Pyruvate Kinase Deficiency and Disorders of Glycolysis

William C. Mentzer, Jr.

The mature erythrocyte, devoid of nucleus, mitochondria, ribosomes, and other organelles, has no capacity for cell replication, protein synthesis, or oxidative phosphorylation. The glycolytic production of adenosine triphosphate (ATP), the sole known energy source of erythrocytes, is sufficient to meet their limited metabolic requirements. The discovery that hemolytic anemia may result from any of several glycolytic enzymopathies has underscored the dependence of erythrocytes on glycolysis. In this chapter the clinical, biochemical, and genetic features associated with abnormalities in erythrocyte glycolysis are described in detail.

Hereditary hemolytic anemias resulting from altered erythrocyte metabolism are distinguished from hereditary spherocytosis by the absence of spherocytes on the peripheral blood smear, by normal osmotic fragility of fresh erythrocytes, by a partial therapeutic response to splenectomy, and by a recessive mode of inheritance. Hemoglobin structure and synthesis are normal. Because no specific morphologic abnormality is associated with these disorders, they have become known as congenital nonspherocytic hemolytic anemias (CNSHAs).[1] Although CNSHAs are usually transmitted in an autosomal recessive fashion, phosphoglycerate kinase (PGK) deficiency is an X-linked abnormality, and adenosine deaminase (ADA) overproduction is an autosomal dominant disorder. Symptoms and signs may be limited to the manifestations of hemolysis or, if the enzymopathy is present in other tissues, may involve other organ systems. The pattern of involvement of nonerythroid tissues may be of assistance in diagnosis.[2]

Initial attempts to classify these anemias were based on the autohemolysis test, in which saline-washed erythrocytes were incubated without glucose in vitro at 37° C under sterile conditions and the percentage of hemolysis was determined after 48 hours.[3,4] Autohemolysis was greater than normal in almost all patients with CNSHA. If glucose was added before incubation, hemolysis was reduced in control subjects and in some patients with CNSHA (type I) but was unchanged or actually increased in others (type II). Type II erythrocytes did not metabolize glucose well[3] and contained subnormal amounts of ATP but markedly increased amounts of 2,3-diphosphoglycerate (2,3-DPG), thus suggesting a defect in glycolysis below the site of 2,3-DPG synthesis. In 1961, Valentine and associates[5] identified the glycolytic defect to be a deficiency of erythrocyte pyruvate kinase (PK) in three patients with CNSHA. Subsequently, abnormalities of other glycolytic enzymes have also been associated with CNSHA, as indicated in Figure 16-1. Specific alterations in protein structure underlie many of the enzyme deficiency states, and many of the underlying mutations have been identified.[6-8]

The presence of a glycolytic enzymopathy should be suspected when chronic hemolysis occurs in the absence of marked abnormalities in erythrocyte morphology or osmotic fragility. An exception to the usually unremarkable red cell morphology in CNSHA is the pronounced

basophilic stippling found in pyrimidine-5′-nucleotidase (P-5′-N) deficiency.[9] Hemoglobin electrophoresis, stains for inclusion bodies, hemoglobin heat stability, acid hemolysis, and appropriate studies for immune hemolysis are normal. Despite its initial usefulness in directing the attention of investigators to the glycolytic pathway, further experience with the autohemolysis test has shown that it lacks specificity and has, at best, limited value in the evaluation of CNSHA.[10] Unfortunately, no other simple, convenient laboratory screening test has been developed that will unequivocally reveal the presence of a glycolytic enzymopathy. Therefore, the appropriate diagnostic strategy for the evaluation of a suspected enzymopathy is first to eliminate easily identified causes of hemolysis, such as hemoglobinopathies or spherocytosis, before proceeding to tests for enzyme disorders.[11] Definitive diagnosis depends on quantitative assay of the activity of the suspected enzyme or identification of a specific mutation by DNA analysis. The availability of such assays is limited, but screening tests for deficiencies in PK, triose phosphate isomerase (TPI), and glucose phosphate isomerase (GPI) can be carried out in any well-equipped clinical laboratory.[12] The in vitro properties of mutant enzyme proteins vary (Table 16-1), and characterization of such properties has improved understanding of the genetics

TABLE 16-1	Parameters Commonly Used In Vitro to Characterize Mutant Enzyme Protein
V_{max}	Maximal enzyme velocity obtainable with saturating substrate concentrations
K_m	The substrate concentration yielding half-maximal activity; an index of catalytic efficiency
pH optimum	The pH at which maximal enzyme activity is present
Heat stability	Resistance of enzyme protein to heat denaturation
Electrophoretic mobility	Migration of enzyme protein in an electric field
Specific activity	Enzyme activity per defined amount of enzyme protein (e.g., milligram); enzyme protein is measured immunologically with antienzyme antibodies

and pathogenesis of anemias associated with defective glycolytic enzymes. Measurement of glycolytic intermediates extracted from freshly obtained erythrocytes has provided confirmation of the in vivo significance of in vitro abnormalities in enzyme function. The usual finding is accumulation of proximal intermediates and depletion of distal intermediates, thereby giving rise to a characteristic transition or crossover pattern at the locus of an abnormal enzyme. Secondary crossovers sometimes take place and are due to the influence of altered concentrations of metabolites on key regulatory enzymes such as hexokinase (HK), phosphofructokinase (PFK), and PK. As a result of secondary crossovers, the pattern of glycolytic intermediates may become so complex that it has only limited usefulness in the identification of an enzymopathy. In contrast, measurement of intracellular metabolites is currently the most convenient way to screen for abnormalities in nucleotide metabolism. Red cell ATP levels are below normal with overproduction of ADA, whereas P-5'-N deficiency is associated with increased concentrations of red cell ATP and reduced levels of glutathione. The apparent increase in ATP is, in fact, due to the presence of large amounts of cytidine and uridine nucleotides, which are also measured in the enzymatic assay for ATP. Spectral analysis of a deproteinized extract of red cells provides a straightforward means of identifying such nucleotides, and it is a simple method to screen patients for suspected P-5'-N deficiency.[9]

Caution is needed in interpreting the results of quantitative assays of enzyme activity. First, only surviving cells are available for sampling in circulating blood, and the metabolic circumstances of these favored cells cannot necessarily be extrapolated to indicate the status of cells already hemolyzed. Second, assay in vitro under optimal conditions may not adequately reflect the performance of an enzyme under less favorable circumstances in vivo. Third, the high specific activity of certain enzymes in leukocytes may result in spurious normal values for erythrocyte enzyme activity unless contaminating leukocytes are removed before assay or their contribution to total activity is compensated for by appropriate calculations. Fourth, transfusion therapy with normal erythrocytes within several months before assay may obscure the presence of an enzyme defect. Fifth, the mean enzyme activity that is determined fails to portray the distribution of activity within individual erythrocytes. The endowment of intracellular enzymes is fixed, and protein synthetic ability disappears at the reticulocyte stage; thereafter, the inevitable denaturation of enzyme protein that accompanies cell aging reduces enzymatic activity at a rate characteristic for each enzyme. Transient accentuation of reticulocytosis, therefore, is often accompanied by rising mean enzyme activity. Certain glycolytic enzymes (notably HK and PK) are strikingly more active in reticulocytes than in postreticulocyte red cells, and the majority of this excess activity is rapidly lost coincident with reticulocyte maturation.[13-15] The true magnitude of an enzyme deficiency may not be apparent unless comparison is made to blood that is equally rich in reticulocytes[14] or corrections are applied that eliminate the contribution of the reticulocyte subfraction to total enzyme activity.[15]

Finally, there is evidence that reversible binding of glyceraldehyde-3-phosphate dehydrogenase (G3PD), HK, and PFK to the band 3 membrane protein is involved in the regulation of glycolysis,[16] and altered binding of mutant forms of these enzymes (and perhaps others) is not assessed in conventional assays performed on hemolysates.

HEXOKINASE DEFICIENCY

Clinical Manifestations

CNSHA has been attributed to deficient erythrocyte HK activity in 22 patients (Table 16-2). Severely affected individuals may exhibit neonatal hyperbilirubinemia and thereafter require transfusion at regular intervals for intractable anemia. In patients with mild disease, the hemolysis is fully compensated for and anemia is absent. However, jaundice, reticulocytosis, and splenomegaly are usually present in such patients. Gallstones may be evident, even in early childhood.[25] Hyperhemolytic episodes are not a feature of the disorder. The results of red cell morphologic examination are usually unremarkable, but occasional burr cells, target cells, stippled cells, and densely stained spiculated cells may be observed after splenectomy. The osmotic fragility of fresh erythrocytes is normal, but a fragile population of cells may appear after incubation at 37° C.

Biochemistry

In human red cells, HK is a monomer (molecular weight, 112,000).[35] It is encoded by a gene (*HK1*) located on

chromosome 10q22.[20] HK activity declines as red cells age. Loss of activity is particularly striking during reticulocyte maturation. In human reticulocytes, two major isoenzymes of HK have been identified by chromatographic techniques.[36] One (HKR) has an apparent half-life in vivo of only 10 days, whereas the other (HK1) has a longer half-life of 66 days. These two proteins are the products of two closely similar messenger RNAs (mRNAs) that are transcribed from a single gene (*HK1*) by the use of alternate promoters. Exon one is unique to each mRNA species, but the remaining 17 exons are identical.[37] Differential loss of these two isoenzymes appears to explain the biphasic character of the decay in HK activity during erythrocyte aging. An ATP- and ubiquitin-dependent proteolytic system capable of degrading about 80% of HK activity may explain the rapid loss of HK in rabbit reticulocytes,[38] or the loss may be secondary to an intrinsic property of the HK molecule itself.[39] Previous oxidative injury appears to be necessary for recognition and destruction of HK by the ubiquitin-dependent system.[40] Because ATP- and ubiquitin-dependent proteolysis is limited to reticulocytes,[38] it cannot be responsible for the loss of HK in aging human red cells.

HK is the glycolytic enzyme with the lowest activity in normal red cells, and a variety of observations indicate that it plays a rate-limiting role in erythrocyte glycolysis.[41-45] The maximal activity of erythrocyte HK from deficient patients has varied from 13% to 91% of normal (see Table 16-2). In evaluating these findings, comparisons of enzyme activity between red cell populations of equivalent age must be made. In the case described by

Valentine and associates,[45] for example (Fig. 16-2), although HK activity was 62% of the normal value for mature erythrocytes, it was only 14% of the activity found in blood with high reticulocyte counts. Separation of young and old red cell populations by centrifugation revealed only the expected moderate diminution (to 0.11 mol/min/10[10] red blood cells) of HK activity in older cells from this patient.[45] HK activity was even lower (0.075 mol/min/10[10] red blood cells) in an asymptomatic brother, yet no evidence of undue hemolysis was present. However, Figure 16-2 shows that the brother's cells are actually far less deficient with respect to cell age than the immature cells of the propositus. The impact of HK deficiency is clearly greater in energetic young erythrocytes, whereas cells that survive to an older age can meet their limited metabolic requirements even at very low HK levels.[46] As the erythrocyte ages, in vivo changes in stability or kinetics peculiar to mutant HK may also render older cells liable to undergo premature hemolysis. In rats and rabbits, HK from immature erythrocytes has a higher K_m (Michaelis constant) for glucose than mature cells do, but such is not the case in normal human erythrocytes.[46]

In keeping with their enzymatic defect, HK-deficient erythrocytes have usually demonstrated subnormal glucose consumption and lactate production in vivo. Such cells also metabolize fructose poorly but utilize mannose or galactose normally[45] because these substrates are not metabolized by HK. Some HK-deficient erythrocytes are capable of normal glucose consumption at the glucose concentrations (5 mmol/L) customarily found in

FIGURE 16-2. Hexokinase (HK) activity observed in 54 patients with hemolytic anemia of various causes plotted against percentages of reticulocyte in cells assayed. Patients are grouped according to reticulocyte levels. Mean HK activity for each group is plotted against the mean reticulocyte percentage in cells of that group. Standard deviations are indicated by *vertical bars*. Values for a single HK-deficient patient (proposita) and her family are designated separately. *(From Valentine WN, Oski FA, Paglia DE, et al: Erythrocyte hexokinase and hereditary hemolytic anemia. In Beutler E [ed]: Hereditary Disorders of Erythrocyte Metabolism. New York, Grune & Stratton, 1968, pp 288-300.)*
plasma but utilize glucose poorly or not at all at lower glucose concentrations, either because of an abnormally low affinity for glucose[34] or because of enzyme instability under conditions of low substrate availability.[30] Such erythrocytes may encounter a particularly unfavorable metabolic environment within the spleen. The concentration of glucose in normal splenic homogenates has been found by Necheles and co-workers[34] to be only 5 to 11 μmol/g of tissue, and in a patient with HK deficiency the concentration was even lower (1.1 μmol/g of tissue). Furthermore, because splenic tissue metabolizes glucose rapidly,[47] prolonged vascular pooling in the spleen is probably accompanied by profound local hypoglycemia. Erythrocytes with unfavorable kinetics for glucose metabolism are clearly at a disadvantage in competing with reticuloendothelial cells for such a reduced glucose supply. Another disadvantage of the splenic environment is its relative acidity. The optimal pH of erythrocyte HK is approximately 8; at lower pH values, diminished enzyme activity may be expected. Possibly of greater importance, at low pH values, glucose 6-phosphate, a potent inhibitor of HK, accumulates because of PFK inhibition.[48] An erythrocyte that has diminished HK activity under optimal pH conditions will be further compromised in the acidic environment of the spleen. The clinical improvement that follows splenectomy attests to the importance of this organ in the pathogenesis of hemolysis. Detailed isotopic studies to define red cell kinetics and sites of hemolysis have yet to be reported. Although no splenic sequestration of chromated autologous erythrocytes was noted in two patients,[25,31] in another sequestration was present. Thus, in this disorder the red cells may be damaged by the spleen and die elsewhere.

Significant alterations in intracellular metabolites are associated with defective HK function. The erythrocyte ATP concentration is sometimes,[31,35] but not always[21,24,29,33] subnormal. The glucose-6-phosphate concentration is reduced to approximately half normal, and the concentrations of other more distal intermediates, most notably 2,3-DPG, are also usually reduced. These metabolites may exert a significant regulatory influence on glycolysis. For example, Brewer[49] has shown that concentrations of 2,3-DPG in the physiologic range inhibit HK, so the low 2,3-DPG levels in HK-deficient red cells may facilitate the performance of available HK. The increased affinity of hemoglobin for oxygen expected to be associated with subnormal 2,3-DPG levels has been documented in one anemic patient with HK deficiency by Delivoria-Papadopoulos and co-workers[50] and by Oski and associates.[51] This patient, whose hemoglobin-oxygen affinity (P-50) was 19 mm Hg (normal, 27 ± 1.2), was capable of just minimal exercise despite only moderate anemia (hemoglobin, 9.8 g/dL). On exercise, her central venous partial pressure of oxygen (PO_2) promptly fell to minimal levels as oxygen consumption rose. Increased oxygen delivery was achieved primarily by an increase in cardiac output because the unfavorable oxygen affinity curve precluded any substantial further desaturation of hemoglobin.[51]

Thus, the altered concentration of intracellular metabolites induced by HK deficiency may, as in this patient, accentuate symptoms associated with anemia.

Because of its reactive sulfhydryl group, HK is susceptible to oxidant inactivation in the absence of sufficient glutathione.[52] Both normal and low glutathione levels have been reported in HK deficiency, but Heinz bodies have not been observed. Resting hexose monophosphate (HMP) shunt activity, measured with ^{14}C-glucose-1, was quantitatively normal in one patient despite subnormal glucose consumption, but stimulation with methylene blue was suboptimal.[45] Failure of the shunt at low glucose concentrations has also been noted in an HK mutant with a high K_m for glucose.[32] Methylene blue–stimulated methemoglobin reduction was subnormal in the single instance that it was evaluated.[17] When HK-inactivating antibodies are incorporated into normal red cells by the process of hypotonic lysis and isotonic reannealing, enzyme-deficient cells exhibit a greatly impaired response to HMP shunt stimulation by methylene blue.[42] These studies, though not indicating a central role for defective shunt activity in the pathogenesis of hemolysis, do suggest that under unusual circumstances, HK-deficient cells might be compromised by a limited shunt. Such circumstances might arise on exposure to a potent oxidant in the low glucose environment of the spleen.

