) include spasticity, choreoathetosis, dental enamel dysplasia of the deciduous teeth, and sensorineural hearing loss. Milder forms of bilirubin encephalopathy include cognitive dysfunction and learning disabilities.[133,134] In 17-year-old males, the risk of having an IQ score lower than 85 was found to be significantly higher in full-term subjects with neonatal serum bilirubin levels above 20 mg/dL.[135] The mechanisms of bilirubin cytotoxicity are complex and have been reviewed elsewhere.[130,131,136-138] Although the neonatal period is the most common time for bilirubin-related brain damage, the neurotoxicity of bilirubin has also been documented in older children and adults with Crigler-Najjar syndrome type I.[139,140]

The absolute level of serum bilirubin has not been a good predictor of the risk for bilirubin encephalopathy. However, it has long been known that kernicterus is likely with serum unconjugated bilirubin levels greater than 30 mg/dL and unlikely with levels less than 20 mg/dL.[141-143] In one study, 90% of patients with a bilirubin level higher than 35 mg/dL either died or had cerebral palsy or physical retardation.[143] Alternatively, no developmental retardation was found in 129 infants with bilirubin levels less than 20 mg/dL. The albumin concentration is an important variable because of its high-affinity binding with bilirubin and because the ratio of bilirubin to albumin is a risk factor that has been included in the most recent American Academy of Pediatrics guidelines.[125] Drugs and organic anions also bind to albumin and can displace bilirubin, thereby increasing free bilirubin, which can diffuse into cells and cause toxicity.[144,145] The most notable example of this is kernicterus, which occurred with low bilirubin levels when sulfisoxazole was given to premature infants.[146] Walker has reviewed neonatal bilirubin toxicity and drug-induced bilirubin displacement.[136] In recent years there has been a re-emergence of kernicterus.[131] Although it has been acknowledged that

total serum bilirubin may not be the most important factor related to risk, there are, at present, no other generally accepted tests (e.g., albumin saturation, reserve bilirubin binding capacity, or free bilirubin concentration) that are more helpful in identifying infants at risk for bilirubin encephalopathy. Recently, the basics of bilirubin-albumin binding and neonatal jaundice have been reviewed by Ahlfors and Wennberg.[147] Additionally, Ahlfors and colleagues have recently described how to use zone fluidics to measure free bilirubin and overcome some of the existing problems with measurement of unbound (free) bilirubin.[148] Wennberg and co-workers speculate that the enhanced sensitivity and specificity of newer methods of measurement of free bilirubin will establish an improved risk threshold for kernicterus and therefore reduce unnecessary aggressive intervention (i.e., exchange transfusion) and its associated cost and morbidity.[149]

Another approach aimed at measuring early changes in the CNS caused by bilirubin has assessed the use of brainstem auditory evoked potentials (BAEPs).[150,151] Abnormalities in BAEP have been demonstrated in jaundiced infants and were shown to improve after exchange transfusion.[152,153] Data have shown that even moderate hyperbilirubinemia (mean ± SD: 14.3 ± 2.8 mg/dL) affects the BAEP, specific components of the Brazelton Neonatal Behavioral Assessment Scale,[154] and cry characteristics.[155]

Another reported adverse effect of neonatal jaundice relates not to the CNS of a jaundiced infant but rather to the attitude of the infant's parents. Mothers of jaundiced infants more frequently exhibit behavior suggesting the "vulnerable child syndrome,"[156,157] including inappropriate visits to the physician because of unrealistic perceptions of illness, separation difficulty, and early termination of breast-feeding. Another study, however, showed that hyperbilirubinemia, phototherapy, or both during the neonatal period is not associated with impaired mother-child attachment after the first year of life.[158]

Nonpathologic Unconjugated Hyperbilirubinemia

Physiologic Jaundice

The term "physiologic jaundice" has been used to describe the frequently observed jaundice in otherwise completely normal neonates. However, physiologic jaundice is merely the result of a number of factors involving increased bilirubin production and decreased excretion.

Jaundice should always be considered a sign of possible disease and not routinely explained as physiologic. Specific characteristics of neonatal jaundice to be considered abnormal until proved otherwise include (1) the development of jaundice before 36 hours of age, (2) persistence beyond 10 days of age, (3) serum bilirubin greater than 12 mg/dL at any time, and (4) elevation of direct bilirubin (direct bilirubin >1.0 mg/dL if total bilirubin is less than 5 mg/dL or direct bilirubin >20% of total bilirubin if total bilirubin is greater than 5 mg/dL[159]).

The physiologic immaturity of premature infants is associated with both higher peak serum bilirubin levels and pathologic conditions.[160]

In general, infants are not jaundiced at the moment of birth because of the impressive ability of the placenta to clear bilirubin from the fetal circulation. However, within the next few days, elevated serum bilirubin levels (>1.4 mg/dL) will develop in most if not all infants, with clinical jaundice becoming evident when the total bilirubin level exceeds 2 to 5 mg/dL. As serum bilirubin rises, the skin becomes more jaundiced in a cephalocaudad manner.[161] Icterus is first observed in the face and progresses caudally to the palms and soles. Kramer found the following serum indirect bilirubin levels as jaundice progressed: head and neck—4 to 8 mg/dL; upper part of the trunk—5 to 12 mg/dL; lower part of the trunk and thighs—8 to 16 mg/dL; arms and lower part of the legs—11 to 18 mg/dL; and palms and soles—greater than 15 mg/dL.[162] Hence, when the bilirubin level was higher than 15 mg/dL, the entire body was icteric. However, darker skin tones can make jaundice difficult to estimate visually.[125] Jaundice is best observed by blanching the skin with gentle digital pressure under well-illuminated (white light) conditions. Visible jaundice develops in at least a third of infants. A combined analysis of several large studies involving thousands of infants during the first week of life showed that moderate jaundice (bilirubin >12 mg/dL) occurs in at least 12% of breast-fed infants and 4 percent of formula-fed infants whereas severe jaundice (>15 mg/dL) occurs in 2% and 0.3% of these respective feeding groups.[163]

There are a number of epidemiologic risk factors related to neonatal jaundice that have been reviewed elsewhere.[125,164-166] Risk factors include male gender, low birth weight, prematurity, polycythemia, certain ethnicities (Asian, Native American, Greek), maternal medications (e.g., oxytocin, promethazine hydrochloride), premature rupture of membranes, increased weight loss after birth, delayed passage of meconium, breast-feeding, and neonatal infection. Delivery with a vacuum extractor increases the risk for cephalohematoma and neonatal jaundice.[167] Data suggest that pancuronium is associated with an increased risk for hyperbilirubinemia.[168] A significant correlation has been found between the umbilical cord serum bilirubin level and subsequent hyperbilirubinemia.[169,170] The maternal serum bilirubin level at the time of delivery and the transplacental bilirubin gradient also correlate positively with neonatal serum bilirubin concentrations.[170] Factors associated with decreased neonatal bilirubin levels[125,171] include African race, exclusive formula feeding, gestational age of 41 weeks or older, maternal smoking, and certain drugs given to the mother (e.g., phenobarbital).

Breast-Feeding and Jaundice

Breast-feeding has clearly been identified as a factor related to neonatal jaundice,[163] and this subject has been reviewed elsewhere.[172,173] Breast-fed infants have been

shown to have significantly higher serum bilirubin levels than formula-fed infants on each of the first 5 days of life,[174] and this unconjugated hyperbilirubinemia can persist for weeks[175] to months.[176,177] Jaundice during the first week of life is sometimes described as "breast-feeding jaundice" to differentiate it from "breast milk jaundice syndrome," which occurs after the first week of life.[178-180] The former is frequently associated with inadequate breast milk intake, whereas the latter generally occurs in otherwise thriving infants. There is probably overlap between these conditions and physiologic jaundice. Early reports linking breast milk and neonatal jaundice with a steroid (pregnane-3α,20β-diol) in some milk samples[181] have not been confirmed by more recent larger studies using more sensitive methods.[182] There are also conflicting data regarding efforts to attribute this jaundice to increased lipase activity in breast milk with resultant elevated levels of free fatty acids, which could inhibit hepatic glucuronosyltransferase.[183] It has been suggested that the enterohepatic circulation of bilirubin can be facilitated by the presence of β-glucuronidase[96,184] or some other substance in human milk.[185] Other factors possibly related to jaundice in breast-fed infants include caloric intake, fluid intake, weight loss, delayed passage of meconium, intestinal bacterial flora, and inhibition of bilirubin glucuronosyltransferase by an unidentified factor in the milk.[98] Lascari suggested that a healthy breast-fed infant with unconjugated hyperbilirubinemia, a normal hemoglobin concentration, reticulocyte count, and blood smear, no blood group incompatibility, and no other abnormalities on physical examination may be presumed to have early breast-feeding jaundice.[179] Because there is no specific laboratory test to confirm a diagnosis of breast milk jaundice, it is important to rule out treatable causes of jaundice before ascribing the hyperbilirubinemia to breast milk. Some infants with presumed breast milk jaundice exhibit elevated serum bile acid levels suggesting mild hepatic dysfunction or cholestasis,[186] although in general this is not the case. Breast-fed infants who are fed specific nutritional ingredients that inhibit β-glucuronidase,[99] such as L-aspartic acid, excrete more fecal bilirubin and have lower levels of jaundice[100] than do breast-fed infants who receive no supplements. No commercial preparations of these specific ingredients are presently available.

DISORDERS OF PATHOLOGIC UNCONJUGATED HYPERBILIRUBINEMIA

Disorders of Production

Isoimmunization

The most common cause of severe early jaundice is fetal-maternal blood group incompatibility with resulting isoimmunization. Maternal immunization develops when erythrocytes leak from the fetal to the maternal circulation. Fetal erythrocytes carrying different antigens are recognized as foreign by the maternal immune system, which forms antibodies against them (maternal sensitization). These antibodies (IgG immunoglobulins) cross the placental barrier into the fetal circulation and bind to fetal erythrocytes. In Rh incompatibility, sequestration plus destruction of the antibody-coated erythrocytes takes place in the reticuloendothelial system of the fetus. In ABO incompatibility, hemolysis is intravascular, complement mediated, and not usually as severe as in Rh disease.[187] Significant hemolysis can also result from incompatibilities between minor blood group antigens (e.g., Kell).[188] Although hemolysis is predominantly associated with elevation of unconjugated bilirubin, the conjugated fraction can also be elevated.[189] Any type of isoimmune hemolytic disease is a risk factor for kernicterus.[125]

Rh incompatibility problems do not usually develop until the second pregnancy; thus, prenatal blood typing and serial testing of Rh-negative mothers for the development of Rh antibodies provide important information to guide possible intrauterine care. If maternal Rh antibodies develop during pregnancy, potentially helpful measures include serial amniocentesis (with bilirubin measurement),[190,191] ultrasound assessment of the fetus,[192,193] intrauterine transfusion,[194,195] and premature delivery. The prophylactic administration of anti-D gamma globulin[196] has been most helpful in preventing Rh sensitization. A newborn infant with Rh incompatibility exhibits pallor, hepatosplenomegaly, and rapidly developing jaundice in the first hours of life. In severe cases the infant may be born with generalized edema (fetal hydrops). Laboratory findings in the neonate's blood include reticulocytosis, anemia, a positive direct Coombs test, and a rapidly rising serum bilirubin level. Conjugated hyperbilirubinemia is occasionally observed in Rh erythroblastosis, particularly when intrauterine transfusions have been administered.[117] It may be the result of exceeding the hepatic excretory capacity. Alternatively, cholestasis may also be caused by hepatic congestion from extramedullary erythropoiesis and heart failure or by tissue hypoxia from reduced hepatic blood flow and anemia.[197] In addition, cholestasis in infants with erythroblastosis fetalis may be exacerbated by secondary complications, including biliary obstruction, sepsis, and hepatic failure.[198]

Therapeutic intervention consisting of phototherapy and consideration of exchange transfusion should be initiated at lower serum bilirubin concentrations in infants with isoimmune hemolysis, and intravenous gamma globulin has been shown to reduce the need for exchange transfusions in infants with Rh and ABO hemolytic disease.[125] Serum bilirubin should be measured as frequently as every 4 hours to establish the rate of increase and to assess the effect of therapy. Exchange transfusions may be performed as emergency procedures in severe cases almost immediately after delivery to treat anemia and heart failure.

In contrast to Rh incompatibility, ABO incompatibility is usually clinically apparent with the first pregnancy.

ABO hemolytic disease is largely limited to blood group A or B infants born to group O mothers.[199] ABO hemolytic disease is relatively rare in type A or B mothers. Development of jaundice is not as rapid as with Rh disease, and a serum bilirubin level greater than 12 mg/dL on day 3 of life would be typical. Laboratory abnormalities include reticulocytosis (>10%) and a weakly positive direct Coombs test, although it is sometimes negative. Anti-A or anti-B antibodies may be seen in the serum of the newborn if examined within the first few days of life before they rapidly disappear. Spherocytes are the most prominent feature seen in a peripheral blood smear with ABO incompatibility.

Erythrocyte Enzymatic and Structural Defects

A number of specific abnormalities of RBCs can result in neonatal jaundice, including hemoglobinopathies and RBC membrane and enzyme defects. Hereditary spherocytosis is not usually a neonatal problem, but hemolytic crises can occur and be manifested as a rising bilirubin level and a falling hematocrit.[200] A family history of spherocytosis, anemia, or early gallstone disease (before 40 years of age) is helpful in suggesting this diagnosis. The characteristic spherocytes seen in the peripheral blood smear may be impossible to distinguish from those seen with ABO hemolytic disease. Other erythrocyte conditions associated with neonatal jaundice include drug-induced hemolysis, deficiencies of erythrocyte enzymes (glucose-6-phosphate dehydrogenase [G6PD] deficiency,[201,202] pyruvate kinase deficiency, and others), and hemolysis induced by vitamin K or bacteria. Recent studies of G6PD activity in African American neonates suggest that hemolysis is neither the predominate factor in the pathogenesis of hyperbilirubinemia nor predictive of hyperbilirubinemia by itself,[203] although African American male neonates may be at higher risk for hyperbilirubinemia, particularly if breast-fed and premature.[204] This emphasizes the important relationship between bilirubin excretion and serum bilirubin concentration.[205] α-Thalassemia can result in severe hemolysis and lethal hydrops fetalis.[206] β-Thalassemia may also be accompanied by hemolysis and severe neonatal hyperbilirubinemia.[207] A wide variety of clinical findings are associated with the thalassemias, from profound intrauterine hydrops and death, to mild neonatal jaundice and anemia, to no jaundice or anemia. Southeast Asian ovalocytosis has been associated with severe hyperbilirubinemia.[208] These RBC abnormalities are more likely to result in hyperbilirubinemia in the presence of Gilbert's syndrome, as described later in this chapter.

Drugs or other substances responsible for hemolysis can be passed to the fetus across the placenta or to the neonate via breast milk. Induction of labor with oxytocin has been shown to be associated with neonatal jaundice. There is a significant association between hyponatremia and jaundice in infants of mothers who received oxytocin to induce labor.[209,210] The vasopressin-like action of oxytocin prompts electrolyte and water transport such that erythrocytes swell and increased osmotic fragility and hyperbilirubinemia can result. Steroid administration at the initiation of oxytocin and 4 hours later may be helpful in preventing this hyperbilirubinemia.[211]

Infection

Bacterial sepsis increases bilirubin production through initiation of erythrocyte hemolysis or via endotoxin-mediated reduction of canalicular bile secretion resulting in a combination of conjugated and unconjugated hyperbilirubinemia. However, hyperbilirubinemia is rarely the only manifestation of bacteremia or sepsis,[212] and some data suggest that sepsis may result in lower peak levels of unconjugated bilirubin through consumption of bilirubin as an antioxidant in response to oxidant production by phagocytic cells.[213]

Sequestration

Extravascular blood within the body can be rapidly metabolized to bilirubin by tissue macrophages. Examples of this increased bilirubin production include cephalohematoma, ecchymoses, petechiae, and hemorrhage. Although the diagnosis can often be made on physical examination, occult intracranial, intestinal, or pulmonary hemorrhage can also produce hyperbilirubinemia. Similarly, swallowed blood can be converted to bilirubin by the HO of intestinal epithelium. From a red sample of bloody gastric contents, meconium, or stool, the Apt test can be used to distinguish blood of maternal or infant origin because of differences in alkali resistance between fetal and adult hemoglobin[214,215]; however, this test has low sensitivity and poor reproducibility, and an HPLC method has been shown to be superior.[216]

Polycythemia

Polycythemia can cause hyperbilirubinemia because the absolute increase in RBC mass results in elevated bilirubin production through normal rates of erythrocyte breakdown. A number of mechanisms may result in neonatal polycythemia (usually defined by a venipuncture hematocrit >65%), as reviewed by Werner.[217] Maternal-fetal transfusion during peripartum placental separation, a delay in umbilical cord clamping at birth, and twin-twin transfusion syndrome are all commonly encountered causes of polycythemia. Similarly, intrauterine hypoxia and maternal diseases such as diabetes mellitus can result in neonatal polycythemia. Therapy for symptomatic polycythemia is partial exchange transfusion, although therapy for asymptomatic polycythemia remains controversial.[218]

Disorders of Conjugation

The disorders described in this section, summarized in Tables 4-1 and 4-2, are those in which there is a primary abnormality in bilirubin metabolism without other liver disease.[219] The disorders can best be understood in the context of the normal pathway in which bilirubin is

TABLE 4-1	Comparison of Disorders of Unconjugated Hyperbilirubinemia		
	Gilbert's Syndrome	**Crigler-Najjar Syndrome Type 1**	**Crigler-Najjar Syndrome Type 2**
Prevalence	3%	Rare	Rare
Inheritance	Autosomal dominant or recessive	Autosomal recessive	Autosomal recessive, rarely dominant
Genetic defect	*UGT1A1* gene	*UGT1A1* gene	*UGT1A1* gene
Hepatocyte defect site	Microsomes ± plasma membrane	Microsomes	Microsomes
Deficient hepatocyte function	Glucuronidation ± uptake	Glucuronidation	Glucuronidation
BUGT activity	5-53% of controls	Severely decreased	2-23% of controls
Hepatocyte uptake	Decreased in 20-30%	Normal	Normal
Serum total bilirubin level (mg/dL)	0.8-4.3	15-45	8-25
Serum bilirubin decrease with phenobarbital (%)	70	0	77
HPLC SERUM BILIRUBIN COMPOSITION **Normal (%)**			
Unconjugated 92.6	98.8	≈100	99.1
Diglucuronide 6.2	1.1	0	0.6
Monoglucuronide 0.5	0	0	0
BILE BILIRUBIN CONJUGATES **Normal (%)**			
Diglucuronide ≈80	60	0 to trace	5-10
Monoglucuronide ≈15	30	Predominant if measurable	90-95
Other routine liver function tests	Normal	Normal	Normal
Prognosis	Benign	Kernicterus common	Occasional kernicterus

TABLE 4-2	Comparison of Disorders of Conjugated Hyperbilirubinemia	
	Rotor's Syndrome	**Dubin-Johnson Syndrome**
Prevalence	Rare	Rare
Inheritance	Autosomal recessive	Autosomal recessive
Genetic defect	Unknown	*cMOAT/MRP2/ABCC2* gene
Hepatocyte defect site	GST	Apical canalicular membrane
Deficient hepatocyte function	Intracellular binding of bilirubin and conjugates	Canalicular secretion of bilirubin conjugates
Brown-black liver	No	Yes
Serum total bilirubin level (mg/dL)	2-7	1.5-6.0
Serum conjugated bilirubin (%)	>50	>50
Other routine liver function tests	Normal	Normal
Oral cholecystogram	Usually visualizes	Usually does not visualize
⁹⁹ᵐTc-HIDA cholescintigraphy		
Liver	Poor to no visualization	Intense, prolonged visualization
Gallbladder	Poor to no visualization	Delayed or nonvisualization
BSP clearance test	Serum BSP levels elevated (delayed clearance)	Serum BSP levels normal at 45 min but elevated at 90-120 min
ICG clearance test	Delayed clearance	Normal
Response to estrogens or pregnancy	No change	Increased jaundice
Total urinary coproporphyrin excretion (isomers I + III)	2.5-5.0 times increased	Normal
Urinary coproporphyrin isomer I composition (normal = 25%)	Usually <80% of total	>80% of total
Prognosis	Benign (asymptomatic)	Benign (occasional abdominal complaints—probably incidental)

BSP, bromsulfophthalein; GST, glutathione-S-transferase; HIDA, hepatobiliary iminodiacetic acid; ICG, indocyanine green.

cleared from the circulation (see Fig. 4-2). Defects in these metabolic steps are responsible for the disorders to be described in the final section of this chapter.

Gilbert's Syndrome

Clinical Findings

Gilbert's syndrome (GS, OMIM 143500) was first described in 1901 by Gilbert and Lereboullet.[220] It is characterized by a hereditary chronic or recurrent, mild unconjugated hyperbilirubinemia with otherwise normal liver function test results (for reviews see elsewhere[221-223]). The elevation in serum unconjugated bilirubin is variable and usually ranges from 1 to 4 mg/dL (1 mg/dL = 17 μmol/L). Frequently, patients are first identified when an elevated serum bilirubin level is found on screening blood chemistry or mild jaundice (perhaps only scleral icterus) is noted during a period of fasting associated with a nonspecific viral illness or religious activities.[224] Icteric plasma from a blood donor may suggest GS.[225] Alternatively, hyperbilirubinemia after liver transplantation may be a sign that the donor had GS.[226-229] GS is generally associated with no negative implications for health or longevity; however, a large variety of common symptoms have been reported by patients with GS,[230,231] including vertigo, headache, fatigue, abdominal pain, nausea, diarrhea, constipation, and loss of appetite. The possible relationship of these symptoms to GS was evaluated in a group of 2395 Swedish subjects.[232] The only symptom that was more common in GS was diarrhea in men aged 57 to 67 years. The authors suggested that this was most likely a type I error because of the large number of comparisons made and concluded that there was no higher prevalence of symptoms associated with GS. There are limited reports suggesting that GS is a risk factor for chronic fatigue syndrome.[233,234]

In two large surveys of normal individuals, approximately 3% had serum bilirubin levels greater than 1.0 mg/dL.[235,236] If the normal upper limit of serum bilirubin is defined as 1.4 mg/dL, there is a strong male preponderance ($\approx 4:1$). This finding might be related to the observation that females clear bilirubin better than males do.[237] GS may be inherited in either an autosomal dominant[238-241] or recessive[242] fashion.

Although GS is a congenital disorder, it rarely becomes clinically apparent until after puberty. The reasons for this are unknown but have been suggested to be related to the hormonal changes of puberty. Steroid hormones can suppress hepatic bilirubin clearance.[73] During pregnancy, increased estrogen levels are associated with impaired clearance of exogenous bilirubin.[243] Gonadectomy has been shown to alter BUGT activity.[244] Odell speculated that some infants with nonhemolytic neonatal jaundice are manifesting GS.[245] Use of genetic markers (see later) has allowed investigation of the role that GS plays in neonatal jaundice. Individuals carrying such markers have been shown to have a more rapid rise in their jaundice levels during the first 2 days of life,[246] a
FIGURE 4-8. Incidence (percentage) of hyperbilirubinemia (serum total bilirubin ≥ 257 μmol/L = 15.1 mg/dL) in glucose-6-phosphate dehydrogenase (G6PD)-deficient neonates and normal controls, stratified for the three genotypes of the UGT1A1 promoter. *(Redrawn from Kaplan M, Renbaum P, Levy-Lahad E, et al. Gilbert syndrome and glucose-6-phosphate dehydrogenase deficiency: a dose-dependent genetic interaction crucial to neonatal hyperbilirubinemia. Proc Natl Acad Sci U S A 1997;94:12128-12132. predisposition to prolonged or severe neonatal hyperbilirubinemia,[247-249] and variably increased jaundice when the GS polymorphism occurs with pyloric stenosis[250,251] or is coinherited with hematologic abnormalities such as G6PD deficiency,[205,252] β-thalassemia,[252-255] or hereditary spherocytosis.[256] Thus, studies from several different parts of the world indicate that GS, as detected by *UGT1A1* analysis, does play some role in neonatal jaundice. Kaplan and colleagues[205] noted in their study that neither G6PD deficiency nor the GS type UDPGT1 promoter polymorphism (also known as UGT1A1*28) alone increased the incidence of hyperbilirubinemia but that both in combination did (Fig. 4-8). They speculated that this gene interaction may serve as a paradigm of the interaction of benign genetic polymorphisms in the causation of disease; that is, it may take two genetic abnormalities to produce disease symptoms.

Pathophysiology

GS consists of a heterogeneous group of disorders, all of which share at least a 50% decrease in hepatic BUGT activity.[257-260] Based on plasma clearance of other organic anions (BSP and ICG) that share the same hepatocyte uptake receptor-carrier, there appear to be at least four subtypes of GS.[261,262] In GS type I, clearance of BSP and ICG is normal. In GS type II, BSP clearance is delayed but ICG clearance is normal. Because BSP uptake is normal in type II, the delayed clearance must be related to subsequent intrahepatic metabolism or canalicular excretion.[263] In GS type III, clearance of both BSP and ICG is delayed. The delay in the initial rate of disappearance from plasma suggests a defect in uptake at the

hepatocyte plasma membrane.[263] Those with GS type IV have delayed uptake of ICG but not BSP. Thus, some individuals with GS have delayed uptake of bilirubin into the hepatocyte, others have delayed biotransformation, and others demonstrate both abnormalities.[53,264-266] Immunohistochemical staining for UDP-glucuronosyl-transferase shows a clear reduction throughout the hepatic lobule in specimens from individuals with GS when compared with normal individualss.[267]

Elucidation of the structure of the *UGT1* gene, which encodes human bilirubin, phenol, and other UDP-glucuronosyltransferase isozymes,[268,269] led to the discovery of *UGT1A1* mutations or polymorphisms associated with GS. In white populations, the homozygous finding of an additional TA repeat in the promoter region of the so-called TATA box (i.e., $[TA]_7 TAA$ rather than $[TA]_6 TAA$) of the *UGT1A1* gene has been shown to be a necessary, though not sufficient condition for GS.[270-272] Individuals who are heterozygous for seven TA repeats have significantly higher serum bilirubin levels than do those with the homozygous wild-type six repeats.[270] In Asian populations, the $(TA)_7 TAA$ mutation is relatively rare,[273] but several different *UGT1A1* mutations have been associated with GS.[241,274,275] These Asian mutations involve exon 1 of the *UGT1A1* gene rather than the TATA promoter region. One of the most common mutations in Asians, a Gly71Arg mutation in exon 1, has also linked GS and severe neonatal hyperbilirubinemia.[248] It has been reported that although the promoter TA repeat number and bilirubin level in whites have a strong positive correlation, in other ethnic groups (e.g., Africans, where two other variants, $[TA]_5$ and $[TA]_8$, have been identified) there is a negative correlation.[276] Rarely, the $(TA)_8$ variant has been reported in white individuals,[277] so the ethnic implications of these genetic polymorphisms of the *UGT1A1* gene require further analysis.

Although decreased hepatic BUGT activity is universal in GS, there is poor correlation between measured enzyme activity in the liver and the serum bilirubin level.[278] This may be explained by the increased bilirubin production associated with the decreased RBC half-life seen in as many as 40% of patients with GS.[240,266] Although early authors[258,260] concluded that there was little or no induction of BUGT after the administration of phenobarbital, more recent work has revealed that in fact, phenobarbital does increase UGT1A1 activity via a phenobarbital-responsive enhancer module (PBREM) of the *UGT1A1* promoter region[279] and that such polymorphisms could represent an additional risk factor for GS.[280]

Related to the decreased BUGT activity is the observation that duodenal bile from individuals with GS contains a decreased amount of bilirubin diglucuronides and an increased amount of bilirubin monoglucuronides in comparison to normal persons[50,53,260,281] (Fig. 4-9). This distribution is similar to that seen in infants.[282] Administration of phenobarbital has been shown to normalize the bile pigment profile in duodenal fluid,[53] lower plasma
FIGURE 4-9. Bile pigment composition in bile from normal ($n = 8$), Crigler-Najjar (CN) type I ($n = 3$), CN type II ($n = 3$), and Gilbert's syndrome ($n = 16$) patients receiving (+) or not receiving (–) phenobarbital. The relative bile pigment composition is indicated in the vertical columns as a percentage of the total $\pm$ SD. Shading: red, unconjugated bilirubin; blue, bilirubin monoconjugate; green, bilirubin diconjugate. (*Redrawn from Sinaasappel M, Jansen PL. The differential diagnosis of Crigler-Najjar disease, types 1 and 2, by bile pigment analysis. Gastroenterology 1991;100:783-789. bilirubin levels, and increase hepatic clearance of bilirubin.[283,284] Clofibrate and glutethimide also normalize serum bilirubin concentrations but do not normalize the duodenal bile pigment profile.[285] In animals, clofibrate is an inducer of BUGT but does not affect BSP uptake or GST.[286] An additional unexplained phenomenon in GS is the exaggerated rise in serum bilirubin associated with fasting.[287-290] Even though normal individuals can double their serum bilirubin level in response to fasting, in GS a more pronounced rise occurs. This increase is not related to decreased hepatic blood flow because ICG clearance is not affected.[288] Although fasting can reduce BUGT activity[290] and increase HO (the enzyme responsible for bilirubin production) activity,[291] neither of these effects are believed to explain the fasting hyperbilirubinemia of GS.[283,292] The enhanced enterohepatic circulation of bilirubin is suggested to be a major factor in the pathogenesis of fasting-induced hyperbilirubinemia.[293] Intraluminal noncalorie food bulk can blunt the bilirubin rise.[294]

Diagnosis and Treatment

Generally, a diagnosis of GS can be made when there is mild, fluctuating unconjugated hyperbilirubinemia, the results of the other liver function tests are normal, and there is no hemolysis. Hemolysis can add confusion because it can result in similar findings and is not unusual in GS. Hence, other tests are sometimes used to aid in diagnosis.

One test frequently used to aid in diagnosing GS involves the intravenous administration of nicotinic acid (niacin) with assessment of the subsequent rise in serum bilirubin concentration.[295] Nicotinic acid is usually

administered to adults in a dose of 50 mg[296-298] over a period of 30 seconds, although results were similar with 300-mg injections in one study.[299] Nonconjugated serum bilirubin is then measured every 30 to 60 minutes for the next 4 to 5 hours. Nicotinic acid produces a rise in serum unconjugated bilirubin in normal individuals and in those with GS. However, in GS the rise in bilirubin is higher and clearance is delayed longer than in normal people.[295,299-302] Nicotinic acid causes increased osmotic fragility and hemolysis of RBCs with sequestration in the spleen. Splenic HO is also induced, with rapid conversion of heme to bilirubin.[301] Nicotinic acid–induced hemolysis produces a rise in serum iron that is similar in healthy controls and those with GS.[302] Hence, the prolonged serum bilirubin levels are related to delayed hepatic clearance of bilirubin. Nicotinic acid infusion has been suggested to be a better method to diagnose GS than a 400-kcal fast because delayed bilirubin clearance was seen after the administration of nicotinic acid to GS subjects who otherwise had normal serum bilirubin levels.[296] The nicotinic acid test is not useful in differentiating GS from chronic liver disease because both groups showed positive tests.[303]

Rifampin, given to fasting or nonfasting adults in one oral dose of 900 mg, increases total serum bilirubin levels in normal individuals and those with GS, although there is an exaggerated rise in patients with GS (fasting: >1.9-mg/dL rise in bilirubin concentration 2 to 6 hours after rifampin; nonfasting: >1.5-mg/dL rise 4 to 6 hours after rifampin).[304] This exaggerated rise in serum bilirubin enabled differentiation of 10 normal individuals and 15 GS patients with high sensitivity and specificity. This finding could not be explained by hemolysis, although haptoglobin levels were significantly lower in GS patients, compatible with baseline hemolysis.

Another test suggested to aid in the diagnosis of GS involves fractionation of total serum bilirubin by alkaline methanolysis and thin-layer chromatography.[77,189] This test allows precise measurement of conjugated and unconjugated bilirubin levels. This approach has shown that in GS, approximately 6% of the total serum bilirubin is conjugated, as opposed to about 17% in normal persons and those with chronic hemolysis. Individuals with chronic persistent hepatitis had 28% of their total bilirubin present as conjugates. Fasting did not change the percentage of conjugates in GS despite the rise in total serum bilirubin concentration. An overlap of only three individuals was seen among the 77 with GS and 60 normal subjects.[189] Other studies support these findings.[305] In patients with GS, fractionation of total serum bilirubin by HPLC showed significantly decreased bilirubin monoglucuronides (1.1% versus 6.2% in normal individuals) and increased unconjugated bilirubin (98.8% versus 92.6% in normal individuals).[306]

Monaghan and associates[247] have suggested GS genetic screening for the *UGT1A1* TA repeat as a simple, useful additional test in the investigation of very prolonged neonatal jaundice in North American, African,

and European populations and for the Gly71Arg mutation in Asians. However, the value of such a genetic test cannot be fully determined until accurate data regarding the prevalence and penetrance of the GS genotype are known.[307] Thus, genetic testing for GS cannot be routinely recommended.[307]

GS has no significant negative implications regarding morbidity or mortality. In general, drug metabolism studies have revealed no major dangers,[305,308] although there appears to be an increased incidence of slow acetylators[309,310] and clearance of lorazepam is decreased 20% to 40%.[311] Concurrent genetic deficiencies in other xenobiotic pathways may put individuals with GS at increased risk for drug toxicity with compounds such as acetaminophen,[312,313] the cancer chemotherapeutic agents CPT-11 (irinotecan)[314] and TAS-103,[315] or the viral protease inhibitor indinavir.[219,316] For this reason, Bosma suggests that screening for GS is of clinical importance.[219] No specific treatment is necessary for GS, although phenobarbital has been shown to lower serum bilirubin levels in these patients.[317] If the well-documented antioxidant effect of bilirubin[318] provides a biologic advantage,[319] the mild hyperbilirubinemia of GS might actually be a significant benefit in patients with conditions such as vascular disease,[320,321] in which free radicals are involved in the pathogenesis. However, Bosma concluded that a selective advantage in GS because of the antioxidant capacity of bilirubin seems unlikely.[219]

Crigler-Najjar Syndrome Types I and II

In 1952, Crigler and Najjar described seven infants with congenital familial nonhemolytic jaundice in whom severe unconjugated hyperbilirubinemia developed shortly after birth, with death from kernicterus ensuing within months.[322] These infants were from three related families. The serum bilirubin concentration reached 25 to 35 mg/dL despite a lack of hemolytic disease. Other liver function test results were normal. Liver histology was normal except for the deposition of bile pigments. Subsequent reports documented that the main risk in patients with Crigler-Najjar syndrome (CN) is kernicterus.[1] An excellent review of the neurologic perspectives of CN has been published.[323] Although some patients survive into the second decade with normal development,[324] the possibility of kernicterus developing late is always a concern, even in adulthood.[325-328] Serum bilirubin levels vary from approximately 15 to 45 mg/dL.

In 1969, Arias and co-authors described a second, more frequent type of severe nonhemolytic hyperbilirubinemia.[329] The previous syndrome was termed Crigler-Najjar syndrome type I (CNI, OMIM 218800), whereas the new findings were termed Crigler-Najjar syndrome type II (CNII, OMIM 606785) or Arias' syndrome.[329] Hyperbilirubinemia is less severe in type II patients and varies from approximately 8 to 25 mg/dL. Hence, these individuals have a much lower incidence of kernicterus, but such damage does occur.[330,331]

Pathophysiology

Both CNI and CNII are generally inherited in an autosomal recessive manner, although one case of autosomal dominant inheritance of CNII has been reported.[332] CNI and CNII result from mutations in the *UGT* gene complex.[43] Patients with one normal allele demonstrate normal metabolism of bilirubin.[333] The genetic details determine the severity of clinical disease. In CNI there is complete absence of functional UGT1A1, whereas in CNII, UGT1A1 activity is markedly reduced.[334] In CNI, 18 of 23 mutations described in the *UGT1* gene are found in the common exons 2 to 5 (see Fig. 4-4) and thus affect many UGT1 enzymes.[43,335] Intronic mutations causing CNI have also been reported.[336] However, in CNII, four of nine known mutations are found in exon 1A1. There is some overlap in classification of mild CNII and GS (e.g., Gly71Arg) that relates to differences in definitions based on serum bilirubin levels.[43] The TATA box $(TA)_7$ repeat mutation found in GS can be seen along with other mutations resulting in either CNI or CNII.[337] In both CNI and CNII, assays of liver tissue from affected patients demonstrate negligible or very low BUGT activity.[50,51,260,326,329,338,339] Therefore, patients with these disorders experience a profound block in bilirubin excretion because they lack the ability to conjugate bilirubin with UDPGA. Thus, liver biopsy is not helpful in differentiating CNI and CNII. Study of resected livers from four patients with CNI after liver transplantation showed that there was heterogeneous glucuronidation of various substrates other than bilirubin.[340] Hence, several of the family of glucuronosyltransferase isoenzymes can be affected in the same patient. There is considerable overlap of hepatic BUGT activity between CNII and GS[260] (see Table 4-2).

In family studies of CNI patients,[341,342] partial deficiencies in the glucuronidation of salicylate and menthol have been found in siblings, parents, and grandparents. As a result, it has generally been accepted that this condition is inherited in an autosomal recessive manner.[341] In family studies of CNII patients, the original report by Arias and colleagues found abnormalities in glucuronidation (menthol) in only one parent, thus suggesting autosomal dominant inheritance. Subsequent studies of siblings or parents often found elevated serum bilirubin levels (1.2 to 4 mg/dL), delayed bilirubin clearance, and decreased hepatic BUGT activity, as would be seen in GS.[284,326,329,331,343,344] These findings in both parents[284,343] suggested that CNII may represent homozygous GS. However, if CNII were truly the homozygous form of GS, one would expect many more affected individuals because GS occurs in at least 3% of the population. Pertinent genetic data have been reviewed[337] and support the inheritance mode of CNII as autosomal recessive.

The major differentiating characteristic between CNI and CNII is the response to drugs that stimulate hyperplasia of the ER. When CNII patients received phenobarbital or diphenylhydantoin, there was a significant decline in the serum bilirubin level, increased hepatic clearance of radiolabeled bilirubin,[284,329,330,345-348] and increased biliary levels of bilirubin diglucuronides[50,331] (see Fig. 4-9). In a study of five CNII patients, the magnitude of the phenobarbital-induced decrease in serum bilirubin ranged from 2.1 to 12.1 mg/dL (27% to 72%), with prephenobarbital and postphenobarbital serum bilirubin levels ranging from 7.8 to 16.9 and 4.7 to 10.1 mg/dL, respectively.[50] Data from seven earlier studies[284,329,330,345-348] regarding the response of CNII patients to oral phenobarbital revealed that 11 females and 13 males had a total serum bilirubin level of 15.7 ± 13.8 mg/dL (mean ± SD) before the administration of phenobarbital. After doses ranging from 90 to 390 mg/day or, alternatively, 4 mg/kg/day, serum bilirubin decreased 12.0 ± 4.0 mg/dL (77% ± 13%). The lowest total serum bilirubin after phenobarbital therapy was 5.9 mg/dL. In contrast, CNI patients show neither a decrease in serum bilirubin nor significantly increased biliary bilirubin conjugates in response to drugs[50,325] (see Fig. 4-9). The response to phenobarbital is the criterion used to differentiate between these two disorders.[349] Bile analysis has also been suggested as another method to differentiate CNI and CNII.[50] In CNI, bile contains insignificant bilirubin conjugates (<10%), and unconjugated bilirubin predominates. In CNII, bile contains small amounts of bilirubin conjugates, and those present are predominantly bilirubin monoglucuronides (>60%).[260]

Two cousins with CN have been described with unique features that raise the possibility of a new variant of this syndrome (type III).[350] This new variant resembled CNI in that there was no biliary excretion of bilirubin diglucuronide or monoglucuronide. However, the type III patients did excrete monoglucoside and diglucoside conjugates of bilirubin. It has been speculated that type III patients lack the long proposed permease[41] that has been hypothesized to transport UDPGA to the luminal side of the ER where glucuronosyltransferase is located. This absence is suggested to force utilization of a very inefficient substrate for conjugation to bilirubin, UDPG.

Diagnosis and Treatment

Although CN can be diagnosed during the prenatal period,[351,352] evaluation of infants with CN more typically begins during the first days of life when serum bilirubin levels exceed 20 mg/dL. The conjugated fraction will not be elevated except possibly for the factitious elevation sometimes seen when the total serum bilirubin level is very high.[110] Evaluation of such infants will eliminate hemolysis, hypothyroidism, infection, and other more common causes of jaundice. Formula feedings will help identify infants with jaundice related to human milk. During this period of testing, the magnitude of the elevation in serum bilirubin will prompt the use of phototherapy to avoid kernicterus.[130] Exchange transfusion may be necessary. Yet despite these efforts, CN patients

will have persistent jaundice. There is currently no widely available, simple clinical test to confirm a diagnosis of CN. CN can be excluded by finding significant amounts of bilirubin conjugates in neonatal stool if collected before the establishment of sufficient intestinal bacteria to convert bilirubin conjugates to urobilinoids.[1] HPLC analysis of duodenal bile will show that in CNI there are negligible bilirubin diglucuronides or monoglucuronides whereas in CNII these conjugates are present but in low concentration.[43,50] An easy method to collect such fluid for analysis involves use of the pediatric Enterotest capsule.[281] This approach to diagnosis is much less invasive than performing a liver biopsy to confirm negligible BUGT activity in an in vitro assay. The ratio of serum bilirubin conjugates (as determined by alkaline methanolysis with thin-layer chromatography) to total bilirubin, though abnormally low, does not allow differentiation of CN patients from those with GS.[189] Similar overlap occurs with HPLC fractionation of serum bilirubin conjugates.[306] DNA analysis can be very helpful in establishing the correct diagnosis,[353] and in the future it is expected that DNA array technology will allow rapid screening for known mutations.

A world registry of patients with CNI aimed at developing management guidelines has been published.[354] Phenobarbital (4 mg/kg/day in infants) should be used when there is concern about deficiency of BUGT. Within 48 hours, CNII patients can demonstrate a significant decrease in serum bilirubin levels (as detailed earlier) and increased biliary excretion of bilirubin diglucuronide and monoglucuronide,[51,331] whereas CNI patients will show no significant response. Occasionally, CNII patients do not respond to the first trial of phenobarbital therapy, but subsequent trials months later will demonstrate a significant decrease in serum bilirubin levels.[349] However, despite the decrease in serum bilirubin in response to phenobarbital, CNII patients will usually continue to manifest significant hyperbilirubinemia (approximately 5 to 15 mg/dL). Phototherapy for 6 to 12 hours daily has been the primary modality to keep serum bilirubin levels below 20 mg/dL during the first several months of life[355] because CNI patients can excrete all bilirubin photoisomers.[356] CNI patients will require lifelong treatment with phototherapy until more definitive therapy such as liver transplantation is available. Phototherapy has been found to be least intrusive when given at night, and improvements have been made in effectiveness and comfort.[357,358] Although phototherapy is very helpful in infancy, in adolescence, social inconvenience and compliance problems can increase the risk for kernicterus.[354]

Other therapeutic considerations involve the oral administration of binding agents such as agar, cholestyramine, or calcium phosphate.[359-362] These agents bind to bilirubin in the intestinal lumen as a result of phototherapy or through direct intestinal permeation.[363] They prevent the enterohepatic circulation of bilirubin. Problems associated with the use of cholestyramine include cost, taste, and concern about bile salt depletion and fat

malabsorption. Problems regarding agar include significant variation in bilirubin binding affinity among various preparations and batches.[326,359,364] During acute episodes of severe hyperbilirubinemia after the first year of life, plasmapheresis has been shown to rapidly decrease serum bilirubin levels.[326,365] Peritoneal dialysis and exchange transfusion have not been helpful in this setting.[325] Repeated intramuscular injections of tin-protoporphyrin, an HO inhibitor that blocks bilirubin formation, have been used in one CNI patient, with data suggesting a decreased need for phototherapy.[366] Two patients with CNI were treated with tin-mesoporphyrin to block bilirubin formation and also underwent daily phototherapy and intermittent plasmapheresis over a 400-day period.[367] Iron deficiency anemia believed to be due to the porphyrin therapy developed in these patients,[368] but tin-mesoporphyrin (stannsoporfin) (6 μmol/kg or 4.5 mg/kg)[369] is suggested to be a promising, though still experimental additional therapy for controlling episodes of acute, severe jaundice.[370] Drugs that bind to albumin and can potentially displace bilirubin should be avoided at all times.[371]

Because patients with CN have good hepatic function other than conjugating bilirubin, they are ideal candidates for auxiliary liver transplantation. This option has recently become clinically available.[372-374] More commonly, orthotopic liver transplantation has been performed,[375-382] and this represents the only true cure for the hyperbilirubinemia of CNI. Ideally, transplantation would be timed so that it precedes irreversible neurologic injury.[383,384] Transplantation of other BUGT-containing tissues (e.g., segments of the small intestine,[385,386] kidneys,[387] or hepatocytes[388]) remains experimental. Successful cloning of the gene responsible for bilirubin glucuronosyltransferase activity offers the hope of future gene therapy to correct this deficiency based on studies in Gunn rats, the congenitally jaundiced model for CNI.[383,389-391]

Disorders of Enterohepatic Circulation

Increased enterohepatic circulation of bilirubin is believed to be an important factor in neonatal jaundice. As previously reviewed, neonates are at risk for intestinal absorption of bilirubin because (1) their bile contains increased levels of bilirubin monoglucuronide, which allows easier conversion to bilirubin; (2) they have significant amounts of β-glucuronidase within the intestinal lumen that hydrolyzes bilirubin conjugates to bilirubin, which is then more easily absorbed from the intestine; (3) they lack the intestinal flora to convert bilirubin conjugates to urobilinoids; and (4) meconium, the intestinal contents accumulated during gestation, contains significant amounts of bilirubin.[392] Conditions that prolong passage of meconium (e.g., Hirschsprung's disease, meconium ileus, meconium plug syndrome) are associated with hyperbilirubinemia.[393,394] Earlier passage of meconium has been shown to be associated with lower serum bilirubin levels.[395,396] This may be facilitated by rectal temperature

measurement during the neonatal period.[397] The enterohepatic circulation of bilirubin can be blocked by the enteral administration of compounds that bind bilirubin, such as agar,[89,359,364,398] charcoal,[399] and cholestyramine.[360]

Other Causes of Unconjugated Hyperbilirubinemia

Various hormones may cause the development of neonatal unconjugated hyperbilirubinemia. Congenital hypothyroidism can be accompanied by serum bilirubin levels higher than 12 mg/dL before the development of other clinical findings.[400] Prolonged jaundice is seen in a third of infants with congenital hypothyroidism.[401] Similarly, hypopituitarism and anencephaly may be associated with jaundice as a result of inadequate thyroxine, which is necessary for hepatic clearance of bilirubin.

Certain drugs may affect the metabolism of bilirubin and result in hyperbilirubinemia or displacement of bilirubin from albumin. Such displacement increases the risk for kernicterus and can be caused by sulfonamides,[402] moxalactam,[403] and ceftriaxone[404] (independent of its sludge-producing effect[405]). The popular Chinese herb Chuen-Lin, given to 28% to 51% of Chinese newborn infants, has been shown to have a significant effect in displacing bilirubin from albumin.[406] Pancuronium bromide[168] and chloral hydrate[407] have been suggested as causes of neonatal hyperbilirubinemia.

Infants of diabetic mothers have higher peak bilirubin levels and a greater frequency of hyperbilirubinemia than normal neonates do.[408] These patients have shown a positive correlation between total bilirubin and hematocrit, thus implicating polycythemia as a possible mechanism.[408] Other potential causes of this hyperbilirubinemia include prematurity, deficiency of substrate for glucuronidation (secondary to hypoglycemia), and poor hepatic perfusion (secondary to either respiratory distress, persistent fetal circulation, or cardiomyopathy).

The Lucey-Driscoll syndrome[409] consists of neonatal hyperbilirubinemia within families in whom there is in vitro inhibition of glucuronosyltransferase by both maternal and infant serum. It is presumed to be caused by gestational hormones.

Prematurity is frequently associated with unconjugated hyperbilirubinemia in the neonatal period. Hepatic UDP-glucuronosyltransferase activity is markedly decreased in premature infants and rises steadily from 30 weeks' gestation until reaching adult levels 14 weeks after birth.[410] In addition, there may be deficiencies in both uptake[411] and secretion.[412] Bilirubin clearance improves rapidly after birth.[413]

Hepatic hypoperfusion can result in neonatal jaundice. Inadequate perfusion of the hepatic sinusoids may not allow sufficient hepatocyte uptake and metabolism of bilirubin. Causes might include patent ductus venosus,[414] congestive heart failure, and portal vein thrombosis.

| Box 4-1 | **Causes of Neonatal Hyperbilirubinemia** |

INCREASED PRODUCTION OF BILIRUBIN

Fetal-maternal blood group incompatibilities
Extravascular blood in body tissues
Polycythemia
Red blood cell abnormalities (hemoglobinopathies, membrane and enzyme defects)
Induction of labor

DECREASED EXCRETION OF BILIRUBIN

Increased enterohepatic circulation of bilirubin
Breast-feeding
Inborn errors of metabolism
Hormones and drugs
Prematurity
Hepatic hypoperfusion
Cholestatic syndromes
Obstruction of the biliary tree

COMBINED INCREASED PRODUCTION AND DECREASED EXCRETION OF BILIRUBIN

Sepsis
Intrauterine infection
Congenital cirrhosis

Other specific liver diseases, as listed in Box 4-1 and described elsewhere in this text, can result in neonatal jaundice.

MANAGEMENT AND TREATMENT OF UNCONJUGATED HYPERBILIRUBINEMIA

Phototherapy

In recent years, changes in perinatal care have made severe neonatal jaundice a larger problem, and there has been a re-emergence of kernicterus.[415-417] Possible reasons[417,418] include (1) early hospital discharge (before the extent of jaundice is known and signs of impending brain damage have appeared)[419]; (2) lack of adequate concern for the risks associated with severe jaundice in healthy term and near-term newborns[416]; (3) an increase in the incidence of breast-feeding[173]; (4) medical care cost constraints; (5) a paucity of educational materials to enable parents to participate in safeguarding their newborns; (6) limitations within health care systems in monitoring the outpatient progression of jaundice[420]; (7) difficulty estimating the degree of jaundice, particularly in dark-skinned infants[421]; and (8) demonstration of bilirubin being an antioxidant.[20] There are case reports of newborn infants who, following early hospital dis-

charge, develop severe hyperbilirubinemia (30-40 mg/dL) at home and present with classic signs of kernicterus.[1,125,416,422-425] This has been reported in otherwise healthy breast-fed infants with no other identified cause of their jaundice.[426-428] Although early postpartum discharge has advantages, one disadvantage is the risk associated with the delayed diagnosis of severe hyperbilirubinemia. The American Academy of Pediatrics has recommended that infants discharged at younger than 48 hours of age be seen in follow-up within 48 hours of discharge.[429] Many physicians do not follow these recommendations[125,430] despite the serious impact that a short hospital stay has on a jaundiced newborn.[431] The Academy updated its 1994 guideline[432] for the management of hyperbilirubinemia in newborn infants in 2004.[125]

Jaundice can be caused by increased bilirubin production, decreased bilirubin excretion, or a combination of these mechanisms (see Box 4-1 for specific examples). An approach to the management of jaundice in the newborn nursery has been published elsewhere.[125] Although Newman and associates found that obtaining a direct bilirubin measurement was seldom helpful because of low yield and poor specificity,[433] others advocate early measurement of conjugated bilirubin as a population screening test that could lead to earlier diagnosis of neonatal liver disease.[434] Bhutani and colleagues advocated universal bilirubin measurement before hospital discharge to identify infants at risk for severe neonatal hyperbilirubinemia on the basis of a predischarge hour-specific total serum bilirubin measurement[435,436] (Fig. 4-10). Such universal predischarge screening is now recommended by the American Academy of Pediatrics[125] and has been shown in a recent study to reduce the incidence of significant hyperbilirubinemia and the rate of hospital readmission of infants for the treatment of jaundice.[437] Despite the large number of causes of neonatal jaundice, no cause of jaundice could be identified in nearly half of the infants evaluated during one study of 447 infants[101] and in a third of the infants in a kernicterus registry.[428]

Hyperbilirubinemia is the most frequent reason that infants are readmitted to the hospital in the first weeks of life.[419,438,439] Management of neonatal jaundice has been reviewed elsewhere[125] (Figs. 4-11 and 4-12). The most important step in treatment of jaundice is determination of the primary cause. However, independent of the cause of the jaundice, elevation of the serum unconjugated bilirubin fraction prompts concern about possible kernicterus. As previously reviewed,[136,145] when the unconjugated bilirubin fraction is elevated, care must be taken to avoid the administration of agents that bind to albumin and displace bilirubin, thereby promoting kernicterus. Although sulfonamides are historically the most well known bilirubin-displacing agents, drugs such as ceftriaxone and ibuprofen are also strong bilirubin displacers with a potential for inducing bilirubin encephalopathy.[404,440] Therapeutic options to lower unconjugated bilirubin levels include phototherapy, exchange transfusion, interruption of the enterohepatic circulation, enzyme induction, and alteration of breast-feeding. Research into these and other modalities continues actively. The outcome of rational therapeutic guidelines for unconjugated hyperbilirubinemia during the first 7 days of life has been published elsewhere.[441]

Phototherapy consists of irradiation of the jaundiced infant with light and has been reviewed.[442,443] Photon energy derived from light changes the structure of the bilirubin molecule in two ways (Fig. 4-13) that allow bilirubin to be excreted into bile or urine without the usual requirement for hepatic glucuronidation. One change involves a 180-degree rotation around the double bonds between either the A and B or the C and D rings[444] to convert the normal Z configuration to the E configuration. 4Z,15E-bilirubin is formed preferentially and can spontaneously reisomerize to native bilirubin. FIGURE 4-11. Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation. These guidelines are based on limited evidence and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy, which should be used when total serum bilirubin (TSB) exceeds the line indicated for each category. "Intensive phototherapy" implies irradiance in the blue-green spectrum (wavelengths of approximately 430 to 490 nm) of at least 30 μW/cm^2/nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's surface area as possible. If TSB does not decrease or continues to rise in an infant who is undergoing intensive phototherapy, the presence of hemolysis is strongly suggested. In infants who receive phototherapy and have an elevated direct-reacting or conjugated bilirubin levels (cholestatic jaundice), the bronze-baby syndrome may develop. Total bilirubin should be used without subtracting direct-reacting or conjugated bilirubin. Risk factors include isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin less than 3.0 g/dL. For well infants 35 to 37^6/$_7$ weeks, TSB levels can be adjusted for intervention around the medium-risk line. It is an option to intervene at lower TSB levels for infants closer to 35 weeks and at higher TSB levels for those closer to 37^6/$_7$ weeks. It is also an option to provide conventional phototherapy in the hospital or at home with TSB levels of 2 to 3 mg/dL (35 to 50 μmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors. *(Reproduced with permission from Pediatrics 2004;114:297-316; Copyright © 2004 by the American Academy of Pediatrics.)*

importantly, a new seven-membered ring structure can be formed between rings A and B and result in "lumirubin"[445] or "cyclobilirubin"[446] via the 4E,15Z-isomer intermediate.[447] This isomerization interferes with the internal hydrogen bonding of native bilirubin and, by exposing the propionic acid groups, results in a more polar compound. Thus, the lumirubin and E-isomers can be excreted directly into bile. Lumirubin appears to be the major route by which bilirubin is eliminated via phototherapy.[448,449] The choice of light for phototherapy is a subject about which there are much conflicting data.[442] Special Blue light (or Super Blue, but not regular blue) appears to be better than white or green light, although white is less disturbing to nursery personnel.[450] New phototherapy devices using woven fiberoptic pads are currently available,[451] are effective (comparable to conventional phototherapy) and safe, eliminate the need for eye patches, and permit greater time for maternal-infant bonding.[452-454] Proposed guidelines for phototherapy have been published elsewhere.[455-457] In general, phototherapy is used to prevent serum bilirubin concentrations from reaching levels necessitating exchange transfusion (see

Fig. 4-12). Phototherapy is now frequently performed at home,[458,459] a practice accepted and recommended by the American Academy of Pediatrics.[125] Despite documented complications,[460-462] phototherapy is widely used and generally safe.[463] Although phototherapy does affect cardiac output and blood flow to other organs (e.g., increased cerebral blood flow) and may be associated with opening of the ductus arteriosus, these effects are not generally problematic.[464,465] In extremely premature infants (<800-g birth weight), prolonged phototherapy and low peak serum bilirubin levels (<9.4 mg/dL) were shown in one study to be independently associated with blindness.[466] This could possibly be related to the direct effects of light on the unshielded immature eye or decreased antioxidant protection by low serum bilirubin levels. Phototherapy should not be used without previous diagnostic evaluation of the cause of the jaundice. The shielding of phototherapy units should never be removed because of the ultraviolet radiation hazards that can result.[467] Although it has been recommended that infant position be changed every 6 hours during phototherapy,[468] data from one study showed that position change
FIGURE 4-12. Guidelines for exchange transfusion in infants 35 or more weeks' gestation. These suggested levels are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if total serum bilirubin (TSB) rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, TSB measurement should be repeated every 2 to 3 hours and exchange transfusion considered if TSB remains above the levels indicated after intensive phototherapy for 6 hours. The *dashed lines* for the first 24 hours indicate uncertainty because of a wide range of clinical circumstances and a range of responses to phototherapy. Immediate exchange transfusion is recommended if the infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if TSB is 5 mg/dL (85 μmol/L) or greater above these lines. Risk factors include isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase deficiency, asphyxia, significant lethargy, temperature instability, sepsis, and acidosis. Total bilirubin should be used without subtracting direct-reacting or conjugated bilirubin. If the infant is well and 35 to 37⁶/₇ weeks (median risk), TSB levels can be individualized for exchange based on actual gestational age. *(Reproduced with permission from Pediatrics 2004;114:297-316; Copyright © 2004 by the American Academy of Pediatrics.)*

made no difference in serum bilirubin levels.[469] One study of 264 neonates (some with hemolytic jaundice) who completed an average of 121 hours of phototherapy indicated that significant rebound hyperbilirubinemia did not occur.[470] Similarly, no significant rebound hyperbilirubinemia occurred in 163 healthy full-term infants with nonhemolytic jaundice (including breast-feeding and formula and mixed feeding) who underwent an average of 54 to 65 hours of phototherapy.[471] In term, healthy newborns, phototherapy may be stopped when the serum bilirubin level falls below 14 to 15 mg/dL, and hospital discharge need not be delayed to observe for rebound.[432]

Exchange Transfusion

Exchange transfusion is the most rapid method to acutely lower the serum bilirubin concentration. Indications for exchange transfusion vary, have been published elsewhere,[125,456,460,472,473] and can be related to either anemia or elevated serum bilirubin levels. The American Academy of Pediatrics has published guidelines that represent the most widely accepted indications for initiation of exchange transfusion based on risk factors, including the hour-specific total bilirubin level, response to intensive phototherapy, serum bilirubin-to-albumin ratio, and the presence of hemolytic disease, sepsis, acidosis, or other acute conditions (see Fig. 4-12). Additionally, exchange transfusion should be initiated if the infant displays signs of acute bilirubin encephalopathy (see the section "Kernicterus"). In neonatal hemolytic disease, suggested indications for transfusion include (1) anemia (hematocrit <45%), positive direct Coombs test, and bilirubin greater than 4 mg/dL in cord blood; (2) postnatal rise in serum bilirubin concentration that exceeds 1 mg/dL/hr for more than 6 hours; (3) progressive anemia and rate of increase in serum bilirubin greater than 0.5 mg/dL/hr; and (4) continuing progression of anemia despite control of hyperbilirubinemia. Sometimes, exchange transfusion for hemolytic disease can be avoided through the use of high-dose intravenous immunoglobulin therapy.[474] Suggested indications for exchange transfusion because of hyperbilirubinemia alone include (1) bilirubin concentration higher than 15 mg/dL for more than 48 hours, (2) salicylate saturation index higher than 8.0 or 2(4′-hydroxyazobenzene) benzoic acid (HABA) binding less than 50% on two successive determinations 4 hours apart, (3) ratio of total serum bilirubin (mg/dL) to total serum protein (g/dL) greater than 3.7, and (4) molar concentration ratio of serum bilirubin to serum albumin of greater than 0.7.[460]
FIGURE 4-13. Products of phototherapy. Light induces isomerization of 4Z,15Z-bilirubin (1) to produce the configurational isomers 4E,15Z-bilirubin (4), 4Z,15E-bilirubin (5), and 4E,15E-bilirubin (6) and the structural isomers Z-lumirubin (2) and E-lumirubin (3) as shown. Isomerization exposes one or both of the propionic acid side chains, which increases the polarities of the isomers with respect to biosynthetic bilirubin (1) and allows excretion in bile without hepatic glucuronidation. The formation of 4E,15Z-bilirubin, 4Z,15E-bilirubin, and 4E,15E-bilirubin is reversible, and these isomers spontaneously revert to the parent 4Z,15Z-bilirubin (1) isomer after excretion in bile. The predominant isomer present in the circulation of infants exposed to light or phototherapy is 4Z,15E-bilirubin (5). Although the structural isomers (2 and 3) are formed more slowly than the configurational isomers, they may contribute more to the overall effect of the treatment because of their relatively faster excretion. *(Redrawn from McDonagh A. Phototherapy: From ancient Egypt to the new millennium. J Perinatol 2001:21:S7-S12. Although there are many well-described risks with exchange transfusion, mortality should be low (<0.6%) if it is performed properly.[413,475,476]

Pharmacotherapy

A number of pharmacologic approaches to the prevention and treatment of neonatal hyperbilirubinemia have been reviewed.[477] The enterohepatic circulation can be interrupted by the enteral administration of agents that bind bilirubin in the intestine and prevent reabsorption. Such agents include agar,[89,359,364] cholestyramine,[360] activated charcoal,[399] and calcium phosphate.[362,478,479] Increased intestinal peristalsis would be expected to allow less time for bilirubin absorption. Frequent feedings[480] and rectal stimulation[397] are associated with lower serum bilirubin levels. Enteral feeding of bilirubin oxidase, an enzyme that degrades bilirubin to biliverdin, dipyrrols, and other unidentified products,[481] is an additional method to block the enterohepatic circulation but remains experimental at

present.[482] Another experimental approach involves the use of intravenous bilirubin oxidase.[483,484]

Because neonatal hepatic BUGT activity has been shown to be low in neonates,[410] it is not surprising that induction of hepatic BUGT results in lower serum bilirubin levels. Such induction in neonates can be accomplished with the prenatal maternal use of phenobarbital or diphenylhydantoin.[485,486] Even very low–birth weight infants (<2000 g) have been shown to respond to in utero phenobarbital therapy with significantly increased serum levels of conjugated bilirubin and decreased need for phototherapy.[487] In the postnatal period, use of phenobarbital by the neonate has the same bilirubin-lowering effect.[488] Clofibrate is advocated by French workers as a simple, nontoxic pharmacologic treatment that induces BUGT and is being used increasingly in France to prevent and treat neonatal jaundice.[489] An alternative approach to treat neonatal hyperbilirubinemia is to block the first enzyme responsible for the production of bilirubin, HO. This can be accomplished by several different metalloporphyrins.[490,491] Sn-protoporphyrin has been used successfully in the experimental management of jaundice in neonates with ABO incompatibility.[492] Treatment of neonatal jaundice by inhibition of HO remains experimental at this time, although clinical trials appear promising. Two studies showed that phototherapy could be abolished by using tin-mesoporphyrin.[493,494] In addition to inhibiting bilirubin production, metalloporphyrins are photosensitizers that can accelerate the destruction of bilirubin by light but also cause other unwanted side effects.[495] Because CO is now suggested to be a significant neurotransmitter, blocking HO activity early in life may not be a completely benign process. Thus, a major concern about metalloporphyrins is the lack of detailed long-term follow-up studies addressing safety issues.[496] At the present time, phototherapy and exchange transfusion remain the primary modalities to control neonatal unconjugated hyperbilirubinemia, and pharmacologic interventions remain largely adjunctive or experimental.

Feeding Strategies

Optimization of breast-feeding in the perinatal period is important.[497] If the bilirubin level is rising, published recommendations support encouraging mothers to breast-feed more frequently,[432,498,499] with an average suggested interval between feeding of 2 hours and no feeding supplements[500] or at least 8 to 10 feedings per 24 hours.[432] A strong dose-response relationship has been shown between feeding frequency and decreased incidence of hyperbilirubinemia.[501] More frequent nursing may not increase intake but has been suggested to increase peristalsis and stool frequency, thus promoting excretion of bilirubin.[456] The frequency of breast-feeding during the first 24 hours of life has been shown to be significantly correlated with the frequency of meconium passage.[501] The serum bilirubin level at which breast-feeding should be discontinued is controversial, and recommendations

include 14,[502] 15,[179] 16 to 17,[499] and 18 to 20 mg/dL.[500] When breast-feeding is interrupted, formula feeding may be initiated for 24 to 48 hours, or breast-feeding and formula feeding can be alternated with each feeding.[432] No studies have addressed the cost-effectiveness of various formulas in their jaundice-lowering effects, although two independent studies have shown that infants exclusively fed Nutramigen (a casein hydrolysate formula, Mead Johnson) have lower jaundice levels than do infants fed routine formula.[503,504] Supplementing breast-fed infants with small volumes of specific nutritional ingredients has been shown to result in increased fecal bilirubin excretion and lower transcutaneous bilirubin levels,[100] but no commercial preparations of these ingredients are currently available. Feeding heated expressed breast milk is also said to reduce serum bilirubin levels.[500] A fall in the serum bilirubin level of 2 to 5 mg/dL[456] is consistent with a diagnosis of breast milk jaundice. Breast-feeding may then be resumed with the acknowledgment that serum bilirubin levels may rise for several days but will gradually level off and decline.[179,498] If breast-feeding is to be resumed after the interruption, it is important to preserve lactation with the use of a breast pump. In one study, interruption of breast-feeding for approximately 50 hours (during which time formula was given) was shown to have the same bilirubin-lowering effect as a similar duration of phototherapy.[505] Interruption of breast-feeding for 24 to 48 hours has been shown to be successful in lowering serum bilirubin levels and avoiding the need for phototherapy in 81 of 87 jaundiced infants.[502] Formula feedings in Asian neonates undergoing phototherapy resulted in a greater decrease in serum bilirubin levels than in infants who were exclusively breast-fed.[471] Careful counseling and support can prevent the interruption in breast-feeding from becoming a permanent discontinuance of nursing.[502]

DISORDERS OF CONJUGATED HYPERBILIRUBINEMIA

Rotor's Syndrome

Rotor's syndrome (RS, OMIM 237450), first described in 1948, is a familial disorder that involves chronic elevation of both the conjugated and unconjugated serum bilirubin fractions.[506,507] Half or more of the total serum bilirubin is conjugated, and total bilirubin levels usually range from 2 to 7 mg/dL but may occasionally reach 20 mg/dL.[508] Liver functions test results are otherwise normal, and there is no evidence of hemolysis. Liver histology is normal when examined with both light and electron microscopy. Oral cholecystograms reveal normal gallbladder opacification. This disorder can occur in early childhood[509] or possibly the first months of life if coinherited with G6PD deficiency or heterozygous β-thalassemia[510] and has no gender predisposition. Family studies suggest an autosomal recessive mode of inheritance.[506,507,511]

Pathophysiology

The primary abnormality in RS is listed in the OMIM as unknown but appears to be a deficiency in the intracellular storage capacity of the liver for binding anions,[512,513] which can be demonstrated by constant infusion of BSP and ICG.[514] Patients with RS demonstrate delayed plasma clearance of both BSP and ICG, and heterozygotes show delayed BSP clearance with values intermediate between normal individuals and those with homozygous RS.[512] GST serves as an intracellular carrier protein for certain organic molecules and acts as an intracellular equivalent to albumin in blood plasma.[515] A patient with RS has been shown to have a deficiency of hepatic GST,[516] and this would be consistent with observations regarding the pathogenesis of this disorder. Deficiency of GST would result in impaired uptake of bilirubin within the cytosol. In addition, because bilirubin conjugates are bound to GST while awaiting excretion from the hepatocyte via the canalicular membrane,[517] deficient intracellular storage would result in leakage of bilirubin conjugates back into the circulation. Serum elevations of both conjugated and nonconjugated bilirubin result.

Another important observation in RS relates to the urinary excretion of coproporphyrin. In normal healthy individuals, only the I and III isomers of coproporphyrin are excreted in urine. In RS there is a marked increase in urinary coproporphyrin excretion, and usually, less than 80% of the total (I + III) is isomer I. Heterozygotes demonstrate urinary coproporphyrin values that are intermediate between those of normal individuals and homozygotes.[518] Urinary excretion of coproporphyrin is believed to be increased because biliary excretion is impaired, similar to findings in other liver diseases.[519]

Diagnosis and Treatment

A diagnosis of RS should be considered in all individuals with elevation of both conjugated and nonconjugated serum bilirubin fractions, along with otherwise normal liver function test results. The diagnosis can be confirmed by the presence of urinary coproporphyrin levels that are 2.5 to 5 times higher than normal.[518] Of the total urinary coproporphyrin isomers I plus III, isomer I constitutes less than 80% of the total in RS.[520] 99mTc-labeled hepatobiliary iminodiacetic acid (HIDA) cholescintigraphy has also been shown to be useful in diagnosing RS but provides poor to no visualization of the liver.[521,522] Patients with RS require no specific therapy and are asymptomatic. Although jaundice is a lifelong finding, it is associated with no morbidity or mortality.

Dubin-Johnson Syndrome

Dubin-Johnson syndrome (DJS, OMIM 237500), first described in 1954,[523] involves elevation of both the conjugated and unconjugated serum bilirubin fractions.[524] More than half of the total serum bilirubin is conjugated

and total bilirubin levels usually range from 1.5 to 6 mg/dL, although levels as high as 25 mg/dL have been reported during intercurrent illness.[525] It is not unusual for patients with DJS to report vague abdominal complaints, but this is not believed to reflect serious pathology. Even though hepatomegaly is sometime seen, liver functions test results are otherwise normal, including bile acids,[526] and there is no evidence of hemolysis.[523,524,527] Although this syndrome occurs in both sexes, males predominate and are affected at an earlier age. DJS occurs in all races, but Iranian Jews have an increased incidence.[528,529] It is usually diagnosed after puberty, although cases have also been reported in neonates,[530] at which time cholestasis can be significant.[531-535] DJS is inherited as an autosomal recessive trait with heterozygotes manifesting normal serum bilirubin levels.[528,536,537] This syndrome is far more common than RS, and the jaundice can be worsened by pregnancy and oral contraceptives.[538] Frequently, the gallbladder is not visualized in patients with DJS when undergoing oral cholecystography.[524]

A striking characteristic of DJS is brown to black discoloration of the liver. There is still debate about the identity of this pigment, which is located in lysosomes.[539] Though originally thought to be lipofuscin, more recent data provide conflicting evidence for a relationship to melanin,[540-542] polymerized epinephrine, or other metabolites[543,544] that accumulate in lysosomes. It is hypothesized that these pigments accumulate in the liver because of impaired secretion of various metabolites from the hepatocyte into bile.[544] This pigment disappears from the liver during acute viral hepatitis, with subsequent reappearance.[545] Other than this striking pigmentation, the liver is histologically normal. Recently, a black liver was reported in an individual who did not have DJS.[546]

Pathophysiology

The primary defect in DJS is deficient hepatic excretion of non–bile salt organic anions at the apical canalicular membrane by the ABC transport system known variously as cMOAT, MRP2, or ABCC2 (OMIM 601107).[547,548] cMOAT is encoded by a single-copy gene located on chromosome 10q24.[549] Mutations in this gene have been shown to produce a highly defective cMOAT that is associated with DJS.[62,547,548,550-553] Similar findings made in the homologous cMOAT gene of two rat models of hyperbilirubinemia (TR– and Eisai) have been very helpful in understanding DJS in humans.[62]

Although hepatic BSP clearance tests are no longer performed, they nicely demonstrate the effect of deficient transport via the canalicular membrane, characteristic of DJS.[554] Initially, the clearance rate of intravenously administered BSP from the circulation is rapid and results in BSP retention that is often normal at 45 minutes. However, a subsequent rise in serum BSP concentration occurs at 90 and 120 minutes because the conjugated BSP cannot be excreted and thus refluxes out of the hepatocyte back into the circulation.[554-557] Data suggest that BSP hepatic storage is normal, but there is a 90%

decrease in the BSP excretory transport maximum.[538,556] Other substances (e.g., ICG, rose bengal, and dibromo-sulfophthalein) have also been shown to have a decreased excretory transport maximum, although these substances do not require hepatic biotransformation and do not show the late rise in plasma levels during clearance tests.[558] Hence, in DJS, deficient excretion of bilirubin glucuronides at the canalicular membrane in the presence of otherwise normal intrahepatic metabolism results in reflux of conjugated bilirubin back into the circulation.

An important observation in DJS patients relates to the urinary excretion of coproporphyrins.[559,560] Patients with this disorder have an increase in the urinary excretion of coproporphyrin I with a concomitant decrease in the excretion of coproporphyrin III. This results in total coproporphyrin excretion (I + III) that is normal or only slightly increased but consists of greater than 80% coproporphyrin I (normal, 25%).[560-563] In heterozygotes, the coproporphyrin I/III ratio is intermediate between that of normal individuals and homozygotes,[560,562,563] although there is some overlap between heterozygotes and normal individuals. The explanation for these findings regarding urinary coproporphyrin excretion is unclear. Several pathogenetic mechanisms have been suggested.[560] Fecal coproporphyrin levels are normal.[560] Healthy neonates have been shown to have impressive elevations in urinary coproporphyrin levels, with more than 80% isomer I on the first 2 days of life.[564] By day 10, levels fell to overlap normal adult values.

Diagnosis and Treatment

A diagnosis of DJS should be considered in all individuals with elevated serum conjugated bilirubin levels along with otherwise normal liver function test results. The diagnosis can be confirmed by measuring urinary coproporphyrin levels of isomers I and III. Although the total coproporphyrin level will be approximately normal, more than 80% will be isomer I. This finding is pathognomonic for DJS when congenital erythropoietic porphyria[565] or arsenic poisoning[566] have been excluded. Even though oral cholecystography may fail to visualize the gallbladder, ultrasound examination will show a normal biliary tree. Cholescintigraphy demonstrates prolonged intense visualization of the liver with delayed appearance of the gallbladder and only faint visualization or nonvisualization of the biliary ducts.[522,567,568] Computed tomography of the liver has shown increased attenuation in one report.[569] Because cMOAT transport of leukotrienes into bile is defective in DJS, there is increased excretion of leukotriene metabolites into urine, and this has been suggested to be a new approach to the noninvasive diagnosis of this disease.[570] Another proposed diagnostic tool for DJS involves micro–positron emission tomography (micro-PET) of a copper complex studied in normal and cMOAT-deficient (TR⁻) rats.[571] In normal rats, the radioactive copper complex was cleared quickly from the liver into the intestine, whereas radioactivity accumulated continuously in the liver of TR⁻ rats and was not excreted into the small intestine.

Patients with DJS require no specific therapy. Although jaundice is a lifelong finding, it is associated with no morbidity or mortality, as demonstrated in a 30-year follow-up of 10 Japanese individuals.[553] Avoidance of oral contraceptives has been recommended[572] because they can increase jaundice. Anticipatory guidance regarding pregnancy[538] is appropriate. Increased fetal wastage has been reported in one study.[573] In one case report of neonatal DJS with severe cholestasis, phenobarbital significantly decreased serum levels of bilirubin and bile acids,[531] although chronic phenobarbital therapy is not recommended.[574] Drugs such as rifampin and ursodeoxycholic acid should be used with caution if cMOAT expression is decreased, as in DJS.[575]

Developmental Hemostasis: Relevance to Newborns and Infants

Alan B. Cantor

Development of the human hemostatic system begins in utero and continues until well after birth. As a result, functional levels of many of the procoagulants, coagulation inhibitors, fibrinolytic components, and platelet-associated factors differ from those of older children and adults, with "adult" values often not reached until about 6 months of age. These unique aspects of fetal and neonatal coagulation were first fully documented in the pioneering work of Dr. Maureen Andrew in the 1980s and have been termed "developmental hemostasis." A firm understanding of these differences, as well as access to tables listing the "normal" ranges of various hemostatic factors in infants at different gestational and postnatal ages, is critical to proper interpretation of laboratory tests performed on newborns and infants. Despite broad differences from adults in functional levels of hemostatic factors, healthy newborns rarely have difficulties with hemorrhage or thrombosis. Thus, these differences in prothrombotic and antithrombotic factors are uniquely balanced in the neonate and fetus and represent a normal physiologic state. However, this system provides little reserve, which often contributes to significant morbidity in sick and preterm infants. In addition to these developmental aspects of hemostasis, many inherited bleeding and clotting disorders can present in the newborn period. This chapter reviews the normal development of the hemostatic system, presents data tables for normal ranges at different developmental ages, and briefly reviews inherited disorders of hemostasis and thrombosis that can occur in the newborn period. For additional discussion of the investigation and management of neonatal hemostasis and thrombosis, see recent evidence-based guidelines published by the British Haemostasis and Thrombosis Task Force.[1]

ONTOGENY OF THE HUMAN HEMOSTATIC SYSTEM

Coagulation Factors

The biochemistry and function of the individual coagulation factors are reviewed in detail in Chapter 26. Coagulation proteins do not effectively cross the placental barrier and are independently synthesized by the fetus.[2-14] mRNA transcripts for coagulation factors VII, VIII, IX, and X and fibrinogen are detectable at about 5 weeks of gestation in hepatocytes of the embryo (Fig. 5-1).[15] By 10 weeks of gestation, plasma protein levels of most factors are measurable but range from 10% of the normal adult level for factor IX to about 30% for most of the other coagulation factors.[16] In general, these levels continue to increase gradually in parallel with gestational age (Table 5-1). However, with the exception of fibrinogen and factors V, VIII, and XIII, these levels remain considerably below the normal adult range, even at the time of birth for full-term infants.[16-18] They then continue to gradually increase and near the normal adult range by about 6 months of age (Tables 5-2 and 5-3). Premature infants have an accelerated increase in levels after birth

and, in general, "catch up" to the full-term infant range by 3 months' postnatal age (Table 5-4).[19] True reference ranges for extremely premature infants (<30 weeks' gestation) are not available because the majority of these infants have postnatal complications. Table 5-5 provides reference ranges for older children.[20] The nearly normal "adult" levels of fibrinogen and factors V and VIII in neonates make them useful markers for the investigation of possible consumptive coagulopathy or hemophilia A.

Regulation of fetal coagulation protein levels occurs by both transcriptional and translational mechanisms.[15,21] In addition, ratios of hepatocyte to plasma levels of many factors are relatively high in comparison to adults, thus suggesting that delayed hepatocyte release may also contribute to the relatively low coagulation factor levels in fetuses and newborns.[22]

Natural Inhibitors of Coagulation

Like many of the procoagulant factors, functional levels of most coagulation inhibitors in fetuses and neonates are significantly lower than those in adults (Tables 5-6 and 5-7; also see Table 5-3).[16,18,23] Awareness of these differences is critical to proper interpretation of laboratory studies obtained during evaluation of neonatal thrombosis. Most coagulation inhibitors reach the adult range of activity by 6 months of age.

As reviewed in Chapter 26, at least three mechanisms/pathways exist for inhibition of procoagulant activity: (1) cleavage of factors V and VIII by the protein C/S system; (2) direct inhibition of thrombin by antithrombin III (ATIII), heparin cofactor, and α_2-macroglobulin; and (3) inhibition of factor VIIa by the tissue factor pathway inhibitor (TFPI)/factor Xa complex. When thrombin binds to thrombomodulin on endothelial surfaces, it no longer cleaves fibrinogen but activates protein C. Activated protein C, in complex with protein S, proteolytically inactivates factors V and VIII. At birth, plasma concentrations of protein C are quite low and remain decreased during the first 6 months of life.[17,19,23] Neonates also have about a twofold higher amount of the single-chain form of protein C than adults do and may

All values are expressed in units per milliliter, with pooled plasma containing 1.0 U/mL. All values are given as means followed by the lower and upper boundary encompassing 95% of the population. Between 40 and 75 samples were assayed for each value in newborns. Some measurements were skewed because of a disproportionate number of high values. The lower limits exclude the lower 2.5% of the population.

α_1AT, α_1-antitrypsin; α_2M, α_2-macroglobulin; AT, antithrombin; C1E-INH, C1 esterase inhibitor; HCII, heparin cofactor II.

★Values indistinguishable from those of adults.

[†]Values different from those of full-term infants.

From Andrew M, Paes B, Johnston M: Development of the hemostatic system in the neonate and young infant. Am J Pediatr Hematol Oncol. 1990;12:95-104.

exhibit increased protein C glycosylation. Despite these alterations, there is no evidence that protein C from neonates differs functionally from that of adults when compared at equivalent concentrations.[24,25]

In adults, protein S circulates in either a free form or bound to the carrier protein C4b binding protein. In fetuses and neonates, circulating protein S is almost entirely of the free type because levels of C4b binding protein are extremely low.[26,27] Thus, the protein S activity-to-antigen ratio is greater for fetuses and neonates than for adults. Nonetheless, both total and free protein S levels are lower in fetuses and neonates. They rise gradually after birth, with the adult range of free protein S reached by 4 months and total protein S by about 10 months.[1] The interaction of protein S with activated protein C in the plasma of newborns may be modulated by increased levels of α_2-macroglobulin.[28]

Healthy full-term newborns have lower functional ATIII levels than adults do, with an average of 0.55 U/mL based on several studies.[12,13,18,29-32] This is most likely due to a reduced amount of absolute ATIII protein inasmuch as most studies have found no significant difference in the antigen-to–functional activity ratio, immunoelectrophoresis, or chromatographic properties of purified ATIII from neonates and adults.[12,29,32,33] The reduced ATIII levels in neonates probably account, at least in part, for the relative heparin resistance seen in this age group. ATIII levels typically reach the adult range by 3 months of age in full-term healthy infants. Preterm infants with respiratory distress syndrome (RDS) have significantly lower levels of ATIII, typically less than 0.2 U/mL, and the ATIII present often has additional dysfunctional properties.[29,34-37] Lower ATIII levels correlate with increased catheter-related thrombosis, intracranial hemorrhage (ICH), and mortality.

Like ATIII, levels of heparin cofactor II are also substantially lower in infants than adults.[38] A circulating fetal dermatan sulfate proteoglycan has been described that has natural anticoagulant properties mediated through heparin cofactor II.[39] This fetal anticoagulant is also present in the plasma of pregnant women and is produced by the placenta. The length of time that it circulates in newborns is not known; however, it is still present during the first week of life in sick premature infants with RDS.

α_2-Macroglobulin is a more important inhibitor of thrombin in plasma from newborns than in adults.[40] It compensates, in part, for the low levels of ATIII and heparin cofactor in newborns, even in the presence of endothelial cell surfaces.[40,41] However, the overall rate of thrombin inhibition is still lower in newborns than adults.[40]

TFPI binds to factor VIIa/tissue factor complexes in a factor Xa calcium-dependent reaction that results in the inhibition of factor VIIa. After generation of small amounts of thrombin, TFPI prevents further generation of thrombin via tissue factor/factor VIIa. TFPI levels in cord plasma have been reported to be approximately 50% of adult values.[42]

Vitamin K–Dependent Factors

Factors II, VII, IX, and X and proteins C, S, and Z undergo vitamin K (VK)-dependent post-translational γ-carboxylation of certain glutamic acid residues (see Chapter 26). Typically, 9 to 12 glutamic acid residues, often clustered within a 45–amino acid region referred to as a "Gla" domain, are modified.[22,43] γ-Carboxylation of glutamic acids enhances calcium-dependent phospholipid interactions of the coagulation factors and helps catalyze the coagulation cascade. Because of the association of relative VK deficiency and hemorrhagic disease of the newborn (HDN; see detailed description later), development of these VK-dependent factors in utero has been the focus of considerable research. During gestation, a steep gradient of VK concentration is maintained across the placenta, with fetal levels being 10% or less of maternal levels.[22,44-49] This gradient is even further enhanced during the third trimester.[45] Consequently, VK stores in newborns are low, as shown by low levels of VK in the cord blood and liver of aborted fetuses.[44,47,50] The teleologic explanation for maintenance of low fetal VK levels is not known. However, VK has been shown to promote DNA mutagenesis in vivo. For this reason, several investigators have suggested that maintenance of low fetal VK levels might be a mechanism to prevent chromosomal damage during the rapid cellular proliferation of embryogenesis.[51-53] In addition to these low VK levels, deficiency of VK reductase activity (a rate-limiting step in the reaction) as a result of immaturity of the hepatocyte may contribute to inefficient γ-carboxylation of coagulation factors.[22] In fact, undercarboxylated prothrombin and protein C have been detected in up to 7% and 27% of the cord and peripheral blood of healthy term infants, respectively, and these levels correlate with gestational age.[54,55] Even when corrected for this relative VK deficiency, levels of VK-dependent factors are still considerably lower than the normal adult range because the values presented in Tables 5-1 to 5-4, 5-6, and 5-7 were measured in infants who received VK prophylaxis at birth.

VK-dependent glutamic acid carboxylation also occurs on proteins outside the coagulation system, many of which play roles in development. Such proteins include Gas-6, the ligand for the receptor kinases Sky and Axl; the bone growth– and calcification-related factors osteocalcin and matrix Gla protein; the urine calcium binding protein nephrocalcin; and PRPG1 and PRPG2, two proline-rich predicted signaling proteins expressed in the central nervous system (CNS) and endocrine tissues.[43,55,56,57] Thus, VK is predicted to have pleiotropic effects on development.

Although VK is maintained at low levels in the fetus, further deficiency of VK during gestation can reduce functional levels of the VK-dependent coagulation factors

to an even greater extent. Maternal use of certain anti-convulsant medications, including phenytoin, phenobarbital, valproic acid, and carbamazepine, is associated with an increased risk of VK deficiency in the fetus and neonate.[22,58] Fetal or neonatal bleeding has been linked to maternal use of these medications on rare occasion. Fetal VK deficiency can be prevented in such cases by antenatal oral administration of 10 mg of VK$_1$ daily to the mother beginning at 36 weeks' gestation.[59]

Warfarin is a potent VK antagonist commonly used for long-term anticoagulation. It crosses the placenta and inhibits VK-dependent carboxylation in the fetus. Its use during pregnancy at 6 to 12 weeks of gestation is associated with an embryopathy syndrome consisting of limb deformities, nasal hypoplasia, ophthalmologic malformations, mental retardation, hypotonia, and ear abnormalities.[60] Warfarin exposure during the second or third trimester is associated with fetal wastage and CNS anomalies. The developmental defects related to warfarin use during pregnancy are thought to be due to bleeding into the developing limb buds or effects on bone and cartilage growth from inhibition of bone-associated Gla proteins, or both.

The Fetal and Neonatal Fibrinolytic System

The enzyme plasmin degrades polymerized fibrin and is responsible for clot dissolution. It is generated from its precursor plasminogen by two known activators, tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA). These activators, in turn, are inhibited by the plasminogen activator inhibitors PAI-1 and PAI-2. In addition, plasmin itself is inhibited by the circulating blood protein α_2-antiplasmin. See Chapter 27 for more detailed description of the fibrinolytic system. In newborns, plasminogen levels are only 50% of adult values, α_2-antiplasmin levels are 80% of adult values, and plasma concentrations of PAI-1 and tPA are significantly greater than adult values (Table 5-8).[17,19,23,61-64] The increased levels of tPA and PAI-1 found on day 1 of life contrast markedly with values obtained from cord blood, which are significantly lower than adult levels. The discrepancy between newborn and cord plasma concentrations of tPA and PAI-1 may be explained by the enhanced release of both proteins from the endothelium shortly after birth. PAI-2 levels are detectable in cord blood but are significantly lower than they are in pregnant women.[65] Unique glycoforms of plasminogen with an increased content of mannose and sialic acid exist in the fetus.[66-68] This fetal form of plasminogen is less efficiently converted to plasmin by tPA than adult plasminogen is.[66] No significant differences exist in activation kinetics by uPA.[66]

D-Dimers

D-dimers are the breakdown product of fibrin mesh cross-linked by factor XIII. Neonates have markedly elevated D-dimer levels in comparison to older children and adults that persist for at least 3 days after birth (Table 5-9).[18] These high levels suggest activation of the coagulation system at birth, decreased clearance of D-dimers in neonates, or both.

Plasminogen units are those recommended by the Committee on Thrombolytic Agents. Values for tPA are given as nanograms per milliliter. For α_2AP, values are expressed as units per milliliter, with pooled plasma containing 1.0 U/mL. Values for PAI-1 are given as units per milliliter, with 1 unit of PAI-1 activity being defined as the amount of PAI-1 that inhibits the 1 IU of human single-chain tPA. All values are given as means followed by the lower and upper boundaries encompassing 95% of the population.
*Values indistinguishable from those of adults.
†Values different from those of full-term infants.
α_2AP, α_2-antiplasmin; PAI-1, plasminogen activator inhibitor 1; tPA, tissue plasminogen activator.

von Willebrand Factor

von Willebrand factor (VWF) is a large protein that mediates adhesion of platelets to exposed subendothelium and is involved in platelet aggregation (see Chapter 30). Its synthesis can first be detected as early as 4 weeks of gestation in placental endothelial cells and by 4 to 8 weeks in bone marrow.[22,69,70] In contrast to other coagulation factors, VWF functional levels are considerably elevated in neonates in comparison to the normal adult range (see Tables 5-2 and 5-5). They gradually decline to the normal adult range by about 3 to 6 months. It is important to keep these physiologically elevated levels in mind when using VWF as a marker of inflammation in infants.

VWF is released from endothelial cells and megakaryocytes as large multimers with molecular weights in the millions-of-dalton range. They are then cleaved into smaller multimers by the metalloproteinase ADAMTS-13. Unusually large VWF (ULVWF) multimers are VWF multimer forms larger than those found in normal plasma. These ULVWF multimers are 10 to 20 times more active in shear stress–induced platelet aggregation and bind more avidly to the extracellular matrix of fibroblasts than do the VWF multimer forms found in normal plasma.[71,72] In older children and adults, the presence of ULVWF plasma forms is the hallmark of thrombotic thrombocytopenic purpura, a microangiopathic disorder. It is due to deficiency, acquired or congenital, of ADAMTS-13. ULVWF forms are consistently found in platelet-poor plasma (PPP) from fetuses less than 35 weeks' estimated gestational age (EGA) and most fetuses older than 35 weeks' EGA, as well as in umbilical cord blood.[73,74] These forms are not seen in simultaneously sampled maternal PPP, thus indicating that the ULVWF forms are fetal specific. The ULVWF in fetal PPP is similar to the VWF directly released from endothelial cells. This similarity may be explained by the recent finding of low VWF cleaving protease (ADAMTS-13) activity in many neonates.[75,76] Serial monitoring of PPP from neonates shows a gradual reduction in ULVWF to the normal size range within 8 weeks after birth.[74] The presence of ULVWF during fetal development is probably physiologically relevant because plasma derived from umbilical cord blood shows increased shear stress– and ristocetin-induced

VWF platelet-binding activity in comparison to plasma derived from adults, even when adult platelets are used in the assay.[77] The enhanced hemostatic efficacy of ULVWF may therefore balance the low functional levels of other coagulation factors to achieve reliable hemostasis in the fetus and newborn.

Platelets

Megakaryocytes during Fetal Development

In humans, megakaryocytes are first detectable in the liver and spleen by 10 weeks of gestation.[78] By 30 weeks, megakaryocytes are present in bone marrow and actively contributing to thrombopoiesis. Circulating megakaryocyte progenitors are detectable in the blood of neonates, and their number decreases as a function of postconceptional age (gestational age + days of life).[79]

Several pieces of evidence suggest that fetal liver megakaryocytes have unique features when compared with adult bone marrow–derived megakaryocytes. Megakaryocytes that develop from murine neonatal liver progenitors after transplantation into myeloablated mouse recipients are smaller and have lower ploidy levels than do those derived from transplanted adult bone marrow.[80] These differences disappear by 1 month after transplantation. In addition, several congenital disorders of megakaryopoiesis in humans, such as Down syndrome–transient myeloproliferative disorder (DS-TMD) and thrombocytopenia with absent radii (TAR), resolve spontaneously after the newborn period, thus suggesting specific effects on fetal megakaryopoiesis. In support of this hypothesis, experiments in mice show stage-specific effects of a mutation in the transcription factor GATA-1 associated with DS-TMD and Down syndrome–acute megakaryoblastic leukemia (DS-AMKL) that affect fetal liver megakaryopoiesis but not adult bone marrow megakaryopoiesis.[81] It has been proposed that stage-specific differences in megakaryopoiesis may account for the delayed platelet engraftment in humans often observed when umbilical cord blood is used as a source of hematopoietic stem cells rather than bone marrow or peripheral blood mobilized stem cells.[80] The potential differences between fetal liver and adult bone marrow megakaryocytes could be due to

intrinsic differences in the progenitors themselves or their interactions with different microenvironments, or both.

Platelet Number, Size, and Survival during Development

In humans, circulating platelets are first detected by 11 weeks' gestational age.[78] Thereafter, the plasma platelet concentration rises rapidly and reaches the adult range of 150 to 450 × 10^9/L by about 18 weeks of gestation.[22,23,62,78,82-88] During the earliest phase of platelet production, mean platelet volume (MPV) is larger than the adult range.[22] However, platelet volume "normalizes" soon thereafter and reaches the adult range of 7 to 9 fL.[89,90] It is possible that the larger platelets arise from a unique wave of "primitive" megakaryopoiesis that occurs early in gestation, as demonstrated in several mouse studies,[91,92] but this mechanism remains to be determined in humans. Platelet survival has not been measured in healthy infants. In rabbits, survival of ^{111}In oxine–labeled platelets is similar in adult and newborn rabbits.[93] However, in humans, levels of reticulated platelets, which represent those recently released from megakaryocytes, are elevated about 20-fold in comparison to adults.[94] Concentrations of thrombopoietin (TPO), the major cytokine for megakaryocyte progenitor proliferation and development, are increased about twofold in fetal versus adult plasma.[95] These findings suggest possible increased platelet turnover in human fetuses versus adults.

Platelet Structure

Peripheral blood platelets from newborns contain similar numbers of platelet-specific granules as platelets from older children and adults; however, serotonin and adenosine diphosphate (ADP), which are stored in dense granules, are present at concentrations less than 50% of adult values.[96] Newborn platelets contain normal levels of the receptors glycoprotein Ib (GPIb) (part of the VWF binding complex), GPIa/IIa, P-selectin, and PI^A1. Variable levels of GPIIb/IIIa have been reported, with some studies indicating significantly reduced expression.[97-99] Functional epinephrine receptors are significantly diminished in newborn platelets.[100]

Platelet Function

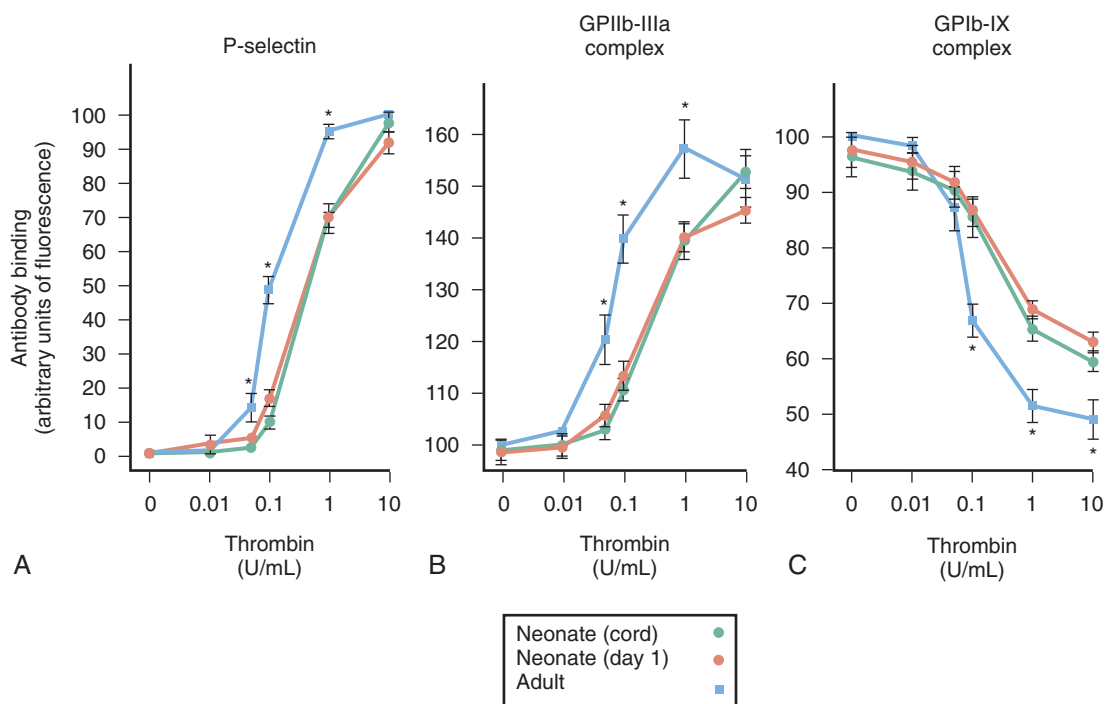
Platelet aggregometry studies of neonatal and cord blood platelets have shown variable results, but most demonstrate a modest hyporesponsiveness to ADP, epinephrine, collagen, and thrombin when compared with platelets from older children and adults (Fig. 5-2).[101-104] The hyporesponsiveness spontaneously resolves by 2 to 9 days after birth in full-term infants.[105] Several explanations have been proposed to account for this hyporesponsiveness, including impaired calcium channel transport and signal


FIGURE 5-2. Effect of thrombin on the surface expression of P-selectin, the glycoprotein (GP) IIb/IIIa complex, and the GPIb/IX complex on neonatal and adult platelets in whole blood. Results were similar for cord and neonatal day 1 values. Expression of P-selectin and GPIIb/IIIa complexes was decreased in newborns, whereas GPIb/IX expression was relatively preserved in newborns in comparison to adults after stimulation with thrombin. Data are expressed as means ± SEM; $N = 20$. *Asterisks* indicate $P > .05$ for both cord blood and day 1 neonatal platelets in comparison to adult platelets. *(Redrawn from Rajasekhar D, Kestin AS, Bednarek FJ, et al: Neonatal platelets are less reactive than adult platelets to physiological agonists in whole blood. Thromb Haemost 1994;72:957-963.)*

transduction,[22,106-108] decreased availability of α-adrenergic receptors because of either delayed receptor maturation or occupation by catecholamines released during birth,[96,101,102,104,106,109-112] and the presence of inhibitory placenta-derived prostaglandins.[113]

In contrast to the agonists just described, agglutination in response to low concentrations of ristocetin is significantly enhanced in fetal and newborn platelet-rich plasma in comparison to that of adults,[96] probably partly because of high VWF levels and the presence of ULVWF forms in newborn plasma.[73,74,106,114-116] In the end, the hyporesponsiveness to certain platelet agonists and the hyperresponsiveness to VWF appear to balance each other out inasmuch as most healthy term infants do not experience bleeding or thrombotic complications in the newborn period.

Platelet Activation during the Birth Process

There is strong evidence that platelets are activated during the birth process. Cord plasma levels of thromboxane B_2, β-thromboglobulin, and platelet factor 4 are increased; the granular content of cord platelets is decreased; and epinephrine receptor availability is reduced, perhaps as a result of occupation.[117-120] The mechanisms of activation are probably multifactorial and include thermal changes, hypoxia, acidosis, adrenergic stimulation, and the thrombogenic effects of amniotic fluid.

Blood Vessel Wall: Age and Anticoagulant Properties

The endothelium fulfills a complex role in hemostasis in that it prevents thrombotic complications under physiologic conditions and promotes fibrin formation when injured. One of the anticoagulant properties of endothelial cell surfaces is mediated by lipoxygenase and cyclooxygenase metabolites of unsaturated fatty acids. Prostacyclin (prostaglandin I_2 [PGI_2]) production by cord vessels exceeds that by blood vessels in adults.[121] A second endothelial cell–mediated antithrombotic property is promotion of antithrombin (AT) neutralization of thrombin by cell surface proteoglycans. Structurally, there is evidence that the vessel wall glycosaminoglycans of the young differ from those of adults.[122,123] In a rabbit venous model, increased amounts of glycosaminoglycans are seen in the inferior venae cavae of rabbit pups as compared with adults. Similarly, in the rabbit arterial model, greater glycosaminoglycan-mediated AT activity is seen in rabbit pups than in adult rabbits.[124,125]

Maternal Preeclampsia and Fetal Hemostasis

Preeclampsia is a pregnancy-associated syndrome consisting of maternal hypertension and proteinuria. Alterations in maternal coagulation and fibrinolysis, including reduced ATIII and PAI-2 levels and increased tPA antigen, PAI-1 antigen, and fibrin degradation product levels, have been described in women with preterm preeclampsia.[126-130] This suggests a state of enhanced thrombin generation and fibrinolysis in the maternal circulation. Analysis of cord blood from infants born to mothers with preeclampsia shows no statistical difference in the levels of these factors versus those of age-matched controls born to mothers without preeclampsia, thus indicating a probable protective effect of the placenta on the fetal circulation.[126,131]

Summary of Hemostatic Differences between Neonates and Older Children and Adults

In summary, the salient differences in the hemostatic system of neonates and older children or adults are (1) decreased plasma concentrations of many of the procoagulant proteins, including factors II, VII, IX, X, XI, and XII, prekallikrein, and high-molecular weight kininogens; (2) a unique fetal glycoform of fibrinogen; (3) decreased plasma concentrations of the coagulation inhibitors ATIII, heparin cofactor II, TFPI, protein C, and protein S, with a concomitant slower rate of thrombin inhibition; (4) a unique glycoform of plasminogen that is less efficiently converted to plasmin by tPA; (5) markedly elevated D-dimer levels until at least 3 days after birth; (6) increased plasma VWF concentration and elevated levels of circulating ULVWF multimers; and (7) modest, transient hyporesponsiveness of platelets to certain agonists such as collagen and epinephrine, but increased agglutination with low-dose ristocetin. In general, most of these differences resolve within the first 6 months of life.

CLINICAL ASPECTS OF DEVELOPMENTAL HEMOSTASIS

Hemorrhagic Disorders

Although acquired disorders are more commonly seen, severe forms of congenital factor deficiencies or platelet disorders can present in early infancy and should be seriously considered in otherwise healthy infants who are bleeding.[22,34,62,132-136] Recent studies estimate that about 15% to 30% of children with inherited bleeding disorders have hemorrhage in the neonatal period.[137,138] In addition, a third of new cases of severe hemophilia represent new mutations and are therefore not accompanied by any antecedent family history.[138]

Clinical Findings

The clinical manifestations of bleeding disorders are different in newborns than in older children and adults. Bleeding may appear as oozing from the umbilicus,

bleeding into the scalp, large cephalohematomas, bleeding after circumcision, bleeding from peripheral phlebotomy sites, and bleeding into the skin. A small but important proportion of infants are seen with ICH as the first manifestation of their bleeding tendency.[136,139-145] Sick infants can bleed from mucous membranes, the bladder, and sites of invasive procedures. Joint bleeding is rare. The most common causes of bleeding in healthy infants are thrombocytopenia secondary to transplacental passage of a maternal antiplatelet antibody, sepsis, VK deficiency, and congenital coagulation factor deficiencies.

Laboratory Evaluation

In addition to a workup for sepsis, laboratory evaluation of infants with bleeding complications should include determination of the prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin clotting time (TCT), fibrinogen level, and platelet count. As discussed earlier, results need to be compared with the expected range of values for neonates because some may not reflect the normal adult range (see later). Abnormalities in test results usually prompt additional tests, such as specific factor assays. For a male child in whom hemophilia A or B is suspected, specific factor assays should be performed regardless of the APTT value. The PT, APTT, and TCT are not prolonged in those with factor XIII and α_2-antiplasmin deficiency. Therefore, levels of these factors must be measured directly if deficiencies are suspected.

Sample Collection

Collection of samples for laboratory investigation of hemostatic defects in neonates, especially premature infants, presents particular challenges because of the patient's small size and increased hematocrit. Specialized microcollection tubes (1 mL) should be available in the neonatal unit. Blood sampling techniques should avoid contamination with intravenous fluids and heparin and should also avoid activating the coagulation system. Slow transit time and contact with plastic tubing are most likely to cause activation. All neonatal samples should be inspected for the presence of fibrin clumps before processing, and those containing clumps should not be used for analysis. Ideally, the volume of anticoagulant in the sample should be based on the volume of plasma, not the total volume of blood, because the increased hematocrit of neonates causes accentuated dilution of the coagulation factors if not taken into account.[1] This is particularly important for neonates with very high hematocrit values, such as those with cyanotic congenital cardiac disease. Overfilled or underfilled samples should not be analyzed.

Screening Coagulation Tests in Neonates

Screening tests of plasma clotting activity, including the PT, APTT, and TCT, are all prolonged during fetal development and in neonates when compared with the normal adult range (see Tables 5-1 to 5-3), probably because of physiologic "deficiencies" of the VK-dependent factors, contact factors, and the presence of fetal glycoforms of fibrinogen.[1] The absolute values for these tests, as well as specific coagulation factor tests, depend on the reagents and analyzer used. Table 5-3 provides reference ranges recently generated by Monagle and co-workers using the STA Compact analyzer and Diagnostica Stago reagents, a system currently used in many clinical laboratories.[18] In contrast to some earlier systems, such as the ACL system, the STA Compact analyzer is not affected by plasma bilirubin levels. The differences observed underscore the need for each clinical laboratory to establish its own normal age-related reference ranges.[18]

Bleeding Time

The bleeding time has traditionally been used as an in vivo test of platelet function, particularly for testing adhesion to injured vasculature.[114] However, it is subject to considerable operator-dependent variability and is not routinely used in newborns. Automated devices modified for newborns and children are available and have been standardized.[146] In contrast to the prolonged coagulation screening tests, multiple studies have shown that bleeding times in infants during the first week of life are significantly shorter than those in adults.[106,114-116,146] This somewhat paradoxical finding can be explained by several mechanisms, including higher plasma concentrations of VWF,[17,19,23] enhanced function of VWF because of a disproportional increase in ULVWF multimers,[73,74] large red cells,[147] and high hematocrits.[148]

Platelet Functional Analyzer

The Platelet Functional Analyzer 100 (PFA-100) system provides an in vitro method of assessing primary platelet-related hemostasis by measuring the time (closure time) required for a platelet plug to occlude a microscopic aperture cut into a membrane coated with collagen and either epinephrine or ADP. It uses the patient's own platelets and plasma. The PFA-100 system is attractive for use in neonates because of the small volume required, rapidity of testing, and standardization of testing cartridges. Like the bleeding time, most studies of neonates' peripheral or cord blood report PFA-100 closure times, for both epinephrine and ADP, that are shorter than those for older children and adults (Table 5-10).[1,149-152] This is probably due to similar mechanisms as described earlier for the shortened bleeding time.[150] Normal ranges for premature infants of different postconceptional ages have not been reported. Although the PFA-100 system may eventually become a standard screening test for platelet function in neonates, older children, and adults, its clinical utility has not yet been clearly established.[153] Thus, further studies will be required to determine the optimal method of assessing primary hemostasis in newborns and children, particularly premature infants.

Hereditary Coagulation Factor Deficiencies

For most hemostatic components, both severe and mild forms of deficiency can occur, with severe deficiencies often characterized by significant bleeding in newborns. Chapter 30 and 31 discuss hereditary factor deficiencies in detail.

Inheritance

Deficiencies of factors II, V, VII, XI, and XII, prekallikrein, and high-molecular-weight kininogen are rare autosomally inherited disorders, with consanguinity present in many families. Deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen do not result in hemorrhagic complications and thus are not considered further here. Deficiencies of factors VIII and IX are sex linked and the most common congenital bleeding disorders in newborns. Rarely, combined deficiencies of factors II, VII, and IX and/or factors V and VIII occur in the neonatal period.[154,155] The latter is due to mutations in LMAN1 (also called ERGIC-53), a mannose-binding type I transmembrane protein, or its binding partner MCFD2, which together form a specific cargo receptor complex in the endoplasmic reticulum.[155,156] It is typically inherited in an autosomal recessive manner. Tests are available to diagnose most congenital factor deficiencies prenatally so that either termination of pregnancy or management of affected infants can be planned (see Chapters 30 and 31).

Clinical Findings

In the majority of newborns with congenital coagulation factor deficiencies, bleeding does not occur in the perinatal period unless a hemostatic challenge is present. On the other hand, unexplained bleeding in an otherwise healthy newborn should be carefully investigated because it may be due to a congenital coagulation factor deficiency.

ICH is rare in full-term newborns and usually occurs either spontaneously or after insults such as birth asphyxia or trauma, VK deficiency, or severe congenital factor deficiencies. Other risk factors include small birth weight, young gestational age, and ethnic background.[157-165] The

risk for ICH in children with severe hemophilia A or B ranges from 2% to 8%. The location of the ICH is most commonly the subarachnoid area, but subdural and parenchymal bleeding also occurs. Head ultrasound may not detect small parafalcine bleeding, so computed tomography (CT) is the preferred modality when deficiency of a coagulation factor is suspected. Some infants require surgical intervention, and many have long-term neurologic deficits.

Full-term infants with unexplained ICH should be carefully evaluated for congenital or acquired hemostatic defects.[139,157-165] Unfortunately, the diagnosis of ICH may be delayed because of the nonspecific nature of the early clinical findings, including poor feeding, lethargy, apnea, vomiting, and irritability. Further delays can result when secondary coagulopathies such as disseminated intravascular coagulation (DIC) occur or because of confusion related to the physiologically low levels of some coagulation factors in newborns.[166,167] The more extreme clinical manifestations of ICH are usually recognized early and include seizures, meningismus, and a tense fontanelle.

Although severe deficiency of factor VIII is the most common cause of ICH from a coagulation factor deficiency, severe congenital deficiencies of fibrinogen and factors II, V, VII, VIII, IX, X, XI, and XIII can also cause ICH at birth.[168] The incidence of ICH in newborns is unknown and is probably changing because of improvements in perinatal care. The widespread use of ultrasound, a safe modality for monitoring fetuses at risk, has resulted in the detection of ICH in utero. In utero factor replacement has also been accomplished in several infants.[10] Though less common than ICH, subgaleal bleeding with concurrent shock and DIC may be the initial manifestation of a congenital factor deficiency.[169]

Diagnosis

In newborns, the diagnosis of many congenital factor deficiencies based on plasma concentrations can be difficult because of neonates' physiologically low levels at birth (see Tables 5-2 and 5-3). Mild to moderate

hereditary deficiencies of factors II, VII, IX, X, and XI result in plasma concentrations that may overlap with the normal neonatal range. In contrast, plasma concentrations resulting from either mild to moderate factor VIII deficiency or severe deficiency of factors V, VII, VIII, IX, X, and XIII can easily be distinguished from physiologic values. Prenatal diagnosis of most hereditary factor deficiencies is performed by amniocentesis or chorionic villus biopsy and is largely confined to severe hemophilia A and B, although deficiencies of factors V, VII, and XIII and VWF have also been diagnosed prenatally.[9,10,170-172]

Treatment

In the presence of active bleeding or a planned hemostatic challenge, the fundamental principle of management is to increase the plasma concentration of the deficient coagulation protein to a minimal hemostatic level. This target level varies, depending on the protein and nature of the hemostatic challenge (see Chapters 30 and 31). When possible, recombinant protein products or detergent-treated pooled donor preparations should be used to reduce the risk of infectious complications. Most products available for the treatment of older children and adults can be used in neonates. Although it has not been well studied, the half-lives and volumes of distribution of recombinant factor VIII (rFVIII) and rFIX appear to be similar in full-term newborns and older children, so standard initial dosing regimens can be used. However, it is critical to monitor trough levels closely and make appropriate dose modifications to ensure achievement of the proper target level. There are a few case reports of extremely premature infants (<1500 g or <30 weeks' EGA) having a slightly shortened half-life of factor VIII (about 6 hours versus 8 to 12 hours in full-term infants and older children).[173,174]

Fresh frozen plasma (FFP) should be given for bleeding emergencies in neonates in whom a coagulation defect is suspected but a specific factor deficiency has not yet been documented. There are case reports of a small number of infants (<4 months) treated successfully with rFVIIa for catastrophic bleeding of varying causes.[175] However, rFVIIa treatment of patients without congenital factor VII deficiency or hemophilia with high-titer inhibitors should be considered investigational at this time. Infants with known or suspected deficiencies in coagulation factors should receive vaccinations by subcutaneous rather than intramuscular route, and arterial puncture should be avoided when possible.

Mode of Delivery

The optimal mode of delivery for infants of hemophilia carrier mothers has yet to be determined.[138] However, normal vaginal delivery appears to be generally safe for many babies with hemophilia.[176] Use of vacuum assistance is associated with an increased risk for significant cranial hematomas in newborns with hemophilia and should be avoided if possible.[138,176]

Specific Coagulation Factor Deficiencies

Fibrinogen Deficiency. Deficiency of fibrinogen is rare. Bleeding secondary to afibrinogenemia has been reported in newborns after circumcision or as umbilical stump bleeding and soft tissue hemorrhage, with some cases being fatal. Reported replacement therapies have included whole blood, cryoprecipitate, FFP, and fibrinogen concentrates.[177-180] One fibrinogen concentrate (Haemocomplettan HS, Centeon/Aventis Behring) is available in Europe and North America.

Factor II Deficiency. Deficiency of prothrombin is very rare. Reported bleeding complications in newborns include gastrointestinal bleeding and ICH.[181,182] Reviews of adult patients have reported bleeding after invasive events such as circumcision and venipuncture or as soft tissue hematomas.[178] Although FFP can be used as initial therapy, factor II concentrate or prothrombin complex concentrate (PCC) is the preferred replacement product.

Factor V Deficiency. Bleeding as a result of severe factor V deficiency has been reported in newborns. Clinical manifestation include ICH, subdural hematoma, bleeding from the umbilical stump, gastric hemorrhage, and soft tissue hemorrhage.[183,184] Antenatal intraventricular hemorrhage was reported in two newborns.[185] Replacement therapy included whole blood, FFP, and the local application of pressure on sites of bleeding. Although thrombotic complications occur in some patients with factor V deficiency, they have not been reported in newborns.[183-187]

Factor VII Deficiency. Severe factor VII deficiency (factor VII level <1%) usually causes significant bleeding equivalent to that seen in patients with severe hemophilia. Patients with factor VII levels greater than 5% generally have mild hemorrhagic episodes. The most commonly reported bleeding complication in newborns with congenital factor VII deficiency is ICH.[188-190] In a review of 75 patients with factor VII deficiency, ICH was observed in 12 (16%). In 5 (42%) of these 12 patients, ICH occurred in the first week of life with a fatal outcome. Congenital factor VII deficiency may occur in infants with Dubin-Johnson syndrome[189,191] or Gilbert's syndrome[192] in certain populations. Bleeding episodes secondary to factor VII deficiency can be treated with FFP, PCC, purified factor VIIa concentrates, or preferably, rFVIIa.[175,188-190,193,194] Lower doses of rFVIIa (15 to 20 μg/kg) than those used for patients with severe hemophilia A or B and high-titer inhibitors (90 μg/kg) are often sufficient to control bleeding in patients with factor VII deficiency.[195,196] However, this has not been carefully defined in prospective clinical trials, and the Food and Drug Administration (FDA) has not yet approved rFVIIa for the treatment of congenital factor VII deficiency. Moreover, dosing has not been optimized for neonates

and infants. Caution should be used in combining treatment with rFVIIa and PPC because thrombotic complications have been reported.

Factor VIII Deficiency. The severity of factor VIII deficiency is determined by the plasma concentration of factor VIII, with a level of less than 1% being severe, 1% to 5% being moderate, and 5% to 50% being mild. Severe factor VIII deficiency is the most common inherited bleeding disorder of the neonatal period. In addition, a small number of neonates with moderate and mild hemophilia are seen after a hemostatic challenge.[141,143,197-199] Large cohort studies have revealed that approximately 10% of children with hemophilia have clinical symptoms in the neonatal period.[168] In approximately 50% of factor VIII–deficient children with bleeding in the neonatal period, it occurred after circumcision. Almost 20% had intracranial bleeding. Death may occur from neonatal bleeding. In contrast to older infants and children, bleeding into joints is extremely rare in neonates.[200] Severe factor VIII deficiency can, on rare occasion, occur in female infants as a result of skewed lyonization and be clinically manifested in the neonatal period.[201,202] Management of bleeding secondary to factor VIII deficiency is discussed in detail in Chapter 30.

Factor IX Deficiency. Classification of the severity of factor IX deficiency is identical to that used for factor VIII deficiency. Diagnosis of milder forms of factor IX deficiency is complicated by physiologic levels of factor IX that can be as low as 0.15 U/mL and, in rare infants, by the potential for concurrent VK deficiency. Bleeding after circumcision and ICH can occur in neonates with factor IX deficiency.[141,143,197,203,204] Management of bleeding secondary to factor IX deficiency is discussed in detail in Chapter 30.

Factor X Deficiency. Severe factor X deficiency can be manifested as bleeding in the newborn period.[205-209] ICH was present in a high proportion of reported cases, several of which were fatal. Additional sites of bleeding that have been noted include umbilical, gastrointestinal, and intra-abdominal. Whole blood, FFP, factor X concentrate, and PCC have been used as replacement therapy.

Factor XI Deficiency. Severe deficiency of factor XI is rare. It is different from other coagulation protein deficiencies in that bleeding symptoms are not necessarily tightly correlated with factor plasma concentrations. Bleeding complications as a result of severe factor XI deficiency were reported in two newborns. One bled after circumcision at the age of 3 days and had a factor XI level of 0.07 U/mL. In another newborn, factor XI deficiency with bilateral subdural hemorrhage was diagnosed prenatally.[210-212] Either FFP or cryoprecipitate can be used for the treatment of factor XI–deficient patients if factor XI concentrate is not available.

Factor XIII Deficiency. Severe factor XIII deficiency is typically manifested at birth as bleeding from the umbilical stump or ICH.[142,213-222] Other clinical manifestations of homozygous factor XIII deficiency include delayed wound healing, abnormal scar formation, and recurrent soft tissue hemorrhage with a tendency to form hemorrhagic cysts. ICH occurs even in the absence of trauma in approximately a third of all affected patients.[138] Newborns with heterozygous factor XIII deficiency are not clinically affected.

FFP, cryoprecipitate, or factor XIII concentrates can be used for the treatment of factor XIII–deficient patients. Newborns with known factor XIII deficiency should receive a prophylactic regimen of factor XIII because of the high incidence of ICH. Plasma concentrations of factor XIII greater than 1% are effective, and the very long half-life of factor XIII permits once-per-month therapy. Therefore, prophylactic replacement therapy consists of either small doses of FFP (2 to 3 mL/kg) administered every 4 to 6 weeks, cryoprecipitate at a dose of 1 bag/10 to 20 kg of weight every 3 to 6 weeks, or preferably, factor XIII concentrate at a dose of 10 to 20 U/kg every 4 to 6 weeks, depending on the clinical situation and the preinfusion plasma concentration of factor XIII.[142,213-224]

Hereditary Deficiencies of Multiple Coagulation Factors. Hereditary deficiencies of two or more coagulation proteins have been reported for 16 different combinations of coagulation factors.[225] Combined deficiency of factors V and VIII has been described in patients with mutations in the genes encoding LMAN1 (also called ERGIC-53) and MCFD2.[154,156,226,227] Administration of FFP is usually the initial therapy. Subsequent treatment varies, depending on the specific factors affected.

Hemorrhagic Disease of the Newborn

Historical Background

HDN, as first described by Townsend in 1894, consists of hemorrhage on days 1 through 5 of life from multiple sites in otherwise healthy infants.[228] Subsequently, a causal link between HDN and abnormal blood coagulation was established.[62,229,230] Initial treatment of infants with HDN consisted of intravenous, intramuscular, or subcutaneous injection of blood or serum. Even at this very early time, the difficulty of separating treatment response from spontaneous improvement was recognized. Later, a randomized, controlled trial showed that intramuscular injection of blood was not helpful in preventing the abnormalities in blood coagulation that occurred during the first week of life.[229] The link between VK deficiency and spontaneous hemorrhage was first recognized in chicks in 1929.[231] The association between VK deficiency and HDN quickly followed, as subsequently did treatment of infants with HDN.[62,232-234]

The next historical step was recognition of the link between decreased prothrombin activity and increased

PT on days 2 to 4 of life in the absence of prophylactic VK. Prothrombin activity was observed to return to normal by days 5 to 7 of life.[62,235-238] These observations led to the hypothesis that VK administered prophylactically could prevent HDN.[235,236,239-241] There was uniform agreement that the prophylactic administration of VK to mothers or infants prevented the decrease in prothrombin activity during the first 3 to 4 days of life.[62,234,235,239] On the basis of these studies, VK prophylaxis was widely recommended. Subsequently, the scientific basis for this policy became less clear for several reasons. First, plasma concentrations of other coagulation proteins in addition to prothrombin were shown to be low in newborns. Second, there was increasing recognition that bleeding in neonates was often not due to VK deficiency.[62,230,242-244] Third, administration of high amounts (50 to 70 mg) of a water-soluble form of VK resulted in hemolytic anemia with kernicterus in some infants.[62,245,246] Fourth, many clinicians suggested that VK prophylaxis was not needed for all healthy full-term infants.[244,247-249] Consequently, VK prophylaxis was suspended in some countries, and recurrence of HDN ensued.[62,236,250-261] Most of the controversy concerning prophylactic use of VK can be explained by the design of the trials and subsequent interpretation of their results. The best evidence comes from large randomized, placebo-controlled trials. Such trials have consistently shown a statistically significant benefit from VK prophylaxis in terms of clinical bleeding.[262-264] No randomized, controlled trials with large enough sample size have shown that prophylactic VK does not prevent bleeding.

Prophylactic Vitamin K Administration

VK exists in three forms: VK_1 (phytonadione), which is present in leafy green vegetables; VK_2 (menaquinone), which is synthesized by intestinal bacterial flora; and VK_3 (menadione), which is a synthetic, water-soluble form. VK_3 is rarely used in newborns because at high doses it causes hemolytic anemia, which results in jaundice and potential morbidity.[62,245,246] The recommendations for VK prophylaxis in many countries are reasonably similar.[46] Daily requirements of VK are approximately 1 to 5 µg/kg of body weight for newborns.[46] Most groups recommend a single dose of 0.5 to 1 mg intramuscularly or an oral dose of 2 to 4 mg at birth, with subsequent dosing for breast-fed infants. Oral VK prophylaxis is preferable to parenteral prophylaxis; studies have shown that oral administration of VK is as effective, less expensive, and less traumatic than intramuscular administration in preventing the classic signs and symptoms of VK deficiency.[46] However, orally administered VK_1 or VK_3 is not as effective as intramuscularly injected VK in the prevention of late VK deficiency. In a 1991 randomized, controlled trial in Thailand, infants were given a single 2-mg dose of VK orally, 5 mg orally, or 1 mg intramuscularly.[265] Although mean levels of VK_1 were not significantly different in the treated infants given the various dosage forms, a trend toward higher levels was observed in intramuscularly

treated infants. Strategies for preventing late VK deficiency include repeat administration of oral VK[260,266] or continuous low-dose VK supplementation.[260] A mixed micelle oral VK_1 preparation that is readily absorbed has been tested in children.[46] However, optimal dosing of this preparation to prevent late VK deficiency bleeding remains to be determined.[267]

In addition to general prophylaxis at birth, patients in certain risk groups require additional VK prophylaxis (e.g., infants with α_1-antitrypsin deficiency, chronic diarrhea, cystic fibrosis, or celiac disease). Pregnant women receiving oral anticonvulsant therapy should take 10 mg of oral VK_1 daily beginning at 36 weeks' gestation for the prevention of overt VK deficiency in their infants at birth.[59]

In 1990, a cohort study aimed at determining perinatal risk factors for childhood cancer reported an association between drugs administered in the peripartum period (maternal pethidine or neonatal VK) and childhood cancer (odds ratio, 2.6).[268] A subsequent case-control study by the same group found no association between maternal pethidine and childhood cancer; however, they again reported an increased risk of childhood cancer after neonatal intramuscular VK administration (odds ratio, 1.97).[269] In contrast, a later large case-control study of 2530 children with cancer, one ecologic study, and one meta-analysis have shown no association between VK administration and childhood cancer.[270,271] The current consensus of the American Academy of Pediatrics Committee on Fetus and Newborn is that the risk for increased childhood cancer is probably minimal, if any, and the benefits of VK prophylaxis in terms of reduced bleeding are substantial.[272]

Bleeding Caused by Vitamin K Deficiency in the Newborn

In the absence of prophylactic VK, the incidence of vitamin K–dependent bleeding (VKDB) ranges from 0.25% to 1.7%.[62,262] Infants are at greater risk for hemorrhagic complications from VK deficiency than similarly affected adults are because their plasma concentrations of VK-dependent factors are physiologically decreased.[17,19,23,62,261,273] The clinical manifestation of VKDB can be classified as classic, early, or late on the basis of the timing and type of complications (Table 5-11). Classic VKDB initially occurs on days 2 to 7 of life in breast-fed, healthy full-term infants.[54,62,256,273-276] Causes include poor placental transfer of VK,[45,47-49] marginal VK content in breast milk (<20 µg/L), inadequate milk intake, and a sterile gut.[62] VKDB rarely occurs in formula-fed infants because commercially available formulas are supplemented with VK.[277,278] How often classic VKDB occurs in the absence of VK prophylaxis depends on the population studied, the supplemental formula, and the number of mothers breast-feeding. Early VKDB develops in the first 24 hours of life and is linked to maternal use of specific medications that interfere with VK stores or func-

*More common in Southeast Asia.
†A single intramuscular injection is better than a single oral dose; repeated small doses are closer to physiologic conditions.

tion, such as some anticonvulsants.[279-281] Late VKDB occurs between weeks 2 and 8 of life and is linked to disorders that compromise ongoing VK supply.[282,283]

Laboratory Diagnosis of Vitamin K Deficiency in the Newborn

Laboratory tests used to detect VK deficiency include screening coagulation tests, specific factor assays, measurement of decarboxylated forms of VK-dependent factors, PIVKA (protein induced by VK antagonists) assays, and direct measurements of VK levels. The results of these tests must always be compared with values for age-matched, healthy, non–VK-deficient infants to distinguish physiologic and pathologic deficiencies.[55,284]

Treatment

An infant suspected of having VK deficiency should be treated immediately with VK while laboratory confirmation is awaited. All infants with VKDB should be given VK either subcutaneously or intravenously, depending on the clinical problem. VK should not be given intramuscularly to infants with VKDB because large hematomas may form at the site of the injection. Absorption of subcutaneously administered VK is rapid, and its effect occurs only slightly slower than that of systemically administered VK. Intravenous VK should be given slowly and with a test dose because it may induce an anaphylactoid reaction. Infants with major bleeding because of

VK deficiency should also be treated with plasma products to rapidly increase levels of VK-dependent proteins. Plasma is the product of choice for treatment of a non–life-threatening hemorrhagic event, whereas PCCs should be considered for the management of life-threatening bleeding.

Liver Disease

The coagulopathies associated with liver disease in newborns are similar to those of adults and reflect the failure of hepatic synthetic function. However, in newborns this problem may be superimposed on the already "physiologic" immaturity of the coagulation system, activation of the coagulation and fibrinolytic systems, poor clearance of activated coagulation factors, and loss of hemostatic proteins into ascitic fluid.[285] Secondary effects of liver disease on platelet number and function also occur in newborns.[286,287] Common causes of hepatic dysfunction in newborns include viral hepatitis, hypoxia, total parenteral nutrition, shock, and fetal hydrops. Rare causes include genetic diseases such as α_1-antitrypsin deficiency,[288] galactosemia,[289] and tyrosinemia.[290]

Laboratory abnormalities induced by acute liver disease include prolongation of the PT and low plasma concentrations of several coagulation proteins, including fibrinogen.[291,292] However, it is important to compare these levels with those of normal age-matched controls

(see Tables 5-1 to 5-3) because some of these factors are considerably lower than the adult range. Fibrinogen is present at adult levels in newborns and may be a useful marker. Chronic liver failure with cirrhosis is also characterized by a coagulopathy and mild thrombocytopenia.[288-290,293] Secondary VK deficiency may occur as a result of impaired absorption from the small intestine, particularly in those with intrahepatic and extrahepatic biliary atresia.[294] Patients with clinical bleeding may benefit temporarily from replacement of coagulation proteins with FFP, cryoprecipitate, or exchange transfusion. However, without recovery of hepatic function, replacement therapy is futile. VK should be administered to infants in whom cholestatic liver disease is suspected.

von Willebrand Disease

Although von Willebrand disease (VWD) is the most common inherited bleeding disorder, patients with the disease are rarely seen in the neonatal period. Plasma concentrations of VWF are increased in neonates, as is the proportion of ULVWF multimers.[73,74] Nonetheless, severe deficiency (type 3) and some qualitative VWF disorders (type 2) have been reported in the newborn period.[295-298] Management of VWD is discussed in detail in Chapter 30. Use of arginine vasopressin (DDAVP) in the newborn period is contraindicated because of associated excess free water retention.

Platelet Disorders

Quantitative Platelet Disorders

Healthy full-term infants have platelet counts within the normal adult range (150 to 450×10^9/L).[62,86] Healthy premature infants typically have platelet counts in the low end of the normal adult range.[62,83,84] The definition of thrombocytopenia in newborns is the same as that in adults: a platelet count less than 150×10^9/L. Studies of fetuses between 18 and 30 weeks' gestation show a stable platelet count of approximately 250×10^9/L.[2] Consequently, platelet counts less than 150×10^9/L are abnormal and indicate the need for investigation and, sometimes, treatment. Mean volumes of platelets in newborns are similar to those of adults (range, 7 to 9 fL).[86-88] Postnatally, MPV increases slightly over the first 2 weeks of life, concomitantly with an increase in platelet count.[89,90]

Epidemiology. Thrombocytopenia is the most common hemostatic abnormality in newborns admitted to neonatal intensive care units (NICUs).[83,85,87,88,299] A single prospective cohort study[87] and six retrospective reviews[88,300-304] have provided the most reliable information on the occurrence, natural history, mechanisms, and clinical impact of thrombocytopenia in newborns. There is general agreement that thrombocytopenia indicates the presence of an underlying pathologic process; however, the clinical relevance of mild thrombocytopenia is unknown. Thrombocytopenia develops in approximately 22% of infants admitted to the NICUs of tertiary hospitals.[87] In some infants the thrombocytopenia is trivial, with platelet counts between 100 and 150×10^9/L. However, in 50% of affected infants, platelet counts decrease to less than 100×10^9/L, and in 20% of infants, platelet counts are lower than 50×10^9/L.[87] What constitutes a safe platelet count in a neonate remains to be rigorously determined, but many neonatal units attempt to keep the platelet count higher than 50×10^9/L, although this figure may vary, depending on the postconceptional age of the infant and comorbid conditions.

Pathogenesis. Causes of thrombocytopenia in neonates, like those in older children and adults, can be divided into disorders involving increased platelet destruction, decreased platelet production, or sequestration (Box 5-1). Although many of these causes overlap with those seen in older children and adults, several entities are unique to neonates or may occur in the newborn period and are considered in more detail later. Increased platelet destruction is the mechanism responsible for thrombocytopenia in most infants.[87,305] Characterization of mechanisms responsible for thrombocytopenia is important because they have practical implications in assessing the risk for bleeding and in guiding management.

Increased Platelet Destruction. Thrombocytopenia secondary to increased platelet destruction can be divided into immune and nonimmune causes.

IMMUNE THROMBOCYTOPENIA. Immune thrombocytopenia is defined as an increased rate of platelet clearance caused by platelet-associated immunoglobulin G (IgG) or complement. It is the most common form of increased platelet destruction in newborns and should always be suspected in otherwise healthy infants with isolated severe thrombocytopenia. Neonatal immune thrombocytopenia can be further broken down into one of three processes: transplacental passage of a maternal antibody directed against a nonshared platelet antigen (termed "alloimmune thrombocytopenia" or sometimes "isoimmune thrombocytopenia"), transplacental passage of a cross-reactive maternal autoimmune-derived antiplatelet antibody, or generation of an autoreactive antiplatelet antibody by the newborn itself (termed "autoimmune thrombocytopenia"). The second can be distinguished from the other two by examining the mother for a low platelet count. Differentiation of autoimmune thrombocytopenia from alloimmune thrombocytopenia in neonates is critical because the management and severity of these disorders are quite different. Chapter 33 discusses these two forms of immune thrombocytopenia and their management in detail.

Neonatal Alloimmune Thrombocytopenia. Neonatal alloimmune thrombocytopenia (NAIT) is the most common cause of immune-mediated thrombocytopenia in the newborn period, with an estimated incidence of about 1 in 1000 to 5000 live births in white popula-

Box 5-1	Causes of Thrombocytopenia in Newborns

INCREASED DESTRUCTION OF PLATELETS

Immune Mediated

Neonatal alloimmune thrombocytopenia
Maternal idiopathic thrombocytopenic purpura
Drug-dependent antibody (could be from maternal medication use)
Autoimmune thrombocytopenic purpura

Non–Immune Mediated

Pseudothrombocytopenia (platelet clumping) in vitro
Disseminated intravascular coagulation
Asphyxia
Perinatal aspiration
Necrotizing enterocolitis
Hemangiomas (Kasabach-Merritt syndrome)
Neonatal thrombosis
Respiratory distress syndrome
Maternal preeclampsia
Cardiopulmonary bypass (including ECMO)
Familial thrombotic thrombocytopenic purpura

Other

Hyperbilirubinemia
Phototherapy
Polycythemia
Rh hemolytic disease
Total parenteral nutrition

DECREASED PRODUCTION OF PLATELETS

Acquired

Viral infection (e.g., HIV, CMV, Rubella, HHV-6)
Congenital leukemia
Down syndrome–transient myeloproliferative disorder (DS-TMD)
Neuroblastoma

Histiocytosis
Osteopetrosis

Inherited

Disorders associated with small platelets
　Wiskott-Aldrich syndrome (WAS)
　X-linked thrombocytopenia (associated with WASP)
Disorders associated with normal-sized platelets
　Thrombocyopenia with absent radii (TAR)
　Amegakaryocytic thrombocytopenia with radioulnar synostosis
　Congenital amegakaryocytic thrombocytopenia (CAMT)
　Familial platelet disorder with a propensity for the development of AML (FPD/AML)
Disorders associated with large platelets
　X-linked macrothrombocytopenia with or without anemia (GATA-1 mutations)
　MYH9-related disorders (May-Hegglin anomaly; Sebastian's, Fechtner's, and Epstein's syndromes)
　Bernard-Soulier syndrome
　Paris-Trousseau/Jacobsen syndrome
　Velocardiofacial syndrome
　Montreal platelet syndrome
　Gray platelet syndrome
　Platelet-type or pseudo–von Willebrand disease
Other
　Fanconi's anemia
　Metabolic disorders (methylmalonic academia, ketotic glycinemia, isovaleric academia, etc.)
　Drug-mediated suppression

SEQUESTRATION

Hypersplenism

tions.[306-309] It arises when the mother, who lacks a common platelet antigen, is exposed to the antigen (inherited from the father) on neonatal platelets and generates a neutralizing IgG. This crosses the placenta and mediates premature clearance of fetal and newborn platelets. First-born infants can be affected. Frequently, the thrombocytopenia is severe. It is critical to make the diagnosis because the risk of life-threatening bleeding and CNS morbidity is high, estimated at up to 10% to 15% of cases. A useful diagnostic test is to assay the reactivity of the mother's serum with the father's platelets. If such samples are not available, it is possible to look for reaction of the mother's serum with the newborn's platelets or the presence of antiplatelet antibodies in the newborn's serum. The most common antigen is Pl[A1], although other antigens, such as Bak[a], Pen[a] (more common in Asian populations), Br[b],

and Br[a], have been described.[310] However, not all cases in which the pregnant mother generates allosensitive antiplatelet antibodies result in neonatal thrombocytopenia.

Treatment of NAIT includes transfusion with washed platelets donated by the mother. Because the mother's platelets lack the offending antigen, they should have a normal life span. Many blood banks also maintain registries of Pl[A1]-negative donors who can be contacted for platelet donation in cases involving antibodies against Pl[A1]. If antigen-negative platelets are not available, treatment with intravenous immunoglobulin (IVIG), 1 g/kg as a single daily bolus for 1 or 2 consecutive days, along with random donor platelets if the patient is bleeding, is effective in reducing the rate of platelet destruction. Endogenous platelet counts typically rise by 36 to 48

hours. There is no role for corticosteroids because all of the antibody production occurs in the mother. All infants with NAIT should undergo head ultrasonography or CT to rule out ICH. The natural history of NAIT is gradual resolution of the thrombocytopenia over the first few months of life as the offending antibody is cleared. Close monitoring of the platelet count is indicated for at least the first month of life until the platelet count normalizes. The safety of breast-feeding in the setting of NAIT has not been rigorously studied. One case report suggested that breast-feeding did not significantly worsen the clinical course, even though the breast milk contained anti-platelet IgG.[311]

Immune Thrombocytopenia Caused by Maternal Antiplatelet Autoantibodies. Maternal autoimmune anti-platelet IgG can cross the placenta and result in increased platelet destruction in the fetus. A common cause is maternal systemic lupus erythematosus. Like NAIT, the thrombocytopenia gradually resolves over the first few months of life as the maternal antibodies are cleared. In severe cases, use of IVIG in the neonate may help reduce the rate of platelet destruction. Corticosteroids are of no utility. Drug-dependent antibodies can result in both maternal and neonatal thrombocytopenia.[109]

Autoimmune Thrombocytopenia. True autoimmune thrombocytopenia, in which neonates generate an antibody against their own platelets, is very rare in the newborn period. If present, it typically signals an underlying immune dysregulatory disorder. If heparin-induced thrombocytopenia is suspected, heparin therapy should be discontinued immediately and alternative forms of anticoagulation considered if necessary (see Chapter 33).

NONIMMUNE THROMBOCYTOPENIA

Sepsis and Disseminated Intravascular Coagulation. A common nonimmune cause of thrombocytopenia in the newborn period is sepsis, with or without DIC. Viral (rubella, herpesvirus, echovirus, cytomegalovirus, human herpesvirus 6 [HHV-6], and human immunodeficiency virus [HIV]), protozoal (*Toxoplasma*), and bacterial infections cause severe thrombocytopenia.[312] Mechanisms responsible for bacterial sepsis–induced thrombocytopenia are multifactorial and include consumption resulting from DIC, endothelial damage, platelet aggregation caused by binding of bacterial products to platelet membranes, and decreased production as a result of marrow infection.[313] Mechanisms responsible for virus-induced thrombocytopenia include loss of sialic acid from platelet membranes because of viral neuraminidase, intravascular platelet aggregation, and impaired megakaryopoiesis (see later). Congenital rubella causes thrombocytopenia in three quarters of infants, with platelet counts ranging from 20 to 60×10^9/L for the first 4 to 8 weeks of life.

In premature infants, thrombocytopenia often complicates other disorders such as RDS, persistent pulmo-nary hypertension, necrotizing enterocolitis, and hyperbilirubinemia treated by phototherapy. Activation of coagulation with platelet consumption occurs in RDS, and mechanical ventilation may be an independent factor contributing to thrombocytopenia.[314] It has been suggested that persistent pulmonary hypertension in newborns may be due in part to intrapulmonary platelet aggregation and the release of platelet-derived vasoactive substances such as thromboxane A_2.[315] Approximately half of infants with necrotizing enterocolitis are thrombocytopenic, with about 20% having laboratory evidence of DIC.

Exchange Transfusion, Hyperbilirubinemia, and Phototherapy. Intrauterine and exchange transfusions cause thrombocytopenia by a dilutional effect that depends on the amount of blood transfused.[301] After exchange transfusion, platelet counts increase within 3 days and reach pre-exchange levels by about 7 days.[34] Both hyperbilirubinemia and phototherapy are associated with mild thrombocytopenia in newborn humans and shortened platelet survival in rabbits.[305]

Hypoxia and Placental Insufficiency. Acute asphyxia is a consistent cause of DIC and thrombocytopenia.[93] Chronic hypoxia is associated with placental dysfunction, intrauterine growth retardation, and significant thrombocytopenia.

Vascular Malformations. Certain types of large vascular malformations are associated with Kasabach-Merritt syndrome, in which a local consumptive coagulopathy occurs as a result of abnormal endothelium. This causes hypofibrinogenemia, elevated levels of fibrinogen-fibrin degradation products, microangiopathic fragmentation of red cells, and thrombocytopenia (see Chapter 33).[316-320] The thrombocytopenia can be severe, with platelet counts lower than 50×10^9/L. Approximately 50% of affected infants experience systemic bleeding during the first month of life. Sometimes the vascular malformations are not apparent on physical examination and may require imaging studies to detect.

Thrombosis and Familial Thrombotic Thrombocytopenic Purpura. Thrombocytopenia is loosely associated with thromboembolic complications and polycythemia in infants with hematocrit values greater than 70%. However, thrombocytopenia may also indicate the presence of other concurrent disease processes. Infants with a familial form of hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura have a microangiopathic hemolytic anemia in association with transient neurologic or renal abnormalities.

Decreased Platelet Production. Thrombocytopenia secondary to decreased platelet production is rare and accounts for less than 5% of thrombocytopenic infants.[34,83-85] Causes include viral infections, drug-induced thrombocytopenia, congenital leukemia, DS-TMD, neuroblastoma, histiocytosis, osteopetrosis, congenital amegakaryocytic thrombocytopenia (CAMT), TAR,

other inherited genetic platelet disorders, and bone marrow failure syndromes.

CONGENITAL VIRAL INFECTION. Congenital viral infections with rubella, herpesvirus, echovirus, cytomegalovirus, HHV-6, and HIV have been associated with thrombocytopenia in the newborn period, in part through deleterious effects on megakaryopoiesis and thrombopoiesis. It may occur via direct infection of megakaryocytes in the case of HIV because the HIV coreceptor CXCR4 is expressed on the surface of human megakaryocytes and their precursor cells.[321]

DRUG-INDUCED THROMBOCYTOPENIA. Transplacental passage of drugs or the use of drugs in neonates can cause thrombocytopenia via bone marrow suppression or the development of drug-dependent antibodies, or both.[109] However, these causes are rare, and evidence for them is weak.[322-325] Agents implicated are salicylates, quinine, hydralazine, tolbutamide, and thiazide diuretics.

CONGENITAL LEUKEMIA AND OTHER MALIGNANCIES. Infantile leukemia, as well as other neonatal malignancies characterized by bone marrow infiltration such as neuroblastoma, can be accompanied by thrombocytopenia in the newborn period. Typically, other hematopoietic lineages are affected and other clinical signs are apparent. An infantile form of myelofibrosis has been described is several families in Saudi Arabia.[326,327]

DOWN SYNDROME–TRANSIENT MYELOPROLIFERATIVE DISORDER. Some children with Down syndrome (trisomy 21) are born with a transient myeloproliferative disorder (DS-TMD) characterized by leukocytosis, predominance of circulating early erythromegakaryocytic precursor cells, pancytopenia, and in some cases, severe liver fibrosis. Remarkably, this myeloproliferation resolves spontaneously over the first few months of life. In about 20% of symptomatic cases, acute megakaryocytic leukemia (DS-AMKL) develops within a few years, sometimes preceded by a myelodysplastic phase.[328] The DS-TMD and DS-AMKL cells harbor acquired mutations in the gene encoding GATA-1, a zinc finger transcription factor essential for normal megakaryocyte and erythroid development.[329-335] Although a wide spectrum of mutations have been identified, including missense, deletion, insertion, and splice site mutations, they essentially all result in the same outcome: exclusive production of a short isoform of GATA-1 that lacks the amino-terminal 83 amino acids of the full-length protein (Fig. 5-3). These mutations are highly specific for DS-TMD and DS-AMKL. There has been only one reported case of such a mutation in AMKL without trisomy 21.[336] Why these mutations are so highly selected for in a Down syndrome genetic background and how they may participate in the pathogenesis of DS-TMD and DS-AMKL are not known.
FIGURE 5-3. Acquired mutations of GATA-1 in Down syndrome–transient myeloproliferative disorder and acute megakaryoblastic leukemia. In this schematic diagram of full-length GATA-1, mutations are represented by *asterisks*. Introduction of premature stop codons, or splicing around exon 2, results in exclusive generation of a shorter isoform of GATA-1 (GATA-1s) because of initiation of translation from a downstream in-frame ATG at codon 84. AD, classic transcriptional activation domain; C, C-terminal zinc finger; N, N-terminal zinc finger.

Knock-in mice that recapitulate the truncating GATA-1 mutation show unexpected stage-specific effects on megakaryopoiesis.[81] During fetal liver hematopoiesis, the mutant megakaryocytes markedly hyperproliferate, similar to what is observed for GATA-1–deficient megakaryocytes. However, during adult-stage bone marrow hematopoiesis, megakaryopoiesis and thrombopoiesis appear to be normal. This suggests that the fetal liver and bone marrow cellular contexts interact differentially with the GATA-1–truncated molecule, which may explain restriction of TMD to the neonatal period and infers that additional genetic events occur and lead to clonal evolution of a rare TMD cell to full DS-AMKL.[337]

INHERITED PLATELET DISORDERS

Though considerably less common than consumptive processes or viral suppression, inherited platelet disorders can occur in the newborn period and should be considered in the differential diagnosis of thrombocytopenia in a neonate. They are discussed in more detail in Chapter 29. Several classifications, diagnostic algorithms, and management recommendations have recently been published.[338,339] Brief descriptions, with particular focus on neonatal manifestations, are given here. Infants with aplastic disorders have the greatest risk of serious bleeding in the form of ICH in the first months of life.

DISORDERS WITH SMALL PLATELETS. Wiskott-Aldrich Syndrome. Wiskott-Aldrich syndrome (WAS; OMIM 301000) is an X-linked disorder caused by deficiency of the Wiskott-Aldrich syndrome protein (WASP), which functions in actin dynamics in megakaryocytes and T lymphocytes. It is one of the few disorders characterized by small platelets. The small size of the platelets is not always apparent by standard automated blood cell MPV measurements. Therefore, if the diagnosis is being considered, it is imperative to evaluate platelet size by examination of the peripheral smear and to confirm small

platelet volume with cytometer devices calibrated for platelets. The other clinical hallmarks of WAS are immunodeficiency (usually severe) and eczema. Bloody diarrhea is often seen and can be an initial sign. The immunodeficiency is frequently the most significant clinical problem associated with this disease. It is important to recognize the syndrome early so that appropriate interventions can be instituted, including prophylactic treatment against opportunistic infections such as *Pneumocystis carinii*. A destructive component of the thrombocytopenia in WAS is also likely because splenectomy increases platelet counts in a large number of patients. In addition, the thrombocytopenia can be exacerbated by development of immune thrombocytopenic purpura secondary to the immune dysregulation. Bone marrow transplantation is curative for WAS, and early diagnosis is helpful in initiating listing for transplantation before significant complications arise.

X-Linked Thrombocytopenia. X-linked thrombocytopenia (OMIM 313900) is a less severe form of WAS that is manifested predominantly as thrombocytopenia. Typically, there is no or minimal immunologic dysfunction. However, more severe immunologic disturbances may develop in some patients over time. This clinical entity is distinct from X-linked macrothrombocytopenia, which is associated with mutations in GATA-1 (see later).

DISORDERS WITH NORMAL-SIZE PLATELETS. Congenital Amegakaryocytic Thrombocytopenia. CAMT (OMIM 604498) is characterized by severe thrombocytopenia with a markedly reduced number or absence of megakaryocytes. Patients are typically seen shortly after birth with petechiae, bruising, or bleeding. Biallelic inactivating mutations in the gene for c-mpl, the receptor for the major megakaryocyte cytokine TPO, have been identified in a large number of patients. Interestingly, no patients have been reported to date with mutations in the TPO gene itself. Patients with severe CAMT are at high risk for the development of complete bone marrow failure, usually within the first few years of life.[340] Such failure is most likely due to a role of TPO signaling in hematopoietic stem cell function.[341,342] Bone marrow transplantation has been used successfully to treat patients with severe CAMT.

Thrombocytopenia with Absent Radii. TAR syndrome (OMIM 274000) is characterized by hypomegakaryocytic thrombocytopenia and bilateral radial hypoplasia with the presence of thumbs.[343] Other hematopoietic lineages are not affected. Additional skeletal features may include shortening or, rarely, aplasia of the humerus and ulna. The lower limbs are frequently affected, but to a lesser extent. Congenital cardiac disease and cow's milk intolerance have also been associated in some cases. The genetic basis of TAR is unknown. The inheritance pattern is unclear, but some have suggested an autosomal recessive pattern. Recently, Klopocki and colleagues

identified a common interstitial microdeletion of 200 kilobases (kb) on chromosome 1q21.1 in several families with TAR.[344] However, the incomplete penetrance of the phenotype suggests that additional genetic loci may be involved. Patients with TAR have elevated circulating TPO levels, and their platelets exhibit defective TPO receptor (c-mpl) signaling, which suggests a possible role for downstream cytokine signaling in this disorder.[345]

Neither splenectomy nor steroids are beneficial for infants with TAR.[346,347] Platelet transfusions are highly effective but should be reserved for symptomatic infants because prophylactic platelet transfusions could result in refractoriness as a result of allosensitization.[347] By several months of age, increased numbers of megakaryocytes usually appear in the bone marrow, and platelet counts increase.[346,347] A functional platelet defect may be present in some children with TAR.[348]

Amegakaryocytic Thrombocytopenia with Radioulnar Synostosis. Amegakaryocytic thrombocytopenia with radioulnar synostosis (ATRUS, OMIM 605432) is a rare disorder characterized by reduced or absent megakaryocytes, severe thrombocytopenia, possible aplastic anemia, and proximal radioulnar synostosis leading to difficulty with forearm pronation. Sensorineural hearing loss may also be present. Mutations in the gene encoding the homeobox containing transcription factor HOXA11 have been found in some familial cases of ATRUS.[349,350]

Familial Platelet Disorder with a Propensity for the Development of Acute Myelogenous Leukemia. Familial platelet disorder with a propensity for the development of acute myelogenous leukemia (AML) (OMIM 601399) is a rare autosomal dominant disorder characterized by thrombocytopenia, an aspirin-like functional platelet defect, and increased risk for the development of myelodysplastic syndrome (MDS) and AML.[351-353] It is caused by constitutional haploinsufficieny of RUNX-1, a transcription factor involved in multiple stages of hematopoiesis, including megakaryopoiesis, and a frequent target of chromosomal translocations in human leukemias.[351,354] Bone marrow or peripheral blood from these patients has reduced ability to form megakaryocyte colonies, thus indicating a role for RUNX-1 dosage in megakaryopoiesis. A family history of MDS or AML should raise suspicion for this disorder in a newborn with thrombocytopenia and bleeding out of proportion to the platelet count.

DISORDERS WITH LARGE PLATELETS. Paris-Trousseau or Jacobsen's Syndrome. Paris-Trousseau syndrome (OMIM 188925) (also called Jacobsen's syndrome; OMIM 147791) is a constitutional contiguous gene deletion disorder involving the long arm of chromosome 11 (11q23).[355,356] The constellation of findings in these syndromes includes severe congenital cardiac abnormalities, trigonocephaly, mental retardation, dysmorphogenesis of the hands and face, and macrothrombocytopenia.[357] The cause of the thrombocytopenia appears to be related to impaired platelet production because platelet survival time is normal.[358] These patients can also exhibit a pre-

disposition to thrombosis, thus suggesting possible qualitative defects in platelet production. Examination of bone marrow reveals significant dysmegakaryopoiesis with an abundance of micromegakaryocytes and death of large numbers of megakaryocytes during the late stages of maturation.[359] Peripheral blood platelets contain giant alpha granules, which are thought to arise from aberrant alpha granule fusion during prolonged residence in bone marrow.[360] The minimal chromosome regions deleted in Paris-Trousseau and Jacobsen's syndromes associated with thrombocytopenia include genes for the Ets family transcription factors FLI-1 and ETS-1, both of which play roles in megakaryocyte development.[361] Lentiviral expression of FLI-1 in CD34+ cells from patients with Paris-Trousseau thrombocytopenia rescues megakaryocyte differentiation in vitro, thereby providing strong evidence that deficiency of FLI-1 is the cause of impaired thrombopoiesis in these patients.

X-linked Macrothromboctyopenia with and without Anemia. Germline missense mutations in the gene encoding GATA-1 have recently been identified in several families with X-linked macrothrombocytopenia.[362] Some of the mutations impair binding of GATA-1 to its essential cofactor Friend of GATA-1.[362-366] Although all the mutations described produce thrombocytopenia to varying degrees, the more severe mutations also result in dyserythropoietic anemia. In the most severe cases, infants have required in utero red blood cell transfusions and bone marrow transplantation after birth.[362] Mutations in the N-terminal zinc finger of GATA-1 that impair binding to double GATA consensus DNA sites are associated with X-linked thrombocytopenia with β-thalassemia,[367-369] congenital erythropoietic prophyria,[370] X-linked gray platelet syndrome, or any combination of these conditions.[371]

Bernard-Soulier Disorder. Bernard-Soulier disorder (OMIM 231200) is caused by deficiency of the GPIb/IX/V complex on platelets, which binds VWF. Most reported mutations have been in the gene encoding the GPIb subunit, but mutations have also been found in GPIX.[372,373] Homozygous deficiency is associated with severe thrombocytopenia, giant platelets, defective ristocetin-induced platelet aggregation, and clinical bleeding. Heterozygous deficiency typically leads to mild thrombocytopenia with normal ristocetin-induced platelet aggregation in vitro and is now thought to be the underlying cause of benign Mediterranean macrothrombocytopenia.[374]

Velocardiofacial Syndrome. Velocardiofacial syndrome (OMIM 192430) is a contiguous gene deletion disorder involving chromosome 22q11.2. Clinical manifestations include cleft palate, cardiac anomalies, typical facies, learning disabilities, and defective GPIb/IX/V function. The platelet effects are due to heterozygous loss of the GPIbα gene, which resides in this region, and the condition should be considered a mild form of Bernard-Soulier disorder.[375]

MYH9-Related Disorders. MYH9-related disorders include May-Hegglin anomaly (OMIM 155100),

Sebastian's syndrome (OMIM 605249), Fechtner's syndrome (OMIM 153640), and Epstein's syndrome (OMIM 153650). All four disorders involve mutations in the gene encoding nonmuscle myosin heavy-chain type IIA (MYH9) and are inherited in an autosomal dominant fashion.[376] They are all associated with giant platelets but differ in the presence of neutrophil inclusions (Döhle bodies), sensorineural hearing loss, cataracts, and renal defects.[338]

Hypersplenism. As in adults, thrombocytopenia resulting from hypersplenism is usually mild to moderate, with platelet counts ranging from 50 to 100 × 10^9/L in newborns.

Clinical Impact of Neonatal Thrombocytopenia. Clinically important bleeding is less likely to occur in patients with consumptive platelet disorders than in those with production defects. The bleeding risk is increased in patients who have both thrombocytopenia and a defect in platelet function. Selection of a platelet count at which one should intervene, though a simplistic response, provides a guideline for therapy. A platelet count less than 50 × 10^9/L places some otherwise healthy full-term newborns at risk for serious ICH.[377] The importance of "moderate" thrombocytopenia (platelet counts between 50 and $100 × 10^9$/L) in sick premature infants has been a subject of controversy. A randomized, controlled trial assessed the potential benefits of platelet concentrate transfusions in 154 premature thrombocytopenic infants during the first 72 hours of life.[378] Treated infants received platelet concentrates to maintain platelet counts higher than 150 × 10^9/L. No beneficial effect on the incidence or extension of ICH was shown in this study, which was designed to detect an effect of 25% or greater. However, infants who received transfusions had shortened bleeding times and required significantly less blood product support. A more recent retrospective study of 53 neonates with severe thrombocytopenia treated at a single NICU showed no significant difference in major hemorrhage in those transfused to maintain a platelet count greater than $30 × 10^9$/L versus greater than $50 × 10^9$/L.[304]

Treatment. Management of thrombocytopenic infants depends in part on the underlying disorder. If an infant is bleeding, a trial of platelet concentrates (10 to 20 mL/kg) is indicated. The increased platelet count usually shortens the bleeding time and is frequently clinically effective.[116] Autoimmune and alloimmune thrombocytopenia typically does not respond to random donor platelet concentrates and requires specific forms of therapy.

Thrombocytosis in the Newborn. Elevated platelet counts are frequently observed in premature infants at approximately 4 to 6 weeks after birth.[379] There are no clinical manifestations of neonatal thrombocytosis, and therapeutic intervention is not indicated.

Qualitative Platelet Disorders

Despite the physiologic hyporeactivity of neonatal platelets in response to exposure to some agents, healthy infants do not have an increased risk of bleeding. Pathologic impairment of platelet function may occur, to a variable extent, as a result of the use of certain drugs or the presence of pathologic states in either mothers or infants. In mothers, causative factors include the use of some drugs, diabetes,[380-383] dietary abnormalities,[384-389] smoking,[390-392] and ethanol abuse[393]; in infants, they include the use of some drugs, perinatal aspiration syndrome,[301,394-397] hyperbilirubinemia,[398,399] phototherapy,[399,400] renal failure,[401] and hepatic failure.

Phototherapy. When platelets are exposed to a broad-spectrum blue fluorescent light in vitro, aggregation is decreased and microscopic alterations in granules and external membranes occur.[402]

Medications

Aspirin. Salicylate crosses the placenta and can be detected in fetuses after maternal ingestion.[322-325,403-407] Clearance of salicylate is slower in newborns than in adults, and thus infants have a potential risk of bleeding for a prolonged time.[323] However, in vitro studies have not demonstrated increased sensitivity of newborn platelets to salicylates as compared with adult platelets,[118,405] and the evidence linking maternal aspirin ingestion to clinically important bleeding in newborns is weak.[325] There is little reason to have serious concerns about maternal ingestion of aspirin, but it is reasonable to advise mothers to not ingest aspirin unless specifically indicated by their physician.

Indomethacin. Indomethacin is used for nonsurgical closure of a patent ductus arteriosus in premature infants, but it also has antiplatelet activities. Indomethacin, like salicylate, has a longer half-life in newborns than in adults (21 to 24 hours in newborns versus 2 to 3 hours in adults).[408] This extended half-life is probably due to underdevelopment of hepatic drug metabolism or renal excretory function or to altered protein binding.[409,410] Indomethacin inhibits platelet function in newborns, as shown by prolongation of bleeding times.[411,412] Randomized, controlled trials have provided conflicting conclusions on the effect of indomethacin on intraventricular hemorrhage in premature infants.[413]

Maternal Diabetes. The reactivity of platelets from diabetic mothers and their infants is increased, as demonstrated by enhanced thromboxane B_2 production, enhanced platelet aggregation,[382,414] and a lower threshold to many aggregating agents.[414] The enhanced platelet function in diabetes is associated with increased synthesis of a prostaglandin E–like substance that crosses the placenta and affects the fetus.[415] Despite these in vitro findings, the evidence linking enhanced platelet reactivity to clinically significant thromboembolism in newborns of diabetic mothers is weak.[416,417]

Diet. Alterations in the diet of mothers or infants during the postnatal period can affect newborn platelet function. Increases in the ratio of polyunsaturated fatty acids to saturated fatty acids in the diet of mothers who breast-feed their infants result in increases in the concentration of linoleic acid and enhanced thromboxane B_2 production.[384] Infants receiving a diet deficient in essential fatty acids may exhibit arachidonic acid depletion and platelet dysfunction.[385,387] Vitamin E functions as an antioxidant and as an inhibitor of platelet aggregation/release in humans.[388,389,418,419] Instances of vitamin E–deficient infants with increased platelet aggregation that reversed after vitamin E supplementation have been reported.[389,420]

Amniotic Fluid. Amniotic fluid contains procoagulant activity that enhances the generation of thromboxane A_2 by platelets.[394-397] Infants in whom perinatal aspiration syndrome develops have pulmonary hypertension with platelet thrombi in the pulmonary microcirculation. The exact mechanism or mechanisms leading to persistent pulmonary hypertension in these infants is unknown.

Nitric Oxide. Nitric oxide prevents adhesion of platelets to endothelial cells and inhibits ADP-induced aggregation of cord platelets in a manner similar to that in adults.[421-424]

Extracorporeal Membrane Oxygenation. Extracorporeal membrane oxygenation (ECMO) permits transfer of oxygen into blood across a semipermeable membrane and is currently used for infants with life-threatening severe respiratory insufficiency. Underlying respiratory disorders include meconium aspiration syndrome, severe RDS, congenital diaphragmatic hernia, persistent pulmonary hypertension, and sepsis. Hemorrhage, particularly ICH, is one of the most serious complications of this technique. Hardart and Fackler reported an overall incidence of new ICH of about 10% in infants included in the Extracorporeal Life Support Organization Registry ($N = 4550$) from 1992 through 1995.[425] Of 1398 evaluable premature infants (born at <37 weeks' EGA) reported to the registry between 1992 and 2000, ICH developed in 13%.[426] Similar to that found with cardiopulmonary bypass, the increased risk of bleeding during ECMO is due mostly to the use of heparin in combination with other hemostatic defects, including significantly decreased plasma concentrations of coagulation factors and platelet dysfunction secondary to chronic activation.[427-429] Other recognized contributing factors include prolonged hypoxia, ischemia, general anesthesia, acidosis, sepsis, and treatment with epinephrine.[425,427,430-435] In premature infants, the risk for ICH with ECMO correlates inversely with postconceptional age.[426] Although

anticoagulation is required for ECMO, the optimal use of heparin has never been tested in clinical trials. Whether lower doses of heparin or the use of low-molecular-weight heparin (LMWH) has a role in ECMO remains to be determined.

Thrombotic Disorders in the Neonate

Congenital Prothrombotic Disorders

Patients with heterozygous defects for recognized inherited prothrombotic disorders are rarely seen with their first thromboembolic complication during childhood unless another pathologic event unmasks the problem. In contrast, patients who are homozygotes or double heterozygotes for a congenital prothrombotic disorder are often initially encountered in the newborn period or during early childhood. The following discussion is limited to the unique aspects of these inherited deficiencies in newborns. Chapter 32 discusses congenital prothrombotic disorders in detail.

Homozygous Prothrombotic Disorders

Though rare, the most commonly reported homozygous prothrombotic disorder encountered during the newborn period is protein C deficiency. Homozygous protein S deficiency is even less common.[436-458] All patients seen in the newborn period had undetectable levels of protein C (or protein S), whereas children with a delayed manifestation had detectable levels ranging between 0.05 and 0.20 U/mL.

Clinical Findings. The classic clinical manifestation of homozygous protein C/protein S deficiency consists of cerebral or ophthalmic damage (or both) in utero, purpura fulminans within hours or days of birth, and on rare occasion, large vessel thrombosis. Purpura fulminans is an acute, lethal syndrome of DIC characterized by rapidly progressive hemorrhagic necrosis of the skin secondary to dermal vascular thrombosis.[459-461] The skin lesions start as small, ecchymotic sites that increase in radial fashion, become purplish black with bullae, and then turn necrotic and gangrenous.[459,461] The lesions develop mainly on the extremities but can occur on the buttocks, abdomen, scrotum, and scalp. They also occur at pressure points, at sites of previous puncture, and at previously affected sites. Moreover, affected infants have severe DIC with hemorrhagic complications.

Diagnosis. The diagnosis of homozygous protein C/protein S deficiency in infants is based on the appropriate clinical picture, a protein C/protein S level that is usually undetectable, a heterozygous state in the parents, and ideally, identification of the molecular defect. The presence of very low levels of protein C/protein S in the absence of clinical manifestations and a family history cannot be considered diagnostic because physiologic plasma levels can be as low as 0.12 U/mL. Homozygous forms of ATIII (or heparin cofactor II) deficiency have not been confirmed in newborns, but one would anticipate that affected infants might have life-threatening thromboembolic complications. Molecular diagnosis is available for identified families (see Chapter 32).

Initial Treatment. The diagnosis of homozygous protein C/protein S deficiency is usually unanticipated and made at the time of clinical evaluation. Although numerous forms of initial therapy have been used, 10 to 20 mL/kg of FFP every 6 to 12 hours is usually the form of therapy that is most readily available.[462] Plasma levels of protein C achieved with these doses of FFP vary from 15% to 32% 30 minutes after the infusion and from 4% to 10% at 12 hours.[447] Plasma levels of protein S (which was entirely bound to C4b) were 23% at 2 hours and 14% at 24 hours, with an approximate half-life of 36 hours.[463]

A protein C concentrate (Ceprotin) has recently received FDA approval for use in treating congenital protein C deficiency. Recommended initial doses for acute thrombotic episodes and short-term prophylaxis in patients with severe protein C deficiency are 100 to 120 IU/kg in neonates, with subsequent doses of 60 to 80 IU/kg every 6 hours and maintenance doses of 45 to 60 IU/kg thereafter every 6 to 12 hours. However, dosing should be adjusted to maintain peak protein C activity of 100%. After resolution of the acute event, the patient should continue on a dose to maintain the trough protein C activity level above 25% for the duration of treatment. Replacement therapy should be continued until all the clinical lesions resolve, which usually takes place at 6 to 8 weeks. In addition to the clinical course, plasma D-dimer concentrations may be useful for monitoring the effectiveness of protein C replacement.[26]

Long-Term Therapy. Modalities used for the long-term management of infants with homozygous protein C/protein S deficiency include oral anticoagulation therapy, replacement therapy with either FFP or protein C concentrate, or liver transplantation.[455] When oral anticoagulation therapy is initiated, replacement therapy should be continued until the international normalized ratio (INR) is at a therapeutic value so that skin necrosis can be avoided. The therapeutic range for the INR can be individualized to some extent but is usually between 2.5 and 4.5. Risks associated with oral anticoagulation therapy include bleeding with high INR values and recurrent purpuric lesions with low INR values. Frequent monitoring of INR values is required if these complications are to be avoided. Bone development should also be monitored because the long-term effect of warfarin use on the bones of young infants is unknown. Long-term use of LMWH could be considered, but it also has the potential for osteopenia. Moreover, it is expensive and requires twice-daily subcutaneous injections.

Heterozygous Prothrombotic Disorders

Thromboembolic events related to heterozygous genetic prothrombotic disorders rarely occur in infants. When

they do, a secondary, acquired insult is usually present. The few case reports in the literature describe a diversity of clinical manifestations that usually reflect the site of the thrombus. Purpura fulminans did not occur in any case.[464-470]

Treatment. Treatment consists of supportive therapy alone, anticoagulation with heparin, thrombolytic therapy, and replacement with specific factor concentrates.[471-473] Removal or treatment of the secondary acquired insult is important. For ATIII deficiency, ATIII concentrates were administered to four infants as either boluses or continuous infusions. Boluses of 52 and 104 U/kg of ATIII concentrate increased ATIII levels from 0.10 U/mL to 0.75 and 1.48 U/mL, respectively, at 1 hour.[473] At 24 hours, levels of ATIII had decreased to approximately 0.20 U/mL. A continuous infusion of ATIII concentrate at a rate of 2.1 U/kg/hr maintained a plasma level of 0.40 to 0.50 U/mL.

Acquired Prothrombotic Disorders

Symptomatic secondary thromboembolic complications occur more frequently in sick newborns than in children of any other age, with an incidence of approximately 2.4 per 1000 hospital admissions to the NICU.[474] Intravascular catheters are responsible for more than 80% of venous and 90% of arterial thrombotic complications.[474] Their contribution to thrombosis is probably multifactorial, including the presence of a foreign surface, endothelial cell damage, impairment of flow, and infusion of noxious substances. Renal vein thrombosis (RVT) is the most common form of non–catheter-related thrombosis. Other risk factors include increased blood viscosity because of a high hematocrit, poor deformability of physiologically large red cells, dehydration, and activation of the coagulation and fibrinolytic systems secondary to a variety of medical problems. Very low ATIII levels have been observed in preterm infants with RDS, which probably contributed to their increased risk for thromboembolic complications.[29]

Venous Catheter–Related Thrombosis

The use of umbilical venous catheters and other forms of central venous catheters is associated with a significant risk for thrombosis.[474-476] According to autopsy studies, 20% to 65% of infants who die with an umbilical venous catheter in place have an associated thrombus. Appropriate placement of umbilical venous catheters is critical to prevention of serious organ impairment, such as portal vein thrombosis and hepatic necrosis. Long-term sequelae of umbilical venous catheters have not been rigorously studied but include portal vein thrombosis with portal hypertension, splenomegaly, gastric and esophageal varices, and hypertension. Until recently, pulmonary embolism was rarely diagnosed in sick newborns because its clinical signs were easily confused with those of RDS. The use of ventilation lung scintigraphy in newborns has facilitated the diagnosis of pulmonary embolism.[477]

Arterial Catheter–Related Thrombosis

Seriously ill infants require indwelling arterial catheters, which are associated with a risk of thrombosis regardless of the vessel or catheter type chosen.[478-482] Catheter-related thrombosis not only occludes catheters but may also obstruct major arterial vessels. In a retrospective examination of approximately 4000 infants who underwent umbilical artery catheterization, 1% had severe symptomatic vessel obstruction. Asymptomatic catheter-related thrombi occur more frequently, as evidenced by postmortem (3% to 59% of cases) and angiographic (10% to 90% of cases) studies.

Diagnosis. Contrast-enhanced angiography is considered the reference test for the diagnosis of arterial thrombosis. Noninvasive techniques such as Doppler ultrasound offer advantages, but their sensitivity and specificity are unknown. A review of 20 neonates with aortic thrombosis treated in one institution revealed that ultrasound failed to identify thrombi in 4 patients, 3 of whom had complete aortic obstruction.[483]

Sequelae. The sequelae of catheter-related thrombosis can be immediate or long term. Acute symptoms reflect the location of the catheter and include renal hypertension, intestinal necrosis, and peripheral gangrene.[484] The long-term side effects of symptomatic and asymptomatic thrombosis of major vessels have not been studied but are probably significant.

Prophylaxis with Heparin. A low-dose continuous heparin infusion (3 to 5 U/hr) is commonly used to maintain catheter patency. The effectiveness of heparin was assessed in seven studies focusing on three outcomes: patency, local thrombus, and ICH.[479-482,485,486] Patency, which is probably linked to the presence of local thrombus, is prolonged with the use of low-dose heparin. Local thrombosis was assessed by ultrasound in two randomized studies. The evidence linking low-dose heparin prophylaxis to ICH in newborns is weak.[482,487] One study had a sample size of only 15 per arm,[482] and another case-control study had a broad odds ratio that ranged from 1.4 to 11.0.[487] Thus, the magnitude of risk for ICH is uncertain. Heparin is used in at least three quarters of American nurseries.[484]

Renal Vein Thrombosis

RVT occurs primarily in newborns and young infants. Approximately 80% of cases occur within the first month and usually within the first week of life. In some infants RVT develops in utero. The incidence in male and female infants is similar, and the left and right sides are affected equally. Bilateral RVT occurs in 24% of pediatric patients.

Clinical Findings and Etiology

The initial symptoms and clinical findings are different in neonates and older patients and are influenced by the extent and rapidity of thrombus formation. Neonates generally have a flank mass, hematuria, proteinuria, thrombocytopenia, and impaired function of the involved kidney. Clinical findings suggesting acute inferior vena cava thrombosis include cold, cyanotic, and edematous lower extremities. RVT results from pathologic states characterized by reduced renal blood flow, increased blood viscosity, hyperosmolality, or hypercoagulability.

Coagulation Abnormalities

The most common coagulation abnormality in RVT is thrombocytopenia, which is usually mild, with average values of 100×10^9/L. Thus, RVT should be considered in the differential diagnosis of thrombocytopenia in neonates. Coagulation may be prolonged and levels of fibrinogen-fibrin degradation products increased. Children with RVT are often evaluated for a congenital prothrombotic disorder, although the significance of thrombophilic markers in this disease is unknown.[466]

Diagnosis and Treatment

Ultrasound is the radiographic test of choice for the diagnosis of RVT because of ease of testing and sensitivity to an enlarged kidney. Treatment options include supportive care, anticoagulation, and thrombolytic therapy. In the 1990s, there has been uniform agreement that aggressive supportive care is indicated. However, the use of anticoagulants and thrombolytic agents is controversial. One approach is to use supportive care for unilateral RVT in the absence of uremia and extension into the inferior vena cava. Heparin therapy should be considered for unilateral RVT that extends into the inferior vena cava or for bilateral RVT because of the risk of pulmonary embolism and complete renal failure. Thrombolytic therapy should be considered in the presence of bilateral RVT and renal failure. Thrombectomy, though a common therapeutic choice in the past, is rarely indicated.

Outcome

RVT has changed from a frequently lethal complication to one that more than 85% of children survive. Unfortunately, no recent studies have assessed long-term morbidity, such as hypertension and renal atrophy.

Spontaneous Venous and Arterial Thrombosis

Spontaneous venous thrombosis occurs in the adrenal veins, inferior vena cava, portal vein, hepatic veins, and venous system of the brain.[484,488] Spontaneous occlusion of arterial vessels in the absence of a catheter is unusual, but it can occur in ill infants. As in catheter-related thrombosis, the clinical findings reflect the vessel that is occluded. Complete occlusion of a vessel can lead to gangrene and loss of the affected limb or to ischemic organ damage. The presence of systemic hypertension in newborns is frequently related to renal artery thrombosis, even in the absence of a catheter.

Anticoagulation Therapy in Newborns

Heparin Therapy in Newborns

The lack of consensus for prophylaxis and treatment of thromboembolic complications in newborns reflects the lack of controlled trials in this area. Recommendations for adult patients provide useful guidelines but probably do not reflect the optimal therapy for newborns. Current therapeutic options include supportive care alone, anticoagulant therapy, thrombolytic therapy, and thrombectomy. For most infants in whom thrombotic complications develop, the cause of thrombosis is a catheter-related thrombus that does not produce clinical symptoms. In most nurseries, catheters are not routinely checked for associated thrombosis; thus, by exclusion, most infants with clinically silent thrombi receive supportive care alone.

Age-Dependent Features. Indications for heparin therapy in newborns remain unclear. Although the benefits of heparin therapy in newborns are probably similar to those in adults, the relative risk that major bleeding will occur with its use may be increased. Infants with thromboses that are extending or infants whose organ or limb viability is threatened by thrombosis may benefit from heparin therapy.

Heparin's anticoagulant activities are mediated primarily through acceleration of inhibition of thrombin and factor Xa by ATIII. Although dosing for heparin therapy in newborns differs from that in adults, optimal dosing cannot be predicted. Several observations suggest that the heparin requirements of neonates are decreased in comparison to those of adults. First, the capacity of plasma from healthy newborns to generate thrombin is both delayed and decreased in comparison to that of adult plasma, but similar to that of plasma from adults receiving therapeutic amounts of heparin.[489,490] Second, at heparin concentrations in the therapeutic range, the capacity of plasma from healthy newborns to generate thrombin is barely measurable.[491] Third, the amount of clot-bound thrombin is decreased in newborns because low plasma concentrations of prothrombin probably reduce heparin requirements.[492] Observations suggesting higher heparin requirements include the following: (1) clearance of heparin is accelerated in newborns,[29,493,494] and (2) plasma concentrations of ATIII are decreased to levels frequently less than 0.40 in premature infants, which may limit heparin's antithrombotic activities[17,19,23473,495]

Therapeutic Range and Dose. Therapeutic ranges reflect the optimal risk-benefit ratio of anticoagulant therapy with regard to recurrent thrombotic events and bleeding complications. In the absence of clinical trials in newborns, one approach is to use heparin in doses that

achieve the lower therapeutic range for adults (see Chapter 32).

General guidelines for initial dosing and subsequent dose adjustment of unfractionated heparin in full-term and premature neonates have been published.[496] Average doses of heparin required in newborns are bolus doses of 50 or 100 U/kg, depending on gestational age, and average maintenance doses of 20 to 25 U/kg/hr, again depending on gestational age. Adjustments are made most reliably with heparin assays, with a target-level range of 0.30 to 0.70 U/mL. Because of the short half-life of unfractionated heparin, simple discontinuation of the infusion is typically sufficient to reverse anticoagulation in the event of hemorrhage. For more rapid reversal, protamine sulfate can be used to neutralize heparin in vivo. However, anaphylactoid reactions with hypotension and bradycardia have been associated with protamine use in children and adults, and it should therefore be used with caution.[497]

The use of LMWH offers significant therapeutic advantages over unfractionated heparin, and there is now considerable experience using these preparations in newborns.[484,496,498,499] Potential advantages include more predictable pharmacokinetics, the need for less frequent monitoring than with unfractionated heparin, ease of administration, decreased bleeding, and possibly a lower incidence of heparin-induced thrombocytopenia. Full-term and moderately preterm (28 to 36 week' EGA) infants metabolize heparin at considerably faster rates than older children and adults do and typically require higher doses to maintain the same levels. Very premature infants (<28 weeks) have similar pharmacokinetics for heparin as older children and adults do. General guidelines for initial therapeutic dosing and subsequent sliding-scale dose adjustments of LMWH in neonates of different gestational age have been published.[496] Levels should be monitored with anti-Xa heparin assays on samples drawn via fresh venipuncture 4 hours after the subcutaneous dose is given to achieve levels of 0.5 to 1.0 U/mL for full therapeutic dosing. Levels should be checked every two to four doses for the first week of therapy, then once a week for a month, and then monthly if stable.[496] Infants who do not respond appropriately to heparin therapy, despite adequate levels, may benefit from infusions of ATIII concentrate, even if the levels are close to the normal physiologic range for their age.[496] Intramuscular and arterial puncture and the use of antiplatelet medications should be avoided in newborns receiving heparin therapy, and platelet counts should be monitored periodically.

Like unfractionated heparin, LMWH can be reversed with the use of protamine, with dosing dependent on the last dose of LMWH given.[500] As discussed earlier, protamine must be given slowly, and caution must be exercised to avoid potential hypersensitivity reactions. Repeat doses of protamine may be required to reverse the effects of LMWH because of the relatively shorter half-life of protamine than LMWH. Protocols for reversal of LMWH with protamine in adolescents and adults have been published, and case reports exist for its use in neonates.[501,502]

Close monitoring of the thrombus with objective means such as ultrasound is recommended. The duration of heparin therapy required for the treatment of thromboembolic complications is uncertain. One approach is to treat the infant for 10 to 14 days with heparin alone. If there is subsequent extension of the thrombus in the absence of anticoagulation therapy, treatment with oral anticoagulants may be considered.

Adverse Effects. There are two clinically important adverse effects of heparin therapy: hemorrhage, including ICH, and heparin-induced thrombocytopenia.[503,504] In the absence of an alternative cause, thrombocytopenic patients should be evaluated for heparin-induced thrombocytopenia and treated with alternative therapies.

Oral Anticoagulant Therapy in Newborns

Age-Dependent Features. Oral anticoagulation therapy in children is discussed in Chapter 32, and only specific issues related to newborns are discussed in this section. The oral anticoagulant warfarin works by reducing functional plasma levels of the VK-dependent proteins. At birth, levels of the VK-dependent proteins are similar to those found in adults receiving therapeutic amounts of warfarin for deep venous thrombosis/pulmonary embolism.[17,19,23,82,491,505,506] In addition, stores of VK are low, and a small number of newborns have evidence of functional VK deficiency.[55] These features significantly increase the sensitivity of newborns to warfarin and potentially their risk for bleeding. Oral anticoagulant therapy should be avoided when possible during the first month of life.[55,507] Unfortunately, a small number of infants require extended anticoagulation therapy, and heparin cannot be used for extended periods because of the risk for osteopenia.

Indications, Therapeutic Range, and Dose. The optimal therapeutic INR range is unknown for newborns and almost certainly differs from that for adults. Recommendations for oral anticoagulation therapy in adults can be used as a guideline for determining the lowest effective dose, which to some extent can be individualized. Maintenance doses for warfarin are age dependent, with infants requiring the highest doses (0.32 mg/kg).

Adverse Effects. Close monitoring of oral anticoagulation in newborns is required if both hemorrhagic and recurrent thrombotic complications are to be prevented. Unfortunately, these infants often have poor venous access, as well as complicated medical problems. Weekly or biweekly INR measurements and frequent dose adjustments are required.[508] Doses are affected by diet, medica-

tions, and intercurrent illnesses. Breast-fed infants are very sensitive to oral anticoagulants because of low concentrations of VK in breast milk.[62,44,50,277,509] Daily supplementation of breast-fed infants with small amounts of commercial formulas reduces their sensitivity to oral anticoagulants and the risk of sudden increases in INR values. In contrast to breast-fed infants, infants receiving commercial formulas or total parenteral nutrition are resistant to oral anticoagulants because of VK supplementation.[277,510] Reducing or removing VK supplementation in infants receiving total parenteral nutrition significantly decreases the dose requirements. Most infants requiring oral anticoagulants also require other medications on an intermittent and long-term basis. The effects of dosage changes and the introduction of new medications must be closely supervised.

Antiplatelet Agents in Newborns

Antiplatelet agents are rarely used in newborns for antithrombotic therapy. The hyporeactivity of neonatal platelets and the paradoxically short bleeding time suggest that optimal use of antiplatelet agents differs in newborns and adults. Aspirin is the most commonly used antiplatelet agent. The empirical use of low doses of 1 to 5 mg/kg/day has been proposed as adjuvant therapy for patients with Blalock-Taussig shunts, some endovascular stents, and some thrombotic cerebrovascular events.[511] Use of the antiplatelet agent clopidogrel (Plavix) in infants as young as 6 weeks of age has been reported in a small retrospective series.[512] The agent appears to be well tolerated at doses of 1 mg/kg/day.

Thrombolytic Therapy in Newborns

Age-Dependent Features. The activity of thrombolytic agents depends on endogenous concentrations of plasminogen, which are physiologically decreased at birth.[513] Low plasminogen levels result in impairment of the capacity to generate plasmin[63] and a decrease in the capacity to thrombolyse fibrin clots.[513] In addition, fetal glycoforms of plasminogen are less efficiently converted to plasmin by tPA than adult plasminogen is.[66] Thus, neonates have an overall reduced capacity to respond to tPA in comparison to adults. If an infant's condition does not respond to thrombolytic therapy, replacement of plasminogen should be considered.

Indications, Therapeutic Range, and Dose. Infants in whom serious thrombotic complications develop, as defined by organ or limb impairment, may benefit from thrombolytic therapy. The clinical objective is removal of the clot as quickly and safely as possible. Surgical removal of a clot in a major vessel can be curative; however, it is technically difficult and poses a considerable life-threatening risk to infants, who are often premature. In the absence of contraindications, the use of thrombolytic agents in these infants is a preferred approach (see Chapter 32).

CONCLUSIONS

Over the past several decades, the developmental timing and functional maturation of the human hemostatic system have been examined in great detail. These studies show critically important differences in many components of the hemostatic system in premature and full-term newborns versus older children and adults. The reason for this unique physiologic state in the fetus and neonate is not clear but appears to be appropriately balanced for healthy full-term infants. Of clinical importance has been the determination of gestational and postnatal age-specific activity ranges of factors involved in hemostasis, which has allowed appropriate interpretation of clinical data. As newer diagnostic tests and treatments are introduced for older children and adults, it will be critical to carefully evaluate them separately in the context of neonates, both premature and full-term, given their unique physiologic state.

6 Anatomy and Physiology of Hematopoiesis

Colin A. Sieff and Leonard I. Zon

This chapter offers a review of the anatomy and physiology of normal hematopoiesis that is intended to provide a basis of understanding of the marrow failure syndromes described at length in the following chapter. In this chapter we briefly discuss the phylogeny of hematopoiesis and describe marrow anatomy and the egress of recognizable hematopoietic cells from the marrow into peripheral blood. Then follows a more detailed analysis of the cellular bases of erythrocyte, granulocyte-macrophage, and megakaryocyte development, including discussion of the pluripotent stem cell, the more committed but still undifferentiated progenitor cell, and differentiated precursors of the mature formed elements of blood. Much of this chapter is devoted to the interactions of growth factors and the cells that produce them in the upregulation of hematopoiesis. The mechanisms of downregulation of hematopoiesis by cell interactions and cytokines are touched on here, but they are less well understood despite the fact that they are likely to influence the pathophysiology of aplastic anemia and other marrow failure syndromes.

HISTORY*

That "blood is life" was appreciated by Empedocles in the fifth century BC. The theory that the vasculature contains blood, phlegm, black bile, and yellow bile, all revealed when freshly let blood is permitted to separate, is attributed to Polibus, the son-in-law of Hippocrates.

Servetus recognized the systemic and lesser circulations in the 16th century. He was burned at the stake, in part because he did not accept the dogma that blood must pass through the intraventricular cardiac septum. (Grant disapproval and, more recently, approval without funding have been substituted for immolation. The effects are not entirely dissimilar.)

In view of the present growth of knowledge of hematology, it is remarkable to realize that the concept of the circulation of blood was finally established by Harvey only a little more than 300 years ago. This began the clinical application of blood transfusion, of which Pepys wrote, "It gave rise to many pretty wishes as of the blood of a Quaker to be let into an Archbishop and such like."

In the mid-17th century, Swammerdam observed red blood corpuscles in the microscope and Malpighi discovered the capillary circulation in the lung and omentum. However, it was not until the 19th century that the source of blood cell production began to be suc-

cessfully explored. Houston suggested that red cells were derived from leukocytes in the lymphoid system. Zimmerman believed that erythrocytes were derived from platelets, an opinion shared by Hayem. Addison, perhaps not surprisingly, attributed red cell production to the adrenals, and Reikert finally suggested that red cells might be produced in the embryonic liver. In fact, not until 1868 did Neumann demonstrate that red cells arise from precursors in the marrow. The modern understanding of the physiology of hematopoiesis then began.

PHYLOGENY

Much can be learned about the physiology of hematopoiesis from study of the evolution of oxygen transport, a subject reviewed by Lehman and Huntsman.[1]

One of the major advantages of mammalian life over that of invertebrates is the capacity to package large amounts of hemoglobin within cells. This permits the delivery of oxygen to tissues without the enormous increase in oncotic pressure that would be induced by a similar concentration of high-molecular-weight hemoglobin free in plasma. The renewal rate of red cells is a function of the metabolic rate or basal heat production. This is illustrated dramatically in studies of the animal kingdom, ranging from the turtle to the pygmy shrew, and by comparisons of red cell renewal in marmots during periods at ambient and cold temperature,[2] in rats,[3] and in frogs.[4]

Production of blood cells in bone marrow is a late development in phylogeny. Red cells are found in the coelomic cavity of the worm and are produced in the kidneys of the goldfish. The influence of oxygen demand on the production of red cells[5] is illustrated by the effects of hyperoxia on bled rats[6] and the behavior of the European eel, one of the few vertebrate forms that ordinarily lacks erythrocytes in its juvenile state. When the adult eel struggles against the current up the rivers of Europe, hemoglobin-containing nucleated cells appear in its plasma. This influence of oxygen demand on respiratory pigment production is also illustrated in non–red cell–producing organisms such as *Daphnia*, the English water flea, a creature that produces high-molecular-weight hemoglobin in its ovaries when exposed to the low oxygen tension in stagnant ponds. The recent discovery of transcription factors that function as oxygen sensors provides a potential molecular explanation for these regulatory mechanisms.[7-10]

MARROW ANATOMY

The relative red (active) marrow space of a child is much greater than that of an adult, presumably because the high requirements for red cell production during neonatal life demand the resources of the entire production potential of the marrow. During postnatal life the

FIGURE 6-3. Scanning electron micrograph of rat femoral marrow. The hematopoietic cells are grouped between the interlacing network of the vascular sinuses. Many cells are dislodged when the marrow is transected, and separate spaces are present where cells had been. *(From Lichtman MA, Chamberlain JK, Santillo PA. Factors thought to contribute to the regulation of egress of cells from marrow. In Silber K, LoBue L, Gordon AS [eds]. The Year in Hematology, 1978. New York, Plenum, 1978, pp 243-279.)*

demands for red cell production ebb, and much of the marrow space is slowly and progressively filled with fat (Fig. 6-1). In certain disease states that are usually associated with anemia, such as myeloid metaplasia, hematopoiesis may return to its former sites in the liver, spleen, and lymph nodes and may also be found in the adrenals, cartilage, adipose tissue, thoracic paravertebral gutters, and even the kidneys.

The microenvironment of the marrow cavity is a vast network of vascular channels or sinusoids in which float fronds of hematopoietic cells, including fat cells. This complex area of cell biology and anatomy has been the subject of several reviews.[11-15] The cells are found in the intrasinusoidal fronds. The vascular and hematopoietic compartments are joined by reticular fibroblastoid cells that form the adventitial surfaces of the vascular sinuses and extend cytoplasmic processes to create a lattice on which blood cells are found. The lattice itself is illustrated by reticulin stains of marrow sections (Fig. 6-2). The comformation of the meshwork of reticulin and the location of hematopoietic cells in the network of vascular sinuses are best illustrated by scanning electron microscopy (Fig. 6-3). The fibroblastoid network provides two major functions—an adhesive framework onto which the developing cells are bound and production by these cells

of essential hematopoietic colony-stimulating factors (CSFs),[16] to be discussed later. Cell-cell adhesion may be mediated by binding of the hematopoietic very late antigen 4 (VLA-4) integrin to stromal fibronectin or vascular cell adhesion molecule 1 (VCAM-1).[17-20] In addition, cytokine receptors such as c-kit can bind to the membrane-bound form of stem cell factor or Steel factor (SCF),[21] and the extracellular matrix proteins secreted by stromal cells may actually provide a binding site for some growth factors or for hematopoietic cells.[22-24] In addition, chemokines, a family of small molecules, may have a role in stromal function. Specifically, stromal cell–

derived factor 1 (SDF-1) is a potent attractant for hematopoietic cells, both mature leukocytes and progenitor cells that express its receptor CXCR4.[25] Gene disruption of both ligand and receptor in mice is embryonically lethal, with defects in B lymphopoiesis and myelopoiesis.[26,27] These defects may relate to a critical role for CXCR4 in bone marrow engraftment in nonobese diabetic (NOD)/severe combined immunodeficiency (SCID) mice[28]; SDF-1 has been shown to activate the integrins VLA-4, VLA-5, and lymphocyte function antigen 1 (LFA-1) on CD34+ cells.[29] Last, there is evidence that SDF-1 may also play a role in the egress of progenitor cells from bone marrow to blood during stem cell mobilization.[30,31]

A schema of the marrow circulation is shown in Figure 6-4. The central and radial arteries ramify in the cortical capillaries, which in turn join the marrow sinusoids and drain into the central sinus. Cells that egress from the marrow sinusoids then join the venous circulation through comitant veins. The inner, or luminal, surface of the vascular sinusoids is lined with endothelial cells, the cytoplasmic extensions of which overlap, or interdigitate with, one another. Escape of developing hematopoietic cells into the sinus for transport to the general circulation occurs through gaps that develop in this endothelial lining and even through endothelial cell cytoplasmic pores.