Genetics

Inheritance of HK deficiency is autosomal recessive. Biochemical identification of asymptomatic carriers is not always possible because enzyme activity often falls within the low-normal range. In a few pedigrees (see Table 16-2), the heterozygous state appears to be severe enough to result in hemolytic anemia. One such heterozygote appeared to be doubly heterozygous for HK and glucose-6-phosphate dehydrogenase (G6PD) deficiency.[53]

The qualitative abnormalities characteristic of mutant HK (see Table 16-2) may reflect either a structural or a regulatory gene mutation. On electrophoresis, mutant HK lacks one or more of the normal bands of activity, but no bands migrating in an abnormal position have been observed. The various bands represent the presence of several isozymes of HK. Diminished synthesis of one or more isozymes with predominance of the remaining isozymes accounts for the electrophoretic differences observed (see Table 16-2). DNA analysis has defined two separate HK mutations in a compound heterozygote who exhibited nonspherocytic hemolytic anemia.[20,54,55] One was a missense mutation (T1667→C) and the other was a deletion of exon 5 (96 base pairs [bp]). Expression of each HK mutation in a bacterial system allowed recovery of sufficient purified enzyme to determine that the missense mutation completely abolished HK activity whereas the deletion reduced activity to about 10% of normal.[55] In another individual,[24] a homozygous missense muta-

tion in the active site of HK1 (2039 C→G in exon 15) was discovered.[56] In a Japanese family, a stillborn fetus with HK deficiency was found to be homozygous for a large deletion that removed exons 5 through 8 in HK mRNA and led to premature termination of translation.[20] The kinetic abnormalities noted in many other mutant forms of HK undoubtedly also reflect as yet undefined structural abnormalities in enzyme protein.[17,18,22,27,28,32]

Studies of the tissue distribution of HK deficiency have been performed in blood cells and cultured fibroblasts. Electrophoresis of leukocyte or platelet HK reveals an anodal isozyme (Hk3) distinct from those of the erythrocyte (Hk1 and Hk2), as well as a shared isozyme (Hk1).[57,58] Leukocyte HK activity has been normal in some patients,[30,45] but the qualitative abnormality in leukocyte HK described by Necheles and colleagues,[34] as well as the case of generalized HK deficiency in all blood cells reported by Rijksen and co-workers,[24] indicates that to some extent the enzyme is under common genetic control in different tissues. When platelet HK activity has been low, platelet function has been normal despite subtle defects in in vitro energy metabolism.[59] Cultured fibroblasts from two individuals with different HK mutants contained HK with properties and activity like those found in red cells,[23] thus suggesting that this source of fetal tissue could be used for prenatal diagnosis.

A murine model of HK deficiency, termed Downeast anemia, is due to homozygous inheritance of a mutation that markedly decreases the expression of HK1 in erythroid tissues, spleen, and kidney. The mutation is the result of insertion of a transposon into intron 4 of the *HK1* gene. Mice exhibit nonspherocytic hemolytic anemia, marked reticulocytosis, splenomegaly, and striking accumulation of iron in the liver and kidney. Echinocytes and red cells split into two poles of hemoglobin connected only by thin strands of membrane are features of erythrocyte morphology in affected homozygous mice that are of interest because they have not been reported in human HK deficiency.[60]

Therapy

Treatment consists of red cell transfusion as indicated, supplemental folic acid, and close observation for cholelithiasis. Splenectomy may alleviate but does not eliminate the anemia.[18,22,24,30,34,45]

GLUCOSE PHOSPHATE ISOMERASE DEFICIENCY

Clinical Manifestations

A deficiency of erythrocyte GPI has been reported in more than 60 patients with congenital hemolytic anemia.[61] Hemolytic anemia usually appears in infancy and often requires red cell transfusion therapy. Hyperbilirubinemia,[62] hydrops fetalis,[63,64] or death[65] may occur during the neonatal period. Several patients have experienced hyperhemolytic crises after infections or drug exposure.[62,66] In some of these individuals, G6PD, as well as GPI, has been deficient.[66,67] Hemolytic anemia is usually the sole clinical manifestation of GPI deficiency. A subset of patients also exhibit neurologic dysfunction.[68-73] In one patient, neuromuscular abnormalities were correlated with a severe reduction in muscle and cerebrospinal fluid GPI activity.[71] Blockade of glycolysis at the GPI step may divert the flow of glucose metabolism in the direction of glycogen synthesis. Several patients with GPI deficiency have been reported to have increased hepatic glycogen stores,[74,75] and in one, muscular fatigue was severe enough to suggest a diagnosis of glycogen storage disease.[75] An animal model of GPI deficiency and chronic hemolytic anemia has been developed in the mouse. The clinical and biochemical features of the disease in mice closely resemble those found in humans.[76]

Red cell morphologic characteristics are generally similar to those seen in other types of CNSHA. In severely anemic patients, dense, spiculated, or "whiskered" microspherocytes have been noted after splenectomy. In one instance, sufficient numbers of such cells were present before splenectomy to suggest the diagnosis of hereditary spherocytosis.[77] In another, the predominant morphologic abnormality was stomatocytosis.[78] The reticulocytosis may be profound. Mean corpuscular volume is elevated (97 to 139 fL). With incubation at 37° C, a variable fraction of erythrocytes may exhibit abnormally increased osmotic fragility, whereas fresh cells are usually normal. Survival of chromated autologous red cells is reduced, often[79-81] but not invariably,[65,79,82] with evidence of splenic sequestration.

Biochemistry

GPI is a dimer[83] composed of two identical subunits, each with a molecular weight of approximately 60,000.[81,83] Subunit synthesis is directed by a single genetic locus on chromosome 19.[84] The crystal structure of human GPI has been defined.[85] GPI is a multifunctional protein. The dimeric form exhibits glycolytic enzyme activity, whereas the monomeric form functions as a cytokine. Monomeric GPI is 100% homologous to neuroleukin, a neurotrophic growth factor secreted by lectin-stimulated T cells[61,86,87]; to autocrine motility factor, which stimulates cell motility and the growth of metastases[88]; and to a differentiation and maturation mediator for human myeloid leukemia cells in tissue culture.[89] Altered neuroleukin function may explain the neurologic disorder associated with several GPI mutations.[61,73]

The metabolic events that precede hemolysis of GPI-deficient erythrocytes are poorly understood. Erythrocyte glycolysis is impaired in vivo, as reflected by an increased ratio of substrate to product (i.e., glucose 6-phosphate to fructose 6-phosphate) in freshly obtained GPI-deficient cells.[67,77,90-95] Paradoxically, with only occasional exceptions,[77,96] such cells are fully capable of

glycolysis in vitro.[67,82,97-00] In contrast to HK deficiency, in which 2,3-DPG levels are low, sufficient glycolysis generally occurs in GPI deficiency to maintain the 2,3-DPG concentration at or above the normal level.[88,90,92,96,100] Except for three patients with diminished ATP concentrations, two of whom also exhibited reduced in vitro glycolysis for cell age,[68,78,83] the erythrocyte ATP concentration has been normal.

A profound defect in recycling of fructose-6-phosphate through the pentose phosphate pathway has been observed repeatedly in GPI-deficient red cells.[77,99,100] The increased formation of Heinz bodies[65,78] and glutathione instability[69,94] after exposure to acetylphenylhydrazine, an abnormal ascorbate cyanide test, and diminished concentrations of red cell glutathione[78,82,91,92,94] in fresh erythrocytes all suggest that diminished shunt activity in vivo may contribute to hemolysis.

With rare exceptions,[71] mutant forms of red cell GPI exhibit considerable thermal lability in vitro, thus making it likely that enzyme lability in vivo as red cells age will lead to premature metabolic collapse and hemolysis. Separation of red cells by centrifugation into young and old subpopulations has usually demonstrated accelerated decay of enzyme activity in the older cells.[82,101] Arnold and co-workers[101] simulated the in vivo process of aging by incubating red cells in vitro at 37° C for 8 days and changing the incubation medium often to ensure that glucose availability and pH remained constant. GPI activity declined by 66% in GPI-deficient red cells during incubation, with a level of only 6% of normal being reached, and lactate production, normal at the onset, was reduced to 11% of normal. In contrast, normal reticulocyte-rich blood lost only 6% of the original GPI activity after 8 days, and lactate production fell only 7%. If mannose rather than glucose was used, GPI-deficient and normal red cells made equivalent amounts of lactate, and there was little or no loss in lactate production after 8 days. The normal glycolytic rate noted with mannose, which is isomerized by mannose phosphate isomerase and thus bypasses the GPI reaction, clearly pinpoints defective GPI activity as the cause of glycolytic failure in GPI-deficient cells. ATP depletion with consequent erythrocyte rigidity and reticuloendothelial entrapment would be anticipated to follow failure of glycolysis. GPI-deficient red cells are, indeed, less deformable than normal cells, particularly when comparison is made to young, reticulocyte-rich populations of cells.[89,90,102,103] Goulding studied a 9-year-old patient with GPI deficiency and priapism and concluded that the priapism was the consequence of abnormal erythrocyte deformability.[104] Studies by Coetzer and Zail revealed aggregation of membrane spectrin in GPI-deficient erythrocytes.[105] The extent of the aggregation is a function of cell age.

Even reticulocytes may be severely GPI deficient.[74] Deficient reticulocytes with limited anaerobic glycolytic capability may also be incapable of effective oxidative phosphorylation in the acidic, hypoglycemic splenic environment (see the section "Pyruvate Kinase Deficiency"), thereby leading to metabolic failure and hemolysis. Large numbers of reticulocytes were found when specimens from the spleen of a patient with GPI deficiency were examined by transmission electron microscopy.[74] Furthermore, the reticulocyte count often increases after splenectomy.[65,74,80,82] Because hemoglobin levels also increase, this observation suggests survival of a population of reticulocytes that would otherwise be hemolyzed almost immediately after their release from bone marrow.

Genetics and Inheritance

Like most other glycolytic enzymopathies, GPI deficiency is inherited as an autosomal recessive trait. Heterozygotes are hematologically normal but exhibit reduced erythrocyte GPI activity (usually to about 50% of normal). They inherit one mutant and one normal GPI allele, which results in the synthesis of two unlike GPI subunits that may combine in one of three ways to form a normal homodimer, a mutant homodimer, or a heterodimer that contains both normal and mutant subunits. Electrophoresis of GPI from the erythrocytes of heterozygotes will demonstrate one to three bands, depending on the extent to which the charge or activity of the mutant subunit is altered. Post-translational events, such as oxidation of enzyme protein, may alter the electrophoretic pattern and confuse its interpretation.[106,107]

GPI mutations associated with hemolytic anemia are listed in Table 16-3. Of the 31 known mutations, 2 are splice site, 3 are nonsense, and 26 are missense mutations involving a single amino acid substitution.[61,108] The mutations are found in 12 of the 18 exons and are generally unique to one or at most a few families. The rarity of GPI deficiency and the heterogeneity of the mutations identified indicate that no selective advantage is conferred to affected individuals. Half of the homozygotes or compound heterozygotes for missense mutations have mild to moderate hemolytic anemia, and half have severe anemia. In contrast, all compound heterozygotes for missense mutations and either splice site or nonsense mutations have severe hemolytic anemia. Hemolytic anemia occurs in individuals when GPI activity drops below about 40% of the normal mean activity. Substrate kinetics and the optimal pH of mutant enzymes have almost always been normal, but most mutant enzymes have exhibited varying degrees of thermal instability. Short of direct detection of the mutation at the DNA level, the most useful means of classifying the numerous GPI variants reported has been on the basis of stability, electrophoretic mobility, or residual enzyme activity in red cells and leukocytes.[64,65,67-71,78-82,90-99,109-112] Until DNA mutation analysis has been completed on these variants, it will not be clear how many are truly unique. Immunologic titration of functionally inactive enzyme protein in red cells indicates that some mutant GPI alleles are "silent" and produce no detectable enzyme protein whereas

*Severe disease (splenectomy, frequent red cell transfusions, and/or reticulocyte count >15%).
†The Spanish patients are described by Repiso and colleagues.[108,108a]
Adapted from data summarized by Kugler W, Lakomek M: Glucose-6-phosphate isomerase deficiency. Baillieres Clin Haematol. 2000;13:89-101.

others produce structurally altered protein with varying degrees of activity and stability in vivo.[109-111]

A single GPI isozyme is present in all human tissues.[84] GPI deficiency is usually less severe in nonerythroid tissues than in erythrocytes because nonerythrocytic tissues retain the ability to synthesize GPI subunits. Clinical abnormalities outside the hematopoietic system are rare and, if present, are neuromuscular in nature. Leukocytes are capable of normal phagocytosis and chemotaxis despite a reduction in GPI activity to 25%[90] to 73%[98] of normal, but if GPI activity is more severely depressed, granulocyte function is impaired.[71,112] Similarly, platelet GPI may be only 20% to 30% of normal; however, clot formation, platelet aggregation, and other clotting studies are normal.[90,98] Prenatal diagnosis is feasible by DNA analysis if the mutations are known or by measurement of GPI activity in amniotic fluid fibroblasts[63] or chorionic villus trophoblasts.[113]

Therapy

Transfusion requirements are usually eliminated by removal of the spleen, but the anemia persists.[65,74,80,98] The postsplenectomy hemoglobin levels of 6.7 to 10.3 g/dL and reticulocyte counts of 36% to 73% observed in three siblings by Paglia and co-workers[100] reflect the magnitude of the continued hemolysis that may be present. Attempts by Arnold and colleagues[98] to enhance glycolysis in a GPI-deficient patient by intravenous administration of methylene blue or inorganic phosphate (P_i) did not have a lasting benefit.

PHOSPHOFRUCTOKINASE DEFICIENCY

Clinical Manifestations

Inherited deficiency of PFK can involve erythrocytes, muscle, or both, depending on the PFK subunit affected and the nature of the biochemical defect (Table 16-4). Although low erythrocyte PFK activity and mild hemolytic anemia are commonly found in type VII glycogen storage disease (Tarui's syndrome), the dominant clinical feature of this disorder is exertional myopathy caused by deficient muscle PFK activity.[118,119] Physical activity is limited not by anemia but by weakness, easy fatigability, and severe muscle cramps associated with the myopathy. The disease may be evident at birth and cause death during infancy as a result of respiratory insufficiency and other complications,[120] or it may be so mild that it is not manifested until old age.[121] However, in most affected individuals the disorder is first detected during adolescence or young adulthood. The diagnosis may be suspected if no lactate is produced during an ischemic (anaerobic) forearm exercise test, but confirmation requires muscle biopsy for determination of PFK activity or noninvasive magnetic resonance imaging (MRI) studies of muscle carbohydrate metabolism.[122]

When PFK deficiency is confined to erythrocytes, there are no symptoms of myopathy, and the blood lactate response to anoxic exercise is normal.[123-125] Such patients may be hematologically normal[116,126,127] or exhibit mild to moderate hemolytic anemia.[123,127] In general, red cell morphologic characteristics are not strikingly abnormal, although prominent basophilic stippling has occasionally been noted.

Biochemistry

PFK is one of several glycolytic enzymes that reversibly bind to the inner aspect of the erythrocyte membrane.

Binding, which is thought to occur between the amino-terminal position of the transmembrane protein band 3 and the adenine nucleotide binding site, located in a cleft between the two dimers that form the PFK tetramer, may serve to both activate the enzyme and protect it against proteolytic degradation during erythrocyte aging.[128]

The active form of human erythrocyte PFK is a tetramer (molecular weight, 380,000) composed in varying combinations of two different subunits, one identical to the M subunit found in muscle PFK and the other identical to the L subunit found in liver PFK.[129,130] The molecular weight of the M subunit is 85,000 and that of the L subunit is 80,000.[129] About 50% of the erythrocyte enzyme is formed from M subunits,[124,129] whereas muscle PFK is composed entirely of M subunits.[124,131] A deficiency in M subunits severely depresses muscle PFK activity and results in myopathy, but it has a lesser effect on erythrocyte PFK because residual L subunits, under separate genetic control, combine to form an active L4 tetramer of PFK. However, PFK formed entirely from L subunits is unstable to heat or dilution in vitro and is more sensitive to ATP inhibition than muscle (M4) PFK is.[123] At the in vivo concentrations of ATP that are present within normal erythrocytes, the enzyme activity of L4 PFK tetramers is severely inhibited, thus possibly explaining the presence of hemolytic anemia even when enzyme activity, as measured in vitro, is approximately 50% of normal. Most recognized examples of PFK deficiency are the result of either missing[116,118] or structurally altered[125] M subunits. An interesting exception was found in a clinically normal individual, fortuitously discovered when he volunteered to serve as a "control" during studies of red cell PFK carried out by Vora and colleagues.[116] Normal M subunits but mutant, unstable L subunits were found in his red cells. There was no myopathy, and although erythrocyte PFK was only 65% of normal, hemolytic anemia was not present, presumably because residual enzyme activity within the red cell was entirely

due to the presence of M4 tetramers of PFK. The relatively greater stability and lesser susceptibility to ATP inhibition of this form of PFK apparently allowed adequate enzyme activity under conditions normally found within the red cell in vivo.