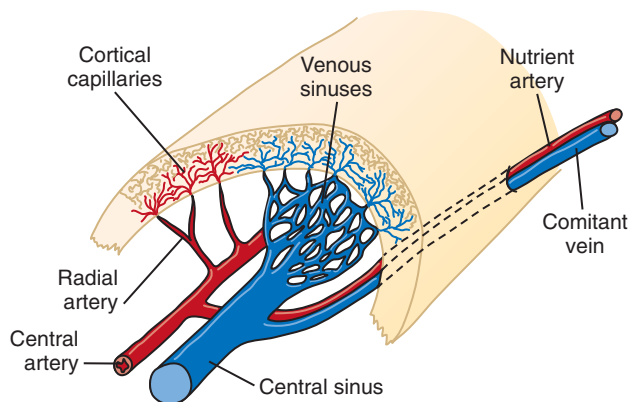
The location of the different hematopoietic cells is not random. Clumps of megakaryocytes are found adjacent to marrow sinuses. They shed platelets, or fragments of their cytoplasm, directly into the lumen. This reduces


FIGURE 6-4. Schematic representation of the circulation of the marrow. The nutrient artery, central arteries, and radial arteries feed the cortical capillaries. The cortical capillaries anastomose with the marrow sinuses, which drain into the large central sinus. The central sinus enters the comitant vein, through which the marrow effluent enters the systemic venous circulation. An interesting feature of the circulation of marrow is the transit of nearly all arterial blood through cortical capillaries before entering the marrow sinuses. Not shown are the arterial communications from muscular arteries that feed the periosteum and penetrate the cortex to anastomose with intracortical vessels. *(Redrawn from Lichtman MA, Chamberlain JK, Santillo PA. Factors thought to contribute to the regulation of egress of cells from marrow. In Silber K, LoBue L, Gordon AS [eds]. The Year in Hematology, 1978. New York, Plenum, 1978, pp 243-279.)*

the requirement for movement of bulky mature megakaryocytes, a mobility characteristic of the granuloid- and erythroid-differentiated precursors as they approach the point at which they egress from the marrow. A schema that illustrates the transfer of hematopoietic cells into the sinus is shown in Figure 6-5. Disruption of the function of microenvironmental cells inhibits long-term murine marrow cultures.[32] Such disruptions may be responsible for certain cases of aplastic anemia.

HEMATOPOIETIC CELLS

Stem Cells

The concept that sustained hematopoiesis derives from pluripotent stem cells was first suggested by Jacobson and colleagues,[33] who showed that mice can be protected from the lethal effects of whole-body irradiation by exteriorization and shielding of the spleen. This protective effect was shown to be cell mediated by the observation that the injection of spleen cells could initiate recovery and re-establish hematopoiesis in irradiated animals.[34] The clonal nature of hematopoiesis and the concept that a single pluripotent stem cell exhibits the capacity to repopulate the entire hematopoietic system was first demonstrated experimentally by Till and McCulloch,[35] who also used the mouse as an experimental system. They demonstrated that colonies of hematopoietic cells could be observed in the spleen of transplanted, irradiated recipients within 10 days after the transplant. These colonies contained precursors to erythrocytes, granulocytes, macrophages, and megakaryocytes. Subsequent experiments using karyotypically marked donor cells confirmed the clonal origin of the differentiated cells in the colony, thus proving that a single pluripotent stem cell had given rise to these differentiated cells.[36] It was also shown that each colony contained a number of stem cells that could again form a colony of differentiated progeny in a second irradiated recipient, thus demonstrating their self-renewal capacity. This is true only of spleen colony-forming units that are present on day 12 to 14 (CFU-S$_{12}$). Colonies observed on days 7 to 8 after marrow infusion are transient, disappear by day 12, and are neither multipotential nor self-maintaining.[37] Under steady-state conditions, no more than 10% of the CFU-S become committed to differentiation during any given 3-hour period. The demonstration of a stem cell that can differentiate to form progenitor cells for erythropoiesis, granulopoiesis, and megakaryopoiesis is completely consistent with subsequent observations in disease states such as chronic myelogenous leukemia[38,39] and polycythemia vera (PCV),[40,41] in which a clonal origin of abnormal erythroid, granulocytic, and megakaryocytic precursor cells and lymphocytes can be demonstrated (see the Myeloid Leukemia, Myelodysplasia and Myeloproliferative Disease in Children in the companion volume *Oncology of Infancy and Childhood*).

FIGURE 6-5. Schematic diagram of the factors that may be involved in controlling the release of marrow cells. The central relationship between the hematopoietic compartment and the marrow sinus is depicted. The drawing highlights the similarity of the egress process for the three major hematopoietic cells: reticulocytes in the *top* pathway, granulocytes and monocytes in the *central* pathway, and platelets in the *lower* pathway. Immature cells undergo biophysical changes under the influence of cytopoietins that favor egress. In the case of the reticulocyte, enucleation precedes egress. This is shown by the *solid black* inclusion in the perisinal macrophage, which represents nucleophagocytosis before digestion of the erythroblast nucleus. The cytoplasmic protrusion of the megakaryocyte presumably detaches itself from the cell and will further fragment into platelets in the circulation. *(Redrawn from Lichtman MA, Chamberlain JK, Santillo PA. Factors thought to contribute to the regulation of egress of cells from marrow. In Silber K, LoBue L, Gordon AS [eds]. The Year in Hematology, 1978. New York, Plenum, 1978, pp 243-279.)*
Demonstration of a pluripotent stem cell in adult bone marrow led to a systematic search for the ontogenic origins of hematopoietic stem cells (HSCs). Experiments performed by Metcalf and Moore[42] clearly demonstrated the presence of cells capable of repopulating adult marrow in the yolk sac and the murine fetal liver. Subsequent work has confirmed and extended these observations,[43] although data show that HSCs may arise simultaneously in the yolk sac and the intraembryonic aorta/gonad/mesonephros (AGM) region.[44] A difficulty here is that primordial germ cells also arise or migrate through this region and have been shown to have the potential to generate HSCs.[45] A point of interest that arises is whether the stem cells observed in the yolk sac, fetal liver, and adult marrow and spleen are functionally equivalent in every respect. One experimental finding that suggests functional differences between CFU-S at different stages of development of the mouse was made by Micklem and Ross.[46] Their experimental approach was to transfer spleen cells sequentially from a repopulated recipient to an irradiated recipient. Experiments of this type had previously shown that the capacity for transfer of CFU-S from adult marrow or spleen was finite, and in fact only three serial transfers could be accomplished.[47] Micklem and Ross showed that cells transplanted from the yolk sac to the spleen of an irradiated recipient could be serially transplanted as many as seven times before further proliferative capacity was lost. CFU-S derived from fetal liver was capable of five to six serial transfers.

The placenta has recently been found to be a source of HSCs during development.[48,49] The origin of stem cells within the placenta remains controversial inasmuch as it is possible that the stem cells arrive from intraembryonic sources such as the AGM region or the placenta may be a de novo producer of blood stem cells. It is interesting that the stem cells produced within the aorta appear to be on the arterial surfaces during embryogenesis, and the placenta is rich in this particular process. The placenta is quantitatively a large source of HSCs during development.

Studies of Hellman and co-workers[50] have provided a model of the stem cell compartment in which there is a continuum of cells with decreasing capacity for self-renewal, increasing likelihood for differentiation, and increasing proliferative activity. Cells progress in a unidirectional fashion in this continuum. It is the most primitive cells with the greatest self-renewal capacity that reconstitute long-term hematopoiesis after transfer into irradiated recipient mice. These cells, termed long-term–reconstituting hematopoietic stem cells (LTR-HSCs), were shown to be separable from CFU-S$_{12}$ in a limiting-dilution assay designed to detect and enumerate "cobblestone areas."[51] This assay is derived from the original "Dexter" technique for long-term culture of murine marrow in which CFU-S, colony-forming unit–granulocyte-macrophage (CFU-GM), and burst-forming unit–erythrocyte (BFU-E) flourish for many months on and within an adherent stromal monolayer.[52] The areas of active hematopoiesis have a "cobblestone" appearance. In the limiting-dilution assay, different concentrations of bone marrow cells are plated onto a series of microwells that contain a pre-established stromal monolayer, and at 5 weeks the cobblestone areas that comprise proliferating blast cells within the stromal cell layer are counted.[51] In cell separation experiments, their numbers correlate with a cell fraction that is characterized by low mitochondrial mass per cell (minimal retention of the supravital fluorochrome rhodamine 123); this cell fraction is enriched

with marrow-repopulating cells but depleted of CFU-S$_{12}$.[51,53] Even more impressive separation of pre–CFU-S from CFU-S$_{12}$ was obtained by countercurrent elutriation.[54] Intermediate and rapidly sedimenting cells contained greater than 99% CFU-S$_{12}$, as well as the cells responsible for short-term reconstitution. In contrast, long-term–reconstituting cells (>60 days) came from a slowly sedimenting fraction that contained only 0.25% CFU-S$_{12}$.

In summary, LTR-HSCs are cells capable of long-term reconstitution of myelopoiesis and lymphopoiesis. More mature progenitor cells, represented by CFU-S$_{12}$, give rise to spleen colonies 12 to 14 days after injection into irradiated recipients, exhibit less self-renewal and proliferative capacity, and are generally limited to myeloid differentiation. The most mature compartment, represented by cells that give rise to spleen colonies 6 to 8 days after transplantation (CFU-S$_8$), have limited self-renewal and proliferative capacity. The relationship between the in vivo LTR-HSC assay and in vitro assays that measure blast cell colonies capable of forming additional colonies after replating,[55] high–proliferative potential colony-forming cells (HPP-CFCs) that form large monocyte colonies (up to 5×10^4 cells),[56] or cells that survive in long-term cultures[57] is at this point unresolved.

The stem cell model of hematopoiesis has parallels in other organ systems. That rapidly self-renewing epithelial tissues such as skin and intestine have stem cells that continually replenish the cells lost by differentiation is well described. However, demonstration of the existence of neural stem cells[58,59] has raised the possibility that many organ systems might retain a population of self-renewing stem cells. Muscle satellite cells also appear to fulfill this role. These organ- or tissue-specific stem cells arise during early fetal development from embryonic stem (ES) cells of the inner cell mass of the blastocyst that are totipotent and give rise to all body cell types.

Many assays have been proposed as "surrogate" stem cell assays, but until homogeneous populations can be evaluated in both in vitro and in vivo assays it will be impossible to determine the precise cell type measured by these methods. Fauser, Messner, and others[39,60-62] demonstrated colonies in semisolid media that contain granulocytes, erythrocytes, monocytes, and megakaryocytes (CFU-GEMM) in methylcellulose cultures of human bone marrow. A unique type of in vitro blast cell colony that contains small numbers of blast cells with higher self-renewal capacity (secondary colonies on replating) than CFU-GEMM possesses has been described.[55] Evidence for the presence of pluripotent HSCs is also derived from the human "Dexter" technique for liquid culture of marrow in which myeloid progenitors (mostly CFU-GM) are sustained for about 2 months on and within an adherent stromal monolayer.[63,64] The progenitors can be detected by replating into methylcellulose with several growth factors at 5 to 8 weeks, thereby demonstrating that unipotent and multipotent cells are gener-

ated in this culture system. Eaves and colleagues have adapted this long-term culture technique to a limiting-dilution assay in which long-term culture–initiating cells (LTC-ICs) can be quantitated after culture at different concentrations on a stromal layer for 5 weeks, followed by replating in methylcellulose and counting the number of wells that do not contain colonies.[65] The analogous cobblestone area–forming cell (CAFC) assay has also been adapted to human cells.[66] Another method that measures the enormous proliferative capacity of primitive progenitor cells is the HPP-CFC assay, which gives rise to macroscopically (>5 mm) visible in vitro colonies.[56,67] In an effort to establish a more direct measure of the ability of human stem cells to reconstitute hematopoiesis, Kamel-Reid and Dick developed an in vivo assay.[68] In this method human cells are injected into immunodeficient NOD/SCID mice, and 5 to 8 weeks later the animals are sacrificed and tested for the presence of human cells in blood and progenitors in bone marrow. By limiting dilution these SCID-reconstituting cells (SRCs) can be quantitated. Cell fractionation and gene-marking studies provide some evidence that SRCs are more primitive than LTC-ICs.[69,70] Although SRCs may still be a heterogeneous population of cells that includes LTR-HSCs, this assay provides a better measure of stem cell properties than the LTC-IC assay does, especially with regard to the multipotent (i.e., myeloid and lymphoid) and self-renewal properties of HSCs. A tentative relationship of the cells measured in these different assays to the stem cell is shown in Figure 6-6.

Application of these assays plus analysis of HSCs has in general been hindered by the low frequency of the cell in the hematopoietic population and the lack of reagents to identify stem cells. However, it is now possible to purify murine stem cells by several methods. Murine HSCs can be highly purified by density gradient centrifugation combined with labeling with antibodies, lectins, or intracellular dyes (alone or in combination), followed by separation via fluorescence-activated cell sorting (FACS), immunopanning, or immunomagnetic beads. Immunologic reagents that define murine stem cell populations include antibodies to Thy-1, c-kit, and stem cell antigen (Sca-1). Spangrude and co-workers[71] used FACS in combination with negative expression of T-cell, B-cell, granulocyte, and monocyte lineage–specific markers, low expression of Thy-1, and expression of Sca-1 to isolate HSCs. Transplantation of single c-kit$^+$, Thy-1^{lo}, lin$^-$, Sca-1$^+$ (KTLS) cells can ensure long-term survival of lethally irradiated syngeneic recipients,[72] and approximately 20% of such cells are LTR-HSCs. Murine HSCs can be even further enriched by using cell surface receptors of the signaling lymphocyte activation molecule (SLAM) family. HSCs are CD150$^+$, CD244$^-$, CD48$^-$, whereas multipotent progenitors lose CD150 expression and begin to express the other family members CD244 and CD48. Purification of CD150$^+$, CD48$^-$, D41$^-$ cells (CD41 is also expressed on megakaryocyte lineage cells) provides a population of cells in which 45% are LTR-HSCs.[73]

IN VITRO

IN VIVO

FIGURE 6-6. Schematic view of some general properties and assays for the heterogeneous cells that constitute the stem cell and progenitor cell compartments. As indicated on the diagram, cells capable of permanently reconstituting in vivo hematopoiesis are separable from cells that give rise to day 12 CFU-S, but the precise developmental stage of in vitro long-term culture–initiating cells (LTC-IC), cobblestone area–forming cells (CAFC), high–proliferative potential colony-forming cells (HPP-CFC), and blast CFC is not established. In the progenitor compartment, mixed colonies of almost all lineage combinations have been described. BFU-E, burst-forming unit–erythroid; CFU-GEMM, colony-forming unit–granulocyte-erythrocyte-macrophage-megakaryocyte; CFU-GM, colony-forming unit–granulocyte-macrophage.
Expression of the CD34 antigen has been used to enrich for human stem cells. Although most colony-forming cells (CFCs) express both the CD34 and CD33 antigens, cells that give rise to CFCs in long-term bone marrow culture (i.e., pre-CFCs) can be separated by their expression of CD34, lack of expression of CD33, and intermediate forward light–scattering property.[74] A G_0 CD34$^+$ cell population has been isolated by exploiting the resistance of these cells to 5-fluorouracil (5-FU) in the presence of SCF and interleukin-3 (IL-3).[75] G_0 cells are also c-kit, interleukin-6 receptor (IL-6R), and IL-1R positive; do not form progenitor-derived colonies on direct culture in methylcellulose; but after 5 weeks in culture on stromal cells, do form primary colonies in methylcellulose, 40% of which are replatable. The importance of CD34$^+$ marrow cells is emphasized by in vivo simian studies. Similar to human bone marrow, the CD34 antigen is expressed by a minority of baboon cells, and infusion of these cells after isolation by immunoabsorption chromatography and FACS can reconstitute lymphohematopoiesis in lethally irradiated baboons.[76] Cloning of murine CD34 cDNA has cast some doubt on expression of CD34 by LTR-HSCs, at least in the mouse. A monoclonal antibody raised to a murine CD34-GST fusion protein was used to separate purified Sca-1$^+$, c-kit$^+$, lin$^-$ bone marrow cells into CD34$^{lo/-}$, CD34^{lo}, and CD34$^+$ fractions. Interestingly, long-term multilineage reconstitution was observed after transplantation of the CD34$^{lo/-}$ cells, whereas the CD34$^+$ fraction provided early but unsustained multilineage reconstitution.[72] It is possible that murine and primate LTR-HSCs differ in their expression of CD34; however, the human and primate transplants did not use very highly purified cells, and thus it is also possible that CD34$^{lo/-}$ cells could account for the long-term engraftment. These data are supported by experiments demonstrating that a tiny subset of murine bone marrow cells that exclude the Hoechst 33342 dye (called the side pop-ulation) contains all the LTR-HSC activity but is CD34$^-$.[77] Primate and human studies have also raised the possibility that HSCs do not express CD34.[78] When primitive human lin$^-$ cells are separated into CD34$^+$ and CD34$^-$ fractions, the capacity to reconstitute hematopoiesis in immunodeficient mice (called SRCs) is found in both cell fractions.[79] Resolution to this controversy may come from the demonstration that resting murine HSCs are CD34$^-$ whereas HSCs activated with 5-FU or cytokines such as granulocyte colony-forming factor (G-CSF) express the CD34 antigen.[80,81] Most interesting, transplantation of activated CD34$^+$ HSCs showed that these HSCs can lose CD34 expression after return of the recipients to the resting steady state and still retain the capacity to reconstitute secondary recipients, thus demonstrating that CD34 expression is reversible.[81]

Progenitor Cells

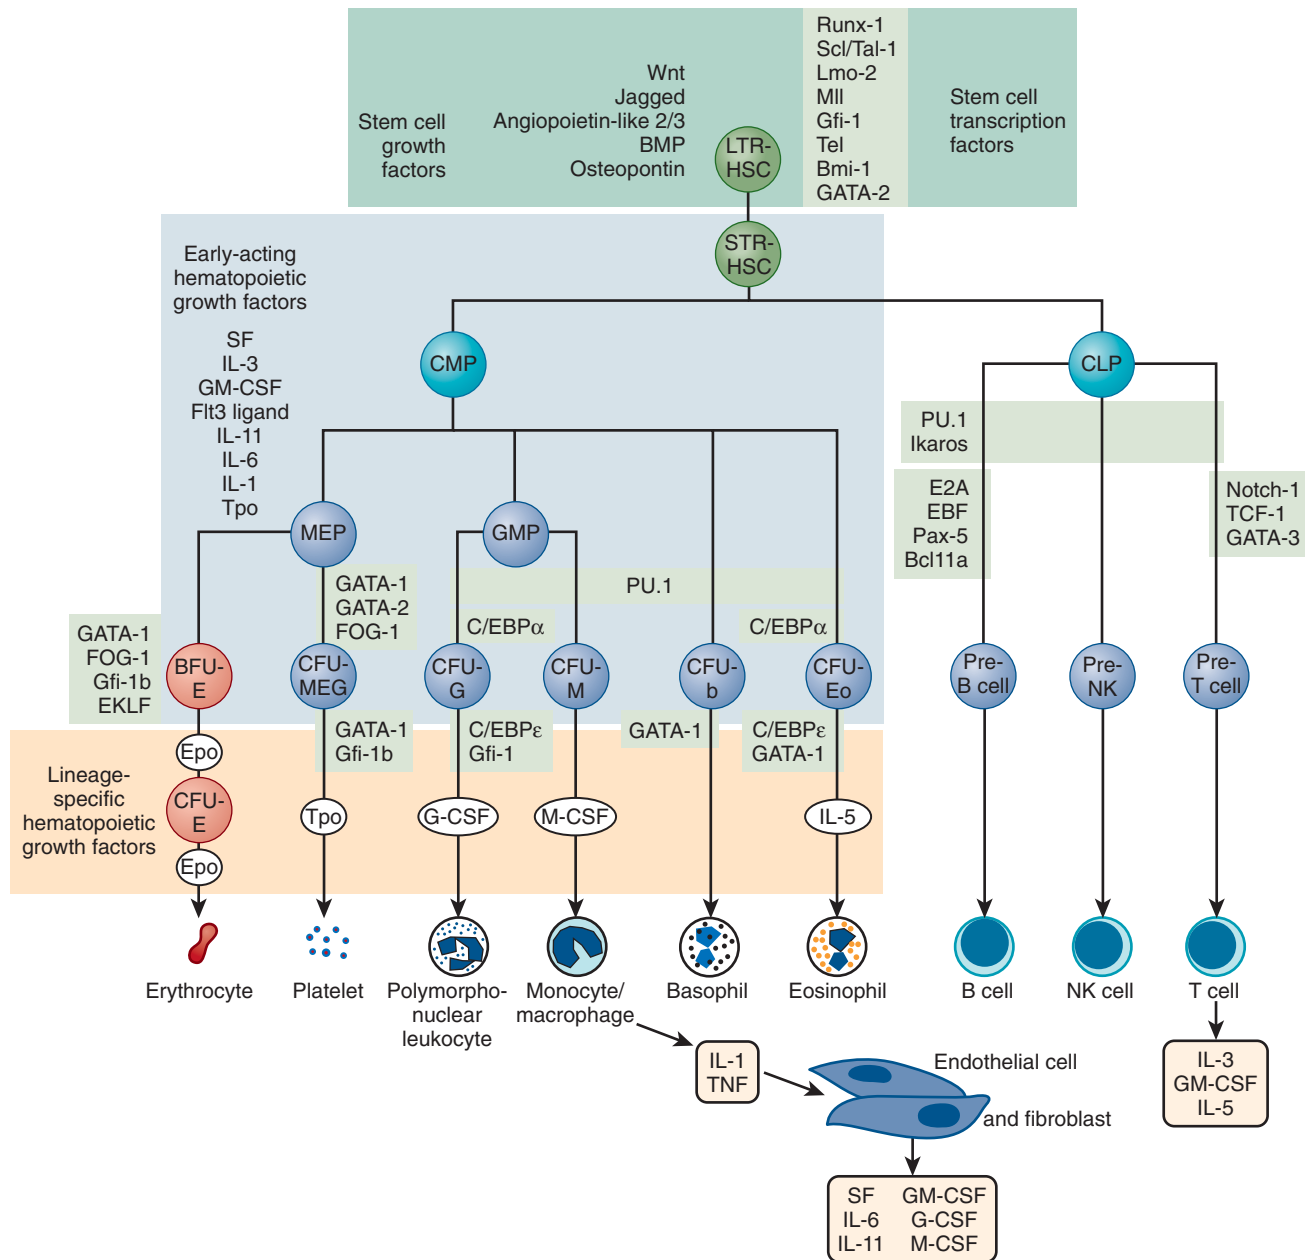
The pluripotent stem cells of the marrow slowly self-replicate while occasionally (and stochastically) differentiating into cells that are multipotent but have reduced self-renewal capacity (short-term–reconstituting HSCs [STR-HSCs]) and then into either common lymphoid (CLP) or common myeloid progenitors (CMP). These cells can be prospectively isolated according to their expression of unique combinations of cell surface markers (Fig. 6-7).[82-84] Lymphoid differentiation will not be further considered here. The CMP differentiates into all of the progenitors of blood cells other than lymphoid cells. These include more committed progenitors of the granulocyte, monocyte (GMP), and eosinophil lineages or progenitors of the megakaryocyte, erythroid, and basophil (MEP) lineages. These cells can be isolated prospectively, and transplantation into lethally irradiated mice can confer transient but not long-term hematopoiesis.[85]


FIGURE 6-7. Major cytokine sources and actions and transcription factor requirements for hematopoietic cells. Cells of the bone marrow microenvironment such as macrophages, endothelial cells, and reticular fibroblastoid cells produce M-CSF, GM-CSF, G-CSF, IL-6, and probably SCF after induction with endotoxin (macrophage) or IL-1/TNF (endothelial cells and fibroblasts). T cells produce IL-3, GM-CSF, and IL-5 in response to antigenic and IL-1 stimulation. These cytokines have overlapping actions during hematopoietic differentiation, as indicated, and for all lineages optimal development requires a combination of early- and late-acting factors. Transcription factors important for survival or self-renewal of stem cells are shown at the top (*light green panel*), and stages of hematopoiesis blocked after the depletion of indicated transcription factors for multipotent and committed progenitors are shown in *light green boxes* throughout. Abbreviations are spelled out in the text.

Erythroid Colony-Forming Cells

The erythroid progenitor compartment is invisible to the light microscope. These committed progenitors of a single lineage are derived from stochastic differentiation of bipotential or multipotential progenitors,[86] which in turn are derived from a tiny population of pluripotential stem cells (see Fig. 6-7). In humans, the most primitive single-lineage–committed erythroid progenitor is the

BFU-E. BFU-E progenitors are so named because in response to the combination of erythropoietin (EPO) and either SCF, IL-3, or granulocyte-macrophage colony-stimulating factor (GM-CSF) in vitro in semisolid (methylcellulose) culture, the progenitor divides several times while still motile, thereby forming subpopulations of erythroid colony-forming units (CFU-E).[87] Each of the latter then form a large colony of proerythroblasts that

eventually form more mature erythroblasts and even reticulocytes. The burst-like morphology of the colony is responsible for the name of the progenitor. The entire process requires about 2 weeks in vitro. Bone marrow also contains more mature CFU-E progenitors, which under the influence of EPO, form small colonies of erythroblasts in 7 days.

Granulocyte and Macrophage Colony-Forming Cells

The first colony assays relevant to the study of the production of granulocytes and monocytes in the mouse were described in 1965 by Pluznik and Sachs[88] and in 1966 by Bradley and Metcalf.[89] Analogous assays have been developed in the human system.[90] These groups demonstrated that individual cells derived from mouse spleen or bone marrow could give rise to colonies of up to several thousand differentiated granulocytes, macrophages, or both in soft agar medium. A period of 7 to 8 days was required for full maturation of these colonies (12 to 14 days is required in humans). Appropriate studies were performed to demonstrate the single-cell origin of the colonies. These studies also demonstrated that a single progenitor cell, which was termed the colony-forming unit in culture (CFU-C), was capable of differentiation into both granulocytes and macrophages, thus the designation CFU-GM. Unit gravity sedimentation and other separation methods have been used to demonstrate that CFU-GM represents a cell population distinguishable from pluripotent stem cells.[91] Long-term liquid bone marrow cultures have been particularly helpful in defining the humoral and cell-cell interactions that induce myeloid differentiation.[92] CFU-GM give rise to the more mature granulocyte and macrophage colony-forming units, CFU-G and CFU-M respectively.[89,90] In addition, CFU-GM can be distinguished from the eosinophil progenitor, CFU-Eo, each arising independently from the myeloid stem cell. A progenitor more mature than CFU-GM that differentiates to smaller clusters of mature myeloid cells earlier in culture than CFU-GM does has been described.[56,90,93,94] This is analogous to the erythroid system, in which BFU-E differentiates to the more mature progenitor CFU-E. A pre–CFU-GM similar to the most immature BFU-E but with a slower sedimentation rate and lower cycling index than CFU-GM has been described in humans.[95-97] Thus, the myeloid progenitor population, like the erythroid one, represents a continuum with respect to proliferative potential.

Megakaryocyte Colony-Forming Cells

Figure 6-7 provides an accepted if idealized schema of lineage-restricted megakaryocyte progenitor development. Evidence strongly suggests that the initial phase of differentiation into erythrocyte and megakaryocyte commitment involves a single progenitor capable of giving rise to colonies of differentiated cells, all of which express a nuclear transcription factor known as GATA-1.[98,99] Of great interest is the fact that another transcription factor, NF-E2, has been shown to regulate platelet production.[100] Mice rendered NF-E2 deficient die of bleeding from the absence of platelets. The thrombocytopenia is due to a block late in megakaryocyte maturation. Interestingly, these animals do not show an increase in thrombopoietin (TPO) levels, thus suggesting that the megakaryocyte mass rather than the platelet count regulates TPO production.

Precursors and Mature Cells

The erythroid precursor, or erythroblast, pool represents about a third of the marrow cell population in normal children older than 3 years and adults. Proerythroblasts are the earliest recognizable forms. These cells divide and mature through various stages that involve nuclear condensation and extrusion and hemoglobin accumulation. On average, each erythroblast can form about eight reticulocytes. Measurement of the total marrow proerythroblast content[101] and daily reticulocyte production shows that under normal conditions, replicating proerythroblasts largely maintain the reticulocyte pool by renewal from the progenitor compartment at a rate of about 10% per day.[102]

Erythroid Development

Up to this point we have discussed the nondescript progenitors of erythropoiesis without reference to their physical appearance or to the appearance of their differentiated daughter cells. The best evidence to date suggests that hematopoietic progenitors or stem cells look like lymphoblasts,[103-105] and studies of peripheral blood have shown BFU-E to reside in the nonadherent "null" lymphocyte population.[106]

The pathway of erythroid *precursor* differentiation between the development of proerythroblasts and the mature red cell is known as the erythron and includes the functioning differentiated precursor cells observed in bone marrow aspirates and biopsy sections. The morphology of erythroid precursor maturation is well described in several texts and will not be repeated here. The salient features of the morphologic changes during cell development are related to biochemical and kinetic alterations, as reviewed by Granick and Levere[107] and shown in Figure 6-8. Times spent in each morphologic compartment are shown at the bottom of the figure, but the average transit time from proerythroblast to emergence of the reticulocyte into the circulation is approximately 5 days.[108] In acute anemia, the transit time may decrease to as little as 1 or 2 days by means of skipped divisions.[109] The red cells that emerge are macrocytic and may bear surface i antigen and other fetal characteristics because the abbreviated time in the marrow compartment does not permit complete conversion of i antigen to I antigen or acquisition of certain other adult characteristics.[110] The cells also contain excessive burdens of the rubbish that normally
FIGURE 6-8. Erythroid maturation: alterations in cell size, rates of DNA and RNA synthesis, enzymes involved in heme synthesis, and hemoglobin concentration. Substances listed in the *left* column are represented by corresponding *solid black lines*. Unless specified, graphs represent relative values. ALA refers to δ-aminolevulinic acid and PROTO to protoporphyrin. It will be noted that considerable protein synthesis takes place during the earliest phase, after which the nucleolus disappears but mitochondria remain. As the concentration of DNA decreases and that of RNA starts to fall, hemoglobin begins to appear and increases rapidly in amount. *(Redrawn from Granick S, Levere RD. Heme synthesis in erythroid cells. In Moore CV, Brown EB [eds]. Progress in Hematology, vol. 4. New York, Grune & Stratton, 1964, p 1.)*

accumulates during cell assembly[111] because less time is available for the cleansing action of cell proteases and nucleases.[112] Thus, stress erythropoiesis is associated with circulating Pappenheimer bodies (iron granules), basophilic stippling (ribosomes), Heinz bodies (hemoglobin inclusions), and Howell-Jolly bodies (nuclear remnants).

The kinetics of erythropoiesis can be monitored with the use of radioactive iron and surface scanning. The various ferrokinetic patterns in human diseases are shown in Figure 6-9. The total distribution of erythroid marrow can be determined by scintigraphy with [111]InCl bound to transferrin, as shown in Figure 6-10. Both ^{59}Fe kinetics and [111]InCl scintigraphy can be useful in the diagnosis of marrow failure, but these techniques are rarely necessary. Initial uptake of ^{59}Fe in marrow primarily occurs in pro-erythroblasts and early basophilic erythroblasts.[113]

Neutrophil Production

A model that describes the production and kinetics of neutrophils in human is shown in Figure 6-11. It is highly compartmentalized. The relatively tiny peripheral blood pool is divided into two components in equilibrium: the circulatory granulocyte pool (CGP) and the marginating

granulocyte pool (MGP). These pools provide entrance into tissues. The level of circulating cells is buffered by an immense narrow reserve of identifiable precursors, some of which are located in the mitotic compartment and others in a maturing storage compartment. Transit times within each compartment are relatively long, so a huge reserve remains available. The responses of these compartments to various diseases are detailed in Chapter 21. The kinetics of proliferation of recognizable cell precursors has been studied with labeled precursors of DNA. The so-called labeling indices from which measurements of cell cycle times can be made have served as important approaches to study of the pharmacology and toxicity of chemotherapy (see the chapter Chemotherapy in the Pediatric Patient in the companion volume *Oncology of Infancy and Childhood*).

The final stages of granulocyte production, their release from marrow, is also multifaceted.[114] At least four factors may influence granulocyte egress: organization and localization of the cells in relation to vascular channels, development of nuclear and cytoplasmic changes that increase cell deformability, factors that cause cell release, and finally, regulation of blood flow through vascular channels in the marrow.

TABLE 6-1	Cytologic Characteristics of Megakaryocyte Maturation Stages					
Stage	Nuclear Morphology	Cytoplasmic Staining (Wright-Giemsa)	Approximate Size Range	Demarcation Membranes	Granules	Suggested Name
I	Compact (lobed)	Basophilic	6-24 µm	Present by electron microscopy	Few present by electron microscopy	Megakaryoblast
II	Horseshoe	Pink center	14-30 µm	Proliferating to center of cell	Starting to increase	Promegakaryocyte
III	Multilobed	Increasingly more pink than blue	15-56 µm	Extensive but asymmetric	Great numbers	Granular megakaryocyte
IV	Compact but highly lobulated	Wholly eosinophilic	20-50 µm	Evenly distributed	Organized into "platelet field"	Mature megakaryocyte

Bone Marrow Examination and Megakaryocytopoiesis

Despite the fact that the morphology of megakaryocyte development is fairly well established (Fig. 6-12 and Table 6-1), bone marrow examination can be of limited value in the various platelet disorders. Bone marrow smears and biopsy sections provide insufficient data about thrombopoiesis because the final stage of platelet production, extrusion of cytoplasm into the sinusoid and shedding of platelets (to be described later), is not appreciated by these techniques; just the relative numbers of megakaryocytes and their size and ploidy can be determined by routine morphologic methods. It is not surprising that such information is only loosely correlated with platelet production (Fig. 6-13). Furthermore, sampling errors can be responsible for serious misinterpretations. This is a particular hazard with aspirates of neonatal marrow, in which megakaryocytes may be hard to detect regardless of whether platelet production is normal. Furthermore,

megakaryocytes are not evenly distributed in marrow smears. They are more readily found around the edges of the particles and may be mistaken for broken cells by an untrained observer. Megakaryocyte nuclei are often found lying free in marrow smears, where they may be erroneously scored as tumor cells. Biopsy sections provide more accurate assessment of megakaryocyte number and distribution than smears do, although the latter are usually sufficient (except in neonates) if examined carefully. Biopsy should not be attempted in neonates merely to define megakaryocytes; clinical judgment is a safer tool in these patients.

Examination of routine marrow smears and biopsy samples, though instructive, is limited by the two-dimensional views and thickness of the sections. Megakaryocytes have a peculiar predilection to lie next to the endothelial cell lining of the fronds of developing marrow cells, perhaps because TPO is produced by these cells. In general, megakaryocytes are too large to squeeze through

Blood. 1982;60:1122-1131.)*

the sinusoidal meshwork, so they merely push their cytoplasm through the fenestrations. These cytoplasmic structures, called proplatelets, serve as microtubule conduits for platelet packaging and release at sinusoids.[115] The protruding cytoplasm forms demarcation lines and then shatters into platelets, which are swept into blood, regulated in part by fibrinogen interacting with platelet $\alpha_{IIb}\beta_3$ integrin.[116] Megakaryocyte nuclei rarely make the transfenestration journey into the sinusoids and thence blood. If they do, they may be mistakenly interpreted by an unwary microscopist as tumor cells in the blood. Intact or partial megakaryocytes are regularly observed in the blood of patients with marrow-invasive diseases such as certain leukemias, metastatic cancers, granulomatous disorders, and fibrosis.

HEMATOPOIETIC GROWTH FACTORS

Since the pioneering work of Metcalf,[89] Sachs,[88] and their co-workers in the early 1960s, it has been recognized that normal and leukemic blood progenitor cells can be propagated in culture in the presence of soluble protein growth factors. These factors were originally termed *colony-stimulating factors* based on their ability to support the formation of colonies of blood cells by bone marrow cells plated in semisolid medium.[117] During the 1970s and 1980s it was recognized that there are multiple types of CSFs based on the different types of blood cells found in the colonies that grew in the presence of the different factors, thus leading to the hypothesis that the growth and differentiation of different lineages of blood cells are controlled, at least in part, by exposure of progenitor cells to CSFs with different lineage specificities.[117-119] With molecular cloning of the genes for many of these factors and their receptors during the 1980s and 1990s it became possible to study in detail the structure, function, and biology of the recombinant CSFs, as well as the molecular biology of their respective genes.[117-122] This analysis, along with similar work on regulation of cells in the immune system, led to the realization that there exists a large number of interacting regulatory molecules now
FIGURE 6-13. Thrombopoiesis. Shown *horizontally* in the center is the progression from uncommitted multipotential stem cells, through the proliferating progenitors detected in the in vitro clonogenic assays, to the spectrum of maturing megakaryocytes. The relative DNA levels of megakaryocytes and their precursors are given as ploidy values (n), where $2n$ is a diploid cell. The megakaryocytes are also presented *vertically* in terms of their maturation stages, with platelet shedding being the end stage; a detailed classification of these stages is given in Table 6-1 and Figure 6-16. The columns show the maturation stages at particular ploidy ranges. Thus, $4n$ megakaryocytes are found at maturation stages I and II. The *top* row shows a postulated two-level regulatory process with megakaryocyte colony-stimulating activity (Meg-CSA) primarily influencing the proliferation of progenitors and thrombopoietin required for megakaryocyte ploidy amplification and possibly for maturation. It is not certain that these regulators are completely exclusive in their target cell specificities as shown. Furthermore, no clear distinction is currently possible between the specific or nonspecific control of the two factors. Thrombopoietin production is sensitive to variations in platelet mass, as indicated in the figure; it is assumed that this feedback mechanism operates on the source of thrombopoietin. The progenitors might be controlled by cell cycle inhibition, perhaps as a consequence of normal numbers of megakaryocytes. *(Redrawn from Williams N, Levine RF. The origin, development and regulation of megakaryocytes. Br J Haematol. 1982;52:173-180.)*

generally known as cytokines or lymphohematopoietic cytokines that together serve to control the hematopoietic and immune systems and integrate the responses of these systems with those of many other physiologic systems.[120,123-126] These control molecules serve to regulate the growth, development, differentiation, activation, and trafficking of cells within the hematopoietic and immune systems. With elucidation of the sequence of most of the human genome in the final years of the 1990s, even more cytokine and growth factor genes have been discovered and have provided both new insight into how all these systems have evolved with common themes and further challenges to cell biologists in their attempt to understand the functions and interactions of all of the different molecules.

Cytokine gene families that contain at least one member that functions within the hematopoietic or immune system include the lymphohematopoietic cytokines (including many interleukins and CSFs)[117,122]; the receptor tyrosine kinase ligands CSF-1,[127] stem cell factor (SCF; also known as SF),[128] and the ligand for the Flks/Flt3 receptor (FL)[129]; the IL-1 gene family[130]; the chemokines[131]; the tumor necrosis factors (TNFs)[132]; the interferons[133]; the IL-10 gene family[134]; transforming growth factor β (TGF-β)[135]; and the IL-17 gene family.[136] We will briefly describe these families and molecules

among the family members selected as hematopoietic growth factors (HGFs) for further discussion.

Lymphohematopoietic Cytokines

For our purposes, the lymphohematopoietic cytokines are defined as protein ligands for members of the hematopoietin receptor gene family, also known as the cytokine receptor class I gene family.[137] This gene family is characterized by an extracellular domain with pairs of conserved cysteine residues and the distinctive amino acid sequence element Trp-Ser-Xaa-Trp-Ser (WSXWS).[138] These receptors all signal at least partly through the JAK-STAT (Janus kinase–signal transducer and activator of transcription) pathway.[139,140] This rather large family of hematopoietins now includes many interleukins[1] (IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-13, IL-15, IL-21, and IL-23),[122,141-143] GM-CSF,[117,144] G-CSF,[145] EPO,[146] TPO,[147] thymic stromal thymopoietin (TSLP),[148-150] leukemia inhibitory factor (LIF),[151] oncostatin M (OSM), cardiotropin-1 (CT-1), and ciliary neurotrophic factor (CNTF).[152] The hematopoietin receptors on the cell surface signal as multimers, either homomeric or heteromeric, and the family can be further divided into subfamilies based on the molecular composition of their receptor complexes. The lympho-

hematopoietic cytokines with homodimeric receptors include EPO, TPO, and G-CSF.[122] A second subgroup consisting of GM-CSF, IL-3, and IL-5 in the human system has receptor complexes that share a common subunit known as the β_c chain that forms heterodimers with unique cytokine α subunits to provide selectivity for the respective cytokines.[122] A third group that includes IL-6, IL-11, LIF, OSM,[153] CNTF, and CT-1 all share a common receptor signaling chain known as gp130, but with unique chains that provide ligand specificity.[152] A fourth group of cytokines largely involved in lymphocyte development and activation, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21,[154] share a hematopoietin receptor component known as the γ_c chain, originally identified as a component of IL-2R.[126] A fifth group, comprising IL-7 and TSLP, share the IL-7Rα chain,[155] and finally, IL-12 and IL-23, heterodimeric cytokines with a common subunit (p40) shared by each cytokine, also share the IL-12Rβ1 component.[143] Cytokines from the first two groups (EPO, TPO, G-CSF, GM-CSF, IL-3, and IL-5) all have predominant activities on the growth and differentiation of various myeloid cell populations and are traditionally included among the HGFs. Among the gp130 family of cytokines, IL-6 and IL-11 have multiple activities in different biologic systems but in addition, at least in vitro, play important roles in regulating myeloid cell growth and development, and therefore we will also consider them HGFs.[156] Although IL-4, IL-9, IL-12, and LIF display some activity as growth factors for myeloid cells, they all have prominent activity in other system as well and will not be considered further here.[122] The other interleukins, CNTF,[157] and CT-1 (the latter two of which act primarily outside the hematopoietic and immune systems) act predominantly on the growth, development, and activation of various lymphocyte populations, and although these activities are extremely important in controlling the immune system and possibly in indirectly controlling the hematopoietic system, we will leave them aside for simplicity and concentrate on the activity of the previously mentioned lymphohematopoietic HGFs.

Receptor Tyrosine Kinase Ligands

Three HGFs—macrophage CSF (M-CSF, also known as CSF-1[127]), SCF,[129,158] and FL[159]—have been identified that signal through related receptors, which themselves have tyrosine kinase activity.[129] The receptors for these HGFs are all evolutionarily related, as are the ligands themselves, and each plays an important role in controlling blood cell production.[160,161]

Interleukin-1 Gene Family

The IL-1[162,163] gene family has grown substantially and now includes at least IL-1α through IL-1χ, the IL-1 receptor antagonist (IL-1RA), and IL-18.[130,164] IL-1α, IL-1β, and IL-18 all have potent ability to induce cytokine production. IL-18, particularly in combination with IL-12, induces interferon-γ [IFN-γ],[165] but IL-1α and IL-1β have also been shown to synergize with other HGFs in support of early blood cell proliferation and therefore will be considered further here.[166] The functions of the other novel members of the IL-1 gene family are still unknown.

Chemokines

The chemokines represent a large family of generally small proteins (usually 8 to 12 kd) that are readily identifiable by sequence homology, including characteristic twin cysteine residues near the amino-terminals, which separates the family into CC chemokines if the cysteines are adjacent or into CXC cytokines if they are separated by one residue.[131] Currently, more than 50 members of the gene family have been demonstrated to have important roles in cell trafficking in many systems. The receptor gene family for this cytokine family comprises about 20 members of the G protein–coupled receptor (GPCR) family. However, their biologic function is not limited to chemotaxis inasmuch as several have been shown to effect gene transcription, apoptosis, and cell proliferation. IL-8 is a prominent CXC chemokine that regulates neutrophil trafficking and is therefore a prominent player in inflammatory responses.[131] However, two chemokines, SDF-1 and macrophage inflammatory protein 1α (MIP-1α),[167] have been reported to inhibit the cycling of very early stem cells and hence may be important molecules in halting cycling stem cells and returning them to their normal, quiescent state. SDF-1 is clearly very interesting and important in the hematopoietic system as a chemotactic factor for very primitive stem cells; it provides a possible mechanism for homing of cells both as hematopoiesis moves from the fetal liver to the bone marrow and during transplantation of cells in adults.[168]

Tumor Necrosis Factors

The TNF gene family[137] now includes TNF-α, lymphotoxin α and β, CD27 ligand, CD30 ligand, CD40 ligand, Fas ligand, TRAIL, and Trance.[126] Many of these molecules are involved in regulating the activation and death of various cells, including T lymphocytes. TNF-α itself has many biologic activities, particularly in inflammation. However, it is mentioned here because of its potent and important role in promotion of dendritic cell differentiation and activation.[169,170]

Interferons

Type I interferons (13 species of IFN-α, IFN-β, and IFN-ω) are closely linked on human chromosome 9. The type II IFN-γ demonstrates little if any sequence homology with the type I interferons, but the receptors for all of these cytokines are members of cytokine receptor class 2, which is related to but distinct from cytokine receptor class 1 (hematopoeitin receptors) because they lack the

distinctive WSXWS sequence.[171] In addition to their anti-viral activities, both type I and type II interferons have multiple other regulatory activities with many cell types, including T cells. In the human system, type I interferons play a prominent role in polarizing helper T cells toward the type 1 (T_H1) phenotype.[126] However, none of these molecules appear to have prominent roles in directly controlling blood cell production and will not be considered further here.[133]

Transforming Growth Factor-β Gene Family

The TGF-β gene family is a large family of genes that includes TGF-β1, TGF-β2, and TGF-β3; bone morphogenetic proteins (BMPs) 2 through 16; growth and differentiation factor (GDF) genes 1 to 10; activin; and inhibin. Like many of the other cytokines, receptors for the TGF-β family members are multimers composed of two different members of the serine/threonine kinase receptor gene family.[135] Receptors with different ligand specificities are generated by combining these gene products in different groupings. TGF-β1 itself is a very important regulator of cell cycling in many cell systems, including the hematopoietic system, and will be considered here further as a negative regulator of hematopoiesis.[172,173] Mutations in its receptor cause the Loeys-Dietz syndrome.[174] The BMPs and GDFs have been implicated in many developmental systems, but interestingly, BMP-4 has been shown to be essential in *Xenopus* for embryonic development of HSCs, and it seems at least possible that this molecule might play a role in mammals as well in blood cell development during embryogenesis, if not in adult hematopoiesis, an area worth following. However, for our purposes, we will include only TGF-β1 itself as an HGF for simplicity's sake.

Action of Hematopoietic Growth Factors

Predominantly Lineage-Specific Hematopoietic Growth Factors: GM-CSF, M-CSF, IL-5, TPO, and EPO

Early on it was recognized that different CSFs could selectively support the growth of specific types of hematopoietic colonies.[117] Thus, when human bone marrow cells are cultured in semisolid medium in the presence of G-CSF, 7 to 8 days later colonies emerge that consist largely of mature neutrophilic granulocytes and their precursors.[145] This led to the model that G-CSF to a large degree interacts with relatively late hematopoietic progenitors that have already committed to the neutrophil lineage (CFU-G) and serves to support their growth and final maturation into functional neutrophils.[145] Similar analysis has revealed that the other major hematopoietic cell lineages have analogous lineage-specific late-acting factors and that these molecules frequently serve as important, if not primary regulators of the respective pathways. Thus, M-CSF supports monocyte/macrophage

colony growth and is important in supporting the growth and maturation of monocyte progenitors (CFU-M)[127]; IL-5 supports eosinophilic granulocyte colony formation and therefore supports the growth and maturation of eosinophil progenitors (CFU-Eo), as well as activating eosinophils[175,176]; EPO is necessary for the growth and maturation of both earlier (BFU-E) and later (CFU-E) progenitors of the erythroid lineage[146]; and TPO directly supports the growth and maturation of megakaryocyte progenitors (CFU-Meg) and the subsequent production of functional platelets.[147,177]

Although regulation of the respective blood cell pathways by the lineage-specific HGFs is likely to be their major function, in no case is this lineage specificity absolutely maintained. G-CSF has been found to influence the migration and proliferation of endothelial cells, cells that express high-affinity receptors for this cytokine.[178] IL-5 serves as a growth factor for activated B cells, particularly in the mouse, and affects the type of immunoglobulin secreted by mature B cells.[179] EPO[180] and TPO[181] have been noted to interact with megakaryocyte and erythroid progenitors, respectively. M-CSF appears to be important in trophoblast development.[127] Finally, populations of early HSCs have been found to express receptors for many cytokines; typically, these cells do not respond to single factors but require combinations of factors to trigger them into cycle.[182,183] "Lineage-specific" factors that have been reported to act in various combinations to trigger cycling of early "stem" cells include G-CSF,[184] M-CSF,[185] and TPO,[186] thus demonstrating that the molecules are not strictly "lineage specific," even within the hematopoietic system. Mice deficient in either the TPO receptor (mpl) or G-CSF are deficient in levels of all progenitor cells, consistent with the idea that these factors are indeed involved in expansion of early-lineage cells.[121] However, when administered in vivo, each of these molecules largely influences the growth and development of the expected lineage, and the designation of lineage specificity therefore seems warranted.

Multilineage Hematopoietic Growth Factors: IL-3 and GM-CSF

Initial analysis of human bone marrow cell cultures grown in the presence of GM-CSF revealed that a variety of different colony types develop over a period of 10 to 14 days.[187] Mature blood cells that could be readily identified included neutrophils, monocytes/macrophages, and eosinophils. This led to designation of the molecule as a "granulocyte-macrophage" colony-stimulating factor, or GM-CSF. When compared with G-CSF, it was found that GM-CSF took longer to produce colonies with identifiable neutrophils, but the ultimate variety of cell types was greater. This led to a model in which GM-CSF acts on progenitors committed to produce either neutrophils or monocytes (CFU-GM), which is a precursor to the G-CSF–responsive CFU-G and the M-CSF–responsive CFU-M.[117,187] These later progenitors apparently retain responsiveness to GM-CSF as well because mature

monocytes and neutrophils can be observed in cultures supported by GM-CSF alone. That this model is not strictly correct was shown when recombinant GM-CSF was introduced into human bone marrow cultures in the presence of EPO and it was found that this combination of factors was very effective in supporting the development of erythroid colonies (murine GM-CSF is somewhat less effective in this regard).[188,189] Thus, despite its name, GM-CSF generally interacts with intermediate multilineage progenitors that yield neutrophils, eosinophils, monocytes, erythroid cells, and megakaryocytes (CFU-GEMM). At the time, these activities were similar to those ascribed to IL-3 in the murine system.[190] When human IL-3 was identified, it proved to be able to support multilineage colony formation similar to human GM-CSF, thus indicating that it interacts with slightly different but strongly overlapping subsets of progenitors.[191,192] When compared with GM-CSF, IL-3 is somewhat more effective in supporting multilineage, erythroid, and megakaryocyte colony formation, and GM-CSF is slightly more effective in mediating granulocyte and monocyte/macrophage colony formation.[191,192] In serum-free conditions, the ability of IL-3 to support final neutrophil and monocyte maturation is significantly depressed, thus indicating that later-acting factors, G-CSF or GM-CSF in the case of neutrophils or M-CSF or GM-CSF in the case of monocytes, are necessary for final end cell production.[193]

In addition to acting slightly earlier than GM-CSF, IL-3 is clearly distinguished in its activity by its ability to support the growth and maturation of mast cells and basophils.[194,195] In the mouse, this was one of the first recognized activities of IL-3,[190] and when first administered to primates, basophilia was one of the most prominent findings.[195,196] Hence, IL-3 appears to be capable of supporting the growth and development of basophil and mast cell progenitors. In the human system, both IL-3 and GM-CSF can support the development and differentiation of dendritic cells of either myeloid or lymphoid origin, especially in combination with SCF, FL, and TNF.[197-199]

IL-4 in mice and humans has also been reported to support multilineage colony formation, including colonies that contain cells from the erythroid, megakaryocytic, neutrophilic, and monocytic lineages.[200-202] IL-4 in the mouse supports mast cell growth and therefore shares many activities with IL-3.[179] However, IL-4 plays very important roles in the development and maturation of T and B cells,[179,202,203] particularly in the polarization of cytokine production by helper T cells toward the type 2 (T_H2) response.[204] Therefore, on balance IL-4 is likely to be more important in controlling immune cell development and function and will not be discussed further here. IL-9 in both the murine and human systems has been shown to enhance erythroid colony formation in the presence of EPO[205] and appears to play a role in T- and B-cell development as well.[206] More recently, IL-9 has been shown to have some effects on the growth and activation

of mast cells and may play some role in the pathology of asthma.[207]

Early-Acting Hematopoietic Growth Factors: SCF and FL

SCF[128,129,158] and FL,[159,208,209] both receptor tyrosine kinase ligands, interact with a variety of hematopoietic progenitor cells, perhaps most importantly with very early stem cell populations. SCF also plays an important role in melanocyte growth and development, which is reflected in the coat color effects of mutations in SCF or its receptor c-kit.[128] Genetic analysis of mice clearly shows that mice defective in either SCF (*Sl* mice) or c-kit (*W* mice) have serious hematopoietic (and many other) defects, including macrocytic anemia, mast cell deficiencies, and deficiencies in the stem cell compartment (reviewed by Galli and colleagues[128]). These early studies had already indicated the critical importance of SCF in the survival and development of stem cells. Mutations in the human c-kit gene lead to a similar phenotype in melanocyte development in humans known as the piebald mutation; however, these patients do not have any hematologic problems, probably because severe mutations in this locus are likely to be lethal.[210] In vitro, the activities of SCF are generally most evident when combined with other HGFs; its proliferative activity when used with hematopoietic cells in culture as a single factor is minimal.[128] In fact, culture of murine bone marrow cells with SF alone ultimately yields largely mast cells.[211] However, SF acts synergistically to enhance the activities of most of the other HGFs in culture and is particularly effective when combined with HGFs such as IL-3, IL-1, or IL-11 in promoting the expansion of "blast"-like cells that retain considerable potential for yielding multilineage colonies in secondary culture.[212-214] These colonies, when replated under conditions that support B-lymphocyte development or when transplanted into animals, also yield B and T lymphocytes, thus indicating that SCF-responsive cells include primitive stem cells with both lymphoid and myeloid potential.[215,216] SCF has also been implicated in combination with IL-2 or IL-7 in early stages of T-cell development in the thymus,[217] with IL-7 in pre-B-cell growth,[218] and with IL-7 in enhancing natural killer (NK) cell responsiveness to IL-2.[128] However, that none of these lineages are dramatically affected in *W* or *Sl* mice indicates that SCF-independent mechanisms can compensate in these systems.

SCF,[219] M-CSF,[220] and FL[161] are all expressed as both membrane-bound and soluble forms. In the case of SCF, expression of membrane-bound forms of the molecule in the marrow microenvironment provides a nice model for how this growth factor might act locally. Indeed, cell lines that express exclusively membrane-associated SCF are much more effective in supporting long-term hematopoiesis in vitro than are cell lines that exclusively produce soluble forms of the molecule.[219] This interaction of membrane-associated SCF with c-kit

provides one mechanism for the adherence of hematopoietic cells to stroma in that binding of human megakaryocytes to fibroblasts can be blocked by antibodies to c-kit.[221] Finally, membrane-associated forms of SCF in which the cytoplasmic domain is essentially missing results in male but not female sterility, thus suggesting that the cytoplasmic domain may have an as yet undetermined important biologic function.[128,222]

As shown by early genetic studies and confirmed through analysis of the recombinant protein, SCF is not specific for the hematopoietic system. It is also an important growth factor for melanocytes and primordial germ cells, and it appears to play a role in development of the nervous system, perhaps as a neuronal guidance factor, although it has been difficult to demonstrate neurologic defects in *W* or *Sl* mice.[128]

The Flt3 receptor tyrosine kinase was originally identified as a novel receptor present in HSCs; in human marrow, expression is largely limited to the CD34$^+$ cell population.[223-225] FL alone yields low numbers of CFU-GM from human bone marrow but acts synergistically with other cytokines, including IL-3, GM-CSF, EPO, and SCF, to yield enhanced colony formation in terms of both size and number of colonies.[208,226,227] The synergy observed between FL and the other HGFs is comparable to that observed with SCF in similar systems, with the exception that FL has little effect on BFU-E.[209] Multifactor combinations with SCF have been used for expansion of CFCs in long-term cultures; FL has effects comparable to those of SCF when combined with IL-1, IL-3, IL-6, and EPO in 4-week cultures.[228,229] Like SCF, FL in combination with other cytokines such as GM-CSF supports dendritic cell development from CD34$^+$ bone marrow cells.[197] In contrast to SCF, FL does not support the growth and development of mast cells.[208,226] Despite this overlap in bioactivities, mice in which the Flt3 receptor tyrosine kinase has been disrupted appear to have normal hematopoiesis, with the only detectable defects being observed within the B-lymphocyte lineage.[230] However, mice with disruption of both the c-kit and Flt3 receptor tyrosine kinase genes display more severe hematologic complications than do mice with either single mutation, thus suggesting that the two pathways can to some degree compensate for one another.[230] The importance of Flt3 ligand in B-cell growth has also been shown with cultures of primitive B-cell progenitors (CD43$^+$B220^{low}) in combination with either IL-7 or SF.[231] Altogether, these findings argue for an important role for Flt3 ligand in hematopoiesis.

Other Stem Cell Factors: Wnt, Jagged, BMP, and Angiopoietin-like Growth Factors

Several new growth factors have been shown to regulate HSC production during embryogenesis, as well as adulthood. The Wnt family of factors regulates stem cell homeostasis.[232-238] Overexpression of Wnt 3a led to a threefold expansion of HSCs. This is the first time that stem cell number was actually increased in a competitive repopulation assay. In separate experiments, overexpression of β-catenin led to an expansion of HSCs, and sorting by activated β-catenin in HSCs based on a Wnt reporter line that turned cells green when Wnt is activated demonstrated HSC activity. Further studies in chronic myelocytic leukemia demonstrated that Wnt activation was present in leukemia.[239] These studies showed that Wnt activity could drive HSC production; however, other experiments have demonstrated that knockout of β-catenin within HSCs is not required for stem cell homeostasis.[240] Two recent papers demonstrated that constitutively activated β-catenin in HSCs leads to aplastic anemia.[241,242] Activation of the Wnt pathway may not be necessary for stem cell homeostasis, but it may be sufficient to drive HSCs to produce more self-renewal cell divisions.

The Wnt pathway clearly interfaces with HSC production. It is possible that pulses of Wnt will have different activity than a constitutively active Wnt signal. In addition, redundancy within the marrow space among other signaling pathways, including the Notch and BMP pathways, have left the stem cell compartment with significant chances of survival. Wnt acts through canonical and noncanonical pathways. In the former case this leads to activation of β-catenin to the nucleus through the complex involving adenomatous polyposis coli and β-catenin. In the latter, there is stem cell activation by the Rho guanosine triphosphatases (GTPases). Wnt activation acts at multiple places during hematopoiesis, both at the stem cell level and at the pre-B level, as well as at multiple places in T-cell development. Wnt factors bind to canonical Frizzled receptors and activate a signaling pathway. An antagonist Wnt signal, Wnt 5a, suppresses B-cell proliferation and may act to suppress stem cell homeostasis. Other Wnt factors have been found to regulate hematopoiesis, including Wnt 2b and Wnt 10b for human bone marrow CD34$^+$ cells.

The Notch pathway has been shown to regulate HSC production based on retroviral transduction of hematopoietic cells.[243,244] This expands the population of HSCs significantly. Notch works through a ligand-receptor interaction in which Deltas and Jaggeds are presented on the stem cell niche. In general, Jagged2 is thought to be the predominant Notch ligand in marrow and is presented by the osteoblast. Modulation of Jagged2 leads to expansion of HSC production. The Notch pathway has been put into a genetic pathway with Runx1 based on the zebra fish mutant mindbomb.[245] Mindbomb mutants have no Notch signaling because of a defect in an E3 ubiquitin ligase that promotes ligand recycling. This mutant lacks HSCs during development, and overexpression of Runx1 rescues hematopoiesis. A pulse of Notch signaling has been shown to expand HSCs in the zebra fish system. Furthermore, Runx1 rescue of Notch1 mutants was demonstrated in the mouse system, and it was also shown that GATA-2 was a target of the Notch pathway.[246,247] Modulation of Wnt and Notch demonstrates synergy of Wnt 3a and activation of the Notch

pathway. It is possible to activate Wnt pathways with the chemical called BIO drug, which is an inhibitor of glycogen synthase kinase 3β (GSK3β). Thus modulation of the Wnt and Notch pathways plays a significant role in stem cell homeostasis.

The BMP family has been demonstrated to induce HSC production in the *Xenopus* and zebra fish systems.[248-255] This leads to expansion of erythroid blood islands during early development. Interestingly, a dominant-negative version of BMP activated later in development leads to enhanced erythropoiesis, thus demonstrating two independent effects of BMP regulation of HSC differentiation and proliferation. Furthermore, BMP has recently been shown to expand HSC production in the AGM region. BMP was shown to expand or maintain HSC production in human ES cells and functions as a key regulator of stress-induced erythropoiesis.[256] BMP also regulates the stem cell niche. It is unclear how BMP and the Notch and Wnt pathways interact.

Angiopoietin-related proteins are potent activators of HSC production.[257] For example, angiopoietin-like 2 and angiopoietin-like 3 were shown to lead to a 20- or 30-fold expansion of long-term HSCs when cultured for 10 days in the presence of the ligands. This was demonstrated by a limiting-dilution competitive repopulation assay. Thus, angiopoietin-like genes must also participate in the stem cell niche. Another growth factor glycoprotein called osteopontin is also involved in stem cell homeostasis and negatively regulates the stem cell pools.[258,259] A number of factors, including TGF-β1, also demonstrate negative regulation. Ligands produced by the stem cells themselves may also regulate stem cell homeostasis.

Synergistic Factors: IL-1, IL-6, and IL-11

Early in the 1980s, factors were identified that had the ability to enhance hematopoietic colony formation supported by other HGFs, particularly early progenitor cells. One factor, designated hematopoietin 1, was subsequently purified and discovered to be IL-1.[185] In this fashion, IL-1 was recognized as having little ability on its own to stimulate hematopoietic colony formation but can act in synergy with other HGFs, notably IL-3, to increase both the frequency of colony formation and the number of cells per colony.[166] Subsequent to discovery of the synergistic activity of IL-1, numerous other cytokines have emerged with similar activity, including IL-6,[260] IL-11,[261] LIF,[262] and IL-12.[263] Of these, IL-6, IL-11, and LIF all signal through a common signal-transducing molecule, the gp130 component of IL-6R.[264] Because these molecules are likely to behave similarly in most systems and because IL-6 and IL-11 have been the most thoroughly studied, we will limit our discussion to these two members of this family. IL-12, which signals through a distinct but perhaps similar pathway to gp130,[265] has interesting effects in combinations with other cytokines[263] but appears to be more important in regulating the development and activities of T and NK cells[266,267] and will therefore not be discussed further here.

The effects of IL-1 on hematopoiesis have been highly complicated by the fact that this cytokine is a potent inducer of secondary cytokine production, frequently by accessory cells in the culture.[268] The induction of other growth factors, notably IL-6, G-CSF, GM-CSF, and IL-11, is likely to contribute to the activity of IL-1 as a synergistic factor in hematopoietic colony formation. Nevertheless, combinations of IL-1 with other factors in cultures of highly purified hematopoietic cells typically yield synergistic effects, thus suggesting that at least some of the effects are direct.[269,270] However, even with highly purified hematopoietic progenitor cell populations, the effects of IL-1 can be indirect. For example, Rodriguez and co-authors reported that IL-1 can prevent the apoptotic death of CD34+lin− human bone marrow cells but that the effect is largely abrogated by antibodies to GM-CSF, which suggests that some progenitor cells in the population can produce their own GM-CSF.[271] Consequently, the survival effect of IL-1 in some systems may also be indirectly mediated by induction of GM-CSF expression in CD34+lin− bone marrow cells themselves.

IL-6 is an extremely pleiotropic cytokine with important effects on the growth and differentiation of T and B cells, on induction of the hepatic acute phase response, and on enhancement of the proliferation of hematopoietic progenitor cells.[223] IL-6 signaling, mediated by two members of the hematopoietin receptor gene family, IL-6R[272] and gp130,[273] was the first example of signaling through a commonly shared receptor subunit, gp130, which is now known to be involved in the signaling of LIF, IL-11, OSM, CNTF, and CT-1.[264,274] Because most cells express gp130, expression of other receptor components such as IL-6R or IL-11R generally determines whether a cell will respond to one of these family members; cells that express receptors for multiple members of this cytokine subgroup generally exhibit identical or nearly identical responses to each member whose receptor component is expressed by the cell.[152,264,275]

The HGF activity of IL-6 was recognized when the cDNA for this cytokine was cloned by functional expression cloning from a human T-cell line that produced weak colony-stimulating activity that supported modest CFU-GM colony formation with murine bone marrow target cells.[276] More detailed analysis of the murine system and subsequently the human system led to the realization that IL-6 has little if any ability to support colony formation on its own but can enhance colony formation when supported by other HGFs, particularly IL-3 and SCF.[212,260] This effect was most prominent with bone marrow cells from mice isolated 2 days after treatment with 5-FU, a drug that enriches for primitive progenitors by selectively killing later, actively cycling cells in the bone marrow.[182] Bone marrow cells treated in this fashion generally yield significant numbers of colonies only when plated in the presence of multiple HGFs. In this system, IL-6 was found to enhance colony formation when supported by IL-3 or SCF. These early cells are typically quiescent in

the G_0 phase of the growth cycle, and combined effects of cytokines, such as IL-3 and IL-6, are required to push them into active cycling.[182] Similar effects have been observed in cultures of purified early human hematopoietic progenitor cells.[277]

IL-11 was originally identified as a stimulatory factor for a murine hybridoma cell line,[278] but characterization in various hematopoietic cell culture systems soon revealed a much broader spectrum of biologic effects.[279,280] Evaluation of the various properties of IL-11 led to the realization that the IL-11R complex uses the IL-6 gp130 signal-transducing system. These two HGFs appear to have somewhat overlapping biologic activities.[281] In general, IL-6 has proved to have more effects on T and B cells than IL-11 does[223,280] and similar effects on the hepatic acute phase response[282] and on osteoclast formation,[283] but IL-11 is somewhat more potent in megakaryocytopoiesis.[284] Like IL-6, the effects of IL-11 in hematopoietic cultures are largely observed only when combined with other factors. IL-11 in combination with SCF or FL has proved to be very effective in supporting the growth of primitive hematopoietic progenitors.[227] Early after its discovery, IL-11 was shown to have important effects on the growth and development of megakaryocyte progenitors.[280,284,285] Again, in this system IL-11 had little effect on colony formation on its own but was found to act in synergy with IL-3, with SCF, or more recently, with TPO in supporting CFU-Meg colony formation.[286]

Negative Regulator of Hematopoiesis: TGF-β

A variety of cytokines have been reported to reversibly inhibit cycling of early hematopoietic cells, including the chemokines SDF-1[208] and MIP-1α,[167] as well as TGF-β, perhaps the most potently of all.[287-289] Very interestingly, when individual early cells were plated in wells, either antibody to TGF-β1 or an antisense oligonucleotide to the mRNA for this factor could trigger the release of cells from quiescence in the presence of appropriate combinations of early-acting cytokines, which by themselves failed to trigger cycling of the cells.[288,289]

MOLECULAR BIOLOGY OF THE HEMATOPOIETIC GROWTH FACTORS

Genomic Analysis of Cytokine and Cytokine Receptor Genes

From analysis of the human genome, several common themes and relationships have emerged from the different types of cytokine/growth factor and receptor genes. First, as already noted, most of the cytokines and their receptors exist as members of distinct evolutionarily related gene families; examples of single cytokine or growth factor genes with no relatives are rare. Similarly, the receptors also fall into gene families. Thus, a relatively small number of primordial growth factor/cytokine genes were duplicated many times to form families of genes that evolved into serving regulatory functions for many different systems. As already discussed, members of the cytokines that signal through the gp130 receptor component are important regulators in many different systems, including embryonic development, the central nervous system, the myocardium, and the hematopoietic and the immune systems.[193] That different physiologic systems share cytokines and receptor components from common gene families gives us more assurance that lessons learned from the relatively accessible hematopoietic system will at least provide guidance as we begin to dissect other systems. Interestingly, in most cases each of the individual cytokines of a particular gene family use members of a single receptor gene family. For example, all of the chemokines use G protein–coupled receptors as their signaling/recognition molecules,[131] whereas all members of the TGF-β gene family use different combinations of serine/threonine kinase receptors as their recognition and signaling molecules.[135] All these receptor-ligand pairs must have evolved in concert as they were selected to control different cellular processes.

Despite the obvious gene duplications that have occurred in all these gene families, there is no absolute rule regarding how the genes are arranged today. In some cases, the related genes are still closely linked in tandem in the genome, as is the case for the IL-3 and GM-CSF genes on chromosome 5 at 5q31.1 (Fig. 6-14). In this case, another duo of related genes, IL-4 and IL-13, are very closely linked to one another but slightly more separated from the IL-3/GM-CSF cluster. Similarly, in the case of the IL-10 gene family, several of the members are closely linked at 1q32 (IL-10, IL-19, IL-20, MDA-7), whereas IL-22 and AK155 are linked at 12q15 (MDA, AK195),[290] another example in which genes have either been split out of a tandem array on one chromosome during recombination or have migrated from the original site of the primordial gene and subsequently undergone further gene duplication and separate evolution events.

Structures of the Hematopoietic Growth Factor Proteins

The availability of cDNA for the individual cytokines allowed rapid determination of their primary amino acid sequence, expression in quantities large enough for direct x-ray determination of their crystal structure, and more broadly, prediction of structures based on those of proteins related even distantly by sequence. One of the clear results of analysis of the structures of the different cytokines was the realization that despite generally low conservation of amino acid sequence, many of the lymphohematopoietic cytokines are distantly related in evolution. Most of the lymphohematopoietic cytokines are believed to assume a tightly packed, antiparallel, four–α-helix bundled structure with either short or long

Gene	Orient.	Loc.	Description
FACL6	↑	5q31	Fatty acid coenzyme A ligase, long-chain 6
IL3	↓	5q31.1	Interleukin-3 (colony-stimulating factor, multiple)
CSF2	↓	5q31.1	Colony-stimulating factor 2 (granulocyte-macrophage)
RIL	↓	5q31.1	LIM domain protein
SLC22A5	↓	5q31	Solute carrier family 22 (organic cation transporter), member 5
IL5	↑	5q31.1	Interleukin-5 (eosinophil colony-stimulating factor)
RAD50	↓	5q31	RAD50 homologue *(Saccharomyces cerevisiae)*
LOCI53854	↓	5q31.1	Similar to interleukin 13 *(Homo sapiens)*
IL4	↓	5q31.1	Interleukin-4
QP-C	↓	5q31.1	Low-molecular-mass ubiquinone-binding protein (9.5 kd)
IL13	↓	5q31	Interleukin-13
SCYB 14	↑	5q31	Small inducible cytokine subfamily B (Cys-X-Cys), member 14 (BRAK)
TCF7	↓	5q31.1	Transcription factor 7 (T-cell specific, HMG-box)
CDKL3	↑	5q31	Cyclin-dependent kinase-like 3
MGC13017	↑	5q31.2	Similar to RIKEN cDNA A430101B06 gene
PITX1	↓	5q31	Paired-like homeodomain transcription factor 1
KLAA0801	↑	5q31.2	RNA helicase
IL9	↑	5q31.1	Interleukin-9
FBXL3B	↓	5q31	F-box and leucine-rich repeat protein 3B
MADH5	↓	5q31	MAD, mothers against decapentaplegic homologue 5 *(Drosophila)*

FIGURE 6-14. Cytokine gene cluster at 5q31.1. The region from chromosome 5, which consists of 5 megabases of DNA sequence, is expanded as shown, with the structures of the individual genes, GenBank notations, descriptions, and gene orientations indicated. The region contains approximaley 115 genes, 21 of which are illustrated. The data were collected and assembled from the National Center for Biotechnology Information database.

helical bundles.[122,126] Lymphohematopoietins with the short helical bundle structure include IL-2, IL-3, IL-4, IL-5, IL-7, IL-9, IL-13, IL-15, and GM-CSF. Cytokines with long helical structures include the gp130 signaling proteins IL-6, IL-11, LIF, and OSM; IL-12p35; and the homodimeric receptor signaling proteins EPO, TPO, and G-CSF.[122,177,291] With the exception of IL-12, which is a covalently linked heterodimer of two chains, designated p40 and p35,[267] all these cytokines are believed to act as monomers.

Sequence and structural information suggests that the long helical bundle–structured cytokines are all distantly related in evolution. Members of the IL-6 subfamily, including IL-6, IL-11, and G-CSF, show rather modest sequence similarity but display common gene organization and certain structural features that suggest evolutionary relatedness.[125,291,292] Sequence alignment of IL-6 and G-CSF shows conservation of cysteine residues.[293] Interestingly, a cytokine identified in the chicken, myelomonocytic growth factor (MGF),[294] displays sequence similarities with G-CSF and IL-6, which suggests that all three are derived from a common ancestral gene. EPO shows some structural features similar to growth hormone and to G-CSF, but at a very low level.[291] In contrast, the amino-terminal half of TPO shows strong sequence similarity with EPO, whereas the carboxy-terminal half is unrelated to any known protein.[295-297] The four–helical bundle structure of EPO is clearly related to the amino-terminal helically structured portion of TPO, whereas the additional domain of TPO, which is heavily glycosylated, may serve to increase the serum half-life of the molecule. Both these family members are believed to act as monomers.

Ligands for the receptor tyrosine kinase gene family members SCF, FL, and M-CSF share many common structural similarities.[128,161,298] All three contain transmembrane domains and are initially synthesized as homodimeric integral membrane proteins. Although the membrane-bound forms are functional, dimeric soluble forms released from the cell by proteolysis also display

biologic activity. The extracellular domains have low but significant sequence similarity, including conservation of the position of the cysteine residues involved in disulfide bridge formation.[161] Modeling of these extracellular domains indicates that they, too, are likely to form four–α-helix bundle structures tethered to the membrane through variable spacer domains with dimerization through a cysteine located in the spacer domain.[122,160,161]

Hematopoietic Growth Factor Gene Disruptions

Hematopoietin Receptor Ligands

G-CSF

The combination of technology for regenerating mice from cultured ES cells and the ability to selectively disrupt genes in cultured mammalian cells has led to methodology for studying gene function in vivo (mutants related to HGFs are summarized in Table 6-2).[318] Using this approach, Lieschke and co-workers[313] were able to generate mice with both copies of the G-CSF gene disrupted. These animals develop normally but as adults display a 70% to 80% reduction in levels of circulating neutrophils, a 50% reduction in the number of progenitors in all lineages, and impaired resistance to challenge by infection with *Listeria monocytogenes*. These findings, which are in agreement with earlier observations by Hammond and colleagues[319] in dogs that had developed cross-reacting antibodies to canine G-CSF, demonstrate a central role for G-CSF in controlling neutrophil levels. However, the decline in all populations of progenitors is consistent with a role for G-CSF before commitment to the neutrophil lineage, perhaps at the early stem cell stage as suggested by the synergy of G-CSF and SCF in generating blast cell colonies.[156,320]

TABLE 6-2	Genetic Defects in Receptors or Signaling Proteins			
HUMAN MUTATIONS				
Gene	**Mutation**		**Phenotype**	**Reference**
IL-2Rγ$_c$	Deletion		SCID	299
JAK3	Deletion		SCID	300
G-CSFR	C-terminal deletion		Kostmann's disease	301
EPOR	C-terminal deletion		Benign erythrocytosis	302
NONHUMAN MUTATIONS				
Species	**Gene**	**Name**	**Phenotype**	**Reference**
Mouse	c-kit	White-spotting	Macrocytic anemia, mast cell deficiency, lack of pigmentation, sterile	303-305
	Steel factor	Steel	Macrocytic anemia, mast cell deficiency, lack of pigmentation, sterile	303-305
	CSF-1	Microphthalmia	Osteopetrosis secondary to decreased osteoclast function	306
	HCP	Motheaten	Immunodeficiency, autoimmune disease, increased sensitivity to erythropoietin	307
Drosophila	JAK homologue	Hopscotch	TumL allele is a gain-of-function mutation that causes leukemia	308, 309
TARGETED DISRUPTION IN MURINE EMBRYONIC STEM CELLS				
Gene	**Phenotype**			**Reference**
IL-6	Decreased CFU-S and stem cell function			310
GM-CSF	Hematopoiesis normal; progressive accumulation of pulmonary surfactant			311, 312
G-CSF	Neutrophils 25% normal; impaired response to *Listeria monocytogenes* infection			313
EPO	Embryonic lethal—failure of definitive erythropoiesis			314
EPOR	Embryonic lethal—failure of definitive erythropoiesis			314
TPOR (c-mpl)	Platelets 15-20% normal			315
IL-3Rβ	Normal hematopoiesis			316
IL-3/IL-5/GMRβ$_c$	Similar to GM-CSF$^{-/-}$ mice; also low eosinophils and impaired eosinophil response to *Nippostrongylus brasiliensis*			316
Vav	Not required for hematopoiesis			317

CFU-S, colony-forming unit–spleen; CSF-1, colony-stimulating factor 1; EPO, erythropoietin; EPOR, erythropoietin receptor; G-CSFR, granulocyte colony-stimulating factor receptor; GM-CSFR, granulocyte-macrophage colony-stimulating factor receptor; HCP, hematopoietic cell phosphatase; IL, interleukin; JAK, Janus kinase; SCID, X-linked severe combined immunodeficiency; TPOR, thrombopoietin receptor.

EPO and TPO

The TPO and EPO genes have clearly evolved from a common ancestor, and at some point the extra protein-coding region found in the final coding exon of the TPO gene was either removed (in the case of the EPO gene) or added (in the case of the TPO gene) after the early duplication event.

Mice with deletion of either the TPO or the c-mpl gene have been described.[315,321] Although these animals develop normally and do not display significant abnormalities in bleeding times, they have only 15% to 20% of normal levels of circulating platelets. This result implies that TPO is very important for maintaining circulating levels of platelets but that other cytokines might have some capacity to generate platelets at low levels. Interestingly, through an elegant study of various combinations of receptor gene disruptions, Gainsford and associates[322,323] have shown that cytokines with megakaryocyte-stimulating activity in culture, including IL-3, IL-6, IL-11, and LIF, play no role in basal platelet production in mice with the *mpl* gene disruption.

In the case of EPO, gene disruption results in embryonic lethality because of failure of fetal liver erythropoiesis.[314]

IL-6–gp130 Complex Ligands: IL-6 and IL-11

Animals that have been engineered to lack the IL-6 gene develop normally but display significant deficiencies in various immune and inflammatory responses.[324] Interestingly, the hepatic acute phase response in these animals is severely compromised after tissue damage, but only moderately in response to lipopolysaccharide (LPS). The effects of disruption of the IL-6 gene on normal hematopoiesis are relatively minor: a slight decrease in peripheral blood leukocyte counts, a 10% reduction in bone marrow cellularity, a 50% reduction in CFU-S$_{12}$, and fourfold to fivefold reduction in pre-CFU-S.[310] This relatively minor effect of disruption of the IL-6 gene on hematopoiesis points out the difficulty in evaluating the relative importance of cytokines in vivo through in vitro culture systems; IL-6 in cultures of mouse bone marrow cells is one of the most potent synergistic factors for all lineages, yet gene disruption experiments suggest that either it is highly redundant with other cytokines or its role in regulating normal hematopoiesis is relatively minor.[121]

GM-CSFR Complex Ligands: IL-3, GM-CSF, IL-5

The genes for each of these proteins consist of approximately 3000 base pairs divided among four (GM-CSF,[325,326] IL-5,[179,327]) or five (IL-3[326,328]) exons with somewhat similar structure. All these genes have been localized to the long arm of chromosome 5 at 5q31.1,[329] a region commonly disrupted or deleted in patients with various malignant myeloid neoplasms.[330] This region also contains the genes for other important cytokines, including IL-4, IL-9, IL-12p40, and IL-13.[329-331] Detailed mapping of the region has demonstrated that several of these genes are very closely linked: the GM-CSF and IL-3 genes are tandemly arrayed within 9 kilobases (kb) of one another,[332] whereas IL-4 and IL-13 are separated by only 12.5 kb.[329] This clustering of molecules with similar structure and function, including sharing of receptor components in the case of GM-CSF, IL-3, and IL-5,[333,334] provides further strong support for the evolutionary relatedness of their respective genes.

Mice with homozygous disruption of the GM-CSF gene develop normally and do not display any numerical defects in levels of circulating granulocytes or monocytes or in levels of CFU-GM progenitors in the marrow or spleen.[311,312] However, these animals exhibit alveolar proteinosis with accumulation of surfactant in the lungs as a result of defective aveolar macrophage function. Thus, GM-CSF plays an irreplaceable role in the function/development of certain macrophage populations, but any function played by this cytokine in controlling basal or stimulated production of granulocytes or monocytes can be replaced by other factors.

To evaluate the role of the entire IL-3/GM-CSF/IL-5 complex, Nishinakamura and co-workers[335] engineered a mouse without the β$_c$ receptor component shared by all three cytokines, as well as with a disruption in the IL-3 gene. Mice lacking β$_c$ have a pulmonary alveolar proteinosis–like disease and reduced numbers of peripheral eosinophils, which is explained by the lack of GM-CSF and IL-5 function, respectively. Combined disruption of the IL-3 gene showed no further abnormalities in hematopoiesis, thus demonstrating that the entire IL-3/GM-CSF/IL-5 axis is dispensable for hematopoiesis in both normal and stressed mice.

Receptor Tyrosine Kinase Ligands: M-CSF, SCF, Flt3 Receptor Ligand

With the isolation of the genes encoding SCF and FL, it has become clear that like their receptor genes, the M-CSF, SCF, and FL genes are all evolutionarily related.[160,161] The first of these to be identified was the gene for M-CSF. The more recently cloned gene for FL also shows similar gene structure, with locations of introns reasonably well preserved with those of M-CSF and SCF.

The gene for M-CSF proved to be defective in the spontaneous mutant Osteopetrosis (*op/op*).[306] Female *op/op* mice are infertile, thus confirming the role of M-CSF in the biology of the pregnant uterus.[336] Such mice also have a severe deficiency in the ability to produce osteoclasts derived from the monocytic lineage that results in the development of osteopetrosis and failure to form teeth.[337] However, that fact that some macrophage populations do develop in the animals indicates that M-CSF is important in many but not all macrophage-related lineages. The observation that some of the defects in the *op/op* mouse are corrected as the animals mature has led to speculation that alternative splicing of the mutant M-CSF transcript can lead to the production of some functional M-CSF.[338] This raises the necessity of genetically

engineering mice with substantial deletions in this gene to see whether there is some redundancy in HGF function or whether *op* is not a true null mutation.

Naturally occuring mutations in the SCF locus (*Sl*) or in c-kit (*W*), the receptor for SCF, result in profound effects on many stages of hematopoiesis, most notably in the stem cell, erythroid, and mast cell compartments (reviewed by Galli and colleagues[128]). These studies have clearly demonstrated the central role of SCF in controlling hematopoietic cell function. Interestingly, disruption of the flt3 receptor gene has relatively minor effects on hematopoiesis, the most notable being somewhat depressed levels of B-lymphocyte precursors.[230] However, mice with disruption of both the c-kit and Flt3 receptor tyrosine kinase genes display more severe hematologic complications than do mice with either single mutation,[230] thus suggesting that the two factors do, at some level, complement one another in vivo.

Hematopoietic Growth Factor Genes: Regulation of Expression

Expression of Hematopoietic Growth Factor by Monocytes/Macrophages and Dendritic Cells: G-CSF, M-CSF, GM-CSF, IL-6, and Steel Factor

Monocytes/macrophages and related cells, including dendritic cells, Kupfer cells in the liver, and Langerhans cells in the skin, are key cells that serve many important functions in regulating the immune system.[339] Among the functions performed by these cells is the production of many cytokines, including TNF,[340] IL-1,[165] G-CSF,[145] M-CSF,[340] GM-CSF,[118] IL-6,[223] and IL-12,[339] in response to various stimuli, including LPS,[339,340] IL-1, IL-3,[341] GM-CSF,[342] and M-CSF.[343] Other cytokines, such as IL-4,[344] IL-10,[345] and IL-11,[346] downregulate monocyte production of many of these cytokines. Several of the newer cytokines, including IL-18,[165] various members of the IL-17 gene family,[347] and IL-23,[143] are likely to play important roles in controlling cytokine production by monocytes and macrophages.

All these interactions are key components of the interactions between T cells and monocytes in determining the nature and direction of the immune response. Different regulators have been found to induce different subsets of these cytokines. For example, LPS has been shown to induce the expression of IL-1, IL-6, TNF, IL-1RA, GM-CSF and G-CSF.[341] In contrast, IL-3 and GM-CSF failed to induce the expression of either GM-CSF or G-CSF but were found to induce M-CSF expression. M-CSF has been shown to induce peritoneal macrophages to activate expression of GM-CSF and IL-6 at the transcriptional level, but additional signals are necessary to induce the release of functional cytokine proteins from the cells.[348] Murine bone marrow–derived macrophages have been reported to constitutively express the mRNA for M-CSF and SCF, and the level of expres-

sion can be enhanced by treating the cultures with pokeweed mitogen.[349]

The different HGF genes in monocytes can be upregulated by a variety of different mechanisms. In the case of IL-6, LPS and *Mycobacterium tuberculosis* activate gene expression at the transcriptional level through activation of the transcription factors NF–IL-6 and NF-κB.[350] In contrast, activation of IL-1 and IL-6 expression by *Salmonella typhimurium* porins is largely mediated by mRNA stabilization.[351] Cytokine activation of monocyte IL-6 expression also occurs by various mechanisms, often involving interactions between NF-κB and NF–IL-6.[352] IL-2, IL-3, and GM-CSF have all been shown to induce monocyte expression of IL-6, and such expression is inhibited, post-transcriptionally, by treatment with IL-4.[341,344] LPS-activated expression of IL-6 is potently inhibited at the transcriptional level by IL-10.[353] Activation of IL-6 expression by the combination of TNF and IFN-γ in the human THP-1 monocytic cell line requires activation of NF-κB. Perhaps surprisingly, treatment of monocytes with the anti-inflammatory cytokine TGF-β also activates IL-6 expression.[354] In the case of G-CSF, expression can be activated by treating monocytes with either IL-1 or LPS (IFN-γ potentiates the LPS response[355]), and IL-4 given simultaneously can block this induction, an effect that is not mediated by mRNA stability but rather at the transcriptional level.[356] However, the IFN-γ enhancement effect appears to be largely at the level of mRNA stability; the half-life of mRNA with LPS treatment alone is roughly 20 minutes, but after exposure to IFN-γ, the half-life increases to 120 minutes.[356] M-CSF gene expression can be activated in HL-60 cells, an event mediated by NF-κB.[357] These interactions between monocytes and T cells and the cytokines that they produce, though complicated, are clearly important in determining the direction and extent of the resulting immune responses and are likely to play a key role in controlling the cytokine network.

Dendritic cells, which have been characterized as potent antigen-presenting cells, are also an important source of HGFs and other cytokines.[358] With the availability of cytokines such as FL, GM-CSF, IL-3, and IL-4, it has become much easier to generate dendritic cells from both myeloid and lymphoid sources in signficant numbers for further studies.[198,359] Originally believed to be largely of myeloid cell origin, it is now recognized that some are probably derived from myeloid cells whereas others have their origins in the lymphoid lineages.[360] Interestingly, different types of dendritic cells, matured under different conditions, can serve to polarize cytokine production by maturing helper T cells[361] and are therefore likely to play key roles in determining the outcomes of immune responses. Murine bone marrow–derived immature dendritic cells (CD86⁻) produce high levels of IL-1α, IL-1β, TNF-α, and TGF-β1, but upon maturation (CD86⁺) in the presence of CD40 ligand, levels of TGF-β dropped whereas levels of IL-6, IL-12p40, IL-15, IL-18, and TNF-α increased, as did the ability of the cells to

prime naïve T cells.[361] With the newly available cytokines for expanding both myeloid and dendritic cells in culture it will be very interesting to further elaborate how these important cells interact with T cells through the cytokine network in upregulating and downregulating immune responses.

Different populations of fibroblasts, endothelial cells, and epithelial cells can be stimulated to produce cytokines by treatment with LPS,[362] phorbol esters,[326] or other cytokines, including IL-1,[162] TNF,[363] and platelet-derived growth factor (PDGF).[364] In many tissues this is likely to be an integral part of the host response to infection—cytokine production at the site of infection should result in local activation of host defense effector cells and systemic recruitment of more effector cells until the infection is cleared.[365] In the bone marrow, thymus, and spleen, these cell populations are likely to be critical components of the local microenvironment that are involved in the normal proliferation, development, and differentiation of cells of the hematopoietic and lymphopoietic systems. Control of production of the various HGFs in the steady state, however, is still poorly understood.[365]

Fibroblasts and endothelial cells are important sources of many of the HGFs, including G-CSF,[145] M-CSF,[127] GM-CSF,[326] IL-6,[366] IL-11,[280] SCF,[128] and FL.[208,226] Such expression is regulated both transcriptionally and post-transcriptionally by exposure to LPS, phorbol esters, or cytokines such as IL-1, TNF, and IFN-γ.[145,367,368] SCF expression has been reported to be constitutive in human stromal bone marrow cultures, in endothelial cells, and in bone marrow–derived fibroblasts and is not responsive to IL-1.[369]

Although it is not clear that stromal fibroblasts from bone marrow are any more or less capable of cytokine production than fibroblasts from other tissues, because of their proximity to stem and progenitor cells, they have long been studied for their ability to express HGFs. Many of these cells constitutively express the tyrosine kinase receptor ligands M-CSF and SCF.[369,370]

After myeloablation, circulating levels of many HGFs increase dramatically. In some cases this might result from mechanisms that sense low levels of the various blood cells. However, Hachiya and colleagues[371] have found that in culture, TNF and IL-1 synergize with irradiation to upregulate expression of GM-CSF through both mRNA stabilization and activation of gene transcription. These observations raise the possibility that the myeloablative agents themselves may directly induce or enhance HGF production in vivo after various cancer therapy regimens.

Endothelial cells are another important source of HGFs. Human endothelial cells produce G-CSF, GM-CSF, and M-CSF in response to inflammatory cytokines such as IL-1 and TNF.[372,373] In contrast to G-CSF and GM-CSF, SCF mRNA is expressed constitutively by human umbilical vein endothelial cells (HUVECs).[374] Levels of SCF mRNA are further increased in response

to inflammatory mediators, including IL-1 and LPS. Such induction results predominantly from mRNA stabilization by approximately threefold. Increased expression of GM-CSF mRNA in HUVECs is also mediated at least in part by mRNA stabilization.[375] Possibly, induction of SF mRNA in endothelial cells contributes to the elevated plasma levels of this factor in sepsis patients and those with inflammatory diseases.[374] Finally, vascular endothelial cells express M-CSF in response to minimally modified low-density lipoprotein though transcriptional activation mediated by NF-κB; however it is not clear how this might contribute to the biology of macrophage-derived foam cells in the atherosclerotic lesion.[376]

Regulation of Erythropoietin Expression by Hypoxia

EPO has long been recognized as the physiologic regulator of red cell production (reviewed elsewhere[377-379]). It is produced in the kidney and in the fetal liver in response to hypoxia or exposure to cobalt (II) chloride; the mechanism of the switch of production from predominantly fetal liver to predominantly kidney in adults is largely unknown.[380] Beck,[381] Semenza,[382] and their colleagues showed that the EPO gene contains a hypoxia response element (HRE) in the 3′ flanking sequence.

Nuclear factors present in hypoxic but not normoxic cells were identified as a heterodimeric basic helix-loop-helix (bHLH) transcription factor complex designated hypoxia-inducible factor 1 (HIF-1); the complex consists of inducible HIF-1α and constitutively expressed HIF-1β[8,383] (reviewed by Semenza[9]). HIF-1 is induced in a variety of cell types in response to hypoxia or cobalt, which indicates that although it is important in activation of EPO expression, it is also important in the activation of many other hypoxia-inducible genes.[8,384] HIF-1 has been shown to bind to an enhancer sequence located approximately 130 bp downstream from the poly(A) addition signal of the EPO gene. This enhancer segment has been shown to render other promoter-reporter gene constructs hypoxia responsive, with typical inductions in the range of 4- to 15-fold, significantly less than the 50- to 100-fold induction observed with the chromosomal EPO gene in Hep3B cells.[382] In addition to HIF-1 and its role on the 3′ EPO gene enhancer, other studies have identified a 53-bp sequence from the EPO promoter that confers oxygen sensitivity (6- to 10-fold inducibility) to a luciferase reporter gene.[385] The combination of the enhancer and promoter sequences together results in cooperative (50-fold) inducibility of transcription in response to hypoxia that approaches that observed in vivo.