Because of the central role of PFK in regulation of erythrocyte metabolism, it is not surprising to find that a deficiency of this important enzyme is associated with hemolysis, but the mechanism of hemolysis is not well understood. Erythrocyte sodium and potassium concentrations, sodium influx, and lactate production were normal in one patient.[122] Despite their normal glycolytic capability in vitro, deficient cells were incapable of maintaining normal ATP concentrations in vivo. The low (73% of normal) intracellular ATP concentration in these cells, though indicative of an abnormality in cellular metabolism, may also exert a positive influence by partially relieving the inhibitory influence of ATP on PFK. Extensive in vitro study of erythrocytes obtained from a Swedish family with Tarui's disease and mild compensated hemolytic anemia found elevated intraerythrocytic calcium levels associated with increased calcium permeability of the erythrocyte membrane. High intracellular calcium levels activated the Gardos channel with subsequent ATP depletion, potassium depletion, increased mean corpuscular hemoglobin concentration (MCHC), and diminished erythrocyte deformability. The authors point out that the PFK and Ca^{2+} channel genes are in close proximity to one another on chromosome 12q, but the reason for abnormal Ca homeostasis remains undefined.[132,133]

The complex interaction between metabolites that may dictate actual PFK activity in vivo is illustrated by physiologic studies performed on four individuals with Tarui's syndrome.[134] At usual levels of physical activity, the pattern of erythrocyte glycolytic intermediates clearly reflected inhibition at the PFK step, and the concentration of the important downstream metabolite 2,3-DPG was only 50% of the level found in normal red cells. After the patients had 2 days of bed rest, their red cell 2,3-DPG levels sank to just a third of normal. Subsequently, ergometric exercise on a bicycle eliminated the glycolytic intermediate pattern of PFK inhibition and allowed downstream intermediates, including 2,3-DPG, to increase toward normal. Release of large amounts of inosine and ammonia from enzymopathic muscle during exercise into plasma was observed in these patients. Ammonia is a powerful activator of PFK; inosine can be metabolized to lactate by glycolytic pathways (i.e, the HMP shunt) that bypass the PFK reaction. Thus, the muscle metabolic abnormalities created by PFK deficiency generate metabolites that alleviated the enzymopathy in erythrocytes. (Diversion of the flow of erythrocyte glycolysis through the HMP shunt by the block at PFK may also generate increased amounts of purines and pyrimidines from 5-phosphoribosylpyrophosphate [PRPP].) The hyperuricemia sometimes noted in individuals with PFK deficiency (see Table 16-4) may be explained on this basis.[117]

An inherited deficiency of PFK found in English springer spaniels allows interesting comparisons to be made with the human condition.[135-137] As in humans, canine PFK deficiency is an autosomal recessive disorder. Red cell PFK levels are only 7% to 22% of normal in homozygotes because the muscle subunit, which is lacking, accounts for the majority of the available subunits in normal dog red cells.[138] PFK deficiency in dogs is associated with severe hemolytic anemia. Newborn dogs are not anemic because there is a greater abundance of L subunits and thus of functional PFK enzymes in their red cells. The hemolytic anemia appears because the normal developmental pattern of replacement of L by M subunit synthesis occurs in a setting in which M subunits either are not synthesized or are defective.[139]

A unique feature of dog PFK deficiency is episodic hemolysis induced by hyperventilation during exercise, mating, barking, or other similar activities.[137] Dog red cells with high sodium levels exhibit spontaneous hemolysis at alkaline pH; even the small pH change induced by hyperventilation is sufficient to generate the effect in PFK-deficient animals. Underlying the susceptibility of PFK-deficient dog red cells to hyperventilation-induced hemolysis may be their low 2,3-DPG levels, which increase intracellular pH. Raising 2,3-DPG levels to normal in vitro normalizes the response to alkalinity.[140] In comparison to humans, there is less evidence of exertional myopathy, even though dog muscle PFK activity is nearly absent,[141] because dogs do not rely on anaerobic glycolysis for generation of energy during exercise.[142] During exercise, PFK-deficient dogs do exhibit less extraction of oxygen from hemoglobin than normal dogs do, either because the affinity of hemoglobin for oxygen is high (caused by low 2,3-DPG levels in their erythrocytes) or because oxidative metabolism is impaired.[143]

PFK activity in erythrocytes from newborn infants is about 50% to 60% of that in normal adult cells.[144] PFK deficiency is more evident in older cells made earlier in gestation, perhaps because of accelerated enzyme decay.[145] Vora and Piomelli[146] showed that 25% to 30% of newborn erythrocyte PFK consists of L4 isozyme, with the remainder being divided equally between three hybrid isozymes of L and M subunits (LlM3, L2M2, and L3Ml). The L4 isozyme, not found in normal adult red cells, is unstable and presumably accounts for the reduced PFK activity of older cord red cells. The demonstration that PFK deficiency may result in hemolytic anemia in adults suggests that the enzyme deficiency characteristic of normal newborn red cells may contribute to their shortened survival.

Genetics and Inheritance

The gene locus for the L subunit of PFK has been assigned to chromosome 21, whereas the M subunit locus is on chromosome 12.[117,147] The erythrocytes, but not the leukocytes and platelets of individuals with trisomy 21, consistently contain increased PFK

activity.[148] Increased erythrocyte PFK activity is due to increased amounts of L subunit, consistent with a simple gene dosage effect.[117]

Inheritance is autosomal recessive. Type I PFK deficiency (Tarui's disease), which is found predominantly in Ashkenazi Jews and Japanese individuals, is the result of mutations involving the *PFKM* gene.[149,150] The 15 reported mutations[145] (5 splice site, 8 missense, 1 nonsense, and 1 frameshift) are shown in Figure 16-3.[151] The widely scattered location of the mutations makes it difficult to correlate genotype and phenotype. In PFK-deficient dogs, a missense mutation involving 120 nucleotides from the 3′ end of the coding region produces a truncated mRNA and an unstable PFKM subunit tetramer with altered kinetic properties.[152,153]

Therapy

Supportive care with red cell transfusions as needed and daily folic acid supplementation are the mainstays of therapy for the hemolytic anemia.

ALDOLASE DEFICIENCY

Clinical Manifestations, Biochemistry, and Genetics

Aldolase A is found in erythrocytes, muscle, and the fetal brain. Only six individuals with CNSHA and erythrocyte aldolase deficiency have been reported. Their clinical course has varied, with one also exhibiting mental retardation, three an associated myopathy, and two no abnormalities other than hemolytic anemia (Table 16-5). Two members of a Japanese family who had a severe deficiency of red cell aldolase[155] exhibited severe chronic hemolytic anemia, sometimes exacerbated by infections. In vitro, red cell glycolysis and HMP shunt activity were depressed, thus indicating that the deficiency of aldolase was of functional significance. Both parents were hematologically normal but had intermediate reductions in red cell aldolase A activity. The mutant aldolase was strikingly thermolabile. A missense mutation (GAT→GGT) giving rise to a single amino acid substitution (Asp→Gly) at position 128 was present in the mutant enzyme.[156]

Transfection of *Escherichia coli* with an expression plasmid containing normal, mutant, or modified (by site-directed mutagenesis) aldolase A complementary DNA (cDNA) generated functional aldolase molecules that were used to confirm that the amino acid substitution at position 128, a site distant from the catalytic site but within an exposed hinge region, was responsible for the enzyme thermolability.[162]

In a German child, homozygosity for a point mutation at residue 206 (Glu→Lys) in the coding region of aldolase A also led to thermolability and severe enzyme deficiency in both erythrocytes and skeletal muscle.[157] Unlike the Japanese subjects, this child had a metabolic myopathy, as well as mild to moderate hemolytic anemia. The mutation at residue 206 would be predicted to disrupt the main subunit interface of the aldolase tetramer and cause thermolability. Why myopathy was noted in one setting but not in the other is unknown.

A girl of Sicilian ancestry whose red cell aldolase activity was less than a quarter of normal also exhibited myopathy and chronic hemolytic anemia.[158] Elevated plasma creatine phosphokinase activity was noted with febrile illnesses. She died at the age of 54 months of rhabdomyolysis and hyperkalemia during an acute febrile illness. Like the German patient, her aldolase A enzyme was thermolabile, which offered an explanation for the exacerbation of myopathy during fever.[159] DNA analysis revealed two mutations in the aldolase A gene in this patient: one was a premature stop codon mutation (931C→T) and the second was a missense mutation (1037G→A) that conferred thermolability on the enzyme.[158,159]

Another patient with aldolase deficiency exhibited CNSHA, mental retardation, mild glycogen storage disease, intestinal lactase deficiency, growth retardation, and peculiar facial features. Enzyme activity was approximately 15% of normal in erythrocytes and cultured skin fibroblasts.[154] No structural abnormality of residual erythrocyte aldolase was detected by electrophoresis, isoelectric focusing, heat stability studies, or kinetic examination. The patient was the offspring of a consanguineous marriage, but both parents were hematologically normal and had normal red cell aldolase activity.

A sixth patient, heterozygous for a thermostable mutation of aldolase A, had myopathy, arthrogryposis multiplex congenita, and hypopituitarism but normal IQ and no evidence of hemolytic anemia.[160,161] Because both parents were clinically normal, the aldolase mutation in the patient may have no relationship to his clinical abnormalities.

TRIOSE PHOSPHATE ISOMERASE DEFICIENCY

Clinical Manifestations

An association with TPI deficiency has been documented in approximately 50 patients with congenital hemolytic anemia.[163-178] In addition to chronic hemolysis, a severe neuromuscular disorder characterized initially by spasticity and psychomotor retardation and often progressing to weakness and hypotonia has been found in nearly all patients surviving beyond the neonatal period. Increased susceptibility to bacterial infection has also been noted. The neurologic abnormalities are not usually manifested before 6 to 12 months of age and are progressive, with death occurring before the age of 5 years. Occasionally, these abnormalities may stabilize during childhood[179] or adolescence.[164] In a Hungarian family, one adult son with severe TPI deficiency had extrapyramidal neurologic symptoms, whereas his older brother, who was equally TPI deficient, remained symptom free.[176,180] Further investigation has shown that these brothers have both inherited the same two TPI mutations (see later) but that levels of dihydroxyacetone phosphate (DHAP), methylglyoxal, and advanced glycation end products were much higher in the neurologicly affected brother.[181] The basis for the prolonged survival of both brothers and their different neurologic status is unknown, but epigenetic factors are suspected.

Anemia is variable, but most patients require at least occasional blood transfusions. Macrocytosis and polychromatophilia are evident on the blood smear because of the presence of reticulocytosis, which may reach 50% on occasion. Aside from occasional small, dense spiculated cells, no striking changes in erythrocyte morphologic characteristics are present.

Biochemistry

TPI is a homodimer whose two subunits (molecular weight, 26,750[182]) are the product of a single locus on the short arm of chromosome 12.[183] Post-translational modification of one or both subunits may occur by deamidination of aspartines at positions 15 and 71, thereby resulting in multiple forms of the enzyme.[184,185] The 248–amino acid sequence of human (placental) TPI has been determined directly[182] and is nearly, but not completely identical to the sequence predicted by nucleotide analysis of adult human liver cDNA.[169]

TPI is a classic housekeeping gene, present in all tissues, whose amino acid sequence has been remarkably well conserved during evolution.[186] The eight-stranded $\alpha\beta$-barrel structure of the human enzyme has been confirmed at 2.8-nm resolution by x-ray crystallography.[186] TPI has no requirement for cofactors or metal ions, and there is no evidence of cooperativity or allosteric interactions between subunits.

When measured in vitro, erythrocyte TPI activity is approximately 1000 times that of HK, the least active glycolytic enzyme. Even TPI-deficient erythrocytes exhibiting only 2% to 35% of normal TPI activity in vitro possess far more TPI than HK activity. Not surprisingly, TPI-deficient erythrocytes are capable of normal glycolysis in vitro, even when compared with reticulocyte-rich normal blood.[164] Furthermore, mathematical modeling

shows that increased activity of glycolytic kinases can lead to normal conversion of glucose to lactate in TPI-deficient cells.[187] Nonetheless, DHAP, the substrate for TPI, accumulates to high levels in TPI-deficient erythrocytes,[187] and the ATP concentration is usually low for cell age. These results indicate the presence of a substantial impairment in glycolysis in vivo. Reduction of residual TPI activity in deficient cells by binding to the red cell membrane or to brain microtubulin has been proposed to account for some of the differences between in vitro determinations of TPI activity and the evidence of a more severe impairment in enzyme function in vivo.[188-190] The defect can be partially bypassed by way of the HMP shunt, which generates glyceraldehyde 3-phosphate from glucose without the participation of TPI. Methylene blue stimulation of the shunt produces a lesser increase in glycolysis relative to baseline in TPI-deficient erythrocytes than in reticulocyte-rich control blood.[164] This has been interpreted as indicating a markedly greater "resting" shunt rate in the deficient cells, consistent with the proposed reliance of such cells on the shunt. Evidence indicates that TPI-deficient red cells are relatively deficient in antioxidant capabilities and that this deficiency may contribute to their shortened life span.[165,191]

Rare electrophoretic variants of TPI, not associated with reduced enzyme activity or hemolysis, have been described.[185,186,192,193] In anemic patients, enzyme kinetics and electrophoretic mobility are usually normal, but in vitro evidence of enzyme lability after heating is often obtained,[167-169,171] thus suggesting that instability and rapid loss of enzyme protein play an important role in the pathogenesis of hemolysis in vivo.[167,169] A single amino acid substitution (Glu→Asp) at position 104 has been identified in at least 17 geographically widely distributed families with clinically affected children and is the most commonly encountered mutation responsible for TPI deficiency.[173,178] Its relative rate of occurrence is thought to be due to a founder effect. The Glu104→Asp TPI gene product is thermolabile.[194] Computer modeling indicates that a substituted amino acid at position 104, which is buried in a hydrophilic side pocket of the normal enzyme, will reduce the stability of the pocket, promote unfolding, and enhance thermolability.[194]

Fourteen TPI mutations have been defined.[173] Most clinically affected individuals are homozygous for a single mutation or compound heterozygous for two different mutations. In the Hungarian pedigree mentioned earlier,[180] a point mutation at codon 240 (Phe→Leu) produced a moderately thermolabile TPI with abnormal substrate kinetics and electrophoretic migration.[195] Phe240 is near the active site of the enzyme and appears to be essential for maintaining its correct geometry.[186] Furthermore, both anemic brothers in this pedigree inherited a nonsense mutation at codon 145 that terminated TPI protein synthesis, thereby producing a truncated protein, and also reduced the output of TPI mRNA from the affected allele by 10- to 20-fold.[196] The red cells

of the brothers had less than 10% of the TPI activity found in normal cells.[180,195]

The enzyme deficiency is manifested not only in red cells but also in leukocytes, platelets, muscle, serum, and cerebrospinal fluid. Histologic examination of muscle from a girl with TPI deficiency and myopathy revealed marked degenerative changes of the contractile system, altered mitochondria, and absent TPI by histochemical staining.[197] Brain and nerve tissue have not yet been analyzed, but the cerebrospinal fluid deficiency suggests that deficient TPI activity in neural tissue is responsible for the neurologic abnormalities observed in enzymopenic patients. Although increased susceptibility to infection might be the consequence of defective function by TPI-deficient leukocytes,[170] functional studies carried out on such cells in vitro have often been normal.[166,179] A functional defect in TPI-deficient platelets has been described.[198]

Genetics and Inheritance

Several large pedigrees display an autosomal recessive mode of inheritance of TPI deficiency.[166,169,173] Obligate heterozygotes are clinically normal, but their erythrocytes contain only approximately half the TPI activity of control erythrocytes. As is often the case in other glycolytic enzymopathies, no clear boundary exists between heterozygous deficient and low-normal enzyme activity. Several upstream polymorphisms are found at a high rate of occurrence in African American populations.[173,199] Although they may be associated with mild reductions in erythrocyte TPI activity, they do not seem to be associated with clinical abnormalities, even in homozygotes.[173] At the other extreme, in mice the homozygous state for a TPI null allele is lethal early in embryogenesis.[200] Simultaneous heterozygous inheritance of TPI deficiency and either G6PD deficiency or sickle cell trait has not altered the typical clinical pattern of the disorders when either is present alone.[165] TPI deficiency can be diagnosed prenatally by analysis of fetal blood cells,[172] cultured amniocytes,[171] or trophoblastic cells[177] with suitable precautions.[201] If the mutation is known, mutation analysis can be performed directly on fetal DNA.[177,196]

Therapy

Transfusions and folic acid supplementation are the therapies presently available. Splenectomy in one patient did not alter the intensity of hemolysis.[166] In vitro studies point to the possibility of transfer of TPI enzyme protein from normal to deficient cells with transient improvement in enzyme activity and a reduction in DHAP levels.[202] There have been no attempts to deliver normal TPI enzyme to patient tissues, but in other disease settings direct enzyme transfer from normal hematopoietic stem cell–derived microglial cells to enzyme-deficient nervous tissue after allogeneic stem cell transplantation has been successful.[202]

GLYCERALDEHYDE-3-PHOSPHATE DEHYDROGENASE DEFICIENCY

Clinical Manifestations, Biochemistry, and Genetics

Study of a large kindred in which three members exhibited a reduction in erythrocyte G3PD activity to 50% of normal levels yet were hematologically normal have clearly established that G3PD deficiency need not result in hemolysis.[203] The clinical severity of hemolytic anemia in four members of this pedigree who inherited both hereditary spherocytosis and G3PD deficiency was no greater than that associated with spherocytosis alone. Affected members of this kindred were presumed to be heterozygotes because the amounts of both G3PD enzyme activity and enzyme protein were reduced equally to about 50% of normal and the amount of residual G3PD was qualitatively normal. Two of three anemic patients with G3PD deficiency in other kindreds had even lower levels of enzyme activity (20% to 30% of normal) and conceivably were either homozygotes or doubly heterozygous for two mutant G3PD genes.[204,205] However, as with the spherocytosis pedigree, a cause-and-effect relationship between hemolytic anemia and G3PD deficiency was not established.