HIF-1α protein levels are regulated by binding to the von Hippel-Lindau (VHL) tumor suppressor, followed by ubiquitin-mediated proteosomal degradation (Fig. 6-15).[386,387] Under normoxic conditions, a prolyl hydroxylase uses molecular O_2, iron (Fe[II]), and α-ketoglutarate to hydroxylate Pro402 and Pro564 in human HIF-1α, which leads to VHL binding and proteosome-mediated
FIGURE 6-15. Hypoxia-inducible regulation of erythropoietin production. Under normoxic conditions, hypoxia-inducible factor 1α (HIF-1α) undergoes prolyl hydroxylation at Pro402 and Pro564, which leads to binding of HIF-1α to von Hippel-Lindau (VHL) protein and subsequent ubiquitin-mediated destruction. This dioxygenase enzymatic reaction is catalyzed by a prolyl hydroxylase termed prolyl hydroxylase domain 2 (PHD2). A second hydroxylation at asparagine 803 prevents binding of HIF-1α to its transcriptional coactivator p300 and is catalyzed by an HIF asparaginyl hydroxylase called factor inhibiting HIF (FIH). Both these reactions are dependent on oxygen, Fe(II), and α-ketoglutarate, which is oxidized to succinate with the release of CO_2. Under hypoxic conditions, both hydroxylases are inhibited, thereby leading to an increase in HIF-1α and recruitment of the p300 coactivator, which together with the ubiquitously expressed HIF-1β, activates transcription.

proteolysis. A second hydroxylation of Asn803 by an asparaginyl hydroxylase (similarly dependent on O_2, Fe[II], and α-ketoglutarate) blocks the C-terminal interaction of HIF-1α with the transcriptional coactivators p300/CREB-binding protein (CBP) (reviewed by Ratcliffe[10]). Under hypoxic conditions. both hydroxylases are inhibited, thereby leading to escape from ubiquitin-mediated proteolysis and an increase in HIF-1α protein, as well as recruitment of p300/CBP and transcriptional activation.[388-391]

Regulation of Thrombopoietin Gene Expression

Cloning and expression of the gene for TPO[392] have provided new insight into the regulation of levels of platelets.[129] Gene disruption studies of c-mpl, the receptor for TPO, in mice have shown that in the absence of function of this pathway, mice have only 15% of the normal levels of circulating platelets.[315] Thus, although redundancy among the growth factors, perhaps including SCF, IL-3,

IL-6, and IL-11, can partially compensate for dysfunctional c-mpl signaling, TPO, like EPO in the erythrocyte lineage, appears to be the major regulator of circulating platelet levels.[177] However, in contrast to the control of EPO production, TPO gene expression does not seem to be transcriptionally regulated or significantly influenced by platelet levels.[393] It may be regulated by megakaryocyte/platelet mass.[394] In adult mice, the major sources of TPO mRNA are the liver and kidney; in both organs the gene is constitutively expressed and is not significantly upregulated during thrombocytopenia. However, circulating levels of TPO increase rapidly during thrombocytopenia and decline as platelet counts return to normal.[395,396] The observation that platelets themselves can remove TPO from thrombocytopenic plasma in vitro has led to the model that TPO is constantly produced and released into circulation but, in normal circumstances, is rapidly removed by circulating platelets and possibly megakaryocytes as well.[394-396] During thrombocytopenia,

the platelet shortage fails to remove TPO as fast as it is made, which results in elevated levels and stimulation of platelet production. This mechanism is similar to one proposed some years ago by Stanley and co-workers for the regulation of circulating M-CSF levels directly through consumption by the monocytes themselves.[397]

HEMATOPOIETIC GROWTH FACTOR RECEPTORS

Types of Hematopoietic Growth Factor Receptors

Analysis of the actions of HGFs on purified murine or human stem and progenitor cells (see later) has shown that there is considerable overlap in the action of HGFs. Some insight into the apparent overlap in biologic activities of many cytokines has come from analysis of their structural homologies and from cloning of many of their receptors. These receptors are all type 1 membrane glycoproteins with extracellular N-terminals and single transmembrane domains, and they fall into two major classes. Receptors such as c-kit, c-fms (the M-CSFR), and Flt3 are characterized by a cytoplasmic tyrosine kinase domain (receptor tyrosine kinase), whereas most of the other receptors lack cytoplasmic tyrosine kinase activity and can be divided into four subclasses (Table 6-3). Most of the HGR receptors (HGFRs, class 1) fall into a superfamily with structural features based on two linked fibronectin (FBN) type III domains (Fig. 6-16). Analogous FBN domains are found in the interferon (class 2) receptors, and the class 1 and 2 structures probably evolved from a common primitive adhesion molecule.[398] Whereas the TNF family of receptors (class 3) are characterized by an extracellular fourfold repeat of approximately 40 amino acids that contains six conserved cysteine residues (Cys repeat),[125] the IL-1Rs (class 4) feature extracellular immunoglobulin-like repeats. Although the discussion later is focused mainly on the HGFRs, the receptor tyrosine kinases activate many of the same signaling cascades (see elsewhere[399,400] for reviews).

Structure and Binding Properties

Prototypes for the class 1 structure are the (nonhematopoietic) prolactin and growth hormone receptors.[401-403] These polypeptides share a number of features (Fig. 6-17). The major homology lies in the extracellular domain, which is characterized by four conserved cysteine residues in the N-terminal FBN III repeat and a WSXWS motif in the linked C-terminal FBN III repeat that forms a hydrophobic hinge between the two domains. In addition, the IL-6 family of receptors is composed of members that each have an N-terminal immunoglobulin-like domain, as well as extra FBN III repeats. The cytoplasmic regions of the receptor family show much less homology, although membrane proximal domains rich in prolines (box1, within 20 amino acids of the membrane) and acidic residues (box2), separated by a positionally conserved tryptophan, have been defined. Mutations within the box1/2 domains have inactivated the mitogenic function of the receptors that have been examined,[404] whereas mutations of the conserved tryptophan inactivate some but not other receptors.[405] An additional interesting feature of many of the HGFRs is that receptor subunits are shared. GM-CSF, IL-3, and IL-5 all have receptors with unique α chains that bind their respective ligands with low affinity. They share a common β chain ($β_c$) that converts ligand binding from low to high affinity in each case and is thought to be critical for signal transduction (reviewed by Miyajima and associates[406]). A similar arrangement is evident with the IL-6, LIF, OSM, IL-11, and CNTF receptors, all of which share a common β chain, namely, gp130. An additional subunit, the low-affinity leukemia inhibitory factor receptor (LIFR), is shared by LIF, OSM, and CNTF. IL-6 and CNTF also use ligand-specific α receptor components, and gp130 is thought to form homodimers when IL-6 binds IL-6Rα and heterodimers with LIFR in the presence of LIF, OSM or CNTF. The finding of shared subunits explains to a

Type	**Receptor**	**Cytokine**
Tyrosine kinase (Ig repeats)	c-kit, M-CSFR (c-fms)	Four–α-helix bundle
Non–tyrosine kinase		
Class 1: HGFRs (FBN III domains)		Four–α-helix bundle
Shared $β_c$	IL-3R, GM-CSFR, IL-5R	
Shared gp130	IL-6R, LIFR, IL-11R, IL-12R, OSMR	
Shared $γ_c$	IL-2R, IL-4R, IL-7R, IL-9R, IL-15R	
Single chain	G-CSFR, EPOR, TPOR (c-mpl)	
Class 2 (FBN III domains)	IFNRα/β, IFNRγ	
Class 3 (Cys repeats)	TNFR I, TNFR II, FAS, CD40	β-Jellyroll wedge
Class 4 (Ig repeats)	IL-1R I and II	β-Trefoil fold

TABLE 6-3 Hematopoietic Growth Factor Receptor Classes

EPOR, erythropoietin receptor; FBN, fibronectin; GM-CSFR, granulocyte-macrophage colony-stimulating factor receptor; G-CSFR, granulocyte colony-stimulating factor receptor; HGFR, hematopoietic growth factor receptor; IFNR, interferon receptor; Ig, immunoglobulin; IL, interleukin; LIFR, leukemia inhibitory factor receptor; M-CSFR, macrophage colony-stimulating factor receptor; OSMR, oncostatin M receptor; TNFR, tumor necrosis factor receptor; TPOR, thrombopoietin receptor.
FIGURE 6-16. Receptors such as c-kit, c-fms (macrophage colony-stimulating factor receptor [M-CSFR]), and Flt3 are characterized by a cytoplasmic tyrosine kinase domain, whereas most of the other receptors lack cytoplasmic tyrosine kinase activity and can be divided into four subclasses. Most of the hematopoietic growth factor receptors (HGFRs) (class 1) fall into a superfamily with structural features based on two linked fibronectin (FBN) type III domains; analogous FBN domains are found in the interferon (class 2) receptors (IFNRs); the tumor necrosis factor family of receptors (TNFR, class 3) are characterized by an extracellular four-fold repeat of approximately 40 amino acids that contains six conserved cysteine residues (Cys repeat), and the interleukin-1 receptors (IL-1Rs, class 4) feature extracellular immunoglobulin-like repeats.

certain extent why the actions of GM-CSF and IL-3 overlap on many cells and why IL-6, LIF, and IL-11 all share pleiotropic actions on HSCs and hepatic cells. The fact that IL-12 is a heterodimer of two polypeptides that are similar to IL-6 and IL-6Rα provides an explanation for its biologic activities falling into the IL-6 group, at least on stem cells.[293] The γ chain of IL-2R is now known to be shared by the IL-4,[407,408] IL-7,[409] IL-9,[410] and IL-15[411] receptors. Other members of the HGFR superfamily that act on lineage-restricted cells such as the EPO, G-CSF, and TPO receptors appear to not require an additional subunit for ligand binding or signal transduction.

The number of IL-3, GM-CSF, G-CSF, and EPO receptors per cell is strikingly low (≈1000 sites per cell), whereas those for M-CSF are about 1 log higher. In all cases, affinity of a receptor for its ligand is high, with dissociation constants usually in the picomolar range. Stimulation of target cells can occur at factor concentrations orders of magnitude lower than the equilibrium constant at which 50% of receptors are occupied, and therefore it is apparent that low receptor occupancy is sufficient to produce biologic effects.

Receptor Function

Lineage-Specific Factors and Induction of Differentiation

Do lineage-specific receptors direct differentiation or do intracellular proteins specific for lineage-restricted cells have that function? With respect to receptor-driven events,

a proximal cytoplasmic domain of the G-CSFR is essential for proliferation, whereas a more distal domain is important for induction of acute phase plasma protein expression when the receptor is transfected into hepatoma cell lines[412] or for induction of granulocyte-specific proteins when it is introduced into murine IL-3–dependent FDC-P1 cells.[413] Support for a role of G-CSFR in granulocyte differentiation comes from sequence analysis of the receptor in two patients with severe congenital neutropenia (Kostmann's disease) in whom acute myeloid leukemia eventually developed.[301] Two different point mutations in the G-CSFR gene resulted in truncations of the C-terminal cytoplasmic region of the receptor and coexpression of both mutant and wild-type genes. The mutation was present in the neutropenic phase in one of the patients, thus suggesting that the mutation was not acquired along with the leukemia. Functional analysis by transfection of mutant or wild-type genes into murine 32D.C10 cells showed that the mutation acted as a "dominant negative" and prevented differentiation in response to G-CSF. Other evidence for an inductive role of receptors comes from murine long-term bone marrow cultures infected with a retroviral c-fms vector that yielded a pre-B line with an immunoglobulin heavy-chain gene rearrangment. This line grew in IL-7 or M-CSF; interestingly, the switch to M-CSF led to macrophage maturation, which suggests that signals from this receptor can determine differentiation in these bipotent cells.[414] Last, transduction and stable expression of the EPO receptor (EPOR) in IL-3–dependent Ba/F3 cells result in cells that produce globin mRNA on EPO but not IL-3 stimu-
FIGURE 6-17. Diagram of some of the hematopoietic growth factor receptors (HGFRs) that have been cloned. The extracellular domains are all characterized by one or two regions that contain four conserved cysteines and a tryptophan-serine-x-tryptophan-serine (WSXWS) motif, such as the prolactin receptor. Unique features consist of interleukin-6 (IL-6) containing an immunoglobulin-like domain (*open circle*) and granulocyte colony-stimulating factor (G-CSF) containing a fibronectin type III–like region (*cross-hatched*). The intracellular domains show less homology. An additional interesting feature of many of the HGFRs is that receptor subunits are shared, in particular the IL-3R, IL-6R, and IL-2R groups. In contrast, lineage-restricted receptors such as the erythropoietin receptor (EPOR), G-CSF receptor (G-CSFR), and thrombopoietin receptor (TPOR) appear to not require an additional subunit for ligand binding or signal transduction.

lation,[415] and a chimeric receptor that comprises the extracellular domain of GM-Rα and the cytoplasmic domain of EPOR can induce increased glycophorin A expression in Ba/F3 cells, in contrast to the GM-Rα/βc control.[416] Although these experiments suggest that elements of the cytoplasmic domains of these receptors can direct both proliferation and differentiation, experiments with cell lines must be interpreted with caution. Definitive proof that EPOR is not specifically required for erythroid differentiation comes from retroviral expression of the prolactin receptor in wild-type and EPOR$^{-/-}$ progenitors; these cells differentiate efficiently in prolactin, thus indicating that there is no unique instructive role for EPO in erythropoiesis.[417] However, the prolactin receptor activates similar signaling pathways to EPOR such as STAT5 and therefore could perhaps readily substitute for EPOR function. In contrast, GM-CSF cannot rescue lymphopoiesis in GM-CSFR transgenic mice crossed with IL-7–deficient animals; furthermore, common lymphoid progenitors (CLPs) that express ectopic GM-CSFR differentiate into myelomonocytic cells, thus indicating plasticity in CLPs and an instructive role for GM-CSF in this context.[418]

Taken together, it is reasonable to conclude that the major role of HGFRs is survival, amplification, and particularly in the case of lineage-specific receptors, completion of an intrinsic differentiation program of committed progenitor cells. However, there is overlap of expression, such as EPOR expression on megakaryocyte progenitors.[419]

Signal Transduction

HGF-Induced Tyrosine Phosphorylation

Several signaling proteins and pathways are common to many different receptor types. A paradigm common to receptors both with and without endogenous tyrosine kinase activity is that ligand binding induces homodimerization or heterodimerization of receptor subunits, followed rapidly by transient tyrosine phosphorylation of the cytoplasmic domain of the receptor itself, cytoplasmic tyrosine kinases, and other cytoplasmic proteins involved in generating different signaling cascades (Fig. 6-18). In the case of receptors with intrinsic tyrosine kinases, ligand-induced activation of their catalytic func-
FIGURE 6-18. Signal transduction through a receptor tyrosine kinase such as c-kit. The figure illustrates that the cytosolic domains contain a protein tyrosine kinase catalytic site that forms a functional dimer after ligand binding. The kinases phosphorylate each other, which causes the activation lip to move out of the catalytic site and allows binding of adenosine triphosphate or a protein substrate. The kinase phosphorylates other tyrosines in the receptor cytosolic domain that function as docking sites for other signaling proteins. One of the major pathways is Ras activation and phosphorylation of c-raf, mitogen-activated protein kinase (MAPK) kinase (MEK), MAPK, p90S6k (or p90rsk), and induction of c-fos/c-jun and probably bcl-2, important for cell proliferation and survival. GDP, guanosine diphosphate; GTP, guanosine triphosphate; SCF, stem cell factor.

tion leads to transphosphorylation or autophosphorylation of dimerized receptor subunits and activation of three major signaling cascades: Ras/mitogen-activated protein kinase (MAPK), phosphatidylinositol 3′-kinase (PI3K)/protein kinase B (PKB, also known as Akt), and phospholipase C (PLC)/inositol triphosphate (IP$_3$)/diacylglycerol (DAG)/protein kinase C (PKC). Receptors that lack a tyrosine kinase domain must recruit cytoplasmic tyrosine kinases. For class 1 cytokine receptors, the JAK family fulfills this role, but other nonreceptor kinases have been identified and may also be important. Tyrosine phosphorylation within the receptor cytoplasmic domain creates docking sites for substrates characterized by the presence of Src homology 2 (SH2) domains. These SH2 domains recognize phosphotyrosine in the context of specific short sequences of amino acids.[420] This leads to activation of the three signaling cascades just mentioned (Ras, PI3K, and PLC), as well as activation by JAK of a critical family of signal transducers and activators of transcription (STAT proteins).

There are four known members of the JAK family, JAK1, JAK2, JAK3, and Tyk2 (for reviews see elsewhere[421-423]). All are 130- to 134-kd related proteins that have an amino-terminal receptor-binding domain, a carboxy-terminal kinase domain, and a middle domain that regulates kinase activity (Fig. 6-19). Although it first appeared that HGFs activate JAK proteins in a rather promiscuous manner, some patterns have emerged (Table 6-4).[465] Thus, receptors that consist of single chains, such as EPOR, G-CSFR, and TPOR, associate with JAK2 (or to a lesser extent with JAK1) in either a constitutive or ligand-dependent manner. Ligand binding and consequent clustering of receptor molecules lead to JAK2 aggregation and transphosphorylation at the lysine–glutamic acid–tyrosine-tyrosine (KEYY) site in the kinase activation loop (see Fig. 6-19). For example, the inactive EPOR exists as a homodimer, and each cytoplasmic domain is irreversibly bound to a molecule of JAK2. Binding of EPO to the extracellular domain of the receptor induces a conformational change that brings the JAK kinase domains together and results in rapid tyrosine transphosphorylation.[456] In vitro experiments show that JAK2 phosphorylation leads to activation of its kinase function, which taken together with evidence of association of JAK2 with EPOR, suggests that JAK2 may act as the "master" protein tyrosine kinase that mediates the

TABLE 6-4 **JAK/STAT and Nonreceptor Protein Tyrosine Kinases Activated by Hematopoietic Growth Factor Receptors**

Receptor	JAK Family	JAK-Activated STATs	Other Nonreceptor PTKs
c-kit	JAK2[424]		PI3K[425,426]
IFNRα/β	JAK1,[427-429] Tyk2[430]	STAT1,[431] STAT2,[431] STAT3[432]

Nonreceptor tyrosine kinases that associate with receptors are indicated in bold, and references are in superscript.

EPOR, erythropoietin receptor; G-CSFR, granulocyte colony-stimulating factor receptor; GM-CSFR, granulocyte-macrophage colony-stimulating receptor; IFNR, interferon receptor; IL, interleukin; JAK, Janus kinase; PI3K, phosphatidylinositol 3′-kinase; PTK, protein tyrosine kinase; STAT, signal transducer and activator of transcription.

Adapted from a detailed review by Taniguchi T. Cytokine signaling through non-receptor protein tyrosine kinases. Science. 1995;268:251-255.
FIGURE 6-19. Signal transduction through a cytokine receptor such as the erythropoietin receptor, with JAK2 being tightly bound to the receptor. The JAKs contain a C-terminal tyrosine kinase domain and an N-terminal receptor-binding domain separated by a regulatory domain. The homodimeric receptor undergoes a conformational change after ligand binding that brings together associated JAK2 molecules, which then phosphorylate each other on a tyrosine in the activation lip and result in tyrosine phosphorylation of the receptor. These tyrosines act as docking sites for STAT5 and other Src homology 2 (SH2) and phosphotyrosine-binding domains containing signal transduction proteins. The STAT proteins have an SH2 domain that contains the completely conserved GTFLLRFSS sequence; mutation of the arginine residue eliminates function. The SH2 domain is critical for recruitment to the receptor and for STAT dimerization. The N-terminal DNA-binding domain is highly conserved and, after STAT dimerization, binds similar symmetrical dyad sequences (e.g., STAT5: TTCC[A→T]GGAA). DNA binding is totally dependent on phosphorylation of a critical tyrosine at the C-terminal. For an excellent review see *Molecular Cell Biology*, 6th ed., 2007. PI3K, phosphatidylinositol 3′-kinase; PI3,4bisP, phosphatidylinositol 3,4-bisphosphate; PI3,4,5trisP, phosphatidylinositol 3,4,5-trisphosphate; PIP, phosphatidylinositol 4-phosphate; PKB, protein kinase B; UTR, untranslated region.

biologic response to EPO. Support comes from observations that a kinase-negative JAK2 acts as a dominant-negative suppressor of the proliferative response to EPO[466] and that the box1/box2 proximal cytoplasmic domain of the EPOR is the region that both binds JAK2 and is essential for receptor function.[456] Furthermore, an acquired JAK2V617F mutation, found in almost all patients with PCV and about half with essential thrombocytosis and myelofibrosis, confers constitutive tyrosine kinase activity on JAK2; it transforms hematopoietic cells when coexpressed with homodimeric cytokine type 1 receptors and is sufficient for the development of PCV in murine recipients of transplanted JAK2V617F stem cells.[467] A number of other substrates are phosphorylated in response to EPO,[468-470] including nonreceptor kinases such the p85 subunit of PI3K, substrates such as PLCγ1 and the adaptor molecule Shc, and the tyrosine phosphatases hematopoietic cell phosphatase (HCP or PTP-1C) and Syp (also known as PTP-1D or SH-PTP2), which downregulate signal transduction; other kinases such as c-fes[459] and Vav are also activated.

The other heterodimeric receptors appear to associate with and activate several JAKs (see Table 6-4 and reviewed by Ihle and associates[421]). The $β_c$ component of the IL-3/GM-CSF receptor is tyrosine-phosphorylated after IL-3 or GM-CSF stimulation.[471,472] The tyrosine kinase that is responsible for ligand-induced receptor phosphorylation could be JAK2[422] or JAK1,[442] but the role of other recruited nonreceptor kinases such as lyn,[438] fyn,[439] or c-fes[440] has not been clearly defined. Truncation mutants of $β_c$ show that the proximal cytoplasmic domain (amino acids 449 to 517) can induce JAK2 tyrosine phosphorylation and kinase activation,[443] and this truncated receptor also retains the capacity to induce myc and pim-1 and promote proliferation in serum-replete but not serum-free conditions.[471,473-475] Both gp130 and LIFR can associate with and activate JAK1, JAK2, and Tyk2, but the pattern of such JAK family activation is distinct in different cell types.[476]

HGF-Induced Activation of STAT Proteins

The paradigm of the response to IFN has provided another major insight into a subsequent step in JAK family signal transduction. The kinase activities of Tyk2 and JAK1 that are activated after IFN-α binding lead to phosphorylation of STAT1α/STAT1β and STAT2. STAT proteins are characterized by an amino-terminal DNA-binding domain, a conserved carboxy-terminal SH2 domain, and a critical tyrosine at the carboxy-terminal (see Fig. 6-19). Tyrosine-phosphorylated STAT1α/β and STAT2 form heterodimers through their SH2 domains, bind to a 48-kd protein, translocate to the nucleus, and activate gene expression by binding to an interferon-stimulated response element (ISRE).[433,477,478] STAT1α is also tyrosine-phosphorylated (at Y701) after IFN-γ binds to the IFN-γR, and this event is associated with tyrosine phosphorylation of JAK1 and JAK2.[428,479] STAT1α homodimerizes, translocates to the nucleus, and binds to the IFN-γ–activated sequence (GAS), thereby transcriptionally activating genes that contain this sequence in their promoters.

Activation of JAK proteins by HGFRs also leads to phosphorylation and DNA binding of STAT proteins, and four additional members of the STAT family have been cloned, STAT3, STAT4, STAT5, and STAT6 (see Table 6-4). Thus, ligand-induced activation of gp130, the signal-transducing component of the IL-6, LIF, IL-11, OSM, and CNTF family of receptors, leads to tyrosine phosphorylation of the JAK-Tyk family and activation of STAT3.[444,445,476] STAT4 expression is restricted to spermatogonia, as well as thymic and myeloid cells. STAT4 mRNA levels appear to decline when 32Dcl1 cells differentiate in culture with either G-CSF or EPO.[480] An ovine DNA-binding activity induced by prolactin, called mammary gland factor, was cloned and is named STAT5.[481] STAT5 is activated by EPO and growth hormone,[435] as well as by IL-3, GM-CSF, and IL-5.[436] This 92-kd protein exists as two highly related proteins, STAT5A and STAT5B (96% identical), that are encoded by different genes. STAT6 is most closely related to STAT5 and is induced by IL-4.[482]

HGF Signaling through the Ras Pathway

Ras is a "turnstile" through which signals from many receptors are routed.[483] Ras guanosine triphosphate (GTP) associates with and activates Raf-1 and MAPK.[484] Ras is a 21-kd membrane-associated protein that cycles between the active GTP-bound and the inactive guanosine diphosphate (GDP)-bound forms in response to extracellular signals from various HGFRs, including c-kit, IL-3R and GM-CSFR, T-cell receptor, IL-2R, and EPOR.[485-488] Activation of Ras is mediated by guanine nucleotide–releasing factors (GRFs) that catalyze the release of bound GDP and its exchange for GTP, whereas deactivation occurs by GTPase-activating proteins (GAPs) such as p120[GAP] and neurofibromin, which accelerate the intrinsic activity of Ras and thereby lead to hydrolysis of GTP to GDP. The mammalian prototype for GRF-mediated Ras activation is the epidermal growth factor receptor (EGFR), the cytoplasmic domain of which bears intrinsic tyrosine kinase activity. After ligand-mediated dimerization, the EGFR is activated through autophosphorylation or transphosphorylation of tyrosine 1068. An adaptor protein, Grb2, binds to this phosphotyrosine through its SH2 domain. This in turn leads to the formation of a ternary complex of EGFR, Grb2, and a GRF called SOS, which is analogous to the *Drosophila* son of sevenless (SOS) protein.[489] SOS contains a proline-rich region that recognizes two SH3 domains of Grb2, and the complex then activates membrane-bound Ras GDP to Ras GTP. The protooncogene *vav* also has Ras GDP/GTP nucleotide exchange activity[490] and is activated through tyrosine phosphorylation after cross-linking of the T-cell antigen receptor–CD3 complex. With respect to the HGFRs, IL-2–mediated activation of IL-2R leads to IL-2Rβ chain tyrosine phosphorylation and associa-

tion of the receptor with Shc, another adaptor protein that is characterized by both an SH2 domain and a second phosphotyrosine-binding (PTB) domain.[491,492] Shc itself becomes phosphorylated on tyrosine, and this in turn leads to the recruitment of Grb2 and SOS.[493] The IL-3/GM-CSF–mediated signaling cascade involves phosphorylation of the β subunit itself as well as Shc, with subsequent increased levels of Ras GTP and activation of Raf-1, MEK (also called MAPK kinase), and MAPK, followed by induction of c-fos and c-jun (see Fig. 6-18). This activity was mapped to the cytoplasmic domain of β_c between amino acids 626 and 763, whereas a more proximal domain (amino acids 449 to 517) retains the capacity to induce myc and pim-1.[474] The PTB domain of Shc binds to tyrosine 577 of β_c after JAK2-mediated phosphorylation of β_c.[494] Ras activation is important for both proliferative and survival (prevention of apoptosis) functions.[475,495] In the case of EPOR, ligand-induced phosphorylation of Shc and association of Shc with EPOR have also been demonstrated; phosphorylated Shc associates with Grb2, and the Ras and MAPK pathway is activated.[496-500] In summary, these three examples show that Ras is activated by a number of HGFRs and that the Ras-Raf-MEK-MAPK pathway is important for the proliferation and survival of hematopoietic cells.

The Ras pathway may also be important in certain leukemias. Neurofibromin, encoded by the NF-1 gene, is mutated in patients with autosomal dominant neurofibromatosis type 1 (NF-1). NF-1 shows sequence homology with yeast and mammalian GAP genes. Children with neurofibromatosis have an increased risk for juvenile myelomonocytic leukemia (JMML), monosomy 7 syndrome, and acute myeloblastic leukemia (AML).[501,502] Importantly, leukemic cells from children with NF-1 and myelodysplastic syndrome (MDS) show loss of the normal NF-1 allele, thus implicating NF-1 as a tumor suppressor gene.[502] NF-1[GAP] activity is significantly lower in cell lysates prepared from NF-1–associated leukemias than in normal bone marrow or non–NF-1 leukemic lysates.[503] Bone marrow mononuclear cells from patients with JMML show an increase in CFU-GM in response to GM-CSF, but not IL-3. Interestingly, fetal liver cells from mice that are rendered null for the NF-1 gene show similar hypersensitivity to GM-CSF, thus indicating that NF-1[GAP] may play a crucial and specific role in the response of myeloid cells to GM-CSF.[503,504] NF-1[−/−] mice die in utero around day 13.5 to 14.5 as a result of complex cardiac defects, but transplantation of day 11.5 to 13.5 fetal liver cells into lethally irradiated recipients produces a myeloproliferative syndrome similar to the human disease.[504] BCR-ABL is a chimeric oncogenic protein that shows dysregulated tyrosine kinase activity and is implicated in the pathogenesis of Philadelphia chromosome–positive chronic myeloid leukemia. A phosphorylated tyrosine (Y177) in the first exon of BCR binds to the SH2 domain of Grb2 and activates Ras.[505] Mutation of the Y177 BCR-ABL to phenylalanine abolishes Grb2 binding and abrogates both BCR-ABL–induced Ras activation and transformation of primary bone marrow cultures.[505] In summary, Ras dysregulation may contribute to the increased proliferation that characterizes these two chronic leukemias.

Phosphatases and Receptor Signaling

The C-terminal domain of the EPOR has a negative regulatory role.[506] It is likely that this effect is mediated by a phosphatase that dephosphorylates kinase-associated tyrosines in this region, as has been shown for IL-3R.[507] There is a fascinating report of a Finnish family with dominantly inherited benign erythrocytosis.[508] The proband, an Olympic cross-country skier, has a mutation in EPOR that introduces a premature stop codon and generates a receptor lacking the C-terminal 70 amino acids. This mutation cosegregates with the disease phenotype in this large family. Recent data show that the nontransmembrane protein tyrosine phosphatase SH-PTP1 (also called SHP-1, HCP, and PTP-1C) associates via its SH2 domain with the tyrosine-phosphorylated EPOR.[509] Mutational analysis mapped the binding site most probably to Y429, and this tyrosine is deleted with the C-terminal truncation of the EPOR in the Finnish family with benign erythrocytosis. Factor-dependent cells that express a Y429,431F mutant EPOR show increased sensitivity to EPO, as do cultured erythroid progenitors from patients with benign erythrocytosis.[509] CFU-E progenitors from mice that lack or have impaired SH-PTP1 activity (Motheaten or Motheaten viable) show similar increased sensitivity to EPO.[307,510] Therefore, EPO-induced activation and subsequent tyrosine phosphorylation of EPOR leads to recruitment of SH-PTP1, which then plays a major role in terminating the EPO signal, possibly through dephosphorylation of JAK2[509] or other tyrosine kinases.

Another nonreceptor protein tyrosine phosphatase called SH-PTP2 or SHP2, encoded by the *PTPN11* gene, has 50% to 60% identity with SH-PTP1 in both the SH2 and catalytic domains. Despite this similarity, SH-PTP2 appears to be a positive regulator of some growth factor pathways (for review see Sun and Tonks[511]), in particular, Ras. Approximately 50% of patients with Noonan's syndrome (NS), a developmental disorder characterized by short stature, dysmorphic features, and cardiac defects, have germline mutations in SH-PTP2, and 35% of non-NS JMML patients have somatic mutations in this gene. JMML develops in some patients with NS, and it appears that the mutations in NS/JMML differ from those found in de novo nonsyndromic JMML[512] and differ in the degree to which they activate the phosphatase.[513]

Other Inhibitors of HGF Signaling

Another family of negative regulators is the suppressor of cytokine signaling (SOCS) proteins. SOCS-1 was discovered by three groups, contains an SH2 domain, and has sequence and structural similarities to an immediate early gene called CIS (cytokine-inducible SH2-containing protein).[400,514-516] It is one of an eight-member gene

family (SOCS-1 to SOCS-7 and CIS) characterized by a central SH2 domain and a C-terminal conserved motif called a SOCS box. Unlike the constitutively expressed phosphatases, SOCS expression is induced by many cytokines, including IL-3, EPO, TPO, IL-6, and LIF, and the proteins are expressed in hematopoietic and other tissues (for a detailed review see Greenhalgh and Hilton[517]). SOCS-1, expressed predominantly in the thymus, interacts directly with the phosphorylated activation loop of (activated) JAKs, and its N-terminal is thought to inhibit binding of adenosine triphosphate (ATP) to the activation cleft.[400,514,518] Subsequently, the SOCS box was hypothesized to target the SOCS/signaling complex to the proteosome for degradation by recruiting components of the proteasome machinery, including elongins B and C and Cullin 2.[519,520] SOCS-3 has been shown to inhibit signaling by a different mechanism—binding directly to activated receptors and to JAKs without inhibiting JAK activity,[521] whereas CIS can bind to phosphorylated tyrosines on the EPOR and thereby inhibit STAT5 signaling.[522]

SOCS knockouts have provided insight into the important physiologic roles of some of these proteins. SOCS-1[−/−] mice die before weaning with fatty degeneration of the liver, reduced thymic size, lack of T and B cells, and monocytic infiltration of organs.[523,524] This phenotype is similar to that of mice with elevated IFN-γ, and indeed, SOCS-1[−/−] mice have increased IFN-γ levels; rescue of the animals can be achieved with antibodies to IFN-γ or by crossing them with IFN-γ[−/−] mice.[525,526] SOCS-2[−/−] mice are normal at birth but then become significantly larger than wild-type mice, with thickening of the dermis caused by excess collagen deposition.[527] Therefore, SOCS-2 appears to play an important role in postnatal growth, possibly through the growth hormone/insulin-like growth factor I (IGF-I) axis. SOCS-3[−/−] mice are hematopoietically most interesting in that they die at embryonic day 12 to 14 of massive erythrocytosis.[528] Progenitor cells appear to be hyperresponsive to IL-3 and EPO. Thus, SOCS-3 plays a crucial role in inhibiting fetal erythropoiesis. Although CIS-deleted mice show no abnormalities, overexpression of CIS induces a phenotype similar to STAT5a[−/−] or STAT5b[−/−] animals.[529-532]

BIOLOGY OF HEMATOPOIESIS

Stem Cells

The formed elements of the blood in vertebrates, including humans, continuously undergo replacement to maintain a constant number of red cells, white cells, and platelets. The number of cells of each type is maintained in a very narrow range in physiologically normal adults—approximately 5000 granulocytes, 5×10^6 red blood cells, and 150,000 to 300,000 platelets per microliter of whole blood (see Appendix for normal values in infancy and childhood). In this section we examine the normal regu-

latory mechanisms that maintain balanced production of new blood cells. These regulatory systems are far from completely understood, but present evidence strongly supports the following basic principles, schematically depicted in Figure 6-7:

1. A single pluripotent stem cell is capable of giving rise to many committed progenitor cells. These committed progenitors are destined to form differentiated recognizable precursors of the specific types of blood cells.

2. Pluripotent stem cells are capable of self-renewal. Committed progenitor cells are limited in proliferative potential and are not capable of indefinite self-renewal. In addition to their limited proliferative potential, committed progenitors also "die by differentiation,"[533] and their numbers depend on influx from the pluripotent stem cell pool.

3. The proliferative potential and differentiation of stem cells and committed progenitors may be influenced by niche cells or factors derived from them. Thymus-derived lymphocytes appear to contribute to the induction of spleen colony formation in irradiated recipients.[534-537] The hematopoietic role of thymus-derived cells is further supported by experiments demonstrating defective restorative capacity of bone marrow from congenitally athymic[538] or neonatally thymectomized[539] mice or from rigorously T-depleted human bone marrow.[540]

4. Committed progenitor cells are capable of response to humoral or marrow stroma–derived regulators, some produced in reaction to circulating levels of a particular differentiated cell type. In this response, they proliferate and differentiate to form the recognizable blood cells. Under this type of control, amplification of production occurs at the committed progenitor cell level. Most of the regulatory molecules are produced by hematopoietic accessory cells in close proximity to progenitor cells. These molecules are produced as part of an incompletely understood complex regulatory network operating at close range and may involve accessory cell–progenitor cell interactions. For most hematopoietic lineages studied, there appear to be at least two humoral regulators that work sequentially. The immature progenitor of a particular lineage has a greater requirement for a regulator that acts on all or many immature progenitors than its more mature counterparts do. As differentiation proceeds, sensitivity to the late-acting factor increases. This variable degree of response to the late-acting regulators that are present at high concentration during hematopoietic stress (e.g., EPO in anemia) may serve to protect the highly proliferative, but numerically limited immature progenitor compartment from exhaustion or death by differentiation under these stress conditions.

5. Hematopoietic differentiation requires an appropriate microenvironment. In normal humans, this environ-

ment is confined to the bone marrow, whereas in the mouse the microenvironment includes both the spleen and bone marrow. The existence of Steel (*Sl*) strains of mutant mice,[303,541] which exhibit a deficiency in the hematopoietic microenvironment (see later), suggests that interactions between hematopoietic progenitors and the bone marrow microenvironment involve very specific molecular mechanisms.[304] A number of early hematopoietic cells, including pluripotent stem cells and certain committed progenitor cells, have been demonstrated in the circulation of normal individuals and experimental animals.[60,542-544] The capacity of HSCs to negotiate nonhematopoietic tissues via the circulation is especially significant with regard to bone marrow transplantation, which is carried out by infusion of bone marrow or blood cells from the donor into the circulation of the recipient.[545] For example, blockade of hepatic asialoglycoprotein receptors enhances stem cell engraftment in murine spleen and marrow.[546] There is also convincing evidence that murine stem cells (CFU-S) and progenitors (CFU-GM) express "homing" or adhesive lectin receptors that bind to the mannose or galactose (or both) presented on stromal cells. For example, homing of transplanted mouse progenitors can be blocked by synthetic neoglycoproteins with these specificities, thus suggesting that stromal cells are likely to express these sugars.[547] SDF-1/chemokine (CXCR4) signaling and adhesion molecules, including VLA-4/VCAM-1 and CD44/hyaluronic acid interactions, are also important in the regulation of homing.[548]

If only 10% to 20% of stem cells are in cycle in the resting state, what is their role with regard to self-renewal versus differentiation, and what is the role of the noncycling stem cells? The hypothesis that a series of stem cells may contribute clones successively to maintain hematopoiesis throughout the life span of an individual was first advanced by Kay.[549] Support for this hypothesis comes from transplant studies of recipients of small numbers of bone marrow cells[550,551] and from experiments in which mixtures of fetal liver cells from different inbred mouse strains were introduced into *W*-mutant fetuses. *W* mutants exhibit a genetically determined deficiency of HPCs (as well as germ and follicle cells; see later). Long-term monitoring showed clonal dominance followed by the decline of cells of particular genotypes.[551]

The use of retrovirally mediated gene transfer to mark HSCs at first lent support to this hypothesis. Analysis of the viral integration patterns at intervals after transplantation documented concurrent contributions of small numbers of stem cells to hematopoiesis, with changing patterns over time.[552,553] These conclusions are not supported by the work of Harrison and associates, who measured variances at successive intervals in recipients of marrow mixtures from two congenic donors. The high correlations observed in this study suggest that the trans-

planted stem cells continuously produce descendants.[554] However, if 10 to 20 (or more) clones are contributing to hematopoiesis simultaneously, even with clonal succession one might expect variances between two alloenzymes at sequential samplings to be minimized. Furthermore, longer-term analysis of viral integration patterns in multiple-lineage progeny of stem cells transplanted into mice shows that integration patterns are unstable initially but then stabilize and maintain a consistent pattern for many months.[555] Although this consistency does not appear to support the clonal succession hypothesis, the contributory role of unmarked stem cells in these experiments cannot be assessed. Furthermore, it is not possible to determine whether the immediate progeny of the transplanted (and retrovirally marked) stem cells might not all still have self-renewal capacity and subsequently contribute to hematopoiesis successively. Such clones would carry the same integration marker. Long-term analysis of female Safari cats (heterozygous for two glucose-6-phosphate dehydrogenase [G6PD] isoforms) that received transplants of small numbers (1 to 2×10^7/kg) of autologous marrow cells showed extensive variation in G6PD phenotype over a $4\frac{1}{2}$-year period.[556] Computer modeling of the data was consistent with a stochastic model in which stem cells did not replicate more frequently than once every 3 weeks, which challenges many of the current strategies for inserting foreign genes into HSCs. A problem with the transplant approach discussed earlier is that the preparation required for successful transplantation may perturb hematopoiesis and complicate interpretation of the results. Resolution of the problem came from studies in which a nontoxic dose of bromodeoxyuridine (BrdU) was fed to mice in drinking water.[557,558] BrdU is incorporated into DNA by proliferating cells, and measurement of incorporation rates into primitive stem cell populations over time can be used as a monitor of proliferative history. Under steady-state conditions, approximately 5% of LTR-HSCs were in cycle and another 20% in the G_1 phase, with approximately 8% entering the cell cycle per day. By 6 days, 1 month, and 6 months, 50%, 90%, and 99%, respectively, of the stem cell pool had incorporated the label.[558] Because the size of the stem cell pool remains constant, these data indicate that 50% of dividing LTR-HSCs must self-renew; this could be accomplished by asymmetric division or by symmetrical division in which half the cells give rise to LTR-HSCs and the other half to differentiating cells.

Transcription Factors and Stem Cells

Although the factors that control the decision of stem cells to undergo either self-renewal or commitment to differentiate down one of the alternative lineage pathways are poorly understood, in recent years nuclear transcription factors have been characterized that play a role in stem or early progenitor cell proliferation and lineage commitment (reviewed by Orkin and colleagues[559,560]). The tal-1/SCL, Rbtn2/LMO2, and GATA families of

transcription factors are important in this regard. In particular, tal-1/SCL, a bHLH transcription factor, is expressed in biphenotypic (lymphoid/myeloid) and T-cell leukemias,[561,562] as well as in both early hematopoietic progenitors and more mature erythroid, mast, mega-karyocyte, and endothelial cells.[563,564] Targeted disruption of the tal-1/SCL gene leads to death in utero from absence of blood formation, and lack of in vitro myeloid colony formation suggests a role for this factor very early during hematopoiesis at the pluripotent or myeloid-erythroid stem cell level.[565,566] Another transcription factor impli-cated in T-cell acute lymphoblastic leukemia (ALL) is the LIM domain nuclear protein rhombotin 2 (rbtn2/LMO2).[567,568] Mice that lack this factor die in utero and have the same bloodless phenotype as the tal-1/SCL$^{-/-}$ animals.[569] Interestingly, although rbtn2/LMO2 does not show sequence-specific DNA binding, immunoprecipi-tates in erythroid cells show that rbtn2/LMO2 exists in a complex with tal-1/SCL,[570,571] thus suggesting physio-logic interaction in vivo. GATA-2 is expressed in the regions of *Xenopus* and zebra fish embryos that are fated to become hematopoietic and is highly expressed in progenitor cells.[564,572-574] Overexpression of GATA-2 in chicken erythroid progenitors leads to proliferation at the expense of differentiation.[575] Targeted disruption of the GATA-2 gene by homologous recombination in ES cells results in reduced primitive hematopoiesis in the yolk sac and embryonic death by day 10 to 11.[576] Definitive hema-topoiesis in the liver and bone marrow is profoundly reduced with loss of virtually all lineages, and in vitro differentiation data show a marked deficiency in SCF-responsive definitive erythroid and mast cell colonies and reduced macrophage colonies, which suggests that GATA-2 serves as a regulator of genes that control HGF responsiveness or proliferation of stem or early progeni-tor cells (or both).

These data contrast with the later time of embryonic death (day 15) from anemia during the mid–fetal liver stage in mice with targeted disruption of c-myb[577] and Rb[578-580] and severe forms of *W* and *Sl* mutations (see later).[305] C-myb has been shown to be absolutely required for normal hematopoietic production during embryogen-esis.[581] Embryonic erythropoiesis in c-myb knockout mice is normal, but there is complete failure of erythro-poiesis in fetal liver. Progenitors of other lineages, but not megakaryocytes, were also decreased, which indicates that c-myb is required for early definitive cellular expan-sion.[577] Furthermore, a knockdown allele of c-myb shows that suboptimal levels of c-myb favor macrophage and megakaryocyte differentiation whereas higher levels are particularly important for erythropoiesis and lymphopoi-esis.[582] An N-ethyl-N-nitrosourea (ENU)-induced allele of c-myb (M303V) affects the transactivation domain of the protein that interacts with the transcriptional coacti-vator p300; recessive mice (c-myb$^{M303V/M303V}$) demonstrate increased platelet production, anemia, absence of eosino-phils, and defects in B- and T-cell lymphopoiesis.[583] Inter-estingly, these animals were found to have an increase in

transplantable HSCs, thus indicating that c-myb has a negative role in HSC self-renewal. Hence, c-myb appears to have a negative role in HSC and megakaryocyte pro-genitor proliferation and positive effects on erythropoie-sis, eosinophil production, and lymphopoiesis.

Loss of function of the AML-1 gene, which encodes one of the α subunits of the heterodimeric core-binding factor (CBF), results in fetal death by day 12.5 because of failure of production of all definitive hematopoietic lineages.[584] CBF recognition sequences are present in the IL-3R, GM-CSFR, M-CSFR, and T-cell antigen receptor promoters. The AML-1 gene is frequently rearranged in AML and childhood ALL and is expressed in myeloid and lymphoid cells.[568] AML-1 has been shown to interact with a number of repressors, including GROUCHO domain factors. AML-1 is also a regulator of HSC pro-duction in the AGM region, as well as in adult stem cell homeostasis. Rescue of AML-1 by a tie2 promoter sal-vages hematopoiesis during development.

Interestingly, the order of expression of transcription factors is thought to regulate a stem cell hierarchy.[585] This can be demonstrated in purified progenitor cells by looking at a variety of transcription factors, including GATA-1, GATA-2, CCAAT/enhancer-binding protein α (C/EBPα), PU.1, and others. It is clear that competition of hematopoietic transcription factors is a prominent theme. There are GATA-1–PU.1 interactions that regu-late an erythroid/myeloid decision, and there are many other decisions, including PAX5, C/EBPα, and PU.1 interactions, for lymphoid and myeloid systems. Such competition for transcription factors and regulation of stem cell differentiation appears to be a mechanism in the hematopoietic system. Manipulation of the process actually leads to altered hematopoiesis that can favor a single lineage. This involves a cell fate change rather than a proliferative event.

Homeobox (HOX) genes encode transcription factors involved in the establishment of body pattern and tissue identity during development.[586] The human genes occur in four clusters, *HOXA* to *HOXD*, on chromo-somes 7, 17, 12, and 2, respectively. *HOXA* and *HOXB* genes are expressed in CD34^{+} cells and downregulated as these cells mature. Intriguingly, murine bone marrow cells engineered to overexpress HOXB4 by retrovirus-mediated gene transfer show a dramatic upregulation in stem cell activity both in vitro and in vivo, although it may not be required for normal hematopoiesis.[587,588] Serial transplantation studies showed a greatly enhanced ability of HOXB4-transduced bone marrow cells to regenerate the most primitive HSC compartment; such regeneration resulted in a 50-fold higher number of transplantable totipotent HSCs in primary and second-ary recipients than in serially passaged control cells. This in vivo expansion of HOXB4-transduced HSCs was not accompanied by identifiable anomalies in the blood of these mice, thus suggesting that HOXB4 is an important regulator of very early but not late hematopoietic cell proliferation. Recent data show that ectopic expression

of HOXB4 in yolk sac and ES cells confers long-term engraftment capacity in primary and secondary recipients.[589] Daley, Jaenisch, and colleagues reported that nuclei from Rag2 knockout (Rag2$^{-/-}$) tail cells could be transferred into enucleated oocytes and embryonic stem (ntES) cell lines derived from the resulting blastocysts. The Rag2 mutation was then corrected by homologous recombination. Insertion of HOXB4 into the corrected ES cells allowed their expansion into transplantable HSCs. These cells were able to partially correct the defect in immunoglobulin production in Rag2$^{-/-}$ recipients after bone marrow transplantation.[590] The HOX pathway has been expanded to include HOXA7 and HOXA9 as major regulators of hematopoiesis and leukemia formation.[591] The posterior HOX genes therefore drive HSC production; this was highlighted by the finding that mutations in CDX4, a controller of HOX gene expression, leads to absence of HSCs in the zebra fish and lack of control of HOX gene expression for the formation of HSCs.[587]

The Gfi 1 locus was originally identified as an oncogene causing lymphoma based on retroviral insertion.[592] Gfi 1 contains an internal SNAG domain and a six–zinc finger DNA-binding domain. There are two nearly identical genes called Gfi 1 and Gfi 1b. Gfi 1 is restricted to the lymphoid system, whereas Gfi 1b seems to be distributed throughout the entire hematopoietic system. Gfi 1 is also expressed in neutrophils. Gfi 1 knockout animals have a severe reduction in lymphoid progenitors. This leads to an early lack of both CD4$^+$ and CD8$^+$ cells. In addition, IL-7R signaling is suppressed. Gfi 1 is a major regulator of neutrophil maturation. Normal neutrophils are absent in the knockout animals, and yet eosinophils are present in the normal number. The response to G-CSF by neutrophils is preserved, but differentiation does not take place. There is a significant interaction of Gfi 1 with other transcription factors, including PU.1, C/EBPβ, and C/EBPε, which regulate neutrophil maturation.

Gfi 1 has also been shown to be involved in HSC self-renewal. In Gfi 1 knockout animals, HSCs actually increase and outcompete other cells. This leads to stem cell exhaustion. Gfi 1b may also regulate stem cell homeostasis. The HSCs appear to be more active in terms of their cell cycle and have increased proliferation rates. It is clear that p21 is probably one of the mediators of Gfi 1 in HSC production.[593] There is also modulation of STAT3 activity as a consequence of the interaction of Gfi 1 with PIAS3, a factor that simulates transcription factors. This is interesting because other genes such as SCL, Runx1, Notch1, Notch2, RBPJ, integrin1, HOXB4, and β-catenin are dispensable for most HSC activities whereas p21, Bmi 1, tel1, C/EBP, PU.1, and Gfi are actually required.

Growth Factors and Stem Cells

HGFs also appear to influence at least some classes of stem cells. Analysis of the actions of HGFs on "purified" murine or human stem and progenitor cells has led to several major conclusions that should be interpreted in the light that to date, even the most highly purified "stem cell" fractions are still heterogeneous with respect to the content of LTR-HSCs, HSCs with short-term–reconstituting potential, and lineage-committed progenitors. HGFs such as SF and perhaps IL-3, GM-CSF, and G-CSF can independently support the survival of murine or human stem cell populations (or both).[277,5948-596] However, of all these HGFs, only SF has been shown to enhance the survival of murine LTR-HSCs, and no single HGF or combination of HGFs has unequivocally shown the capacity to induce significant self-renewal of LTR-HSCs.[597,598] IL-6–deficient mice show a reduction in CFU-S and failure of IL-6$^{-/-}$ bone marrow cells to contribute to long-term hematopoiesis after serial transfer.[310] In addition to its effect on megakaryocyte and platelet formation, TPO is also vital for stem cell production. Mice that lack the receptor for TPO (c-mpl) show reduced numbers of blast colonies and CFU-S and fail to compete effectively with normal stem cells for reconstitution of hematopoiesis in irradiated recipients, even when transplanted in 10-fold excess.[599] Furthermore, both murine and human repopulating activity segregates with primitive cells that express c-mpl.[600] In the human system, information on HSC self-renewal is not available because no human assay measures this property.

Analysis of mutations that affect the function of stem cells and the hematopoietic microenvironment through HGF interactions have provided important insight. Two murine mutations have been characterized in some detail, the Steel (*Sl*) and dominant White-spotting (*W*) mutations.[303,305,541] Genetically affected mice that are defective at these loci have severe macrocytic anemia associated with increased radiation sensitivity, lack of pigmentation, poor gastrointestinal motility, and sterility. Though phenotypically similar, these mutations map to different chromosomes (*W*, chromosome 5; *Sl*, chromosome 10) and have distinct hematologic characteristics. Best characterized at the molecular level, the *W* mutation results in a functional deficiency of HSCs, particularly erythroid progenitors. Transplantation of normal bone marrow into homozygous *W* recipients completely corrects the hematopoietic abnormalities, whereas transplantation of *W* bone marrow into normal mice fails to reconstitute hematopoiesis.[541,601] The *W* gene is allelic with the c-kit proto-oncogene,[602,603] which as discussed earlier, is known to be a member of a tyrosine kinase receptor family,[604] as is c-fms, the receptor for M-CSF. Several variants of the *W* mutation have been shown to be phenotypic expressions of specific mutations of the c-kit gene, and the severity of the phenotypic changes associated with specific alleles correlates with the degree of functional impairment in kinase activity.[605]

In contrast, the Steel mutation affects the function of cells of the microenvironment. *Sl/Sl^d* bone marrow cells are capable of reconstituting hematopoiesis in irradiated normal mice, whereas transplantation of normal bone marrow into *Sl/Sl^d* animals fails to cure the defect.[606] Deeper insight into the molecular nature of this defect

was provided by purification of a factor that is active on mast cells and on post–5-FU mouse bone marrow (enriched for primitive stem cells but depleted of mature progenitors).[607,608] This "stem cell factor" or "mast cell growth factor" was purified and its cDNA cloned. Labeling studies with the purified recombinant protein demonstrate that it is the ligand for c-kit.[609-612] Furthermore, administration of the factor to Sl/Sl^d mice corrects their macrocytic anemia and repairs their mast cell deficiency. Less severe mutations at the Sl locus such as Sl^d are associated with smaller deletions at the Sl locus. The gene encodes a protein that exists in both transmembrane and secreted forms.[609,613,614]

Recently, other growth factor pathways that are important during embryogenesis and have been subverted in certain cancers have also been implicated in stem cell self-renewal. Notch receptors (four members, Notch1 to Notch4) are expressed on the surface of a variety of hematopoietic cells as proteolytically cleaved dimers consisting of an EGF repeat-rich extracellular domain and a transmembrane/intracellular domain that contains two motifs (RAM and ANK) that can bind to a transcriptional repressor, CBF1/RBPJκ (see Kojika and Griffin[615] for a detailed review). After ligand binding (three ligands, Delta, Jagged1, and Jagged2), the transmembrane/intracellular domain is cleaved to release the active intracellular domain of Notch (ICN), which translocates to the nucleus, binds to CBF1/RBPJκ, and transactivates genes such as Hairy and Enhancer of Split 1 (HES-1), a bHLH protein that suppresses transcription of N-box (CACNAG) target genes. Human Notch1 was first identified as a gene called TAN-1 that is involved in some T-cell leukemias by generating an intracellular activated form of Notch1 (ICN1).[616] Remarkably, overexpression of ICN1 in murine stem cells leads to immortalization of cytokine-dependent cell lines that can generate lymphoid or myeloid progeny in vitro and in vivo, thus suggesting a role for Notch1 in stem cell self-renewal.[617] Activating mutations in Notch have been found in many T-cell leukemias.[618] Addition of soluble Jagged1 to cultures of human purified stem and progenitor cells also increased NOD/SCID repopulating activity.[619] A second signaling pathway that may be involved in stem cell self-renewal involves the Sonic hedgehog protein.[620] Shh activates the Smoothened receptor (Smo) by binding to its inhibitor Patched. Smo initiates signaling that regulates transcription factors of the Gli family, which modify expression of genes that encode BMP-4 and its inhibitor Noggin. Shh has recently been shown to induce expansion of human NOD/SCID repopulating cells, possibly through regulation of BMP-4. Last, Wnt signaling may also be involved in stem cell self-renewal. Wnt signals through the receptors Frizzled and lipoprotein receptor–related protein (LRP) to activate a cytoplasmic protein called Dishevilled, which in turn stabilizes β-catenin, a transcriptional coactivator that associates with the Tcf/LEF family of transcription factors (reviewed by Taipale and Beachy[621]). Without Wnt signaling, β-

catenin is normally destabilized by a cytoplasmic complex that comprises Axin, adenomatous polyposis coli (APC), and GSK3β. Overexpression of activated β-catenin in highly purified murine HSCs appears to be capable of expanding the pool of transplantable cells.[622]

Two models have been proposed to explain the mechanisms that influence the choice of stem cells between self-renewal and commitment. A *stochastic model* was proposed by Till, McCullough, and Siminovitch.[533] In this model, self-renewal or differentiation is considered to occur in a random or stochastic manner, only dictated by a certain probability. Because no extrinsic source of stem cells exists, under steady-state conditions the overall probability of stem cell division resulting in self-renewal must be 0.5; probabilities less or greater than this value would lead to progressive stem cell depletion (aplasia) or expansion (leukemia), respectively. The commitment of stem cells could occur symmetrically, where half the stem cells overall divide to produce progeny that enter a differentiation pathway and half generate progeny in which all remain undifferentiated stem cells. Alternatively, asymmetric division would give rise to one stem cell and one cell committed to differentiation. Analysis of single cells from blast cell colonies has shown that hematopoietic cells can divide asymmetrically; these micromanipulated single cells give rise to colonies that comprise almost all possible lineage combinations.[86] Single-cell analysis of purified human CD34$^+$CD45RA^{lo}CD71^{lo} provides evidence for quiescent survival, self-renewal, and asymmetric division.[623] These data provide strong support for a stochastic mechanism to explain both commitment and restriction of differentiation potential. Differentiation of single blast cells into mature cells occurs in these methycellulose cultures in the absence of an intact microenvironment. A source of HGFs is obligatory, however, as is the case for all colonies grown in semisolid media. It is important to recognize that although these random events occur with a given probability, it must be possible to favor self-renewal versus differentiation as circumstances demand. For example, during the regeneration of hematopoietic tissue after injury by irradiation or cytotoxic drugs, the probability of generating stem cells must increase. How this probability is altered is one of the outstanding unanswered questions in hematopoiesis.

A contrasting model proposed by Curry and Trentin[624] in which it was postulated that the *hematopoietic microenvironment is inductive* (HIM) was based on the observation that domains of a given lineage exist within single spleen colonies. Although this model is no longer tenable in its original formulation, the observation that the osteoblastic niche in bone marrow plays a role in stem cell self-renewal whereas the sinusoidal endothelial niche regulates proliferation, differentiation, and mobilization suggests a mechanism for the external control of stem cell expression. This plus other observations related to the morphology of the focal development of hematopoietic islands attached to adherent cells has led to the pos-

tulate that HSCs reside within stromal cell "niches" that play a vital role in supporting stem cell survival, perhaps by intimate cell contact.[15]

Whether a stochastic mechanism or one influenced by environmental cues dictates the outcome of the stem cell's decision to commit to one or another hematopoietic lineage is also uncertain. Recent experiments suggest that cross-antagonism among lineage-specific transcription factors may provide a mechanistic explanation for lineage specification. Forced expression of the erythroid-specific factor GATA-1 in myelomonocytic cells perturbs their ability to differentiate,[625] and evidence is accumulating that this is due to direct physical interaction and cross-antagonism of PU.1, the myeloid transcription factor, and GATA-1; GATA-1 inhibits PU.1 by preventing it from interacting with its cofactor c-jun, whereas PU.1 prevents GATA-1 from binding to DNA.[626-629] Down syndrome patients have mutations in GATA-1 that lead to a truncated protein missing its N-terminus.[630] This appears to give competitive advantage to a yolk sac/fetal liver progenitor in the genesis of leukemia and transient myeloproliferative disorder. Another example is the antagonism between friend of GATA-1 (FOG-1) and C/EBPβ in an eosinophilic cell line in that enforced expression of FOG-1 blocks C/EBPβ-mediated eosinophil differentiation.[631] It is therefore possible that lineage-specific transcription factors not only have potent inductive effects but also exert blocking effects on alternative lineage choices. The observation that forced expression of C/EBPβ in pancreatic cells promotes their differentiation into a hepatic phenotype raises the intriguing possibility that this mechanism underlies stem cell plasticity as well (reviewed by Cantor and Orkin[560]).[632]

Erythropoiesis

It is well established that the level of oxyhemoglobin and the rate of delivery of oxygen to tissues is the fundamental stimulus of erythropoiesis.[5] In species that package hemoglobin in erythrocytes, EPO mediates the response to oxygen demand and does so by interacting with specific receptors[633] found on the surface of committed erythroid progenitor cells[634-636] and erythroblasts.[637] As discussed earlier, insight into the mechanism by which hypoxia induces a transcriptional increase in expression of the EPO gene has come from the identification of HIF-1α.[383,638]

It is believed that BFU-E progenitors do not directly give rise to erythroblasts in vivo except under conditions of extreme anemic stress. Instead, they mature to single erythroid colony-forming units, or CFU-E, that divide in vivo and, under the influence of lower concentrations of EPO, form single, relatively small colonies of proerythroblasts at about 1 week in vitro. Many (at least half) of the CFU-E progenitors will form erythroid colonies in vitro in response to EPO alone. They do not require the additional presence of either GM-CSF or IL-3 because they have differentiated beyond this requirement.[639] All

proerythroblasts can differentiate in the presence of EPO alone. In the steady state, the number of human CFU-E progenitors exceeds the number of BFU-E progenitors by a factor of 10. CFU-E progenitors are larger than BFU-E progenitors, and because a higher fraction of CFU-E than BFU-E progenitors are in the S-phase of DNA synthesis, the former exhibit a higher rate of "suicide" in response to exposure to tritiated thymidine. The membranes of mature BFU-E and CFU-E are $CD34^+$ and $HLA-DR^+$, and various negative and positive selection methods may be used to purify them from sources such as bone marrow and human fetal liver.[103,640] They have the appearance of lymphoblasts.

The bone marrow of an adult mouse contains about 500 CFU-E per 10^5 nucleated cells. In response to anemic stress, such as hemorrhage or hemolysis, nearly the entire burden of accelerated reticulocyte production is born by rapid EPO-dependent influx into the proerythroblast pool from the progenitor compartment.[102,113] This produces an expanded proerythroblast pool. Little or no increase in the mitotic rate of recognizable erythroid precursors occurs.[102] Instead, the late BFU-E and CFU-E proliferate in response to engagement of their EPO receptors by the hormone and, in addition, differentiate to proerythroblasts and beyond. In normal murine marrow, the CFU-E frequency of about 500 per 10^5 nucleated cells increases to 1000 to 2000 CFU-E per 10^5 nucleated cells after experimental hemorrhage or hemolysis. In contrast, hypertransfused mice exhibit a reduced number of CFU-E per 10^5 nucleated marrow cells (values between 10% to 20% of normal have been reported).

During stress erythropoiesis induced by anemia, the orderly progression from immature BFU-E through CFU-E to proerythroblast is interrupted inasmuch as high EPO levels appear to permit or induce differentiation of immature progenitors to proerythroblasts. In the rhesus monkey this premature terminal differentiation may account for the marked increase in fetal hemoglobin content and F cells seen in simian stress erythropoiesis.[641] The ability of human progenitors to generate erythroblasts capable of synthesizing large quantities of fetal hemoglobin is less pronounced.[642] Thus, the accumulation of F cells in peripheral blood in response to anemia is relatively limited.[643] Such red cells are usually macrocytic and carry the i antigen as well, but these two characteristics may relate to a short transit time through the marrow in response to EPO rather than an intrinsic characteristic of the fetal hemoglobin–containing cells themselves (see later). F cells are also present in very small numbers in the blood of normal individuals, but these cells are not macrocytic and do not bear i antigen. F-cell progenitors can easily be detected in the bone marrow of patients with various hemoglobinopathies[644,645] and even in normal marrow.[646]

Transcription Factors and Erythropoiesis

As discussed earlier, targeted disruption of the tal-1/SCL, rbtn2/LMO-2, and GATA-2 genes leads to embryonic

lethality secondary to failure of blood production, probably at the HSC level. GATA-1 expression is limited to multipotent progenitors and the erythroid, megakaryocyte, mast, and eosinophil lineages.[98,647,648] Injection of chimeric mice at the blastocyst stage with GATA-1$^{-/-}$ ES cells leads to failure of contribution of the GATA-1$^{-/-}$ cells to erythrocytes but development into other hematopoietic lineages, as well as other tissues.[649,650] Differentiation assays in vitro show proerythroblast arrest and apoptosis of these cells.[651-653] FOG-1, a transcriptional cofactor of GATA-1, was discovered and found to be essential for erythropoiesis and megakaryopoiesis.[654,655] Evidence that this interaction is essential in vivo comes from studies of a family with severe dyserythropoietic anemia and thrombocytopenia. Affected family members have a mutation in GATA-1 that disrupts its interaction with FOG-1 without affecting DNA-binding affinity.[656] The EKLF transcription factor was found as an activity bound to the CACCC site of the β-globin promoter.[657] It controls globin expression and some aspects of erythroid development. The NF-E2 protein complex binds to the locus control region to regulate globin gene transcription; it is a dimer of a tissue-restricted (erythroid/megakaryocyte/mast cell) subunit of 45 kd and a smaller widely expressed subunit of 18 kd that is essential for platelet but not erythrocyte production.[658,659]

Growth Factors and Erythropoiesis

Regulation of the proliferation and maturation of erythroid progenitors depends on interaction with a number of growth factors. The availability of pure recombinant growth factors, the enrichment of target progenitor cells, and the use of defined "serum-free" culture conditions have provided insight into the role of these factors during hematopoiesis.

EPO is essential for the terminal maturation of erythroid cells. Its major effect appears to be at the level of the CFU-E during adult erythropoiesis, and recombinant preparations[639] are as effective as the natural hormone.[660,661] These progenitors do not require "burst-promoting activity"[662,663] in the form of IL-3 or GM-CSF, and their dependence on EPO is emphasized by the observation that they will not survive in vitro in the absence of EPO. Because most CFU-E progenitors are in cycle, their survival in the presence of EPO is probably tightly linked to their proliferation and differentiation to mature erythrocytes. EPO also acts on a subset of presumptive mature BFU-E, which also require EPO for survival and terminal maturation. A second subset of BFU-E, presumably less mature, survive EPO deprivation if IL-3 or GM-CSF (IL-3 > GM-CSF) is present. When EPO is added to these cultures on day 3, these BFU-E progenitors form typical colonies. Under serum-deprived culture conditions, the combination of IL-3 and GM-CSF results in more BFU-E than either factor alone when EPO is added on day 3.[664] Although EPO is crucial for the terminal differentiation of erythroid progenitors, mice with homo-

zygous null mutations of the EPO or EPOR genes form BFU-E and CFU-E normally, but they fail to differentiate into mature erythrocytes.[314] Both the EPO$^{-/-}$ and EPOR$^{-/-}$ mutations are embryonically lethal because of failure of definitive (fetal liver) erythropoiesis. However, yolk sac erythropoiesis is only partially impaired, thus indicating the existence of a population of EPO-independent primary erythropoietic precursors. SF has marked synergistic effects on BFU-E cultured in the presence of EPO,[128] although alone it has no colony-forming ability. SF is crucial for the normal development of CFU-E because mice that lack SF (Sl mutants) or its receptor c-kit (*W* mutants) are severely anemic and have a reduction in fetal liver CFU-E.[665] Further studies showed that SF induces tyrosine phosphorylation of EPOR and that c-kit associates with the cytoplasmic domain of the tyrosine-phosphorylated EPOR. Further insight into the molecular mechanism by which EPO prevents apoptosis in erythroid cells comes from studies of STAT5A$^{-/-}$5B$^{-/-}$ mice. During fetal development the embryos are severely anemic; the erythroid progenitors in fetal liver are reduced in number and show increased apoptosis.[666] This result was explained by the finding that STAT5 mediates early induction of the antiapoptotic gene Bcl-X$_L$ through direct binding to its promoter. Interestingly, although adult animals were thought to be hematologically normal, about half have chronic anemia with splenomegaly as a result of an increase in early erythroid precursors; erythropoiesis is ineffective because of an increase in apoptosis in these early normoblasts that have reduced levels of Bcl-X$_L$.[667]

Factors distinct from the classic CSFs may positively regulate erythropoiesis, either directly or indirectly. Limiting-dilution studies of highly purified CFU-E in serum-free culture show that insulin and IGF-I act directly on these cells.[668] The presence of EPO is essential in these studies, in contrast to earlier murine studies of unfractionated cells in which CFU-E respond to IGF-I or insulin in the absence of EPO.[669] Another factor that enhances both BFU-E and CFU-E colony formation is activin. This protein dimer, also known as follicle-stimulating hormone–releasing protein, appears to have a lineage-specific effect on erythropoiesis that is indirect because removal of monocytes or T lymphocytes (or both) abrogates its effect.[670] It is interesting that activin has been identified as the factor produced by vegetal cells during blastogenesis that induces animal ectodermal cells to form primary mesoderm.[671] Hepatocyte growth factor has also been shown to have synergistic effects on CFU-GEMM and BFU-E in EPO-containing cultures.[672]

Negative Regulation of Erythropoiesis

Observations that subsets of lymphocytes with an immunologic suppressor phenotype isolated from normal subjects can inhibit erythroid activity in vitro[673-675] correlate with reports of patients with a variety of disorders in whom anemia or granulocytopenia is associated with expansion of certain T-lymphocyte populations (see also

Chapter 7).[676-678] In the rare disorder T lymphocytosis with cytopenia,[679] in vitro suppression of erythropoiesis has been correlated with the expansion of a T-lymphocyte population that may be the counterpart of the hematopoietic suppressor cells isolated from normal blood. The phenotype of these cells has been described in detail.[679,680] The cell is a large granular lymphocyte that is both E rosette positive and CD8 (classic suppressor phenotype) positive. Suppressor T cells may also be involved in some cases of aplastic anemia[681,682] or neutropenia[683] without an underlying immunologic disorder or overt T-cell proliferation. Exactly how such suppressor T cells interact with hematopoietic progenitors and what surface antigens are "seen" by the suppressors are uncertain. There is evidence to support the concept that suppression of erythroid colony expression in vitro is regulated by T cells and may be genetically restricted.[680,684] Cell-cell interactions in immunologic systems have been well characterized with regard to surface determinants that allow cellular recognition. That certain phenotypes of T cells "recognize" distinct classes of histocompatibility antigens on immunologic cell surfaces has been well described.[685] Thus, the observation that hematopoietic progenitors have a unique distribution of class II hiscompatibility antigens on their cell surface[686-689] suggests a role for these antigens in the cell-cell interactions that regulate hematopoietic differentiation.

TNF also suppresses erythropoiesis in vitro.[690,691] Injection of peritoneal macrophages into Friend murine leukemia virus–infected animal results in rapid, but transient resolution of the massive erythroid hyperplasia associated with this disease. This may be due to elaboration by macrophages of IL-1α, which does not suppress erythropoiesis itself but acts by induction of TNF. This effect is reversed by EPO.[692]

Myelopoiesis

Phagocyte Development

Although a clonogenic assay of granulocyte progenitors was developed almost a decade before the erythroid clonogenic assay, the various factors responsible for granulocyte/macrophage development remain incompletely understood. Excellent reviews of early work in this field have been provided by Metcalf[94] and Moore.[90]

It is now accepted that CFU-GM is derived from the pluripotent progenitor and, under the influence of SCF, IL-3, GM-CSF, G-CSF, or M-CSF (or any combination of these factors), ultimately gives rise to mature granulocytes and monocytes. Monocytes irreversibly leave the circulation[693,694] and differentiate further into fixed-tissue macrophages, a category comprising alveolar macrophages,[695] hepatic Kupffer cells,[696] dermal Langerhans cells,[697] osteoclasts,[698] peritoneal and pleural macrophages, and perhaps brain microglial cells.[699] The enormous diversity of this system and the high turnover rate of granulocytes, as well as the necessity to maintain

splenic, marginated, and bone marrow granulocyte pools to meet sudden demands caused by infection, have led to the evolution of an extremely complex regulatory network. Indeed, although many of the factors that allow release of granulocytes from storage pools are distinct from CSF,[13] GM-CSF can inhibit granulocyte motility,[700] as well as serve as an activator of granulocyte superoxide anion generation.[701] This complexity in vivo does not permit studies analogous to those in which erythropoiesis is influenced by hypertransfusion or hemorrhage[702,703] and megakaryocytopoiesis is stimulated by induced thrombocytopenia.[704] Thus, investigators have relied heavily on in vitro progenitor assays to study the regulation of myelopoiesis.

Transcription Factors and Myelopoiesis

A family of transcription factors important for commitment to the myeloid and lymphoid lineages, as well as regulation of myeloid-specific promoters such as those of the myeloperoxidase (MPO) and neutrophil elastase (NE) genes, are factors that were first identified on the basis of their ability to bind to the polyomavirus enhancer–binding protein 2 (PEBP2)/CBF. Two α subunits (CBFα1 and CBFα2 [the human homologue is known as AML-1 or Runx1]) bind DNA with low affinity, and affinity is strengthened in the presence of the non–DNA-binding β subunit (CBFβ). As noted earlier, AML-1$^{-/-}$ mice die in utero by day 12.5 because of failure production of all definitive hematopoietic lineages.[584] The C/EBP family of transcription factors bind to DNA through a basic region–leucine zipper domain (bZIP). There are several family members (C/EBPα, C/EBPβ [NF–IL-6], C/EBPγ, C/EBPδ, C/EBPζ, and C/EBPϵ) that are differentially expressed during myelopoiesis, with increased (C/EBPβ) or increased followed by either partial (C/EBPδ) or marked (C/EBPα) decreased levels of expression during maturation of 32D cl3 cells to terminally differentiated granulocytes.[705] C/EBPα has been implicated in the regulation of hepatocyte and adipocyte differentiation (levels are low in undifferentiated dividing cells but high in quiescent terminally differentiated cells), as well as in myeloid CSF receptor promoter function; AML-1 can act synergistically with C/EBPα to activate the M-CSFR promoter.[706] C/EBP$\alpha^{-/-}$ mice show arrested myelopoiesis at the myeloblast stage as a result of failure of expression of G-CSFR and IL-6R.[707,708] Mice that lack C/EBPβ produce monocytes that are defective in bactericidal and tumoricidal function, and their macrophages and fibroblasts, but interestingly not their endothelial cells, fail to produce G-CSF in response to LPS.[709] C/EBPϵ is produced primarily in myeloid lineages. Knockout mice are viable and fertile but die at 50 to 75 days as a result of opportunistic infections with *Pseudomonas aeruginosa*.[710] Nullizygous animals fail to produce normal neutrophils and eosinophils. Functional abnormalities include diminished release of hydrogen peroxide in response to phytohemagglutinin stimulation because of failure to produce secondary and tertiary granules, which

are important reservoirs of membrane-bound components of the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase apparatus. Additional components of secondary and tertiary granules, lactoferrin and gelatinase B, are absent because of failure of transcriptional activation of C/EBPε.[710,711] Interestingly, similar abnormalities characterize the rare neutrophil-specific granule deficiency,[712] and indeed, mutations in C/EBPε have recently been found in these patients.[713-715] The PU.1 (Spi-1) transcription factor is a member of the Ets family and is expressed principally in monocytes/macrophages and B lymphocytes, as well as in erythroid cells and granulocytes.[716,717] Potential target genes include the integrin CD11b, M-CSFR, GM-CSFRα, G-CSFR, and the immunoglobulin λ light chain.[718-722] Mice that lack PU.1 die in utero with absence of monocytes, granulocytes, and T and B lymphocytes; the presence of anemia is variable and thus does not explain the prenatal mortality.[723]

Growth Factors and Myelopoiesis

Murine IL-3 stimulates a broad spectrum of myeloid progenitor cells, including pluripotent stem cells, CFU-GM, CFU-G, CFU-M, BFU-E, CFU-Eo, CFU-Meg, and mast cells. As its name implies, GM-CSF was initially shown to be more restricted as a stimulus of the proliferation and development of CFU-GM. However, murine studies with purified or recombinant factor have shown that it also stimulates the initial proliferation of other progenitors such as BFU-E (see earlier).[189,724] The other murine factors, G-CSF and M-CSF, are more restricted and predominantly stimulate CFU-G and CFU-M, respectively.[725,726]

With the possible exception of GM-CSF, the activities of human CSFs are similar to those of the corresponding murine factors. Both IL-3 and GM-CSF affect a similar broad spectrum of human progenitor cells, including CFU-GEMM, CFU-GM, CFU-G, CFU-M, CFU-Eo, and CFU-Meg. In full serum cultures, IL-3 and GM-CSF alone stimulate the formation of colonies derived from CFU-GM, CFU-G, CFU-M, CFU-Eo, and CFU-Meg. Data from serum-free cultures suggest that in the presence of IL-3 or GM-CSF alone, myeloid colony formation is much reduced and optimal CFU-G or CFU-M proliferation requires the addition of G-CSF or M-CSF, respectively, to the cultures.[193,664] Even in serum-replete conditions, IL-3 acts additively or synergistically with G-CSF to induce more granulocyte colony formation than observed with either factor alone.[192]

Insight into the in vivo role of GM-CSF comes from studies in which the GM-CSF gene was disrupted by homologous recombination in ES cells.[321] GM-CSF knockout mice showed normal basal hematopoiesis, but surfactant lipids and proteins progressively accumulated in the alveolar space, the defining characteristic of idiopathic human pulmonary alveolar proteinosis. Extensive lymphoid hyperplasia associated with lung airways and blood vessels was also found. Surfactant proteins and lipids are synthesized by type II pneumocytes and cleared from the alveolar space by type II cells and alveolar macrophages. Lungs from the null animals showed normal surfactant synthetic capacity and no accumulation in type II pneumocytes. In contrast, alveolar macrophages showed a marked increase in surfactant protein and lipid, which strongly suggests that these cells cannot process surfactant as a result of the lack of GM-CSF. Mice generated with null mutations of the common chain of the GM-CSF/IL-3/IL-5 receptor (β_c) have similar pulmonary pathology and also show low basal numbers of eosinophils and absence of blood and lung eosinophilia in response to infection with the parasite *Nippostrongylous brasiliensis*.[316] The G-CSF gene has also been disrupted by homologous recombination in ES cells.[313] G-CSF$^{-/-}$ mice have a chronic neutropenia (20% to 30% of normal levels) and reduced bone marrow myeloid precursors and progenitors. The animals also exhibited a markedly impaired capacity to increase neutrophil and monocyte counts after infection with *Listeria monocytogenes*.

In addition to their effects on progenitor differentiation, the CSFs also induce a variety of functional changes in mature cells. GM-CSF inhibits polymorphonuclear neutrophil migration under agarose,[700] induces antibody-dependent cytotoxicity (ADCC) in human target cells,[701] and increases neutrophil phagocytic activity.[187] Some of these functional changes may be related to the GM-CSF–induced increase in cell surface expression of a family of antigens that function as cell adhesion molecules.[727] The increase in antigen expression is rapid and associated with increased aggregation of neutrophils; both are maximal at the migration inhibitory concentration of 500 pM, and granulocyte-granulocyte adhesion can be inhibited by an antigen-specific monoclonal antibody. GM-CSF also acts as a potent stimulus of eosinophil ADCC, superoxide production, and phagocytosis.[728] G-CSF acts as a potent stimulus of neutrophil superoxide production, ADCC, and phagocytosis,[729] whereas M-CSF activates mature macrophages[730] and enhances macrophage cytotoxicity.

Megakaryocytopoiesis

The cloning of TPO has greatly clarified our understanding of the regulation of megakaryocytopoiesis.[177] Before the discovery of TPO, several factors,[731] including IL-3,[732] IL-6,[733] IL-11,[734] kit ligand,[735,736] and even EPO,[737,738] were shown to stimulate megakaryocytopoiesis and thrombopoiesis in vitro and in vivo. IL-3, IL-6, and IL-11 engage heterodimeric receptors of the β_c (IL-3R) and gp130 families (IL-6R and IL-11R). Kit ligand engages a receptor whose intracellular domain expresses tyrosine kinase activity upon ligand binding. As already emphasized in this chapter, ligand engagement of these receptor families is known to induce early multipotent progenitors to proliferate and even differentiate toward lineage-specific progenitors, and kit ligand, IL-3, and IL-11 participate in the induction of proliferation and differentiation

of lineage-specific progenitors. Single-cell analysis of prospectively isolated murine megakaryocyte progenitors shows that a large proportion (≈60%) express EPOR,[419] which is consistent with the potent effect of EPO on megakaryocyte colony formation.[739]

The discovery of TPO provided a major step in understanding megakaryocytopoiesis because this factor induces lineage-restricted megakaryocyte progenitor proliferation, differentiation of these committed progenitors to megakaryoblasts, and finally, differentiation of megakaryoblasts to megakaryocytes, which in turn produce platelets (see Fig. 6-13).

Thrombopoietin

TPO is produced at the site of hematopoiesis. Therefore, although its activity is increased in blood during episodes of thrombopenia, it does not necessarily function as a hormone because it is produced directly at the site of thrombopoiesis. In this sense it differs from EPO, which is not produced at all in marrow stroma. Blood levels may increase in thrombocytopenic states merely because circulating platelets or tissue megakaryocytes, or both, sop up the growth factor and carry it out of the circulation.[395,740] This theory has received support from observations in mice with disruption of the murine transcription factor gene NF-E2[100]; although these animals are thrombocytopenic, they have an increase in megakaryocyte mass and no increase in serum TPO levels.[741]

As reviewed by Kaushansky,[177] the TPO molecule is considerably longer than the other HGF polypeptides. Its 5′ half bears 23% sequence homology to EPO, whereas the 3′ half bears no structural homology to any cytokine and may be removed by a proteolytic mechanism. Indeed, removal of this half does not ablate its physiologic function. The resemblance of the 5′ domain of the molecule to EPO may explain the synergy of TPO and EPO in megakaryocyte colony formation and platelet production.[177,730] It is well recognized that splenectomized individuals with persistent anemia usually have significant thrombocytosis and that many individuals with red cell aplasia and high EPO levels also have thrombocytosis and megakaryocytosis.

The function of TPO has been studied carefully in vivo and in vitro. Lineage-specific CD34+ megakaryocyte progenitors bear receptors for SF, IL-3, IL-11, and TPO, the four major classes of hematopoietic cytokine receptors. Maximal megakaryocyte colony formation probably requires signaling by all four receptors, but TPO is absolutely required for the final stages of megakaryocyte maturation, including maximal ploidy, cytoplasmic volume, and therefore platelet production.

Therapeutic trials of TPO in mice have shown that TPO is species specific. Treatment of mice with murine TPO induces massive thrombocytosis, whereas human TPO is much less active in these animals. More importantly, TPO is active in reducing the platelet nadir in mice and primates rendered thrombcytopenic by chemotherapy or radiation.

Circulating Platelets

The differential diagnosis of thrombocytopenia rests first on evaluation of platelet morphology. In conditions in which megakaryocytopoiesis is accelerated, circulating platelet volume (and usually diameter) is increased. The reasons for this shift in volume are disputed. Some claim that young platelets are larger than old platelets.[742] Others suggest that large megakaryocytes give rise to large platelets.[743] Neither explanation satisfies all experimental and clinical conditions, but in general, thrombocytopenia secondary to increased destruction of platelets is associated with platelets with large volume, and thrombocytopenia related to decreased production of platelets is associated with platelets of normal size. There are major exceptions to this rule. Patients with hyposplenism tend to have large platelets in their blood, regardless of whether thrombopoiesis is increased, and patients with primary abnormalities in platelet function, such as Wiskott-Aldrich or Bernard-Soulier syndrome, have platelet sizes that bear no relationship to platelet production. TPO increases platelet production by increasing both the number and size of individual megakaryocytes. Although TPO is probably solely responsible for the later stages of recognizable megakaryocyte differentiation and proliferation of megakaryocyte progenitors, its function depends, at least in part, on additional stimulation of megakaryocyte progenitors (and probably early megakaryocytes as well) with other growth factors, including IL-3, IL-11, SCF, and EPO.

CLINICAL USE OF HEMATOPOIETIC GROWTH FACTORS

Correction or amelioration of marrow failure syndromes by the administration of HGFs has been and continues to be a major practical goal of research in hematopoiesis. The goal could not be achieved, however, until recombinant DNA technology provided sufficient amounts of the hormones to permit interpretable investigations.

Human Clinical Studies

Several recombinant HGFs are currently under evaluation in a variety of clinical settings. G-CSF and EPO are widely used clinically. G-CSF shortens the hypoplasia that follows chemotherapy and makes more intensive myeloablative chemotherapy regimens possible.

Malignant Disease

G-CSF

In the first phase I/II clinical studies in patients with malignant disease, administration of G-CSF by bolus or continuous intravenous infusion for 5 to 6 days before chemotherapy led to a dose-related increase in polymorphonuclear neutrophils.[744,745] Rapid increases in neutro-

phil counts were observed, with maximal counts of 80 to 100×10^9/L at doses of 10 to 30 mg/kg/day. A transient depression in neutrophil counts was noted to precede this increase in one study.[746] In another study, recombinant human GM-CSF (rhGM-CSF) was given for 14 days after alternate cycles of intensive chemotherapy.[747] The period of neutropenia was reduced by a median of 80% (52% to 100%) in the chemotherapy/G-CSF cycles, with a return to normal neutrophil counts within 2 weeks after chemotherapy. Infective episodes were observed during the cycles of chemotherapy that did not include G-CSF, whereas no infective episode occurred in those that did. G-CSF treatment after chemotherapy results in a significant reduction in the number of days per patient in which the neutrophil count is less than 1.0×10^9/L.[744] Antibiotic use to treat fever and neutropenia is also reduced, and all the patients could receive their next course of chemotherapy on schedule (versus 29% of patients who did not receive G-CSF). The mature neutrophils produced in response to G-CSF have normal mobility and bactericidal capacity.[748] A double-blind, randomized, placebo-controlled U.S. multicenter trial was conducted in which patients with lung carcinoma who received up to six cycles of cyclophosphamide, doxorubicin, and etoposide were given G-CSF or placebo from days 4 to 17 of each cycle. The results showed a reduction in the median duration of severe neutropenia ($<0.5 \times 10^9$/L) from 6 to 3 days in the G-CSF arm and a 50% reduction in febrile neutropenia, hospitalizations, confirmed infections, and antibiotic use with G-CSF (see Fig. 6-2).[749] This study and other reports[750,751] have led the American Society of Clinical Oncology and the European Organization for Research and Treatment of Cancer to recommend primary use of G-CSF in patients with an expected rate of neutropenia that exceeds 20%.[752,753] The use of G-CSF is recommended to support dose-dense or dose-intense chemotherapy regimens in adult carcinoma patients, but most studies do not show a significant effect on progression-free survival.[753] Patients in the placebo arm of the U.S. multicenter trial[749] in whom fever developed in the first treatment cycle were subsequently treated with G-CSF, which reduced the duration of severe neutropenia from 6 to 3 days and neutropenic fever from 100% in cycle 1 to 1% to 23% in cycle 2. Thus, the prophylactic use of G-CSF in chemotherapy-induced neutropenia is supported. However, the literature does not support the use of G-CSF or GM-CSF once afebrile[754] or febrile neutropenia has developed,[755,756] with the exception of one study.[757] Although days of neutropenia may be shortened, it has been difficult to show an effect on clinically significant end points such as shortened duration of hospitalization, which was seen in only one of the studies.[756]

GM-CSF

rhGM-CSF has been administered in phase I/II studies to several adult groups of patients with advanced malignancy, both before and after chemotherapy.[758-760] Glyco-sylated GM-CSF produced in either mammalian (Chinese hamster ovary) cells or yeast and *Escherichia coli*–derived nonglycosylated GM-CSF have been evaluated with comparable results. A rapid, dose-related increase in polymorphonuclear neutrophils, monocytes, and eosinophils is observed in patients treated before chemotherapy. Neutrophils peak at around 20 to 30×10^9/L with doses of 4 to 32 mg/kg/day, and GM-CSF is well tolerated at doses up to this level. Capillary leak syndrome and venous thrombi are observed at higher doses (64 mg/kg/day).[758] Phase III randomized trials in patients with lymphoma or breast cancer have confirmed that GM-CSF given after chemotherapy is associated with shorter periods of neutropenia and higher leukocyte nadirs.[761-763] However, one of these studies included only patients able to tolerate treatment and was not significant on an intention-to-treat basis. Furthermore, another study of GM-CSF after chemotherapy showed decreased neutropenia after the first treatment cycle only,[764] whereas another two studies showed no improvement in neutrophil counts.[765,766] In one of these studies,[765] patients with small cell lung cancer were given chemotherapy and radiation therapy; when compared with the placebo control, patients in the GM-CSF arm suffered more infections, toxic deaths, and longer hospital stays, and therefore the American Society of Clinical Oncology panel has cautioned against the use of CSFs in combined chemotherapy/radiotherapy regimens.[767,768]

Similar encouraging results have been obtained in children with solid tumors undergoing intensive chemotherapy.[769-771] Significantly shorter durations of severe neutropenia and thrombocytopenia were observed in a study of 25 children in whom yeast-derived GM-CSF was administered at 60 to 1500 μg/m^2/day for 14 days after chemotherapy.[769]

Like G-CSF, GM-CSF also produced an increase in blood progenitor cells of both the erythroid and myeloid lineage. Before chemotherapy, an 18-fold increase in blood CFU-GM and an 8-fold increase in BFU-E was noted; after chemotherapy, GM-CSF produced a much greater increase in progenitors (60-fold) when given during the recovery period.[769]

Erythropoietin

Anemia is frequent in cancer patients and correlates with poor performance status and decreased quality of life (reviewed by Beutel and Ganser[772]). There is good evidence that recombinant human EPO (rhEPO) can increase the hemoglobin level in adults[773,774] and children[775] with anemia associated with cancer or its treatment. Three different EPO preparations are available, epoetin alfa (Epogen [Amgen], Procrit [Ortho Biotech], and Eprex [Ortho Biologicals, not sold in the United States]), epoetin beta (NeoRecormon [Roche], sold in Europe), and darbopoetin alfa (Aranesp [Amgen], sold in the United States, Europe, Canada, and Australia). Differences in the sialic acid carbohydrate composition of epoetin alfa and beta account for an increase in half-

life from 8.5 hours (natural EPO) to 20 to 24 hours, whereas hyperglycosylation of darbopoetin results in a half-life of 49 hours.

Two 2003 randomized studies of patients with anemia and either head and neck cancer or breast cancer showed shorter survival in the groups receiving EPO, thus raising concern that EPO can lead to progression of disease.[776,777] Another study of advanced non–small cell lung cancer designed to compare EPO with placebo was stopped early when a safety analysis of 70 patients showed a significant survival advantage in the placebo group. Whether carcinoma cells express EPOR and respond to EPO is controversial. Antibodies to EPOR lack specificity and do not distinguish cell surface from intracellular expression, and functional in vitro effects are frequently limited and found at supraphysiologic doses. However, EPO could still have adverse consequences through indirect effects on endothelial cells or on angiogenesis.[778]

Thrombopoietin

Because of TPO's potent in vitro activity and its role as the factor essential for terminal megakaryocytic differentiation, analogous to EPO for the erythroid lineage, clinical studies designed to assess its effect on platelet production have been reported. Both recombinant human TPO (rhTPO) and pegylated megakaryocyte growth and development factor (PEG-MGDF) are safe and show no organ toxicity, and in normal volunteers, a single bolus of 3 µg/kg/day of PEG-MGDF doubles the blood platelet concentration by day 12 with a return to baseline by day 28 (reviewed by Harker[779]). A stimulatory effect on platelet production was observed when TPO or PEG-MGDF was administered after chemotherapy to more than 100 cancer patients, with a decrease in the time for platelet counts to return to normal and elevated platelet nadirs.[780-782] Further studies showed that TPO and PEG-MGDF were effective in malignancies treated with nonmyeloablative chemotherapy but were less effective in myeloablative regimens followed by stem cell transplantation for the treatment of leukemia (reviewed by Kuter and Begley[783]). Moreover, PEG-MGDF has caused the development of antibodies to TPO that resulted in severe thrombocytopenia (see later), and these cytokines have been withdrawn from clinical use. Small molecules, peptides, and a peptide–Fc antibody combination (AMG 531 "peptibody") that have no sequence homology with TPO but activate the receptor are under investigation (reviewed by Szilvassy[784]).

Bone Marrow Transplantation

GM-CSF, G-CSF, and M-CSF have been evaluated in clinical autotransplantation trials.

GM-CSF

Patients with nonhematopoietic malignancies were treated with high-dose combination chemotherapy, autologous bone marrow transplantation, and rhGM-CSF given by continuous intravenous infusion for 14 days beginning 3

hours after bone marrow infusion. There was a dose-related increase in neutrophil count at day 14 (1411/µL at 2 to 8 mg/kg/day, 2575/µL at 16 mg/kg/day, and 3120/µL at 32 mg/kg/day as compared with 863/µL in 24 historical controls).[785] Though not statistically significant, there was an improved neutrophil response in patients who had not received previous chemotherapy versus those who had (1832 versus 833/µL). Lower morbidity and mortality were also noted in patients who received GM-CSF; bacteremia occurred in 16% of treated patients as compared with 35% of evaluable controls. Comparable results were reported in a study of patients with lymphoid malignancies who received rhGM-CSF as a 2-hour infusion daily for 14 days after chemotherapy, radiotherapy, and autologous bone marrow transplantation.[786] Neutrophil and platelet counts recovered more rapidly, there were fewer days of fever, and the extent of hospitalization was reduced in comparison to a historical control group. In a pediatric study, nine patients received 5 to 10 µg/kg/day GM-CSF after bone marrow transplantation. Neutrophil recovery was accelerated, although there was no difference in fever, infection, or length of hospitalization when compared with historical controls.[787] Similar results were obtained in a larger prospective double-blind randomized study of 40 patients.[788]

The response to GM-CSF after myelosuppression may be dependent on the infusion of sufficient progenitor cells. In an autotransplantation study of patients with ALL, bone marrow was purged with 4-hydroperoxycyclophosphamide and anti–T- or anti–B-cell lineage-specific antibodies before transplantation.[789] Thirty percent of the patients who received more than 64 µg/m^2/day GM-CSF achieved an absolute neutrophil count (ANC) of greater than 1000/µL by day 21, whereas none of the nonresponders reached this level by day 27 after transplantation. The responders required only a third as many platelet transfusions, and there was a trend toward fewer red cell transfusions, higher myeloid-erythroid ratio, and earlier day of discharge in the responder group as well. Although the bone marrow cell dose did not differ between the two groups, the number of CFU-GM progenitors infused per kilogram was significantly higher in the responders than in the nonresponders (17.5 [12 to 27] × 10^3/kg versus 2 [0 to 7.2] × 10^3/kg). Although it is possible that this accounts for the more rapid recovery rather than the rhGM-CSF infusion, the responder group all showed a rapid decrease in ANC within 48 to 72 hours of discontinuing GM-CSF; this is consistent with a stimulatory effect on bone marrow. One can conclude that GM-CSF is effective in this context, provided that sufficient progenitor cells are present.

G-CSF

Recombinant human G-CSF (rhG-CSF) was evaluated in patients with hematopoietic and nonhematopoietic malignancies after intensive chemotherapy and reinfusion of cryopreserved autologous bone marrow.[790] rhG-CSF was given by continuous intravenous infusion

starting 24 hours after marrow infusion for a maximum of 28 days; the initial dose of 20 μg/kg/day was reduced after the neutrophil count persistently exceeded 1×10^9/ L. The mean time to neutrophil recovery ($>0.5 \times 10^9$/L) was 11 days, 9 days earlier than in historical controls. This led to significantly fewer days of parental antibiotic therapy, but there was no effect on red cell or platelet recovery. Although the rate of recovery from neutropenia was faster than that reported for rhGM-CSF, the latter studies were phase I dose escalation evaluations, and many patients did not receive an optimal dose of GM-CSF. A prospective randomized study of 221 children receiving allogeneic or autologous bone marrow or peripheral blood stem cells showed more rapid neutrophil recovery in the G-CSF–treated patients, and this translated to clinical benefit in the bone marrow group (platelet transfusion independence and time to discharge).[791] A study compared G-CSF with GM-CSF in exactly the same analogous bone marrow transplant protocol. The G-CSF group contained more patients with breast carcinoma who had previously received chemotherapy, and this group did not show a dose-related increase in neutrophil count after a 14-day continuous intravenous infusion at doses of 16, 32, and 64 μg/kg/day. Overall, however, total leukocyte recovery was slightly more rapid in the G-CSF group than in the GM-CSF group. Administration of G-CSF resulted in two leukocyte peaks. The first at day 10 involved lymphocytes, whereas the second at day 14 consisted of mostly granulocytes; in contrast, GM-CSF produced a single peak at the end of the period of infusion. A major difference was observed with respect to neutrophil migration to an inflammatory site during CSF infusion after hematopoietic reconstitution.[792] Neutrophils did not migrate to skin chambers filled with autologous serum during GM-CSF treatment, a defect not encountered during the administration of G-CSF. There was, however, a similar reduction in the incidence of bacteremia with both GM-CSF and G-CSF (18% and 19%, respectively) in comparison to historical controls (35%).