PHOSPHOGLYCERATE KINASE DEFICIENCY

Clinical Manifestations

PGK deficiency is a sex-linked disorder that largely affects males. Nonspherocytic hemolytic anemia may occur alone or in combination with neurologic abnormalities ranging from emotional instability to seizures, movement disorders, psychomotor retardation, aphasia, or tetraplegia.[151,206] In a subset of individuals with PGK deficiency, myopathy is the dominant and sometimes the only clinical manifestation (Table 16-6). Individuals with one form of mild PGK deficiency (PGK München) exhibit no clinical abnormalities (Table 16-6). In females, erythrocyte PGK activity is less depressed than it is in males, hemolytic anemia is mild or absent, and neurologic and muscle abnormalities are not seen (see Table 16-6).

Hematologic findings in anemic individuals with PGK deficiency have been those customarily associated with hemolysis, namely, jaundice and reticulocytosis. Hemolytic episodes are often associated with acute febrile illnesses. No changes in erythrocyte morphologic characteristics have been seen, and osmotic fragility has usually been normal.

Biochemistry

PGK is a monomeric enzyme with a primary structure consisting of 417 amino acids.[238] Horse and pig muscle PGK has a primary structure that is highly homologous to that of human PGK.[239,240] Crystallographic studies show that its tertiary structure consists of two lobes (the C and N domains) connected by a hinge-like structure that allows considerable conformational change to occur during substrate binding (Fig. 16-4).[239,240] Because the nucleotide (adenosine diphosphate [ADP] and ATP) combining site is located within the C domain and the phosphoglycerate (1,3-DPG or 3-phosphoglyerate) binding site is within the N domain, bending of the enzyme is required to bring the several substrates required for the PGK reaction into close proximity.[240] Mutant PGKs often exhibit abnormal enzyme kinetics and diminished stability in vitro, properties that are likely to impair enzyme function in vivo (see Table 16-6).

PGK-deficient red cells are capable of normal glycolysis in vitro.[207,236] Intracellular ATP concentrations are normal or slightly low,[207,212,236] whereas the 2,3-DPG concentration is elevated, sometimes to two or three times the normal level.[207,212,217,222,236] These results reflect increased flow through the 2,3-DPG cycle (see Fig. 16-1) at the expense of the ATP-generating PGK reaction. Despite the availability of an alternative pathway (the Rapoport-Luebering shunt or the 2,3-DPG cycle) to bypass PGK, substantial accumulation of glycolytic intermediates proximal to the enzyme defect is found in fresh red cells, thus indicating that the normal flow of erythrocyte glycolysis is impeded in vivo.

Little is known about the mechanism of hemolysis of PGK-deficient red cells. Most PGK activity is membrane associated.[241] It has been suggested that the ATP for membrane adenosine triphosphatase (ATPase)-mediated cation transport is mostly (or entirely) generated by membrane-bound PGK. Indeed, ADP derived from membrane ATPase exerts an important regulatory influence on glycolysis by its participation in the PGK reaction.[242] However, the implication of a special role for PGK in cation transport has been challenged.[243] Active transport of Na⁺ and K⁺ by PGK-deficient red cells with residual PGK activity only 10% to 15% of normal was not impaired, even with the challenge of an increase in intracellular Na⁺ concentration.[244] Thus, it seems unlikely that hemolysis of PGK-deficient red cells is related to premature cation pump failure as a direct result of inadequate PGK activity.

PGK activity in leukocytes is consistently subnormal in affected males, but white cell function is not usually compromised.[218,245]

Genetics and Inheritance

The major structural gene for PGK, located on the long arm of the X chromosome, is 23 kb in size and composed of 11 exons and 10 introns.[246-249] PGK-deficient male hemizygotes demonstrate very little active enzyme and have more symptoms than heterozygous females do, who have higher levels of PGK activity (see Table 16-6). A second functional PGK gene, expressed only in

FIGURE 16-4. Three-dimensional model of human phosphoglycerate kinase (PGK). This figure is based on the three-dimensional model of horse PGK published by Banks et al.[240] Positions of the amino acid substitutions and the clinical features associated with 14 PGK point mutations are indicated by *filled circles* (H, hemolytic anemia; M, muscle disease; N, neurologic manifestations; O, no clinical abnormalities). The *shaded ellipse* in the C domain indicates the location of the adenosine triphosphate (ATP) and adenosine diphosphate (ADP) binding site. Random coil (*clear*), β strands (*solid*), and α helices (*striped*) are indicated by shading. (Modified from Fujii H, Kanno H, Hironi A, et al: A single amino acid substitution [157 Gly→Val] in a phosphoglycerate kinase variant [PGK Shizuoka] associated with chronic hemolysis and myoglobinuria. Blood 1992;79:1582-1585.)
spermatozoa, is found on chromosome 19.[250] This autosomal PGK gene lacks introns but is otherwise similar to the X-chromosomal PGK gene. A single isozyme of PGK is found in all human nonhematopoietic tissues except spermatozoa.[251] It is therefore not surprising that nonerythroid tissues may be compromised in patients with erythrocyte PGK deficiency.

In 1972, Yoshida and co-workers[252] succeeded in purifying and sequencing both normal erythrocyte PGK and a clinically normal but electrophoretically distinct human mutant PGK, the New Guinea variant. The mutant enzyme differed from normal PGK by the substitution of arginine for threonine at position 352.[238] Subsequently, the structure of 17 other PGK mutants, most associated with clinical manifestations, has been determined by peptide or nucleotide sequencing (see Table 16-6). Fifteen of these mutants involve only a single amino acid (14 missense mutations and 1 deletion). The 16th activates a cryptic splice site that leads to the insertion of 10 additional amino acids into the PGK polypeptide, and the 17th, a 4–amino acid deletion, also affects splicing and produces a truncated polypeptide. The majority of the mutants are found within the C domain, as shown in Figure 16-4. It is not clear how the particular spectrum of clinical abnormalities associated with each mutation is related to its position within the molecule. For example, PGK Michigan, a point mutation at amino acid 316, is associated with hemolytic anemia and neurologic abnormalities, whereas individuals with PGK Creteil, a point mutation of the adjacent amino acid at position 315, do not have anemia and neurologic abnormalities but exhibit rhabdomyolysis.[253] Both mutants are thermolabile and demonstrate kinetic abnormalities in vitro, and both have similarly reduced activity in erythrocytes (see Table 16-6). Random inactivation of the mutant

X chromosome may produce differing proportions of enzyme-deficient cells in female heterozygotes. Some may be anemic (see Table 16-6), whereas others are clinically and hematologically normal.[213] In the latter, the population of PGK-deficient red cells may be so small that erythrocyte PGK activity will be completely normal.[212]

Therapy

In one patient, splenectomy had no beneficial effect on anemia,[237] but in several others, surgery has decreased or eliminated the need for transfusions, reduced the degree of reticulocytosis, and sometimes resulted in an increase of several grams in the hemoglobin level.

2,3-BISPHOSPHOGLYCERATE MUTASE DEFICIENCY

Clinical Manifestations

Absence of erythrocyte 2,3-bisphosphoglycerate mutase (BPGM) activity does not affect red cell life span but may have other hematologic consequences. In one pedigree, four siblings who completely lacked functional red cell BPGM had polycythemia but were otherwise clinically and hematologically normal. All three children of these individuals had about 50% of the normal amount of red cell BPGM and were hematologically normal except for polycythemia.[254,255] In another patient with polycythemia, BPGM activity was only 4% of normal, 2,3-DPG was almost undetectable, and hemoglobin's oxygen affinity curve was shifted to the left. Despite the concomitant inheritance of severe erythrocyte G6PD deficiency, this individual did not have evidence of hemolytic anemia.[256]

Biochemistry

Human red cell BPGM is a homodimer whose identical subunits (molecular weight, 29,840) each consist of 258 amino acids.[257] Nearly all 2,3-bisphosphoglycerate phosphatase activity also resides in the BPGM molecule, so 2,3-DPG metabolism is controlled by a single, multifunctional enzyme. In fact, purified BPGM is also capable of performing as a monophosphoglycerate mutase (MPGM), though at a low rate of activity.[258] Considerable structural homology exists between red cell 2,3-DPG mutase and MPGM,[259,260] and the enzymes, to some extent, exhibit overlapping functions. However, both biochemical[259] and genetic[261] evidence indicates that they are each unique and under separate genetic control.

The BPGM molecule has been modified in vitro by site-directed mutagenesis in an attempt to model a potential therapeutic approach to sickle cell disease.[262] Replacement of Gly13 by Arg enhances phosphatase activity at the expense of the mutase. The effect of such an alteration in vivo, achieved by gene therapy or by pharmacologic means, would be to lower erythrocyte 2,3-DPG levels, increase the affinity of hemoglobin for oxygen, and in this way retard the polymerization of hemoglobin S.

BPGM deficiency results in reduced synthesis of 2,3-DPG. In complete BPGM deficiency, there is virtually no 2,3-DPG within the red cell.[254-256] The affinity of whole blood for oxygen is increased because of lack of 2,3-DPG, thereby accounting for the polycythemia noted in individuals with BPGM deficiency.[254-256] The pattern of glycolytic intermediates is disturbed,[241] with a crossover at PFK sometimes being exhibited,[255] which is consistent with relief of the inhibitory influence of 2,3-DPG on PFK. The erythrocyte ATP concentration is usually normal or slightly increased, compatible with diversion of 2,3-DPG into the PGK reaction as a consequence of reduced flow through BPGM. Erythrocyte glycolysis and pentose phosphate pathway activity have been normal in vitro.[254] Probably as a consequence of the large amount of 1,3-DPG present in BPGM-deficient red cells, hemoglobin A may undergo post-translational modification by glycerylation at $\alpha82$. The modified hemoglobin, about 3% of the total, has a lower isoelectric-electric point than hemoglobin A_{1C} does and is easily identified by isoelectric focusing.[263]

Genetics and Inheritance

The BPGM locus is on chromosome 7 (7q22-34).[264] The gene is fully expressed only in erythroid tissue.[255] BPGM deficiency has the expected autosomal recessive mode of inheritance.[254-256] Individuals from the large pedigree with polycythemia and virtually no red cell BPGM activity have been shown to be compound heterozygotes for two different BPGM mutations.[265] One, BPGM Creteil I, is a point mutation (Arg89→Cys) at or near the BPGM active site,[266] and the other, BPGM Creteil II, is a frame-shift mutation caused by a deletion of nucleotide 205 or 206.[267] Only BPGM Creteil I enzyme protein is found in red cells.[268] It is catalytically inactive and thermolabile in vitro and exhibits altered electrophoretic mobility.[268] Although BPGM and 2,3-bisphosphoglycerate phosphatase activity was virtually absent in compound heterozygotes, MPGM activity was nearly normal, thus illustrating the complex nature of this multifunctional enzyme.[266] The individual with severe BPGM and G6PD deficiency was homozygous for a missense mutation (185G→A; Arg 62→Gln) in exon 2.[256]

Therapy

Polycythemia, if symptomatic, may require phlebotomy.[255]

MONOPHOSPHOGLYCERATE MUTASE DEFICIENCY

Clinical Manifestations, Biochemistry, Genetics, and Therapy

A woman with hereditary spherocytosis whose erythrocyte MPGM activity was reduced to about 50% of normal was found to have inherited two copies of a missense mutation (230met→isol) in the MPGM-BB isoenzyme, which is the form that contributes most of the MPGM activity in erythrocytes.[269] The mutant enzyme exhibited reduced thermal stability but normal kinetics.[270] Family members who inherited a single copy of the mutation were healthy, and no evidence was presented to indicate that in homozygotes MPGM deficiency influences the hemolysis associated with hereditary spherocytosis.[271]

ENOLASE DEFICIENCY

Clinical Manifestations, Biochemistry, Genetics, and Therapy

A woman in whom red cell enolase activity was only 6% of normal exhibited a modest reduction in the survival of ^{51}Cr-labeled autologous erythrocytes (half-life of 18 days; normal, 25 to 30 days) but no overt chronic anemia.[272] A severe, life-threatening acute hemolytic episode occurred when nitrofurantoin was administered for the treatment of a urinary tract infection. Enzymes of the HMP shunt all exhibited normal or increased activity, and glutathione stability was normal. Such drug-induced hemolysis is distinctly uncommon in disorders of the Embden-Meyerhof pathway, although it is theoretically possible in enzyme-deficient reticulocytes.[273] In this patient, in whom sudden massive hemolysis involved predominantly mature red cells, no biochemical mechanism has yet been defined, and the association between enolase deficiency and hemolytic anemia may be coincidental. A

sister was hematologically normal, even though her red cells were as deficient in enolase activity as those of the propositus.

Partial red cell enolase deficiency was inherited in an autosomal dominant manner by six members of a second pedigree that spanned four generations. With the exception of the propositus, a 13-day-old boy with profound hemolytic anemia, affected family members were not anemic and had little or no evidence of hemolysis. Spherocytes were present on the peripheral blood smear, and the MCHC was usually elevated.[274]

Therapy remains undefined, but avoidance of oxidant drugs would seem prudent.