In conclusion, if neutrophil recovery is the goal after bone marrow transplantation, G-CSF appears to be the factor of choice. It preserves neutrophil function and is well tolerated. The inability to hasten platelet recovery is still the major challenge.

Thrombopoietin

PEG-MGDF was evaluated in a controlled trial of 50 breast cancer patients who received chemotherapy along with autologous bone marrow; the time during which the platelet count remained lower than 20,000/μL was reduced ($P \leq 0.6$), and the time to recovery of normal platelets was significantly shortened. However, when mobilized blood progenitors were given rather than bone marrow, the more rapid recovery made it difficult to demonstrate an effect of PEG-MGDF on duration of thrombocytopenia or platelet transfusion requirements. Furthermore, a phase III randomized placebo-controlled double-blind study of 64 patients failed to show a consistent reduction in the duration of severe thrombocytopenia.[793]

Myelodysplasia

GM-CSF

Despite the theoretical risks of administering CSFs to patients with myeloid stem cell clonal diseases, the factors have been evaluated in patients with refractory anemia (RA), RA with an excess of blasts (RAEB), RAEB in transformation (RAEBIT), and chronic myelomonocytic leukemia.[794-796] In an early study, GM-CSF was given by continuous infusion for 14 days and repeated after a 2-week rest period.[794] Five of the eight patients had received chemotherapy up to 4 weeks before the study. Doses of 30 to 500 μg/m² were used. Blood leukocytes rose 5- to 70-fold and neutrophils 5- to 373-fold, and an absolute increase in monocytes, eosinophils, and lymphocytes was also observed. Three of the eight patients also had a 2- to 10-fold increase in platelet count and improvement in erythropoiesis, and two of the three became transfusion independent. Marrow cellularity increased and the proportion of blasts decreased, although there was a transient and dose-related increase in the absolute number of circulating blasts. In no patient did overt leukemia develop during the period of follow-up (up to 32 weeks). There was no cytogenetic evidence of a reduction in abnormal clones, and it is likely that the stimulatory effect on hematopoiesis affects both normal and abnormal cells. A dose-related increase in neutrophils, monocytes, eosinophils, and lymphocytes was also noted in a study of 11 patients with myelodysplasia. However, four patients with greater than 14% blasts in bone marrow showed an increase in blasts after therapy, and an additional three patients showed an increase in blasts in blood; five patients progressed to acute leukemia either during or within 4 weeks after treatment.[796] Unlike the earlier report, none of these patients had previously received chemotherapy.

G-CSF

A number of patients have also been treated with G-CSF.[797,798] Neutrophil responses were seen in five patients with myelodysplasia who received 50 to 1600 μg/m²/day by 30-minute infusion daily for 6 days. At higher doses (400 μg/m²/day), the increase was sustained and associated with an increase in bone marrow cellularity. No reticulocyte or platelet increases were observed, and no patient progressed to an acute phase. Similar results were reported in a study of 12 patients given G-CSF by daily subcutaneous injection, with dose escalation from 0.1 to 3 μg/kg/day over an 8-week period.[798] Although 10 of the 12 patients showed elevations in neutrophils (5- to 40-fold), an increase in reticulocytes occurred in 5 patients with a reduction in transfusion requirements in 2. There was no response in other cell lineages and no conversion to acute leukemia.

Other HGFs and HGF Combinations

Approximately 20% of patients have an increase in platelet count during treatment with IL-3,[799,800] and a similar proportion have an increase in hematocrit or reduced transfusion requirement with EPO.[7801] This erythroid response can be increased to about 40% if EPO is combined with either G-CSF or GM-CSF.[802,803]

In a review of this subject, Marsh and colleagues concluded that although EPO can increase hemoglobin levels and reduce the need for transfusion, the cost-effectiveness of the approach is uncertain, as is safety with regard to the risk of progression. There is no compelling evidence for a survival benefit with the use of EPO or G-CSF in MDS.[804]

Aplastic Anemia

GM-CSF

Establishing a role for the CSFs in aplastic anemia has challenged investigators. Severe aplastic anemia is a heterogeneous disease that may result either from absent or defective stem cells, from microenvironmental defects, or from immunologically mediated suppression. Mortality is high and therapeutic options are limited to bone marrow transplantation if an appropriate donor is available or to immunosuppression (see Chapters 7 and 8). Although bone marrow transplantation can be curative, treatment with antithymocyte globulin (ATG) and cyclosporine is sometimes effective but not generally curative. For these reasons, rhGM-CSF has been evaluated in a number of phase I/II studies. Administration of rhGM-CSF by bolus or continuous intravenous infusion for 7 or 14 days resulted in increased granulocytes, monocytes, and reticulocytes in six of eight patients.[795] In another small study, rhGM-CSF was given to cohorts of patients in escalating doses of 4 to 64 µg/kg/day by continuous intravenous infusion for 14 days. Although a dose-related effect was not observed, 10 of 11 evaluable patients had partial or complete responses in neutrophil, monocyte, and eosinophil counts, along with increases in bone marrow cellularity. Importantly, the greatest increments occurred in patients with higher pretreatment neutrophil counts and more cellular marrow. Only 10% to 20% of patients show an increase in hemoglobin concentration and platelet count, and in all cases counts return to baseline after cessation of treatment.[794,805] In the first report of rhGM-CSF treatment in childhood, three quarters of the evaluable patients responded with a significant rise in neutrophil count during the 28-day induction period.[806] Although neutrophil counts returned to baseline after cessation of treatment in all the responders with severe aplastic anemia, one patient with moderate aplasia maintained a trilineage response off therapy for longer than 1 year. One cannot extrapolate from such a small experience, but the data underscore the point that responses are more likely in less severely affected cases.

Thus, in summary, it appears as though rhGM-CSF is palliative in aplastic anemia, with greater neutrophil responses evident in less severely affected patients. The most severely affected patients respond poorly.[807] No infections were observed during the study period in several reports, whereas infections were reported in others. Longer-term prospective comparative studies will be necessary to investigate morbidity.

G-CSF

Neutrophil responses have also been reported in a study of 20 children given 400 µg/m²/day G-CSF for 14 days.[808] Twelve patients responded by doubling their neutrophil counts, but other lineages were unaffected. In another pediatric study, high doses of G-CSF (400 to 2000 µg/m²/day) induced neutrophil responses in 6 of 10 patients with very severe aplastic anemia.[809] Long-term treatment may be associated with multilineage responses when given alone[810] or in combination with cyclosporine.[811]

IL-3, IL-6, and EPO

Hematopoietic responses have been reported in a small phase I study of nine aplastic anemia patients given IL-3, 250 to 500 µg/m² (five of nine doubled their neutrophil counts, four of nine showed an increase in reticulocyte counts but no reduction in transfusion requirement, and in one platelet counts increased from 1 to 31×10^9/L).[812] An increase in platelet count was reported in one of six patients entered in a phase I study of IL-6, although a dose-related decrease in neutrophils, monocytes, and lymphocytes was observed; a proportion (approximately a third) of patients given EPO had reduced transfusion requirements or an increase in hemoblobin, or both (reviewed by Kojima[813]). Trilineage responses have been reported in a small number of refractory aplastic anemia patients treated with low-dose GM-CSF plus EPO[814] or G-CSF plus EPO.[815] The effects of EPO are unexpected because endrogenous levels are very high in patients with aplastic anemia.

Human Immunodeficiency Virus Infection

GM-CSF

Human immunodeficiency virus (HIV) infection is associated with several hematologic abnormalities, including neutropenia, anemia, and thrombocytopenia. Anemia and neutropenia can be exacerbated by treatment with azidothymidine, and rhGM-CSF has been evaluated in an effort to enhance immunologic and hematopoietic function and improve tolerance to therapeutic agents. In the first report of the use of rhGM-CSF in humans, cohorts of patients with acquired immunodeficiency syndrome (AIDS) were treated with increasing doses of factor given by 14-day continuous intravenous infusion.[816] Such treatment resulted in a rapid, dose-related increase in neutrophils, bands, and eosinophils, with a slight increase in monocytes. A follow-up study with subcutaneous administration showed that these effects could

be sustained for up to 6 months without evidence of tachyphylaxis.[816]

A concern with the use of GM-CSF in AIDS is possible enhancement of HIV replication. In one study of azidothymidine given on an alternate-week schedule with GM-CSF, some patients showed increased viral p24 levels during therapy with GM-CSF. There is evidence, however, that GM-CSF may in fact augment azidothymidine levels in monocytes, which suggests that the combination of azidothymidine and GM-CSF might be advantageous.[817] Such is not the case, however, with newer nucleoside analogues such as dideoxycytidine and dideoxyinosine (reviewed by Mueller).[818] Two clinical studies have documented an increase in HIV p24 antigen in patients undergoing GM-CSF therapy,[819,761] and therefore GM-CSF has been replaced by G-CSF for the treatment of neutropenia.

G-CSF

In a pilot study at the National Institutes of Health, G-CSF was evaluated in 19 pediatric AIDS patients in whom neutropenia developed during treatment with azidothymidine. The neutrophil count increased from a median of 1 to 2.9×10^9/L at doses of 1 to 20 μg/kg/day, and in 17 of the 19 patients continued azidothymidine was well tolerated.[820] Of note was the development of thrombocytopenia in some patients; G-CSF–dependent disseminated intravascular coagulation developed in 2 patients, and an increase in myeloblasts that disappeared after stopping G-CSF treatment was observed in 1 patient.[818]

Erythropoietin

EPO has been used in 12 anemic pediatric patients to determine whether tolerance to azidothymidine could be improved.[818] EPO was well tolerated, and at doses of 150 to 400 U/kg subcutaneously or intravenously three times per week, all patients could be maintained on azidothymidine with a marked (four patients) or moderate (four patients) reduction in transfusion requirements.

Thrombopoietin

PEG-MGDF has been evaluated in six HIV-infected thrombocytopenic patients in a randomized placebo-controlled study.[821] Platelet counts increased 10-fold within 14 days and were sustained for the 16 weeks of the study, with return to previous levels within 2 weeks of cessation of treatment. There was no evidence of increased viral load or anti–PEG-MGDF antibodies. Megakaryocytic apoptosis, which was abnormal before treatment, shifted into the normal range by TPO treatment, thus suggesting that the mechanism of action involves increased effectiveness of the platelets that are produced.

Inherited Bone Marrow Failure Syndromes

The use of HGFs in the treatment of inherited bone marrow failure syndromes has been reviewed in detail.[822,823]

Fanconi's Anemia

GM-CSF has been studied in seven patients with Fanconi's anemia,[824] and trials of IL-3 and G-CSF[822] show that all three HGFs can improve the neutrophil count in most pancytopenic patients, but platelet and hemoglobin levels are unaffected.

Diamond-Blackfan Anemia

Although there is no evidence that Diamond-Blackfan anemia (DBA) is due to deficiency of EPO,[825] IL-3, or GM-CSF[826] or an abnormality of c-kit or its ligand SF,[827,828] it is possible that pharmacologic doses of these factors might stimulate erythropoiesis. Niemeyer and co-workers[829] observed no reticulocyte or hemoglobin responses in nine patients treated with rhEPO doses as high as 2000 U/kg/day. In contrast, three of six patients treated with IL-3 (60 to 125 μg/m²/day subcutaneously for 4 to 6 weeks) had increases in reticulocytes, and two of the responders remained transfusion independent for 1.5 to 2 years off therapy.[830] Another IL-3 study[831] reported 4 responders out of 18 patients treated with 0.5 to 10 μg/kg subcutaneously. In two responders deep venous thrombosis developed and necessitated discontinuation of treatment, whereas the other two patients sustained their responses, one receiving maintenance IL-3 for 31 months and one off treatment for 12 months after 30 months of therapy. In another study of 13 patients no responses were observed.[832] Thus, 6 patients have had significant erythroid responses to IL-3 out of a total of 37 (16%), a rate similar to that reported by the European working group for DBA (3/25).[833]

Amegakaryocytic Thrombocytopenia

Amegakaryocytic thrombocytopenia (AMT) is a rare disease manifested in infancy or early childhood with thrombocytopenia, frequent anemia, and progression to pancytopenia. Bone marrow megakaryocytes are absent or extremely scarce, and the disease results from mutations in the TPO receptor c-mpl. A phase I/II IL-3 dose escalation study without or with sequential GM-CSF in five children with AMT showed that IL-3 (but not IL-3/GM-CSF) induced platelet responses in two patients and improvement in bruising, bleeding, and transfusion requirements in the other three.[732] The two platelet responders became unresponsive after several months of IL-3 maintenance (125 to 250 μg/m²/day), whereas another patient became platelet transfusion independent after 4 months of IL-3 and had a trilineage response sustained for almost 2 years.

Severe Congenital Neutropenia (SCN)

Severe congenital neutropenia, or Kostmann disease (see also Chapter 8), is a disorder of myelopoiesis characterized by impaired neutrophil differentiation and ANCs greater than 200/μL. In contrast, monocyte and eosinophil counts are normal or increased. The bone marrow shows maturation arrest at the promyelocyte stage, and

these cells are often atypical, with abnormal nuclei and vacuolated cytoplasm. The pathophysiology is uncertain despite the identification of mutations in NE (ELA2) and more recently HAX-1 in recessively inherited disease, including patients from the original Kostmann pedigree.[834] Serum from these patients contains normal or elevated levels of G-CSF, as determined by Western blot[783] and bioassay.[835] Other investigations showed mutations in the C-terminal "differentiation" domain of the G-CSFR in two patients.[301]

The responses of these patients to exogenous G-CSF and GM-CSF are therefore of great interest. One study has compared the effects of GM-CSF and G-CSF in a small number of patients, and G-CSF alone was evaluated in other studies.[836-838] In these investigations G-CSF produced a remarkable increase in neutrophils in all patients. The dose necessary to maintain a neutrophil count greater than 1000/µL varied, with ranges of 3 to 15 µg/kg/day. The monocyte count was also increased. In contrast, rhGM-CSF produced an increase in neutrophils in only one patient, whereas the others showed an increase in eosinophils and monocytes. Although the period on study was short, no new episodes of severe bacterial infection occurred during either GM-CSF or G-CSF treatment, in contrast to the recurrent bacterial and fungal infections that occurred before treatment. A multicenter phase III study of G-CSF in 120 patients with severe chronic neutropenic disorders, including SCN, Shwachman-Diamond syndrome, and myelokathexis, showed complete responses in 108 patients (ANC $> 1.5 \times 10^9$/L), partial responses in 4 patients, and failure to respond in 8 patients.[839] Although the majority of patients respond with an ANC of 1.0×10^9/L or higher at doses ranging from 3 to 20 µg/kg/day, about 25% patients need 20 to 100 µg/kg/day or more.[823]

Somatic mutations of a single allele of the G-CSFR that result in loss of the C-terminal "differentiation" domain of the receptor were described in several SCN patients and shown to act as a dominant negative in transduced cells.[840,841] MDS or AML may eventually develop in these patients.[401] Data from the Severe Congenital Neutropenia International Registry[842] on 506 patients with severe congenital neutropenia, cyclic neutropenia, or idiopathic neutropenia who were treated in phase I to phase III clinical G-CSF trials showed that MDS/AML developed in 23 of 249 patients with SCN/Schwachman-Diamond syndrome (neutropenia and pancreatic insufficiency), as compared with none of the 97 cyclic or 160 idiopathic neutropenia patients. The observation that MDS/AML develops in SCN but not cyclic or idiopathic neutropenia patients receiving G-CSF is consistent with reports of AML in SCN before the introduction of G-CSF treatment[843,844] and shows that SCN is a preleukemic disease. Additional cytogenetic changes (translocations and monosomy 7) and oncogene (*ras*) mutations are common in the patients in whom MDS/AML eventually develops.[845] The G-CSFR mutation occurs in myeloid cells only and was not present

in first-degree relatives of affected patients, including a sibling with SCN,[846] thus demonstrating that the mutation is acquired. Interestingly, detailed study to identify the risks for leukemic transformation shows increased risk over time (2.9%/yr after 6 years and 8%/yr after 12 years, with a cumulative incidence of 21% after 10 years). Importantly, the risk of MDS/AML developing correlates with the dose of G-CSF; MDS/AML developed in 40% of the poor responders (G-CSF dose greater than the median of 8 µg/kg/day and ANC less than the median of 2188 cells/µL at 6 to 8 months) versus only 11% of the good responders.[847] Similar results were reported by the French Severe Chronic Neutropenia study group.[848]

In summary, treatment with recombinant G-CSF has had a major positive impact on the lives of the majority of these patients. Continued treatment has increased the risk for emergence of leukemic clones in this preleukemic disease, and patients need to be monitored regularly for the acquisition of such clones. Patients who respond poorly to G-CSF should be considered earlier for stem cell transplantation.

Cyclic Neutropenia

Cyclic neutropenia (see also Chapter 8) is a rare HSC disease caused by mutations in NE (ELA2). It is characterized by regular 21-day cyclic fluctuations in numbers of neutrophils, monocytes, eosinophils, lymphocytes, platelets, and reticulocytes. Patients typically have recurrent episodes of fever, malaise, mucosal ulceration, and occasionally life-threatening infection during periods of neutropenia. Six patients were treated with intravenous or subcutaneous rhG-CSF for 3 to 15 months at doses ranging from 3 to 10 µg/kg/day.[849] The median neutrophil count increased from 0.7 to 9.8×10^9/L. In five of the patients, cycling of blood counts continued, but the length of cycles decreased from 21 to 14 days. The number of days of severe neutropenia (<200/µL) was reduced from a mean of 12.7/mo to less than 1/mo, and importantly, the nadir counts increased, neutrophil turnover increased almost fourfold, and migration to a skin window was normal. Average counts of other cells did not increase. One patient with disease of adult onset had a qualitatively different response consisting of an increase in neutrophils and disappearance of the cyclic fluctuations in count. Therapy reduced the frequency of oropharyngeal inflammation, fever, and infections, thus demonstrating that treatment with rhG-CSF is effective management in such patients. These results have been confirmed in other studies and the treatment is well tolerated.[850-852] GM-CSF has not been effective in two patients but eliminated severe neutropenia when given in low dose (0.3 µg/kg/day).[853-855]

Chronic Idiopathic Neutropenia

This disorder of myelopoiesis is characterized by maturation arrest of neutrophil precursors in the bone marrow, neutrophil counts lower than 1.5×10^9/L, and normal other cell lineages. Patients have mucosal ulcers, peri-

odontal disease, and recurrent infections. The pathophysiology is uncertain; in vitro bone marrow culture shows normal numbers of myeloid progenitors, and antineutrophil antibodies are absent. A single patient who received 1 to 3 µg/kg/day rhG-CSF by subcutaneous injection showed normalization of the ANC with healing of chronic oral ulceration, reduction of episodes of recurrent infection, and minimal side effects.[856] Cycling of neutrophils, monocytes, and platelets was induced with a 40-day periodicity; this contrasts with the normal 21-day cycle and out-of-phase fluctuation of neutrophils and monocytes seen in cyclic neutropenia.

Anemia of Chronic Renal Failure

Erythropoietin

Anemia is a major complication of end-stage renal failure and is due primarily to a reduction in EPO production. Other mechanisms that may be involved are shortened red cell survival, iron deficiency, hypersplenism, possible circulating inhibitors of erythropoiesis, and aluminum-induced microcytosis. Several phase I, II, and III studies have documented that rhEPO can induce a dose-dependent increase in effective erythropoiesis.[857-859]

In a phase III study patients received 150 or 300 units of rhEPO three times per week after hemodialysis and reached a target hematocrit of 35% by 8 to 12 weeks.[858,859] The majority of patients required 50 to 125 U/kg intravenously three times per week after dialysis to maintain a hematocrit of approximately 35%. The increase in erythropoiesis needed to normalize hemoglobin requires mobilization of a considerable amount of iron; in patients who improve, rapidly in particular, absolute or relative iron deficiency can develop. If iron is not given, the response to rhEPO becomes blunted; the standard corrective measure is intravenous administration of iron dextran or oral iron supplementation. Regular measurements of ferritin and transferrin saturation are necessary to ensure that iron stores are adequate.

EPO has been well tolerated and has resulted in elimination of transfusion dependency. Hypertension, occasionally with encephalopathy, has been observed, particularly with rapid rises in hematocrit that lead to an increase in peripheral vascular resistance; induction with doses not greater than 150 U/kg is recommended to produce a gradual increase in hemoglobin levels. Some patients require either the initiation of antihypertensive medication or dose adjustment A marked increase in pure red cell aplasia occurred from 1998 to 2004 because of the development of anti-EPO antibodies,[860-8627] with reports of approximately 250 suspected or proven cases. The complication, characterized by reticulocytopenia, absence of erythroid precursors, and severe anemia, has occurred mostly in adults (a few children are included) with renal disease treated with Eprex outside the United States, but cases have been reported in the United States as well. Differences in EPO glycosylation status and drug formulation, processing, storage, and route of administration appear to affect the immunogenicity of EPO. The estimated exposure-adjusted incidence per 100,000 patient years was 18 cases for Eprex without serum albumin (epoetin alfa, Ortho Biotech), 6 for Eprex with serum albumin, 1 for NeoRecormon (epoetin beta), and 0.2 for Epogen (epoetin alfa).[862] Changes in drug formulation and drug monitoring programs have led to an 80% reduction in the incidence of pure red cell aplasia, and EPO should not be withheld for this reason.

The effect of rhEPO in most studies appears to be restricted to the erythroid lineage. However, data from a phase III study of 303 patients showed a significant increase in mean platelet count (224 to 241×10^9/L at 6 months), which is not biologically meaningful. There is also a slight increase in blood urea nitrogen, creatinine, and serum potassium levels. Bone marrow progenitors from patients with end-stage renal failure were studied before and 2 weeks after rhEPO treatment. The concentration of BFU-E, CFU-E, and CFU-Meg increased after therapy. Surprisingly, an increment in CFU-GM also occurred, and the number of progenitors of all classes in cell cycle almost doubled.[863]

Subjective improvement in appetite, energy, sleep pattern, and libido are also noted. A Canadian double-blind placebo-controlled study of rhEPO treatment has provided objective evidence of benefit.

Extending this treatment to patients who do not yet require dialysis has met with similar success.[864] An issue that has yet to be resolved is financial; rhEPO is not inexpensive, and the National Kidney Foundation in the United States has issued guidelines for the use of rhEPO in which all patients with a hematocrit of less than 30% will be eligible. rhEPO is more effective when administered by the subcutaneous route, and this is more convenient for patients and also allows dose reduction.[865,866] In predialysis patients, 100 U/kg subcutaneously provided a response similar to 150 U/kg given intravenously.[865] There is evidence that the bioavailability of subcutaneous EPO is seven times greater than that of the intravenously administered drug, and a large controlled study showed that the mean EPO dose to maintain a stable hematocrit was 32% lower with the subcutaneous than with the intravenous route.[867]

Similar results have been obtained in several rhEPO studies in children (reviewed by Müller-Wiefel and Amon[868]). Anemia was corrected by 3 to 4 months in 24 children with preterminal chronic renal failure (CRF) treated with rhEPO and iron, which was adjusted by careful monitoring of iron status. Hypertension is the most common side effect.[869-872] Interestingly, although the growth failure of children with terminal CRF is unaffected by rhEPO treatment, mean growth velocity in 22 children with preterminal CRF increased from −2.29 to −0.56 within the first 6 months of treatment.[868] Other possible benefits include reports of delay in progression of renal dysfunction in children with preterminal CRF and improvement in cognitive function.

Other Indications for Recombinant Erythropoietin Therapy

Several small clinical trials have evaluated the use of rhEPO for the anemia of prematurity.[873-879] These studies have been reviewed by Mentzer and Shannon,[880] and although differences in patient populations, transfusion criteria, rhEPO dose, and iron therapy make comparisons difficult, rhEPO treatment is safe and stimulates a reticulocyte response. An effect on hematocrit was observed only in the studies in which doses greater than 500 U/kg/wk were used,[873,875,877 878] and there appears to be a modest effect on transfusion requirement. Increasing the dose from 750 to 1500 U/kg/wk was not supported by a large European study of 184 very-low-birth-weight infants.[881]

Preliminary data suggest that rhEPO may be useful in the treatment of patients with the anemia of chronic disease associated with rheumatoid arthritis[882] and the anemia that complicates azidothymidine treatment in patients with AIDS (see earlier).

In simian studies, hemoglobin F levels can be increased by administration of EPO.[883] If similar changes occur in humans, EPO may have a role in the management of sickle cell disease and thalassemia. Several small studies in sickle cell disease have shown that hemoglobin F reticulocytosis can occur in some patients whereas others show an increase in hemoglobin without a sustained F reticulocyte response, a finding that is of some concern because blood viscosity might be increased.[884] There are also data suggesting that hydroxyurea in combination with EPO can augment the F reticulocyte response, although the contribution of EPO is still uncertain.[885,886] In patients with transfusion-dependent or untransfused thalassemia, variable responses to EPO alone have also been reported,[887-890] with some patients showing an increase in hemoglobin and F cells. The only report to show a consistent increase in fetal hemoglobin was a study of 10 untransfused thalassemic patients who received rhEPO (400 to 800 U/kg three times per week), as well as iron and hydroxyurea (4 days/wk). Hemoglobin increased significantly in 8 of the 10 patients with concomitant increases in fetal hemoglobin 5% to 20% above baseline.[890]

Finally, EPO can be used to increase the number of units of blood that can be obtained preoperatively in the context of autologous blood donation.[891]

Stem and Progenitor Cell Mobilization

The effect of G-CSF on progenitor cells is interesting. After melphalan and G-CSF, the absolute number of *circulating* progenitor cells of the granulocyte-macrophage, erythroid, mixed, and megakaryocyte lineages show a dose-related increase of up to 100-fold after 4 days of treatment with rhG-CSF,[892] thereby confirming earlier animal studies.[893,894] The relative proportion of early and late granulocyte progenitors and early progenitors of different lineages remains unchanged; however, CFU-E, normally undetectable in blood, is markedly increased. The mechanism for the increase in all progenitors in blood is unclear; G-CSF has been shown to affect immature blast CFCs, and it is possible that stem cells are stimulated in vivo to produce increased progenitors of all classes; alternatively, G-CSF may indirectly stimulate progenitors by induction of HGF production or by release of bone marrow progenitor cells into the circulation.

These early studies set the stage for attempts at high-dose chemotherapy followed by mobilized blood progenitor cell rescue in a number of chemosensitive tumors such as lymphoma, breast cancer, and multiple myeloma. Time to engraftment is critically related to the number of CD34+ cells infused, and a number of studies indicate that a dose of 5×10^6 CD34+ cells/kg or greater results in prompt neutrophil and platelet engraftment.[895-898] G-CSF is the usual HGF used to mobilize progenitors, and multiple apheresis procedures (four or more) are commonly required to achieve this dose of CD34+ cells. Strategies to increase the yield and thereby reduce the number of apheresis procedures include the combination of G-CSF with chemotherapy, SCF,[898-901] TPO,[902,903] high-affinity IL-3RA,[904] or FL in animal studies.[905-909] Two studies suggest that SCF in combination with G-CSF can decrease the number of apheresis procedures required,[887,910] which might be expected to have several advantages, including reduction of apheresis-associated morbidity, less delay in administration of chemotherapy, and decreased cost.

Toxicity of Colony-Stimulating Factor Treatment

The CSFs tested in all these clinical trials have in general been well tolerated. Both GM-CSF and G-CSF induce *transient leukopenia* in the first 30 minutes after intravenous bolus injection. GM-CSF rapidly induces surface expression of the leukocyte adhesion protein CD11b (MO1) in vitro, and this is accompanied by an increase in neutrophil aggregation.[727] CD11a (LFA-1) and CD11c (gp150, gp95), two other members of this family of cell surface adhesion glycoproteins that have distinct α chains but share a common β chain (CD18) with CD11b, are unaffected by GM-CSF. These results have been corroborated by in vivo studies of sarcoma patients who received 32 or 64 µg/kg/day GM-CSF. A marked increase in CD11b was noted that was evident by 30 minutes and persisted for 12 to 24 hours after treatment.[911] Radionuclide-labeled leukocytes are sequestered in the lungs after GM-CSF treatment,[746] probably because of the aggregability and adhesiveness induced by increased CD11b expression. Breathlessness and hypoxia have been observed in some patients, particularly after short-duration intravenous administration. CD11b is not modulated by G-CSF, and the reason for the transient leukopenia after treatment with G-CSF is at present unclear.

Both GM-CSF and G-CSF have been associated with bone pain coincident with or shortly after administration. Occasional increases in leukocyte alkaline phosphatase or lactate dehydrogenase (or both) have been noted. In contrast, GM-CSF has also induced flu-like symptoms, including fever, flushing, malaise, myalgia, arthralgia, anorexia, and headache. Mild elevations in transaminase levels and rash are also reported. These effects are usually mild, are alleviated by antipyretics, and disappear with continued administration. More serious GM-CSF toxicity has been observed at higher dose levels (>32 μg/kg/day intravenously or >15 μg/kg/day subcutaneously), including capillary leak syndrome with weight gain as a result of fluid retention manifested as pericardial or pleural effusions, ascites, or edema.[758,785] Phlebitis was noted in initial studies when GM-CSF was infused into small veins; large vessel thrombosis has occurred with infusion of high doses into central veins.[758]

Antibodies to Recombinant Factors

The rhGM-CSF that is produced in mammalian cells (Chinese hamster ovary cells) is variably glycosylated on both O-linked and N-linked sites. Production in *E. coli* results in nonglycosylated GM-CSF, and the yeast product is glycosylated at N-linked sites. All three products appear to be equally efficacious, but antibodies have been reported in 4 of 13 patients given the yeast-derived product in phase I/II studies.[912] The IgG antibodies developed by 7 days after the start of the infusion in all four patients, three of whom had received a bolus test dose; the antibodies were non-neutralizing as judged by bone marrow colony-forming assay, and they were directed at sites on the protein backbone of the GM-CSF molecule that are normally protected by O-linked glycosylation but are exposed in the yeast and *E. coli*–derived products. Transient antibodies to TPO have been reported in one cancer patient.[913] However, the development of antibodies in both patients and volunteers given PEG-MGDF led to termination of further clinical development of this TPO formulation because transient decreases in platelet count were noted.[779,914-916] Antibodies to EPO can also develop in patients with the anemia of CRF during treatment with EPO.[917] Some formulations of EPO were associated with an antibody to EPO that resulted in pure red cell aplasia, and this complication is discussed more fully earlier in the section on the use of EPO in renal failure.

No dose-limiting toxicity has been observed with G-CSF. However, one case of pathogenic neutrophil infiltration (acute febrile neutrophilic dermatosis, or Sweet's syndrome) has been reported.[918] In one patient with SCN, cutaneous necrotizing vasculitis (leukoclastic vasculitis) developed during G-CSF treatment.[835,837] As noted earlier, there is also concern that G-CSF will induce or accelerate the development of AML or MDS with monosomy 7 in aplastic anemia and SCN, perhaps more likely in patients with G-CSF receptor mutations that can transduce a proliferative but not a differentiation signal.

As noted earlier, EPO treatment has been associated with increased risk for thromboembolic complications in adults, particularly when target hemoglobin concentrations were in the normal range, and it has a possible adverse effect on progression of breast cancer.[777,919] Two randomized studies in which the targeted hemoglobin level was either in the normal (>13.5 g/dL) or subnormal (10.5 to 11.5 g/dL) range showed an increased risk for adverse cardiovascular effects in the normal hemoglobin groups.[920,921] A 2006 update of a Cochrane review of 57 trials that included more than 9000 patients showed strong evidence that epoetin and darbepoetin increase the risk for thromboembolic complications (relative risk of 1.67, 95% confidence interval of 1.35 to 2.06).[922] There are no comparable large studies in children. As a result of these and other studies, the Food and Drug Administration has recommended the lowest dose possible to increase hemoglobin to a level that avoids transfusion, not to exceed 12 g/dL or a rise of greater than 1 g in any 2 weeks (http://www.fda.gov/cder/drug/InfoSheets/HCP/RHE2007HCP.htm).

CONCLUSION

Advances in molecular and cellular biology have led to an unraveling of some of the most challenging and confusing aspects of the study of hematopoiesis. Therapeutic benefits have emerged from these discoveries. The field of hematopoiesis, once a jumble of unknown factors and activities, has come of age and is providing direct benefits to countless patients.

7 Acquired Aplastic Anemia and Pure Red Cell Aplasia

Akiko Shimamura and David G. Nathan

Acquired and congenital bone marrow failure syndromes are characterized by a reduction in the effective production of mature erythrocytes, granulocytes, and platelets by bone marrow. Bone marrow failure leads to various peripheral blood cytopenias. In some conditions, only one or two cell lines may be affected. In others, such as aplastic anemia, the result is pancytopenia. In this chapter we deal only with the acquired bone marrow failure syndromes, although we use the term rather loosely because seemingly acquired marrow failure syndromes may have a genetic basis. The known inherited/congenital bone marrow failure syndromes are described in detail in Chapter 8. Acquired marrow failure syndromes that affect only granulocytes or platelets are described in Chapters 21 and 33, respectively. Acquired single-lineage deficiency syndromes that involve red cell production (pure red cell aplasia) are also described in this chapter, except that the 5q– syndrome is discussed in Chapter 8 and in more detail in *Oncology of Infancy and Childhood*.

APLASTIC ANEMIA

Decreased production of *mature blood cells* may result from a reduction in the number or function of their *progenitors*. Aplastic anemia is a descriptive term referring to a clinical state in which peripheral blood pancytopenia results from reduced or absent production of blood cells in bone marrow. Aplastic anemia may arise in the setting of inherited/congenital syndromes associated with a predisposition to marrow failure (discussed in Chapter 8), may develop secondary to marrow-toxic stressors in an otherwise seemingly normal host, or may lack any apparent underlying cause. Classification of the aplastic anemias is presented in Box 7-1. A careful medical history, physical examination, and laboratory evaluation are critical to discern inherited versus acquired causes of aplastic anemia. The distinction between inherited and acquired causes of aplastic anemia carries profound implications for medical management and treatment, so a careful search for possible underlying inherited syndromes should be undertaken before initiation of therapy.

Camitta and co-workers classified the severity of aplastic anemia in an effort to make possible the comparison of diverse groups of patients and different therapeutic approaches.[1] Diagnosis of *severe aplastic anemia* requires that the patient have at least two of the following anomalies: a granulocyte count below 500/µL, a platelet count below 20,000/µL, and an absolute reticulocyte count of 40×10^9/L or less. In addition, the bone marrow biopsy specimen must contain less than 25% of the normal cellularity or less than 30% hematopoietic elements. Very severe aplastic anemia is further defined by a granulocyte count lower than 200/µL.[2] *Mild* or *moderate aplastic anemia*, sometimes called "hypoplastic anemia," is distinguished from the severe form by the presence of

Box 7-1 **Classification of the Aplastic Anemias**

ACQUIRED

Secondary
Radiation
Drugs and chemicals
    Direct toxicity: chemotherapy, benzene
    Idiosyncratic: chloramphenicol, anti-inflammatory
        drugs, antiepileptics, carbonic anhydrase inhibitors
Viruses
    Epstein-Barr virus
    Hepatitis (non-A, -B, -C, -E, or -G)
    Human immunodeficiency virus
Immune diseases
    Eosinophilic fasciitis
    Hypoimmunoglobulinemia
    Systemic lupus erythematosus (uncommon)
Thymoma
Graft-versus-host disease in immunodeficiency
Pregnancy
Paroxysmal nocturnal hemoglobinuria
Myelodysplasia

Idiopathic

INHERITED
Fanconi's anemia
Dyskeratosis congenita
Shwachman-Diamond syndrome
Amegakaryocytic thrombocytopenia
Diamond-Blackfan anemia
Reticular dysgenesis
Familial aplastic anemias
Nonhematologic syndromes (e.g., Down, Dubowitz', and
    Seckel's syndromes)

    aetiology of the aplastic anaemias. Clin Haematol.
    1978;7:431-465.

---

mild or moderate cytopenia and more variable, but still deficient bone marrow cellularity. These distinctions are more than semantic; they are critical for prediction of outcome and selection of therapy.

Epidemiology

Epidemiologic studies performed in Europe estimate that the annual incidence of aplastic anemia is 2 per million per year[3]; by comparison, the incidence of acute leukemia is about 50 per million per year. Higher figures for the incidence of aplastic anemia have been obtained from smaller studies in the United States and earlier surveys in Europe, but these figures may have been inflated by the inclusion of cases of the more common syndrome myelodysplasia. Aplastic anemia is more common in Asia (4 to 7 per million per year[4]) than in the West. Chloramphenicol has been widely used in much of Asia because of its efficacy and low cost, but reductions in its use have

not been accompanied by reductions in the incidence of aplastic anemia in Japan[5,6] or elsewhere,[7,8] and no association was observed in case-control studies in Thailand.[9] A recent case-control study[10] in Thailand spanning 1989 to 2002 described an association between aplastic anemia and exposure to benzene or pesticides. Although an increased risk for aplastic anemia was also associated with animal exposure and ingestion of nonbottled or nondistilled water, no significant associations with known infections or hepatitis were observed.

The peak age for the development of aplastic anemia is 15 to 25 years or older than 60 years, with a male-to-female ratio of approximately 1:1.

Causal Factors

When no causative factors are ascertained, the cases are classified as "idiopathic." A search for possible causative agents is warranted because some patients may improve after removal of the offending agent. Many patients have been exposed to several potentially myelosuppressive agents, and the number of possible associations depends in part on the intensity of the investigation. A drug or toxin is often implicated if the exposure is to a previously implicated agent and is appropriately extensive or temporally proximate; sometimes, a drug history is given significance only because all other factors are excluded. Therefore, the course, management, and outcome are related more to the severity of the hematopoietic depression than the cause, and they are generally similar for cases with apparent cause and those that are idiopathic.

Drugs

The incidence of drug- and chemical-related aplastic anemia[11] varies over time and from place to place. Many drugs and toxins have been implicated by inferential and circumstantial evidence; the magnitude of the risk is usually unknown (Box 7-2). The presence of an agent on this list suggests caution regarding its use, but no drug on the list should be proscribed if there are strong clinical indications for its use. From a public health perspective, even drugs associated with an increased risk for marrow failure do not cause large numbers of cases of aplastic anemia.[3]

Note that even confirmed associations do not substantiate causality. Antibiotics thought to be causative may have been administered for the viral infection that led to the aplastic anemia or for symptoms from already established neutropenia in an undiagnosed case of aplastic anemia. Bleeding may be precipitated in undiagnosed thrombocytopenic patients who receive nonsteroidal anti-inflammatory drugs. As an example of known errors in association, among six patients reported to have sniffed glue and become aplastic, five had sickle cell anemia and aplastic crises now known to be due to parvovirus infection.[12]

The incidence of drug-related aplasia in pediatric cases is low, mainly because many of the drugs consid-

---

Box 7-2 Classification of Drugs and Chemicals Associated with Aplastic Anemia*

AGENTS THAT REGULARLY PRODUCE MARROW DEPRESSION

Antibiotics: daunorubicin, doxorubicin hydrochloride (Adriamycin), chloramphenicol
Antimetabolites: antifolic compounds, nucleotide analogues
Antimitotics: vinblastine, colchicine
Benzene and chemicals containing benzene: carbon tetrachloride, chlorophenols, kerosene, Stoddard's solvent
Cytotoxic cancer chemotherapy with alkylating drugs: busulfan, melphalan, cyclophosphamide

AGENTS POSSIBLY ASSOCIATED BUT WITH A LOW PROBABILITY RELATIVE TO USE

Chloramphenicol
Insecticides: chlordane, chlorophenothane (DDT), γ-benzene hexachloride (lindane), parathion
Anticonvulsants: carbamazepine, hydantoins, phenacemide
Nonsteroidal anti-inflammatory agents: indomethacin, ibuprofen, oxyphenylbutazone, phenylbutazone, sulindac
Antihistamines: cimetidine, chlorpheniramine, ranitidine
Antiprotozoal drugs: quinacrine, chloroquine
Sulfonamides: some antibiotics, antidiabetics (chlorpropamide, tolbutamide), antithyroid drugs (methimazole, methylthiouracil, propylthiouracil), carbonic anhydrase inhibitors (acetazolamide, methazolamide)
Penicillamine
Metals: gold, arsenic, bismuth, mercury

AGENTS MORE RARELY ASSOCIATED

Allopurinol (may potentiate marrow suppression by cytotoxic drugs)
Antibiotics: flucytosine, mebendazole, methicillin, sulfonamides, streptomycin, tetracycline, trimethoprim/sulfamethoxazole
Carbimazole
Guanidine
Lithium
Methyldopa
Potassium perchlorate
Quinidine
Sedatives and tranquilizers: chlordiazepoxide, chlorpromazine, meprobamate, methyprylon, piperacetazine, prochlorperazine
Thiocyanate

---

*Agents are listed because they have been cited in the literature; inclusion in this list does not imply acceptance by the author of a causal relationship.
Modified from Young NS, Alter BP. Aplastic Anemia: Acquired and Inherited. Philadelphia, WB Saunders, 1994, p 104.

ered to be related to aplasia are not used in childhood, with the exception of antiepileptic drugs, carbonic anhydrase inhibitors, nonsteroidal anti-inflammatory medications, and some antibiotics.

Drug-related aplasia may occur in several ways. Drugs may exert direct cytotoxic or suppressive effects on bone marrow. Myelosuppressive drugs, such as those used in cancer chemotherapy, lead to predictable and dose-related marrow suppression. Benzene, too, can be regularly demonstrated to suppress bone marrow in animals in a dose-linked manner, and most individuals exposed to sufficient amounts of benzene would probably suffer some type of marrow damage. In practice, most drug-related aplastic anemia is "idiosyncratic" and occurs unpredictably in only rare individuals who are prescribed the medication, sometimes weeks to months after its administration is discontinued. This last category of patients may possess a genetic propensity for this phenomenon.

Chloramphenicol

Chloramphenicol was considered to be the most common cause of aplastic anemia at the peak of its use, which began in 1949.[13] A genetic predisposition may exist. The mechanism of the idiosyncratic aplasia remains unknown despite extensive investigation.

Chloramphenicol contains a nitrobenzene ring and thus resembles amidopyrine, a drug known to cause agranulocytosis.[14,15] Chloramphenicol is the prime example of a drug that causes dose-related marrow suppression through mechanisms that include mitochondrial inhibition,[16] as well as idiosyncratic aplastic anemia.[17]

The signs of dose-related toxicity appear more rapidly in patients with hepatic or renal disease because the drug must be inactivated by conjugation with glucuronide in the liver and excreted in urine. High doses and high plasma levels correlate with the characteristic reversible erythroid depression. In vitro, chloramphenicol inhibits the growth of both colony-forming unit, granulocyte macrophage (CFU-GM), and colony-forming unit, erythroid (CFU-E),[18-22] and may also inhibit the hematopoietic microenvironment.[20,23]

Other Drugs

Nonsteroidal anti-inflammatory drugs, which are used more extensively in adults than in children, are associated with aplasia.[3] Nonsteroidal anti-inflammatory drugs associated by occasional case reports with aplastic anemia include aspirin,[24] indomethacin,[25-28] and ibuprofen.[29] Several large studies reported an increased risk for aplastic anemia with phenylbutazone[30,31] and identified even higher probability with some of the other nonsteroidal anti-inflammatory drugs.[3] Another drug associated with a risk for cytopenia in 2 per 100,000 patients is cimetidine.[32,33] Sulfa-containing compounds, which appear as risk factors in most case-control studies of drugs and aplastic anemia, are used in a wide variety of clinical circumstances.[34-43] Other drugs implicated in aplastic

anemia that are commonly used in the pediatric population include anticonvulsants (hydantoins,[44-46] carbamazepine[47-51]) and carbonic anhydrase inhibitors[52] (acetazolamide[53,54] and methazolamide[55,56]). Many of the drugs listed in Box 7-2 have also been associated with agranulocytosis. In general, only a minority of cases of aplastic anemia can be assigned a drug association. The distinction between aplasia secondary to the medication and aplasia arising from the underlying disorder (or occult viral infection) requiring treatment can be difficult.

Chemicals and Toxins

Benzene

Benzene is a particularly dangerous environmental contaminant.[57,58] It is found in organic solvents, coal tar derivatives, and petroleum products.[59-62] Fatal aplastic anemia, leukemia, or both have been reported years later in factory workers exposed to benzene. Benzene concentrates in bone marrow fat,[63] forms water-soluble intermediates,[64-66] and damages DNA.[67-69] It decreases numbers of progenitors and damages stroma. The risk for cytopenia is probably related to cumulative exposure.

Other Aromatic Hydrocarbons

Toxicity thought to be due to other organic solvents may in some instances be caused by benzene contaminants. Neither pure toluene nor xylene is a marrow toxin. Aplastic anemia has been linked by many case reports to insecticides, particularly γ-hexachlorobenzene (lindane) in children.[70] Aromatic hydrocarbons are present in insecticides and herbicides and may be the solvents for these agents. Some organophosphate insecticides have been shown to inhibit in vitro hematopoietic colony formation, as has lindane.[71]

Ionizing Radiation

Marrow aplasia may occur as an acute toxic sequela of irradiation from a nuclear bomb explosion, radioactive fallout, reactor accidents, and accidental exposure in medicine and industry. Bone marrow cells may be affected by high-energy gamma rays, as well as by ingested or absorbed lower-energy alpha particles. The radiation injury is inflicted on the actively replicating pool of precursor and progenitor cells and also on stem cells, in which DNA damage may have a more severe effect. Nonetheless, radiation-related marrow aplasia is infrequent. Even in a restricted episode, such as the Chernobyl reactor accident in 1986, most immediate deaths were due to skin burns and damage to the gastrointestinal and pulmonary systems.

Chronic radiation-induced aplasia is dose related. Patients who underwent irradiation for ankylosing spondylitis had an increased risk for aplastic anemia, and American radiologists have been reported to have an increased death rate from aplasia (for both groups, pathologic distinction between aplasia and myelodysplasia was

not made). The incidence of late aplasia in atomic bomb victims was not increased, nor was it increased in patients undergoing radiation therapy for malignancies. Knospe and co-workers suggested that irradiation with an exposure greater than 4.4 Gy was required for the development of aplasia; they also postulated that low doses might damage only stem cells whereas high doses would also damage the supportive hematopoietic stromal microenvironment.[72]

Infectious Agents

Mild pancytopenia frequently develops in patients with bacterial or viral illnesses during or after the infection (see Chapter 36). Patients with bacterial or viral infections often receive antibiotics and other medications, and it is frequently not clear whether an ensuing aplastic anemia was caused by the infection, by the drug, or by the combination of the two or even whether the infectious illness was the result and not the cause of the pancytopenia.

Hepatitis

Although hepatitis is frequently associated with mild depression of blood cell counts, aplasia is a rare sequela, estimated to occur in less than 0.07% of the total number of pediatric hepatitis cases[73] and in less than 2% of those with non-A, non-B hepatitis.[74] Nonetheless, as an identifiable clinical event, a previous episode of hepatitis was recognized in 2% to 5% of aplastic anemia patients in a Western series.[75] The prevalence of previous hepatitis is about twofold this proportion in the Far East.[76] Among children with aplastic anemia in Taiwan, 24% had a history of recent acute hepatitis.[77] The antecedent hepatitis may be subclinical inasmuch as about 50% of patients with aplastic anemia may have elevated hepatic transaminases before their first transfusion. In a report of 32 patients who underwent liver transplantation for hepatic failure after non-A, non-B hepatitis, aplastic anemia developed in 28%.[78] Although aplasia has been reported after both hepatitis A and B virus infection,[79,80] the majority of cases of hepatitis/aplasia syndrome are not associated with serotypable hepatitis virus.[81,82]

Aplastic anemia associated with hepatitis is particularly severe. More than 200 cases of aplastic anemia and hepatitis have been reported, with two thirds of those affected being male and three quarters being younger than 20 years. In one early series, more than 90% died within a year, and the mean survival was only 11 weeks.[83] More recently, successful treatment with bone marrow transplantation (BMT) or with antithymocyte globulin (ATG) and cyclosporin A has been reported.[87]

Flaviviruses

Flaviviruses cause arbovirus hemorrhagic fever, dengue, and other hematodepressive syndromes. Dengue can propagate in bone marrow cultures without direct cytotoxicity, and dengue antigens induce lymphocyte activation and the release of marrow-suppressive cytokines.[88]

Epstein-Barr Virus

Herpesviruses such as Epstein-Barr virus (EBV) are large, complex DNA viruses.[89] EBV causes infectious mononucleosis, which is associated with pancytopenic complications in less than 1% of cases. More than 12 such cases have been reported, and half of these cases had a fatal outcome. In one study, EBV was demonstrated by immunologic and molecular methods in the bone marrow of six patients with aplastic anemia.[90] Only two had a history of typical mononucleosis, although all six had serologic evidence of such, thus suggesting that EBV may be an unrecognized cause of aplastic anemia. EBV's target is B cells, although T cells may also be infected. Because EBV is a common infection, issues of ascertainment can render the causative determination of aplasia difficult.

Cytomegalovirus and Human Herpesvirus 6

Infection with cytomegalovirus (CMV) may lead to graft failure in immunosuppressed bone marrow transplant recipients.[91] CMV can infect marrow stromal cells in vitro and can inhibit their ability to produce growth factors[92]; direct progenitor cell infection by some CMV strains has also been documented.[92,93] Herpesvirus 6 is the cause of erythema subitum[94] and, like CMV, may be found in the marrow of patients with graft failure after transplantation,[95] as well as in hematopoietic progenitors infected in vitro.[96] As with other viruses, both of these are ubiquitous infections, which makes causality difficult to ascertain.

Human Immunodeficiency Virus

Patients with acquired immunodeficiency syndrome (AIDS) often have cytopenias,[97] but their marrow is much more commonly cellular and dysplastic than empty. Colony formation by marrow from patients may be diminished.[98-101] The action of human immunodeficiency virus type 1 (HIV-1), a lentivirus, on hematopoietic cells remains a subject of controversy. HIV-1 infection of CD34+ cells has been difficult to detect in vivo from patient material[100,102] or after tissue culture infection of normal cells.[100,103] The virus apparently directly infects megakaryocytes that bear the CD4 receptor present on T cells.[104] The virus may also affect stroma function, at least in vitro.[105,106] HIV-1 can act indirectly on hematopoiesis through inhibitory lymphokine production; the envelope glycoprotein can stimulate macrophages to produce tumor necrosis factor, which in turn inhibits hematopoietic colony formation.[107] Hematologic suppression can also be due to opportunistic infections, neoplasms, or marrow suppression from the drugs used to treat AIDS and its complications.

Other Viruses

Blood count abnormalities, which are rarely severe, may be observed in the course of rubella, measles, mumps, varicella, and influenza A.[108]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a disease characterized by variable combinations of mild to severe intravascular hemolysis, thromboses, and aplastic anemia.[109] It is uncommon in adults and even rarer in children. There is a clear association of PNH with aplastic anemia in that pancytopenia and marrow hypoplasia develop in many patients with PNH and PNH clones are detectable in up to 50% to 70% of patients with acquired aplastic anemia.[110-113]

PNH is characterized by an inability to inactivate complement on the erythrocyte cell surface, thereby resulting in increased sensitivity to complement. Deficits were subsequently identified in a family of membrane proteins, all of which were anchored to the cell membrane via glycosylphosphatidylinositol (GPI). GPI binds covalently to specific carboxyl-terminal protein sequences and attaches them to cell membrane phosphatidylinositol residues. The genetic defect in PNH was localized to the X-linked *PIG-A* (phosphatidylinositol glycan class A) gene, whose product functions in the transfer of *N*-acetyl-glucosamine to phosphatidylinositol as an early step in GPI anchor formation. Early tests for PNH, such as the Ham or sucrose hemolysis test, relied on the demonstration of increased sensitivity to complement-mediated red cell lysis. Increased sensitivity and specificity are achieved with flow cytometry assays for the absence of GPI-anchored proteins such as CD59 and CD55.[114] More sensitive tests use aerolysin, a channel-forming toxin that binds GPI-anchored proteins and results in cell lysis but leaves GPI-deficient PNH cells intact.[115] The use of a fluorescently labeled aerolysin variant that binds to GPI but fails to lyse the cells offers increased sensitivity and specificity for detection of the PNH clone.[116]

The clinical significance of small populations of PNH clones is unclear. Small numbers of PNH cells are detectable in healthy controls,[117] although the PNH cells in this context are typically polyclonal. Despite the frequent finding of PNH clones in the bone marrow of patients with aplastic anemia, the clinical syndrome of PNH subsequently develops in only 10% to 15% of patients (reviewed by Parker[118]). In the majority of patients, such clones may persist or disappear. Patients with small asymptomatic PNH clones may respond to the same treatments as other patients with aplastic anemia.

The etiology of marrow aplasia in PNH remains an area of active investigation. Although severe combined immunodeficiency (SCID) mice infused with bone marrow from PNH patients show preferential engraftment with the PNH clones,[115] studies of hematopoiesis in PNH patients have not detected any selective proliferative advantage of the *PIG-A(–)* hematopoietic clones.[120] A subsequent study comparing in vitro proliferation of *PIG-A(–)* and *PIG-A(+)* CD34 cells from PNH patients found a selective growth deficiency in the *PIG-A(+)* cell population rather than an advantage for the *PIG-A* mutant cells; Fas expression was elevated on the wild-type versus the GPI-deficient cells, thus suggesting increased resistance to apoptosis as one potential mechanism to explain their findings.[121] No proliferative advantage of PNH hematopoietic clones was observed in mice mosaic for the *pig-a* gene.[122,123] To evaluate the hypothesis that autoreactive T cells might preferentially eliminate *PIG-A(+)* hematopoietic stem cells while sparing the PNH clones, the sensitivity of normal versus PNH EBV-transformed B-cell lines to autologous EBV-specific T-cell lines was examined.[124] The PNH cells were no less sensitive to T-cell–mediated cytotoxicity than the non-PNH cells were; thus, the GPI-linked cell surface molecules are not required for killing by T cells. An abnormal distribution of expanded T-cell clones detected by size analysis of the complementarity-determining region 3 (CDR3) in the β variable region ($V_β$) mRNA of the T-cell receptor (TCR) has been noted in PNH patients,[125] although the targets of such T-cell populations remain to be ascertained. The mechanisms underlying clonal expansion of the GPI-negative cells in PNH or aplastic anemia are currently unclear. Despite the presence of clonal populations of PNH cells, patients with PNH do not exhibit an increased incidence of leukemia, and the GPI-negative clones do not behave in a malignant fashion. A recent study suggests that additional genetic or epigenetic events, such as elevation of HMGA2 expression, may contribute to clonal expansion.[126]

Immunologic Diseases

Ten percent of patients with the rare collagen vascular syndrome *eosinophilic fasciitis* have associated aplastic anemia.[127] This condition is usually limited to adults. Thymoma associated with hematopoietic failure is generally, but not exclusively manifested as pure red cell aplasia (PRCA).[128] Some of the adults had also received drugs such as chloramphenicol or sulfonamides, and the aplasia could have been due to the drugs alone or to the combination. An iatrogenic aplasia can be induced by the transfusion of competent lymphocytes into immunodeficient hosts. In these cases, marrow failure arises from the transfusional graft-versus-host disease (GVHD).[129]

Pathophysiology

The purported mechanisms for failure of hematopoiesis are predicated on our current knowledge of normal hematopoiesis (see Chapter 6). Disease could result from decreased numbers or defective function of the cellular or soluble components required for blood cell production or from exogenous factors that result in damage or elimination of hematopoietic cells. Figure 7-1 depicts different mechanisms for the loss of hematopoietic cells in aplastic anemia. In model I, marrow toxins such as irradiation, drugs, or chemicals or direct invasion by viruses might cause hematopoietic stem or progenitor cell death (or both). In model II, an underlying abnormality of the hematopoietic cells may result in a predisposition to hematopoietic stem cell damage, premature stem cell
FIGURE 7-1. Models for the pathogenesis of aplastic anemia. **I,** Healthy hematopoietic stem cells and progenitors are damaged by an exogenous agent such as a toxin, medication, or infectious pathogen, with resultant marrow aplasia. **II,** Abnormal marrow cells (e.g., inherited marrow failure syndromes) undergo premature attrition. Marrow aplasia might be exacerbated by external factors. **III,** Immune-mediated attack (cellular or humeral) eliminates hematopoietic stem cells and progenitors. HSC, hematopoietic stem cell.

loss, or insufficient stem cell production (see Chapter 6). In model III, viruses, drugs, toxins, or immune dysregulation may incite a cellular or humoral immunologic reaction against a normal hematopoietic compartment. These possibilities are not mutually exclusive, and supportive data for each model have been described. Current data suggest that aplastic anemia may represent the final seemingly common outcome of different pathogenic mechanisms, with different underlying causes entailing different medical management considerations.

Hematopoietic Stem Cells and Clonality

Patients with aplastic anemia have decreased numbers of blood- and marrow-committed progenitor cells, assayed as myeloid colony-forming cells (CFU-GMs), erythroid colony-forming cells (CFU-Es and burst-forming units, erythrocytes [BFU-Es]), megakaryocytic progenitors (CFU-megas), multipotent colony-forming cells (CFU-GEMMs), and long-term culture-initiating cell (LTC-ICs).[130,131] Hematopoietic cells can also be assessed phenotypically for the presence of the CD34 antigen, which defines a compartment of about 1% of marrow cells that includes progenitors and possibly activated

stem cells.[132-135] CD34$^+$ cells are reduced in aplastic anemia, and almost all patients show not only a severe reduction in numbers of these cells but also poor plating efficiency for colony formation from purified CD34$^+$ cells.[136,137]

Several lines of evidence point to primary abnormalities in the hematopoietic stem cell as a potential cause of aplastic anemia. Multiple studies have noted that simple infusion of stem cells from an identical twin donor without previous conditioning was sufficient to treat the aplasia in many cases.[138-141] These results strongly support a pathogenic stem cell defect and argue against permanent disorders of the bone marrow environment, including immunologic mechanisms, as the cause of stem cell destruction. Low stem cell numbers persist even with hematologic recovery after medical therapy with antithymocyte globulin (ATG) and cyclosporine (see later), and blood cell parameters such as macrocytosis do not return to normal in many cases, again suggestive of an underlying stem cell abnormality. A primary stem cell defect probably also contributes to the observation of clonal hematopoiesis in aplastic anemia,[142] as well as the late development of other hematologic diseases such as myelodysplasia and acute leukemia (see later).

A subset of (and perhaps most) patients with seemingly idiopathic aplastic anemia may actually carry an inherited/congenital predisposition to marrow failure (see Chapter 8). Although the inherited/congenital marrow failure syndromes are often associated with characteristic physical findings, patients may have isolated aplastic anemia as the sole manifestation of their underlying inherited syndrome.[143] In some patients lacking significant physical findings or cytopenia at the time of evaluation, an elevated mean corpuscular volume may be the only clue to an underlying inherited marrow failure syndrome. A careful family history for hematologic abnormalities, predisposition to malignancy, or other characteristic clinical stigmata may be helpful in distinguishing an inherited marrow failure syndrome.[144] For example, a subset of patients with aplastic anemia but without other clinical stigmata of an inherited marrow failure syndrome were found to harbor mutations in the dyskeratosis congenita genes *hTERC*,[145,146] which encodes the RNA component of telomerase, or *hTERT*,[147-149] which encodes the catalytic subunit of the telomerase complex. Telomeres are specialized structures that stabilize the ends of each chromosome to prevent excessive shortening with replication, to distinguish chromosome ends from internal DNA breaks, and to prevent end-to-end fusion. Telomeres consist of 6–base pair (bp) repeated sequences (TTAGGG) associated with a specific protein complex. Telomerase is a ribonucleoprotein enzyme consisting of an H/ACA RNA component (TERC) complexed with a reverse transcriptase (TERT) and additional H/ACA binding proteins, including dyskerin, GAR1, NHP2, and NOP10. When telomerase levels are diminished or absent, telomeres progressively shorten with each cell division. At a critically short telomere length,

a checkpoint is triggered for cells to stop dividing and undergo senescence to prevent chromosomal rearrangements.

Shortened telomeres have been observed in the leukocytes of patients with aplastic anemia.[150] Of five patients noted to have mean telomere lengths less than 5 kb, three had acquired cytogenetic abnormalities, thus suggesting that compromise in the telomere's probable role in stabilizing chromosome ends may contribute to the increased incidence of myelodysplasia and acute leukemia. A study by Brummendorf and colleagues reported relatively normal telomere lengths in patients who responded to immunosuppression, whereas untreated or unresponsive patients showed significant telomere shortening.[151] Telomere shortening is a common feature associated with marrow failure, although telomere lengths are particularly short in patients with dyskeratosis congenita, a disorder of telomerase function, even in comparison to other marrow failure patients.[152] Whether telomere shortening in marrow failure patients lacking telomerase mutations represents a primary defect in telomere maintenance or a secondary effect of increased cycling of the few remaining hematopoietic stem cells remains to be clarified.

Immune Destruction

Several lines of data suggest that immune phenomena may result in aplastic anemia (reviewed elsewhere[153,154]). In some syngeneic (identical twin) bone marrow transplants, simple infusion of stem cells is not sufficient to reconstitute hematopoiesis. The requirement for previous conditioning of the host may reflect some operational immunologic process, although it is also consistent with the presence of an underlying clonal abnormality that requires ablation.[155] Histocompatibility studies conducted in Europe, Asia, and the United States have indicated an increased representation of HLA-DR2 among aplastic anemia patients, consistent with a genetically determined immune susceptibility to disease.[155-157] Evidence for specific immune mechanisms is reviewed in the following sections.

Lymphocytes

Autologous recovery has been reported after either mismatched or matched transplants in patients prepared with antilymphocyte sera or cyclophosphamide.[158-160] An immune mechanism for aplastic anemia is suggested by the observation that aplasia often responds to treatment with antilymphocyte globulin (ALG)/ATG, cyclosporine, or both without transplantation. The antilymphocyte preparations contain heterogeneous mixtures of antibodies to many cells, including lymphocytes, and are clearly immunosuppressive, as well as generally cytotoxic. They lead to rapid lymphopenia during and immediately after treatment, and the reduced levels of activated lymphocytes persist for months. Cyclosporine exerts inhibitory T-cell effects and inhibits the transcription of genes for cytokines, including interleukin-2 (IL-2) and interferon-γ.[161] It has many other toxic effects on several tissues,

including the brain and kidney. The attribution of immune dysregulation as causal in aplastic anemia based on therapy must be tempered with caution because ATG and cyclosporine exert multiple effects in addition to immunosuppression. The diverse antibodies in ATG react with a wide range of antigens, including signal transduction and adhesion molecules.[162] The component or components of ATG active in aplastic anemia have not been isolated. Of note, therapies with mixtures of monoclonal antibodies specific for human T cells have not been effective in clinical trials to date (reviewed by Tisdale and colleagues[163]). Furthermore, ATG can increase colony growth in normal, myelodysplastic syndrome (MDS), and aplastic anemia CD34$^+$ bone marrow cells in culture.[164,165] ATG treatment also reduces the expression of Fas antigen on aplastic anemia bone marrow CD34$^+$ cells.[166] Cyclosporine is thought to be more specifically immunosuppressive than ATG, and thus its efficacy further implicates T-cell participation in the pathophysiology of aplastic anemia. Nonetheless, cyclosporine therapy also has a broad range of additional effects. Effective treatment of myelodysplasia with cyclosporine has recently been reported and may suggest that cyclosporine may exert additional effects on bone marrow,[167] although a possible immune mechanism underlying myelodysplasia is also under investigation.[168]

A role for immune dysregulation in aplastic anemia in some patients is further supported by several studies of T-cell characteristics in aplastic anemia. Activated cytotoxic lymphocyte clones have been isolated from patients with aplastic anemia, and in vitro they overproduce inhibitory cytokines and inhibit hematopoiesis.[169-171] Altered helper and cytotoxic T-cell profiles have been reported in patients with aplastic anemia.[172-174] Identification of a T-cell clone with HLA-DRB10405–restricted cytotoxicity for hematopoietic cells has been reported in one patient with aplastic anemia.[175] Analysis of the CDR3 region of CD4 cells derived from patients with aplastic anemia and an HLA-DR2 haplotype showed a high frequency of clones bearing identical CDR3 DNA sequences that were not found in normal controls.[176] A recent flow cytometry study[177] in which antibodies against different TCR V$_\beta$ subfamilies were used and the CDR3 region of the TCR β chain was sequenced described dominant T-cell clones in aplastic anemia patients. The size of these clones and the total number of T cells decreased after successful treatment with ATG and increased with relapse. The V$_\beta$3 CD8$^+$ cell fraction of one patient with aplastic anemia induced increased levels of apoptosis of autologous bone marrow cells, whereas the V$_\beta$3-depleted CD8$^+$ T-cell fraction did not induce autologous apoptosis but continued to be cytotoxic for allogeneic bone marrow mononuclear cells. All of these findings, though suggestive, could also represent secondary manifestations of whatever inciting damage caused the aplastic anemia in the first place. Direct demonstration of genetically restricted suppression of hematopoiesis by a unique subset of T lymphocytes, as has been shown for PRCA,[178]

remains a critical area of future active investigation for acquired aplastic anemia.

Lymphokines

Whether overproduction or dysregulated production of inhibitory cytokines represents a primary cause versus a secondary effect of an underlying bone marrow abnormality remains unclear. Interferon-γ, a soluble inhibitor produced by T cells, was found to be produced at high levels in culture from aplastic anemia patients.[179-181] Interferon-γ is expressed in the marrow of most patients with aplastic anemia but not in normal persons or those with other hematologic diseases who have undergone frequent transfusions.[182,183] High pretreatment intracellular interferon-γ levels correlated with response to immunosuppressive therapy (IST).[1840] Other inhibitory cytokines, such as *tumor necrosis factor*[185] and *macrophage inflammatory protein-1*,[186,187] are also overexpressed in patients with aplastic marrow. Both interferon and tumor necrosis factor directly and synergistically inhibit hematopoiesis in vitro.[188] In long-term bone marrow culture, constitutive low-level expression of interferon-γ is sufficient to markedly reduce the output of both committed progenitor cells and LTC-ICs, the stem cell surrogate.[189] Both interferon and tumor necrosis factor enhance the potential for programmed cell death within the $CD34^+$ compartment by increasing Fas antigen expression on target cells.[190] Fas antigen is a cell surface molecule in the tumor necrosis factor receptor family; its activation signals apoptosis.

Microenvironment

In theory, aplastic anemia could be due to a microenvironment that fails to support hematopoiesis—a lesion of "soil" rather than "seed."[72] The anemia of the Sl/Sl^d murine strain, which is missing stem cell factor (SCF), the ligand for the c-kit receptor, is an example of such a defect.[191] Although defects in some stromal cell function have occasionally been measured in patients, these defects do not appear to be causative in most cases. After marrow transplantation, most stromal cell elements remain of host origin,[192] yet these cells adequately support the donor's stem cells. In the laboratory, aplastic marrow usually provides normal adherent cell function in long-term or Dexter flask-type cultures; however, a patient's marrow is a poor source of clonogenic cells when grown on normal stroma, consistent with the defect in stem and progenitor cell numbers described earlier.[193] Some investigators have reported low fibroblast colony formation in aplastic anemia,[194] but this assay may not reflect stromal cell function.

Hematopoietic growth factor production and plasma levels are usually increased rather than decreased in patients with aplastic anemia (reviewed by Koijima[195]). Circulating levels of erythropoietin, granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), thrombopoietin, and flt-3 ligand are elevated in patients with aplastic

anemia. SCF levels have been reported to be low to normal. Levels of IL-1, produced by monocytes, may be low in aplastic anemia. Therapeutic trials with these factors have yielded divergent and incomplete responses (reviewed by Marsh[196]), thus casting doubt on the pathophysiologic significance of deficiency of these factors.

Clinical Evaluation

The differential diagnosis of pancytopenia is broad (Box 7-3). The evaluation and diagnostic workup of a patient with presumed acquired aplastic anemia should be directed at eliminating alternative diagnoses for which curative therapies are available or for which therapies for aplastic anemia would be inappropriate (Table 7-1). Because the inherited marrow failure syndromes entail different medical management issues, a careful medical history, family history, physical examination, and appropriate laboratory evaluation to assess for underlying inherited bone marrow failure syndromes should be pursued. The diagnosis of an inherited marrow failure syndrome also carries profound implications for selection of hematopoietic stem cell donors from family members and may be important for family planning. Given the

Box 7-3	**Causes of Pancytopenia**

HYPOCELLULAR BONE MARROW

Acquired aplastic anemia
Inherited bone marrow failure syndrome (Fanconi's anemia, amegakaryocytic thrombocytopenia, dyskeratosis congenita, Shwachman-Diamond syndrome)
Paroxysmal nocturnal hemoglobinuria
Hypoplastic myelodysplastic syndrome
Virus-associated aplastic anemia

CELLULAR BONE MARROW

Primary Bone Marrow Disease

Myelodysplasia
Paroxysmal nocturnal hemoglobinuria

Secondary to Systemic Disease

Systemic lupus erythematosus, Sjögren's syndrome
Hypersplenism
Vitamin B_{12}, folate deficiency
Infection
Storage disease (Gaucher, Niemann-Pick)
Alcoholism
Sarcoidosis

INFILTRATIVE BONE MARROW DISORDERS

Acute myelogenous leukemia
Acute lymphoblastic leukemia
Hemophagocytic lymphohistiocytosis
Metastatic solid tumors
Osteopetrosis
Myelofibrosis

TABLE 7-1 Clinical Evaluation	
Evaluation	**Rationale**
CLINICAL HISTORY	
Recent illnesses	Infectious cause
Medications	Marrow suppression
Exposure to toxins	Marrow suppression
Family history of blood disorders, malignancy, congenital anomalies	Assess for inherited marrow failure
PHYSICAL EXAMINATION	
Vital signs	Clinical sequelae of cytopenia
Height and weight	Assess for inherited marrow failure
Congenital anomalies, stigmata	Assess for inherited marrow failure
	Assess for other systemic diseases
LABORATORY TESTS	
Complete blood count and differential	Defines severity
Morphology	Malignant versus benign
	Vitamin B_{12} deficiency
	Storage disease
Reticulocyte count	Defines severity
	Differentiate production versus destruction
Bone marrow biopsy	Assess cellularity
	Assess architecture (granuloma, fibrosis, hemophagocytosis, infiltrative or metastatic disease)
Bone marrow aspirate	
Morphology	Malignant versus benign
	Storage disease
	Hemophagocytosis
	Congenital disorder
Cytogenetics	Myelodysplasia
Culture	Infectious agent (e.g., tuberculosis, virus)
Other	DNA/antigen-based viral tests
PERIPHERAL BLOOD CHEMISTRY	
AST, ALT, GGT, bilirubin, LDH	Hepatitis
Coombs' test	Autoimmune cytopenia
BUN, creatinine, electrolytes	Chronic renal failure
Serologic testing/PCR	Hepatitis, EBV, HIV, other virus
Flow cytometry for CD55/CD59	Paroxysmal nocturnal hemoglobinuria
Diepoxybutane or mitomycin C chromosomal breakage	Fanconi's anemia
Autoimmune disease evaluation	Evidence of collagen vascular disease
Histocompatibility testing of patient and family	Establish potential donor pool

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; EBV, Epstein-Barr virus; GGT, γ-glutamyltransferase; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase; PCR, polymerase chain reaction.
Modified from Guinan E. Clinical aspects of aplastic anemia. Hematol Oncol Clin North Am. 1997;11:1028.

wide clinical variability of the inherited marrow failure syndromes, even among members of a given family, all siblings of a patient with an inherited marrow failure disorder should be tested regardless of whether they appear to carry clinical stigmata of the disease.

History

The chief initial symptoms relate to low blood counts. Bleeding, such as gum oozing, nosebleeds, easy bruising with minimal trauma, or heavy menses, may be seen. Chronic anemia may be manifested as fatigue, decreased activity, or exercise intolerance, although the gradual onset of severe anemia can be surprisingly well compensated in young children. Serious infection is not a frequent initial symptom early in the course of aplastic anemia. Many patients feel well with few symptoms at initial evaluation. A history of steatorrhea or fatty food intolerance may be a manifestation of Shwachman-Diamond syndrome. Gastrointestinal disorders may also be associated with other inherited marrow failures syndromes such as dyskeratosis congenita or Fanconi's anemia. A careful family history for blood disorders, malignancies, or congenital anomalies that might suggest an inherited bone marrow syndrome should be sought. A developmental history can provide helpful screening for potential congenital, metabolic, or storage diseases. A detailed medication, environmental, and infectious history should be obtained, especially for the preceding 1- to 12-month period.

Physical Examination

Clinical appearance is related to the severity and duration of the underlying pancytopenia. Hemorrhagic manifestations from thrombocytopenia occur early and include petechiae (particularly on the border of the hard and soft palate), ecchymoses, epistaxis, and bleeding from mucous membranes. Neutropenia may be associated with oral ulcerations, bacterial infections, and fever; these signs are rarely present early. Evidence of erythropoietic failure, such as pallor, fatigue, and tachycardia, often appears late because the life span of erythrocytes (120 days) far exceeds that of platelets (10 days) or white cells (variable, but measured in hours for granulocytes). Mucous membranes and nail beds may be pale. Lymphadenopathy, splenomegaly, and severe weight loss are uncommon and may suggest other underlying disorders. Short stature, congenital anomalies (especially of the thumbs and forearms), areas of hyperpigmentation or hypopigmentation, or dystrophic nails should alert the examiner to possible inherited bone marrow failure disorders.

Laboratory Studies

Evaluation should include a complete blood count, reticulocyte count, Coombs test to rule out autoimmune destruction, and biochemical profile, including renal and hepatic evaluation. Laboratory tests for possible infectious causes should be performed as indicated clinically.

Careful evaluation of the peripheral blood smear may suggest infection or dietary deficiency. Blood counts are most often uniformly depressed. The blood smear shows a paucity of platelets and leukocytes. The anemia is often macrocytic, although if erythropoiesis is arrested entirely, it may be normocytic. The red cell distribution width, a numeric measure of anisocytosis, is most often normal. Platelet size is not increased, as it is in most cases of immune thrombocytopenia. The absolute reticulocyte count is decreased. Granulocyte numbers are clearly diminished, as may be those of monocytes and lymphocytes.[197,198] Increases in fetal hemoglobin (HbF) and red cell i antigen are manifestations of the fetal-like erythropoiesis seen in "stress" hematopoiesis[199] but occur irregularly in patients with aplastic anemia, have no prognostic value, and can persist in recovered patients.

Blood chemistry panels should be used to evaluate hepatic and renal function. Blood tests to rule out Fanconi's anemia and PNH are important because these diagnoses would entail alternative treatments. A growing array of genetic testing is available to assist in the diagnosis of many of the inherited marrow failure syndromes (see Chapter 8). Patients with stigmata of collagen vascular disease should be appropriately evaluated. Early HLA typing of the patient and family members is helpful in guiding future therapies.

Bone marrow examination must be done by both aspiration and biopsy so that cellularity can be evaluated both qualitatively and quantitatively. The bone marrow in patients with aplastic anemia is hypocellular with empty spicules and increased fat, reticulum cells, plasma cells, and mast cells (Fig. 7-2). Some dyserythropoiesis with megaloblastosis and nuclear-cytoplasmic asynchrony may be seen. Aspirates alone may appear hypocellular because of dilution with peripheral blood, or they may look hypercellular because of areas of focal residual hematopoiesis. Biopsies provide more reliable specimens for assessment of cellularity, as well as critical information regarding bone marrow architecture, such as fibrosis or granulomas. Bone marrow aspirates should also be sent for cytogenetics and possibly fluorescent in situ hybridization (FISH) to assess for abnormalities associated with myelodysplasia or malignancy. In addition, bone marrow may be sent for culture or DNA-based antigen detection of infectious agents such as viruses.

Management and Outcome

Prognosis

Outcome depends on the types of treatments offered, the causes of the aplasia, and the eras and countries being analyzed. In a large series conducted before 1957, Wolff found a survival rate of only 3%.[200] In other series ending no later than 1965, complete recovery was reported in 10% to 35% of patients. In a series of 40 pediatric patients seen before 1958, Diamond and Shahidi found that only 2 patients recovered, 1 of whom suffered recurrence,[201] although these studies may have included patients with moderate disease, for whom spontaneous recovery is more common.[202,203] The long-term prognosis is adversely affected by delayed complications such as clonal disease. A recent study[204] described the natural history of 24 pediatric patients with moderate aplastic anemia monitored at St. Jude Children's Research Hospital for a median of 66 months (range, 10 to 293 months). Moderate aplastic anemia was defined as marrow hypoplasia of less than 50% and at least two cytopenias, such as an absolute neutrophil count less than 1500/mm³, a platelet count less than 100,000/mm³, or reticulocytopenic anemia lasting at least 6 weeks. Sixteen patients (67%) progressed to severe aplastic anemia, 5 (21%) remained in the moderate range, and in 3 patients (12%) the aplastic anemia resolved. It is currently unclear whether early institution of therapy for moderate aplastic anemia confers an improved outcome. Because current therapies are associated with significant side effects, their use in children with moderate aplastic anemia, for whom the marrow aplasia may resolve spontaneously, warrants careful consideration.

Spontaneous Recovery

Spontaneous recovery from aplastic anemia has been reported anecdotally, although most cases were probably moderate rather than severe. Good supportive care (see later) may contribute to such recovery; in one series 14 of 33 children recovered,[205] and children with moderate aplastic anemia have been found to have an excellent prognosis, even without specific treatment.[206] A study of IST in which 21 patients were randomized (some to receive only supportive care) found no improvement in the control group after 3 months.[207] Spontaneous recovery is sufficiently rare in patients with severe aplastic anemia that all modalities of current therapy should be initiated.

Supportive Care

Blood product support should be used judiciously to avoid sensitization, and blood product donors should never be from the patient's family for the same reason. Complete red cell phenotyping is recommended when feasible to minimize the potential risk of erythrocyte antibodies in patients who may receive long-term blood product support. All blood products should be filtered and irradiated. Exposure to potentially hazardous drugs or toxins should be eliminated.

Bleeding

Platelet (and red cell) support has probably had the greatest impact on survival in patients with aplastic anemia and has changed the cause of death from bleeding to infection. Platelets can be provided from several individual units of blood or, preferably, by plateletpheresis from a single donor to reduce antigenic exposure (see Chapter 35).
FIGURE 7-2. Bone marrow examination in severe aplastic anemia. **A,** Note the hypocellularity in a biopsy specimen. **B,** Residual cells seen in the aspirate are lymphocytes, stromal cells, plasma cells, and mast cells. *(Courtesy of Dr. Gail Wolfe, Boston.)*

The main role of prophylactic platelet support is reduction of the risk for intracranial hemorrhage, which is a rare but potentially devastating event. The general threshold platelet count has traditionally been 20,000 cells/µL; however, this figure and the entire practice of prophylactic administration of platelet transfusions have been questioned.[208-210] Platelet transfusions at platelet counts below 10,000/µL in stable outpatients with chronic severe aplastic anemia was shown to be feasible and safe in a recent study.[211] Chronic platelet transfusions for aplastic anemia are generally given when the patient has symptoms of bleeding or is at increased risk for bleeding (e.g., toddlers learning to walk, patients with hypertension while taking cyclosporine, patients with fever and infection, recent treatment with ATG).

Other measures to reduce bleeding include maintenance of good dental hygiene, use of a soft toothbrush, stool softeners, and avoidance of trauma. Drugs that may interfere with platelet function, such as aspirin or nonsteroidal anti-inflammatory medications, should be avoided in patients with thrombocytopenia. Antifibrinolytic agents such as aminocaproic acid and tranexamic acid may decrease bleeding, particularly from the gums and nasal mucosa.

Infections

There are few reported studies of infection in patients with aplastic anemia.[212-214] Severe granulocytopenia may last for years. However, the immune systems of granulocytopenic patients remain intact, in contrast to the

situation in patients with malignancies who undergo chemotherapy and experience simultaneous neutropenia and immunosuppression. Neutropenia (and perhaps monocytopenia) increases the risk for bacterial infection in patients with aplastic anemia.[197] Because neutropenia precludes the development of an inflammatory response, identification of an infected locus is often difficult. The bacterial organisms may be gram-negative bacilli such as *Escherichia coli*, *Klebsiella pneumoniae*, or *Pseudomonas aeruginosa*, as well as gram-positive cocci, including *Staphylococcus aureus*, *Streptococcus epidermidis*, and other streptococci. Immunosuppression as a result of preparation for BMT or as primary therapy for aplastic anemia may lead to unusual bacterial, fungal, viral, and protozoal infections. Recommendations for specific antibiotics and other anti-infection agents are beyond the scope of this chapter, and regimens are changing rapidly as new generations of treatment are developed.

The use of prophylactic antibiotics has no role in a "well" patient with aplastic anemia. Patients undergoing IST should receive prophylaxis for *Pneumocystis carinii*. In the context of fever and neutropenia, complete evaluation and culture of all possible sites should be followed by the administration of broad-spectrum parenteral antibiotics. Fungal infections occur frequently in neutropenic patients who have received repeated or extended courses of antibiotics; candidiasis and especially aspergillosis, which lead to sinusitis, lung disease, or disseminated infection, are distressingly frequent causes of death in those with aplastic anemia.[212] Antecedent or concurrent administration of steroids increases this risk. Aggressive introduction of antifungal treatment is indicated in a persistently febrile patient who is unresponsive to antibiotics or in the appropriate clinical setting.

Anemia

Red cells should be provided as clinically indicated. Hemoglobin should be maintained at a level consistent with normal activities if routine transfusions are to be used. Chronic anemia can be well tolerated once adaptation has occurred, and some children who can sustain a hemoglobin level greater than 6 to 7 g/dL without transfusions (i.e., a child who is not bleeding) may be carefully observed. Long-term transfusions lead to iron overload with accumulation in critical organs. Permanent damage to the heart, liver, and endocrine glands from iron overload may be prevented by iron chelation therapy.[215]

Treatment

Bone Marrow Transplantation

The general topic of BMT is described in Chapter 9. The discussion that follows is limited to the role of BMT in the treatment of aplastic anemia.

The earliest transplants for aplastic anemia involved identical twins. Subsequent definition of the human histocompatibility gene complex, the development of immunosuppressive regimens, and improved support of severely pancytopenic patients led to more general application of this form of therapy. Stem cell transplantation between identical twins in the absence of any conditioning regimen was curative in around 50% of cases.[138-141] A recent study showed that the highest long-term survival with identical twin transplants was achieved by using an algorithm of initial transplantation without conditioning followed by a subsequent transplant with conditioning for any patients demonstrating engraftment failure with the first transplant. None of the patients in whom the first transplant failed died before receiving a second transplant, and mortality was similar to that in patients who received conditioning up-front.[141] The European Group for Blood and Marrow Transplantation (EBMT) recently reported actuarial 5-year survival rates among syngeneic twin transplants performed between 1976 and 1998 to be 91%.

Initial outcomes with cyclophosphamide regimens were associated with a high risk of graft rejection.[216] The combination of cyclophosphamide and radiation therapy improved engraftment rates but was limited by increased toxicity and increased rates of GVHD associated with radiation therapy.[217,218] The combination of ATG and cyclophosphamide together with the use of cyclosporine to prevent GVHD and increased stem cell infusion doses have resulted in lower rates of graft rejection (3.7% in one recent series of 81 patients).[219] Exposure to blood products before transplantation was associated with an increased risk for allosensitization and subsequent graft rejection. The detrimental role of transfusions may have decreased with the routine use of leukocyte-free products, as well as with strict avoidance of the use of family members as donors.[220] The addition of fludarabine, a highly immunosuppressive nucleoside analogue, has yielded high rates of engraftment, even in heavily pretransfused patients with aplastic anemia.[221] Outcomes of HLA-matched allogeneic BMT have been reported by large registries, which combine the results of many contributing centers, or in single-center studies by the largest referral centers.[222,223] Recent studies of transplants from HLA-matched family donors report survival rates of up to 88% to 97% with 4 to 10 years of follow-up in children (Table 7-2).[218,219,224,225] Transplantation in patients of advanced age is associated with lower survival and increased rates of GVHD.

GVHD remains another factor limiting outcomes after matched sibling transplants.[226] The reader is referred to Chapter 9 for a full discussion of GVHD. Secondary solid tumors may arise after BMT, with a cumulative incidence of 10% 15 years after transplantation noted in a recent report.[218] Nine of the 11 tumors reported in that study arose in patients who underwent a radiation-containing conditioning regimen. The cyclophosphamide-based conditioning regimens currently reported for matched sibling transplants for aplastic anemia are generally associated with few long-term effects. Growth and development, endocrine function (thyroid and adrenal), and long-term gonadal function (ovarian and testicular)

TABLE 7-2	Representative Recent Allogeneic Transplantation Studies That Include Pediatric Patients

are typically preserved. The use of myeloablative radiation-containing regimens may be associated with growth compromise, endocrine dysfunction, and irreversible gonadal failure.[227,228]

The preceding discussion refers to transplants from HLA-matched sibling donors; however, 75% to 80% of transplant patients do not have such a donor. Alternative donors include HLA-matched but unrelated volunteers, phenotypically but not genotypically matched relatives, and partially matched (mismatched) donors. Umbilical cord blood provides an alternative source of stem cells for hematopoietic stem cell transplantation and is discussed in Chapter 9. Ongoing advances in high-resolution HLA typing techniques continue to improve selection of HLA-matched donors. The reader is referred to Chapter 9 for a general discussion of alternative donor bone marrow transplants. Currently, long-term survival after alternative donor stem cell transplantation for aplastic anemia has generally been lower (<50% long-term survival rate) than that after matched sibling donor transplantation.[229] The risk of graft rejection is greater, the higher-intensity conditioning regimens required to promote engraftment entail greater treatment-related toxicity, and the risk for GVHD is higher. The longer delay from diagnosis to transplantation for unrelated donor transplants might also contribute to the higher risk.

Studies to reduce regimen-related toxicity while preserving engraftment are ongoing. Replacement of radiation therapy with fludarabine together with cyclophosphamide and ATG in 38 patients with aplastic anemia undergoing transplantation with an unrelated or family mismatched donor yielded low rates of acute (11%) and chronic (24%) GVHD, but graft failure or rejection rates (18%) remained relatively high. The actuarial 2-year survival rate was 73%.[230] A prospective multi-center study of 87 unrelated donor transplant patients (median age of 18.6 years) who had previously failed therapy for aplastic anemia investigated the effects of de-escalating the dose of radiation from 600-cGy total body irradiation (TBI) down to 200-cGy TBI given together with cyclophosphamide (200 mg/kg) with or without ATG. Engraftment was preserved at the lowest TBI dose, with a graft failure rate of only 2% for HLA-matched unrelated donor transplants. The survival rate was 61% (38/62) for HLA-matched and 40% (10/25) for HLA-mismatched transplant recipients at a median follow-up of 7 years. Outcomes were better for younger patients (<20 years of age), who had a 5-year survival rate of 73%. Rates of GVHD, however, were comparable across all radiation doses (69% to 77% with grade II to IV acute GVHD; 52% to 57% with chronic GVHD). Additional trials are ongoing to investigate whether replacement of cyclophosphamide with fludarabine might reduce toxicity while preserving engraftment.[231] Additional strategies include T-cell depletion[232] (with its attendant high risk of rejection), anti-CD52 antibody,[233] or haploidentical CD34 selection,[234] and research in this field is actively ongoing.

Immunosuppression

Antithymocyte Globulin. ALG and ATG (the sera produced by immunization of horses or rabbits with human thoracic duct lymphocytes or thymocytes) are highly cytotoxic reagents with activity against all blood and marrow cells, including progenitors. These reagents were initially used to decrease the rate of rejection of HLA-matched bone marrow. ALG, cyclophosphamide, or both were also used to permit at least temporary engraftment with mismatched marrow in aplastic patients without a matched donor.[158,159,160,2354,236] Autologous recovery occurred in some of these patients, which

encouraged several groups to examine the use of ATG or ALG with and without haploidentical BMT. Treatment with ALG was superior to controls in both response rate and 3-year survival.[207] The use of other agents in addition to ALG therapy can further enhance the therapeutic effect.

ATG or ALG/antilymphocyte serum is often given up to a total cumulative dose of 100 to 160 mg/kg, typically divided over 4 days. Immediate allergic reactions to ALG are rare and can be predicted by skin testing, followed by desensitization in those who are allergic.[237] The patient begins to make antibodies to horse protein about 1 week after the first exposure, at which point equine antibodies are rapidly cleared from the circulation. This reduces the effective dose and enhances immune complex formation. *Serum sickness* as a result of immune complex deposition may be manifested around 11 days after initiation of treatment as fever, a serpiginous rash at the volar-dorsal border of the hands and feet, arthralgia, myalgia, lassitude, and changes in urine sediment. Bronchospasm or liver chemistry abnormalities may also occur. A short course of corticosteroids is usually given (prednisone, 1 mg/kg) to reduce ATG-related side effects. ATG binds to determinants on all cell types in blood and marrow, reduces platelet and granulocyte counts in addition to the lymphocyte counts, and may lead to a positive Coombs test. Thrombocytopenia may require intensive blood product support during this time.[238]

Responses to ATG given as a single agent usually occur within the first 3 months, if at all, and blood count improvement by 3 months correlates with survival.[239] The earliest response to therapy may be heralded by the appearance of a few granulocytes and nucleated red cells in the circulation. Red cell size distribution histograms typically show a macrocytic shoulder.[240] Reticulocytes appear, transfusions decline, and the hemoglobin level increases slowly. The white cell count rises next. The last cell line to return to normal is often the platelets, whose numbers may remain low for months or even years. The recovering red cells are not normal; in addition to macrocytosis, HbF levels are increased and fetal membrane antigens may remain present.[241] Long-term survivors (except those with successful transplants) often have residual abnormalities such as thrombocytopenia, red cell macrocytosis, and elevated HbF levels.[242] Clearly, we do not understand either the mechanism of action of this poorly characterized drug, the ultimate course of patients with ATG-induced remission, or the basis of their partial recovery.

Cyclosporine. Cyclosporine (formerly cyclosporin A) is a fungal cyclic undecapeptide and an effective immunosuppressive agent.[243] Among its many effects, cyclosporine can inhibit T cells and thereby prevent production of IL-2 and interferon-γ.[161] About half of the patients who had failed ATG or ALG treatment subsequently experienced remission with cyclosporine.[244,245] Treatment with cyclosporine alone yielded significantly lower response

rates and higher rates of disease progression than did treatment with combined therapy.[246,247]

Oral cyclosporine should be administered twice daily to maintain blood trough levels between 100 and 250 ng/mL as measured by radioimmunoassay, although target levels may vary depending on the laboratory methods used to determine cyclosporine levels. Hematologic responses can take weeks to months, and an initial trial period of 3 to 6 months is generally recommended.

Toxic effects from the use of cyclosporine are not insignificant and include hypertension, hypertensive encephalopathy, azotemia, hirsutism, gingival hypertrophy, coarsening of facial features, tremor, immunodeficiency, increase in serum creatinine levels, transient or irreversible nephrotoxicity, hepatotoxicity, seizures, and *P. carinii* pneumonia.[243] As with ATG, in vitro tests of the effect of cyclosporine on progenitor cells do not predict responses.[248]

Combination Immunosuppressive Therapy. The combination of ATG with cyclosporine has resulted in higher rates of hematologic recovery than with either drug alone.[246,247,249] Importantly, intensive IST has greatly improved the results of therapy in two groups commonly refractory to ALG or ATG alone: patients with very severe disease and children.[250,251] In the National Institutes of Health (NIH) Clinical Center trial,[252] survival curves of those older and younger than 35 years were similar. A large study including both children and adults at the NIH reported a response rate of 67% at 43 months and a 5-year actuarial survival rate of 70% (86% for responders and 16% for nonresponders).[253] The EBMT Working Party on Severe Aplastic Anemia and the Gruppo Italiano Trapianto di Midollo Osseo (GITMO) study of 100 patients, including children (median age, 16 years), with severe aplastic anemia treated with ALG, cyclosporine, prednisolone, and G-CSF found a trilineage hematopoietic response in 77% after one or more courses of ALG.[254] Several trials in children have reported the efficacy of combined ATG and cyclosporine in the pediatric population with an overall response rate of close to 80%.[250,251,255-257]

ATG is typically given over a period of 4 days in combination with a 6- to 12-month course of cyclosporine. The lack of a unified definition for response complicates comparison of different studies, but in general, a complete response refers to normal or functionally normal blood counts, a partial response denotes hemoglobin and platelet counts adequate to avoid the need for transfusion and neutrophil counts typically greater than 500/μL, and no response commonly refers to continued severe aplastic anemia. Improvements in blood counts are delayed and may not be evident for many weeks. In a study including both children and adults, response rates, defined as at least a partial response in two blood cell lineages, were 67% at 3 months and 71% at 6 months after initiation of combined ATG and cyclosporine therapy.[252] Cyclosporine should be tapered gradually

with close monitoring of blood counts before each decrease in dosage. A persistent drop in blood counts can often be treated by either an increase in cyclosporine dosage or reinitiation of the full dose. Some patients require continuous cyclosporine, and these patients should be maintained on the lowest effective dose. In a review of ongoing trials by the German multicenter group and the NIH, 29% and 14% of initial responders, respectively, were found to require continuous treatment.[252] Reoccurrence of frank pancytopenia generally requires a second course of ATG followed by full-dose cyclosporine. Patients treated with IST often continue to have subnormal counts and may remain macrocytic. Although the majority of patients respond within 6 months, delayed responses beyond that time may be seen in some patients.

About 20% to 40% of patients in pediatric studies fail to respond to ATG and cyclosporine therapy (Table 7-3), and a recent study of mostly adult patients reported failure to achieve response in around 40% of patients.[259] In most studies, failure of response is typically defined as persistence of severe aplastic anemia. In adult patients failing the first treatment with horse ATG, 63% of those

receiving a second course of horse ATG responded,[260] and 77% (23/30) of those initially treated with horse ATG and cyclosporine responded to a second course of rabbit ATG and cyclosporine.[261] Less acute reactions were noted when the source of ATG was varied between the first and second treatments. The time frame to response after a second course of IST was similar to that observed after initial treatment. Patients failing to response to two courses of IST are unlikely to respond to a third treatment course.[262]

Because androgens are effective in treating some patients with aplastic anemia (see later), the effect of combining androgen treatment with ATG was examined in several trials. Champlin and associates reported no difference in response rate or survival in patients with moderate to severe aplastic anemia.[263] Studies by Kaltwasser and colleagues[264] and the EBMT[265] found significantly higher response rates after ALG plus androgens (73% and 56%) than after ALG alone (31% and 40%). A recent retrospective study in adults reported an overall response rate of 77% and overall survival rate of 78% 5 years after treatment with ATG plus androgens.[266] Because some patients with inherited causes of aplastic

TABLE 7-3   Pediatric Studies of Immunosuppressive Therapy for Aplastic Anemia

ALG, antilymphocyte globulin; ATG, antithymocyte globulin; CR, complete response; Cy, cyclosporine; DAN, danazol; G-CSF, granulocyte colony-stimulating factor; MAA, moderate aplastic anemia; MDS, myelodysplastic syndrome; NR, not reported; OR, overall response; PR, partial response; SAA, severe aplastic anemia; vSAA, very severe aplastic anemia.

anemia may experience hematologic improvement after androgen therapy,[267] it is important to rule out an underlying inherited marrow failure syndrome. The side effects of androgen may be unacceptable to some patients, and their use for acquired aplastic anemia in children is generally limited.

Relapse. Relapse after IST has been reported in around a third of patients in studies that include both children and adults,[258,268] although lower rates of relapse may be attained with slow tapering of cyclosporine and continued maintenance doses at the lowest required cyclosporine dose for some patients. Lack of standardized definitions of relapse hamper comparison between studies. An EBMT study including both children and adults reported an actuarial risk for relapse of 35% at 14 years.[269] Relapses were observed up to 10 years after treatment. Disease severity, age, sex, and cause were not predictive of relapse. Large studies of relapse risk after IST in the pediatric population are scarce. The results of these studies are summarized in Table 7-3.

Tichelli and co-workers studied the efficacy of repeated treatment with ALG in patients with severe aplastic anemia who either failed to respond to an initial course of ALG or experienced hematologic relapse.[260] Independence from transfusion was achieved in 63% and the probability of survival was 52% ± 8% at 10 years. No differences were noted between patients retreated for nonresponse versus relapse. No increases in acute toxicity were noted with additional courses of ALG, although the timing of serum sickness tended to be earlier after repeat ALG administration. Relapse had little effect on survival in patients responding to reinstitution of immunosuppression. A study of 22 patients refractory to combined ATG/cyclosporine reported an overall response rate of only 30% at 6 months. This study included two refractory patients younger than 18 years, neither of whom responded to a second course of IST. Of 21 patients relapsing after ATG/cyclosporine treatment, an overall response rate of 65% was observed.[270] A retrospective study of 18 relapsed or refractory patients reported responses to a third course of an ATG-containing regimen only in those who had previously responded to a prior course of treatment.[262]

Complications of Immunosuppressive Therapy. Patients treated for aplastic anemia with IST have an increased risk for the development of clonal hematopoietic disorders (reviewed elsewhere[271,2720]). Because ATG and cyclosporine are not associated with an increased risk for MDS or leukemia in patients treated for other disorders, these complications are believed to result from the underlying dyspoiesis of aplastic anemia. In an analysis of 860 aplastic anemia patients treated with immunosuppression, 42 malignant conditions were reported, including 19 cases of PNH, 11 cases of myelodysplasia, 15 cases of acute leukemia, 7 solid tumors, and 1 non-Hodgkin's lymphoma.[273] Of 748 aplastic anemia patients

treated by transplantation, nine malignancies were reported: two acute leukemias and seven solid tumors. The cumulative incidence of a malignant tumor developing at 10 years was 18.8% after immunosuppression and 3.1% after transplantation. A recent NIH study of 122 patients treated with immunosuppression showed a 33% actuarial risk of a clonal hematopoietic disorder developing at 10 years.[4] An increased risk for clonal abnormalities as high as 21.9%[258] has been reported in some studies of pediatric patients with aplastic anemia. An increased risk for MDS or acute myelogenous leukemia has also been observed in pediatric patients (Table 7-3). Although an association between the use of G-CSF and risk of clonal disease has been observed,[258] in the absence of randomized studies, the question of causality remains unanswered. These data suggest that a clonal transformation of stem cells may underlie aplastic anemia, at least in a subset of patients. Prolonged survival with ATG/ALG/cyclosporine may permit the expected clonal evolution.

Transplantation versus Immunosuppression

The decision to treat with immunosuppression versus an HLA-identical sibling stem cell transplant for the 25% of patients for whom a suitable donor is available is based on consideration of the risks and benefits, which vary according to patient age and neutrophil count. Up-front toxicities associated with the conditioning regimens, GVHD, and graft rejection are the major problems related to stem cell transplantation, but this treatment offers the potential for long-term cure. Immunosuppressive and cytotoxic therapy is associated with lower acute toxicity but often yields incomplete hematologic recovery and is accompanied by late mortality from long-term complications such as relapse and clonal hematologic disorders. Comparison of outcomes after BMT and IST in children supports the benefit of HLA-matched sibling stem cell transplantation. Kojima and co-authors[224] reported a study of 100 children younger than 17 years with aplastic anemia between 1984 and 1998. Thirty-seven patients received allogeneic bone marrow transplants and 63 received IST with either ATG plus danazol or ATG and cyclosporine with or without danazol. Some patients also received G-CSF. Eleven patients initially treated with IST received subsequent salvage treatment with an unrelated donor transplant. The projected 10-year survival rate was 55% ± 8% with IST and 97% ± 35% with transplantation. The failure-free survival rate at 10 years was 40% ± 8% for the IST group and 97% ± 3% for the transplant group. MDS with monosomy 7 developed in seven patients in the IST group, and the estimated 10-year cumulative incidence of MDS was 20% ± 7%.

A recent report from the EBMT analyzed 1765 patients with aplastic anemia who underwent initial treatment with either an HLA-identical sibling transplant or IST.[222] Analysis was performed on an "intent-to-treat" basis. Patients were 1 to 50 years of age and treated between 1974 and 1996. Five hundred eighty-three

patients received HLA-identical sibling transplants and 1182 underwent IST. A comparison of IST versus BMT in patients stratified by age and neutrophil count showed superior failure-free survival with transplantation for children regardless of their neutrophil count. The advantage of transplantation increased with increasing follow-up time, most likely because of the ongoing risks of late relapse and evolution to myelodysplasia and leukemia in the group receiving IST. Children have lower mortality with stem cell transplantation and a longer post-treatment life expectancy, which places them at higher risk than older adults for late complications. Thus, the current recommendation is to treat young patients (≤10 years) with HLA-identical sibling stem cell transplants when a suitable donor is available. Patients with severe disease also do better with BMT. It is important to note that many patients in these studies of long-term outcomes were treated before the development of current combined immunosuppressive regimens containing both ATG and cyclosporine.

For patients lacking a suitable HLA-matched sibling donor, treatment with ATG and cyclosporine is generally the preferred line of therapy given the higher risk of toxicity and morbidity associated with current alternative donor transplant regimens. For patients who fail to respond to an initial course of ATG and cyclosporine, either a second course of ATG/cyclosporine or an alternative donor hematopoietic stem cell transplant may be considered. The risks and benefits of each approach will vary for each patient, but the risks associated with prolonged delay to potential transplantation[274] should be weighed against the most current data on alternative donor regimens.

Hematopoietic Growth Factors

Although patients with aplastic anemia do not have a deficiency of most hematopoietic growth factors (see earlier), it was hypothesized that pharmacologic levels might stimulate hematopoiesis of one or more cell lines.[196] Small trials of GM-CSF, G-CSF, IL-3, IL-1, IL-6, and SCF in mostly adult patients with aplastic anemia do not support the use of growth factors as primary treatment of aplastic anemia, and serious side effects were noted with some agents. To date, no consistent benefit in terms of response rate or survival after the adjunctive use of growth factors such as G-CSF in immunosuppressive regimens has been observed.[250,275] No improvement in overall response rates were noted in a retrospective study of 18 pediatric patients receiving GM-CSF in addition to ATG and cyclosporine.[276] Responses to single or combined growth factors have been reported in a few refractory patients.

G-CSF is associated with flu-like symptoms, bone pain, and splenomegaly. Symptoms of "cytokine flu"—fever, rash, hives, headache, and myalgia—are common but do respond to acetaminophen or resolve with the passage of time. Bone pain may be a symptom of increased marrow activity, although this is more commonly seen with G-CSF. At higher doses, the severity of symptoms increases, and there may be evidence of visceral engorgement and fluid retention.

The potential risk of promoting or stimulating the development of abnormal hematopoietic clones leading to a further increased risk for myelodysplasia or leukemia after prolonged treatment with growth factors remains a concern in patients with aplastic anemia. Although associations between G-CSF treatment and the subsequent development of MDS and leukemia have been reported,[277] in the absence of randomized prospective trials, it is not clear whether this represents an effect of growth factor treatment or merely an association reflecting the natural history of aplastic anemia of sufficient severity to warrant the addition of G-CSF.

Androgens

Androgens no longer have a primary role in the management of aplastic anemia, unless the first-line therapies discussed earlier are unavailable or unsuccessful. As described previously, androgens have been used as adjuncts to immunosuppression.

The mechanism of action has been reviewed extensively by Gardner and Besa.[278] Androgens increase erythropoietin production[279] and stimulate erythroid stem cells.[280] Hemoglobin levels increase in normal males at puberty and in patients treated with androgens for arthritis or breast cancer or in old age. Shahidi and Diamond were the first to report success with testosterone,[281] and large confirmatory series were published in France[282] and Mexico.[283] However, later critical evaluations revealed no evidence supporting the use of androgens. Despite the use of androgens, greater than 75% mortality has been reported in children[204] and adults.[284] Androgen-treated patients often did not do as well as those who were not treated with these hormones.[203,285] The older publications often failed to distinguish patients with moderate and severe aplastic anemia. Camitta and co-workers performed a prospective, multicenter analysis beginning in 1974 and concluded that androgens (whether oral or intramuscular) were no more effective than supportive care alone for severe aplastic anemia.[286,287]

Improvement, if it occurs, is usually greatest in hematocrit, although increases in granulocyte and platelet counts may also be seen. Response may take weeks to months, and trials of at least 3 months are recommended before declaring a patient unresponsive. The major side effect of androgens is liver toxicity. Cholestatic jaundice and hepatomegaly are usually reversible. Peliosis hepatis (blood lakes) has been reported.[288] Hepatic tumors are a serious risk, although the pathologic picture is usually that of a benign adenoma; such tumors may be reversible when use of the androgen is discontinued. Other side effects include masculinization with hirsutism, baldness, deepening of the voice, and enlargement of the genitalia. Acne, flushing of the skin, nausea, and sodium and fluid retention also occur. The appetite is stimulated, and there is weight gain with increased muscular development. The

rate of skeletal maturation may be increased, with eventual premature fusion and ultimate short stature.[289] All patients who receive androgens should be monitored with frequent liver function testing, annual liver ultrasound examination, and annual bone age determination.

Corticosteroids

Modest doses of methylprednisolone are generally given during ATG or ALG treatment to lessen the side effects of serum sickness. As a single agent, very high doses of corticosteroids have been reported to lead to responses in a few patients.[290,291] Treatment with high-dose steroids is associated with substantial toxicity, including hypertension, hyperglycemia, fluid retention, potassium wasting, psychosis, aseptic necrosis of the femoral and humeral heads, and increased susceptibility to fungal infections. Given the higher response rate and lower toxicity profile of ATG, high-dose steroids are not recommended as first-line therapy for aplastic anemia.

Splenectomy

Splenectomies were performed until recently, perhaps for want of something better to offer to patients. A review in 1957 indicated improvement in 20 of 35 patients.[292] More recently, the operation has been performed to facilitate supportive care.[293] Unless there are clear indications of hypersplenism significantly impeding platelet and red cell transfusion support, the operation does not seem warranted.

Other Therapies

New therapeutic regimens are aimed at improving rates of hematologic response and minimizing acute and long-term complications of therapy.[163] The current status of a few investigational regimens is summarized in the following sections.

Cyclophosphamide

Administration of high doses of cyclophosphamide is effective IST and is not myeloablative in normal hosts. Historically, a few patients who received high-dose cyclophosphamide as preparation for BMT rejected their grafts and underwent autologous recovery. An early study of treatment with this drug without transplantation indicated a complete response in 7 of 10 patients treated with 45 mg/kg/day for 4 days.[294] A study of 19 previously untreated patients with aplastic anemia reported a 73% overall response rate at 24 months with a 65% probability of achieving a complete response at 50 months and an 85% survival rate at 24 months.[295] No relapses or clonal disorders were observed in the responding patients. A phase III prospective randomized trial compared high-dose cyclophosphamide plus cyclosporine with ATG plus cyclosporine as first-line therapy.[296] The trial was terminated prematurely because of invasive fungal infections and three early deaths in the group treated with cyclophosphamide plus cyclosporine (none were noted in the ATG/cyclosporine group). Responses at 6-month follow-up were seen in 6 of 13 (46%) patients treated with cyclophosphamide plus cyclosporine versus 9 of 12 (75%) treated with ATG plus cyclosporine. Trials of high-dose cyclophosphamide as a single agent in patients refractory to previous IST reported a 53% response rate and 59% survival rate at a median follow-up of 29 months.[297] The generally prolonged time to response and associated toxicity are potentially limiting factors, and additional studies are required to determine whether the development of long-term complications such as relapse or clonal disease will be less frequent than with ATG and cyclosporine.

Recombinant Humanized Anti–Interleukin-2 Receptor Antibody

The IL-2 receptor is found on activated T cells and is required for T-cell expansion.[298] A pilot study of 17 patients with moderate aplastic anemia treated for 3 months with a humanized monoclonal antibody against the IL-2 receptor (daclizumab) reported improved blood counts in 38% of patients.[299] Daclizumab was well tolerated with minimal side effects. Further studies on the use of daclizumab in patients with aplastic anemia are warranted.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF, CellCept) is the prodrug of mycophenolic acid, which inhibits B- and T-cell proliferation through inhibition of inosine monophosphate dehydrogenase, which is involved in guanine nucleotide synthesis.[300] MMF has been in clinical use for prevention of solid organ transplant rejection and treatment of autoimmune diseases. Though generally well tolerated, side effects of MMF include leukopenia and marrow suppression. A study of 104 patients with severe aplastic anemia treated with ATG, cyclosporine, and MMF reported an overall response rate of 62% at 6 months.[301] Relapses were seen in 37% of responders, with more than half of relapses occurring while the patients were still receiving MMF. Clonal abnormalities were noted in 8.7% of patients after a median follow-up of 42 months. No difference in overall survival was noted between children and adults. The addition of MMF did not result in improved rates of response, relapse, or clonal abnormalities in comparison to those reported after treatment with ATG and cyclosporine.

ACQUIRED PURE RED CELL APLASIA

Acquired pure red cell aplasia (APRCA) is a term that embraces a range of incompletely understood aregenerative anemias (sometimes associated with neutropenia and thrombocytopenia) that must be considered in the differential diagnosis of congenital Diamond-Blackfan anemia (see Chapter 8). Unifying characteristics of this broad range of disorders are anemia and a paucity of

TABLE 7-4	Classification of Acquired Pure Red Cell Aplasia			
Condition	**Type**	**Mechanism**		**References**
Parvovirus B19 infection	Acute TAC in hemolytic anemia Chronic in immunosuppressed Congenital	Direct infection of erythroid progenitors	P antigen	302-306
Immune	TEC Chronic (usually adults)—SLE, RA, HD, thymoma	Antibody	Red cell progenitors	307-309
	Thymoma			307
	ABO incompatibility after BMT		Blood group antigen A or B	
	EPO		Antibody to EPO	
	T-CLL	Cell mediated MHC restricted or MHC unrestricted	T cell	310
	LGL		T-LGL (CD3$^+$/αβ or γδ TCR) or NK-LGL (CD3$^-$TCR$^-$)	178, 311, 312
Preleukemia and myelodysplasia	5q–	RPS14 haploinsufficiency + other genetic change		313
Drugs and toxins	Phenytoin, azathioprine, isoniazid	Unknown—direct or immune		314

BMT, bone marrow transplantation; EPO, erythropoietin; HD, hemodialysis; LGL, large granular lymphocyte; NK, natural killer; RA, rheumatoid arthritis; RPS, ribosomal protein of the small ribosomal subunit; SLE, systemic lupus erythematosus; TAC, transient aplastic crisis; T-CLL, T-cell chronic lymphatic leukemia; TCR, T-cell receptor; TEC, transient erythroblastopenia of childhood.

recognizable erythroid precursors in bone marrow. The anemia may be macrocytic if some residual "stress" erythropoiesis is present. If there is complete arrest of erythropoiesis, the anemia will be normocytic or even slightly microcytic and hyperchromic if the arrest of erythropoiesis has existed for 2 months or more because red cell volume shrinks as red cells age in the circulation. In some cases, particularly those associated with parvovirus infection, mild neutropenia and even thrombocytopenia may coexist with the anemia. Thus, the term "pure red cell aplasia" may be honored in the breech. APRCA may be classified as outlined in Table 7-4.

Parvovirus B19 Infection

Parvovirus B19 was identified as the cause of outbreaks of aplastic crises in sickle cell anemia patients in 1981.[302,303] This virus is most likely to have caused a similar disease in several earlier descriptions of anemia, fever, and malaise in patients with hereditary spherocytosis or elliptocytosis, immune hemolytic anemia, and thalassemia, to name a few of the conditions whose common feature is shortening of red cell life span.[315-318] Gasser[319] coined the term "transient aplastic crisis" and also noted the presence of gigantic proerythroblasts in bone marrow. Subsequent studies in volunteers established that the virus does not cause significant anemia in individuals with a normal red cell life span.[320] The main target of this small nonenveloped single-stranded DNA virus is the erythroid progenitor, which it enters through binding to the blood group P antigen. Antibodies

(IgM and IgG) to the viral capsid antigen VP1 are neutralizing and confer long-term immunity. Persistent B19 infection can occur in immunodeficient or immunosuppressed patients as a result of either congenital immunodeficiency, lymphoproliferative disorders, organ transplantation, or HIV infection.[304,305] Neutralizing antibodies to VP1 are absent or low and diagnosis requires demonstration of viral DNA in serum by hybridization assay. Fetal infection with parvovirus can lead to miscarriage, hydrops fetalis, or infants born with chronic anemia.[306]

Immune-Mediated Pure Red Cell Aplasia

Much of our understanding of APRCA seen in adults has been derived from the clinical research of Sanford Krantz and Emmanuel Dessypris and their colleagues at Vanderbilt University.[1] The reader is referred to Dr. Dessypris' excellent monograph for a history and reasonable classification and description of these arcane disorders.[321] A more recent set of reviews has been edited by Stephen A. Feig and Melvin H. Freedman[322] and an independent review has been presented by Fisch and associates.[323]

Acute Pure Red Cell Aplasia: Transient Erythroblastopenia of Childhood

Though probably described in the 1960s by Schmid and by DiGiacomo and their colleagues[324,325] who each reported a potpourri of cases of APRCA, transient erythroblastopenia of childhood (TEC) was first clearly enunciated by Wranne in 1970.[326] This frequent disease is well

described by Glader in the book edited by Feig and Freedman.[322]

TEC is certainly the most common aregenerative anemia in childhood and is likely to be a very frequent complication of a host of relatively trivial viral infections. It is well established that erythropoiesis is briefly interrupted during such infections in most individuals. but anemia is not documented because the red cell life span is 120 days and the suppression usually lasts for only a week. In many patients the suppression is protracted, and anemia ensues. Spontaneous recovery without any treatment is virtually the rule, but confusion may result if the pediatrician sees the patient at the time of recovery when reticulocytosis is in full spate.[327] This may lead to a false diagnosis of hemolytic anemia and a gigantic, expensive, and totally unnecessary workup that simply produces more anemia in the blood as well as in the pocketbook. It is important to suspect TEC in an otherwise healthy child whose blood smear does not suggest a red cell disorder or leukemia. Bone marrow examination is not indicated in the vast majority of cases.[328] Because neutropenia and mild thrombocytopenia are frequent concomitants of many viral infections, TEC is often not a "pure" red cell disease; however, the anemia is usually the more striking anomaly.

Much effort has been expended in implicating parvovirus serotype 19 as an offender in TEC. Although rare cases have been noted, parvovirus is not usually detected.[329-331] In many cases it appears to be a result of antibodies to erythroid progenitors.[307] It is, however, a serious risk in patients with immune deficiency, such as those undergoing organ or marrow transplantation[332-334] and in patients with foreshortened red cell life span such as those with sickle cell anemia or hemolytic anemia (see Chapter 19).

Chronic Pure Red Cell Aplasia: Circulating Antibodies and Suppressing T Cells

Thymoma is very rare in children. Freedman and Feig[322] reviewed the pediatric literature in 1993 and little has emerged since. Thymoma, when associated with PRCA, may be successfully treated with surgery coupled with immunosuppression or intravenous immunoglobulin.[334-337]

Dessypris and Krantz have carefully described the course of patients in whom antibodies reactive with erythroid precursors suddenly develop that presumably suppress erythroid progenitors (BFU-E and CFU-E), recognizable precursors, or both. Dessypris' monograph[321] and Krantz's more recent review in the volume edited by Feig and Freedman[322] exhaustively document the evidence for such antibodies and their suppressing activities. In brief, the antibodies may arise de novo and hence are considered primary, or in the setting of immune deficiency, neoplastic disease, collagen vascular disease, or infection they are considered secondary. In either case, the antibodies cause severe aregenerative anemia and, though often responsive to immunosuppressive therapy,

commonly return to the circulation and cause relapse unless therapy is continued for protracted periods. Fortunately, antibody-mediated APRCA is quite rare in children. The pathophysiology, course, and treatment of the disease are better understood in adults.

Autoantibodies that bind and inhibit erythropoietin and are responsible for erythroid aplasia were first inferred from the work of Jepson and Lowenstein in 1966.[339] Although similar reports emerged later, three of which were associated with recombinant erythropoietin therapy, the pathophysiologic evidence for such antibodies was marginal until 2002, when French investigators[340] reported a high incidence of antierythropoietin antibodies in patients (largely with renal failure) who had been treated with a particular brand of recombinant erythropoietin that had been altered by a variation in glycosylation and by improper storage and thereby rendered antigenic. The findings have been confirmed worldwide. The offending brand of erythropoietin has since been modified, and the incidence of such autoantibodies has been markedly reduced. Immunosuppressive therapy induces these antibodies to disappear in most cases.[341-347]

A case of primary APRCA associated with T-cell suppression of erythropoiesis by large granular lymphocytes that carried both T-cell and monocyte surface markers was described in 1983 by Lipton and associates.[178] In this case, the T cells recognized erythroid but not myeloid progenitors in the context of HLA and suppressed in vitro erythropoiesis in the patient and in HLA-identical normal individuals. Before and since that report there have been several papers that describe such T cells in cases of APRCA,[311,322,338,348-350] but the Lipton study provides the best evidence for HLA-specific erythroid inhibition by an offending clone of T cells. Interestingly, this patient was rapidly cured by treatment with cyclophosphamide. The cell expanded in many of these cases and, though originally described as a Tγ cell, has been renamed a large granular lymphocyte, and these cells can be of either T cell (CD3+, T cell receptor [TCR] αβ or γδ), or natural killer cell (CD3−, TCR−) origin.[312]

Preleukemia (the 5q– Syndrome)

The 5q– syndrome is an acquired clonal defect in which a segment of chromosome 5q bearing at least 40 genes is deleted. Severe aregenerative anemia, absent marrow erythroblasts, abnormal megakaryocytes, and a high incidence of acute myelogenous leukemia are the results. The recent discovery by Ebert and co-workers that the deletion responsible is the gene encoding a ribosomal protein[313] classifies the 5q– syndrome as an acquired and clonal form of Diamond-Blackfan anemia, although one might expect that additional genetic defects must be present to explain the growth advantage of the malignant cells. (It is discussed extensively in *Oncology of Infancy and Childhood*).

Other Causes of Acquired Pure Red Cell Aplasia

Very rarely, children with B-cell proliferative diseases may have concomitant PRCA, but almost all of the therapeutic experience is recorded in adults. Of the few cases of PRCA reported in children, most are in the setting of immunodeficiency. Drug-induced PRCA is by far the most common cause of secondary PRCA in childhood, and azathioprine treatment of renal transplant rejection is by far the most frequent offender.[351] The latter drug usually causes megaloblastic anemia, but it may result in nearly total aplasia. Severe renal failure may also cause PRCA in childhood.

8 Inherited Bone Marrow Failure Syndromes

Monica Bessler, Philip J. Mason, Daniel C. Link, and David B. Wilson

Inherited bone marrow failure syndromes (IBMFSs) are genetic disorders characterized by inadequate blood cell production. Bone marrow failure (BMF) may be manifested as an isolated cytopenia (pure red cell aplasia, neutropenia, or thrombocytopenia) or as pancytopenia and the clinical picture of aplastic anemia. Table 8-1 summarizes the more common forms of IBMFSs, the blood cell lineages affected, their association with malignancies, the genes mutated, their mode of inheritance, their chromosomal location, and the pathway involved. Other organ systems are often affected by these genetic abnormalities and result in birth defects or clinical disease in nonhematopoietic organs. Birth defects and extrahematopoietic manifestations are often characteristic and may be noticed before the onset of BMF. BMF may be present at birth (congenital BMF) or develop later in life. IBMFSs are not always inherited; the genetic mutations responsible may also occur de novo during early embryonic development. Several, but not all of the IBMFSs are characterized by a predisposition for malignant transformation, in particular, malignant transformation of the hematopoietic system, including the development of myelodysplastic syndrome (MDS) and acute leukemia, but also a predisposition for a variety of other forms of cancer.

The prevalence of IBMFSs is difficult to ascertain. Originally, IBMFSs were thought to be mainly diseases of childhood. In children, 25% to 30% of BMF cases were thought to be due to a genetic cause, whereas in adults, an inherited genetic cause was considered only in a minority of patients. However, more recent data suggest that the prevalence of IBMFSs has probably been underestimated, particularly in adults. In addition, improved medical care and long-term survival after bone marrow transplantation (BMT) have extended life expectancy and shifted the management of patients with IBMFSs to adult hematologists.[1]

Timely and correct diagnosis of an IBMFS is of importance because management of an IBMFS differs from that of acquired BMF. Treatment of IBMFSs often requires a complex interdisciplinary approach that includes hematologists, geneticists, endocrinologists, oncologists, orthopedists, neurologists, gastroenterologists, gynecologists, dentists, and other specialists. Furthermore, differentiation between acquired and inherited BMF is of importance not only for affected individuals but also for their family members. Early and correct diagnosis of an IBMFS allows intensified and focused disease surveillance, anticipatory guidance, and avoidance of treatment-related toxicity. Identification of a gene mutation known to be associated with BMF can definitively establish the diagnosis before clinical symptoms advance and help identify an unaffected bone marrow donor in the family. It is therefore important that at the time of initial evaluation maximal effort be made to distinguish acquired from inherited forms of BMF.

Despite the considerable advances that have been made in elucidating the genetic causes of IBMFSs, the mechanisms leading to BMF remain poorly understood. The very nature of the diseases, namely, that the affected bone marrow cells are not dividing, are dying, or are simply absent, confounds laboratory investigations into pathogenesis. Therefore, in the past, investigations of IBMFSs were largely restricted to careful observations and descriptions of clinical manifestations of the patient and family, as well as meticulous study of the clinical course of the disease. However, during the last 10 years a number genes have been identified that when mutated, are responsible for certain forms of IBMFSs (see Table 8-1). Identification of these genes and investigation of their role in hematopoiesis have provided powerful new tools to explore the pathways responsible for BMF. Although IBMFSs have traditionally been classified according to their clinical features, in the future this classification may be supplanted by a definition determined by the affected pathway (see Table 8-1). Interestingly and for many investigators unexpectedly, the pathways affected are often "housekeeping" pathways important for the growth/survival of almost every cell, such as DNA repair, redox-related pathways, telomere maintenance, or ribosome biosynthesis, rather than pathways specific for hematopoiesis. Why hematopoiesis is often preferentially and sometimes even exclusively affected by a derangement in these pathways is intriguing and the focus of current investigations in the field of BMF research.

Accumulating insight into the pathogenetic pathways responsible for IBMFSs and detailed knowledge about the clinical disease continuously reshape our current understanding of IBMFSs and directly impinge on our approach to diagnosis, care, and treatment of patients and their families with IBMFSs. Probably one of the most dramatic emerging insights shared by several IBMFSs is that the severity, onset, and manifestations of disease often vary dramatically and that individuals with the classic clinical features often represent merely the "tip of an iceberg" whose dimensions we are only just beginning to appreciate.[2] IBMFSs or an inherited predisposition to the development of BMF is probably much more common than currently appreciated, not only in the pediatric population but also in adults. With the increased knowledge of how the genetic framework influences the development of BMF, distinguishing between inherited and acquired BMF becomes more difficult. Previously, IBMFSs were restricted mainly to patients with BMF caused by gene mutations with high disease penetrance. Today, it is increasingly being recognized that in addition, a growing number of patients have BMF caused by gene mutations that have lower or very low penetrance, with disease developing only occasionally or just under certain circumstances. Thus, the majority of patients in whom acquired idiopathic aplastic anemia was previously diagnosed in fact have an underlying genetic component responsible for the disease. Gene modifiers and environmental factors are additional factors that influence the penetrance of disease and pathobiology of BMF. Figure 8-1 schematically illustrates the possible interrelationship

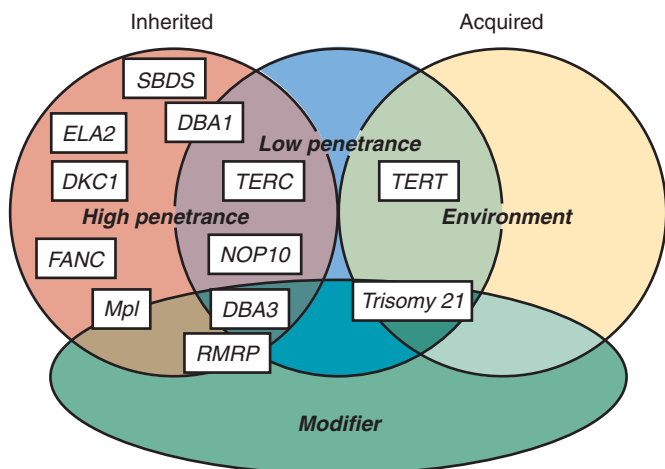

FIGURE 8-1. Interrelationship between disease penetrance of a genetic mutation, the environment, and modifiers in the pathogenesis of bone marrow failure.

| Box 8-1 | **Fanconi's Anemia** |

Fanconi's anemia (FA, MIM 227650) is an autosomal recessive and X-linked disorder characterized by progressive bone marrow failure, congenital abnormalities, and a predisposition for malignancies. Cells from FA patients exhibit spontaneous chromosomal instability and a characteristic hypersensitivity to DNA interstrand cross-linking agents.

| Box 8-2 | **Heritability, Penetrance, and Expressivity** |

Heritability, penetrance, and expressivity are distinct, but related concepts. "Heritability" is the number of family members who have inherited a genotype versus the number of family members who have not. "Penetrance" is defined by the number of individuals who show a phenotype versus the number of individuals who carry the genotype. "Expressivity" measures the variability and severity of an expressed phenotype.

between genetic mutation, environment, and modifiers in the pathogenesis of BMF. The increased understanding of the genetic components and their role and importance in the pathogenesis of disease will allow us to improve diagnosis, management, and treatment of patients with BMF.

INHERITED BONE MARROW SYNDROMES ASSOCIATED WITH PANCYTOPENIA

Fanconi's Anemia

Fanconi's anemia (FA) is a genetically and phenotypically heterogeneous disorder. The disease is named after the Swiss pediatrician Guido Fanconi (1892-1979), who first described the syndrome in 1927.[3] Clinically, FA is characterized by a variety of congenital abnormalities, progressive BMF, and a propensity for the development of leukemia and other forms of cancer. Cells from FA patients have a striking hypersensitivity to DNA interstrand cross-links,[4] which has become the basis of a clinical diagnostic test for FA (Box 8-1).[5]

Epidemiology

The incidence of FA is estimated to be approximately 3 per million with a carrier frequency of 1 in 300.[6,7] Males are affected slightly more frequently than females, with a male-to-female ratio of 1.2:1.[8,9] FA has been reported in all races and ethnic groups. The world's highest prevalence of FA, caused by a founder effect, is seen in Spanish gypsies, who have a carrier frequency of 1 in 70.[10] A high prevalence of FA is also found in individuals of Ashkenazi Jewish decent, who have an approximate heterozygous frequency of 1 in 89,[11] and in South African Afrikaans, in whom carrier frequency is estimated to be 1 in 83.[12,13]

Clinical Manifestations

The clinical manifestations of FA are heterogeneous (variable penetrance and expressivity; for definitions, see Box 8-2). Affected family members can have a wide variety of abnormalities (variable expressivity).[14-18] Even monozygotic twins have been described to differ in their physical and hematologic manifestations.[16] However, the occurrence of malformations is nonrandom. Siblings are usually concordant for the presence or absence of multiple congenital abnormalities; likewise, the age at onset of hematologic manifestations is similar within an individual family.[19] Thus, the variability in clinical findings appears to be partially linked to the different genotypes (also see later).[20-24] The emergence of revertant cells leading to hematopoietic mosaicism further contributes to disease variability (see later).[25-28] Originally, the diagnosis of FA was based on the presence of both aplastic anemia and a specific, though broad range of physical abnormalities.[29] With the availability of more sensitive and specific tests for the diagnosis of FA, including cytogenetic and molecular diagnostics, it has become increasingly evident that a significant proportion of patients lack congenital abnormalities (25% to 40%)[30,31] or aplastic anemia fails to develop, or both (variable penetrance). Nevertheless, these individuals are still at risk for late complications such as leukemia and cancer.

Congenital Abnormalities

The frequency of congenital abnormalities within the FA population is summarized in Table 8-2. Box 8-3 further details the nature of anomalies found in patients with FA. Figure 8-2A shows a 1-year-old girl with FA, and Figure

TABLE 8-2	Physical Abnormalities in Fanconi's Anemia*	
Abnormality	**Alter,[9] 2003**	**IFAR[16,32]**
Total number of patients	1206	>700
Skin pigment and/or café au lait spots	55%	64%
Short stature	51%	63%
Skeletal abnormality (radial ray, hip, vertebral scoliosis, rib)	71%	—
Upper limbs	43%	49%
Abnormal gonads, male	32%	20%
Abnormal gonads, female	3%	—
Head	26%	—
Central nervous system	—	8%
Eyes	23%	38%
Renal	21%	34%
Birth weight ≤2500 g	11%	—
Developmental disability	11%	16%
Ears, hearing	9%	11%
Legs	8%	—
Cardiopulmonary	6%	13%
Gastrointestinal	5%	14%
No anomalies	25%	30%
Short stature and/or skin only	11%	—

*Data represent percentages of patients with the abnormality. IFAR, International Fanconi Anemia Registry.

8-2C shows a 12-year-old boy with several classic phenotypic features, including short stature, microencephaly, broad nasal bridge, epicanthal folds, micrognathia, café au lait spots and hypopigmentation, and an absent and a triphalangeal thumb. FA patients may have a combination or none of the congenital anomalies listed. The phenotypic variability makes a diagnosis of FA difficult when based only on clinical features.

Endocrinopathies

Data from the International Fanconi Anemia Registry (IFAR) indicate that endocrine abnormalities are present in 81% of FA patients, primarily glucose/insulin abnormalities, growth hormone insufficiency, hypothyroidism, and hypogonadism.[31,33,34]

Short Stature. Although short stature is an integral feature of FA,[17,35] a superimposed endocrinopathy may have an additional impact on growth and is responsive to growth hormone therapy.[36,37] Detection of an anatomic abnormality of the hypothalamic-pituitary region by magnetic resonance imaging is a diagnostic marker of permanent growth hormone deficiency. In patients 18 years or older, osteopenia or osteoporosis is frequent.[34]

Fertility. Female patients with FA usually have a shortened reproductive life because of secondary amen-orrhea, irregular menses, anovulatory menstrual cycles, and premature menopause. Congenital abnormalities in the female genitourinary tract further limit fecundity. Though rare, pregnancies have been reported in women with FA. The babies born were normal, and the pregnancies seemed to not have had a significant impact on the mother's hematologic manifestations.[38,39] Pregnancy in women with FA has also been reported after BMT.[40-43] Cryptorchidism, hypogenitalism, hypergonadotropic hypogonadism, and reduced sperm counts are frequent in male patients with FA. Reports of male FA patients fathering children are rare.[44]

Hematologic Abnormalities

Progressive BMF is one of the hallmarks of FA, although the hematologic findings vary. Thrombocytopenia and macrocytosis often precede anemia and neutropenia. Elevated hemoglobin F levels[45] and elevated expression of "i" antigen on red cells usually coincide with macrocytosis and are suggestive of stress hematopoiesis.[46,47] Serum α-fetoprotein levels are consistently elevated in FA patients irrespective of the presence of liver abnormalities.[48] Erythropoietin levels are usually elevated in anemic FA patients. The first hematologic abnormalities in individuals with FA are detected at a median age of 7 years. The majority of FA patients already have pancytopenia at the time of diagnosis (53%). By the age of 40, the cumulative incidence of hematologic abnormalities is 90% to 98%.[21,49]

In rare cases, thrombocytopenia may be present at birth and progress to pancytopenia in the neonatal period or infancy.[19,50,51] Thus, FA also has to be considered in cases of aplastic anemia in neonates and infants. In other patients, hematologic abnormalities never become clinically evident, and the diagnosis of FA is made later in life as a result of late FA-associated complications such as cancer or leukemia. The emergence of revertant cells leading to hematopoietic mosaicism is often associated with a mild or absent hematologic phenotype (also see later). Finally, in a small proportion (2% to 5%) of FA patients, MDS or leukemia is diagnosed but the underlying BMF never becomes clinically apparent.[19,52] Bone marrow examination generally shows reduced cellularity; however, it may also be normocellular or hypercellular, particularly in individuals evolving into MDS or MDS/acute myeloid leukemia (AML). BMF is usually progressive. Fifty percent of individuals who are initially found to have thrombocytopenia progress to pancytopenia within 3 to 4 years. The actuarial risk of progression to pancytopenia is 84% at 20 years after the initial diagnosis of thrombocytopenia.[19]

Bone marrow culture studies show an intrinsic proliferation defect in hematopoietic progenitor cells from FA patients with and without clinical signs of BMF.[53,54] Hematopoietic progenitor cells are exquisitely sensitive to oxidative stress.[53,55,56] Expression of tumor necrosis factor-α (TNF-α) and interferon-γ (IFN-γ) is increased in FA patients.[57-59]

Box 8-3	Specific Types of Anomalies in Fanconi's Anemia

SKIN

Generalized hyperpigmentation on the trunk, neck, and intertriginous areas; café au lait spots; hypopigmented areas

BODY

Short stature, delicate features, small size, underweight

UPPER LIMBS

Thumbs: absent or hypoplastic; supernumerary, bifid, or duplicated; rudimentary; short, low-set, attached by a thread; triphalangeal, tubular, stiff, hyperextensible

Radii: absent or hypoplastic (only with abnormal thumbs); absent or weak pulse

Hands: clinodactyly; hypoplastic thenar eminence; six fingers; absent first metacarpal; enlarged, abnormal fingers; short fingers, transverse crease

Ulnae: dysplastic

GONADS

Males: hypogenitalia, undescended testes, hypospadias, abnormal genitalia, absent testis, atrophic testes, azoospermia, phimosis, abnormal urethra, micropenis, delayed development

Females: hypogenitalia; bicornuate uterus; abnormal genitalia; aplasia of the uterus and vagina; atresia of the uterus, vagina, and ovary

OTHER SKELETAL ANOMALIES

Head and face: microcephaly, hydrocephalus, micrognathia, peculiar face, bird-like face, flat head, frontal bossing, scaphocephaly, sloped forehead, choanal atresia, dental abnormalities

Neck: Sprengel's deformity; short, low hairline; webbed

Spine: spina bifida (thoracic, lumbar, cervical, occult sacral), scoliosis, abnormal ribs, sacrococcygeal sinus, Klippel-Feil syndrome, vertebral anomalies, extra vertebrae

EYES

Small eyes, strabismus, epicanthal folds, hypertelorism, ptosis, slanting, cataracts, astigmatism, blindness, epiphora, nystagmus, proptosis, small iris

EARS

Deafness (usually conductive); abnormal shape; atresia; dysplasia; low-set, large or small; infections; abnormal middle ear; absent drum; dimples; rotated; canal stenosis

KIDNEYS

Ectopic or pelvic; abnormal, horseshoe, hypoplastic, or dysplastic; absent; hydronephrosis or hydroureter; infections; duplicated; rotated; reflux; hyperplasia; no function; abnormal artery

GASTROINTESTINAL SYSTEM

High-arched palate, atresia (esophagus, duodenum, jejunum), imperforate anus, tracheoesophageal fistula, Meckel's diverticulum, umbilical hernia, hypoplastic uvula, abnormal biliary ducts, megacolon, abdominal diastasis, Budd-Chiari syndrome

LOWER LIMBS

Feet: toe syndactyly, abnormal toes, flatfeet, short toes, clubfeet, six toes, supernumerary toe

Legs: congenital hip dislocation, Perthes' disease, coxa vara, abnormal femur, thigh osteoma, abnormal legs

CARDIOPULMONARY SYSTEM

Patent ductus arteriosus, ventricular septal defect, abnormal heart, peripheral pulmonic stenosis, aortic stenosis, coarctation, absent lung lobes, vascular malformation, aortic atheromas, atrial septal defect, tetralogy of Fallot, pseudotruncus, hypoplastic aorta, abnormal pulmonary drainage, double aortic arch, cardiac myopathy

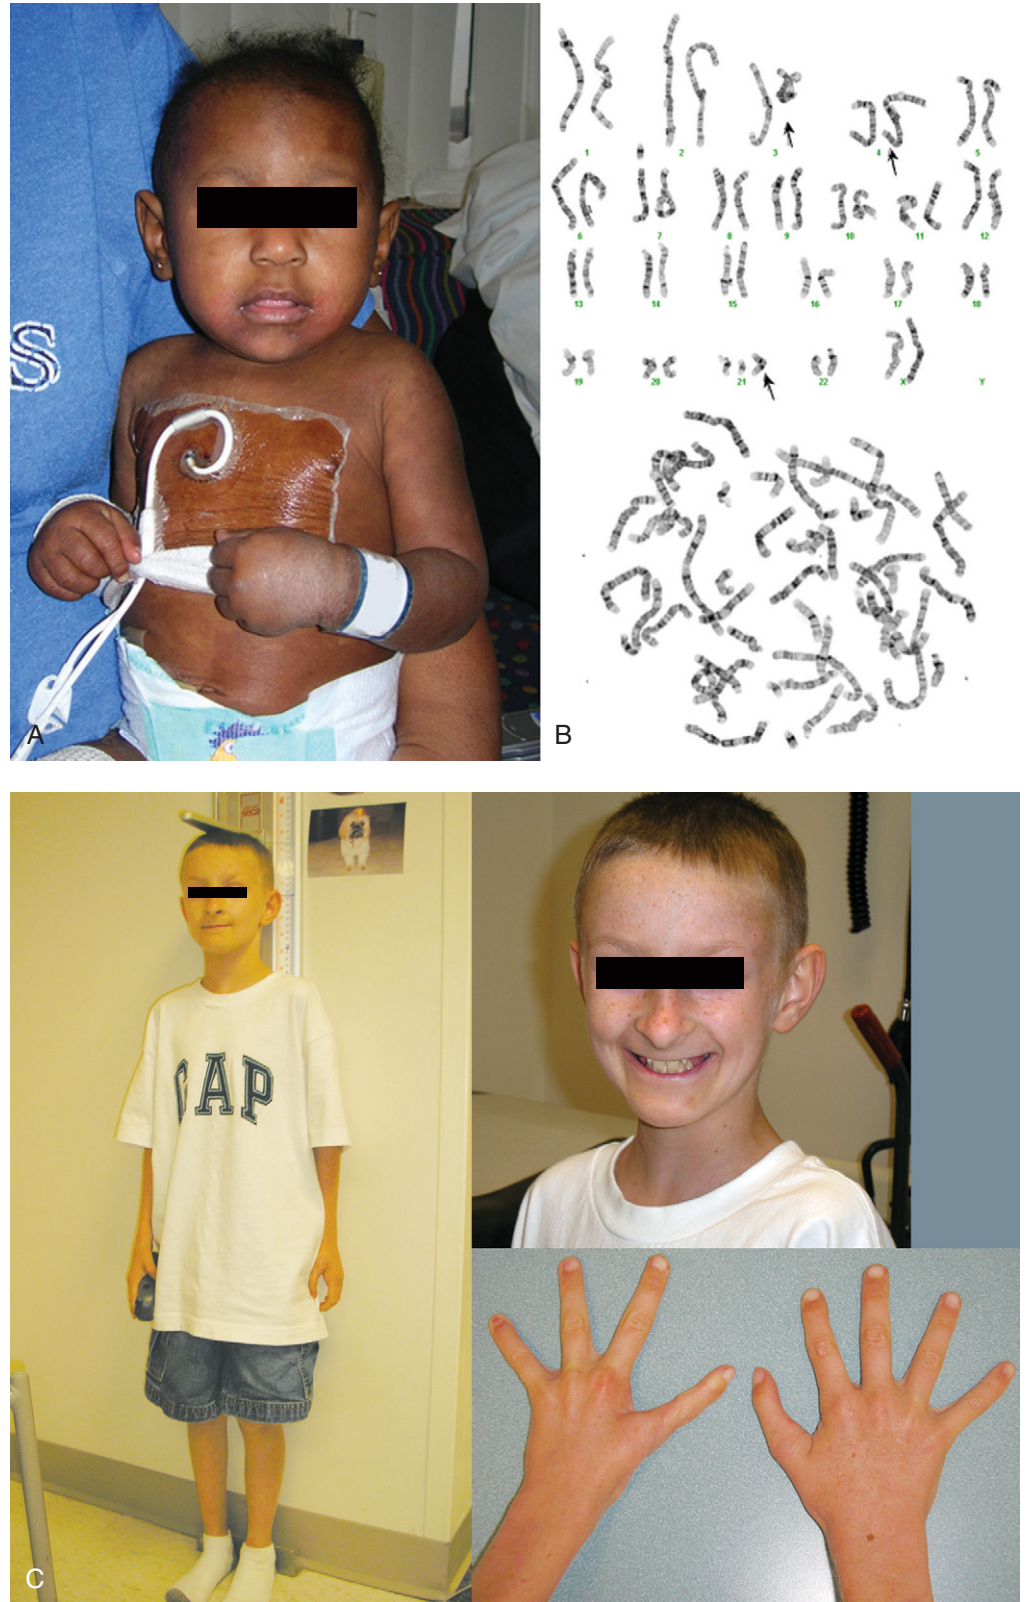
OTHER ANOMALIES

Slow development, hyperreflexia, Bell's palsy, central nervous system arterial malformation, stenosis of the internal carotid artery, small pituitary gland, absent corpus callosum

*Abnormalities are listed in approximate order of frequency within each category.

Modified from Alter BP. Inherited bone marrow failure syndromes. In Nathan DG, Orkin SH, Ginsburg D, Look AT (eds). Nathan and Oski's Hematology of Infancy and Childhood, vol 1, 6th ed. Philadelphia, WB Saunders, 2003, pp 281-365.

Myelodysplastic Syndrome in Patients with Fanconi's Anemia. The risk of MDS developing in FA patients is estimated to be approximately 6%. In the literature the definition of MDS in FA patients varies, which prevents strict comparison and also suggests that a conventional definition of MDS might not always be appropriate. Nonrandom X-inactivation, suggesting clonal hematopoiesis, may be present at the time of BMF before the onset of MDS.[60,61] Clonal cytogenetic abnormalities are found in 34% to 48% of FA patients.[19,62] The actuarial risk of a chromosomal abnormality developing is 67% by the age of 30 years.[19] Clonal fluctuations are frequent, including the disappearance of clones, the appearance of new clones, and clonal evolution.[62,63] Chromosomal abnormalities in MDS most frequently involve chromosomes 1q, 7 (monosomy, isochromosome, or other structural rearrangement), 6, and 13.[19,64,65] Individuals in whom clonal cytogenetic abnormalities develop have

FIGURE 8-2. A, Infant girl with Fanconi's anemia who exhibited several classic phenotypic features, including short stature, microcephaly, broad nasal base, epicanthal folds, micrognathia, and café au lait spots (left side of the forehead). **B,** Cytogenetic findings in peripheral blood lymphocytes in Fanconi's anemia after culture with diepoxybutane. **C,** Twelve-year-old boy with Fanconi's anemia. The classic phenotypic features include short stature, microcephaly, broad nasal base, epicanthal folds, micrognathia, café au lait spots (chin and left temple), absent thumb left (after reconstructive surgery), and triphalangeal thumb left. (**B,** *Courtesy of Shashikanat Kulkarni, Washington University.*)


a reduced survival rate of 35% to 40% as opposed to 92% in FA patients without such abnormities. MDS morphology, as defined by dysplasia in multiple blood cell lineages and found in 32% of patients, has a worse predictive value with a 5-year survival rate of 9%. None of the patients with both morphologic MDS and cytogenetic abnormalities (22%) survived 5 years.[19,62] The yearly risk of progression from MDS to AML is estimated to be about 9%.[66] Gain of the distal portion of chromosome 3q(26-29), frequently present in FA patients even before

the onset of MDS, is associated with a poor prognosis, decreased survival, and an increased frequency of MDS and AML.[67-69]

Predisposition to Malignancy. A major phenotype of FA is a predisposition for cancer, including leukemia and solid tumors. The risk of cancer developing is about 800 to 1000 times higher than in the normal population. There are three reports of the occurrence of solid tumors and leukemia in cohorts of patients with FA (see also Table 8-3). One is a retrospective analysis of the literature between 1927 and 2001 that included 1301 patients with FA.[70] The second, from the IFAR at the Rockefeller Institute in New York, included 754 North American patients evaluated between 1982 and 2001.[21] The third is a North American Survey that included 145 patients.[66] The crude risk of leukemia developing is estimated to be between 5% and 10%, and that for MDS is about 5%, with a yearly risk of evolution to leukemia of about 9%. The crude risk of solid tumors developing is estimated to be

about 5% to 10%. By the age of 40, the cumulative incidence of leukemia and solid tumors is estimated to be approximately 33% and 26% to 30%, respectively. The median age at development of cancer is 16 years versus 68 years for the same types of cancer in the general population. The risk of solid tumors and leukemia developing increases with age. Thus, patients with mild hematologic and phenotypic abnormalities and the longest survival are at the highest risk for the development of tumors or leukemia.[18] However, with increased survival after hematopoietic stem cell transplantation (HSCT), the frequency of cancer might also increase in patients with more severe disease.[1] The most frequent cancers occur in the neck, head, and upper esophagus, followed by the vulva, anus, and lower esophagus. The role of human papillomavirus in the pathogenesis of squamous cell cancer in patients with FA is controversial.[71,72] The risk for development of squamous cell cancer of the head and neck and particularly the tongue is higher in FA patients after HSCT than in those without HSCT and

correlates with the presence and severity of graft-versus-host disease.[49,73] Adenoma of the liver and hepatocarcinoma were found mainly in patients undergoing androgen therapy.[70,74,75] Hepatoadenomas usually regress after cessation of androgen therapy.[76] Multiple neoplasms in patients with FA are not uncommon.[21,70,77]

Leukemia is the most frequent malignancy in patients with FA.[1,21,66,70,78] AML is the most frequent leukemic phenotype, although patients with acute lymphocytic leukemia (ALL) and chronic myelomonocytic leukemia have also been described. The morphologic-histochemical classification developed by the French-American-British (FAB) Cooperative Group[79-82] describes all categories of AML (M0 to M7) in patients with FA, with the exception of M3 (promyelocytic morphology), which has never been reported in patients with FA.[70] The leukemia in FA patients, however, is clinically and molecularly very different from that in the general pediatric and adult population. Chromosomal translocations characteristic of some forms of adult or childhood AML, such as translocation between chromosomes 8 and 21, are not usually found in FA patients with AML.[64] Thus, the conventional FAB classification used to predict a patient's prognosis does not apply to patients with FA and leukemia. However, leukemia in patients with FA shows many molecular and clinical similarities to leukemia occurring in other IBMFSs. Leukemia in FA patients is often difficult to treat, and most patients die within 6 month of diagnosis. Leukemia in patients with FA may arise de novo or develop from MDS. In some FA patients, AML may be the first hematologic manifestation of disease.[52] Leukemic cells often show complex cytogenetic abnormalities, including abnormalities similar to those seen in MDS. Abnormalities of chromosome 7 (monosomy, isochromosome, or other structural rearrangement), followed by abnormalities of 1q (usually duplications), are the most frequent in FA-associated leukemia.[19,64,65,83]

The risk and type of cancer vary for different FA subtypes (also see later). FA patients belonging to complementation group D1 (FA-D1) with biallelic mutations in *FANCD1/BRCA2* have a high risk for the development of malignancies at a very young age, frequently before manifestations of BMF appear, and the cumulative risk for AML or other cancer is 97% by the age of 5.2 years. In addition, the spectrum of cancer is distinct, with medulloblastoma being the predominant malignancy,[24,84,85] possibly because BRCA2 participates in DNA repair outside the FA pathway (see later also). An increased risk for childhood cancer with a very similar spectrum has also been found in families belonging to the FA-N subtype.[86] FANCN/PALB2 binds to BRCA2 and facilitates its binding to chromatin (see later).[87] The interaction between these two proteins explains the similar cancer predisposition in FA individuals belonging to the FA-D1 and FA-N subgroups.

Common to all FA cancer patients is low tolerance for DNA-damaging chemotherapeutic agents. Accordingly, chemotherapeutic regimens often need to be modified, given at low dosage, or avoided in favor of alternative or surgical approaches (also see later).[88]

Diagnosis

The most widely used diagnostic test for FA is hypersensitivity to the clastogenic (chromosome-breaking) effect of diepoxybutane (DEB) or mitomycin C (MMC).[5,89] The increased spontaneous chromosomal instability of FA cells leads to distinctive chromosomal breaks, gaps, and various chromatid interchanges, which were previously used as a cellular marker for FA.[90,91] The frequency of spontaneous chromosomal instability in FA cells is highly variable,[90] and it is thought to be responsible for the increased susceptibility of FA patients to cancer. The sensitivity of FA cells to the clastogenic effect has been studied for numerous cross-linking agents,[4] but DEB and MMC are the agents most widely used for the diagnosis of FA.[5,89] Figure 8-2B shows the increased chromosome breakage after culture in DEB. The diagnosis of FA is made when DEB-treated cultured lymphocytes demonstrate a 3- to 10-fold increase in chromosomal breakage over normal controls.[92] The tests are highly sensitive and fairly specific for FA and are used for the diagnosis of FA before the development of clinical disease and for prenatal diagnosis.[5,93-96] A possible rare exception that can result in a pattern of DEB- or MMC-induced chromosomal breakage similar to that found in FA patients is an individual with specific mutations in the *NBS1* gene in the Nijmegen breakage syndrome.[97-100] However, more frequently, the presence of revertant cells in the specimen may complicate the interpretation of DEB or MMC test results (see later). It is estimated that 10% to 25% of FA patients exhibit two populations of phytohemagglutinin-stimulated lymphocytes, one that is sensitive to the clastogenic effects of DNA cross-linking agents and one that is resistant.[26,101] Thus, the presence of only few metaphases with multiple structural chromosomal changes might indicate FA with somatic mosaicism. In these cases, demonstration of increased chromosomal breakage in patients' DEB- or MMC-treated fibroblasts might help confirm the diagnosis of FA (see later also).

Immunoblotting for FANCD2 Monoubiquitination

Biallelic mutations in 10 of the 13 FA genes (*FANC* genes) lead to failure of FANCD2 monoubiquitination, and failure of FANCD2 monoubiquitination is specific for a defect in the FA pathway (see later). Testing for FANCD2 monoubiquitination by immunoblotting of peripheral blood lymphocytes and fibroblasts has therefore been proposed as an alternative first-line diagnostic tool for the diagnosis of FA.[102,103] Biallelic mutations in *FANCD1/BRCA2*, *FANCJ*, and *FANCN/PALB2*, which have normal FANCD2 monoubiquitination but an abnormal DBE or MMC test (or both), are missed with this diagnostic assay and require additional testing.

Genetic Testing for FANC Gene Mutations

Although only identification of biallelic mutations in a *FANC* gene definitively confirms the diagnosis of FA, genetic testing is not usually recommended as a first-line diagnostic tool for the diagnosis of FA. Possible exceptions are families with a known *FANC* gene mutation and FA in a population with a high frequency of a founder mutation, for example, a case of FA in Spanish gypsies (also see later). The indication, advantages, and difficulties of genetic testing for biallelic mutations in *FANC* genes are discussed later.

Cellular Phenotype of Fanconi's Anemia Cells

In addition to increased spontaneous and induced chromosomal instability, FA cells have several other phenotypic characteristics (Table 8-4). FA cells have increased sensitivity to other DNA-damaging agents, such as ionizing radiation and oxygen radicals.[4,5,109-111,123-125,157-159] FA cells have an abnormality in cell cycle distribution, with an increased number of cells with $4N$ DNA content suggesting a delay in the G_2/M or late S phase (or both) of the cell cycle.[145] The increase in cells with $4N$ DNA content is accentuated after treatment with interstrand DNA cross-linking agents. Flow cytometric measurements of the increase in the proportion of cells with $4N$ DNA content after DNA cross-linking agents may be used as an additional criterion for the diagnosis of FA.[112,113] However, similar results have been obtained in patients with ataxia-telangiectasia.[159a] FA cells show accelerated telomere shortening in vitro and an increase in telomere free ends and chromosome end fusions, thus suggesting a defect in maintenance of telomere integrity and increased breakage at telomeric sequences.[115,116]

Differential Diagnosis

Clinically, FA has to be differentiated from other IBMFSs, particularly dyskeratosis congenita (DC), Diamond-Blackfan anemia (DBA), Shwachman-Diamond syndrome (SDS), thrombocytopenia with absent radii (TAR), and other nonclassified forms of BMF. Clinical manifestations, associated physical abnormalities, family history (pattern of inheritance), and increased chromosomal fragility in the DEB or MMC test performed on cultured peripheral lymphocytes or fibroblasts, or both, are helpful in strengthening the diagnosis of FA. However, only identification of pathogenic mutations on both copies of an FA gene (biallelic mutation) may definitely consolidate the diagnosis of FA. Congenital abnormities in FA may have an overlap with malformations seen in other disorders with genetic and nongenetic causes. Thrombocytopenia and radial ray abnormalities are also characteristic of TAR (see later). However, in FA, if the radii are affected, the thumbs are always abnormal; in TAR, in which the radii are absent, thumbs are always present. Other syndromes that have phenotypic overlap with FA include Holt-Oram syndrome (Mendelian

TABLE 8-4	Cellular Abnormalities in Fanconi's Anemia
Feature	**References**
Spontaneous chromosome breaks	90, 101, 104-108
Sensitivity to cross-linking agents	4, 5, 89, 109-111
Prolongation of the G_2/M and S phase of the cell cycle	112-114
Accelerated telomere shortening	115-118*
Hypersensitivity to ionizing radiation[†]	119-122
SENSITIVITY TO OXYGEN	
Poor growth at ambient O_2	123-126
Overproduction of O_2 radicals	127
Deficient O_2 radical defense	128
Deficiency in superoxide dismutase	129, 130
Sensitivity to ionizing radiation during G_2	131
Overproduction of TNF-α	132
DIRECT DEFECTS IN DNA REPAIR	
Accumulation of DNA adducts	133
Defective repair of DNA cross-links	134, 135
Hypermutability (by deletion)	136-140
Increased apoptosis	141-143
Abnormal induction of p53	142, 144
Failure to arrest DNA synthesis in response to DNA damage	145, 146
Defective nonhomologous end joining	147-149
Increased homologous recombination	150, 151[‡]
INTRINSIC STEM CELL DEFECT	
Decreased colony growth in vitro	53, 54, 152-154
Decreased gonadal stem cell survival	155, 156

*Experiments in mice suggest that accelerated telomere shortening is not a direct effect of Fanconi's anemia gene products on telomeres but rather an indirect effect, such as increased sensitivity to oxygen radicals.

[†]Hypersensitivity to ionizing radiation is controversial. More recent results suggest increased sensitivity in the majority of Fanconi's anemia complementation groups.

[‡]The defect has been found in only some but not in all Fanconi's anemia complementation groups.

Modified from D'Andrea AD, Grompe M. Molecular biology of Fanconi anemia: implications for diagnosis and therapy. Blood. 1997;90:1725-1736.

Inheritance in Man [MIM] 142900), which is characterized by thumb anomalies and atrial septal defects and caused by mutations in the *TBX5* gene, and the Baller-Gerold (MIM 218600) syndrome and Rothmund-Thomson syndrome (MIM 278400), which are caused by mutations in the *RECQL4* gene and characterized by radial defects, craniosynostosis, and cancer predisposition but no BMF. FA patients may have the VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia) or VACTERL (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, and/or esophageal atresia, renal agenesis and dysplasia, and limb defects) association (MIM 192350) or the IVIC syndrome (MIM 147750), which is an acronym for Instituto Venezolano

de Investigaciones Cientificas, the institution where a family with autosomal dominant radial ray defects, hearing impairment, internal ophthalmoplegia, and thrombocytopenia was first described. Chromosome breakage tests were normal in these families.

The increased chromosomal breakage in FA has to be distinguished from that seen in Bloom's syndrome (MIM 210900), another single-gene disorder with a predisposition for leukemia as a result of mutation in the helicase RecQ protein-like-3 gene (*RECQL3*). Chromosomal aberrations are in general more numerous in FA cells than in Bloom cells. Furthermore, in Bloom's syndrome, most interchanges occur between homologous chromosomes, whereas in FA they are more frequently seen between nonhomologous chromosomes.[91] Interestingly, more recent experimental data suggest that the Bloom and FA pathways may be connected and that protein complexes formed by *RECQL3* are abnormal in cell lines from FA patients.[160,161]

Nijmegen's breakage syndrome (MIM 251260), caused by mutations in the *NBS1* gene and characterized by immunodeficiency and a predisposition to lymphoma, is an additional autosomal recessive chromosomal breakage disease. A small number of patients may have FA-like features, including BMF and the development of myeloid leukemia,[100,162] and certain mutations in the *NSB1* gene cause an increased clastogenic response to MMC and DEB. The similarities between these two disorders suggested an interaction between these proteins. In fact, the NSB1 protein interacts with the FANCD2 protein in two distinct cellular functions, one involved in the DNA cross-link response and other involved in the S-phase checkpoint response (see later).[97,163]

A third disease associated with spontaneous chromosomal breakage and hematopoietic malignancies is ataxia-telangiectasia (MIM 208900), which has autosomal recessive inheritance. Cells from patients with ataxia-telangiectasia are hypersensitive to ionizing radiation but not to cross-linking agents. Furthermore, it is associated with immunodeficiency and progressive cerebellar neuronal degeneration, which clearly distinguish this condition from FA. Interestingly, the product of the gene mutated in ataxia-telangiectasia, ataxia-telangiectasia mutated (ATM), interacts with the pathway affected in FA in response to ionizing radiation by phosphorylating FANCD2 (also see later).

One form of Seckel's syndrome (SCKL1, MIM 210600), caused by mutations in the gene encoding ataxia-telangiectasia and RAD3-related protein (*ATR*), may have some clinical similarities to FA, including anemia and an increased risk for AML. ATR interacts with the FA pathway and is essential for efficient FANCD2 monoubiquitination (also see later).[164]

DNA ligase IV (*LIG4*)-deficient patients are characterized by microcephaly, growth retardation starting in utero, distinctive facial appearance ("bird-like face"), developmental delay, immunodeficiency, pancytopenia, and pronounced clinical and cellular radiosensitivity. LIG4 deficiency is another rare IBMFS caused by defective DNA repair.[164,165]

Genetics

Inheritance. FA is a genetically heterogeneous recessive disorder. Mutations in at least 13 different genes, all of which have been identified, may be responsible for FA. Inheritance of FA is autosomal or, in rare cases, X-linked.

Complementation Groups. At least 13 genetic subtypes or complementation groups have been identified (FA-A, FA-B, etc.), each with a distinctive disease gene (Fanconi's anemia gene A [*FANCA*], *FANCB*, etc.). The majority of patients belong to complementation group A (approximately 60% to 70%), followed by complementation groups C and G. Table 8-5 shows the complementation groups and the genes responsible for FA and their frequency as estimated from data from the IFAR.[184] Complementation groups were originally defined by somatic cell fusion and the ability of the heterokaryon to correct the MMC hypersensitivity as measured in a growth inhibition assay.[187-190] Correction of the MMC hypersensitivity indicates that the two fusion partners belong to different complementation groups, whereas no correction indicates that they belong to the same complementation group. More recently and as more *FANC* genes are identified, complementation groups are assigned through the correction of MMC hypersensitivity after introduction of the respective wild-type cDNA (complementation by cDNA expression). Retroviruses expressing *FANC* cDNA may be used to correct the phenotype of T cells from FA patients, which determines the complementation group in a rapid, accurate manner.[191]

Fanconi Genes (*FANC* Genes). *FANC* genes have been identified by expression cloning, positional cloning, protein complex purification, or a combination thereof and are summarized in Table 8-5. Figure 8-3 schematically represents the 13 *FANC* genes and their functional domains. Complementation cloning is based on the principle that the wild-type variant of the defective gene will complement or correct the phenotype (the phenotype of FA cells is MMC hypersensitivity; also see earlier). Complementation cloning is a very powerful method that led to the identification of numerous disease genes, including the *FANCC*,[168] *FANCA*,[192] *FANCG*,[173] *FANCF*,[172] and *FANCE*[171] genes. The *FANCA* gene was also identified independently by positional cloning.[193] *FAND2*[170,194] and *FANCJ*[178,179,195] were cloned by using a combination of positional and expression cloning. *FANCD1* and *FANCN* were identified as FA genes by a candidate gene approach. Screening for mutation in the *BRCA2* gene revealed biallelic pathogenic mutations in patients belonging to the FANCD1 complementation group.[169] Similarly, sequencing of *PALB2* revealed biallelic pathogenic mutations very similar to those in *FANCD1* patients, but not *BRCA2*

TABLE 8-5   Thirteen Complementation Groups and Genes Responsible for Fanconi's Anemia

Complementation Group	Responsible Gene	% of FA Patients	Locus	Protein Size (kd)	FANCD2 Monoubiquitination	Main Function of the Protein	Comments	References
FA-A	*FANCA*	57-65	16q24.30.3	163	+	FA core complex	Phosphorylated after DNA damage	166
FA-B	*FANCB*	0.3	Xp22.31	95	+	FA core complex		167
FA-C	*FANCC*	9-15	9q22.3	63	+	FA core complex		168
FA-D1	*FANCD1/ BRCA2*	3-4	13q12-13	380	−	RAD51 recruitment		169
FA-D2	*FANCD2*	3-6	3p25.3	155, 162	+	Monoubiquitinated protein (part of the FANCI-FAND2 subcomplex) Phosphorylated upon DNA damage	Phosphorylated and monoubiquitinated after DNA damage	170
FA-E	*FANCE*	1	6p21-22	60	+	FA core complex	Direct binding to FANCD2 Phosphorylated after DNA damage	171
FA-F	*FANCF*	2	11p15	42	+	FA core complex		172
FA-G	*FANCG/XRCC9*	8-9	9p13	68	+	FA core complex		173
FA-I	*FANCI*	Rare	15q25-26	150	+	Monoubiquitinated protein (part of the FANCI-FAND2 subcomplex)	Phosphorylated and monoubiquitinated after DNA damage Binds to FACND2	174-177
FA-J	*FANCJ/BACH1/ Brip1*	1.6-3	17q22-q24	130	−	5′ → 3′ DNA helicase/ ATPase	Binding to BRCA1	178, 179
FA-L	*FANCL/PHF9/ POG/FAAP43*	0.1	2p16.1	43	+	FA core complex, ubiquitin ligase		180
FA-M	*FANCM/Hef/ FAAP250*	Rare	14q21.3	250	+	FA core complex, ATPase/translocase ? Sensor for DNA cross-link damage	Helicase/nuclease motif Phosphorylated after DNA damage	181
FA-N	*FANCN/PALB2*	Rare	16p12	130	−	Binding partner of BRCA2	Binding to BRCA2	87, 182, 183

+, gene required for FANCD2 monoubiquitination; −, gene not required for FANCD2 monoubiquitination; ?, possible; NA, not applicable.

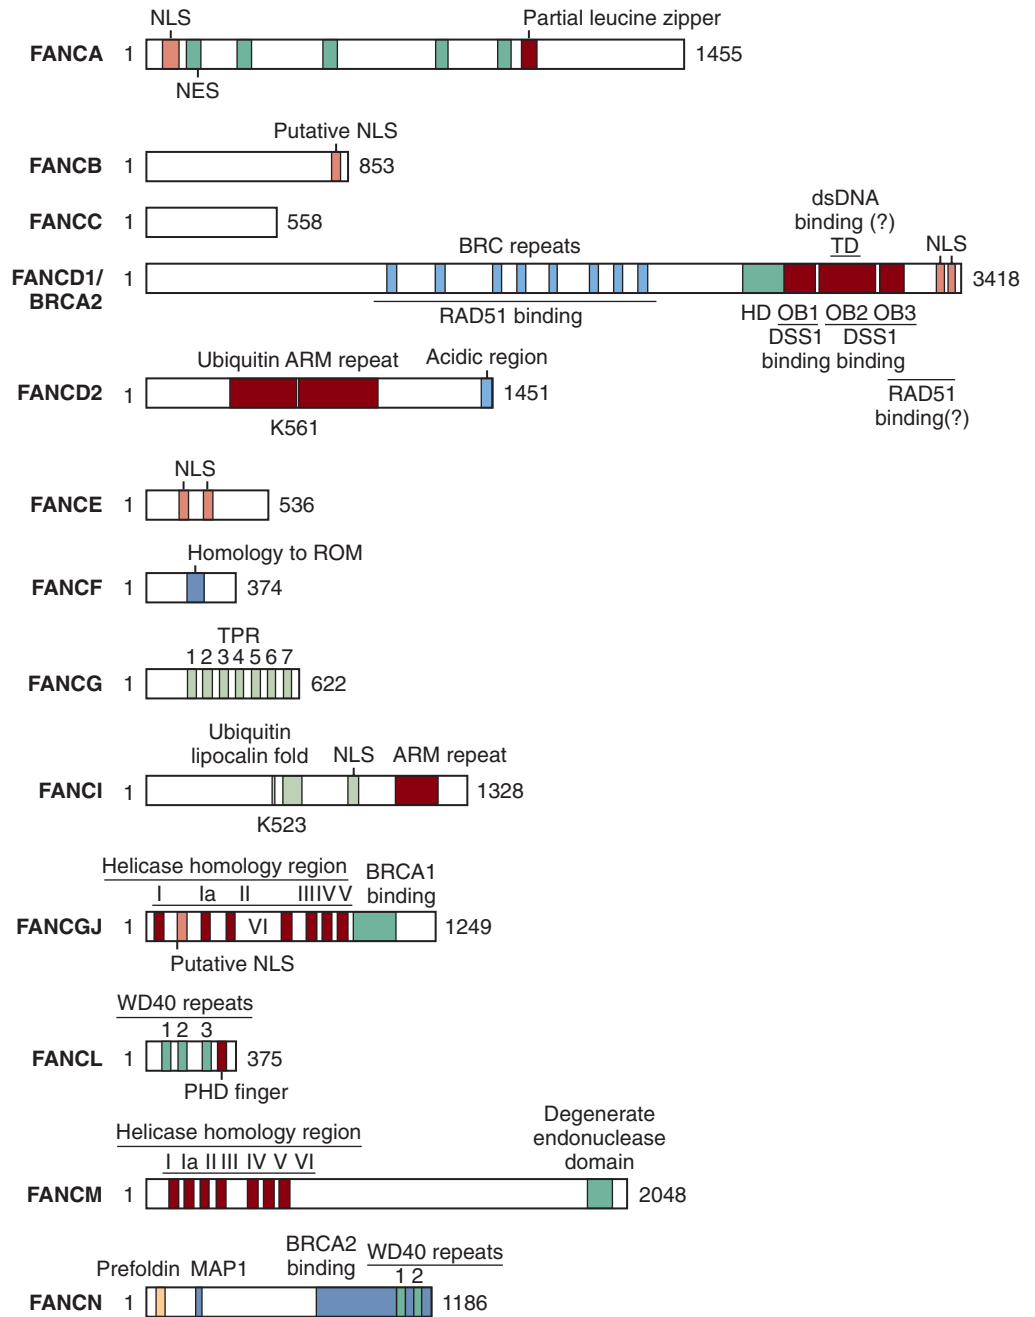

FIGURE 8-3. Schematic representation of the 13 Fanconi's anemia genes and their functional domains. dsDNA, double-stranded DNA; NES, nuclear export sequences; NLS, nuclear localization signals; OB, oligonucleotide/oliosaccharide-binding folds; ssDNA, single-stranded DNA; TD, tower domain; TRP, tetratricopeptide repeat. *(Modified from Taniguchi T, D'Andrea AD. Molecular pathogenesis of Fanconi anemia: recent progress. Blood. 2006;107: 4223-4233.)*

mutations.[86,182] FANCL, FANCB, and FANCM were identified as proteins binding to FANCA. They were initially called Fanconi's anemia–associated proteins (FAAP), followed by a number corresponding to their approximate molecular weight. Mutation screening revealed biallelic mutations in the gene encoding FAAP43 in cells from FA patients belonging to complementation group FANCL[180] and in the gene encoding FAAP250 in cells from patients with FANCM.[181] The gene encoding FAAP95 is on the X chromosome and was found to carry a mutation in the four cell lines from male patients belonging to complementation group FANCB.[167] A fourth protein, FAAP100, has not yet been associated with FA.[160] The most recently identified FA gene is the *FANCI* gene, which was identified almost simultaneously by three different groups of investigators.[174-176]

Function of the FANC Proteins. The FANC proteins have been shown to act during the S phase of the cell cycle[97,145,146,161, 196-207] and are thought to participate in DNA repair of lesions encountered during DNA replication.[184,185,208-213] It is generally thought that FANC proteins promote and coordinate three DNA repair pathways: translesion synthesis at replication-blocking lesions and repair of broken replication forks by homologous recombination and possibly through DNA end joining (nonhomologous end joining) in the absence of homologous recombination.[214,215] Thus, it is thought, as schematically

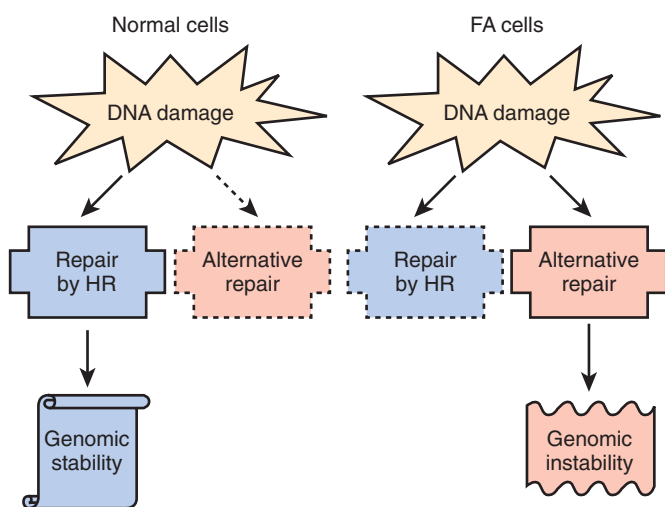
summarized in Figure 8-4, that in normal cells the FA pathway serves to minimize the severity of mutational outcomes by favoring error-free DNA repair and error-prone DNA repair that results in base pair substitutions or small deletions over DNA repair that results in larger deletions and chromosomal rearrangements (Box 8-4 summarizes the main DNA repair pathways).[208,218] However, exactly how these proteins function remains elusive.


FIGURE 8-4. Presumed function of the Fanconi anemia (FA) DNA repair pathway. In normal cells, the FA pathway ensures correct DNA repair, whereas error-prone alternative pathways are rarely used. In FA cells, error-free DNA repair by homologous recombination (HR) is impaired, so alternative DNA repair pathways are more frequently used and lead to genomic instability and cell death. *(Modified from Levitus M, Joenje H, de Winter JP. The Fanconi anemia pathway of genomic maintenance. Cell Oncol. 2006;28:3-29.)*

Box 8-4	**DNA Repair Pathways***

DNA repair pathways are highly regulated pathways that involve detection of DNA lesions, signaling to recruit DNA repair factors, activation of DNA repair enzymes, and disassembly or degradation of DNA repair factors after repair.

EXCISION OF DAMAGED AND MISMATCHED BASES

Nucleotide excision repair, including global genome repair and transcription-coupled repair
Base pair excision repair
Mismatch repair

REPAIR OF DOUBLE-STRANDED BREAKS

Homologous recombination (generally error free)
Nonhomologous end joining (generally error prone)

DNA STRESS REPLICATION PATHWAY; REPLICATION PATHWAY OF DAMAGED TEMPLATES DURING DNA SYNTHESIS

Translesion DNA synthesis (error prone)

*For review, see Kennedy and D'Andrea[216] and Hoeijmakers.[217]

The current model suggests that eight of the proteins responsible for FA—FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL, and FANCM—are part of a nuclear protein complex (core FA complex) that functions as an ubiquitin ligase, of which FANCL is probably the catalytic subunit.[180] Crystallographic and biologic study demonstrated that FANCE recruits FANCD2 to the FA core complex whereas disease-associated FANCE mutations disrupt the FANCE-FANCD2 interaction.[219] Figure 8-5 schematically summarizes the current view of the FANC protein interconnections in the FA DNA repair pathway. In response to DNA damage or in the S phase of the cell cycle, this complex catalyzes monoubiquitination of the downstream targets, the FANCD2 and FANCI proteins (FANCI-FANCD2 complex). A defect in any of these core proteins results in failure to monoubiquitinate the FANCI-FANCD2 complex, thus underscoring the importance of this modification in the FA pathway. FANCI and FANCD2 are dependent on each other for their respective monoubiquitination. The biochemical mechanism of monoubiquitination of FANCI and FANCD2 is not understood, but the reaction is necessary for association of the FANCI-FANCD2 complex to chromatin and its localization into nuclear foci, where it colocalizes with multiple proteins involved in DNA repair, including BRCA1, RAD51, MRE11-RAD50-NBS1, replication protein A, PCNA, and BRCA2.[97,198,203,221-223] The FANC core complex is also necessary for translocation of the monoubiquitinated FANCI-FANCD2 complex to chromatin. Indeed, FANCA, FANCC, and FANCG also associate with chromatin in response to DNA damage.[220] In addition, FANCD2 is phosphorylated in response to various types of DNA damage,[97,199,200] and it is suspected that FANCI and FANCD2 phosphorylation is part of two separate pathways that are controlled by one of the two checkpoint kinases ATR or ATM.[97,174-176,199,200,224]

The FA gene corresponding to FA-D1 has been identified as the breast cancer susceptibility gene *BRCA2*.[169] In *FANCD1/BRCA2*-defective cells, the core FA complex is intact and FANCD2 is appropriately ubiquitinated, thus suggesting that *FANCD1/BRCA2* acts downstream of the other proteins involved in FA. Recently, biallalic mutations were identified in the gene encoding FANCN/PALB2, a nuclear binding partner of BRCA2.[86,182] FANCN binds to the amino-terminal of BRCA2 and facilitates its binding to chromatin.[87] Similar to *FANCD1/BRCA2*-defective cells, the core FA complex is intact and FANCD2 is appropriately ubiquitinated.

FANCJ has been shown to be mutated in FA and act downstream of FAND2 monoubiquitination. FANCJ is an adenosine triphosphate–dependent helicase that binds and unwinds DNA/DNA and DNA/RNA substrates in a 5′-to-3′ direction.[225] It belongs to the RecQ DEAH helicases, which efficiently unwind DNA structures that occur during homologous recombination and during repair of stalled DNA replication forks. FANCJ contains a C-terminal BRCA1-binding domain, again linking the
FIGURE 8-5. Schematic summary of the current view of FANC protein interconnections in the Fanconi anemia (FA) DNA repair pathway (also see text). Upon DNA damage and during DNA replication, the FANCI-FANCD2 complex is activated by monoubiquitination. Eight FANC proteins and three additional proteins (FAAP16, FAAP100, and FAAP24, gray cycles) form the FANC core complex necessary for FANCI-FANCD2 monoubiquitination. In addition to the FANC core complex, ATR (ataxia-telangiectasia and RAD3-related protein) is required for efficient FANCI-FAND2 monoubiquitination. FANCI and FAND2 are dependent on each other for their respective monoubiquitination. The activated FANCI-FANCD2 complex migrates to nuclear foci, most likely at the site of DNA damage, where it colocalizes with other DNA repair proteins and to chromatin. The FANC core complex is necessary not only for the monoubiquitination of FANCI and FANCD2 but also for their translocation to chromatin. Indeed, FANCA, FANCC, and FANCG also associate with chromatin in response to DNA damage.[220] The function of the monoubiquitinated FANCI-FANCD2 complex in chromatin remains unknown but may regulate homologous recombination repair or translesion DNA synthesis (or both). *(Modified from Medhurst AL, Laghmani EH, Steltenpool J, et al. Evidence for subcomplexes in the Fanconi anaemia pathway. Blood. 2006;108:2072-2080; Levitus M, Joenje H, de Winter JP. The Fanconi anemia pathway of genomic maintenance. Cell Oncol. 2006;28:3-29; and Taniguchi T, D'Andrea AD. Molecular pathogenesis of Fanconi anemia: recent progress. Blood. 2006;107:4223-4233.)*

FA pathway to the homologous recombination repair pathway.

It has been proposed that the FA core complex is assembled sequentially from subcomplexes (see Fig. 8-5),[226-229] which may have additional functions aside from DNA repair. In fact, the FANCC protein has been reported to interact with a number of other proteins, including STAT1,[230,231] Hsp70,[232,233] cdc2,[227] PKR,[234,235] and p53,[236,237] thus suggesting that FANC proteins/subcomplexes might also have a separate role in cell cycle control, apoptosis, hematopoiesis, and tumorigenesis that is independent of DNA damage recognition/repair (reviewed by Bagby and Alter[238]).

Despite the extensive literature on the function of the FANC proteins, the pathogenesis of BMF in FA remains poorly understood. Although the FA pathway of DNA damage repair and recognition seems to explain the genomic instability and possibly the increased risk for malignancy in patients with FA, its link to the pathogenesis of BMF remains unclear inasmuch as mutations associated with genomic instability outside FA are not usually associated with BMF. Whether BMF in FA patients is a direct consequence of the FA defect in DNA repair or is caused by impairment of functions apart from DNA repair is the subject of ongoing debate. Naturally, FA DNA repair and non–DNA repair pathways in the pathogenesis of BMF may not be mutually exclusive. For example, the exquisite hypersensitivity of FA hematopoietic progenitor cells to oxidative stress[53,123,239] and the inability of FA hematopoietic progenitors cells to grow unless the culture conditions are optimized to reduce oxidative stress[56] suggest an inability of FA cells to handle oxidative stress. The inability of FA hematopoietic progenitors cells to deal with oxidative stress may occur on several levels, including impairment of the redox-related pathways associated with FANC proteins (function of the FANC proteins outside DNA repair),[55,127,128,240-242] the response to oxidative damage,[199] and impaired repair of oxygen-induced DNA damage (functions of the FANC proteins in DNA damage repair).[53,115,123,124,239,243-249] Thus, it is possible that mutations in FA genes sensitize hematopoietic stem cells to the environmental factors that

prevail in BMF, such as increased levels of TNF-α or INF-γ. To find the specific functions of the FA pathways and to link them to the phenotype seen in patients with FA, it will be necessary to learn still more about the individual FANC proteins, complexes, and subcomplexes and their interactions and functions in and outside of DNA repair. The identification of additional components in the FA pathways and their functional analysis might provide additional pieces and eventually complete the jigsaw puzzle surrounding the pathogenetic pathway of BMF in FA.

***FANC* Gene Mutations in Patients with Fanconi's Anemia.** Detailed information on mutations identified in the *FANC* genes in patients with FA is maintained in the FA Mutation Database at Rockefeller University through the IFAR headed by Arleen D. Auerbach (available at http://www.rockefeller.edu/fanconi/mutate/[21,250]) and in the Leiden Open Variation Database (LOVD; http://chromium.liacs.nl/lovd/) maintained by Ivo Fokkema, John T. den Dunnen, and Peter E. M. Taschner.[251] Frequent FA mutations and mutations with founder effects are presented in Table 8-6.

FANCA is the gene most frequently mutated in FA patients.[21,22,258,259] The mutations are spread throughout the gene and include missense and nonsense mutations, small deletions, insertions, and duplications, as well as splicing mutations.[250] Of note is the substantial number of large genomic, usually intragenic DNA deletions,[13,250,260-264] which account for about 40% of all pathogenic mutations within the *FANCA* gene and are thought to be due to the frequent occurrence of Alu repeats in this genomic region.[250,260] Large gene deletions are not generally detected by routine nucleotide sequence–based mutation detection methods but require more specialized analysis (haplotype analysis) or molecular methods specifically designed for the detection of large gene deletions. Two small deletions (deletion of three nucleotides between positions 3788 and 3790, with c.3788_3790delTCT leading to deletion of phenylalanine at position 1263, 1263delF, and a 4–base pair [bp] deletion at position 1115, c.1115-1118delTTGG, leading to a frameshift and premature stop codon) are the most common pathogenic mutations in the *FANCA* gene, with a frequency of 8.8% and 5.5% in the non-Brazilian and 51.1% and 2.2% in the Brazilian mutated *FANCA* alleles (see Table 8-5).

Mutations in *FANCC* genes account for about 10% to 15% of all FA cases (see Table 8-6).[185,265] The splicing mutation c.711+4A→T (old nomenclature, IVS4+4A→T) in the *FANCC* gene accounts for the majority (80%) of FA cases in Ashkenazi Jewish families (see Table 8-6).[253] Mutations in *FANCG* are responsible for about 8% to 9% of patients with FA. Several mutations with founder effects have been identified in specific populations (see Table 8-6).[254]

Biallelic mutations in *BRCA2* are found in individuals with FA-D1. Biallelic *FANCD1/BRCA2* mutations account for about 3% to 4% of all FA patients.[184,185] The majority of *FANCD1/BRCA2* mutations in FA lead to frameshifts or truncations (see Table 8-6).[85] Interestingly, however, FA-D1 cells are not biallelic for *FANCD1/BRCA2* null alleles but have at least one hypomorphic *FANCD1/BRCA2* allele expressing a FANCD1/BRCA2 protein with some residual activity. Biallelic null *FANCD1/BRCA2* mutations have never been identified and in mice are embryonically lethal. Biallelic mutations in *FANCD1/BRCA2* have a very high risk of early malignancy. The splice cite mutations c.859+1G→A (IVS7+1G→A) and c.859+1G→A (IVS7+1G→A) are associated with a high frequency of leukemia at a very young age,[85,255,256] whereas the frameshift mutations c.886delGT and c.6174delT are associated with brain tumors.[24,84,85]

Mutation in *FANCD2* accounts for 3% to 6% of FA-affected patients. Malformations are frequent in these patients, and hematologic manifestations appear early and progress rapidly. Although hypomorphic mutations exist, patients with *FANCD2* mutations have a relatively severe form of FA. Mutation analysis revealed 66 mutated alleles, 34 causing aberrant splicing. Many mutations are recurrent and have ethnic associations and shared allelic haplotypes. There were no biallelic null mutations, thus suggesting that in contrast to the *Fancd2* knockout mouse, complete absence of FANCD2 does not exist in patients with *FANCD2* mutations.[266,267]

Mutations in *FANCN/PALB2* were identified in families with the new subtype FA-N and cancer in early childhood. Similar to biallelic *BRCA2* mutations, biallelic *FANCN/PALB2* mutations confer a high risk for childhood cancer.[86,182]

Molecular Diagnosis of Fanconi's Anemia

Currently, molecular diagnostics is not routinely performed for FA because it is expensive, labor intensive, and in some cases, possible only though specialized laboratories using research tests that are currently not approved by the Clinical Laboratory Improvement Amendments (CLIAs). However, only identification of biallelic mutations in a *FANC* gene (or hemizygosity for a mutation in the *FANCB* gene) definitively establishes the diagnosis of FA. Furthermore, molecular diagnostics enables the identification of mutation carriers, facilitates prenatal diagnosis for an existing pregnancy, and allows preimplantation genetic diagnosis (PGD) for partners identified as mutation carriers.[268] For a definition of PGD see Box 8-5. In addition, because the clinical manifestations and severity of disease may vary depending on the affected *FANC* gene and the nature of individual mutations, molecular diagnostics may also influence medical management not only for FA individuals carrying biallelic *FANC* gene mutations but possibly also for heterozygous *FANC* gene mutation carriers (also see later). Currently, an educated candidate gene approach is used to identify the affected the *FANC* gene by taking into account the origin and ethnicity of the affected FA individual.[273] After exclusion of the most frequent mutations,

TABLE 8-6 **Frequent *FANC* Gene Variants and Mutations with a Founder Effect Identified in Patients with Fanconi's Anemia**

Gene	Founder Effect	Variation at the DNA level (Old Nomenclature)*	Variation at the Protein Level*	Frequency within the Mutated FA Allele	Population with a Founder Effect (% of All FA Patients)	References

*Sequence variations are described according to the Ad-Hoc Committee for Mutation Nomenclature (AHCMN)[257] (for a summary see http://www.hgvs.org/mutnomen/; for the coding DNA reference sequence see http://www.rockefeller.edu/fanconi/mutate/faarefcdna.html), with the first base of the Met codon counted as position 1. Single-letter abbreviations are used for amino acids: E, glutamic acid; F, phenylalanine; Q, glutamine. del, deletion; fs, frameshift, premature stop codon; spl?, splice site mutations with unknown consequences at the protein level; X, stop codon.

[†]Most frequent *FANCA* gene mutations.

[‡]Associated with a high frequency of leukemia at a very young age (acute myelocytic and lymphocytic leukemia).

§Associated with brain tumors.

Data from Fokkema IF, den Dunnen JT, Taschner PE. LOVD: easy creation of a locus-specific sequence variation database using an "LSDB-in-a-box" approach. Hum Mutat. 2005;26:63-68, available at http://chromium.liacs.nl/lovd/; and Levran O, Diotti R, Pujara K, et al. Spectrum of sequence variations in the FANCA gene: an International Fanconi Anemia Registry (IFAR) study. Hum Mutat. 2005;25:142-149.

it might be necessary to determine the complementation group and perform a mutational screen of the entire coding sequence, including methods that will detect large deletions in compound heterozygotes. Protein expression analysis and functional assays are used to test for the pathogenicity of unclassified variants.[274] Although this approach is successful in the majority of FA patients, in some, the responsible gene mutations remain unclear. In addition to the large number of mutations in *FANC* genes associated with FA, a number of nonpathogenic mutations and mutations of unknown pathogenic significance have been identified. The multitude of FA complementation groups, the heterogeneity of the mutation spectrum, and the frequency of large intragenic deletions present a considerable challenge for the molecular diagnosis of FA.

Heterozygous Carriers of FANC *Gene Mutations*

Heterozygous carriers of *FANC* gene mutations are not at risk for the development of BMF. Similarly, cell lines heterozygous for *FANC* gene mutations do not show the chromosomal instability (either spontaneously or in response to cross-linking agents) characteristic of FA cells with biallelic *FANC* gene mutations. However, an increased frequency of skeletal and genitourinary abnormalities[275] and an increased risk for malignancy have been reported in heterozygous *FANC* gene mutation carriers.[275]

Risk of Malignancy. A strong association exists between heterozygous mutation of *FANC* genes and susceptibility to breast or ovarian cancer,[276] and other forms of malignancy have been identified in heterozygous mutation carriers. Carriers of mutations in *BRCA1* or *BRCA2/FANCD1* have an 82% risk of breast cancer developing and a 54% (*BRCA1*) and 23% (*BRCA2/FANCD1*) risk for ovarian cancer.[277] Heterozygous *BRCA2/FANCD1* mutations additionally predispose to pancreatic, prostate, and gastric cancer, as well as melanoma.[278,279] Monoallelic truncating *FANCN/PALB2* mutations were also associated with familial breast cancer, although the risk for breast cancer was lower (2.3-fold) than that in *BRCA2* mutation carriers.[183] Heterozygosity for *FANCJ* mutations has been identified in patients with early-onset breast cancer.[225] Heterozygous germline mutations in *FANCC* and *FANCG* and loss of heterozygosity or func-

tional biallelic loss in the tumor sample have been identified in rare patients with pancreatic cancer.[280,281] Furthermore, heterozygous germline mutations of *FANCA* have been identified in a small percentage of patients with AML.[282,283]

Somatic FANC *Gene Mutations in Cancer*

Cancer cells often accumulate a large number of mutations within an individual cancer cell, many of which promote cell growth and survival. It is therefore thought that a cancer cell with an increased mutation rate, a mutator phenotype, will have a selective advantage in tumor growth and development. Inactivation or mutation of genes involved in maintaining genetic stability is therefore thought to be an early event in cancer development. The FA pathway has been observed to be one of the pathways that maintains genomic stability and is targeted in several forms of sporadic cancer (for review see elsewhere[184,216]); inactivation of *FANCF* by methylation has been observed in ovarian granulosa cell tumors,[284] breast cancer,[285] non–small cell lung cancer,[286] squamous cell head and neck cancer,[286] cervical cancer,[287] testicular germ cell tumors,[288] and possibly ovarian cancer,[289] although the latter was not confirmed.[290] Aberrant or reduced expression of FANCA, FANCC, FANCF, and FANCG was found in AML cells,[282,283,291-293] thus suggesting a role of the FA pathway in leukemogenesis. Inherited and somatic (loss-of-heterozygosity) mutations in *FANCC* and *FANCG* were observed in a subset of early-onset pancreatic cancer.[280,281,294] Loss of BRCA2 expression has been reported in 13% of ovarian adenocarcinomas.[295] FANCD2 expression was found to be absent in 10% to 20% of sporadic and BRCA1-related breast cancers.[296]

Identification of acquired abnormalities in the FA pathway might become clinically important because these tumors are expected to have increased sensitivity to cross-linking agents such as cisplatin, cyclophosphamide, MMC, and other novel agents.[297] Thus, identification of abnormalities in the FA pathway may serve as a biomarker that identifies a subgroup of patients with cancers selectively sensitive to specific chemotherapeutic agents.[233,248] Similarly, inhibition of the FA pathway in cancer may render cancer cells sensitive to chemotherapy.[216,298,299]

Genotype-Phenotype Correlation

Clinical findings in FA are highly variable, although within an individual family the presence or absence of multiple congenital abnormalities or the age at onset of other disease manifestations is usually concordant (see earlier also). More recent studies have demonstrated that disease severity and manifestations, at least in part, are determined by the *FANC* gene affected (FA complementation group) and by the nature of the mutations.[15,21,22] For example, patients with mutations in the *FANCA* gene usually have a milder form of disease and BMF develops at a later age than it does in FA individuals with muta-

tions in the *FANCC* or *FANCG* genes,[22] whereas in FA patients with biallelic *FANCD1* or *FANCN* mutations, cancer develops even before the manifestation of BMF.[24,84-86] Furthermore, splice site mutations in *FACD1* are more frequently associated with the development of leukemia,[85,255,256] whereas frameshift mutations within the same gene more frequently lead to brain tumors (see earlier).[24,84,85] Malformations are frequent in *FANCD2* patients, and hematologic manifestations appear earlier and progress more rapidly than they do in non-*FANCD2* FA patients.[266]

FA-B is X-linked, in contrast to all other forms of FA, which are autosomal. Thus, a single mutation is sufficient to cause a phenotype and disease in males. In females, because of inactivation of one of the two X chromosomes, a phenotype is expressed only in cells with the *FANCB* mutation on the active X chromosome. Because X-chromosome inactivation occurs at random in early embryogenesis and, once determined, persists clonally, one might expect female *FANCB* mutation carriers to have a mild form of FA-B. Interestingly, however, to date no female FA-B patient with clinical manifestations of FA has been reported, and careful clinical examination of females heterozygous for *FANCB* gene mutations showed no manifestations of disease. Molecular studies investigating X-inactivation revealed that only the X chromosome with the normal *FANCB* gene is expressed in blood and bone marrow and also in fibroblasts.[167] This finding indicates a proliferative disadvantage of cells expressing the mutant *FANCB* allele and complete outgrowth by phenotypically normal cells, not only in bone marrow but possibly also in all other tissues. This situation differs from other X-linked IBMFSs such as X-linked DC (see the section "Dyskeratosis Congenita"). For individuals carrying a *FANCB* mutation, however, longer follow-up and examination of additional mutation carriers will be necessary to determine whether some FA-B cells persist in female carriers and whether these persisting FA-B cells are at risk for malignant transformation. Whether somatic *FANCB* inactivation can be found in malignancies (only a single mutation on the active X chromosome is required) remains to be determined.