PYRUVATE KINASE DEFICIENCY

Clinical Manifestations

PK deficiency is the most commonly encountered glycolytic enzymopathy associated with anemia. Its incidence has been estimated to be 51 cases per million in white individuals.[275] Of the approximately 500 human patients thus far reported,[6] the majority have been of Northern European extraction. Sporadic instances have been seen in other ethnic groups. A hemolytic anemia resembling that seen in human PK deficiency has also been described in basenji dogs,[276,277] beagles,[278] and inbred mice[279] that inherited mutant forms of erythrocyte PK with subnormal activity. Anemia, jaundice, and splenomegaly are regularly present in PK deficiency. The anemia may be profound, occurring in utero[280,281] or in early infancy,[62] and require regular blood transfusions for survival. Conversely, the anemia may be mild enough to evade discovery until adulthood. In a few patients, anemia is absent, hemolysis is fully compensated for, and jaundice may be the sole clinical abnormality. When present, anemia is a lifelong condition and its intensity usually varies little, although it may become more severe during pregnancy.[282,283] Exacerbations of anemia are uncommon and generally result from transient erythroid hypoplasia after infections[284] or, rarely, from increased hemolysis of unknown cause. Iron overload is an occasional problem. Transfusion, splenectomy, and coinheritance of hereditary hemochromatosis genes are factors that make iron overload more likely in PK deficiency.[285] Manifestations of PK deficiency outside the hematopoietic system are uncommon. In several pedigrees, chronic leg ulcers have been observed in family members with PK deficiency and hemolytic anemia.[286,287]

Hyperbilirubinemia is often encountered in newborns with PK deficiency, and these infants may require exchange transfusions.[62] Serum unconjugated bilirubin levels remain elevated in later life, and gallstones are common. Unconjugated bilirubin levels greater than 6 mg/dL are occasionally seen[288]; one brother and sister regularly had levels greater than 20 mg/dL.[289] These patients have abnormal hepatic function in addition to
FIGURE 16-5. Postsplenectomy blood smear from a patient with severe pyruvate kinase deficiency. *(From Nathan DG, Oski FA, Sidel VW, Diamonk LK. Extreme hemolysis and red cell distortion in erythrocyte pyruvate kinase deficiency. I. Morphology, erythrokinetics, and family enzyme studies. N Engl J Med 1964;270:1023-1030. hemolysis. Whether abnormalities in liver PK contribute to hyperbilirubinemia is unknown.[290,291]

Macrocytosis, occasional shrunken, spiculated erythrocytes, and rarely, acanthocytes may be observed on examination of the blood smear; these changes may be accentuated by splenectomy. More extreme alterations in erythrocyte morphologic characteristics are sometimes encountered (Fig. 16-5).[292,293] Such abnormalities in shape may result from the inadequate ATP synthesis characteristic of PK-deficient erythrocytes.[294] A paradoxical increase in the reticulocyte count often follows splenectomy despite evidence of a beneficial reduction in the rate of hemolysis. Reticulocyte counts may exceed 90%, and in many patients counts of 40% to 70% are maintained for years. Conversely, in other patients the expected reduction in reticulocyte count is seen after splenectomy. The osmotic fragility of fresh and incubated erythrocytes is most often normal, although minor populations of fragile or resistant cells may be encountered in occasional patients after incubation. The results of an autohemolysis test are generally, but not invariably[295] abnormal, with hemolysis of as many as 50% of erythrocytes after 48 hours of incubation in saline. Prior addition of glucose may reduce the hemolysis in some instances, but glucose usually has little or no effect. In fact, if the reticulocyte count exceeds 25%, incubation with glucose regularly accentuates the hemolysis. This phenomenon has been attributed to inhibition of oxidative phosphorylation by glucose (the Crabtree effect), with unfavorable consequences in PK-deficient reticulocytes because of their reliance on oxidative phosphorylation for synthesis of ATP.[296]

Biochemistry

The active form of PK is a homotetramer formed from one of four different tissue-specific subunits. The R subunit is found in red cells; the L subunit in liver; the M1 subunit in muscle, heart, and brain; and the M2 subunit in all early fetal tissues and most adult tissues, including leukocytes and platelets.[297] The R and L subunits derive from a common gene (*PKLR*) located on chromosome 1 (1q21),[298] whereas the M1 and M2 subunits are generated by a second gene (*PKM*) located on chromosome 15 (15q22).[299] In the rat, the *PKM* gene is 20 kb long and consists of 12 exons and 11 introns.[300] M1- or M2-specific mRNA is formed from a common primary transcript by alternative spicing involving the removal of either exon 9 (M2) or exon 10 (M1).[301] Because human and rat M2 cDNA is highly homologous,[299] alternative splicing probably also accounts for the differences in M1 and M2 mRNA in humans. The *PKLR* gene also consists of 12 exons.[302] Tissue-specific expression of one of two different promoters generates a transcript containing either an R or an L exon at the 5′ end.[303,304] The remaining 10 exons are identical. L-type cDNA encodes a polypeptide of 543 amino acids,[303] whereas R-type cDNA encodes a product that is longer by 31 amino acids.[305]

The three-dimensional structure of cat and rabbit muscle PK has been studied by x-ray crystallography.[306] There is extensive sequence homology among species and between M and R subunits, particularly in the vicinity of the active site,[307] thus indicating that the enzyme structure has been conserved during evolution. As shown in Figure 16-6, each muscle PK (M1) subunit consists of a short amino-terminal region and three distinct domains (A, B, and C). Domain A is cylindrical and formed by eight parallel strands of β sheet encased by an outer coaxial cylinder of eight α helices, domain B consists of a closed antiparallel β sheet, and domain C is a five-stranded β sheet connected by α helices. The active site lies in a pocket between domains A and B, the potassium and magnesium binding sites are in domain A, and allosteric modulation of PK function primarily involves interactions with domain C.

In erythroid cells, PK is a tetramer (molecular weight, 230,000[307]) whose subunits may vary in type. In erythroid precursors, M2 homotetramers are the predominant PK isoenzyme. With erythroid maturation, synthesis of M2 subunits declines and is replaced by production of R-type subunits.[308-310] The mature red cell enzyme may exist in either of two physical conformations, analogous to the R and T forms proposed by Monod and colleagues[311] for allosteric proteins. Partially purified enzyme preparations usually exhibit sigmoid kinetics in the presence of increasing concentrations of substrate (phosphoenolpyruvate). Small amounts of phospho*enol*pyruvate facilitate further binding of substrate by the enzyme in a manner analogous to that seen with heme-heme interactions. Fructose 6-diphosphate (FDP) induces a transition
FIGURE 16-6. Ribbon representation of the structure of rabbit muscle pyruvate kinase (PK). The three domains (A, B, and C), the position of potassium (K) and magnesium (Mg) ions, and the location of the active catalytic site (Py) that binds pyruvate are indicated. Six point mutations that alter a single amino acid in the primary structure of R-type (erythrocyte) PK are indicated. V295 is an asymptomatic heterozygote. Ter510, which leads to the formation of a truncated PK enzyme that has lost 63 amino acids in the C domain, was found in the mother of a child with severe hemolytic anemia. L504, found in a homozygote with severe hemolytic anemia, is distant from the active binding site but interferes with a salt bridge that holds domain C to domain A. The remaining three mutations (V159, K315, D341) were found in subjects with hemolytic anemia who had also inherited a second PK mutation at another site and were compound heterozygotes. V159 affects the adenosine diphosphate binding site; K315, the Mg²⁺ binding site; and D341, a highly conserved region of the A domain. *(Modified from Demina A, Varughese KI, Barbot J, et al. Six previously undescribed pyruvate kinase mutations causing enzyme deficiency. Blood 1998; 92:647-652.)*

from sigmoid to hyperbolic kinetics, probably by acting directly at the phospho*enol*pyruvate binding site.[312]

A number of factors may result in post-translational modification of the enzyme. Transition between an FDP-sensitive conformation with sigmoid kinetics and an insensitive form with hyperbolic kinetics has been achieved by varying pH,[313] temperature,[313,314] and conditions of storage. Aging of the enzyme in vivo appears to favor the FDP-sensitive conformation.[315] These transitions may play a significant role in modulation of PK activity in vivo. Post-translational modification of enzyme properties mediated by oxidation of exposed thiol groups on the surface of the molecule may explain some abnormalities previously ascribed to genetic or acquired alterations in

the primary structure of the enzyme.[315-320] In several instances it has been possible with the use of sulfhydryl reagents to restore to normal the altered stability and abnormal kinetics of mutant PK from individuals with hemolytic anemia.[316,321] On the other hand, it has often not been possible to implicate oxidation of enzyme thiol groups as a cause of abnormal enzyme properties.[322,323]

The enzyme is subject to numerous other regulatory influences. ATP is a competitive inhibitor ($K_i = 3.5 \times 10^{-4}$ mol/L)[324]; at physiologic ATP concentrations (approximately 1 mmol/L), erythrocyte PK activity should be significantly constrained by ATP. Both potassium[312,314] and magnesium[314,325] activate PK; rubidium (Rb^+) or ammonium (NH_4^+) substitute for potassium (K^+), whereas manganese (Mn^{2+}) or cobalt (Co^{2+}) can replace magnesium (Mg^{2+}).[318] Activation of purified PK by FDP has been demonstrated at concentrations normally found within the erythrocyte.[326] At a higher concentration (0.5 mmol/L), another glycolytic intermediate, glucose 6-phosphate, activates PK.[327] The glycolytic intermediate 2,3-DPG, of particular interest because of its high concentration in PK-deficient erythrocytes, has no influence on PK in hemolysates[328] but has variously been reported to inhibit[329] or activate[330] purified PK. Phosphorylation of PK, mediated by cyclic adenosine monophosphate, alters its kinetic properties and may regulate 2,3-DPG levels and thus oxygen transport by red cells.[330,331] It is clear that intracellular PK activity will be determined by the complex interplay of a number of regulatory factors and may bear little relationship to measures of activity determined in vitro under optimal conditions.

When erythrocyte PK (R homotetramer) is abnormal, hepatic PK (L homotetramer) may also be affected because the R and L subunits are derived from a common gene. In two anemic individuals with PK deficiency, liver PK was reduced to 59%[332] and 46%[333] of normal. Residual liver PK, measured in the latter patient, was mostly of the M2 type. No disorders of hepatic function appear to result from such partial deficiency of PK.[334] In another individual, total liver PK activity was only 22% of normal, virtually no L-type enzyme was detectable, and there were abnormalities in serum aminotransferases.[290] Paradoxically, in still another individual, liver L-type PK exhibited entirely normal activity and properties despite abnormalities in the supposedly identical isoenzyme in the red cells.[291]

The metabolic capabilities of PK-deficient erythrocytes in vitro vary considerably. Although resting HMP shunt activity may be slightly to moderately low for cell age,[335] no significant effect on either oxidized or reduced glutathione (GSH) levels has been observed,[336,337] even after incubation with acetylphenylhydrazine.[336,338,339] However, results of the ascorbate cyanide test are abnormal in patients with PK deficiency, and stimulated HMP shunt activity is modestly depressed.[337] In many instances, glycolysis, as measured by the glucose consumption or lactate production of incubated erythrocytes, is markedly subnormal.[289,296,335] Such diminished glycolysis is relative rather than absolute because the glycolytic rate of enzymopenic cells can be increased substantially by incubation in a high-P_i medium.[296,340] A reduction of residual PK activity within the erythrocyte to 10% of normal will still leave sufficient enzyme to support normal glycolysis if potential enzyme activity is fully used. Such considerations indicate that intracellular regulators of PK function must play an important role in the reduced glycolysis characteristic of enzymopenic cells. Frequently, particularly with kinetic variants of PK, glycolytic rates characteristic of mature normal erythrocytes are achieved.[341-344] However, such rates are clearly subnormal in comparison to those attained by reticulocyte-rich control blood of an equivalent mean cell age.[341] Furthermore, the glucose consumption of incubated normal hemolysate is unchanged when supplemental purified PK is added, whereas the addition of supplemental PK to hemolysate from PK-deficient erythrocytes produces a substantial rise in glucose consumption.[341]

Accumulation of glycolytic intermediates proximal to the enzyme defect has customarily,[341,344] though not invariably[341] been observed.[343] Detection of elevated 2,3-DPG or 3-phosphoglycerate levels in red cells may help confirm a clinical diagnosis of PK deficiency,[345,346] and the degree of elevation in 2,3-DPG or glucose 6-phosphate levels is directly correlated with clinical severity.[101,347] An alteration in the normal ratio of reduced nicotinamide adenine dinucleotide (NADH) to nicotinamide adenine dinucleotide (NAD), as well as complex changes in the substrates governing the rate of PK and 2,3-DPG mutase, appears to be responsible for triose phosphate accumulation when glycolysis is accelerated by P_i in normal red cells.[348] Such striking elevations in triose phosphate intermediates can be returned to normal in both control and PK-deficient red cells by the addition of exogenous pyruvate or another oxidant.[339] Concentrations of both NAD and NADH are low in PK-deficient erythrocytes,[334,349] or if the level of NAD is normal in fresh cells, it falls with undue rapidity on incubation in vitro.[340] The concentration of 2,3-DPG in PK-deficient erythrocytes may be greater than three times normal values, thereby leading to a rightward shift of the oxyhemoglobin dissociation curve.[50,51] The ability to extract a greater percentage of available oxygen from hemoglobin at any given PO_2 associated with such a right-shifted curve increases the exercise tolerance of patients with PK deficiency.[51] Such patients, though anemic, may exhibit none of the expected symptoms of fatigue and exercise intolerance.

The level of erythrocyte ATP and the formation of PRPP[350] are often abnormally low in PK deficiency, although patients with reticulocyte counts greater than 25% usually have normal ATP levels. In blood with such high reticulocyte counts, ATP is unstable on incubation with glucose, in contrast to normal reticulocyte-rich blood. When incubated without glucose, however, the PK-deficient reticulocyte conserves ATP more success-

fully than the normal cell does.[296] The reticulocyte, able to generate ATP from substrates other than glucose via oxidative phosphorylation, can circumvent its glycolytic defect. However, in a high-glucose environment, ATP levels plummet. The PK-deficient reticulocyte is thus exquisitely dependent on oxidative phosphorylation for maintenance of ATP, as was first shown by Keitt.[296] The greater oxygen consumption of PK-deficient reticulocytes than normal reticulocytes (3.75 ± 1.55 versus 0.56 ± 0.5 μL of O_2/109 reticulocytes/hr[289]) underscores the reliance of such cells on oxidative phosphorylation. Reticulocyte oxygen consumption is abolished by hypoxia in vitro at approximately venous PO_2 levels (Fig. 16-7). When exposed to prolonged periods of hypoxia in vivo, therefore, or on maturation with consequent loss of mitochondria, the PK-deficient immature erythrocyte will become reliant on its inadequate glycolytic apparatus, with loss of cell ATP being the inevitable consequence. In contrast, the reduced ATP needs of the mature erythrocyte may be marginally, but adequately served for a time by the diminished glycolytic activity of the PK-deficient cell.

ATP depletion greatly increases the cation permeability of PK-deficient erythrocytes.[289] In part, this is the consequence of failure of the ouabain-inhibitable ATPase cation pump, which transports approximately 1 to 2 mEq of K^+ per hour per liter of erythrocytes.[351] Although adequate membrane ATPase is present,[341,352] a net loss of 0.2 to 6.3 mEq of K^+ per hour per liter of cells occurs in freshly obtained PK-deficient blood.[294,341,351] After ATP depletion, net K^+ loss may exceed 20 mEq/hr/L of cells.[289] Failure of the cation pump cannot explain such large losses of K^+. The effect of ATP depletion on K^+ permeability, first described by Gardos and Straub,[353] is a feature of all metabolically depleted red cells and is not unique to PK deficiency. It is thought to be related to altered binding of membrane-associated Ca^{2+} and can be partially prevented by ethylenediaminetetraacetic acid or quinine, even though these agents have no direct influence on the rate or extent of ATP depletion.[289,354]

Initially, in the ATP-depleted cell, potassium loss exceeds sodium gain. The resultant net loss of cations is accompanied by an obligate osmotic loss of water and a reduction in cell volume. The shrunken, crenated cells produced by ATP depletion in PK-deficient reticulocytes are shown in Figure 16-8. These spiculated cells pass, with difficulty, through 8-μm Millipore filters, and cell suspensions demonstrate increased viscosity in the Wells-Brookfield viscometer.[289] The destiny of such ATP-depleted erythrocytes, then, is to become dehydrated, rigid "desicytes" or "xerocytes," whose unfavorable characteristics may well prematurely terminate their existence.[355] Membranes prepared from PK-deficient or normal ATP-depleted red cells are more dense than normal as a result of absorption of cytoplasmic components—in particular, an as yet unidentified 50,000-dalton protein—on the inner membrane surface.[356] Such changes in the cell membrane may contribute to the increased rigidity of these cells. There is evidence that membrane abnormalities not related to ATP depletion may also exist in PK-deficient red cells, but the role, if any, of such abnormalities
*Microliters O_2/hour/10^9 reticulocytes

Selective reticulocyte destruction in erythrocyte pyruvate kinase deficiency. *J Clin Invest* 1971;50:688-699, by copyright permission of the American Society for Clinical Investigation.)
FIGURE 16-8. Phase-contrast micrograph of pyruvate kinase–deficient blood (patient C.D., whose anemia was severe after a 2-hour exposure to 5 mmol/L of cyanide to deplete adenosine triphosphate). The spiculated cells are, for the most part, reticulocytes (magnification ×6600). (From Mentzer WC, Baehner RL, Schmidt-Schonbein H, et al. Selective reticulocyte destruction in erythrocyte pyruvate kinase deficiency. *J Clin Invest* 1971;50:688-699, by copyright permission of the American Society for Clinical Investigation.)

in the hemolytic process is not established.[357] Not all workers have found abnormalities in the red cell membrane protein profile on sodium dodecyl sulfate–polyacrylamide gel electrophoresis,[358] and results of several other types of membrane analyses (spectrin extractability and membrane fluidity) have been normal.[359]

As enzyme-deficient erythrocytes age, a progressive reduction in glycolysis should accompany the inevitable gradual degradation of enzyme protein. Such deteriorating glycolysis will eventually result in ATP depletion and, subsequently, hemolysis. However, centrifuge studies have not revealed dramatic differences in the PK activity of enzymopenic young and old cells,[289] with the exception of one unstable PK variant[360] in which accelerated denaturation of enzyme protein was present in vivo, as well as in vitro. Deterioration in catalytic efficiency, reported to occur in both normal[315] and variant[361] enzymes on aging in vivo, may also hasten the demise of enzymopenic cells.