Somatic Mosaicism and Functional Reversion of Fanconi's Anemia Cells

About 10% to 25% of FA patients have been found to be mosaic in their peripheral blood inasmuch as two populations of lymphocytes can be detected, one with the classic increased sensitivity to cross-linking agents characteristic of FA cells and the other usually a slowly increasing second population that is resistant to treatment with these agents.[26] For definition of genetic mosaicism see Box 8-6. The presence of mosaicism is usually considered if the clinical course of the disease is milder than expected in comparison to individuals with the same genetic abnormality, if the course of the disease improves spontaneously rather than worsens, or in the presence of

| Box 8-6 | **Genetic Mosaicism** |

Genetic mosaicism is defined as the presence of two or more genetically distinct populations of cells in a single individual that differ from each other at the DNA sequence level but are derived from a single zygote.[300] In Fanconi's anemia (FA), genetic mosaicism results from reversion, which is genetic correction (reversion) of the FA mutation.

classic phenotypic abnormalities but rather mild or absent hematologic disease. The molecular mechanisms of genetic reversion include intragenic recombination (in compound heterozygotes), mitotic gene conversion (nonreciprocal exchange of genetic information as a result of heteroduplex formation between nonsister chromatids),[28] DNA slippage, second-site compensating mutations,[301,302] and site-specific correction by an as yet unknown mechanism.[28] Gene reversion may occur in vivo or in vitro. In FA patients the reverting mutation is thought to occur in progenitor cells with self-renewing capability,[303] possibly stem cells, thereby conferring a proliferative advantage to the revertant cells, which may lead to expansion of the revertant clone and progressive replacement of the FA cells in bone marrow.[26,302,304] Genetic reversion in FA has been documented to date only in hematopoietic cells, not in fibroblasts.[301,302] However, the fact that females heterozygous for *FANCB* mutations have biased X-inactivation in fibroblasts suggests that an intact FA pathway confers a proliferative advantage to nonhematopoietic cells. Thus, the frequency of genetic reversion is largely unknown, and so are its clinical consequences. In many patients genetic reversion is associated with hematologic improvement.[26,302] However, genetic reversion has also been found in leukemic cells from FA patients,[305] thus indicating that genetic reversion may confer a selective growth advantage and resistance of leukemic or preleukemic cells to specific chemotherapy drugs. Furthermore, genetic reversion in hematopoietic cells has no effect on cancer frequency in nonhematopoietic tissue (also see earlier).[306] However, the strong selection for a functional FANC pathway may be used to advantage in gene therapy approaches.[26,302] Genetic mosaicism is responsible at least in part for phenotypic variability, particularly within an individual family, and may create difficulty in interpretation of the chromosomal breakage test (DEB and MMC test, see earlier) or even lead to false-negative testing results.[25,27,28] DEB or MMC testing of fibroblasts should therefore be considered in patients with clinical or genetic suspicion of FA but a negative DEB or MMC test in peripheral blood lymphocytes.

Mouse Models for Fanconi's Anemia

Several mouse models for FA have been generated by introducing mutations into murine *FANC* genes, including *Fancc*,[155,307] *Fanca*,[308] *Fancg*,[309] *Fancd2*,[310] and *Fancd1*.[311] Some models recapitulate the clinical features

seen in patients with FA, specifically, microphthalmos, germ cell defects, chromosomal instability, and an increased sensitivity to cross-linking agents. In some models tumors develop at an increased frequency,[310,312,313] and this effect is more pronounced in the absence of p53.[237,314] These models thereby underline the importance of the FA pathway in tumorigenesis. Hematopoietic progenitor cells from mice homozygous for a null mutation in the *Fancc* gene demonstrate a distinct hypersensitivity to IFN-γ that leads to cell death independent of the DNA repair pathway mediated by FAS-induced apoptosis, thus suggesting that IFN-γ hypersensitivity may play a major role in the pathogenesis of BMF in patients with FA.[155,315] Interestingly, however, spontaneous development of aplastic anemia was not observed in these mice.

Clinical Management

Once the diagnosis is confirmed, the family should be referred to a clinical geneticist for counseling and careful examination of family members. Genetic testing or chromosome breakage analysis should be offered to all family members. Early diagnosis is important for correct management of hematologic complications, diagnosis and appropriate treatment of coexisting congenital abnormalities and associated endocrinopathies, and identification of affected but asymptomatic family members and unaffected family members or pregnancies that may serve as potential hematopoietic stem cell donors. In addition, early diagnosis allows targeted cancer surveillance, not only in patients with FA but also in some cases in heterozygous mutation carriers (also see earlier). Management of patients in whom FA is diagnosed depends on the age at diagnosis and the presence or absence of congenital or hematologic abnormalities (see also Fanconi Anemia Standards for Clinical Care, available from the Fanconi Anemia Research Fund at http://www.fanconi.org/[316]). All diagnosed FA patients should have a full hematologic assessment, including examination of bone marrow, and in anticipation of possible HSCT, HLA typing should be performed. Other investigations at diagnosis should include audiometry, ophthalmic examination, renal ultrasound, and an endocrine assessment (see earlier). Referral to specialized surgeons might be necessary for correction of radial ray defects.

Management of Hematologic Disease

Initially, in the absence of hematologic abnormalities or clinical and laboratory signs of mild BMF, monitoring of peripheral blood values and yearly examination of bone marrow might be sufficient (see also elsewhere[317]). Bone marrow examination should include a trephine biopsy and marrow aspirate for examination of marrow cellularity and morphologic changes characteristic of MDS, as well as for cytogenetic examination by G banding and fluorescent in situ hybridization (FISH) analysis, including probes that identify the most frequent cytogenetic abnormalities seen in patients with FA and progression to MDS or AML (see earlier also). Because of its prognostic value, examination for clonal aberration of 3q should be considered.[68,69] Plans for possible HSCT should be in place because hematologic complications may develop rapidly. With progression of BMF it will become necessary to increase the frequency of hematologic monitoring. HSCT is usually considered in patients with moderate BMF and an available HLA-matched unaffected sibling donor or when BMF becomes severe and an unrelated donor is available. Preventive HSCT in the absence of hematologic disease is highly controversial and currently considered investigational because the risk and time course of disease progression are highly variable and have to be weighed against the morbidity and mortality associated with HSCT.

Management of FA patients with MDS, AML, or both is less standardized. The significance of transient clonal cytogenetic abnormalities is unclear, but if persistent or complex, such abnormalities usually predict a poor prognosis (also see earlier). HSCT with or without induction chemotherapy or enrollment in clinical trials for MDS or MDS/AML is usually considered (see later also).[318] Androgens and hematopoietic growth factors transiently improve BMF in about 50% to 60% of FA patients.[319-322] Side effects of androgen therapy include masculinization, acne, hyperactivity, growth spurt followed by premature closure of the epiphyseal growth plates, liver enzyme abnormalities, hepatic adenomas, and a risk for hepatic adenocarcinomas[75,323] that requires frequent monitoring of liver function and liver ultrasound scans. Hematopoietic growth factors (granulocyte colony-stimulating factor [G-CSF][322] or granulocyte-macrophage colony-stimulating factor [GM-CSF][321]) may transiently improve neutrophil counts and, in rare FA patients, also hemoglobin levels and platelet numbers. The use of hematopoietic growth factors in patients with clonal cytogenetic abnormalities is controversial because of the potential risk of inducing or promoting leukemia. Red cell transfusion therapy and iron chelation (after multiple red cell transfusions) are frequently used in symptomatic FA patients. Platelet transfusions may be indicated in thrombocytopenic patients with bleeding or before surgical procedures.

HSCT from an HLA-matched sibling donor is accepted as the best treatment to cure BMF in FA patients and to prevent progression to MDS and AML. Early experiences with HSCT for the treatment of BMF in FA were disastrous because of excessive regimen-related toxicity.[324-326] Early conditioning regimens consisted of cyclophosphamide alone or in combination with total body irradiation (TBI). Unfortunately, severe toxicities (e.g., gastrointestinal hemorrhage, hemorrhagic cystitis, cardiomyopathy, and skin burns) were common. These poor outcomes prompted in vitro laboratory studies that confirmed the hypersensitivity of FA cells to cyclophosphamide and TBI.[159] Based on these in vitro studies, Gluckman and colleagues[327,328] proposed the use of a less intensive conditioning regimen consisting of

low-dose cyclophosphamide and thoracoabdominal irradiation for patients with FA. This approach proved to be a major advance in the treatment of patients with FA who had HLA-matched sibling donors.[329,330] However, it did not afford consistent engraftment in recipients of unrelated donor transplants, with graft rejection rates exceeding 20%,[331] and head and neck cancer was frequent after HSCT. Consequently, irradiation is no longer recommended for the conditioning of patients with FA undergoing HSCT.[332-336] Recent studies suggest that fludarabine-based conditioning regimens are associated with improved survival rates in patients with FA undergoing related or unrelated donor HSCT.[337-342]

PGD may be used in parents with a previously affected child to select embryos that are both unaffected by FA (if a *FANC* gene mutation is known) and HLA matched to the FA-affected sibling. HSCT is performed with the HLA-matched umbilical cord blood of the unaffected newborn.[342,343] The procedure is often successful but is considered ethically controversial.[269-272]

The prognosis for FA patients without HLA-matched siblings after HSCT with unrelated donors is less favorable. Extensive malformations, a positive recipient cytomegalovirus serology, the use of androgens before transplantation, and female donors were associated with a worse outcome.[344] There is also an increased risk for graft rejection in FA cases with somatic mosaicism.[345]

Cancer Surveillance/Treatment

For FA patients who survive the hematologic complications, follow-up surveillance for solid malignancies becomes increasingly important (also see earlier).[1,66,334,345-349] There are no clear guidelines on the treatment of cancer in FA patients, which is complicated because their increased sensitivity to radiation and certain chemotherapeutic agents may result in enhanced toxicity and an increased risk of therapy-induced secondary malignancies.[119,350,351]

Gene Therapy

HSCT may cure hematologic disease in FA patients; unfortunately, however, HLA-matched sibling donor cells are available only for a minority of patients. Gene therapy to correct hematopoietic stem cells, followed by autologous transplantation, therefore offers an attractive alternative for the treatment of hematologic disease in FA patients. Indeed, gene transfer corrects the hypersensitivity of most FA cell lines to DNA cross-linking agents in vitro (with the exception of FANCM, most likely because of insolubility of the protein) and the hypersensitivity of FA knockout mice in vivo. The high incidence of somatic mosaicism and the often ameliorated course of hematologic disease in these patients (frequently referred to as "gene therapy of Nature") suggests that FA cells corrected by gene therapy are likely to have a selective growth/survival advantage. However, gene therapy attempts in FA patients have thus far been rather disappointing,[352-354] mainly because of the lack of permanent

---

gene correction and the difficulty in culturing FA bone marrow cells in vitro. Multiple investigations are currently addressing the major difficulties of gene therapy for FA, including the scarcity of hematopoietic stem cells in FA patients with BMF, the extraordinary fragility of FA hematopoietic progenitor cells, and the increased sensitivity of FA hematopoietic progenitor cells to oxidative stress, which makes it difficult to culture and transduce FA hematopoietic progenitor cells in vitro. There is also a risk that the transduced hematopoietic cells might already have acquired secondary somatic, possibly oncogenic mutations[355] and that correction by gene therapy would promote rather than prevent leukemogenesis in these patients.

Dyskeratosis Congenita

DC, also known as Zinsser-Cole-Engman syndrome, is genetically and phenotypically heterogeneous (Box 8-7). It was first described by Zinsser and recognized as a clinical entity by Cole and Engman.[358-360] DC was originally perceived to be a dermatologic disorder affecting the skin, nails, and mouth.[358-360] Its association with BMF and squamous cell cancer arising from the skin or from leukoplakia in the mouth or anus was recognized later.[361]

Clinical Manifestations

Originally, DC was clinically recognized by the classic diagnostic triad of reticular pigmentation of the skin, nail dystrophy, and mucosal leukoplakia (Fig. 8-6).[358-360] Other symptoms frequently found in patients with classic DC are summarized in Table 8-7[363-367] (for review, see also Docal[368] and Drachtman and Alter[369]). Disease manifestations are highly variable and range from barely detectable to severe forms that cause death in early childhood. Typically, however, affected individuals are normal at birth, mucocutaneous features develop in childhood, BMF develops in adolescence, and they die in the third decade. BMF, immune deficiency, pulmonary complications, and malignancies are the major causes of death in individuals with DC.

The recent identification of five of the genes responsible for DC and the realization that these genes converge into a common pathway have changed our understanding of this disease. It is now thought that individuals in whom

Microencephaly	—	6
Malignancy	12	10

DC is diagnosed on the basis of BMF and the classic cutaneous manifestations represent only a fraction of those who suffer from this condition.[2,370] Whether affected individuals in the absence of cutaneous disease should be labeled with the diagnosis of "dyskeratosis congenita" or whether the disease should be renamed with a term better reflecting the pathogenetic pathway is currently under debate. Here we will use the conventional nomenclature and clinically classify patients as having classic, atypical, or silent DC. Patients who have two or more of the three diagnostic mucocutaneous features or who have one of the mucocutaneous features and hypocellular bone marrow with all three blood cell lineages affected are those with "classic DC." Patients with BMF but lacking mucocutaneous features or patients with clinical manifestations of DC other than hematologic disease or mucocutaneous features, such as pulmonary fibrosis, are those with "atypical DC," and individuals with no clinical manifestations but carrying a pathogenic mutation will be classified as having "silent DC." Much of what we know about DC is biased because early studies focused on patients with the classic clinical manifestations. Little is known about the course of disease, response to treatment, and late complications in patients with atypical or silent DC.

Classic Dyskeratosis Congenita

Mucocutaneous Features. Mucocutaneous abnormalities are the hallmark of classic DC (see Fig. 8-6).[371] The most commonly observed mucocutaneous abnormality (≈90%) is reticulated skin hyperpigmentation on the neck, face, chest, and arms. It may be extensive or localized and tends to increase with age. Other cutaneous manifestations include alopecia, premature hair graying, hyperhidrosis, hyperkeratosis of the palms and soles, and loss of dermal ridges on the fingers and toes.

Nail dystrophy is another frequent finding (≈80%). Progressive nail dystrophy starts with ridging and longitudinal splitting and may proceed via atrophy and thinning to complete nail loss. The severity of nail dystrophy may vary among the digits; fingernails are usually more severely affected than toenails.[372]

Mucosal leukoplakia occurs in the majority of patients (≈70%) and typically involves the tongue, buccal mucosa, and oropharynx, with the tongue being the most frequently affected site.[373,374] Mucosal leukoplakia may be the initial clinical manifestation of disease. Consequently, dentists or oral surgeons may be the first health professionals consulted. Histologic examination reveals hyperkeratosis or a lichenoid reaction. Other sites reported include the urethra, glans penis, vagina, and anorectal region.[371] DC patients have an increased risk of malignancy arising from the preexisting leukoplakia; the incidence of malignant transformation has been estimated to be 35%.[375]

Hematologic Abnormalities. About 85% of patients with classic DC are initially found to have cytopenia of one or more lineages, and pancytopenia develops in more than 95% of patients by 40 years of age. Complications of BMF, such as hemorrhage or opportunistic infection, represent the major cause of death in patients with DC. In patients with atypical DC, BMF may appear before the classic mucocutaneous features and lead to an initial

FIGURE 8-6. Physical findings in a 31-year-old patient with classic dyskeratosis congenita (DC). **A,** Reticular skin pigmentation. **B,** Dystrophic fingernails, rather mild in this case. **C,** Leukoplakia of the tongue. **D,** Hypocellular bone marrow. **E,** Hypocellular myelodysplastic syndrome in a different 41-year-old patient with atypical DC caused by a *TERC* gene mutation. *(Courtesy of Susan Bayliss, Washington University.)*
diagnosis of idiopathic aplastic anemia. Hypoplastic MDS and MDS/AML are increasingly diagnosed in patients with DC, especially in those with a milder course or an atypical form of the disease. Indeed, MDS or MDS/AML may be the initial manifestation of patients with atypical DC.

Other Clinical Features. Pulmonary complications are common (≈20%) and include pulmonary fibrosis and vascular abnormalities.[376,377] Pulmonary fibrosis is usually a more prominent finding in older patients or after BMT.[378] In some patients with atypical DC, pulmonary fibrosis may be the only clinical manifestation. Figure 8-7 shows a family with autosomal dominant DC and pulmonary fibrosis. Families with hereditary pulmonary fibrosis of adult onset should be investigated for DC.[379,380]

Ocular findings include epiphora (excessive tearing caused by blocked lacrimal ducts), blepharitis, cataracts, loss of eyelashes, conjunctivitis, ectropion, glaucoma, strabismus, ulcers, ocular albinism, and Coats' retinopathy.[381-384]

Multiple dental caries and early loss of teeth are common.[385-387] Web formation in the upper esophagus, esophageal stricture, and a bifid uvula are other findings in patients with DC.[388-390]

Strictures of the urethra, hypospadias, and phimosis are congenital anomalies found in patients with DC. Underdeveloped testes and azoospermia have been reported in more severe and advanced forms of DC.

Enteropathy and malabsorption associated with chronic diarrhea are underdiagnosed but frequent findings in more advanced forms of DC.[391]

Intellectual disabilities such as learning difficulties are often associated with classic DC. In rare cases an association with schizophrenia has been described.

Osteoporosis and avascular necrosis of the bones frequently complicate the course of the disease. Short statue and an elf-like appearance have been associated with classic DC.

Predisposition to Malignancy

DC is a cancer predisposition syndrome.[9,361,368,369,392] After BMF and pulmonary complications, malignancy is the third leading cause of death. The most frequent malignancies in patients with DC are squamous cell carcinoma of the head and neck (especially the tongue but also the lip, mouth, palate, cheek, nasopharynx, and larynx),[373,375,393,394] the upper and lower gastrointestinal tract (esophagus and anus),[395] and the female genital tract. Other cancers found in patients with DC include skin cancer and adenocarcinoma of the stomach,[396] colon, lung, and pancreas. Malignancies usually develop in the third decade and are therefore more frequently found in individuals with milder and later-onset forms of the disease.

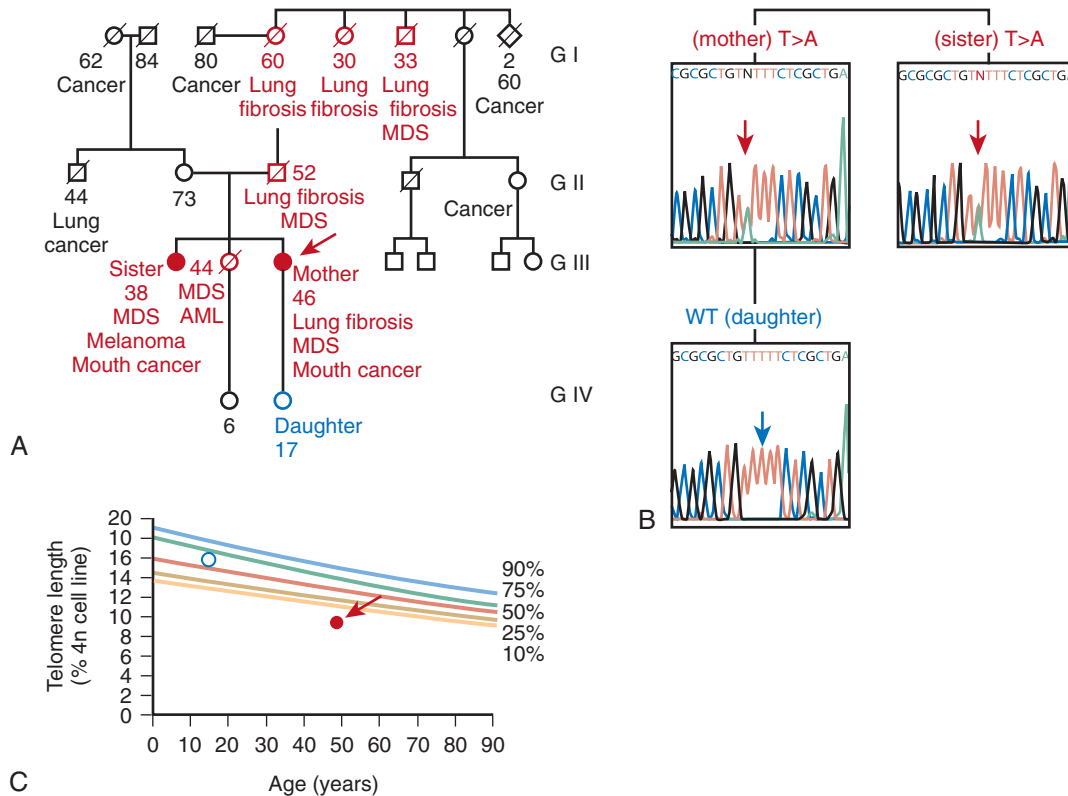
Previously, MDS and MDS/AML were thought to be infrequent in patients with DC; more recently, however, MDS and MDS/AML are increasingly being diagnosed in patients with atypical DC and in patients with late onset of the disease (see also Fig. 8-6E). MDS or MDS/AML may be the first hematologic manifestation of disease. Although DC is rarely a cause of MDS or MDS/AML in children,[397] it should be considered in the differential diagnosis in adults with MDS or MDS/AML. Abnormalities of chromosome 7 (monosomy, isochromosome, or other structural rearrangements) are the


FIGURE 8-7. **A,** Pedigree of a family with dyskeratosis congenita (DC) caused by a *TERC* gene mutation. Note that in addition to myelodysplastic syndrome (MDS), pulmonary fibrosis is a prominent feature in this family with DC. **B,** Chromatogram demonstrating that the mother and her sister are heterozygous for the *TERC* gene mutation whereas the daughter has not inherited the mutation (WT). **C,** Telomere length of the affected mother (below and outside the telomere length distribution of normal controls) and the unaffected daughter (normal telomere length). Colored lines indicate the 10th, 25th, 50th, 75th, and 90th percentiles of telomere length determined in 105 healthy controls between the ages of 1 and 95 years.

most common cytogenetic abnormalities in patients with DC-associated MDS or MDS/AML.

Little is known about the biology of leukemia or other cancers in patients with DC and to what extent these malignancies differ from those seen in patients without DC. The cancer recurrence rate is high in patients with DC.

Laboratory Findings

Common laboratory findings are summarized in Box 8-8. In most patients with DC, the initial hematologic abnormalities are thrombocytopenia or macrocytic anemia followed by pancytopenia. Bone marrow examination often reveals increased cellularity at the outset, thus suggesting an element of hypersplenism. However, hypocellularity then ensues, consistent with the diagnosis of aplastic anemia. Macrocytosis and elevated hemoglobin F levels ("stress erythropoiesis") are common.[383] The number of circulating hematopoietic progenitor cells is decreased, indicative of the impairment in hematopoiesis at the stem cell level.

Bone marrow examination usually shows hypocellular marrow affecting all three blood cell lineages. Hypocellular MDS or MDS/AML is increasingly being found in patients with atypical DC or a late onset of disease. Monosomy 7 is the most frequent clonal

cytogenetic abnormality in DC patients with MDS or MDS/AML.

Long-term culture assays of bone marrow cells from patients with DC show a decreased number of progenitor cells and an impaired capability for colony formation, indicative of a quantitative and qualitative defect.[408]

Immunologic abnormalities may include humoral and cellular defects[366,398] (summarized in Box 8-9). Severe combined immunodeficiency is characteristic of severe forms of DC.

DC cells have increased spontaneous chromosomal instability that leads to distinctive chromosomal breaks, rearrangements,[384,399-401] and sister chromatid exchanges.[384,399,419] Chromosomal instability increases with increasing cell divisions in vitro. However, chromosome breakage does not increase after treatment with alkylating agents such as DEB, MMC, or nitrogen mustard,[399,401-406] which distinguishes DC from FA. Some of the chromosomal abnormalities characteristic of DC include end-to-end fusions, dicentric or tricentric chromosomes, anaphase or telophase bridges, short telomeres, and telomere free ends.

Biased X-inactivation in blood cells, as well as in fibroblasts from buccal mucosa and skin biopsy samples in female mutation carriers, is characteristic of X-linked DC.[417,418]

Box 8-8	Laboratory Findings in Patients with Dyskeratosis Congenita

PERIPHERAL BLOOD

Cytopenia of one or more lineages (80%)
Initial manifestation highly variable
Macrocytosis with or without anemia
Thrombocytopenia
Neutropenia
Pancytopenia
Low number of circulating progenitor cells
Elevated hemoglobin F
Elevated von Willebrand factor

BONE MARROW EXAMINATION

Hypocellular bone marrow affecting all three lineages
Increased number of mast cells
Dyserythropoiesis
Hypocellular myelodysplastic syndrome
Myelodysplastic syndrome/acute myeloid leukemia

IMMUNOLOGIC FINDINGS[368,398]

Humoral abnormalities:
    Hypogammaglobulinemia/hypergammaglobulinemia
Cellular abnormalities:
    Lymphopenia: B cells, T cells, natural killer cells
Functional abnormalities:
    Reduced proliferation upon stimulation
    Increased apoptosis upon stimulation
Anergy
Difficulty in immortalization by Epstein-Barr virus
    transformation (X-linked dyskeratosis congenita)

CYTOGENETICS[384,399-407]

Chromosomal instability: nonclonal complex anomalies in
    cultured cells
Chromosomal breaks, hypodiploidy, micronuclei
Anaphase and telophase bridges*
Short telomeres signal-free ends
End-to-end fusion with no telomeric signal
No increase in chromosomal instability after the
    clastogenic effects of DNA cross-linking agents
Clonal abnormalities in bone marrow cells: monosomy 7
    (myelodysplastic syndrome, myelodysplastic syndrome/
    acute lymphocytic leukemia)

*Laboratory findings in bold are characteristic of dyskeratosis
    congenita.

Box 8-9	Cellular Abnormalities in Dyskeratosis Congenita

Spontaneous chromosome breaks[401,410]
No increased chromosomal breakage after cross-linking
    agents
Hypersensitivity to ionizing radiation (controversial)[413]
Increased sensitivity to certain cytotoxic agents[409,411,412]
Short telomeres*[407,414]
Premature replicative senescence[400,415,416]
Lack of immortalization by TERT (X-linked)[416]
**Biased X-inactivation (female carrier of X-linked
    dyskeratosis congenita)**[417,418]

*Cellular abnormlities in bold are characteristic of dyskeratosis
    congenita.
FIGURE 8-8. Telomere length in peripheral blood mononuclear cells in individuals with dyskeratosis congenita (DC) and bone marrow failure (BMF). Note that in all individuals with DC and BMF, telomere lengths are below and outside the telomere length distribution of normal controls. The colored lines indicate the 10th, 25th, 50th, 75th, and 90th percentiles of telomere length determined in 105 healthy controls between the ages of 1 and 95 years.

mere length excludes DC as the cause of BMF.[356,357] However, in some cases with mild clinical manifestations the interpretation of results can be difficult and requires experience with the test method used and should be done in conjunction with the patient's clinical and laboratory data.

Cellular Phenotype of Dyskeratosis Congenita Cells

In addition to increased spontaneous instability, DC cells have several other phenotypic characteristics as summarized in Box 8-9. DC cells have been reported to have increased sensitivity to ionizing radiation and certain chemotherapeutic agents (e.g., bleomycin), although these findings were not consistently found by all investigators.[401,409-412] Decreased proliferation capacity in vitro and premature replicative senescence are also characteristic of DC cells (see Box 8-9).[400,414-416] Cells from some forms of DC (X-linked DC) fail to immortalize after Epstein-Barr virus–induced transformation or after transfection of a plasmid expressing the telomerase catalytic subunit TERT.[416,421]

The presence of short telomeres in circulating peripheral blood cells is the most characteristic finding in patients with BMF and DC.[407,414] Telomere length in individuals with BMF secondary to DC is far below the normal distribution of telomere length in age-matched healthy control individuals (Fig. 8-8).[356,357] In contrast to other IBMFSs, which may have short telomeres in circulating myeloid cells,[117,420] telomeres are exquisitely short in the myeloid and lymphoid cells of patients with DC-associated BMF. Telomere length measurements may be used to screen patients with BMF for DC; normal telo-

Differential Diagnosis

Clinically, DC has to be distinguished from other IBMFSs such FA, DBA, and SDS. Clinical manifestations, associated physical abnormalities, the family history (pattern of inheritance), and the lack of increased chromosomal fragility in the DEB or MMC test performed on cultured peripheral lymphocytes or fibroblasts (or both) are helpful in strengthening the diagnosis of DC. As noted earlier, telomere length outside the normal distribution strongly suggests the diagnosis of DC, whereas normal telomere length excludes DC as a cause of BMF in these patients.[356,357] X-inactivation studies may be helpful in identifying female carriers of the X-linked form of DC.[417,418]

Genetics

Inheritance

There are four distinct forms of inheritance of DC. Historically, before molecular diagnostics was available, inheritance was determined by examining family members for the presence of clinical manifestations. Today, we know that such classification was often mistaken because of the variability of penetrance of gene mutations.

X-linked Dyskeratosis Congenita. The most common form of classic DC is X-linked (MIM 30500), and many families with classic DC and X-linked inheritance have been described. The X-linked form of DC is almost always due to single point mutations in the *DKC1* gene encoding dyskerin (see later).

Autosomal Dominant Dyskeratosis Congenita. Several families have been described with an autosomal dominant form of inheritance of DC (AD DC, MIM 127550). This form of DC exhibits genetic anticipation (see Box 8-11) and may therefore be misclassified as autosomal recessive (AR DC). Several pedigrees in which AD DC is caused by mutations in the *TERC* gene encoding telomerase RNA have been described. In addition, families in whom AD DC appears to be due to mutations in *TERT*, which encodes the telomerase reverse transcriptase, have been reported. AD DC is very often manifested as atypical DC. Because of the often atypical findings, the frequency of AD DC is currently most likely significantly underestimated.[370]

Autosomal Recessive Dyskeratosis Congenita. A number of families have been described with AR DC (MIM 224230). AR DC is usually inferred when neither parent has any signs of DC and two or more children have the disease or when the parents of an affected child are consanguineous. Some families originally thought to have AR DC were found to have AD DC with variable penetrance and expressivity, thus mimicking sporadic or autosomal recessive disease.[422,423] Recently, a homozygous *NOP10* mutation has been associated with AR DC

in a single consanguineous family.[424] However, more likely, the *NOP10* mutations are hypomorphic mutations that are inherited codominantly.

Sporadic Dyskeratosis Congenita. A large proportion of DC cases arise sporadically. Of 123 such male cases from the DC registry in the United Kingdom, 40 were found to have a de novo *DKC1* mutation and 3 were found to have an inherited *TERC* mutation with variable penetrance and expressivity in the affected family. Eighty had neither *TERC* nor *DKC1* mutations. Similarly, all 35 female cases had neither *TERC* nor *DKC1* mutations. These sporadic cases account for more than half of DC patients.[422] Biallelic hypomorphic mutations may mimic sporadic disease, but it is due to codominant expression of the mutant alleles.[423]

The Dyskeratosis Congenita Genes and Their Functions

DKC1 and Dyskerin. X-linked DC is caused by mutations in the *DKC1* gene at Xq28. *DKC1* was identified by positional cloning in families with affected males and biased X-inactivation in female carriers.[367,417,418] The *DKC1*-encoded protein dyskerin is a 58-kd nucleolar protein orthologous to proteins in yeast, flies, and rats (Cbf5p,[425] Nop60B/minifly,[426] and NAP57,[427] respectively).

Dyskerin is associated with box H/ACA RNA molecules in ribonucleoprotein (RNP) complexes (Fig. 8-9). Box H/ACA RNP complexes consist of four different proteins (dyskerin, GAR1, NOP10, and NHP2) and an integral RNA species.[428,429] The box H/ACA RNA determines the function of the RNP complex. The majority of box H/ACA RNAs are small nucleolar RNAs (snoRNA) found in the nucleolus. These snoRNAs guide the protein complex containing dyskerin by complementary base pairing to specific uridine residues of newly synthesized ribosomal RNA (rRNA) molecules, which are then
FIGURE 8-9. Dyskerin associates with box H/ACA, small nucleolar RNAs (snoRNA), and telomerase RNA *(TERC)*. Dyskerin is a component of box H/ACA ribonucleoprotein (RNP) particles, where it associates with three other proteins, GAR1, NOP10, and NHP2, and a small noncoding RNA of the class of box H/ACA RNAs. The majority of box H/ACA RNAs are necessary for the modification of uridine residues (pseudouridylation) in ribosomal RNA. The 3′ end of the telomerase RNA *TERC* has the structure of box H/ACA RNA and associates with dyskerin and the dyskerin binding partners, as well as with the catalytic component of telomerase, TERT.

modified by pseudouridylation. In snoRNP dyskerin is the enzyme, a pseudouridine synthase, that actually catalyzes the pseudouridylation reaction.[430,431] The role of pseudouridylation is not known, but pseudouridines tend to be found in the conserved sequences of rRNA and transfer RNA (tRNA) in regions of high secondary structure, and it is likely that these modifications stabilize the secondary and tertiary structure of RNA molecules.[432] Other box H/ACA RNAs that associate with dyskerin and the three other proteins of the complex participate in ribosome biogenesis downstream of rRNA modification or messenger RNA (mRNA) splicing or are orphan RNAs, the function of which remains to be determined (for review see Meier[433]).

Telomerase RNA (*TERC*, telomerase RNA component), which along with TERT (telomerase reverse transcriptase) forms the core of the telomerase enzyme, also associates with dyskerin and the other three proteins present in H/ACA-class snoRNP (see Fig. 8-9).[434,435] The conserved secondary structure of the 3′ end of telomerase RNA is very similar to that of H/ACA RNAs.[434] This part of the telomerase RNA and its association with H/ACA RNP components are found only in vertebrates,[436] wherease the H/ACA RNP components themselves are highly conserved among all eukaryotes.[437] The four proteins may be involved in transport, stability, and assembly of the telomerase complex in the nucleolus. At this point there is no evidence that the H/ACA part of telomerase RNA functions as a guide RNA or that dyskerin exhibits any pseudouridylation activity as part of the telomerase complex.

The diverse function of dyskerin in humans raises the interesting question of whether and to what extent the pathogenesis of X-linked DC is caused by defects in telomerase activity or in other functions of RNP, such as rRNA metabolism.

NOP10. Recently, autozygous mutations (homozygous mutations in a consanguineous family) in the *NOP10* gene on chromosome 15q14 have been found to be responsible for disease in a single family.[424] NOP10, like dyskerin, is an essential component of H/ACA RNP complexes and thus participates in the same pathways as dyskerin (see earlier). Whether mutations in *NOP10* cause disease as a result of defects in telomere maintenance or defects in other functions of H/ACA RNP complexes, such as rRNA metabolism, remains to be determined.

***TERC, TERT,* and Telomerase.** AD DC is caused by mutations in the *TERC* gene, also abbreviated as *hTR or TER*, which is found on chromosome 3q26.[438] *TERC* was identified as the gene responsible for AD DC through positional cloning.[438] It encodes the RNA component of the telomerase complex. Telomerase, the enzyme responsible for elongating and maintaining telomeres, synthesizes telomeric DNA repeats by using *TERC* RNA as a template (Box 8-10 and Fig. 8-10A and B).[438] Non-

---

Box 8-10 | Telomeres/Telomerase

Telomeres are complex DNA/protein structures at the ends of chromosomes that are needed to protect chromosome ends from degradation and distinguish them from double-stranded breaks.[439] Human telomere DNA consists of thousands of repeats of TTAGGG. In the absence of telomerase in most somatic cells, telomeres do shorten with each cell division.[440] In most tissues, therefore, telomere length decreases with age.[441] When telomeres become critically short, cell cycle arrest or cell death occurs (see Fig. 8-10).[442]

DNA polymerase I cannot copy the extreme end of a DNA strand,[443] so telomeres would tend to get shorter with each cell division. In germ cells,[444] some stem cells,[445,446] and most cancer cells,[442,447] telomeres are maintained by the action of the enzyme *telomerase*,[448] which contains two core components, a reverse transcriptase TERT (telomerase reverse transcriptase) and an RNA molecule, *TERC* (telomerase RNA component), that acts as a template for the synthesis of telomere repeats (see Fig. 8-10).

---

synonymous mutations have also been identified in the *TERT* gene localized on 5p15.33.[449-452] TERT is the catalytic part of the telomerase complex (see Box 8-10 and Fig. 8-9). *TERT* was identified as a gene responsible for AD DC through a candidate gene approach.[449-451] Telomerase RNA, or the TERC component, which along with TERT forms the core of the telomerase enzyme, also associates with the four proteins present in H/ACA-class RNPs, including dyskerin and NOP10 (telomerase RNP complex, see Fig. 8-9).[434,435]

TINF2. Recently three mutations in exon 6 of *TINF2* encoding TIN2 have been identified in six patients with DC. All mutations were associated with short telomeres. TIN2 associates with the telomere. The mechanism by which the TIN2 mutations cause telomere shortening remains to be determined.[452a]

Other Genes. For about 60% of patients in whom DC and BMF are diagnosed, the mutations or the genes mutated have not been identified. Like patients with DC and BMF caused by mutations in dyskerin, *NOP10*, *TERC*, or *TERT*, these patients also have very short telomeres, thus suggesting that the affected gene or genes participates in the same pathway.

Unraveling of the molecular pathology of DC has greatly advanced our understanding of the disease. The finding that X-linked and AD DC is caused by defects in molecules that are part of the telomerase RNP complex favors the paramount importance of defective telomerase in the pathology of DC. The finding that all patients with DC and BMF have very short telomeres further underscores the importance of telomerase function in this disease. Figure 8-11 summarizes our current model of the pathogenesis of disease in patients with DC.

A

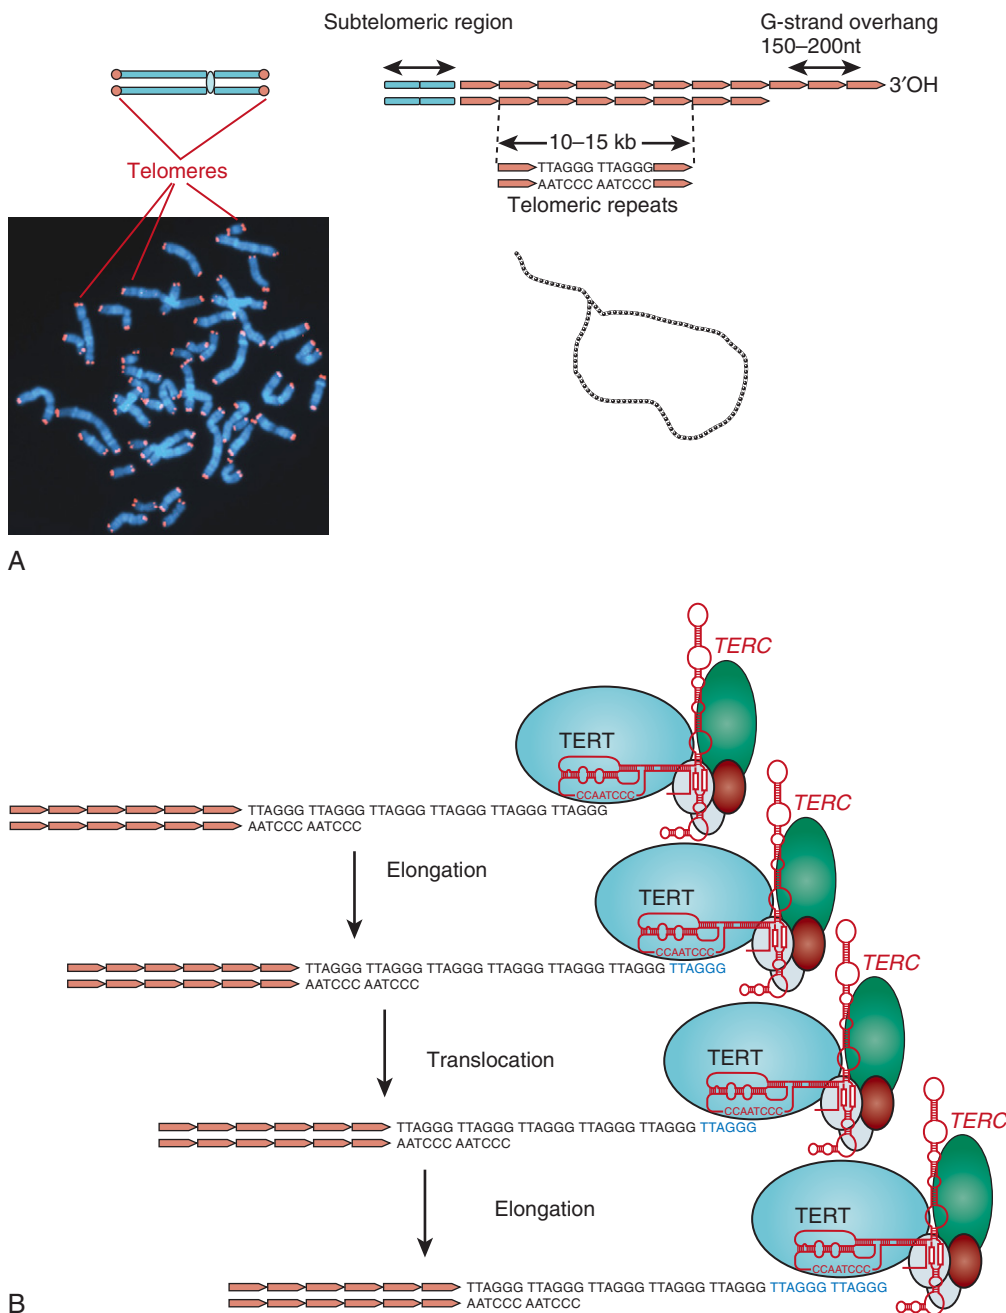
B


FIGURE 8-10. **A,** Telomeres and telomere structure. Telomeres are the end of chromosomes. They are complex protein DNA structures that protect telomere ends from degradation and end-to-end fusion (also see Box 8-7). In nondividing cell telomeres often form a loop stucture, which makes the end inaccessible to DNA repair proteins and DNA exonucleases. **B,** Telomerase adds telomeric repeats to the 3′ end of telomeres (also see Box 8-10).

Dyskeratosis Congenita Gene Mutations in Patients with Dyskeratosis Congenita

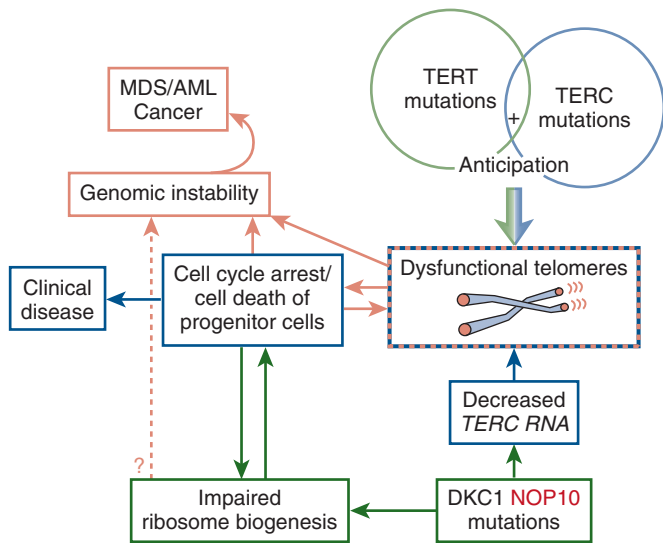
DKC1 **Mutations.** The mutations in the *DKC1* gene that cause DC are mainly single–amino acid missense mutations[453] (Fig. 8-12A) and can be inherited or occur de novo. The A353G mutation is the most frequent de novo *DKC1* mutation and is found in approximately 40% of patients with DC and *DKC1* mutations.[422] *DKC1* mutations are not randomly distributed but are concentrated in the N-terminal of dyskerin. The crystal structure of the archaeal homologue of the H/ACA RNP complex, the Cbf5–Nop10 complex,[454-456] has enabled modeling of human dyskerin. In this model the majority of residues mutated in cases of DC are tightly clustered in or near the PUA domain, which is predicted to bind H/ACA RNA, including *TERC* RNA (Fig. 8-13). The mutations would thus be expected to decrease binding of the cognate RNA and lead to instability. Only two mutations have been found in the TruB catalytic domain, one of which, S121G, is located three residues from the essential aspartate required for pseudouridylation and, interestingly, is associated with a severe form of DC also known as Hoyeraal-Hreidarsson syndrome (HHS, MIM 300240) (also see later). The absence of mutations that would predict a "null" allele, such as frameshifts and nonsense mutations, suggests that a dyskerin null mutation is incompatible with life. In support of this notion, a dyskerin null mutation is embryonically lethal in mice.[457]


FIGURE 8-11. Model of the pathogenesis of disease in patients with dyskeratosis congenita (DC). Our hypothesis is that excessive telomere shortening and dysfunctional telomeres play a central role in the pathogenesis of DC. Dysfunctional telomeres lead to cell cycle arrest and cell death. In patients with *DKC1* and *NOP10* mutations, *TERC* RNA stability and accumulation are decreased, which leads to decreased telomerase activity and telomere shortening. In addition a possible impairment in ribosome biogenesis also impairs cell survival and proliferation. *TERC* gene mutations and *TERT* mutations cause telomere shortening through haploinsufficiency. The inheritance of shortened telomeres is the molecular mechanism of anticipation in autosomal dominant DC. Dysfunctional telomeres lead to genomic instability, which may contribute to the predisposition to cancer in patients with DC. AMC, acute myeloid leukemia; MDS, myelodyplastic syndrome.

The functional consequences of a subset of pathogenic *DKC1* mutations have been investigated in fibroblasts or mononuclear cells from patients with X-linked DC[458,459] and in XY mouse embryonic stem cells harboring a mutated *Dkc1* allele.[460] Analysis of fibroblasts or mononuclear cells from patients with X-linked DC showed a reduced level of *TERC* RNA and decreased telomerase activity, whereas analysis in mouse cells revealed that not only the level of *Terc* RNA but also the levels of other specific snoRNAs were affected and that overall pseudouridylation activity, in particular, site-specific pseudouridylation involving the affected guide snoRNA, was markedly decreased. Thus, it remains controversial whether X-linked DC is due to defective telomere maintenance, defective ribosome biogenesis, or possibly both.[2,370]

NOP10 Mutation. Recently, autozygous *NOP10* mutations have been identified in one consanguineous family. The mutation leads to replacement of a highly conserved arginine with tryptophan at amino acid position 34 (R34W).[424] The three affected family members were autozygous for the mutation. Heterozygous mutation carriers did not show obvious signs of disease but had shortened telomeres and decreased levels of *TERC* RNA in their peripheral blood cells.[424] The inheritance

of hypomorphic gene mutations may mimic a recessive inheritance pattern. The shortened telomeres and reduced levels of *TERC* RNA in heterozygous mutation carriers, however, suggest that both *NOP10* alleles are expressed codominantly. Whether the mutation affects the function of only telomerase RNP or also other H/ACA RNP complexes remains to be determined.

TERC Gene Mutations. The *TERC* mutations found in patients with DC are shown in Figure 8-12B. Investigation of family members revealed that in all patients with clinical manifestations of DC the *TERC* gene mutations were inherited. Many mutations are found in the pseudoknot domain of the molecule, a domain that mediates binding to the telomerase reverse transcriptase TERT and is essential for telomerase activity. Other mutations are found in the CR7 and H/ACA domains and affect the stability and nuclear accumulation of the *TERC* molecule. In many of these mutations it has been demonstrated that the mutations act by disrupting the secondary structure of the *TERC* molecule rather than by altering nucleotide sequences crucial for function,[461-466] in agreement with the fact that although the secondary structure of *TERC* is highly conserved among different species, the primary sequence is not.[436] Large gene deletions encompassing the *TERC* gene have been identified in two independent families with AD DC. Along with the pathogenic mutations, which have been shown by several groups to severely reduce telomerase activity, there are two polymorphisms that are relatively frequent in people of African descent.[467] These sequence changes, G58A and G228A, do not affect telomerase activity,[461,462,467] and individuals carrying these sequence alterations have normal telomere length independent of the presence of BMF. In addition, the mutation G450A, found in a patient with severe aplastic anemia, apparently had no effect on telomerase or telomere length.[461]

The existence of large deletions and in vitro transfection studies led to the conclusion that haploinsufficiency of *TERC* is the mechanism underlying AD DC.

TERT Gene Mutations. Heterozygosity for nonsynonymous mutations in the *TERT* gene have been identified in individuals with aplastic anemia and short telomeres and more recently also in individuals in whom pulmonary fibrosis was originally diagnosed.[379,380,449-452] The mutations identified are summarized in Figure 8-12C. Mutations located in the N-terminal critical for binding of *TERC* RNA and within the central region of *TERT* defining the catalytic region of the reverse transcriptase impair telomerase activity to a variable degree. Mutations in the C-terminal region affect in vivo telomere synthesis after the assembly of a catalytically active enzyme.[468] The A202T and H412W mutations have been identified more than once in unrelated families. Two small deletions causing a frameshift and a truncated TERT protein and two splicing mutations have been identified in individuals in whom pulmonary fibrosis was originally diagnosed.[379]
FIGURE 8-12. A, Mutations in the *DKC1* gene. A schematic representation of the *DKC1* gene is presented below the schematic representation of dyskerin protein and its functional domains. Patient-derived mutations are shown. *Asterisks* indicate recurrent mutations. The A353V mutation, shown in red, is a frequent de novo mutation and accounts for about a third of the mutations in *DKC1*. Mutations shown in purple are found in patients with a severe form of dyskeratosis congenita (DC) also known as Hoyeraal-Hreidarsson syndrome. NLS, nuclear localization signal; TruB and PUA, pseudouridine synthase domains. **B,** Mutations in the *TERC* gene as shown in a schematic representation of the tertiary structure of telomerase RNA (*TERC*). The pseudoknot and the CR4-CR5 domain are important for the association of *TERC* with the catalytic subunit TERT and for telomerase activity. Mutations found in families with autosomal dominant DC are shown, including two large deletions, one deleting the 5' end and the other the 3' end of *TERC*.

Disease manifestations in families with *TERT* gene mutations are highly variable, and frequently disease does not segregate with the mutation in these families, thus indicating incomplete disease penetrance. Interestingly, individuals with a de novo *TERT* gene deletion secondary to a large chromosomal deletion on chromosome 5p (5p–syndrome, cri du chat syndrome) show accelerated telomere shortening but no clinical features characteristic of DC.[469] In contrast, biallelic *TERT* gene mutations have been identified in patients with classic manifestations of DC and in one individual with HHS, a very severe form of DC (see later also), which suggests that the mutant alleles are expressed codominantly and the residual telomerase activity determines the clinical pheno-

type.[423,470] Biallelic *TERT* or *TERC* null mutations have never been described, thus suggesting that in contrast to mice, in humans complete lack of telomerase activity is not compatible with life.[410]

***TINF2* Mutations.** Mutation A838G (TIN2 K280E) was found in a large family with aplastic anemia. Mutation G844A (R282H) was identified in three unrelated patients with early onset and severe disease similar to Hoyeraal-Hreidarsson and Ravesz syndrome. The third C845A (R282S) was found in one patient with early onset of severe aplastic anemia and immune deficiency. Both R282H and R282S were de novo mutation and were associated with very short telomeres.[452a]

Patient-derived mutations are shown. Sequence variants of uncertain pathogenicity are shown in gray. Small deletions are indicated below the diagram. L1 and L2 are linker regions; Sf indicates a frameshift, which results in a premature stop codon X. *Asterisks* indicate recurrent mutations. **D,** Mutation in NOP10. A schematic representation of the NOP10 gene is shown, below the NOP10 protein. The mutation identified in one consanguineous family is shown. The patient was homozygous for the mutation.
FIGURE 8-13. Clustering of pathogenic mutations in dyskerin. The crystal structure of the archaeal homologue of dyskerin is shown.[454-456] In this model the majority of residues mutated in cases of dyskeratosis congenita are tightly clustered in or near the PUA domain, which is predicted to bind box H/ACA RNA, including *TERC* RNA. *(Modified from Rashid R, Liang B, Baker DL, et al. Crystal structure of a Cbf5-Nop10-Gar1 complex and implications in RNA-guided pseudouridylation and dyskeratosis congenita. Mol Cell. 2006;21:249-260.)*

Genotype-Phenotype Correlation

The disease phenotype of patients with DC is highly variable and largely determined by the gene mutated and the pattern of inheritance (X-linked, autosomal dominant, or autosomal recessive), the nature of the mutation, and the history of inheritance (number of generations that the mutations has been passed on).

DCK1 **Mutations.** The severity of disease in individuals with X-linked DC varies from hardly detectable to a severe form of DC known as HHS (see later), which causes death in early childhood (see Fig. 8-12A). *DKC1* maps to the X chromosome, so the majority of affected individuals are therefore males. The most frequent clinical manifestation is classic DC with mucocutaneous findings in early childhood and progressive BMF in adolescence.

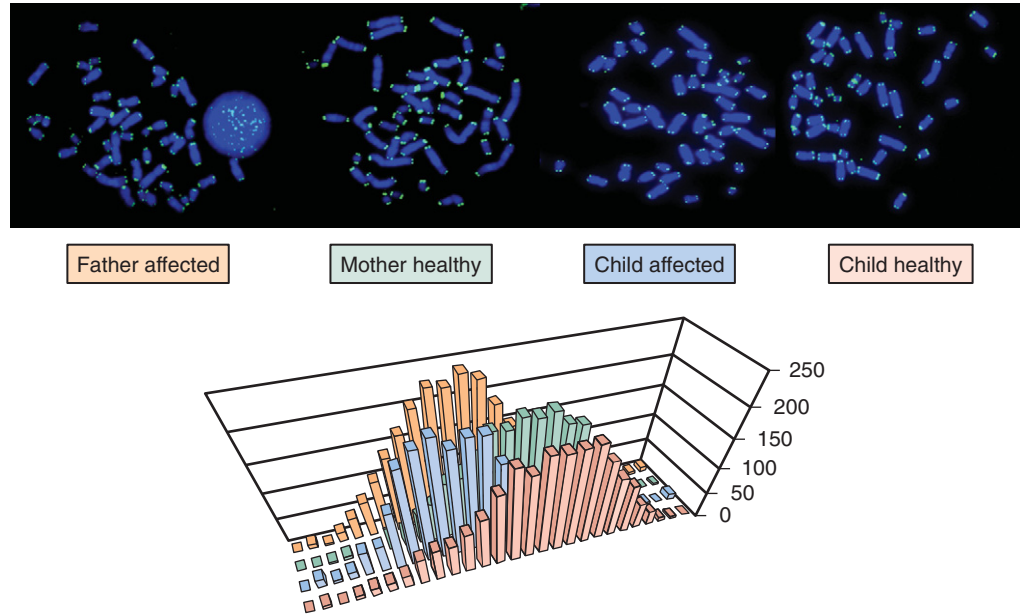
Female carriers of the *DKC1* mutation rarely show signs of hematologic disease. Cutaneous manifestations may be found in female carriers but are usually mild. Female carriers of X-linked DC show a phenomenon known as skewed or *biased X-inactivation*. In females, inactivation of one X chromosome must occur at random early in development to achieve the same dosage of X-linked genes as in male cells. When X-inactivation has been established in a particular cell, it is faithfully passed to all progeny. Thus, in women, tissues are therefore a

mosaic in which half the cells have the maternal and half have the paternal X chromosome active. In female carriers of DC, blood consists entirely of cells in which the X chromosome containing the normal dyskerin gene is active,[417,418] which indicates that after random X-inactivation, cells with wild-type dyskerin have a growth or survival advantage (or both) and outgrow mutant cells. Whether this outgrowth takes place in embryogenesis or childhood and whether all tissues are affected are not known. Telomere length in peripheral blood cells in female DC carriers varies from within normal limits to very short.[357] MDS or MDS/AML has never been described in a female *DKC1* mutation carrier. Whether female carriers are at increased risk for the development of cancer in other organs remains to be determined. Biased X-inactivation can be used to determine whether DC in a family is X-linked (see earlier).

***TERC* Gene Mutations.** The clinical phenotype in patients with AD DC caused by *TERC* gene mutations is usually mild. Analysis of family members of individuals with AD DC showed that mutation carriers frequently have only subtle signs of BMF but lack the mucocutaneous features of classic DC (atypical DC, see also Fig. 8-7). Interestingly, the only patient reported to be a compound heterozygote for two different *TERC* gene mutations showed signs of classic DC and early onset of disease, whereas family members with only one of the two mutations did not.[471] *TERC* gene mutations were identified in a subset of adult patients in whom familial or acquired idiopathic aplastic anemia was originally diagnosed and in patients in whom idiopatic pulmonary fibrosis was originally diagnosed.[379,472-474] Investigation of family members revealed that in all patients the *TERC* gene mutations are inherited and that all mutation carriers have short (below the 10th percentile) or very short (below the 1st percentile) telomeres. However, short and very short telomeres were additionally found in individual family members who did not carry the mutation and had no signs of disease.[475] *TERC* gene mutations were likewise identified in some patients with cytopenic MDS or MDS/AML.[474,476] The mutations identified were associated with reduced telomerase activity in vitro and very short telomeres in the mutation carriers with BMF. The presence of *TERC* gene mutations in patients in whom pulmonary fibrosis, aplastic anemia, MDS, or MDS/AML was originally diagnosed indicates that the underlying problem in these patients is the pathology of DC and that the variable expressivity and penetrance of the clinical manifestations in DC lead to a much broader clinical picture than originally anticipated when investigating only individuals with classic DC. Interestingly, *TERC* gene alterations were rarely found in children with aplastic anemia or MDS in the absence of a family history, consistent with the later onset of disease in individuals with AD DC.[397] Pulmonary fibrosis and liver cirrhosis were frequent and sometimes even the first clinical finding in individuals or families with DC and *TERC* gene mutations.

Anticipation. AD DC is one of a small number of diseases that show genetic anticipation (i.e., the disease becomes more severe and has an earlier age at onset in later generations). Anticipation became apparent when asymptomatic parents of affected individuals were found to also have *TERC* gene mutations (Box 8-11).[438,476] In several cases, examination of these asymptomatic parents revealed that they had signs of mild anemia, such as raised mean corpuscular volume (MCV). In other pedigrees, anemia develops in the parents at an older age than in the children. The mechanism of anticipation appears to be that telomere shortening increases in later generations carrying a defective *TERC* allele.[475,476] Figure 8-14 shows the inheritance of preshortened telomeres in a nuclear family with AD DC caused by a *TERC* gene deletion. Thus, AD DC develops if an individual inherits a defective *TERC* or *TERT* allele and shortened telomeres. It is not known how many generations are needed to produce telomeres short enough to cause the disease. Studies in individuals with a de novo deletion of 5p that includes the *TERT* gene (5p– syndrome) indicate that in the first generation with *TERT* haploinsufficiency, telomere shortening is minimal.[469] Interestingly, in individuals with DC and BMF, the telomeres are all equally short, thus suggesting that there is a minimal length of telomeres required for a progenitor cell to contribute to the peripheral blood cell pool.[469,475]

***TERT* Gene Mutations.** Nonsynonymous mutations, small deletions, and splice site mutations in the telomerase reverse transcriptase *TERT* gene have been identified in individuals in whom aplastic anemia with short telomeres was diagnosed and in individuals in whom pulmonary fibrosis was diagnosed,[379,380,449-452] thus indicating that *TERT* gene mutations may account for cases of atypical DC. Anticipation has also been described in families with AD DC secondary to *TERT* gene mutations.[451] Individuals with heterozygous *TERT* gene mutations rarely have the classic form of DC; the majority have atypical DC. Pulmonary fibrosis is a frequent finding in patients and families with atypical DC caused by *TERT* gene mutations.[379,380,451] Mutation carriers with no signs of disease (silent DC) are often found in families with heterozygous *TERT* gene mutations. Whether telo-

FIGURE 8-14. Inheritance of preshortened telomeres in a family with autosomal dominant dyskeratosis congenita caused by a *TERC* gene deletion. Metaphase spreads of peripheral blood lymphocytes are shown. The green signals at the end of chromosomes show the telomeric repeats hybridized to a fluorescent probe. Below is a graphic representation of the telomere length distribution of each family member. Note that both the affected child and the nonaffected child have inherited preshortened telomeres; in view of their young age, their telomeres should be longer than those of their parents.


mere length may identify silent *TERT* gene mutation carriers remains to be determined. Although one would expect that the disease in AD DC secondary to *TERC* or *TERT* mutations would be similar, initial family studies indicate that penetrance and expressivity differ in families heterozygous for *TERC* or *TERT* gene mutations. The most likely explanation is that TERC or TERT is limiting for different tissues and that expression of a functional TERT protein is regulated differently from regulation of *TERC* gene expression. Biallelic *TERT* gene mutations may lead to the classic manifestations of DC and have also been identified in one individual with HHS, a very severe form of DC (also see later), which suggests that the mutant alleles are expressed codominantly and that residual telomerase activity determines the severity of the clinical phenotype.[423,470] Biallelic *TERT* or *TERC* null mutations have never been described, thus suggesting that in contrast to mice, complete lack of telomerase activity is not compatible with life in humans.[423]

Molecular Diagnosis of Dyskeratosis Congenita

Currently, molecular diagnostics is not routinely performed for DC because it is expensive, labor intensive, and limited to specialized laboratories. However, only identification of pathogenic mutations in one of the DC genes definitively establishes the diagnosis of DC. Furthermore, molecular diagnostics enables the identification of mutation carriers, facilitates prenatal diagnosis for an existing pregnancy, and allows PGD for partners identified as mutation carriers. In addition, because the clinical manifestations, severity of disease, prognosis, and response to treatment may vary, depending on the affected gene and the nature of the individual mutation, molecular diagnostics may also influence medical management not only for the DC individual carrying the mutation but also for unaffected family members. Currently, an edu-

cated candidate gene approach in which the gender and family history of the affected DC individual are taken into account is used to identify the affected DC gene. In an affected male after exclusion of the most frequent *DKC1* mutation (A353V), it might be necessary to perform a mutational screen of the entire coding sequence of all three DC genes (usually only *TERC* and *TERT* in an affected female). For *TERC* and *TERT* the screening methods should include techniques that will detect large deletions. Mutation screening is currently successful in only about half of individuals with DC. In addition to the large number of mutations in DC genes associated with DC, a number of nonpathogenic mutations and mutations of unknown pathogenic significance have been identified. Determining the pathogenicity of a particular mutation may be difficult.

Telomere measurement in peripheral blood cells has emerged as a sensitive screening tool for DC in patients with BMF.[356,357] Whether telomere measurements performed on peripheral blood cells may also identify individuals with DC but nonhematopoietic disease manifestations or DC mutation carriers is controversial.[356,357]

Diseases Related to Dyskeratosis Congenita

Idiopathic Aplastic Anemia

A proportion of patients with idiopathic aplastic anemia or hypolastic MDS were found to have mutations in *TERC* or *TERT*.[449,450,472-474] These patients therefore have AD DC. The prevalence of *TERC* mutations among individuals in whom idiopathic aplastic anemia or hypoplastic MDS is diagnosed appears to be between 2% and 10%. No *TERC* mutations were found in 284 children with severe aplastic anemia or MDS, in agreement with later onset of the autosomal dominant disease.[397] Because parents are often asymptomatic as a result of the anticipa-

tion phenomenon and because of incomplete penetrance of *TERC* and in particular *TERT* gene mutations, a family history is not apparent and a diagnosis of idiopathic aplastic anemia or idiopathic MDS is made.

Hereditary Pulmonary Fibrosis

Pulmonary fibrosis, especially in patients with AD DC, may be an initial and sometimes prominent feature of those with atypical DC. Families with hereditary pulmonary fibrosis of adult onset should be investigated for DC.[379,380] Further investigations are needed to understand the pathogenesis of pulmonary fibrosis in these individuals.

Hoyeraal-Hreidarsson Syndrome

HHS (MIM 300240) is a rare variant of DC that develops in early childhood. It is characterized by intrauterine growth retardation, microcephaly, cerebellar hypoplasia, mental retardation, progressive combined immune deficiency, and aplastic anemia.[477-480] Delayed myelination and hypoplasia of the corpus callosum have been described in patients with HHS.[481] Many but not all patients have a mutation in the *DKC1* gene (see Fig. 8-12A).[482,483] Interestingly, the same mutation (Thr49Met) has been found in four unrelated pedigrees,[422,483,484] and I38T has likewise been found in unrelated HHS patients.[422,485] It is also notable that several cases of HHS are due to the recurrent mutation (A353V) that is responsible for a third of the X-linked *DKC1* cases.[422,453] One of the *DKC1* mutations causing HHS, S121G, is close to the catalytic aspartate residue D125, in the pseudouridylation pocket of the protein. In addition, HHS has been found in one individual autozygous (homozygosity in a consanguineous family) for a *TERT* gene mutation and in an individual heterozygous for a *TERT* gene mutation and anticipation, thus indicating that HHS may also be a consequence of a severe telomerase defect alone. In fact, HHS patients have very short telomeres at the time of diagnosis.[356,357,422]

Revesz' Syndrome

The association of progressive bilateral exudative retinopathy (Coats' retinopathy), intrauterine growth retardation, fine sparse hair, fine reticulate skin pigmentation, ataxia secondary to cerebellar hypoplasia, cerebral calcifications, extensor hypertonia, and progressive psychomotor retardation with progressive BMF and death in early childhood, also known as Revesz' syndrome (MIM 268130), might be another severe form of DC.[486-488] Indeed, similar to patients with HHS, individuals with Revesz' syndrome have very short telomeres.[356] Coats' retinopathy has also been described in patients with classic DC.[384] A R282H TIN2 mutation has been identified in one patient with Revesz' syndrome.[452a]

Ataxia-Pancytopenia Syndrome

Ataxia-pancytopenia syndrome is another BMF syndrome with similarities to severe forms of DC. In patients with this syndrome, BMF is associated with severe cerebellar hypoplasia and chromosomal instability without an increase after DEB or MMC testing.[489] MDS and MDS/AML with monosomy 7 are often associated with this syndrome.[489-491] The molecular lesion in patients with ataxia-pancytopenia syndrome and the association with short telomeres suggesting a defect in the telomere maintenance pathway remain to be determined.

Animal Models

Several animal models of dyskerin dysfunction have been described that highlight the importance of rRNA processing in the pathogenesis of DC. Most of what we know about the biochemistry of dyskerin comes from studies of its yeast orthologue Cbf5p (reviewed by Filipowicz and Pogacic[428]; also see earlier). The *cbf5-1* temperature-sensitive mutant was found to have defects in rRNA synthesis and ribosome biogenesis at the restrictive temperature. Null mutations are not viable, whereas hypomorphic point mutations in *Cbf5* are mostly viable at 25°C but show heat- or cold-sensitive growth phenotypes with reduced levels of pseudouridine in rRNA at restrictive temperatures.[492-494] The dyskerin orthologue in *Drosophila* is the protein Nop60B, also known as minifly (*mfl*).[426] Total loss-of-function mutations are lethal, but partial loss-of-function mutations cause pleiotropic defects, including extreme reduction in body size, developmental delay, and reduced female fertility. *mfl* mutants are deficient in pseudouridylation of rRNA and in the production of mature rRNA molecules.[426,495] These results therefore illustrate that decreasing pseudouridylation of rRNA can slow rRNA production and cell growth. Some of the features of these mutants, small size and male sterility, are reminiscent of DC and can be related to the failure of stem cells in tissue renewal.[426,495] In both yeast and *Drosophila*, dyskerin does not associate with telomerase RNA.

In mice the lack of dyskerin is embryonically lethal,[457] whereas hypomorphic *dkc1* mutations in mice and murine ermbryonic stem cells cause defects in both telomere maintenance and ribosome biogenesis.[460,496] Telomere biology in mice differs to some extent from that in humans. Laboratory mice have very long telomeres (50 to 100 kb) in comparison to humans (10 to 15 kb). In mice, telomerase is expressed in almost every tissue, but in humans it is expressed only in germ cells, stem cells, and their immediate progeny and in activated monocytes and lymphocytes. Nevertheless, the study of telomerase-deficient mice (Terc−/−, and Tert−/−) was important for our current understanding of telomere biology and the significance of premature telomere shortening in a living organism.[497] Telomerase null mice, like DC patients, showed genetic anticipation with increasingly shorter telomeres in subsequent generations, as well as a disease phenotype similar to DC, including a shortened life span, early graying, reduced fertility, decreased wound healing, immune deficiency, decreased hematopoietic proliferative capability, and increased chromosomal instability

leading to a higher frequency of cancer.[498,499] However, in contrast to mice, homozygosity or compound heterozygosity for telomerase null mutations has never been described in humans, thus suggesting that this would not be compatible with life.

Mechanism of Disease Pathogenesis in Dyskeratosis Congenita

Although some mouse studies support the involvement of rRNA processing defects in the pathogenesis of DC,[460,496,500] the general consensus is that the central component in the pathogenesis of DC is defective telomere maintenance. An interesting question is whether the different clinical manifestations grouped as DC and discussed earlier are due to variations in the extent of telomerase deficiency or whether they relate to secondary effects of the altered gene products. Figure 8-11 summarizes our current model of the pathogenesis of disease in DC.

Clinical Management

Most of what we know regarding therapy and prognosis comes from our experience with patients with classic DC. Care must be taken when extrapolating such experience to patients with atypical DC caused by *TERC* or *TERT* gene mutations. The prognosis for patients with classic DC is usually poor. In males with X-linked and sporadic DC, the median age at death was 20 years.[9] Patients with AD DC have milder disease with a better survival rate. Deaths were usually due to complications from aplastic anemia, BMT, pulmonary fibrosis, or cancer.

Only identification of a pathogenetic mutation can confirm the diagnosis. Once confirmed, the family should be referred to a clinical geneticist familiar with new developments in DC for counseling and careful examination of family members. Genetic testing and possibly telomere measurement should be offered to all family members. Early diagnosis is important for correct management of hematologic complications; appropriate treatment of associated pulmonary, gastrointestinal, ocular, dental, and bone disease; identification of affected presymptomatic family members and unaffected family members or pregnancies that may serve as potential hematopoietic stem cell donors; and targeted cancer surveillance, not only in the patient with DC but also in mutation carriers (also see earlier).

Unfortunately, there is currently no consensus on how to manage patients with DC. Management depends on the age at diagnosis, the presence or absence of clinical signs, the gene affected, the molecular characteristic of the mutation identified, and possibly telomere length. All patients with DC and hematologic manifestations should have a full hematologic assessment, including examination of bone marrow, and in anticipation of possible HSCT, HLA typing should be performed. Other investigations at diagnosis should include pulmonary evaluation and examination of the oropharynx, anal region, and in females, cytologic examination of the vagina and cervical epithelium. The prognosis and life expectancy of family members who have inherited only the short telomeres but not the gene mutation is unknown. Whether these family members should be excluded as potential sibling donors of an affected family member is also unknown.

Management of Hematologic Disease

Treatment of BMF in patients with classic DC is similar to that in patients with FA. Initially, in the absence of hematologic abnormalities or clinical and laboratory signs of mild BMF, monitoring of peripheral blood values might be sufficient. In the presence of hematologic abnormalities, yearly bone marrow examination should include a trephine biopsy and marrow aspirate for the examination of marrow cellularity and morphologic changes characteristic of MDS, as well as for cytogenetic examination by G banding and FISH analysis, including probes that identify the most frequent cytogenetic abnormalities seen in patients with DC and progression to MDS or AML, or both (see earlier also). Plans for possible HSCT should be in place because hematologic complications may develop rapidly. With progression of BMF it will become necessary to increase the frequency of hematologic monitoring, and it may have to be individualized. Androgens and hemopoietic growth factors may improve BMF; however, in many patients the response is only transient.[501] Growth factors usually, if at all, have only a transient effect and should not be used in combination with androgens because of the risk of peliosis and splenic rupture.[502] Unlike idiopathic aplastic anemia, immunosuppressive agents such as antithymocyte globulin and cyclosporine are ineffective in cases of DC and BMF.

The ultimate treatment of BMF is allogenic HSCT. However, historically HSCT for DC has been associated with high morbidity and mortality. Treatment toxicity is a major cause of premature mortality in patients with DC.[378,503-505] Reduced-intensity conditioning regimens without irradiation and bleomycin might improve the outcome of HSCT in patients with DC.[485,506-510]

Management of DC patients with MDS or AML (or both) is even less standardized. The significance of transient clonal cytogenetic abnormalities is unclear, but if persistent or complex, such abnormalities usually predict a poor prognosis. Early hematopoietic stem cell harvest for autologous transplantation at a later time before the development of BMF is investigational and, because of the limited repopulating ability of the affected stem cells, is unlikely to be successful.

Management of Pulmonary Disease

There is currently no treatment of pulmonary disease in DC. Patients with DC should refrain from smoking, avoid drugs with pulmonary toxicity (e.g., bleomycin), and have their lungs shielded from radiation during BMT or cancer treatment.[511] Pulmonary fibrosis in patients with DC does not respond to immunosuppressive

therapy. Lung transplantation might be considered in individuals with otherwise mild manifestations of disease.[379,380]

Cancer Surveillance/Treatment

Patients with confirmed DC should avoid excessive exposure to ultraviolet light and use barrier sun creams. Avoidance of smoking and alcohol should be emphasized, particularly in patients with oral leukoplakia.[373,374] DC patients should also undergo regular dental/hygienist review to prevent early tooth loss. It is extremely important to screen for malignancies, especially of the gastrointestinal system. Management of malignancy may be complicated by a number of factors. The diagnosis may be delayed in some cases because of malignant change occurring within an area of persistent leukoplakia, thus resulting in a delay in treatment. There is also a high potential for local recurrence and multiple cancers in these patients. In addition, the presence of BMF makes chemotherapy very difficult and can limit the indications for surgery. The mucosa also has high sensitivity to radiation, which can lead to severe mucosal damage and may thus result in early termination of radiotherapy.

Management of oral malignancy usually includes a regular review and biopsy of the premalignant hyperkeratotic lesion and surgical laser excision of any suspicious areas. Neoadjuvant radiotherapy or surgical resection of confirmed malignancies, along with ipsilateral node clearance with or without adjuvant radiotherapy in accordance with staging of the disease, is the mainstay of treatment.

Gene Therapy

HSCT may cure hematologic disease in DC patients; unfortunately, however, HLA-matched sibling donor cells are available for only a minority of patients. Gene therapy to correct hematopoietic stem cells followed by autologous transplantation might therefore offer an attractive alternative for the treatment of hematologic disease in DC patients. Biased X-inactivation in female *DKC1* mutation carriers suggests that DC cells corrected by gene therapy are likely to have a selective growth/survival advantage. Indeed, gene transfer of *TERT* or *TERC* (or both) corrects the telomere defect in most DC cell lines.[409,512] However, as in many other IBMFSs, there is the problem that the few surviving hematopoietic stem cells might have already acquired secondary somatic and possibly oncogenic mutations and that correction by gene therapy would promote rather then prevent leukemogenesis in these patients.

Shwachman-Diamond Syndrome

SDS (MIM 260400) is a rare recessive multisystem disorder first described in the 1960s that is characterized by exocrine pancreatic insufficiency, bone marrow dysfunction, and skeletal abnormalities (Box 8-12).[513,514]

Box 8-12   Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome (MIM 260400) is a rare recessively inherited bone marrow failure syndrome characterized by exocrine pancreatic insufficiency; bone marrow dysfunction, including increased risk for malignant transformation; and skeletal abnormalities.

Box 8-13   Clinical Diagnostic Criteria for Shwachman-Diamond Syndrome

EXOCRINE PANCREATIC INSUFFICIENCY*

Low serum trypsinogen (in children <3 years old)
Low serum isoamylase (in children >3 years old)
Elevated fecal excretion (72-hour collection) and imaging studies showing fatty infiltration of the pancreas; other causes of steatorrhea should be excluded, including intestinal mucosal disorders and cholestatic liver disease
Abnormal pancreatic stimulation (rarely done today)

HEMATOPOIETIC ABNORMALITIES*

Neutropenia (<1500/μL); can be intermittent or chronic but must be documented at multiple time points (at least three times over a period of more than 3 months)
Anemia: hemoglobin below that for the age-adjusted norm
Thrombocytopenia
Pancytopenia
Myelodysplastic syndrome documented on bone marrow examination
Both exocrine insufficiency and hematopoietic abnormalities must be documented

---

*One of the following

Clinical Manifestations

SDS is an IBMFS with an estimated incidence of 1 per 75,000 live births.[515] It is more commonly diagnosed in boys, with a male-to-female ratio of 1.7:1.[516] The major clinical features associated with SDS have been defined in several large cohort studies and are summarized in Table 8-8.[516-521] It should be noted that with one exception, genetic testing for *SBDS* (Shwachman-Bodian-Diamond syndrome) mutations was not available at the time that these studies were reported. Interestingly, in the study in which the *SBDS* genotype was determined, the phenotype of patients with *SBDS* mutations was similar to that of those who had normal *SBDS* alleles.[521] Nonetheless, it is possible that classifying patients according to *SBDS* mutations may eventually refine the spectrum of clinical features (Box 8-13).

Hematologic Abnormalities

Neutropenia is present in the majority of patients with SDS (range, 77% to 100%); severe neutropenia (as

TABLE 8-8	Major Clinical Features of Shwachman-Diamond Syndrome						
Clinical Feature	Aggett et al.,[517] 1980	Mack et al.,[518] 1996*	Smith et al.,[519] 1996	Ginzberg et al.,[516] 1999	Cipolli et al.,[520] 1999	Kuijpers et al.,[521] 2005†	Total/ Average

Rib cage abnormalities	52%	32%	—	32%	92%	—	40%
Short stature (<3rd percentile)	95%	67%	—	56%	85%	52%	64%

*Short stature was defined as height below the 5th percentile.
†Fifteen of these patients had *SBDS* (Shwachman-Bodian-Diamond syndrome) gene mutations; severe neutropenia is a count less than 600/mL.
‡Hematologic abnormalities and exocrine pancreatic insufficiency are defining features of Shwachman-Diamond syndrome, hence the 100% incidence of these findings.

defined by an absolute neutrophil count [ANC] of less than 500/µL) was observed in a mean of 61% of patients (range, 23% to 67%; see Table 8-8). Neutropenia is intermittent in about two thirds of patients and chronic in the remaining third. Although defects in neutrophil chemotaxis are present in most patients with SDS,[522] the clinical significance of this finding is unclear because neutrophils are recruited to sites of infection.[523] Anemia, typically normochromic and normocytic, is present in approximately 50% of cases and is usually associated with a low reticulocyte count.[520] Thrombocytopenia is seen in approximately 50% of cases, sometimes without concomitant neutropenia. Pancytopenia has been reported in 10% to 44% of patients. The presence of or progression to severe aplastic anemia has been reported.[524,525] Defects in B- or T-lymphocyte function (or both) have been described, including impaired specific immunoglobulin response and altered CD4+ or CD8+ T-cell subsets.[526] Bone marrow findings are variable and nondiagnostic. Bone marrow cellularity ranges from hypocellular to hypercellular; myelodysplasia and left-shifted granulopoiesis are common.[519] An intrinsic cell defect in hematopoietic progenitors and impaired bone marrow stromal cell function have been reported.[527]

Transformation to Myelodysplastic Syndrome and Acute Myeloid Leukemia

Similar to other congenital BMF syndromes, there is a strong predilection for the development of MDS or MDS/AML in patients with SDS.[528,529] Acquired clonal cytogenetic abnormalities are seen frequently; in a prospective study of 14 patients with SDS monitored for a maximum of 5 years via annual bone marrow evaluation, clonal cytogenetic abnormalities were detected in 29%.[530]

Abnormalities in chromosome 7 are the most common and include monosomy 7, isochromosome 7q, and deletion of 7q. The clinical significance of these cytogenetic abnormalities is uncertain. In particular, isochromosome 7q appears to have a benign course with a low risk of transformation to MDS or MDS/AML.[531,532] Transformation to overt MDS or MDS/AML has been reported in 13% to 33% of cases.[519,533] There is a striking male preponderance; in a recent review, 92% of reported cases of MDS or MDS/AML in SDS occurred in males.[529] The malignant clone often displays complex cytogenetic abnormalities frequently involving chromosome 7.

Gastrointestinal Abnormalities

After cystic fibrosis, SDS is the most common cause of congenital exocrine pancreatic insufficiency. Patients are classically seen in early infancy with steatorrhea and failure to thrive. Pathologic analysis shows extensive fatty replacement of pancreatic acini with relative preservation of pancreatic ducts and islets. Exocrine pancreas insufficiency can be assessed by measurement of serum trypsinogen or isoamylase, pancreatic stimulation tests, or fecal fat quantification.[534,535] In addition, imaging of the pancreas may reveal characteristic fatty infiltration (Fig. 8-15).[536-538] For unclear reasons, the pancreatic insufficiency improves with increasing age in most patients. Mild (twofold to threefold) elevation of liver transaminases is often seen in patients younger than 2 years. It is usually of little clinical significance and tends to improve with age.[518]

Skeletal Abnormalities

Most patients with SDS have bony abnormalities, with rib cage abnormalities, metaphyseal dysostosis, and osteopenia being the most common findings (see Table
FIGURE 8-15. Fatty infiltration of the pancreas in Shwachman-Diamond syndrome (SDS) shown by transverse computed tomography images of a normal individual (**A**) and patient with SDS (**B**). The density of the normal pancreas (*arrows*) is similar to that of liver. In contrast, the density of the SDS pancreas (*arrows*) is reduced, consistent with fatty infiltration. *(Reproduced with kind permission of Springer Science and Business Media. From Nijs E, Callahan MJ, Taylor GA. Disorders of the pediatric pancreas: imaging features. Pediatr Radiol. 2005;35:358-373.)*

8-8).[539] Growth retardation is also common in SDS patients, but it is not thought to be secondary to malnutrition. More than half of patients with SDS are below the 3rd percentile for height at 1 year. With adequate pancreatic enzyme replacement, most patients show normal growth velocity but remain below or at the 3rd percentile for height.[516]

Miscellaneous Abnormalities

Many patients with SDS suffer from pyschomotor delay[516-518,540] or dental abnormalities.[541,542] There are reports of other endocrine abnormalities such as diabetes mellitus,[517,518] growth hormone deficiency,[543] renal tubular acidosis,[516] cleft palate,[516] and cardiomyopathy.[544]

Differential Diagnosis

Diagnostic criteria for SDS are outlined in Box 8-12[545]; both exocrine pancreatic insufficiency and hematopoietic abnormality must be documented. Other features of SDS, including short stature or skeletal or hepatic abnormalities, though supportive, are not required for the diagnosis. Genetic testing for *SBDS* mutations is merited since their presence confirms the diagnosis of SDS. However, their lack does not exclude the diagnosis because in approximately 10% of cases of clinically defined SDS, no mutations in *SBDS* are present.[546-548] Other causes of exocrine pancreatic insufficiency should be considered, including cystic fibrosis, which can be excluded by performing a sweat test. Pearson's disease is characterized by exocrine pancreatic insufficiency, sideroblastic anemia, vacuolization of hematopoietic cells in bone marrow, and metabolic acidosis.[549,550] It is caused by deletions in mitochondrial DNA (mtDNA).[551] Cartilage-hair hypoplasia (CHH) syndrome is characterized by short stature, metaphyseal dysostosis, cytopenias, and hypoplastic hair.[552] It is secondary to mutations in the RNase mitochondrial RNA processing (*RMRP*) gene encoding the RNA subunit of the RMRP complex.[553]

Genetics

SDS is an autosomal recessive disorder.[554] The gene responsible for SDS was identified by genetic linkage analysis.[547] Boocock and colleagues reported that compound heterozygous mutations of the *SBDS* gene located on chromosome 7 were present in the majority of patients with SDS.[547] Most of these mutations resulted from gene conversion with a neighboring pseudogene (*SBDSP*). Subsequent studies have confirmed that *SBDS* mutations are present in approximately 90% of clinically diagnosed cases of SDS.[547,549,555,556] The majority of mutations occur within exon 2 and are predicted to result in the production of a truncated protein. The remaining mutations are missense and nonsense mutations scattered throughout the protein. Most of the mutations result in a dramatic reduction in SBDS protein production.[547,549] However, patients carrying homozygous null alleles for *SBDS* have not been reported, which suggests that SBDS is essential for life. Consistent with this conclusion, mice lacking the murine orthologue of SBDS are subject to early embryonic lethality.[557] Interestingly, in the subset of patients who do not have *SBDS* mutations, SBDS protein expression in leukocytes is normal, thus indicating that other genetic mutations may be responsible for these cases of SDS.[548,5491]

Recent studies suggest that there may be a spectrum of disease associated with *SBDS* mutations. Nishimura and colleagues reported that two unrelated patients with neonatal spondylometaphyseal dysplasia (SMD) carried compound heterozygous mutations of *SBDS*.[558] Clinical features included severe metaphysial dysplasia, platyspondyly, and neonatal respiratory failure, similar to the Sedaghantian type of SMD.

There is also evidence that halploinsufficiency for *SBDS* may predispose to the development of aplastic anemia. Calado and colleagues reported that 4 of 91 patients with apparently acquired aplastic anemia had heterozygous mutations of *SBDS*.[559] Affected patients had no evidence of exocrine pancreatic insufficiency or

bony abnormalities but did have short stature. The significance of this finding is unclear because the number of individuals studied is far too small to predict a statistically significant association between heterozygosity for an *SBDS* mutation and the development of aplastic anemia.

The *SBDS* gene encodes a 250–amino acid protein that is highly conserved throughout evolution but lacks any recognizable functional domain. Although there is evidence that SBDS interacts with the actin cytoskeleton,[560] the primary function of SBDS appears to be regulation of ribosome biogenesis. SBDS protein prominently localizes to the nucleolus of cells in a cell cycle–dependent fashion.[546] SBDS coprecipitates with the 28S ribosomal subunit and associates with nucleophosmin, a protein implicated in ribosome biogenesis and leukemogenesis.[561] In yeast, loss of the *SBDS* orthologue *Sdo1* leads to impaired ribosomal biogenesis.[562] Specifically, Sdo1 appears to facilitate release of Tif6 from the pre-60S ribosomal subunit, which allows final ribosome assembly and activation of translation. Together, these observations place SDS in a growing list of bone marrow disorders caused by impaired ribosome biogenesis.

The mechanism for the increased susceptibility to MDS and MDS/AML in patients with SDS is unclear. Rawls and colleagues showed that inhibition of Sbds expression by RNAi in murine hematopoietic progenitors leads to loss of engraftment potential, thus suggesting that hematopoietic stem cell function in SDS may be impaired.[563] The fact that clonal cytogenetic abnormalities are common in SDS suggests genomic instability within hematopoietic progenitors. There is a single report of short telomeres in the leukocytes of patients with SDS; however, the relevance of this finding to chromosomal instability is unclear.[564] Recent data suggest that SBDS protein localizes to the mitotic spindle and stabilizes microtubules in vitro. Depletion of SBDS leads to mitotic abnormalities and aneuploidy, thus implying that defective spindle stability contributes to the mechanisms of BMF and leukemogenesis in patients with SDS.[565]

Clinical Management

Treatment of SDS includes pancreatic enzyme replacement and administration of fat-soluble vitamins for pancreatic insufficiency. Regular assessment of exocrine pancreatic function is recommended because in approximately 50% of patients, steatorrhea resolves spontaneously with increasing age.[518]

Regular blood counts should be performed every 4 months to monitor for cytopenia. In addition, annual bone marrow examination has been recommended to assess for clonal cytogenetic abnormalities.[545] For patients with severe neutropenia or neutropenia and persistent or recurrent infections, a trial of G-CSF treatment is warranted; response rates are generally high.[534] Similar to severe congenital neutropenia (SCN), current recommendations are that the dose of G-CSF be titrated to

achieve and maintain an ANC of 1000 to 1500/μL.[566] As discussed in the later section on SCN, no clear association of G-CSF with malignant transformation has been demonstrated to date. Nonetheless, patients with SDS should receive the lowest dose of G-CSF required to maintain an acceptable neutrophil count.

Allogeneic HSCT is the only curative therapy for SDS. It is generally reserved for patients with BMF or those who have transformed to AML/MDS. The majority of patients reported received a myeloablative conditioning regimen before HSCT consisting of cyclophosphamide, in combination with either busulfan or TBI, and unrelated bone marrow as a source of stem cells. HSCT in patients with SDS is associated with increased regimen-related toxicity, particularly of the heart and lung. The pathobiology of this increased toxicity is not understood. Data from the French Neutropenia Registry reported a 5-year event-free survival rate of 60% in 10 patients with SDS after HSCT.[567] Similarly, the European Group for Blood and Bone Marrow Transplantation reported a 64.5% overall survival rate with a median follow-up of 1.1 years in 25 patients with SDS after allogeneic HSCT.[568] From these studies it is clear that patients who undergo transplantation for BMF do much better than those receiving a transplant for MDS or AML. Combining these studies, the overall survival rate in patients after HSCT for BMF was 86% (18 of 21) versus 36% (5 of 14) in those after HSCT for MDS/AML. Insufficient follow-up data are available to assess the outcome of nonmyeloablative conditioning regimens in SDS patients with bone marrow aplasia.

Cartilage-Hair Hypoplasia

CHH (MIM 250250), also known as metaphyseal chondroplasia, McKusick type, is an autosomal recessive chondrodysplasia.[569]

Clinical Manifestations

CHH is characterized by metaphyseal dysostosis, short-limbed dwarfism, and fine, sparse hair that lacks the central pigment core. Clinical manifestations are highly heterogeneous and vary between and within families. Other skeletal findings include chest deformity, varus lower limbs, lordosis, and scoliosis. Gastrointestinal problems include aganglionic megacolon (Hirschsprung's disease) and other physical anomalies. The disease is more frequent in the Amish and Finnish populations because of a founder effect, with a carrier frequency of 1 in 19 among the Amish and 1 in 76 among the Finns. Mild to severe macrocytic anemia and lymphopenia are present in the majority of patients, whereas neutropenia is seen in only about a fourth. In the majority of individuals the anemia is mild and resolves spontaneously during early childhood. In more severe cases, the anemia resembles that seen in DBA or may be accompanied by severe immunodeficiency. The severity of the anemia inversely correlates with height. Similar severe immunodeficiency

is associated with more severe and persistent anemia. The frequency of lymphoid malignancies and basal cell carcinoma is increased about sevenfold.[570]

Differential Diagnosis

Excluding DBA from the differential diagnosis might be difficult in some cases. Thrombocytosis, increased erythropoietin levels, and increased levels of red cell adenosine deaminase (ADA), characteristic of DBA (see later), may be present in some patients with CHH. Metaphyseal dysplasia has not been reported in patients with DBA. Mutation analysis may be necessary to consolidate the diagnosis.

Genetics

CHH is an autosomal recessive disease. Genetic mapping and DNA sequencing identified the gene encoding the RNA component of *RMRP*, a 265-nucleotide noncoding RNA gene on 9p21-p12.[553] Mutations responsible for CHH are predominantly found in the transcribed and promoter region of the *RMRP* gene (reviewed by Martin and Li[571]). The most frequently found mutation is the A70G transversion, which is the major mutation in Finnish and Amish CHH patients. Other mutations include insertional mutations and duplications between the TATA box and the transcription start site that silence transcription. No patient homozygous or compound heterozygous for the promoter region duplications/insertions have been identified, thus suggesting that these mutations may be lethal. *RMRP* mutations have also been found in a variety of other forms of inherited metaphyseal dysplasia that share features with CHH, including metaphyseal dysplasia without hypotrichosis (MIM 250460), anauxetic dysplasia (MIM 607095), kyphomelic dysplasia (MIM 211350), and Omenn's syndrome (MIM 6035554).[572]

Gene Function

MRPR is the RNA component of the RNP complex RMRP that is involved in several cellular processes, including mtDNA replication,[573] ribosome biogenesis and pre-rRNA processing,[574] and mRNA degradation of cyclin B2 (*CLB2*), thereby regulating cell cycle progression.[575] Which of these pathways is responsible for BMF is unclear; however, differences and similarities to other ribosomal diseases suggest that the defects in ribosome biogenesis might be responsible for the anemia and that degradation of CLB2 contributes to the increased development of lymphoid tumors.[576] Genotype-phenotype correlation studies suggest a strong correlation between the decrease in rRNA cleavage in ribosomal assembly and the degree of bone dysplasia, whereas reduced mRNA cleavage and cell cycle impairment correlate with the presence of hair hypoplasia, immunodeficiency, hematologic abnormalities, and increased cancer risk.[572]

Clinical Management

Severe anemia requiring transfusion is seen rarely in CHH (6%) and often has a poor prognosis. Relapses may occur after recovery. Transfusions and glucocorticoid may improve the anemia. However, possible benefits of the treatment should be carefully weighed against the potential side effects in a condition associated with immune deficiency and short stature. Although many of the patients tended to outgrow their BMF, in some cases the anemia may be severe and persist, as in patients with DBA.[570] In patients with severe combined immunodeficiency, HSCT with or without myeloablation has been shown to provide long-term immune reconstitution.[577]

Pearson's Syndrome

Pearson's marrow-pancreas syndrome (PS, MIM 557000) is a refractory sideroblastic anemia characterized by vacuolization of bone marrow precursors as a result of deletion of mtDNA (Figs. 8-16 and 8-17). Pancreatic dysfunction is frequent but not mandatory for the diagnosis of PS.