The normal or nearly normal survival of radiolabeled, severely PK-deficient erythrocytes reported by several investigators[289,342,343] indicates that diminished PK activity need not significantly curtail the life span of affected erythrocytes. Biphasic erythrocyte survival curves are sometimes obtained[362,363] and suggest that two populations of cells are present, one destined for almost immediate destruction and the other having a considerably better outlook for survival. Ferrokinetic studies[289,363] indicate that destruction of newly made erythrocytes in the bone marrow, spleen, or liver may be the major source of hemolysis in this disorder. Organ monitoring has shown that as reticulocytes are released from the marrow, some are almost immediately sequestered in the spleen. The paradoxical reticulocytosis that follows splenectomy is probably the consequence of improved survival of this population of reticulocytes.

Spleens removed from anemic patients with PK deficiency contain an unduly large number of reticulocytes.[338,364] Splenic histologic analysis shows the following results that contrast with those seen in hereditary spherocytosis: (1) the pulp spaces are empty rather than packed with erythrocytes; (2) erythrophagocytosis of reticulocytes and mature red cells by reticuloendothelial histiocytes is prominent in PK deficiency but rare in spherocytosis; and (3) many more crenated, deformed cells are seen in PK deficiency.[364,365] Studies of such cells obtained from peripheral blood have demonstrated them to be poorly deformable.[366] The hypoxic, acidic environment of the spleen would be expected to produce just such crenation in reticulocytes through the sequence of events outlined earlier—inhibition of oxidative phosphorylation, ATP depletion, selective K⁺ leakage, loss of cell water, and resultant loss of cell volume. These rigid desicytes should negotiate the 3-μm fenestrations between the splenic cords and sinuses only with difficulty. Thus, they are doomed to a stay of uncertain duration in the metabolically unfavorable splenic environment, and further deterioration in cell capabilities would seem inevitable. Isotope studies show that the final coup de grace often occurs in the liver.[367,368]

Splenic destruction of reticulocytes is a variable feature of PK deficiency; in some instances, either bone marrow or liver destruction predominates. Why some reticulocytes are destroyed whereas others survive to reach maturity and thereafter have a nearly normal existence despite their enzyme defect is unclear. It is possible that chance determines which reticulocytes will be detained in unfavorable metabolic circumstances. On the other hand, there is some evidence for actual variation in PK activity among reticulocytes.[289] Those with the most PK activity would be more likely to survive.

Although cellular dehydration has been given a central mechanistic role in the destruction of PK-deficient human red cells, it appears to be unimportant in the hemolytic process in PK-deficient basenji dogs. When PK-deficient dog red cells with high sodium levels are exposed to cyanide in vitro, they rapidly lose ATP. However, the ensuing loss of K⁺ is balanced by an equivalent gain in Na⁺, so no cellular dehydration occurs. Other mechanisms must explain the hemolysis in this setting.[367] Of possible interest in this regard is the finding of apoptosis of erythroid progenitors within the spleen of PK-deficient mice, thus suggesting a role for ineffective erythropoiesis in the anemia seen in this species,[368] and perhaps in humans as well.[368a]

Genetics and Inheritance

Autosomal recessive transmission of the enzyme defect is usually observed in PK deficiency. Homozygotes and compound heterozygotes exhibit hemolytic anemia. Simple heterozygotes can be distinguished from compound heterozygotes or homozygotes by the degree of reticulocytosis, the extent of accumulation of red cell glucose 6-phosphate, and the in vitro properties of the mutant PK.[369,370] Although simple heterozygotes usually remain clinically normal despite an approximately 50% reduction in erythrocyte PK activity, some may exhibit evidence of mild hemolysis.[370,371] Population surveys in different ethnic groups based on assays of red cell PK activity have estimated the incidence of PK heterozygosity to be 0.14% to 6%.[372-376] Because activity assays may sometimes falsely identify heterozygotes as normal and vice versa, DNA analysis should provide a more accurate estimate of the prevalence of PK mutations. A survey based on DNA analysis reported the rate of occurrence of heterozygosity in white individuals for the 1456T mutation, the most common PK mutation in southern Europe, to be 3.5×10^{-3} and that for the 1529A mutation to be 2.03×10^{-3}. In African Americans, the rate of occurrence of heterozygosity was 3.90×10^{-3} for the 1456T mutation, and in Asians, it was 7.94×10^{-3} for the 1468T mutation.[275] Evidence in PK-deficient mice with chronic hemolytic anemia suggests that PK deficiency may play a protective role against malaria.[377] In vitro studies with *P. falciparum*–infected red cells from PK-deficient

homozygotes and heterozygotes indicate that a similar protective effect may be present in humans.[377a]

There is little correlation between the severity of anemia in homozygotes and the level of erythrocyte PK activity as measured by the conventional in vitro assay system unless enzyme activity is corrected for the degree of reticulocytosis present.[347] Variable clinical severity is explained, at least in part, by the existence of numerous mutant forms of the enzyme whose differing properties result in variable degrees of hemolysis. Mutants are distinguishable in vitro on the basis of maximal activity, electrophoretic mobility, substrate kinetics, stability, immunologic properties, and response to the activator FDP. In general, mutants with unfavorable kinetics are usually associated with more severe hemolysis.[347,378,379] Diminished thermal stability of the enzyme in vitro also seems important in determining clinical severity.[380] Homozygous frameshift, promoter, or deletion mutations that greatly reduce or completely abolish PK activity generally lead to such severe phenotypes as intrauterine death or life-threatening neonatal anemia, as does inheritance of a single copy of such deleterious mutations along with another severe PK gene.[381-384,384a]

International standards for the characterization of mutant PK phenotypes have facilitated the comparison of mutants studied in different laboratories.[385] In compound heterozygotes, full characterization is difficult because tetramers formed from varying proportions of the two different mutant subunits are present, each with unique properties.[378] The best-defined phenotypes are those found in true homozygotes, who are usually the offspring of consanguineous matings. The kinetic and electrophoretic abnormalities characteristic of each variant PK reflect underlying structural changes in the enzyme secondary to point mutations or deletions. A total of 180 mutations in the *PKLR* gene associated with chronic hemolytic anemia have been defined at the nucleic acid level.[380,384a,386-388] Single-nucleotide missense mutations (including 2 in the promoter region) account for 124 of the total. The rest are splice site mutations (23), stop codon mutations (9), large deletions (3), and small deletions, frameshifts, or insertions (21). Additional PK mutations are known, but because they are present only as single copies in patients with chronic anemia, their role in the pathophysiology of hemolysis has not been defined.[380,386,387] In the basenji dog, PK deficiency is attributable to a frameshift mutation (deletion of C at nucleotide 433),[389] and in PK-deficient mice, a missense mutation in ribose-phosphate pyrophosphokinase (338Gly→Asp) is responsible for the enzymopathy.[279] Most PK mutations are extremely rare and usually limited to a single family. Exceptions are the 1529G→A and the 1456C→T substitutions, common in European patients with PK deficiency,[380,390-393] and the 1151C→T substitution, common in Japanese patients.[394] The majority of the mutations are located within exon 8 or 9 (A domain), where components of the active site and the K^+ binding site are located, or in exons 10 or 11 (C domain),

a region responsible for the allosteric regulatory properties of the enzyme. Although important information about genotype-phenotype correlation has been developed,[347,380,384a,395-397] detailed analysis of the way in which each mutation disturbs the function of PK and produces the clinical phenotype observed has only recently become available after ascertainment of the crystalline structure of human R-type PK and the use of recombinant ribose-phosphate pyrophosphokinase generated in *E. coli* to study enzyme kinetics and stability.[380,398,399] For example, generation of the 1529G→A (510 Arg→Gln) mutant, the most common mutation found in northern Europe, by site-directed mutagenesis produced a recombinant enzyme with normal substrate kinetics and activation by FDP but with strikingly decreased stability.[399] These studies suggest that the hemolytic anemia seen in 1529G→A homozygotes, which can be moderate to severe, is the result of low PK activity caused by enzyme instability in vivo rather than unfavorable enzyme kinetics. The variable clinical severity seen in different 1529G→A homozygotes remains unexplained by these molecular studies and suggests a role for epigenetic or environmental factors.[380,384a] DNA analysis has indicated that several PK variants thought to be unique because of differing enzyme properties are in fact due to a single shared mutation. For example PK Maebashi, PK Fukushima, and PK Sendai are each the consequence of a substitution of A for C at nucleotide 1261.[380] DNA analysis has also made possible the prenatal diagnosis of PK-deficient fetuses.[400]

When kinetic abnormalities have been discovered in anemic patients, at least one parent has exhibited similar abnormalities. The other parent may also have kinetically aberrant PK[401] or is found to have a low-activity variant with normal kinetics.[402] Occasionally, it has not been possible to demonstrate an abnormality of erythrocyte PK in one[386] or both[360] parents of patients with PK activity in the homozygous deficient range. Staal and co-workers[360] have speculated that in some heterozygotes, a compensatory increase in synthesis of enzyme protein by the normal allele may result in enzyme activity indistinguishable from normal. The "classic" form of PK deficiency is associated with severe enzyme deficiency, persistence of the M2 isoenzyme in mature erythrocytes, and little or no R isozymes. The persistence of M2 isoenzyme may represent an attempt to compensate for the lack of R subunit–containing forms of PK.[293] An analogy to the persistence of fetal hemoglobin synthesis in β-thalassemia has been made by Miwa.[403] When M2 compensation is incomplete or absent,[383] PK activity in mature red cells is low, and hemolytic anemia ensues. When M2 isoenzyme is synthesized at a higher rate, greater than normal amounts of PK activity can accumulate in mature red cells.[310,404-407] Such patients do not have hemolytic anemia, and in fact the increased glycolytic flow through PK at the expense of the 2,3-DPG–generating pathway may lower 2,3-DPG levels, increase the affinity of hemoglobin for oxygen, and result in erythrocytosis. Similarly, mice bearing a mutant form of R-type

PK exhibit a delayed onset of hemolytic anemia after birth that coincides with delayed switching from the M2 isoenzyme to the mutant R isoenzyme.[408]

A kindred in which hemolytic anemia occurred in heterozygotes for PK mutants was studied by Etiemble and colleagues.[409] PK activity was well below (17% to 45%) the 50% activity usually encountered in the presence of one normal and one mutant PK allele. It was thought that perhaps the presence of only one mutant subunit in the PK tetramer might be sufficient to reduce its catalytic function, with greater impairment found in the presence of additional mutant subunits. Similar considerations were raised in another kindred (PK Greensboro), in which heterozygotes exhibited less than 50% of the normal red cell PK activity but no hemolytic anemia.[410] However, in neither kindred was the presence of multiple combinations of mutant and normal subunits (i.e., M4, M3N, M2N2, MN3, and N4, where M is the the mutant subunit and N is the normal subunit) actually confirmed.

To date, no evidence suggests interaction between PK deficiency and other disorders of the erythrocyte such as β-thalassemia minor,[411] band 3 deficiency,[412] or G6PD deficiency.[292] Reports of spherocytosis or paroxysmal nocturnal hematuria in heterozygotes for PK deficiency have not mentioned unusual features of either disease. Markedly increased involvement of the kidneys was noted at autopsy in a patient with Gaucher's disease who also exhibited hemolytic anemia and deficiency of erythrocyte PK. It was suggested that cerebroside production was enhanced as a result of hemolysis.[413]

Therapy

Although complete cure is not achieved by splenectomy, elimination or amelioration of transfusion requirements, a decrease in bilirubin level, and an increase in hemoglobin concentration are seen quite often. Even though splenectomy may be lifesaving in individuals with severe anemia,[338,343] the procedure may have no effect in individuals with mild anemia. When significant morbidity exists, it would seem reasonable to recommend splenectomy while bearing in mind the fact that the degree of benefit cannot be predicted with certainty.[414] The results of therapeutic intervention with agents that either circumvent the metabolic aberrations induced by the defective enzyme or directly modify enzyme activity have generally been disappointing.[321,360,415,416]

Although hemolytic crises are uncommon in patients with PK deficiency and have not been associated with drug ingestion, Glader[273] demonstrated a potential hazard with the use of large doses of salicylate in patients with severe PK deficiency. Salicylates inhibit oxidative phosphorylation and thus cause ATP depletion and cellular dehydration in severely PK-deficient reticulocytes in vitro. The salicylate doses used by Glader were high but were equivalent to serum levels achieved with chronic salicylate therapy for disorders such as rheumatoid arthritis. It is prudent to select alternative therapy for such patients when possible or to monitor them carefully for signs of increased hemolysis.

Bone marrow transplantation has permanently corrected the hemolytic anemia seen in PK-deficient basenji dogs,[417] in PK-deficient mice,[418,419] and in a single human with PK deficiency.[420] The potential feasibility of gene therapy has been demonstrated in PK-deficient mice.[421,421a]

LACTATE DEHYDROGENASE DEFICIENCY

Clinical Manifestations, Biochemistry, and Genetics

Partial or complete absence of the H subunit of lactate dehydrogenase (LDH) in erythrocytes, leukocytes, platelets, and serum is not associated with anemia or hemolysis.[422] M-subunit deficiency, though associated with exertional myoglobinuria and a characteristic skin eruption, also does not lead to hemolytic anemia.[423] In contrast to humans, mice homozygous for a low-activity mutation of the skeletal muscle subunit of LDH have less than 10% of normal enzyme activity in erythrocytes and exhibit severe lifelong hemolytic anemia.[424]

ABNORMALITIES OF ERYTHROCYTE NUCLEOTIDE METABOLISM

In individuals with CNSHA, low erythrocyte ATP levels often play a central role in the pathogenesis of hemolysis. Hemolytic anemia associated with an unusually high erythrocyte ATP level has also been described.[425] Red cell PK levels were normal in the affected pedigree, so the mechanism for ATP elevation would appear to differ from that found in other families with high red cell ATP levels, low 2,3-DPG, erythrocytosis, and a twofold or greater elevation in PK activity.[404-406] In yet another family, two infants with hemolytic anemia, high erythrocyte ATP levels, and low 2,3-DPG levels had reduced 2,3-DPG phosphatase activity.[426] The relationship of this enzyme abnormality to the unusual elevation in erythrocyte ATP level or to hemolysis is uncertain. In the three disorders of erythrocyte nucleotide metabolism to be described in the text that follows, evidence of a relationship between the abnormal enzyme and hemolytic anemia is more convincing, although even in these disorders much remains to be learned about the pathogenesis of hemolysis.

Pyrimidine 5′-Nucleotidase Deficiency

Clinical Manifestations

Deficiency of erythrocyte P-5′-N, the most common inherited abnormality of nucleotide metabolism causing

hemolytic anemia, is associated with lifelong anemia of moderate severity.[9,427-437] Splenomegaly is usually present. Developmental delay is sometimes seen, but whether it is a direct result of P-5′-N deficiency has not been determined. Pronounced basophilic stippling, which may occur in as many as 5% of all erythrocytes, is an important and useful finding and an exception to the usual lack of distinguishing morphologic abnormalities in erythroenzymopathies. Definitive diagnosis requires assay of red cell P-5′-N activity.

Biochemistry

Reticulocyte maturation requires disposition of intraerythrocytic ribosomal RNA, which is no longer required for protein synthesis. The hydrolysis of pyrimidine nucleotides (cytidine monophosphate [CMP] and uridine monophosphate [UMP]) formed by the action of ribonucleases on ribosomal RNA, an essential step in RNA degradation, is catalyzed by P-5′-N. The cytidine and uridine formed can diffuse across the cell membrane, whereas the pyrimidine nucleotide substrates of the nucleotidase reaction are incapable of diffusion and accumulate within the cell when activity of the nucleotidase is subnormal.[9]

Hirono and associates[438] found two different isoenzymes of P-5′-N in hemolysates from normal subjects and those with P-5′-N deficiency. Only one isoenzyme, CMP responsive, was deficient in all five subjects evaluated with P-5′-N deficiency, whereas the other, deoxythymidine monophosphate (dTMP) responsive, was normal. Kinetic and thermostability abnormalities were seen in the CMP-responsive isoenzyme from subjects with P-5′-N deficiency but not in the dTMP-responsive isoenzyme. Apparently, the lack of overlapping substrate sensitivities makes it impossible for the residual normal isoenzyme to substitute for its deficient partner in enzymopenic individuals.

The amount of nucleotides in P-5′-N–deficient red cells is increased by 1.3 to 5.0 times, chiefly as a result of an increase in pyrimidine derivatives (CMP, cytidine diphosphate [CDP], cytidine triphosphate [CTP], UMP, uridine diphosphate, and uridine triphosphate [UTP]).[9,429,430,439,440] The most abundant derivatives are the diphosphodiesters CDP-choline and CDP-ethanolamine.[438] Accumulation of pyrimidine derivatives is undoubtedly due in part to RNA degradation,[430] but it may also reflect de novo synthesis of these compounds from the uridine and orotate transported into the red cell.[441] Classification of P-5′-N deficiency as a high-ATP syndrome was based on early observations of unusually high ATP levels in cells, as measured with an enzymatic assay of ATP content that also reflected the presence of other nucleotide triphosphates, notably CTP and UTP. More specific assays have subsequently shown that cell adenine nucleotide levels are normal or even low rather than elevated.[9,431,440]

The extraordinary accumulation of pyrimidine nucleotides within P-5′-N–deficient red cells is easily detected by subjecting cellular extracts to MRI[442] or to ultraviolet spectroscopy. Extracts from normal cells exhibit an absorbance peak at 255 to 260 nm (caused almost entirely by the presence of adenine nucleotides). In P-5′-N deficiency, a higher absorbance peak slightly shifted in position (266 to 270 nm) is observed as a result of the presence of large amounts of pyrimidine nucleotides and provides a relatively simple means of screening patients for the disorder.[9,430] The secondary effects of P-5′-N deficiency are complex. For example, the concentration of GSH is regularly increased by a factor of 1.5 to 2.3,[429] a finding that may help confirm the diagnosis in patient suspected of having P-5′-N deficiency. Red cell PRPP synthetase activity is markedly low (15% to 35% of normal) in P-5′-N–deficient red cells.[442,443] In fact, PRPP synthetase deficiency was originally thought to be the primary defect responsible for the hemolysis. It is now regarded as a secondary phenomenon.[436] Pyrimidine nucleotides have been shown to bind and sequester magnesium, a cofactor required for subunit aggregation and maximal activation of PRPP synthetase.[445] Magnesium depletion (by the addition of pyrimidine nucleotides) also inhibits PK and pentose phosphate pathway activity in hemolysates. On the other hand, red cell magnesium levels are normal or even elevated in P-5′-N–deficient red cells, and incubation of these cells with exogenous magnesium does not reduce their susceptibility to autohemolysis or to Heinz body formation.[446] The role of magnesium deficiency (or unavailability) in the central abnormalities that limit the life span of P-5′-N–deficient red cells is not clear.

In fact, it is not known why P-5′-N–deficient red cells are destroyed prematurely. Perhaps the pyrimidine nucleotides that accumulate interfere with the normal function of key glycolytic enzymes by competing for available binding sites with the adenine nucleotides that are the normal enzyme substrate. The possible importance of pyrimidine nucleotides in hemolysis is underscored by the report of an individual with chronic hemolysis, basophilic stippling, and normal P-5′-N activity, in whom the only biochemical abnormality detected was a striking elevation in erythrocyte CDP-choline.[447] Accumulation of pyrimidine nucleotide has been shown to lower red cell pH in P-5′-N–deficient red cells as a result of shifts in Donnan equilibrium caused by the increase in fixed intracellular anion.[434,439] This drop of 0.1 to 0.2 pH unit is sufficient to increase the red cell's oxygen affinity above the normal range[440] and may also explain the slightly subnormal glycolytic rate of P-5′-N–deficient red cells.[448] Tomoda and colleagues[434] demonstrated a moderate impairment in stimulated pentose phosphate pathway activity in P-5′-N–deficient erythrocytes, which they attributed to inhibition of G6PD by pyrimidine nucleotides. This impairment in shunt activity is noted in both light and dense red cells separated by centrifugation and is accompanied by a parallel decrease in G6PD activity.[449] It is hard to visualize how pentose phosphate pathway failure could result in the unusually high levels of GSH characteristic of P-5′-N

deficiency because the opposite effect, a deficiency in GSH, would be predicted.[434]

Study of individuals with lead poisoning has confirmed the central role of P-5′-N deficiency in the origin of hemolytic anemia. P-5′-N is markedly inhibited in vitro by low concentrations of lead, and the red cells of patients with significant lead poisoning have depressed levels of P-5′-N activity.[450] The basophilic stippling that is present in some patients with lead poisoning has been attributed to nucleotidase deficiency.[451] Although accumulation of pyrimidine nucleotides within erythrocytes is not found in all patients with lead poisoning in which P-5′-N activity is reduced, it is regularly found in patients exhibiting acute lead-induced hemolytic anemia.[450,451] Perhaps because of the shorter duration or less severe character of the enzyme deficiency, the red cells of lead-poisoned individuals do not exhibit ribose phosphate pyrophosphokinase (RPPK) deficiency.[451] GSH levels are normal[451] or elevated.[430] Despite the less than perfect homology between congenital and acquired P-5′-N deficiency, study of the latter may be expected to provide important insight into the mechanisms of hemolysis in this disorder.

Genetics and Inheritance

The gene for P-5′-N is located on chromosome 7 and consists of 11 exons. Alternative splicing leads to the production of three proteins: one is 286 amino acids long (P-5′-N I), the second is 297 amino acids long, and the third, found only in reticulocytes, is 285 amino acids long.[452,453] P-5′-N I is the major isoenzyme expressed in erythrocytes. Twenty different mutations in P-5′-N I have been identified in patients with P-5′-N deficiency and chronic hemolytic anemia. Six are missense mutations, 2 are in-frame deletions that lead to loss of a single amino acid, and the remaining 12 are nonsense mutations, splice site alterations, insertions, or larger deletions.[437]

Sixty-six patients from 56 unrelated families with P-5′-N deficiency and hemolytic anemia have been described.[436,437,454] The disorder has been found in many ethnic groups.[437] Inheritance is autosomal recessive.[430,437] Nearly all P-5′-N–deficient patients who exhibit hemolytic anemia are homozygous for a single P-5′-N mutation; the remainder are compound heterozygotes for two different mutations.[437] Heterozygotes have no clinical manifestations but exhibit a reduction of about 50% in red cell P-5′-N activity.[9,430,436,437] The wide range of enzyme activity encountered in normal individuals makes detection of heterozygotes difficult in some families.[455] Variation in the severity of disease is, in part, due to heterogeneity in the molecular nature of the defective enzyme.[428,438,456] This has been shown most clearly by study of the biochemical properties of purified recombinant mutant P-5′-N.[457] These studies also revealed that despite profound abnormalities in P-5′-N kinetics or stability in vitro, erythrocytes containing certain P-5′-N mutations exhibited only a moderated reduction in P-5′-N activity, thus suggesting that other pathways or other

P-5′-N isoenzymes could compensate for P-5′-N I deficiency. P-5′-N has been found in the spleen,[456] kidney, and brain.[458,459] The presence of the enzyme in brain may be relevant to the mental retardation noted in several P-5′-N–deficient individuals with hemolytic anemia.[431]

Therapy

The congenital form of P-5′-N deficiency must be distinguished from the acquired form associated with lead poisoning because specific therapy is available for the latter. The benefit of splenectomy in congenital P-5′-N deficiency is limited.[436] Investigational therapeutic use of allopurinol in one affected individual had no effect on hemolysis and actually increased erythrocyte pyrimidine nucleotide levels.[441]

Adenylate Kinase Deficiency

Clinical Manifestations, Biochemistry, and Genetics

Controversy exists regarding the exact role of adenylate kinase (AK) deficiency in hemolytic anemia. Beutler and colleagues[460] studied two African American siblings whose red cells lacked measurable AK activity. One had hemolytic anemia, but the other did not. It was suggested that in this family the hemolysis was unrelated to AK deficiency or that another coexistent defect was required for hemolysis to occur. The latter seemed to be the case in an Arab family in which two siblings had severe red cell AK deficiency but only the sibling who had also inherited severe G6PD deficiency exhibited hemolysis.[461] However, further investigation of this large pedigree disclosed six more individuals with severe AK deficiency and mental retardation.[462] All had chronic nonspherocytic hemolytic anemia. Three had also inherited G6PD deficiency and were severely anemic, with red cell transfusions required 6 to 10 times annually. The other three, who did not have G6PD deficiency, were moderately anemic and only occasionally required transfusions. Family members who had carrier levels of red cell AK activity (50% of normal), either with or without G6PD deficiency, and individuals with G6PD deficiency alone did not have chronic hemolytic anemia. These results suggest that either AK deficiency has a direct role in hemolysis or the enzyme defect is a marker for another genetically linked but as yet unidentified defect that is the primary cause of the anemia.[463] Lachant and colleagues[463] found no AK activity in the red cells of a Syrian girl who had chronic hemolytic anemia. Only modest impairment in the formation of ADP from adenosine monophosphate was observed in intact cells, thus suggesting that alternative pathways might be available to substitute for the missing AK. Alternatively, it was proposed that AK itself might be present in intact cells but somehow became inactivated during preparation of a hemolysate for assay of enzyme activity. Eight additional

patients with AK deficiency associated with hemolytic anemia have been reported in France,[464] Japan,[465,466] Spain,[467] and Italy.[468-470] Molecular study of these patients has defined three missense, two in-frame single-codon, and two nonsense mutations. Site directed mutagenesis of wild type AK1 cDNA followed by expression of mutant enzyme proteins in an *E. coli* system and purification of enzyme protein allowed characterization of five of these mutations. Marked abnormalities in enzyme stability and catalytic properties were found.[470a] Modeling studies using the structure of porcine AK, which is highly homologous to human AK, have begun to define the structural basis for mutation-associated defects in enzyme function.[467] The Japanese subject inherited a missense mutation (Arg128→Trp) in the coding region of the *AK1* gene from her mother and a normal *AK1* allele from her father. Although both mother and child were heterozygous for AK deficiency, only the child exhibited hemolytic anemia, and the mother was hematologically normal.[466] An Italian girl homozygous for a missense mutation at codon 164 had virtually undetectable erythrocyte AK activity and moderate hemolytic anemia.[468,469] Another Italian girl, who also had moderate hemolytic anemia, was homozygous for a deletion that created a frameshift with a premature stop codon. Even though no erythrocyte AK mRNA was detectable, thus implying rapid degradation of the truncated mRNA, a low level of AK enzyme activity was present in hemolysates from the propositus. Evidence of activity of other AK isozymes, not usually present in erythrocytes, was obtained, and this residual AK activity was thought to have mitigated the clinical severity of the enzymopathy.[470] Two siblings in a third Italian family who were homozygous for a nonsense mutation at codon 107 (CGA→TGA) had no detectable erythrocyte AK activity and mild to moderate chronic hemolytic anemia.[469] Both siblings also exhibited psychomotor retardation. Similar findings in other families[462,464] suggest that AK deficiency may be shared by the red cell and the brain.

Therapy

Splenectomy led to prompt disappearance of anemia and hemolysis in five of six Arab patients.[462]

Adenosine Deaminase Overproduction

Clinical Manifestations, Biochemistry, and Genetics

Fourteen individuals in three families have been found to have hereditary hemolytic anemia, sharply diminished amounts of intraerythrocytic adenosine nucleotides (to less than 50% of normal), and a remarkable 45- to 110-fold increase in red cell ADA activity.[471-474] In contrast to virtually all other erythroenzymopathies, ADA excess is transmitted as an autosomal dominant trait. Hemolysis is apparently the consequence of diminished red cell ATP content, which is caused by the diversion of nearly all adenosine metabolism through the unusually active ADA reaction at the expense of the competing adenosine kinase reaction. The former results in irreversible loss of adenosine nucleotides, whereas the latter conserves such nucleotides and preserves cell ATP stores. The finding of abnormalities of lesser magnitude in other enzymes of nucleotide metabolism in affected individuals suggests that the excess ADA activity may be caused by an as yet undefined primary defect. The physical properties of the mutant ADA are normal,[473,475] which indicates that the great excess of ADA activity is due to overproduction rather than an increase in catalytic efficiency. In one subject, an increase in red cell ADA protein equivalent to the striking increase in ADA activity was demonstrated by immunoblotting.[476] Synthesis of ADA by erythroid progenitors grown from bone marrow cells was 11-fold greater in an affected individual.[477] RNase mapping techniques and Northern blotting have revealed at least a 100-fold increase over normal in the ADA mRNA content of affected reticulocytes. Sequencing of ADA cDNA showed no abnormalities in the coding region and 5'- and 3'-untranslated regions of the parent mRNA. Examination of genomic DNA by Southern blotting did not disclose evidence of gene amplification, deletion, or gross rearrangements. Thus, although the basis for ADA excess appears to be an overabundance of apparently normal mRNA, the mechanism underlying this abnormality remains obscure.[478]

Linkage analysis with a polymorphic TAAA repeat located 1.1 kb upstream from the ADA gene strongly indicated that the mutation was located in *cis* rather than in *trans*.[479] DNA constructs containing 10.6 kb of 5'-flanking sequences and 12.3 kb of the first intron of the normal or mutant ADA gene were linked to a reporter gene (chloramphenicol acyltransferase) and used to study expression in transient transfection assays and in transgenic mice. No difference in expression between wild-type and mutant alleles was found. Therefore, the mutation is thought to reside at a more distant 5' site, within a different intron, or 3' to the coding region.[480]

Much lower increases in ADA activity (approximately fourfold) are seen in congenital hypoplastic anemia,[481,482] arthrogryposis multiplex congenita,[483] acquired immunodeficiency syndrome,[484] and cartilage-hair hypoplasia.[485] The origin and implications of these increases are obscure, but they are not associated with hemolysis.

ACQUIRED DISORDERS OF ERYTHROCYTE GLYCOLYSIS

Alterations in the external chemical milieu may profoundly influence erythrocyte metabolism. The rate of glycolysis, for example, is governed by the availability of P_i. High concentrations of P_i augment and low concentrations impede the glycolytic synthesis of ATP and 2,3-DPG. Erythrocytes from uremic patients with hyperphosphatemia contain an average of 70% more

ATP than normal erythrocytes do, and a lesser, but significant increase in 2,3-DPG concentration is also found in the hyperphosphatemic cell.[486] Conversely, hypophosphatemia induced by hyperalimentation with low-phosphate nutrients[487] or by anion resin therapy for hyperphosphatemia[488] is associated with a reduction in erythrocyte organic phosphates. The organic phosphate depletion resulting from hypophosphatemia may be sufficient to displace the oxyhemoglobin dissociation curve to the left, thereby unfavorably influencing tissue oxygenation. Profound hypophosphatemia may produce a spherocytic hemolytic anemia secondary to erythrocyte ATP deficiency.[488-490] Some investigators have found that experimental magnesium deficiency in the rat resembles hypophosphatemia in that erythrocyte glycolysis is inhibited, ATP and 2,3-DPG levels are subnormal, and red cell rigidity is increased. Spherocytes are evident on the blood smear, and red cell survival is reduced.[491] Magnesium is essential for the normal function of a variety of glycolytic and nonglycolytic enzymes. However, using a different diet to induce magnesium deficiency, Piomelli and co-workers[492] showed that although hemolytic anemia accompanies magnesium depletion in rats, erythrocyte glycolysis and the activity of red cell glycolytic enzymes remain normal. Magnesium deficiency also influences other red cell components, notably the membrane,[493] and the relative contribution of such abnormalities to shortened red cell life span remains undefined.