Clinical Manifestations

PS is a multisystem disorder that usually becomes evident in early infancy.[549,578,579] Pancytopenia is frequently asso-
FIGURE 8-16. Characteristics in Pearson's syndrome (PS). **A,** Myeloid bone marrow precursor cell exhibiting prominent cytoplasmatic vacuolization. **B,** Southern blot analysis of the mitochondrial DNA of a patient with PS and a healthy control. The 16.6-kb wild-type mtDNA of the healthy control (lanes 2 and 3) is shown in comparison to the mtDNA of the patient carrying the 4503-bp deletion (lanes 4 and 5) in approximately 70% of the mtDNA molecules as quantified densitometrically. *(From Giese A, Kirschner-Schwabe R, Blumchen K, et al. Prenatal manifestation of pancytopenia in Pearson marrow-pancreas syndrome caused by a mitochondrial DNA deletion. Am J Med Genet A. 2007;143:285-288.)*

FIGURE 8-17. Example of the type of deletion found in Pearson's syndrome as shown in a schematic diagram of mitochondrial DNA. *(Redrawn from Sano T, Ban K, Ichiki T, et al. Molecular and genetic analyses of two patients with Pearson syndrome. Pediatr Res. 1993;34:105-110.)*
ciated with dysfunction of the exocrine pancreas, hepatic failure, and renal tubulopathy, which may lead to lactic acidosis. Vacuolization of hematopoietic precursor cells is characteristic (see Fig. 8-16). Most PS patients die before the age of 3 years. The major cause of death is metabolic acidosis, followed by liver and renal failure.[580,581] The few surviving children showed hematologic improvement, but typical features of Kearns-Sayre syndrome (MIM 530000) eventually developed.[582,583]

The male-to-female ratio of PS is 0.7:1. Patients from all racial and most ethnic groups have been reported.

Physical anomalies in patients with PS are rare. Approximately a third of patients have exocrine pancreatic insufficiency, and insulin-dependent diabetes develops frequently.

Anemia (usually macrocytic) is present in the majority of patients in whom PS is diagnosed before the age 6 months. Half of the patients have neutropenia and thrombocytopenia. Vacuolated myeloid or erythroid precursors, often with decreased erythroblasts, and ringed sideroblasts are present in almost all patients (see Fig. 8-16).

Differential Diagnosis

Vaculolization of the hematopoietic precursor, fibrosis of the pancreas rather than fatty replacement, and the lack of skeletal anomalies distinguishes PS from SDS. PS has to be differentiated from other refractory anemias in children. Mitochondrial enzyme defects and mtDNA deletions usually establish the diagnosis.

Genetics

PS is maternally inherited and follows a mitochondrial inheritance pattern (Box 8-14). PS is caused by deletions

The nucleated cells are megakaryoblasts with small amounts of basophilic cytoplasm, distinct nucleoli, and cytoplasmic blebbing (May-Grünwald-Giemsa stain). *(From Massey GV, Zipursky A, Chang MN, et al. A prospective study of the natural history of transient leukemia [TL] in neonates with Down syndrome [DS]: Children's Oncology Group [COG] study POG-9481. Blood. 2006;107:4606-4613.)*

or duplications of mtDNA (see Fig. 8-17).[550,551] The size of the deletion varies from 2.7 to 7.767 kb[584] (also see Fig. 8-18). The respiratory enzymes involved in the deletions are relevant to oxidative phosphorylation, and alterations include reduced nicotinamide adenine dinucleotide, cytochrome oxidase, adenosine triphosphatase, and tRNA and rRNA.

The severity of the clinical manifestation and the rate of disease progression are variable and correlate with the

Box 8-14	Mitochondrial DNA Disorders

Mitochondria are under genetic control of the mitochondrial and nuclear genomes. Defects in either genome result in mitochondrial disorders. The mitochondrial genome is 16.6 kb in size and encodes 13 enzymes of the respiratory chain, as well as 24 RNA molecules needed for intramitochondrial protein synthesis. Within a cell the mitochondrial genome is present in multiple copies. In healthy individuals, all copies are identical (homoplasmy), whereas in patients with genetic defects of the mitochondrial genome, a mutation can be present in all copies (homoplasmic mutation) or only in some copies (heteroplasmic mutation).

   Mitochondrial DNA (mtDNA) is usually maternally inherited. For heteroplasmic disorders such as Pearson's syndrome, the outcome of a specific pregnancy is difficult to predict, mainly because of considerable variation in the mutated DNA inherited by the offspring and because many of the clinical features correlate with the ratio of mutated to wild-type mtDNA.[579,586,587]

Box 8-15	Transient Myeloproliferative Disorder

Transient myeloproliferative disorder (TMD) in newborns with Down syndrome is a clonal proliferation of blast cells with trisomy 21 that have acquired a somatic mutation in the *GATA1* gene and are thought to originate from fetal liver hematopoiesis. Both the trisomy 21 and the *GATA1* mutation are required for proliferation. Spontaneous remission is common; however, in some cases TMD may be fatal. Acute megakaryoblastic leukemia with leukemic cells carrying the identical *GATA1* mutation develops in about 20% of patients with TMD[592] (see also Fig. 7-18).[593]

ratio of mutated to wild-type mtDNA and with the tissue distribution of mutated mtDNA molecules.[585]

Clinical Management

Anemia is treated mainly by red cell transfusions. Erythropoietin and G-CSF have also been used for the treatment of BMF. Malignant transformation has not been reported. The major cause of death is metabolic acidosis, followed by renal and liver failure. The projected median survival time is 4 years, with a plateau rate of 36% at age 10.

   Genetic counseling is complicated by the unique genetic features of mtDNA that distinguish it from mendelian disorders, including maternal inheritance, heteroplasmy, the threshold effect, the mitochondrial bottleneck, tissue variation, and selection (Box 8-14).[586-588]

Down Syndrome

Hematologic abnormalities are frequent in Down syndrome (DS). Abnormalities can be seen in any of the three blood cell lineages[589] and in some cases may be associated with other medical conditions frequently found in individuals with DS, such as polycythemia in DS patients with cyanotic heart failure. Neutrophilia, thrombocytopenia, and polycythemia were the most common hematologic abnormalities observed in neonates with DS.[589,590] Increased erythrocyte MCV is frequently present in DS infants, even in the absence of heart disease, and may persist throughout life.[591]

   Transient myeloproliferative disorder (TMD) occurs in 10% to 25% of newborns with DS and in phenotypically normal newborns mosaic for trisomy 21 (Fig. 8-18 and Box 8-15).[593-596] TMD is associated with a high inci-

dence of spontaneous remission. Usually, TMD does not cause obvious symptoms and is only an incidental finding of abnormal blood counts and circulating blasts in peripheral blood expressing a megakaryocytic or erythroid phenotype. However, in about 20% of cases the disease may be severe and be manifested as hydrops fetalis or infiltration of the liver or other organs and result in multiorgan failure and death.[597]

   TMD is considered a preleukemic condition because in 20% to 30% of patients with TMD, acute megakaryoblastic leukemia (AMKL) will develop within 3 years of TMD. Recently, it has been shown that blast cells in TMD carry unique mutations in the hematopoietic transcription factor GATA-1[598,599] and that the identical mutation can be found in AMKL blasts, thus indicating that AMKL evolves from TMD.[600-603] The mutations occur in exon 2 of the *GATA1* gene and lead to the production of a variant GATA-1 protein truncated at its amino-terminal. Experiments in mice showed that expression of the truncated GATA-1 protein leads to hyperproliferation of yolk sac and fetal liver progenitor cells with erythroid/megakaryocytic characteristics, thus indicating that TMD and AMKL originate from a hematopoietic progenitor cell of embryonic/fetal hematopoiesis rather than from mature hematopoiesis in bone marrow, a finding that explains the onset in early childhood and the transient nature of TMD.[604] Interestingly, a similar inherited *GATA1* mutation in a family with X-linked anemia and trilineage dysplasia did not show a predisposition to AMKL, which indicates that in humans the *GATA1* mutation leads to TMD and AMKL only in those with a genetic background of trisomy 21.[605] The nature of the interaction between the *GATA1* mutation and trisomy 21 that leads to clonal expansion of the mutant progenitor remains to be determined (for review see Vyas and Crispino[592] and Kirsammer and colleagues[606]).

   AMKL usually has a good prognosis in patients with DS when treated appropriately with regimens that include cytarabine (cytosine arabinoside).[607-611] Increased expression of the chromosome 21–localized genes for cystathionine β-synthase and superoxide dismutase and altered drug metabolism have been implicated in the increased

sensitivity of TMD and AMKL blasts to cytarabine.[612] The high frequency of TMD and AMKL in patients with DS and the favorable prognosis of the disease when treated appropriately suggest that all newborns and infants with DS should be routinely screened for signs of TMD and that children with a history of TMD require close surveillance for the development of AMKL.

The insight gained into the pathogenesis of TMD and AMKL in DS patients is thus another notable example of how increased understanding of the pathogenesis of disease development directly influences the care and management of patients.

Familial Marrow Dysfunction

A large group of patients with BMF do not fit any of the classifications described. If more than one family member is affected, in the absence of environmental exposure explaining BMF, these individuals are classified as having familial BMF, not otherwise classified.

Familial BMF or bone marrow dysfunction therefore represents a heterogeneous group of individuals and families. In many, BMF is found in various family members and may include aplastic anemia, MDS, leukemia, and immunodeficiency. The inheritance pattern may suggest dominant, recessive, or X-linked disease. In others, the condition may be manifested as sporadic BMF but with associated physical anomalies suggesting an IBMFS not characteristic of FA or any other known IBMFS.

Pathogenesis of Disease

It is most likely that a significant number of individuals or families in whom familial BMF is diagnosed have disease caused by one of the major IBMFSs discussed earlier. However, because of variable disease penetrance and expressivity, a possible atypical manifestation, failure to identify the pathogenic mutation, and unawareness of the responsible physician, the correct diagnosis has not been made. For example, BMF secondary to *TERC* or *TERT* gene mutations is certainly underdiagnosed because affected individuals often lack the classic mucocutaneous features characteristic of classic DC (see earlier). In others, a syndrome specific for particular clinical findings might have been diagnosed, but association with one of the major forms of BMF has not yet been made. Examples from the past are the VATERL syndrome in individuals with vertebral defects, anal atresia, tracheoesophageal fistula, renal defects, and radial limb defects, some of whom turned out to have FA (see the section on FA); HHS, which turned out to be a severe form of DC (see the section on DC); or the Kearns-Sayre syndrome, which includes patients with PS who outgrew their BMF (see the section on PS). A small proportion of patients might have an IBMFS resulting from causes that are exceedingly rare and therefore have been missed (see also Table 8-1), or the BMF may be due to a mutation in a gene that is not usually associated with BMF.

An example from the past is specific mutations in the *NBS1* gene, usually responsible for the Nijmegen breakage syndrome, that may be manifested as an FA-like phenotype, including pancytopenia and a positive DEB or MMC test (also see the section on FA). Finally, a proportion of individuals with familial BMF have disease caused by mutations in genes that have not yet been identified.

Clinical Management

The overall prognosis in patients with familial BMF is generally less favorable than that in patients with nonfamilial (acquired) BMF. A DEB or MMC test to rule out FA (see the section on FA) and telomere measurements to rule out DC (see the section on DC) are the minimal diagnostic evaluations that should be performed early in the investigation of individuals with familial BMF. Treatment and supportive care, in general, are the same as those described earlier for FA, DC, or acquired aplastic anemia. Antilymphocyte globulin, cyclosporine, androgens, and hematopoietic growth factors have been used with variable success. HSCT from an HLA-matched sibling donor has to be considered carefully because the potential donor may have the same genetic lesion even in the absence of disease. Failure of engraftment or donor cell–derived malignancies (MDS/AML) have been reported in individuals with familial BMF receiving a transplant from an apparently healthy sibling donor.[474,613] In addition, HSCT may be associated with an unexpected toxicity in patients with familial BMF because the underlying genetic defect may render them hypersensitive to radiotherapy or other agents used for HSCT.

INHERITED BONE MARROW FAILURE SYNDROMES ASSOCIATED WITH ISOLATED CYTOPENIAS

Diamond-Blackfan Anemia

DBA (MIM 105650), also known as congenital erythroid hypoplastic anemia, is a rare inherited hypoplastic anemia that usually occurs in early infancy. The disease is named after Louis K. Diamond and Kenneth D. Blackfan, two pediatric hematologists in Boston who first recognized the disease as a distinct clinical entity.[614] DBA is genetically and phenotypically heterogeneous.

Clinical Manifestations

Clinically, DBA is characterized by failure of red cell production, variable congenital anomalies, and a predisposition to malignancy (Box 8-16). DBA is a rare disease with a frequency of 2 to 7 per million live births and has no ethnic or gender predilection.[615,616] Much of our knowledge of the disease has been gained from patient registries in North America,[617] England,[616] Italy,[618] and France.[619] Classically, patients with DBA are seen in early

childhood with profound macrocytic or normocytic anemia, reticulocytopenia, and a reduction or absence of erythroid precursors in bone marrow. In more than 90% of patients with DBA the diagnosis is made before the age of 1 year,[617,620,621] but in rare cases severe anemia may develop in utero (nonimmune hydrops fetalis)[622] or later in life.[623] The median age at diagnosis is 8 weeks of age.[620]

Congenital Abnormalities

In about 50% of patients DBA is associated with physical anomalies and growth retardation.[619,620,623,624] In some patients a physical anomaly is the only clinical manifestation of DBA. Table 8-9 summarizes the prevalence and range of congenital abnormalities found in patients with DBA. Midline craniofacial defects (e.g., cleft palate), renal anomalies, cardiac malformations, and thumb anomalies (e.g., triphalangeal thumbs) are common.[616,620]

Short Stature. Although short stature is an integral feature of DBA and is frequently seen in association with other congenital anomalies,[626] final height is strongly influenced by glucocorticoid therapy, iron overload, and chronic anemia.[616,626] Intrauterine growth retardation has been documented in about 20%,[626] and characteristically there is an absence of catch-up growth after birth.[626]

Hematologic Abnormalities

Anemia, macrocytosis, reticulocytopenia, and absent or decreased numbers of erythroid progenitor cells in bone marrow are the major diagnostic criteria for DBA. In 13% to 20% of individuals, anemia may be present at birth.[616,618] Macrocytosis is evident in the majority of cases; however, it may be masked by iron deficiency or thalassemia trait. Increased hemoglobin F levels and persistent "i" antigen are additional features of stress hematopoiesis frequently seen in patients with DBA.[616] Elevated levels of red cell adenosine deaminase (ADA), a critical enzyme in the purine salvage pathway, are

---

Box 8-16	Diamond-Blackfan Anemia

Diamond-Blackfan anemia (DBA) is a pure red cell aplasia with autosomal dominant inheritance that is usually seen in early infancy. DBA is associated with a reduction or absence of erythroid precursors in bone marrow, variable congenital anomalies, and a predisposition to malignancy. DBA red cells characteristically have increased adenosine deaminase activity. Mutations in ribosomal proteins of the small and large subunit have been associated with DBA.

†Not including low birth weight or short stature. Many patients had more than one abnormality.

characteristic of DBA erythropoiesis and may be found in 80% to 89% of patients.[619,620,627] Whether macrocytosis, increased fetal hemoglobin, and elevated red cell ADA are integral features of DBA hematopoiesis or rather reflections of stress hematopoiesis is not clear. Macrocytosis, increased fetal hemoglobin, persistent "i" antigen, and elevated red cell ADA may be masked in transfusion-dependent patients. In some individuals, macrocytosis or increased red cell ADA levels are the only manifestations of DBA.[616,628] Parents or siblings of an affected child who have increased red cell ADA levels are likely to be carriers of the pathogenic mutation even in the absence of classic disease (nonclassic DBA).[616,619] In some individuals with DBA the anemia is transient; however, the macrocytosis and elevated red cell ADA levels often persist. Spontaneous remission of anemia in DBA patients has been reported even after years of steroid or transfusion dependence (also see later).[617] Platelet counts are usually normal or mildly increased, although platelet counts greater than $1 \times 10^6/\mu L$ and decreased platelet counts have also been reported.[616] White blood cell counts are generally normal but in some cases decrease with age. In rare cases DBA progresses to the full clinical picture of severe aplastic anemia.[620]

Bone marrow examination reveals normal cellularity, myeloid cells, and megakaryocytes. Lymphocyte counts are often increased. A paucity of erythroid progenitor cells is characteristic. Dyserythropoietic morphology, even ringed sideroblasts, have been reported. Increased iron deposition is seen in patients who have received multiple red cell transfusions. Serum levels of erythropoietin are elevated, and ferrokinetic studies show a delay in plasma iron clearance and low red cell utilization. The slightly shortened autologous red cell survival times and low haptoglobin levels suggest mild hemolysis.[629]

Bone marrow progenitor assays show a severe maturation defect in DBA erythroid progenitor cells, whereas other blood cell lineages are unaffected or only moderately impaired.[6302-633] Erythroid colony size and maturation, as well as colony numbers, are impaired. The defect is intrinsic to the erythroid progenitor cell[631,634,635] and is partially corrected by interleuklin-3 (IL-3) and stem cell factor,[636-639] but not by erythropoietin.[631,632] The rate of apoptosis in erythroid progenitor cell cultures from patients with DBA is increased and accentuated after erythropoietin deprivation.[633] More detailed culture analysis pinpoints the defect to the erythropoietin-dependent phase of expansion and differentiation of erythroid progenitors with no significant defect in the preceding erythropoietin-independent stages.[640] Glucocorticoid treatment increases the erythropoietin sensitivity of both normal and DBA erythroid progenitors, but DBA erythropoietic differentiation and maturation remain suboptimal.[640]

Diagnostic Criteria

Table 8-10 summarizes the diagnostic and major and minor supporting criteria. Patients with "classic DBA" have all of the major diagnostic criteria.[625] Patients with "nonclassic DBA" have at least three diagnostic criteria with one major or two minor supporting criteria, two diagnostic criteria and two major or three minor supporting criteria, or two major supporting criteria.[625]

Predisposition to Malignancy

Patients with DBA have a predisposition to malignancy with a reported frequency of 1.9% to 6.6%.[619,620,646] AML (AML/MDS) is the most frequent reported malignancy, followed by osteosarcoma.[647] Other reported malignancies include hepatocellular carcinoma, gastric carcinoma, fibrous histiocytoma, vaginal melanoma, Hodgkin's and non-Hodgkin's lymphoma, breast cancer, and ALL (reviewed by Alter[9]). The medium age at diagnosis of malignancy was 15 years (range, 1 to 43), as opposed to 68 years in a non-DBA control group.

Differential Diagnosis

Clinically, DBA has to be distinguished from other IBMFSs such FA, DC, SDS, CHH, and PS. Clinical manifestations, associated physical abnormalities, family history, negative chromosome fragility test (DEB or MMC test), and normal telomere length measurements are helpful in strengthening the diagnosis of DBA. Distinguishing DBA from CHH may be difficult. The anemia in CHH is usually less severe but may be similar to that seen in patients with DBA.[570] In the absence of distin-

TABLE 8-10 **Diagnostic Criteria for Patients with Diamond-Blackfan Anemia (DBA)**

Diagnostic Criteria	SUPPORTING CRITERIA	
	Major	**Minor**
Age <1 year	Pathogenic mutations*	Elevated red cell ADA
Macrocytic anemia	Positive family history	Congenital anomalies of DBA
Reticulocytopenia		Elevated fetal hemoglobin
Paucity of bone marrow erythroid precursors		No evidence of other IBMFSs

*Pathogenic mutations have been identified in *RPS19*,[641] *RPS24*,[642] *RPS17*,[643] *RPL35a*,[644] *RPL5*, and *PRL11*.[645] Mutations in additional ribosomal proteins account for additional cases of Diamond-Blackfan anemia.

From Vlachos A, Ball S, Dahl N, et al. Diagnosing and treating Diamond Blackfan anemia: results of an International Clinical Consensus Conference. Br J Haematol 2008 (in press).

ADA, adenosine deaminase.

guishing features, only identification of the responsible mutation may differentiate between the two conditions. Interestingly, either gene product, the RMRP responsible for CHH (see later also) and the ribosomal proteins responsible for DBA, can participate in ribosome biogenesis, which may explain the similarities in hematologic manifestations. In patients with PS, BMF is classically accompanied by characteristic vacuolization of hematopoietic precursors cells.[549]

DBA has to be distinguished from acquired forms of anemia, including transient erythroblastopenia of childhood (TEC, see later and Chapter 7); viral infections, including infection with human immunodeficiency virus and infectious mononucleosis; drug-related anemia; anemia caused by exposure to toxic chemicals; severe renal failure; and anemia after an ABO-incompatible transplant (for a comprehensive list of possible causes of anemia in childhood, see also Lipton[648] and Vlachos and associates[625]).

Genetics

Inheritance

DBA occurs in both familial and sporadic forms. Autosomal dominant inheritance is the most frequently observed pattern of inheritance. Several genes have been identified whose mutations together account for about 45% of DBA patients. All mutations identified affect ribosomal proteins of both the small (RPS) and large (RPL) ribosomal subunit. Mutations in the *RPS19* gene on chromosome 19q13.2[641] account for about 25% of patients with DBA; mutations in the *RPS24* gene on chromosome 10q22-q23 account for about 3% of DBA patients[642]; a mutation in the *RPS17* gene located on chromosome 15q25.2 has been identified in one family[643]; mutations in the *RPL35a* gene on chromosome 3q29 were found in about 2% of patients with DBA[644]; and

mutations in the *RPL5* and *PRL11* genes located on chromosome 1p22.1 and 1p36.12, respectively, were found in about 10% and 6.5% of DBA patients.[644] In all families with mutations in ribosomal proteins of the large or small ribosome subunit (RPS or RPL), the disease was either sporadic (caused by de novo mutations) or followed autosomal dominant inheritance. However, an autosomal recessive pattern of inheritance has been reported.[624,649,650] It remains to be determined whether these are indeed due to biallelic mutations or instead are caused by incomplete penetrance of an otherwise dominant mutation mimicking sporadic or autosomal recessive disease.[620,624]

The Diamond-Blackfan Anemia Genes and Their Functions

Following from the observation that a DBA patient had an X;19 chromosomal translocation,[650] the first gene to be identified as being mutated in DBA (*DBA1*) was the *RPS19* gene at 19q13.2.[640] Subsequently, it was established that a fourth of DBA patients harbor a mutation in *RPS19*,[619,651,652] which encodes the small subunit ribosomal protein 19. The mutations are always heterozygous and include missense, nonsense, frameshift, and splice site mutations, as well as small and large deletions and three translocations (Fig. 8-19). Whereas the nonsense and frameshift mutations are spread evenly throughout the coding region, the missense mutations are clustered. RPS19 haploinsufficiency is thought to be responsible for disease.[653] Analysis of the crystal structure of RPS19 from *Pyrococcus abyssi* suggests that missense mutations in DBA primarily affect the capacity of the protein to be incorporated into preribosomes, thus blocking maturation of pre-40S particles.[654]

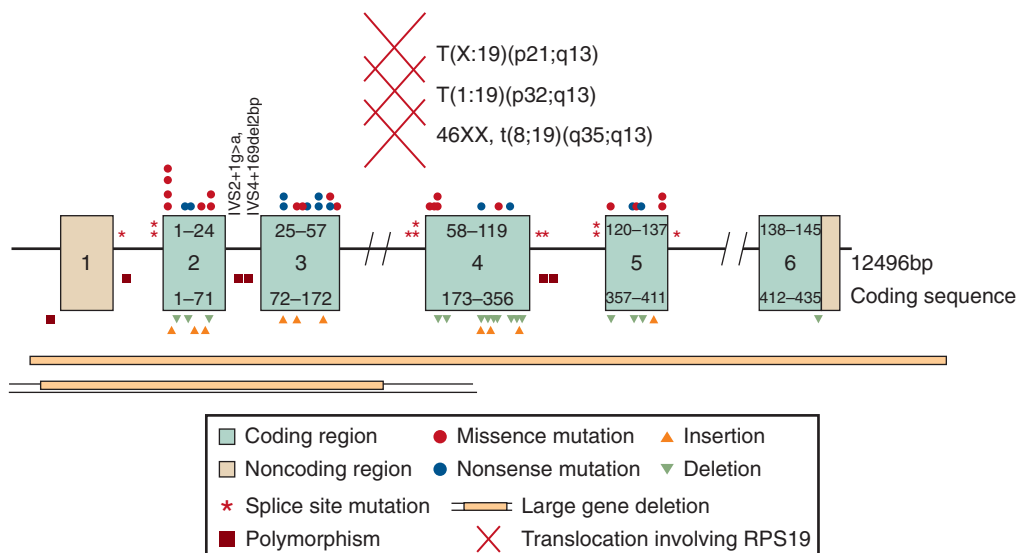
Pathogenic mutations have also been found in another gene encoding a protein of the small ribosomal subunit, the *RPS24* gene on chromosome 10q22-q23.[645] The locus


FIGURE 8-19. Mutations in the *RPS19* gene in patients with Diamond-Blackfan anemia as shown in a schematic representation of the six exons with patient-derived mutations. The *red crosses* above the diagram indicate the three translocation that affected the *RPS19* gene. Nonsense and point mutations are shown above the diagram, and small deletions, small insertions, and two large gene deletions are shown below the diagram. *(Kindly provided by Sara Robledo, modified from Lipton JM. Diamond Blackfan anemia: New paradigms for a "not so pure" inherited red cell aplasia. Semin Hematol. 2006;43:167-177.)*

has been designated *DBA3*. Ribosomal proteins are an integral component of ribosomes (Box 8-17). Although ribosomal proteins do not participate in the protein synthesis activity of the ribosome, they are important for maintaining their structure and during ribosome biosynthesis (Box 8-18 and Figs. 8-20 and 8-21). The finding of a second ribosomal protein being affected strongly suggested that DBA is a disorder of ribosome synthesis.[645] *RPS24* mutations are estimated to account for approximately 3% of cases of DBA.[645] Two nonsense mutations and one combined insertion/deletion affecting the intron/exon boundary resulting in a skipped exon 2 were identified in the *RPS24* gene among 215 unrelated probands.

A de novo mutation in a third ribosomal protein of the small subunit, RPS17, has recently been identified in one DBA patient. The mutation affects the translation initiation start codon, with T changing to G. RNA analysis revealed that the mutated allele was expressed.[643]

Box 8-17	**Ribosomes**

Ribosomes are intracellular organelles about 200 Å in diameter that consist of RNA (ribosomal RNA [rRNA]) and protein (ribosomal proteins). In all organisms, ribosomes are the site of protein synthesis and translation of messenger RNA molecules into continuous chains of amino acids (polypeptides or proteins). The ribosome is a ribozyme, which means that it is the rRNA that catalyzes decoding of the message and the formation of peptide bonds. Ribosomal proteins, on the other hand, are important for maturation of rRNA precursors and ensure their correct structure in the ribosome.

Box 8-18	**Ribosome Biogenesis and Pre-rRNA Processing**

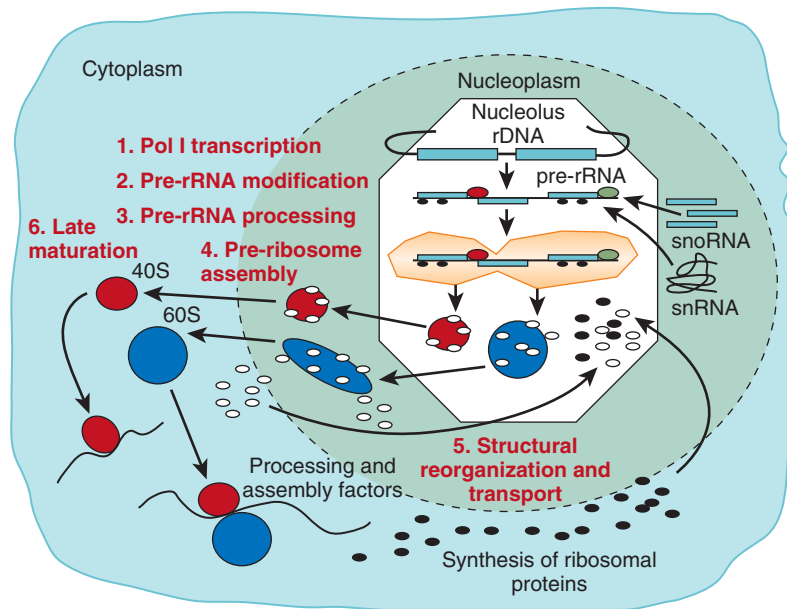
Ribosome biogenesis is the new production of ribosomes. In eukaryotes, ribosome biogenesis takes place in the nucleolus, a specialized compartment within the nucleus. Ribosome biogenesis is a complicated, highly regulated process that begins with the synthesis of large preribosomal RNA. Structural rearrangements and cleavage occur as the ribosomal proteins are incorporated to ultimately give rise to mature ribosome subunits. Final maturation of the ribosome subunits takes place in the cytoplasm before they become assembled to form the mature ribosome (see Figs. 7-20 and 7-21). For review see Granneman and Baserga,[655] Fatica and Tollervey,[656] and Fromont-Racine and colleagues.[657]


FIGURE 8-20. Diagram of the six major steps in ribosome biogenesis. 1. Pol I transcription. The process starts with transcription of multiple copies of the genes for rRNA (rDNA) to form the large pre-rRNA primary transcript. 2. Pre-rRNA modification. The pre-rRNA is methylated and pseudouridylated under the guidance of small nucleolar RNA (snoRNA). Nonribosomal proteins (*open circles*) and snoRNA (*green rectangles*) associate with the nascent transcript. 3. Pre-rRNA processing. The pre-rRNA undergoes a series of cleavages ultimately resulting in 18S, 5.8S, and 28S rRNA. 5S rRNA, a component of the 60S subunit, is added to the maturing complex. The complex is split into the two precursor particles for the small (40S) and large (60S) ribosomal subunits. 4. Pre-ribosome assembly. Ribosomal proteins (*black circles*) are added to the precursor complexes at various stages of assembly. 5. Structural reorganization and transport. The nearly mature subunits are exported to the cytoplasm through the nuclear pore complexes with the aid of adaptor proteins. 6. Late maturation. The small and large subunits are eventually incorporated into ribosomes in the cytoplasm. Dyskeratosis congenita affects ribosome biogenesis at the step of pre-rRNA modification (step 2); Diamond-Blackfan anemia and cartilage-hair hypoplasia affect ribosome biogenesis at the step of pre-rRNA processing (step 3). snRNA, small nuclear RNA.
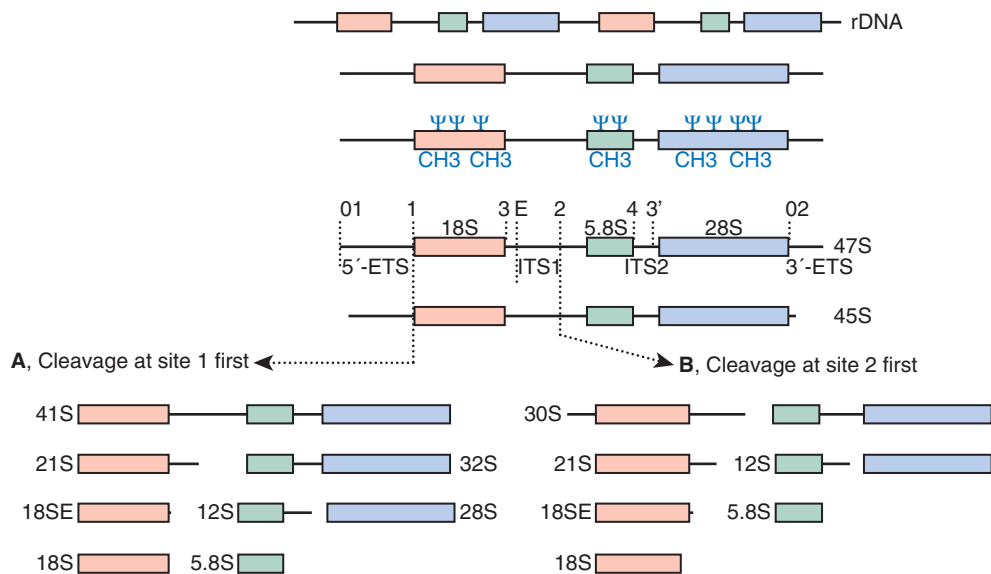

FIGURE 8-21. Pre-rRNA processing in HeLa and lymphoblastoid cell lines (LCL). The 18S, 5.8S, and 28S rRNA is transcribed as a single precursor (45S), which is subsequently processed into mature species by a complex series of cleavage and modification reactions. In addition to the mature rRNA species, the primary precursor (47S) contains two external transcribed spacers at its 5′ and 3′ ends (5′-ETS and 3′-ETS, respectively), as well as two internal transcribed spacers (ITS1 and ITS2). After synthesis of the primary pre-rRNA molecule is completed, the transcribed spacer sequences are removed by a series of endonucleolytic cleavage and exonucleolytic degradation steps. Two alternative pre-rRNA processing pathways, **A** and **B,** have been described in HeLa cells.[658]

Recently, mutations were also identified in three ribosomal proteins of the large subunit, including RPL35a, RPL5, and RPL11.[644,645] Mutations in *RPL35a* include a large genomic deletion, a small deletion, a nonsense mutation, and one missense mutation (G97A, leading to a valine-to-isoleucine substitution of amino acid 33, V33I).[644] Small deletions and insertions causing shift of the reading frame and an early stop codon, nonsense mutations, and one missense mutation (G418A, leading to a glycine-to-serine substitution of amino acid 140, G140S) were identified in the *RPL5* gene.[645] Splice site mutations, small deletions, and insertions accounted for the mutations identified in the *RPL11* gene. Mutations in RPL proteins, like those in RPS proteins, are thought to cause disease by haploinsufficiency.

There was evidence that some families show genetic linkage to chromosome 8p23.2-23.1,[650] and this locus has been designated *DBA2.* No mutations have been identified in ribosomal proteins mapping within this region.[642]

Genotype-Phenotype Correlation

Craniofacial anomalies have not been found in individuals with *RPS19* mutations,[648] nor in the 11 individuals with DBA caused by *RPS24* mutations.[642] No clear genotype-phenotype correlation was identified in individuals with *RPS19*[623,651] or *RPS24*[642] mutations, although null mutations tended to have a more severe phenotype than missense mutations did. The expressivity of individual mutations is highly variable, even within an individual family (Fig. 8-22).[623] The mental retardation noted in individuals with a large deletion of *RPS19* suggested that the concomitant deletion of adjacent genes may account for the additional features in these individuals.[623] Facial anomalies were described in the one patient with DBA secondary to a mutation in *RPS17*.[643] The genotype-phenotype correlation of individuals with RPL mutations remains to be determined.

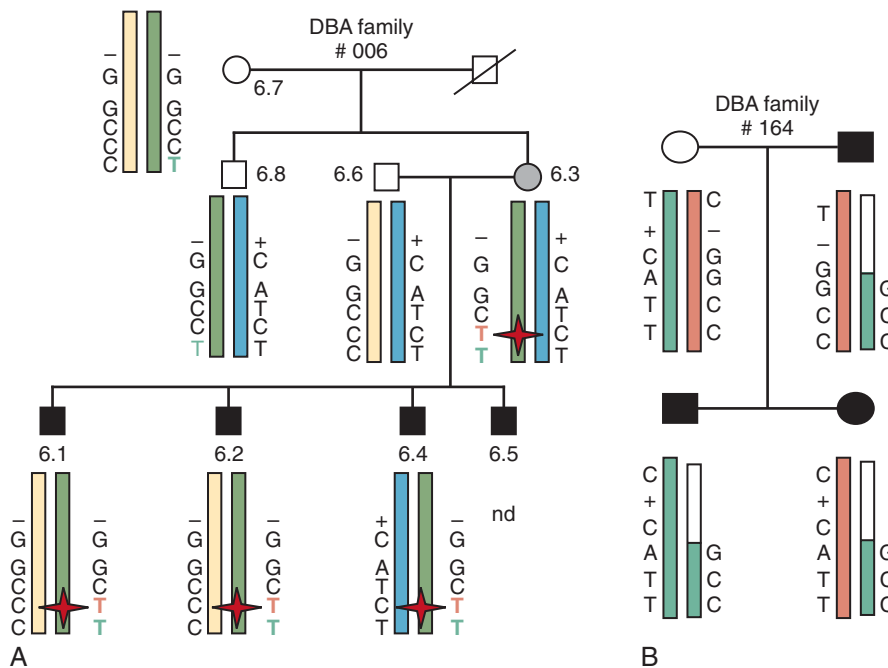
Molecular Diagnosis of Diamond-Blackfan Anemia

Currently, molecular diagnosis is not routinely performed for DBA because it is expensive and provides a definitive diagnosis in only about 40% of cases. However, only identification of pathogenic mutations in one of the DBA genes definitively establishes the diagnosis of DBA. Furthermore, molecular diagnostics enables the identification of mutation carriers, facilitates prenatal diagnosis for an existing pregnancy, and allows PGD for partners identified as mutation carriers. Mutation analysis should include methods that will detect large deletions. Cases of DBA caused by large deletions are probably underdiagnosed. Anomalies in addition to the ones characteristic for DBA, in particular, mental retardation, are suggestive of a large deletion causing haploinsufficiency for additional genes in the vicinity of the deleted DBA gene. In addition to the large number of mutations in DBA genes associated with DBA, a number of nonpathogenetic mutations and mutations of unknown pathogenic significance have been identified.[659] Determining the pathogenicity of a particular missense mutation may be difficult,[659] whereas nonsense and frameshift mutation are likely to be pathogenic in the majority of cases.

Diseases Related to Diamond-Blackfan Anemia

Aase's Syndrome

Congenital red cell aplasia with a triphalangeal thumb has been described by Aase and Smith as a distinct syndrome.[660] Cleft palate and cardiac anomalies have also been associated with this syndrome.[661] Its clinical manifestations have significant overlap with those characteristic of DBA; thus, Aase's syndrome most likely represents a subset of patients with DBA who have a particular phenotype.[661] Autosomal dominant inheritance and vari-

FIGURE 8-22. *RPS19* mutations in two families with Diamond-Blackfan anemia (DBA). **A,** RPS19 haplotype analysis shown that the *RPS19* mutation in this family most likely occurred as a de novo mutation in the parent and was inherited by all of the four children. The parent had only transient anemia as child, whereas two of the children (6.1. and 6.2) are transfusion dependent and two (6.3 and 6.4) respond to steroids. **B,** Sequence-based mutation analysis of the affected child suggested that in this family DBA was not caused by an *RPS19* mutation. However, haplotype analysis indicates that DBA in this family is caused by a large deletion that includes the first three exons of *RPS19*, thus indicating that gene deletions in the *RPS19* gene might be more common than currently thought.


able expressivity have been associated with Aase's syndrome,[662] but no *RPS19* or *RPS24* mutations have been identified in individuals with the classic features of this syndrome.

Myelodysplasia with Deletion of Chromosome 5q (5q– Syndrome)

Patients with a deletion of the long arm of chromosome 5 (5q– syndrome) have severe macrocytic anemia, elevated platelet counts, erythroid hypoplasia in bone marrow, and hypolobulated megakarocytes. Delineation of the critical deletion region on chromosome 5q– includes the *RPS14* gene at position q33.1 and about 40 additional genes.[663] Reducing RPS14 expression in normal CD34+ cells leads to a gene expression profile similar to that found in bone marrow cells from patients with 5q– MDS and results in selective impairment of erythroid differentiation with only minor effects on megakaryopoiesis or myelopoiesis. Similarly, forced expression of RPS14 restores the erythroid phenotype in bone marrow cells from patients with 5q– MDS, thus suggesting that erythroid hypoplasia is caused by *RPS14* haploinsufficiency.[663] In contrast to patients with DBA, the deletion of *RPS14* in patients with 5q– MDS is not inherited but acquired in early hematopoietic progenitor cells (somatic). Although the mutation explains the erythroid phenotype in patients with MDS and 5q–, the *RPS14* mutation is unlikely to be responsible for the proliferative growth advantage of the mutant progenitor cell. More likely, haploinsufficiency or loss of heterozygosity for one or more additional genes affected by the deletion causes the growth advantage of the mutant cells. Interestingly, MDS with 5q– shows a remarkable response to the thalidomide analogue lenalidomide, the mechanism of which is unknown.

Transient Erythroblastopenia of Childhood

TEC (MIM 227050) is a rare pure red cell aplasia that occurs in children most commonly between 6 months and 4 years of age[664] (see also Chapter 7). Laboratory findings consist of normocytic normochromic anemia and reticulocytopenia, sometimes associated with thrombocytosis and erythroblastopenia of bone marrow.[664] The course is characterized by complete recovery, usually within 1 to 2 months after diagnosis. No therapy is usually necessary, although some children may require red cell transfusion.[664] The absence of macrocytosis, increased fetal hemoglobin, and increased red cell ADA levels in individuals with TEC are used to distinguish TEC from DBA.[664] In addition, congenital abnormalities are not present in patients with TEC.[664] The etiology of TEC is not entirely clear, but is thought to be postinfectious and autoimmune mediated.[665] The majority of TEC cases are sporadic and acquired, but there are a few reports of familial TEC. Linkage analysis suggested allelism for TEC at the *RPS19* gene locus; however, no mutations in the *RPS19* coding region were identified.[666]

Animal Models

Ribosomal mutations have been studied in *Escherichia coli* and *Saccharomyces cerevisiae*.[667] In *Drosophila melanogaster*, mutations in ribosomal proteins are associated with the *Minute* phenotype. Minutes are remarkably similar and share three principal phenotypes—a 2- to 3-day delay in larval development, short thin bristles, and recessive lethality.[668]

In yeast, RPS19 is essential for growth and survival. Decreased expression of RPS19 leads to specific defects in pre-rRNA processing and severely limits the production of small 40S ribosomal subunits.[669,670] Mice homo-

zygous for an *Rps19* null mutation exhibit embryonic lethality, whereas mice with only one active allele, the same genotype that gives rise to DBA in humans, have no detectable abnormality.[671,672] Interestingly, these heterozygous mice appear to express normal levels of RPS19, thus suggesting that mouse cells can compensate for the absence of one functional allele.[671]

The Belly spot and tail (Bst) is a spontaneous semidominant, homozygous lethal mutation in mice that impairs *Rpl24* mRNA splicing and RPL24 production. Mice heterozygous for the mutation have reduced body size, decreased pigmentation, a kinked tail, and retinal abnormalities, but no obvious hematologic abnormalities. Mouse embryonic fibroblasts heterozygous for the *Bst* mutation have a defect in large subunit assembly and a growth disadvantage in comparison to wild-type fibroblasts.[673]

Mechanism of Disease Pathogenesis in Diamond-Blackfan Anemia

The mechanism whereby mutations in RPS19 or the other ribosomal proteins cause specific defects in red cell maturation is not fully understood and is the focus of current research in the field. RPS19 overexpression improves erythropoiesis in RPS19 mutant CD34+ bone marrow cells from patients with DBA.[674,675] Similarly, a reduction in RPS19 expression in normal CD34+ cells leads to impairment in erythroid differentiation and to some extent also in myeloid differentiation.[676,677]

Reduced RPS19 expression in mammalian cells leads to decreased levels of 18S rRNA production and the accumulation of unprocessed nuclear pre-18S rRNA molecules.[678-680] As in yeast, production of the 40S ribosomal subunit is greatly reduced. Moreover, subtle alterations in rRNA processing could be detected in isolated bone marrow hematopoietic progenitor cells and lymphoblastoid cell lines from patients with DBA secondary to a mutation in *RPS19*,[678-680] but not in cell lines or bone marrow cells from patients with DBA but no *RPS19* mutation, thus suggesting that such alterations affect a different step of pre-rRNA processing. The amount of ribosome subunits and mature ribosomes, however, is normal in steady-state growing cell lines from patients with DBA.[679] Depletion of RPS19 causes a reduction in the steady-state levels of other ribosomal proteins of the small 40S subunit, whereas proteins of the large subunit are unaltered, thus indicating that levels of ribosomal proteins are determined by subunit assembly and that reduction of any ribosomal protein would have the same effect on the small 40S subunit. This suggests that haploinsufficiency for any ribosomal protein of the small subunit may cause DBA.[679]

The fact that ribosomal proteins of the small and large subunit are affected suggests that insufficient functional ribosomes in the maturing erythroid progenitor cell may be the underlying cause of red cell aplasia in patients with DBA. Why the differentiating red cell progenitor in bone marrow is affected by this deficiency whereas other cells are not or are much less affected remains to be determined. A variety of extraribosomal functions have been attributed to several ribosomal proteins of the small and large ribosome subunit. To what extent these extraribosomal functions contribute to the DBA phenotype remains to be determined.

Interestingly, haploinsufficiency for several ribosomal proteins leads to increased tumor formation in zebra fish, a finding suggesting that ribosomal protein genes may act as tumor suppressors.[681] The role of haploinsufficiency of ribosomal proteins in tumorigenesis is the focus of current research in several laboratories.

Clinical Management

The overall actuarial survival rate at 40 years of age is 75%.[620] Survival is significantly better for steroid-responsive patients than for transfusion-dependent patients.[616,619,620,623] The major causes of death are treatment related[618,619,622] and include infection (in particular, *Pneumocystis jiroveci* pneumonia), complications of iron overload, and complications of HSCT. Other causes of death include evolution to severe aplastic anemia and malignancy.

Glucocorticoid Therapy

Steroids and red cell transfusions are the main forms of therapy. Prednisone (or prednisolone) therapy is usually initiated at a dosage of 2 mg/kg/day. For glucocorticoid responders, the prednisone dosage is slowly tapered until the patient is taking an alternate-day dosage that maintains a reasonable hemoglobin level. Many patients remain on small, alternate-day doses of steroids for years. Seventy percent to 80% of patients with DBA are initially steroid responsive, but only 60% to 70% achieve transfusion independence.[616,617,620,623,625] Response to treatment is usually seen within 1 month of treatment. The likelihood of response cannot be predicted.[618,6257] The steroid dose is tapered to the lowest dose necessary to maintain transfusion independence. The maintenance dose of steroids is highly variable, with some requiring only minimal doses.[625,682] The maximum recommended maintenance dose is ≤1 mg/kg/day every other day or ≤0.5 mg/kg/day.[625]

Side effects of steroid therapy include growth retardation, increased risk of infection, diabetes mellitus, hypertension, cushingoid features, pathologic fractures, cataracts, avascular osteonecrosis, osteopenia without fracture, pseudotumor cerebri, and in infants, delay in neuromotor development.[616,625] Steroid therapy is often not recommended in infants younger than 6 months. Individuals taking high doses of steroids require *P. jiroveci* prophylaxis. The steroid maintenance dosage should not exceed 0.5 mg/kg/day and should be continued in the absence of response (for more detailed information, see the consensus document regarding diagnosis and management of DBA[625]).

Transfusion Therapy

Red cell transfusion remains the mainstay of therapy for steroid-resistant disease, as well as for treatment of DBA in early infancy (<6 months of age). Leukocyte-depleted packed red cells should be given every 3 to 6 weeks to maintain a hemoglobin level of about 8 g/dL.[625] The major complication from transfusions is iron overload. Death from complications associated with iron overload is the second most common cause of death in patients with DBA.[619,620,623] Complications of iron overload include endocrinopathy, diabetes, growth failure, and failure to enter puberty, as well as cardiac failure and liver disease. Symptoms of iron overload develop more slowly in patients with DBA than in patients with thalassemia, in whom ineffective erythropoiesis additionally increases iron absorption. Serum ferritin is not a reliable indicator of the body's iron load. Hepatic iron concentration measured from a liver biopsy specimen is the gold standard for estimating hepatic iron concentration. Noninvasive methods of iron measurements include magnetic susceptometry (superconducting quantum interference device [SQUID]) and magnetic resonance imaging (MRI). Iron chelation should begin as soon as patients have increased iron stores (ferritin >1500 mg/dL, hepatic iron >6 to 7 mg/g, which corresponds to a transfusion history of about 170 to 200 mL packed red blood cells/kg). Subcutaneous infusion of deferoxamine has been the standard chelation therapy in patients with DBA. The recently developed oral iron chelators deferiprone, a bidentate (not available in the United States), and deferasirox, a tridentate (available in the United States), may eventually supplant deferoxamine as the standard of iron chelation therapy.[683]

Side effects of deferiprone include neutropenia (6%) and agranulocytosis (0.6%). Fatal agranulocytosis has been described in one patient with DBA taking deferiprone in addition to deferoxamine.[684] The use of deferiprone in patients with DBA should therefore be carefully considered. Iron chelation is contraindicated during pregnancy and should cease when pregnancy is planned or diagnosed.

Hematopoietic Stem Cell Transplantation

HSCT is curative in patients with DBA and may be considered in transfusion-dependent patients who have an HLA-matched sibling donor, patients with DBA progressing to severe aplastic anemia, or patients in whom MDS/AML develops. Five-year post-transplant survival rates are 73% with transplants from sibling donors and 19% with transplants from alternative donors.[620,685] Survival is similar with unrelated marrow and cord blood donors, but a recent report from the Aplastic Anemia Committee of the Japanese Society of Pediatric Hematology suggests that marrow might be superior to cord blood cells.[685] The decision to perform HSCT in patients with DBA is confounded by the possibility of spontaneous remission. HSCT is generally more successful in young patients who have received relatively few transfusions.

Alternative Therapies

Several other therapeutic approaches that have been used over the last 30 years include androgens, erythropoietin, IL-3, stem cell factor, antilymphocyte globulin, cyclosporine, and valproic acid. Although occasional hematologic responses were observed, none of these therapies became a major player in the treatment of DBA. Treatment with metoclopramide, a dopamine antagonist, elicited transfusion independence in a small number of individuals with DBA.[686-688]

Splenectomy was reported in approximately 40 patients, with no beneficial effect noted except in those who had hypersplenism related to transfusions.[643] More than half of the splenectomized patients died, often from infections. Splenectomy is no longer recommended.

More recently, leucine, an amino acid that increases protein synthesis, has been reported to be beneficial in one patient with DBA.[689]

Spontaneous Hematologic Remission

About 20% to 30% of patients experience spontaneous hematologic remission, defined as a stable, physiologically acceptable hemoglobin level maintained for at least 6 months, independent of glucocorticoids, transfusions, or other therapy.[617,620] In the majority of cases hematologic remission occurs within the first decade of life and is stable. However, relapse of hematologic disease has been observed in particular during pregnancy or in women using estrogen-based oral contraception.[620] The molecular basis of the hematologic remission is not understood. In contrast to FA, where hematologic remission is associated with gene reversion, gene mutations persist in patients with DBA who attain hematologic remission.

Pregnancy

Pregnancy in women with DBA is associated with an increased frequency of complications in the mother and child, including preeclampsia, fetal loss, intrauterine death, premature delivery, intrauterine growth retardation, and congenital anomalies.[616,690] It has been suggested that these complications are of vascular-placental origin, and treatment with aspirin has been reported to be beneficial in some cases.[690] Almost half of pregnant patients had transient worsening of anemia during pregnancy. The maternal hemoglobin level should be maintained at greater than 9 to 10 g/dL to avoid maternal anemia, which might lead to intrauterine growth retardation, preterm delivery, or fetal distress. Women planning to become pregnant should be evaluated for conditions that might compromise the outcome of pregnancy, including blood-borne infectious diseases, iron overload and related diabetes mellitus, hypothyroidism, and cardiomyopathy. Iron chelation is contraindicated during pregnancy and should cease when pregnancy is planned or diagnosed. Deferoxamine is teratogenic in rodents but deferasirox is not; however, neither medication is licensed for use in pregnant women.[625]

Cancer Surveillance/Treatment

In addition to an increased risk for AML, there appears to be an association of osteosarcoma and other malignancies with DBA.[647] Bone marrow biopsy plus cytogenetic evaluation is indicated when abnormalities suggestive of MDS or MDS/AML are noted or when the disease progresses to aplastic anemia.[625] Growth hormone therapy is not usually recommended in individuals with DBA and small stature because of the potential increased risk for osteosarcoma.[647] Whether malignancies occurring in patients with DBA differ in their biology and response to treatment from similar malignancies occurring in non-DBA individuals remains to be determined. Similarly, the toxicity of patients with DBA to certain chemotherapy agents used for the treatment of cancer remains to be determined.

Congenital Dyserythropoietic Anemia

Congenital dyserythropoietic anemias (CDAs) are a group of rare genetic disorders characterized by ineffective erythropoiesis and frequent distinctive morphologic abnormalities in bone marrow erythroblasts. The term was used first by Crookston and colleagues,[691] but similar cases had been described previously.[692] Dyserythropoiesis is the major cause of anemia in patients with CDA, although a shortened half-life of the mature cells in circulation may also contribute to anemia (for the definition of dyserythropoiesis see Box 8-19). CDAs are often not considered to belong to the group of IBMFSs. Nevertheless, CDAs are genetic conditions that affect red blood cell production in bone marrow and lead to anemia and reticulocytopenia. Skeletal abnormalities, usually of the limbs, may be associated with some forms of CDA.

Three major forms of CDA[693] and several minor subgroups have been identified.[694] The diagnosis relies on light and electron microscopic examination of erythroblasts in bone marrow and, in the case of CDA type II, also on serologic characteristics.[693] The main characteristics of the three major forms of CDA are summarized in Table 8-11. Shared clinical symptoms include anemia of variable degree, intermittent jaundice, hepatomegaly and splenomegaly, cholelithiasis, and iron overload.

Box 8-19	Ineffective Erythropoiesis/ Dyserythropoiesis

Ineffective erythropoiesis results when in intact, stimulated bone marrow, red blood cell precursors either fail to mature or die in the bone marrow before delivery to the circulation as erythrocytes. Dyserythropoiesis usually defines a qualitative defect in red cells or red cell precursors (or both). Dyserythropoiesis often leads to ineffective erythropoiesis with intramedulary destruction of red cells and their precursors and often a decreased half-life of circulating red blood cells.

Differential Diagnosis

CDA should be considered when the reticulocyte response is suboptimal for the degree of anemia in a patient with erythroid hyperplasia or when there is unexplained hyperbilirubinemia or iron overload. Other congenital anemias and acquired disorders associated with dyserythropoiesis that should be excluded include thalassemia syndromes, hemoglobin C, certain unstable hemoglobins, hereditary sideroblastic anemias, vitamin B_{12} or folate deficiency, iron deficiency, alcohol abuse, liver disease, heavy metal poisoning, and MDS.

Clinical Management

Treatment is essentially symptomatic. Prevention of severe tissue damage secondary to iron overload is important. Splenectomy results in hematologic improvement in some patients with CDA type II,[699] whereas the benefit of splenectomy in other forms of CDA is controversial. Patients with CDA type I show hematologic improvement and a reduction in iron overload in response to recombinant interferon alfa.[655-658,691-694,699-706] Successful treatment with HLA-matched allogeneic HSCT has been reported in severely affected cases of CDA.[698,707-709] In contrast to other IBMFSs, CDA is not associated with a significantly increased risk for leukemia or cancer.

Congenital Dyserythropoietic Anemia Type I

Clinical Characteristics

The incidence of CDA type I is about 1 per 100,000 births per year, and more than 150 patients have been described. Consanguinity may be the cause of an increased incidence in some areas such as the Middle East. In most patients the diagnosis is made during childhood and adolescence. Clinical manifestations in newborns include small stature, hepatosplenomegaly, jaundice, pulmonary hypertension, abnormal liver parameters, and in some cases, transient thrombocytopenia.[710] Red blood transfusions are often required for newborns and infants but are only occasionally necessary later in life. Splenomegaly is evident in 80% to 90% of adult cases. Occasionally, severe erythroid hyperplasia may cause skeletal deformities such as frontal bossing or paravertebral tumors secondary to extramedullary hematopoiesis.

Iron overload with increased ferritin levels is frequent even in untransfused patients. Liver cirrhosis, increased skin pigmentation, and endocrine dysfunction as a result of iron overload have been reported in occasional patients.[711-713] The increased iron loading is due to the enhanced absorption of iron that usually accompanies ineffective erythropoiesis. In fact, hepcidin levels are reduced in CDA type I patients.[714]

Congenital abnormalities are associated with some CDA type I cases and include abnormalities of the fingers, toes, and wrist; short stature; pigeon chest deformity; deformity of the hips, vertebral bodies, and ribs; abnormal skin pigmentation; congenital ptosis; and deafness

TABLE 8-11	Features of Congenital Dyserythropoietic Anemias		
Feature	Type I (Fig. 8-23)	Type II (HEMPAS,* Fig. 8-24)	Type III (Fig. 8-25)
Male-to-female ratio	1.1	0.9	0.8
Incidence	<1/100,000/yr	<1/100,000/yr	Very rare
Anemia	Mild to moderate	Moderate	Mild to moderate
Red cell size	Macrocytic	Normocytic or macrocytic	Macrocytic
Bone marrow erythroblasts			
Light microscopy	Megaloblastic, binucleated (2%-5%), chromatin bridges	Normoblastic, binucleated (10%-40%)	Gigantoblasts (10%-40%), often multinucleated
Electron microscopy	Spongy "Swiss cheese" appearance of heterochromatin	Peripheral double membranes (60%)	Nonspecific, intranuclear clefts, karyorrhexis
Altered red cell proteins	Low levels of protein 4.1	Unusual appearance of band 3 protein	
	Impaired globin synthesis	Reticular endoplasmic proteins	
Acid serum hemolysis (Ham test)	Negative	Positive	Negative
Agglutinability			
Anti-i	Normal	Strong	Slight
Anti-I	Slight	Strong	Slight
Glycosylation	Some abnormalities	Markedly abnormal	Some abnormalities
Skeletal abnormalities	± Limb defects[695-697]		
RBC transfusion requirement	In children, rarely in adults		
Iron overload		Frequent, independent of red cell transfusions	
Extramedullary erythropoiesis	Sometimes		
Gallstones			Frequent
Splenomegaly			Mild
Splenectomy	Usually not recommended	96%	100%
Interferon alfa		Effective in the majority of patients	
Hematopoietic stem cell transplantation			Effective (1 case report[698])
Inheritance	Autosomal recessive	Autosomal recessive	Autosomal dominant and sporadic
Gene locus[†]	15q15.1-15.3	20q11.2	15q21-25
Gene mutated	codanin-1 (*CDANI*)[‡]	*CDAII*	*CDAIII*

*HEMPAS, hereditary erythroblastic multinuclearity with a positive acidified serum lysis test.
[†]Gene locus for some but not all patients in each category.
[‡]Mutated in the majority but not all patients with congenital dyserythropoietic anemia type I.
Data from Alter BP. Inherited bone marrow failure syndromes. In Nathan DG, Orkin SH, Ginsburg D, Look AT (eds). Nathan and Oski's Hematology of Infancy and Childhood, vol 1, 6th ed. Philadelphia, WB Saunders, 2003, pp 281-365; and Wickramasinghe SN, Wood WG. Advances in the understanding of the congenital dyserythropoietic anaemias. Br J Haematol. 2005;131:431-446.

(for review see Tamary and colleagues[715] and Wickramasinghe[716]).

Laboratory Findings

The anemia in CDA type I is moderate with hemoglobin levels between 6.6 and 11.6 g/dL. Red cell morphology includes macrocytosis, severe anisopoikilocytosis, and basophilic stippling. The bone marrow shows erythroid hyperplasia with megaloblastic changes. Diagnostic of CDA type I is the finding of internuclear chromatin bridges between nearly completely separated erythroblasts, which is seen in about 0.6% to 2.8% of the early and late polychromatic erythroblasts (Fig. 8-23).[693,717] Though characteristic of CDA type I, internuclear chromatin bridges may also be found in acquired dyserythropoietic states, such as MDS. The characteristic electron microscopic abnormality in CDA type I is a spongy "Swiss cheese" appearance of heterochromatin in up to 60% of intermediate and late erythroblasts. Additional findings characteristic of CDA type I are summarized in Table 8-11. The acidified serum lysis test is negative, and red cells usually show normal agglutinability with anti-i.[718] The cause of the unbalanced globin chain synthesis in some patients with CDA type I is not known.[713,719]

Patients with CDA type I mount a substantial hematologic response to recombinant interferon alfa-2a or alfa-2b.[700-704] Long-term interferon alfa therapy has been shown to reduce iron overload.[705,706] The basis of the response to interferon is not known.
FIGURE 8-23. Bone marrow from a patient with congenital dyserythropoietic anemia type I. **A,** Lowercase *a* indicates a binucleate erythroblast with nuclei of different size and maturity. **B,** Lowercase *b* indicates internuclear chromatin bridges connecting two erythroblasts. *(From Lewis SM, Verwilghen RL [eds]. Dyserythropoiesis. London, Academic Press, 1977.)*

Genetics

CDA type I is inherited as an autosomal recessive disease. Homozygosity mapping of Israeli Bedouin families localized the gene responsible for CDA type I to chromosome 15q15.1-15.3[720] and led to identification of the responsible gene, named *CDAN1*.[721] *CDAN1* has 29 exons and encodes a putative 1226–amino acid protein termed codanin-1. The function of codanin-1 is unknown. There are no identifiable functional domains. CDAN1 mRNA is found at low levels in a wide variety of tissues. The majority of mutations in *CDAN1* are missense mutations causing single–amino acid substitutions in the mutant protein. Nonsense mutations, splice site mutations, and nucleotide insertions or deletions causing a shift in the open reading frame are rare. Homozygosity for 3238 C→ T mutation causing an arginine-to-tryptophan substitution at amino acid position 1040 (R1040W) was identified in 45 Bedouin and 11 Israeli Arab families, which suggests a founder effect in these populations. No homozygotes or compound heterozygotes for *CDAN1* null mutations have been identified, thus indicating that residual codanin-1 function is essential during development.[7157,721,722] In some families with classic CDA type I, the disease does not segregate with chromosome 15q15.1-15.3 and no mutations were identified in *CDAN1*, which suggests that the disease might be genetically heterogeneous and that mutations in at least one other gene might be responsible for disease expression.[715,721-723]

Congenital Dyserythropoietic Anemia Type II

Clinical Characteristics

The incidence of CDA type II is about 1 in 100,000 births per year, and with more than 300 reported cases, CDA type II is the most frequent form of CDA. CDA type II is also known as hereditary erythroblastic multi-

nuclearity with a positive acidified serum lysis test (HEMPAS, see later).[693] The extent of anemia in patients with CDA type II varies from mild to severe. About 10% of patients require red cell transfusions in infancy and childhood but rarely thereafter.[691,699,724,725] Splenomegaly and the development of gallstones are common. Extramedullary hematopoiesis with the development of paravertebral tumors is rare.[725,726] Progressive iron overload is seen even in untransfused patients, and liver cirrhosis secondary to iron overload develops in about 20%.[744]

Dysmorphic features appear to be less common than in CDA type I. Mental retardation has been reported in some patients with CDA type II.[699,725]

Laboratory Findings

Hemoglobin in patients with CDA type II is generally between 8 and 11 g/dL with a normal MCV.[725] Red cells are usually normocytic with moderate to marked anisocytosis, anisochromasia, and poikilocytosis (including teardrop-shaped poikilocytes); occasional basophil stippling cells; and a few circulating erythroblasts. There is normoblastic erythroid hyperplasia in the bone marrow, with 10% to 35% of binucleate and rarely multinucleate late polychromatic erythroblasts (Fig. 8-24).[699] Electron microscopy shows stretches of double membrane parallel to the inner surface of the erythroblast cell membrane[727,728] that represents excess smooth endoplasmic reticulum containing proteins normally found in this organelle: calreticulin, glucose-regulated protein (GRP78), and protein disulfide isomerase.[729]

The red cells of most patients with CDA type II are lysed in the acidified serum lysis test (Ham test) when mixed with about 30% to 60% of fresh ABO-compatible normal sera but not the patient's own serum.[724,730] The reactive sera contain a naturally occurring IgM antibody that recognizes an antigen present on CDA type II cells
FIGURE 8-24. Bone marrow from a patient with congenital dyserythropoietic anemia type II showing binucleate and multinucleate erythroblasts (arrows). *(Courtesy of Dr. Gail Wolfe, with permission from Alter BP. The bone marrow failure syndromes. In Nathan DG, Oski FA [eds]. Hematology of Infancy and Childhood, 3rd ed. Philadelphia, WB Saunders, 1987, p 159.)*

but not normal cells. CDA type II red cells show increased agglutinability with anti-i antibody. In contrast to red cells from patients with paroxysmal nocturnal hemoglobinuria, which lyse in the acidified serum lysis test even with autologous serum because of complement activation, CDA type II cells lyse because of persistence of "the HEMPAS antigen" on their surface. Thus, CDA type II cells do not lyse in the sucrose lysis test.

Incomplete processing of N-linked oligosaccharides[731,732] leads to defective glycosylation of several usually highly glycosylated membrane proteins such as band 3 (the anion transport protein),[587,733,734] band 4.5 (glucose transporter 1), and glycophorin A.[587,735] It has been speculated that an abnormality in the endoplasmic reticulum may be responsible for the defective glycosylation of red cell membrane constituents in CDA type II.[736] Interestingly, abnormal glycosylation has also been found in other proteins such as serum transferrin (synthesized by hepatocytes). Reduced activity of specific glycosyltransferases has been described in some patients with CDA type II,[731,732] thus suggesting that CDA type II is caused by an abnormality in enzymes involved in *N*-glycan synthesis.[732,737] However, linkage analysis has not supported this premise.[738] More recently, abnormalities in glycosylation were also found in CDA type I and III red cells,[739] which suggests that abnormal glycosylation is probably a consequence rather than the cause of the dyserythropoiesis.[740]

Genetics

Inheritance of CDA type II is autosomal recessive. Genome-wide linkage analysis has localized the disease gene (*CDAN2*) to a 5-cM region of chromosome 20q11.2.[741] However, thus far sequence analysis of candidate genes has failed to identify the gene responsible gene for CDA type II.[742] In rare families, the disease gene

is not linked to chromosome 20q11.2, a finding indicative of genetic heterogeneity.[743,744]

A zebra fish mutant, *retsina*, shows an erythroid-specific defect very similar to CDA type II. The *retsina* mutation is in the band 3 gene encoding the anion exchanger 1.[745] However, band 3 mutations responsible for CDA type II in humans have not been identified.[746]

CDA Type III

CDA type III is rare. Both familial and sporadic cases have been reported.[747] In familial cases the inheritance pattern is autosomal dominant.[748-750] Splenomegaly was present in some but not others. In contrast to CDA type I and II, iron overload seems to not be clinically significant in patients with familial CDA type III, most likely because of intravascular hemolysis and iron loss by hemosiderinuria. Visual disturbances with macular degeneration and angioid streaks have been described in individual families but are not specific for CDA type III.

In sporadic cases the inheritance is unclear. First- and second-degree relatives are hematologically normal.[752,752] Sporadic cases may occur through a de novo dominant mutation or autosomal recessive inheritance. Alternatively, variability in disease penetrance might cause sporadic disease. Sporadic CDA type III cases are clinically heterogeneous. Hepatosplenomegaly and significant iron overload have been described in some (for review see Wickramasinghe and Wood[694]).

Laboratory Findings

Anisopoikilocytosis, basophilic stippling of red cells, and some very large red cells may be found in the peripheral blood smear. In families with hemosiderinuria, iron deficiency may be found. The bone marrow contains giant multinucleate and mononucleate erythroblasts that may be found throughout erythroid differentiation (Fig. 8-25).[739,748,749,752] Other dysplastic changes include basophilic stippling, nuclear lobulation, and karyorrhexis. Erythroblasts show a variety of nonspecific ultrastructural abnormalities, intranuclear clefts, karyorrhexis, abnormalities in the nuclear membrane, and large autophagic vacuoles.[739] Giant multinucleate and mononucleate erythroblasts may also be seen in MDS and erythroleukemia.

Linkage analysis in one large multiplex family localized the disease gene (*CDAN3*) to chromosome 15q22, distal to the *CDAN1* gene.[747,750]

Additional Variants of Congenital Dyserythropoietic Anemia

A number of forms of CDA cannot be classified as types I, II, or III. In a tentative phenotype-based classification, some of them have been assigned to four groups designated CDA group IV, V, VI, and VII consisting of three or more unrelated families.[694,753] In addition, there are several reports of individual families who have not been further classified.

Congenital Dyserythropoiesis Associated with Thrombocytopenia

X-linked dyserythropoiesis with thrombocytopenia (MIM 305371) is not usually considered a form of CDA; nevertheless, it is associated with mild dyserythropoiesis. X-linked congenital dyserythropoiesis with thrombocytopenia results from mutations in the transcription factor *GATA1*, which cause either recessive X-linked thrombocytopenia and mild dyserythropoiesis or X-linked thrombocytopenia with the thalassemia minor phenotype and mild dyserythropoiesis.[754-757] Because bleeding secondary to thrombocytopenia and impaired platelet function is the major clinical feature, X-linked dyserythropoiesis with thrombocytopenia is discussed in more detail with the inherited thrombocytopenias (see Chapter 32).

Severe Congenital Neutropenia

SCN (MIM 202700) is a heterogeneous group of disorders first described in an extended consanguineous family by the Swedish physician Rolf Kostmann (Box 8-20).[758,759] The disease has thus also been known as Kostmann's syndrome, although this eponym has since been used to define a subset of patients with autosomal recessive inheritance of SCN. The incidence of SCN is estimated to be approximately 1 to 2 cases per million, and both genders are affected equally. SCN has been reported in a broad range of ethnic groups, although there is evidence that the incidence of SCN may be lower in American blacks than in the general U.S. population.[566]

Clinical Manifestations

SCN is characterized by severe neutropenia at birth with ANCs generally below 200 cells/μL. With infection there may be an increase in neutrophils in blood, but this is always transient and usually modest. Other hematologic parameters are generally normal, although peripheral

Box 8-20	**Severe Congenital Neutropenia Associated with *ELA2* Mutations**

Approximately 60% of cases of severe congenital neutropenia are associated with heterozygous mutations of *ELA2* (MIM 202700). This disorder is characterized by chronic severe neutropenia (absolute neutrophil counts below 0.5×10^9/L) and is associated with an arrest in myeloid maturation at the promyelocyte/myelocyte stage of granulocytic differentiation. Affected patients have marked susceptibility to infection and a very high risk of progression to acute myeloid leukemia.
FIGURE 8-26. Bone marrow aspirate from a patient with severe congenital neutropenia showing a paucity of mature neutrophils, relative accumulation of promyelocytes (*black arrows*), and marrow eosinophilia (*red arrows*).

monocytosis and eosinophilia are often observed.[760] Bone marrow cellularity is normal to slightly decreased.[761] Bone marrow in the majority of patients with SCN shows an arrest in myeloid maturation with a relative, but not absolute increase in promyelocytes or myelocytes (Fig. 8-26). The promyelocytes often display vacuolization.[762] Bone marrow eosinophilia and monocytosis are common.[761] The number of progenitors committed to the granulocyte lineage is reduced, and they display decreased responsiveness to G-CSF in vitro.[763-766]

Patients with SCN are prone to infections from birth and may initially have omphalitis.[767] In half of the patients infections develop during the first month of life and in 90% by 6 months. Common types of infection include mouth ulcers, gingivitis, cellulitis, skin abscesses, and otitis media. Pneumonia and deep tissue abscesses occur frequently and are life threatening. The most common causes of infection are *Staphylococci* and *Streptococcus* species. The onset of gingivitis occurs early in childhood, and premature tooth decay and loss result.[768]

There is a high incidence of osteopenia in patients with SCN. In the 422 patients with SCN enrolled in the Severe Chronic Neutropenia International Registry (SCNIR), 28% had bone mineral density measurements or radiographic examinations performed as part of routine care.[566] In this subgroup of patients there was evidence of osteopenia in nearly half. Moreover, pathologic fractures, particularly in vertebrae, have been reported in a substantial minority of patients.[769-771] Although chronic G-CSF treatment has been shown to induce osteopenia in mice,[772] the relationship of long-term G-CSF treatment in humans to osteopenia remains uncertain. A small trial suggested that treatment with bisphosphonates improves the osteopenia in patients with SCN.[771] Given the high incidence of osteopenia and potentially effective therapy, it is reasonable to perform periodic assessment of bone mineral density in all patients with SCN.

Predisposition to Malignancy

Patients with SCN have a markedly increased risk for MDS or AML.[534,773,774] The SCNIR was formed in 1994 to define the natural history of SCN and explore treatment options. As of 2004, 1163 individuals with neutropenia had been enrolled. A recent update of the SCNIR showed that the cumulative incidence of MDS or AML was 21% after 10 years of G-CSF therapy (Fig. 8-27).[774] Even more ominous, the hazard rate for AML/MDS increases with time, reaching 8% per year in patients undergoing G-CSF therapy for 12 years. Approximately
FIGURE 8-27. Cumulative incidence of myelodysplastic syndrome/acute myeloid leukemia (MDS/AML) and death from sepsis in patients with severe congenital neutropenia. The cumulative incidence (cumulative proportion experiencing each event as an initial cause of failure in subjects at risk for each adverse event) is shown by years receiving granulocyte colony-stimulating factor (G-CSF) therapy and 95% confidence intervals at selected years (error bars). The observed cumulative incidence (*stair-step curves*) and smoothed cumulative incidence (*dashed curves*) derived from estimated cause-specific hazard functions are shown. (*Redrawn with permission from Rosenberg PS, Alter BP, Bolyard AA, et al. The incidence of leukemia and mortality from sepsis in patients with severe congenital neutropenia receiving long-term G-CSF therapy. Blood. 2006;107:4628-4635.*)

half of patients in whom myeloid malignancies develop are found to have MDS, typically classified as refractory anemia with excess blasts.[773,775] A consistent feature of myeloid transformation in SCN is the high rate of chromosome 7 abnormalities. In the largest series, nearly 60% of AML/MDS samples displayed complete or partial loss of chromosome 7.[773] Of note, transformation to AML/MDS has been observed in patients with SCN who do or do not have mutations of their *ELA2* gene. Interestingly, malignant transformation is rare (<1%) in individuals with cyclic neutropenia or idiopathic neutropenia.[577]

Differential Diagnosis

A detailed discussion of secondary neutropenia, including immune-mediated, drug-related, and infection-related neutropenia, is provided in the section on the phagocytic system. Inherited causes of congenital neutropenia are shown in Table 8-12. Cyclic neutropenia (MIM 162800), which shares the same gene mutation (*ELA2*) as most cases of SCN, is characterized by 21-day oscillations in the number of circulating neutrophils.[776,777] WHIM syndrome (MIM 193670) (warts, hypogammaglobulinemia, infections, and myelokathexis) can be distinguished from SCN by noting a normal to increased number of mature neutrophils in bone marrow and the presence of *CXCR4* mutations in most cases.[778,779] Both cyclic neutropenia and WHIM syndrome are covered in detail in the phagocytic section. The other disorders can be distinguished by the presence of associated clinical features, including exocrine pancreatic insufficiency (SDS), cardiomyopathy (Barth's syndrome), lactic acidosis (PS), hypoglycemia (glycogen storage disease type Ib), partial albinism (Chediak-Higashi, Griscelli, or p14 deficiency syndromes), and dysgammaglobulinemia (hyper-IgM syndrome); each of these disorders is discussed in detail elsewhere in this text. Genetic testing is becoming an increasingly important tool in the diagnosis of congenital neutropenia.[780] Clinical genetic testing for mutations of most of the genes listed in Table 8-13 is available.[781]

Genetics

SCN demonstrates multiple modes of inheritance, including autosomal recessive, autosomal dominant, X-linked, and sporadic patterns. Accordingly, recent genetic studies have identified multiple gene mutations in SCN, including *ELA2* (MIM 130130), *HAX1* (MIM 605998), *GFI1* (MIM 00871), *CSF3R* (MIM 1389871), and *WAS* (MIM 300392). By far the most common mutations affect the *ELA2* gene encoding neutrophil elastase, which accounts for approximately 60% of all cases (all in autosomal dominant or sporadic SCN).[782-785] To date, more than 50 distinct mutations of the *ELA2* gene have been reported in patients with cyclic neutropenia or SCN (Fig. 8-28). Most of the mutations (≈80%) are missense mutations, although mutations that lead to splicing defects (≈10%) and premature stop codons (≈10%) have also been observed. With a few exceptions, specific *ELA2* muta-

tions are associated with SCN or cyclic neutropenia, but not both, thus suggesting a genotype-phenotype correlation.

The molecular mechanisms by which *ELA2* mutations disrupt granulopoiesis are unclear. Genetic studies provide two important clues. First, in all cases the *ELA2* mutations are heterozygous, which suggests a dominant mechanism of action. Second, a case report of paternal mosaicism for an *ELA2* mutation provides evidence that expression of mutant neutrophil elastase inhibits granulopoiesis in a cell-intrinsic fashion because no toxic paracrine effects of mutant neutrophil elastase on wild-type granulocytic cells in this mosaic individual were observed.[786] Neutrophil elastase is a serine protease stored in the primary (azurophilic) granules of neutrophils and (at a much lower level) monocytes. Although the physiologic substrates have not been fully defined, there are many recognized and potential substrates for neutrophil elastase, including coagulation proteins, growth factors, and extracellular matrix components.[787] However, no consistent effect of *ELA2* mutations on neutrophil elastase proteolytic activity, substrate specificity, or serpin inhibition has been observed.[788] Moreover,

aberrant intracellular trafficking of some, but not all of the neutrophil elastase mutants has been reported.[789,790] There is emerging data suggesting that mutations of *ELA2* may cause disease through induction of the unfolded protein response (UPR).[791,792] In this model, *ELA2* mutations result in the production of misfolded neutrophil elastase protein, activation of the UPR, and ultimately, apoptosis of granulocytic precursors. The propensity of individual neutrophil elastase mutants to misfold may determine the magnitude of UPR-induced apoptosis and ultimately the clinical phenotype. Thus, SCN may represent one of the growing list of disorders caused by protein misfolding.

Homozygous mutations of *HAX1* are associated with autosomal recessively inherited SCN (i.e., Kostmann's syndrome).[793] *HAX1* is a member of the prosurvival bcl2 gene family,[794] thus suggesting that increased susceptibility to apoptosis is the mechanism underlying this form of SCN.

There are three case reports of patients with SCN who have germline mutations in the extracellular domain of their G-CSF receptor (CSFR3) in the absence of *ELA2* mutations.[795-797] These germline G-CSF receptor

mutations are thought to act in a dominant negative fashion by inhibiting receptor trafficking to the cell surface and heterodimerization in response to G-CSF. There are several distinct features of SCN associated with these G-CSF receptor mutations. First, these patients suffer from unusually severe neutropenia that is refractory to suprapharmacologic doses of G-CSF. Second, the bone marrow of these patients displays hypocellularity throughout the myeloid lineage rather than the accumulation of promyelocytes characteristic of most cases of SCN.

Heterozygous germline mutations of *GFI1* have been reported in two families with persistent neutropenia and lymphopenia.[798] *GFI1* encodes a zinc-finger domain transcriptional repressor. The *GFI1* mutations are in the zinc-finger domains and are thought to generate a dominant negative GFI1 mutant protein. Once again, the phenotype of SCN associated with *GFI1* mutations is distinct from that observed in classic SCN in that perturbations in lymphocyte production and function are not typically seen in SCN associated with *ELA2* mutations.

An X-linked form of SCN linked to germline mutations in the *WAS* gene has been identified.[799,800] Unlike classic Wiskott-Aldrich syndrome (WAS), which results from loss-of-function mutations, WAS-associated X-linked neutropenia appears to result from gain-of-function mutations of *WAS* that disrupt an autoinhibitory domain of the WAS protein. Finally, in approximately 25% of cases, the genetic basis of SCN remains obscure.

A recent study suggested that dysregulation of lymphoid enhancer–binding factor 1 (LEF-1) may play a role in the pathogenesis of SCN.[801] LEF-1 is a transcription factor regulated by the canonic Wnt signaling pathway. This study showed that LEF-1 expression is markedly reduced in granulocytic precursors from patients with SCN. Remarkably, restoration of LEF-1 expression in SCN granulocytic precursors partially rescued the block in granulocytic differentiation. These data suggest that loss of LEF-1 may be a key mediator of the block in granulocytic differentiation in SCN. However, no LEF-1 mutations have been detected in SCN, and there is no obvious connection between *ELA2* or *HAX1* mutations and LEF-1 expression.

The genetic factors that contribute to transformation to MDS/AML in patients with SCN are not well defined. Indeed, the spectrum of mutations found in SCN-associated AML is distinct from that seen in de novo AML; whereas mutations in *NPM1, FLT3, KIT*, and *CEBPA* are relatively common in de novo AML, they are rare in SCN-related AML.[802] Conversely, mutations of the G-CSF receptor are uniquely associated with the development of AML or MDS in patients with SCN.[783,803-805] Of note, these mutations are distinct from the previously discussed germline mutations that affect the extracellular domain of the G-CSF receptor and are thought to inhibit G-CSF signaling in a dominant negative fashion. Instead, these are acquired mutations that introduce a premature stop codon that results in truncation of the distal cytoplasmic portion of the G-CSF receptor and enhanced signaling. In the largest published series, the incidence of G-CSF receptor mutations was 78% (18/23) in individuals with SCN and monosomy 7, MDS, or AML versus 34% (43/125) in individuals without signs of malignant transformation.[783] Because these mutations enhance proliferative signaling by the G-CSF receptor in vivo,[806,807] it has been suggested that G-CSF receptor mutations directly contribute to malignant transformation.

Clinical Management

Historically, patients with SCN had a poor prognosis and often succumbed in the first or second decade of life with recurrent severe bacterial infections. The use of G-CSF has changed the natural history of this disease; the results of a randomized phase III trial comparing G-CSF with no treatment in patients with SCN demonstrated that the majority (>90%) of patients had a significant increase in circulating levels of neutrophils and a reduction in the incidence and severity of bacterial infections.[808] There is substantial patient-to-patient variability in the dose of G-CSF that is required to achieve an acceptable neutrophil count, with some children requiring only 1 to 2 µg/kg on alternate days and others responding only to doses of 50 to 100 µg/kg/day. The SCNIR currently recommends a starting dose of 5 µg/kg/day with upward twofold increases in dose until the ANC in blood is 1000 to 1500/µL[568] Recognized adverse effects of chronic G-CSF therapy include splenomegaly, bone pain, and vasculitis. There are case reports of patients who are refractory to G-CSF treatment alone but respond to combination therapy with G-CSF and glucocorticoids.[795] Of note, GM-CSF treatment is not effective in SCN; it increases circulating eosinophils but not neutrophils.[760] In addition to G-CSF treatment, patients with SCN should receive regular and frequent dental care because the rate of periodontal disease remains high despite G-CSF treatment.[768]

Hematopoietic Stem Cell Transplantation

HSCT from an HLA-identical sibling is curative in patients with SCN who are refractory to G-CSF treatment.[567,809,810] A more difficult question is when to perform transplantation in SCN patients who are doing well with G-CSF and have an HLA-matched sibling donor. The limited published data indicate that transplantation cures a high percentage of patients with neutropenia only but is usually ineffective in children who have progressed to MDS/AML.[809,811] Patients less responsive to G-CSF (defined as an ANC <2188/µL after 6 months of treatment) have the highest risk for AMD/MDS, with a cumulative risk of 40% at 10 years.[774] Moreover, patients who acquire a G-CSF receptor mutation or monosomy 7 appear to have an elevated risk for the development of MDS or AML.[773,783] Though not confirmed in prospective studies, these criteria may help identify patients who should undergo transplantation.

Current recommendations of the SCNIR are to reserve HSCT for patients with SCN who are refractory to G-CSF or who require high doses of G-CSF and have a matched sibling donor.[774] Others, because of the high rate of malignant transformation and the favorable outcome of HSCT when performed before the development of AML or MDS, advocate early HSCT in patients with SCN who have a matched sibling donor.[812] Although there are case reports of successful nonmyeloablative transplantation for SCN,[533,813] there is insufficient data at present to assess its efficacy.

Leukemia Surveillance and the Controversy of Leukemia Promotion by Granulocyte Colony-Stimulating Factor

It should be emphasized that there is no definitive proof that G-CSF directly contributes to leukemic transformation. Indeed, reports of AML/MDS in SCN predate the use of G-CSF. Moreover, myeloid malignancies are rare in children and adults with cyclic neutropenia despite many years of G-CSF treatment.[566] Thus, the contribution of G-CSF to the development of AML/MDS in patients with SCN remains controversial, and therapy with G-CSF should not be withheld from patients with newly diagnosed SCN on this basis. Because of the risk of leukemic transformation in SCN, patients should receive the lowest dose of G-CSF that is required to maintain an acceptable neutrophil count and should undergo yearly bone marrow examination with cytogenetic analysis. For a detailed discussion of congenital neutropenia see Chapter 21.

Inherited Thrombocytopenia

Inherited forms of thrombocytopenia are rare. They are summarized in Table 8-13 (for more detailed discussion see Chapter 32).

Two major forms of inherited thrombocytopenia are discussed in the following sections because of their association with aplastic anemia and because they have to be considered as a possible differential diagnosis in individuals with one of the major forms of IBMFSs discussed in this chapter.

AMEGAKARYOCYTIC THROMBOCYTOPENIA

Congenital amegakaryocytic thrombocytopenia (CAMT, MIM 60448) is a rare IBMFS characterized by isolated thrombocytopenia and a paucity or absence of megakaryocytes in bone marrow (Box 8-21). The isolated thrombocytopenia progresses to severe aplastic anemia in the majority of affected children.

Clinical Manifestations

Thrombocytopenia is usually diagnosed within the first week of life because of petechiae and bleeding. The

---

Box 8-21	Congenital Amegakaryocytic Thrombocytopenia

Congenital amegakaryocytic thrombocytopenia (CAMT, MIM 60448) is a rare inherited bone marrow failure syndrome of infancy characterized by isolated thrombocytopenia, a paucity or absence of megakaryocytes in bone marrow, and no physical anomalies. CAMT exhibits autosomal recessive inheritance and is caused by mutations in the thrombopoietin receptor (TPO-R), more commonly known as the protooncogene *MPL*.

---

thrombocytopenia is usually severe, but platelet size and morphology are normal. The diagnosis is established by bone marrow examination. Thrombopoietin levels are high, consistent with the lack of megakaryocytes and low platelet counts (for review see Geddis[814]). Physical anomalies may be present but are generally nonspecific. An increased incidence of psychomotor retardation has been reported.[815] A less severe form of CAMT is associated with moderate or transient thrombocytopenia. In contrast to thrombocytopenia with absent radii (TAR) (see later), the thrombocytopenia in patients with CAMT worsens over the first 10 years of life and eventually progresses to severe aplastic anemia by the second decade. Transformation to MDS or MDS/AML has been reported.[815]

Differential Diagnosis

Severe CAMT has to be distinguished from other IBMFSs associated with thrombocytopenia, such as TAR and WAS (see Chapter 29). CAMT lacks the forearm abnormalities characteristic of TAR and the microthrombocytes characteristic of WAS. Thrombocytopenia and amegakaryocytosis have been reported in patients with Noonan's syndrome (MIM 163950) caused by mutations of *PTPN11* (see Chapter 29). Patients with CAMT who progress to aplastic anemia may resemble those with other IBMFSs such as FA and DC. The lack of increased chromosomal fragility in the DEB or MMC test performed on cultured peripheral lymphocytes or fibroblasts (or both) is helpful in strengthening the diagnosis of CAMT. Whether telomere length distinguishes CAMT from DC remains to be determined. Severe CAMT has to be distinguished from a long list of acquired thrombocytopenias (see Chapter 29), in particular, intrauterine infections, immune thrombocytopenia of the newborn caused by antiplatelet antibodies (neonatal alloimmune thrombocytopenia), or antiplatelet antibodies secondary to maternal idiopathic thrombocytopenic purpura.

Genetics

CAMT is an autosomal recessive disorder. Mutations in the thrombopoietin receptor gene *c-MPL* on chromo-

some 1p34 are responsible for disease.[816] Mutations have been identified throughout the *c-MLP* gene, including nonsense, missense, and splicing mutations. Affected individuals are usually compound heterozygous for *c-MLP* mutations, although homozygous mutations have been reported in consanguineous families. Because of consanguinity in affected families, homozygous *c-MPL* mutations in an affected individual are not uncommon.[815] Genetic testing for *c-MPL* mutations is available through approved commercial laboratories.

Genotype-Phenotype Correlation

Patients with CAMT can be divided in two groups: type I patients have complete loss of functional c-Mpl, whereas type II patients have some residual c-Mpl function. Patients with type II CAMT often show transient improvement in the platelet count and have a later onset of pancytopenia than individuals with type I CAMT do.[815,817] Pancytopenia may be the initial clinical manifestation of individuals with type II CAMT. Heterozygous mutation carriers may have impaired megakaryopoiesis despite normal platelet counts.[818]

Clinical Management

The initial treatment of individuals with CAMT is supportive therapy consisting primarily of transfusion of irradiated leukocyte-depleted single-donor platelets to prevent serious bleeding. Platelet increments and platelet survival should be normal. DDAVP is not recommended in small infants because of hyponatremia, but it may be useful in older children. Hematopoietic growth factors and cytokines do not elicit a sustained response in patients with CAMT. HSCT is the only curative treatment of CAMT and should be considered in affected children with a matched sibling donor.[819] Sibling donors heterozygous for a *c-MLP* mutation have been used successfully.[820] HSCT with an unrelated transplant was historically associated with a poor outcome because of regimen-related toxicity and engraftment failure.[815,821,822] Low-intensity conditioning may improve transplant-related mortality and the outcome of HSCT in patients with CAMT.[823] CAMT is likely to be an excellent candidate for future gene therapy because restoration of normal c-MPL in combination with the high levels of endogenous thrombopoietin would provide a selective growth advantage to the corrected hematopoietic stem cell.[824]

THROMBOCYTOPENIA WITH ABSENT RADII

TAR (MIM 274000) is a rare, but well-characterized cause of neonatal thrombocytopenia. The hallmarks of this disorder are shortened forearms as a result of bilateral defects in development of the radii and severe thrombocytopenia at birth.[825]
FIGURE 8-29. Patient with thrombocytopenia with absent radii syndrome. *(Reproduced with permission from Luchtman-Jones L, Schwartz AL, Wilson DB. The blood and hematopoietic system: diseases of the fetus and infant. In Fanaroff AA, Martin RJ [eds]. Neonatal-Perinatal Medicine, 7th ed. Philadelphia, Mosby–Year Book, 2000, p 1235.)*

Clinical Manifestations

Patients with TAR have absent radii but may have normal or hypoplastic thumbs (Fig. 8-29). Other skeletal anomalies may accompany the absent radii, including ulnar shortening, thumb hypoplasia, and scapular changes. The hands and fingers, however, are not affected. Lower limb abnormalities are frequent but usually less severe and include hip dislocation, patellar anomalies, absence of tibia/fibula joints, and phocomelia, present in about 50% of individuals.[825-828] Common nonskeletal anomalies observed in individuals with TAR include gastroenteritis and cow's milk allergy,[829] genitourinary malformations, cardiac defects, facial dysmorphisms, short stature, macroencephaly, and capillary hemangiomas.[828,830]

Platelet counts in neonates with this condition are generally below 50,000/μL. Platelet size and morphology are normal. Usually, the degree of thrombocytopenia is greatest at the time of birth. Patients demonstrate mucocutaneous bleeding, and platelet transfusions are frequently required in the first year of life. However, thrombocytopenia becomes less severe during the first year of life, and most affected individuals with TAR will not require platelet transfusions after infancy.[827,831] Levels of thrombopoietin are elevated in patients with TAR, yet such patients fail to respond to recombinant thrombopoietin.[832,833] Bone marrow aspiration reveals a decrease in megakaryocytes, although this is not required to make the diagnosis.[834] Eosinophilia and leukemoid reactions have been reported and are usually transient. The development of aplastic anemia has not been observed, but

AML and ALL have been reported in patients with TAR.[835-837]

Differential Diagnosis

Although the phenotypes of TAR and FA overlap, several features distinguish these conditions. FA patients are rarely thrombocytopenic in the neonatal period; rather, progressive BMF develops in these patients as children or adults. Only about 30% of patients with FA have a radial defect, whereas this skeletal anomaly is the sine qua non of TAR. In a patient with TAR, thumbs may be present in the absence of radii, whereas in FA, absence of the radius is always accompanied by thumb abnormalities. Despite these differences in clinical features, it is prudent to test patients with a clinical picture of TAR for increased chromosome fragility to formally rule out FA.

Amegakaryocytic thrombocytopenia with radioulnar synostosis (ARTUS, MIM 605432), caused by a mutation in the *HOXA11* gene, is usually associated with mild deformity of the forearms, the inheritance pattern is autosomal dominant, and severe thrombocytopenia persists, which distinguishes this condition from TAR syndrome.[838,839] Progression to aplastic anemia has been observed in individuals with ARTUS but not those with TAR.

Trisomy 18 can be manifested as radial hypoplasia and thrombocytopenia but is usually associated with esophageal atresia.

Genetics

The genetic basis of TAR is not fully understood. Autosomal dominant, autosomal recessive, and autosomal dominant with incomplete inheritance have been discussed in the past. In general, the parents of children with TAR syndrome are healthy, and there is no male/female dysequilibrium, which suggests an autosomal recessive inheritance pattern. The very low incidence of siblings with TAR suggests that the syndrome may carry an increased risk for fetal demise. There have been reports of parent-to-child transmission, thus suggesting multiple allelism of TAR.[825]

The molecular etiopathogenesis of TAR remains unknown. c-Mpl is normally expressed on megakaryocytes and platelets in individuals with TAR.[832] However, platelets and megakaryocytes do not respond to thrombopoietin, which suggests a defect in c-Mpl signaling.[840] The homeobox transcription factors (HOX) have been considered as mutated candidate genes in individuals with TAR because of their role in limb development and the identification of mutations in the *HOX11* gene in two families with ARTUS.[838,839] However, sequencing of the *HOXA10, HOXA11,* and *HOXD11* coding regions did not reveal mutations in 10 individuals with TAR syndrome.[841]

Recently, high-resolution microarray-based comparative genomic hybridization (array CGH) identified a 200-kb microdeletion on chromosome 1q21.1 in 30 of 30 affected individuals and in 32% of unaffected family members, thus suggesting that a microdeletion on 1q21.1 is necessary but not sufficient and that inheritance of an additional modifier is required to cause a phenotype. In the majority of patients with TAR the deletion was inherited; in 25% the deletion occurred de novo. The deletion was not detected in 700 unrelated normal control individuals, which suggests that the deletion is rare in the normal population and thus the modifier is likely to be more common. Digenic inheritance implies that mutations in each of two unlinked loci have to be present (double heterozygosity) to cause disease and that in an affected family the recurrence rate is about 25%. The nature of the modifier remains to be identified.[842]

Clinical Management

TAR has a much better prognosis than CAMT; the survival curve for TAR plateaus above 70% by 4 years of age. As infants, these patients often require transfusions of single-donor, irradiated platelets to maintain a platelet count above 10,000/μL. After the first year of life, platelet transfusion dependence usually diminishes. DDAVP may be helpful for minor bleeding. Recombinant IL-6 has also been reported to lessen the degree of thrombocytopenia in these patients; however, because of considerable side effects, including fever and chills, IL-6 is no longer used for individuals with TAR.[843] Splenectomy improved persistent thrombocytopenia in an adult patient with TAR. In general, HSCT is not indicated. Treatment of nonhematologic manifestations, in particular, orthopedic interventions, dominate the treatment of TAR later in life. For a detailed discussion of congenital thrombocytopenias, see Chapter 29.