Iron deficiency not only decreases the production of red cells but also accelerates their destruction.[494] Studies of the metabolic properties of iron-deficient red cells have revealed several abnormalities that might reduce cell viability. Although erythrocyte glycolysis in vitro is normal for cell age,[495] cell ATP is unstable on incubation. The ATP concentration in freshly obtained red cells may be either normal[496] or low.[497] The spontaneous autohemolysis of iron-deficient red cells incubated at 37° C is increased.[498] The increased rigidity characteristic of an ATP-depleted cell is present in iron-deficient cells as well.[498] These findings suggest that a defect in energy metabolism may contribute to the shortened survival of iron-deficient red cells.

Alterations in erythrocyte enzyme activity are often found during the course of either acute or chronic leukemia,[499] nonmalignant pancytopenia,[499,500] congenital dyserythropoietic anemia,[501] acquired dyserythropoietic anemia,[499,502] myeloid metaplasia,[499] and polycythemia vera.[499] One, several, or many enzymes may be involved, and activity may be either increased or decreased. The unusual pattern of enzyme activity may, on occasion, be useful in diagnosis, for example, to distinguish congenital hypoplastic anemia from transient erythroblastopenia of childhood.[503]

Several quite different processes appear to be responsible for the development of acquired enzymopathies.[504] Reversion to fetal hematopoiesis may alter enzyme function.[505] Post-translational changes in normal enzyme protein have been demonstrated.[506] Synthesis of enzyme protein by developing erythroid cells may be impaired, perhaps as a result of alterations in chromosome number or disorderly and dyssynchronous nuclear maturation. Although some components of the abnormal pattern of enzymes (such as low PFK or high enolase activity) may suggest a reversion to fetal erythropoiesis, others do not. The possibility that these enzyme abnormalities may be familial and antedate the onset of an acquired blood disorder has not been fully explored.

17 | Glucose-6-Phosphate Dehydrogenase Deficiency

Lucio Luzzatto and Vincenzo Poggi

Most hemolytic anemias can be categorized, at least at first approximation, as being either inherited or acquired, due to either intracorpuscular or extracorpuscular causes. Hemolytic anemia associated with deficiency of glucose-6-phosphate dehydrogenase (G6PD) glaringly defies this categorization. Indeed, the majority of persons with inherited G6PD deficiency have no anemia and almost no hemolysis. Both develop only as a result of challenge by exogenous agents. Because the metabolic role of G6PD in red blood cells is primarily related to its reductive potential, the threat to G6PD-deficient red cells is oxidative damage. Therefore, to understand hemolytic anemia associated with G6PD deficiency, we first need to define the physiologic role of G6PD[1-3] and pinpoint why the red cells are deficient in G6PD.[4-6]

G6PD IN RED CELL METABOLISM

In metabolic maps, G6PD is commonly referred to as the first enzyme of the hexose monophosphate shunt, or the pentose phosphate pathway (Fig. 17-1). Although these time-honored phrases persist in textbooks, it is now clear that the main role of G6PD is not glucose utilization (G6PD accounts for less than 10% of that); rather, it is production of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH). NADPH has a crucial role in preventing oxidative damage to proteins and to other molecules in all cells (Fig. 17-2).[7,8] This role is particularly crucial in red cells because being oxygen carriers par excellence, they have a literally built-in danger of damage by oxygen radicals generated continuously in the course of methemoglobin formation.[9] The highly reactive oxygen radicals either decay spontaneously or are converted by superoxide dismutase to hydrogen peroxide (H_2O_2), which is still highly toxic. Detoxification of H_2O_2 to H_2O is effected by catalase[10] and by glutathione peroxidase[11] (GSHPX). NADPH is crucial for the function of both these enzymes: it is a structural component of catalase,[12] and it is required as a substrate by glutathione reductase, which regenerates GSH when it has been oxidized to GSSG by GSHPX (see Fig. 17-2). G6PD-deficient red cells are highly vulnerable to oxidative damage (see later), even though G6PD deficiency is never complete in humans. When complete G6PD defi-

ciency was produced in mouse embryonic stem cells (ESCs) by targeted inactivation of the G6PD gene,[13] the G6PD-null cells thus obtained were viable, but they formed colonies only in a low-oxygen environment; even so, they had an impaired capacity to form erythroid colonies.[14] When G6PD-null ESCs were injected into mouse blastocysts, chimeric embryos were obtained, and germline transmission was achieved; however, only female heterozygous mice were obtained because hemizygous male embryos died.[15] Thus, a G6PD-null mutation is an embryonically lethal condition.

Structure and Biochemistry of G6PD

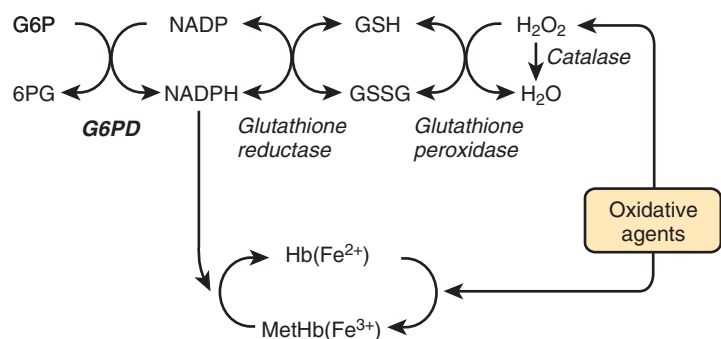
G6PD is a ubiquitous enzyme that must be quite ancient in evolution because it has been found in all organisms, from prokaryotes to yeasts, to protozoa, to plants and animals.[2,16,17] In mammals, G6PD is a good example of
FIGURE 17-1. The role of G6PD in red blood cell metabolism. As a somewhat crude oversimplification, glucose can be visualized, after phosphorylation to glucose 6-phosphate (G6P), as being at the bifurcation between two major pathways: glycolysis, which produces adenosine triphosphate (ATP), and the pentose phosphate pathway, which generates reducing power (reduced nicotinamide adenine dinucleotide phosphate [NADPH]). Under "normal" conditions, probably less than 1% of G6P enters the pentose phosphate pathway; under maximal oxidative stress, the amount may reach 10%.


FIGURE 17-2. G6PD and the glutathione (GSH) cycle. The front-line defense against oxidative damage by hydrogen peroxide (H_2O_2) is GSH by means of GSH peroxidase (GSHPX). GSHPX uses up GSH, and its regeneration can be effected in the red blood cell only through GSH reductase (GSSGR) by NADPH, which is ultimately provided by G6PD. (Redrawn from Luzzatto L, Mehta A, Vulliamy T. Glucose-6-phosphate dehydrogenase deficiency. In Scriver C, Beaudet A, Sly W, Valle D [eds]. The Metabolic & Molecular Bases of Inherited Disease, 8th ed. New York, McGraw-Hill, 2001, pp 4517-4553.)

a housekeeping enzyme produced by a housekeeping gene; indeed, the gene is expressed in all cells of the body. G6PD is a typical cytoplasmic enzyme, although some G6PD activity is associated with peroxisomes in liver and kidney cells.[18] This is consistent with the view that these organelles have evolved as part of the need of early eukaryotes to defend against oxygen, which is germane to the role of G6PD today.

The enzymatically active form of G6PD is either a dimer or a tetramer (Fig. 17-3) of a single polypeptide subunit of about 59 kd.[19] The complete primary structure of the human enzyme has been deduced from the sequence of a full-length complementary DNA clone.[20] The amino acid sequence of rat liver G6PD shows 94% homology to the human sequence and provides evidence that the N-terminal amino acid is *N*-acetylalanine, which must result from post-translational cleavage of the N-terminal methionine. The same is probably true of the human enzyme.[21]

Extensive data are available on the kinetics of G6PD. Its coenzyme specificity is exquisite; human G6PD has practically no activity with nicotinamide adenine dinucleotide (NAD). Its substrate specificity is also very high because activity on other hexose phosphates (e.g., mannose 6-phosphate or galactose 6-phosphate) is negligible. The affinity for nicotinamide adenine dinucleotide phosphate (NADP) is about 1 order of magnitude

higher than the affinity for glucose 6-phosphate (G6P).[2,16]

The tertiary structure of the molecule has been determined (see Fig. 17-3).[23] The G6P binding site is near K205, and the critical role of this amino acid in electron transfer[27] has been confirmed by showing that its replacement with threonine nearly abolishes catalytic activity.[28] The NADP binding site is located near a fan of β-sheet structures, with a critical G-X-X-G-X-X peptide motif corresponding to amino acids 38 to 43 encoded in exon 3.

Although many natural and non-natural substances can affect the activity of G6PD, it is not certain which ones may be important physiologically. NADPH, one product of the G6PD reaction, is a potent quasi-competitive inhibitor,[29] and since most of the coenzyme in cells is in the reduced form,[30] it can be assumed that G6PD is normally under strong inhibition. Because the K_m values for both G6P and NADP are higher than their normal respective intracellular concentrations, it is likely that these two substrates themselves are the main regulators of intracellular G6PD activity, together with NADPH. Any oxidative event affecting the cell will alter the NADPH/NADP ratio in favor of NADP. The simultaneous increase in NADP and decrease in NADPH act additively to increase G6PD activity by increasing the substrate drive on the reaction rate and decreasing

FIGURE 17-3. Three-dimensional structure of the human G6PD tetramer. The structure of the dimer was modeled first,[22] and then the tetramer structure was solved[23,24] and the details of substrate binding elucidated.[25,26] A to D are the four identical monomers. The tetramer is a dimer of a dimer, and both the dimer and the tetramer are enzymatically active, whereas the monomer is not. The monomer consists of two domains—a smaller coenzyme domain encompassing residues 1 to 198 and a larger β + α domain consisting of residues 199 to 514. The *gray background* outlines, within each dimer, the critical area of the monomer-monomer interface, in which 57 amino acid residues are involved. Only some of the many mutations known are indicated; most of those in the dimer interface cause severe G6PD deficiency with congenital nonspherocytic hemolytic anemia (CNSHA). AHA, acute hemolytic anemia (see Table 17-1). *(Redrawn from Mason PJ, Bautista JM, Gilsanz F. G6PD deficiency: the genotype-phenotype association. Blood Rev. 2007;21:267-283.)*
product inhibition.[8] Under most conditions this may be the most important short-term regulatory signal, although it is, of course, possible that other regulatory effects play a role as well.

Notes on Terminology

G6PD is the accepted abbreviation for the enzyme glucose-6-phosphate dehydrogenase (E.C. 1.1.1.49); the G6PD gene is designated *Gd*.[4,16] In this chapter the terms *G6PD normal* and *G6PD deficient* are used to designate the phenotypes of persons; G6PD(+) and G6PD(−) are used to designate the phenotypes of individual cells. Because *Gd* is X-linked (see later), males can be only normal hemizygotes (*Gd*⁺) or deficient hemizygotes (*Gd*⁻); females can be normal homozygotes (*Gd*⁺/*Gd*⁺), deficient homozygotes (*Gd*⁻/*Gd*⁻), or heterozygotes (*Gd*⁺/*Gd*⁻). The phenotype of the last group is often referred to as "intermediate" because their overall red cell G6PD level usually lies in between the normal and the deficient range; however, exceptions do occur (see later). Consequently, G6PD deficiency should not be regarded as a recessive but rather as a codominant trait. According to a classification introduced in 1966 (Table 17-1), G6PD-deficient variants that result in congenital nonspherocytic hemolytic anemia (CNSHA) are designated class I; G6PD-deficient variants that do not result in CNSHA are designated class II or class III, depending on the severity of the reduction in enzyme activity in red cells. The separation between class II and class III is blurred and probably no longer useful. Class IV variants are those with normal activity. Class V was reserved for variants with increased activity, but after an initial report (G6PD Hektoen[31]), none has been found. In practice, because the majority of G6PD-deficient persons are mostly asymptomatic, their G6PD deficiency is referred to as mild, simple, or common (corresponding to class II or III); the minority of persons who have CNSHA are referred to as having rare, sporadic, or severe G6PD deficiency (corresponding to class I).

When a diagnostic test for G6PD is carried out, the phrase "positive result" is sometimes used to indicate that the test has shown G6PD deficiency; this has caused confusion and should be avoided by saying that the test has shown either a *normal* result or a *deficient* result.

Genetics of G6PD

Gd, the G6PD gene, is located near the telomeric region of the long arm of the X chromosome[32-34] (band Xq28); historically, *Gd* has been a valuable X-linked genetic marker and a precious tool for studying the X-chromosome inactivation phenomenon[35,36] and clonal populations of somatic cells.[37-39] The *Gd* region was also one of the first regions of the human genome to be fully sequenced.[40]

X-linkage of *Gd* has three major consequences: (1) *Gd* mutations display the typical pattern of mendelian X-linked inheritance[41]; (2) severe G6PD deficiency is much more common in males than in females; and (3) as a result of X-chromosome inactivation, females heterozygous for two different *Gd* alleles exhibit somatic cell mosaicism.[35,42] This means that if one of the alleles entails enzyme deficiency, about half the cells will be G6PD(+) and the other half will be G6PD(−), although there is a large range of variation around that average[43,44] for various reasons, not all of them fully known. At first approximation it can be assumed that X-inactivation takes place at random, and therefore a binomial distribution would be expected; the width of this distribution depends on the number of cells in the embryo or in individual embryonic tissue at the time of X-inactivation. If this number is 32 to 64, a fraction of about 2% of women with an "extreme phenotype" is predicted, that is, with less than 5% of one of the two cell types; this is in good agreement with observation in an unselected sample of *Gd*⁺/*Gd*⁻ heterozygotes,[44] although some studies have suggested an even larger proportion.[45]

TABLE 17-1   Heterogeneity and Clinical Expression of Glucose-6-Phosphate Dehydrogenase Deficiency

Class*	Clinical Manifestations†	G6PD Activity (% of Normal)	Number of Known Mutant Alleles‡	Examples	Comments
IV	None	>85	2	A, B	G6PD B is the normal "wild type"
II + III	Asymptomatic in the steady state, but risk for NNJ, AHA, favism	<30	75	Med, A⁻, Orissa, Mahidol, Canton, Vanua Lava, Seattle	Most of these variants are known to be polymorphic
I	NNJ (severe), CNSHA, acute exacerbations	<10 in most cases	61	Sunderland, Nara, Guadalajara	Never polymorphic; but same mutation can recur

*The separation between class II and class III is blurred and, in the authors' opinion, no longer useful.
†In brief, variants in class II and III can be regarded as having a *mild* phenotype confined to *acute* episodes; variants in class I have a *severe* phenotype with *chronic* illness.
‡See Fig. 17-4B. We have counted only variants for which the mutation is known and the clinical expression clearly reported.
AHA, acute hemolytic anemia; CHSHA, congenital nonspherocytic hemolytic anemia; NNJ, neonatal jaundice.

Thus, in many cases unbalanced phenotypes may arise simply by chance, according to the laws of statistics. However, in certain cases there is evidence of selection at the somatic cell level after X-chromosome inactivation. This was first well established in women who are heterozygous for hypoxanthine phosphoribosyltransferase (HPRT) deficiency,[46] and it has also been observed in several women heterozygous for severely deficient G6PD variants.[47,48] In these cases one has to infer that the G6PD(−) state is a selective disadvantage for hematopoietic stem cells; interestingly, this disadvantage is cell lineage specific because it does not affect, for instance, fibroblasts.[47] Finally, because selection might take place at other X-linked loci,[49] heterozygotes exhibiting extreme phenotypes by analysis of G6PD may arise from selection acting on an allele at another locus (a "hitchhiking effect"), as has been suggested in a family with G6PD Ilesha.[50-52]

At the genomic level, the *Gd* gene (Fig. 17-4A) consists of 13 exons, the first of which is noncoding.[53] The total length of the gene is about 18.5 kilobases (kb), much of which (about 12 kb) consists of intron 2. The significance of this large intron is unknown; it may be important for efficient transcription or for processing because it is still the largest intron, even in the compressed version of the G6PD gene found in the puffer fish *Fugu rubripes*.[54] The promoter region is highly enriched in guanine and cytosine residues (i.e., GC rich), as found characteristically in other housekeeping genes.[55] Deletion analysis has revealed that the "essential" portion of the promoter is only about 150 bp long.[56] Within this region, two Sp1 binding sites have been identified, either of which is essential for promoter activity.[57] This and other regions are highly conserved between human and mouse,[58] thus supporting the notion that they are important for gene regulation.

Features of G6PD in Red Cells

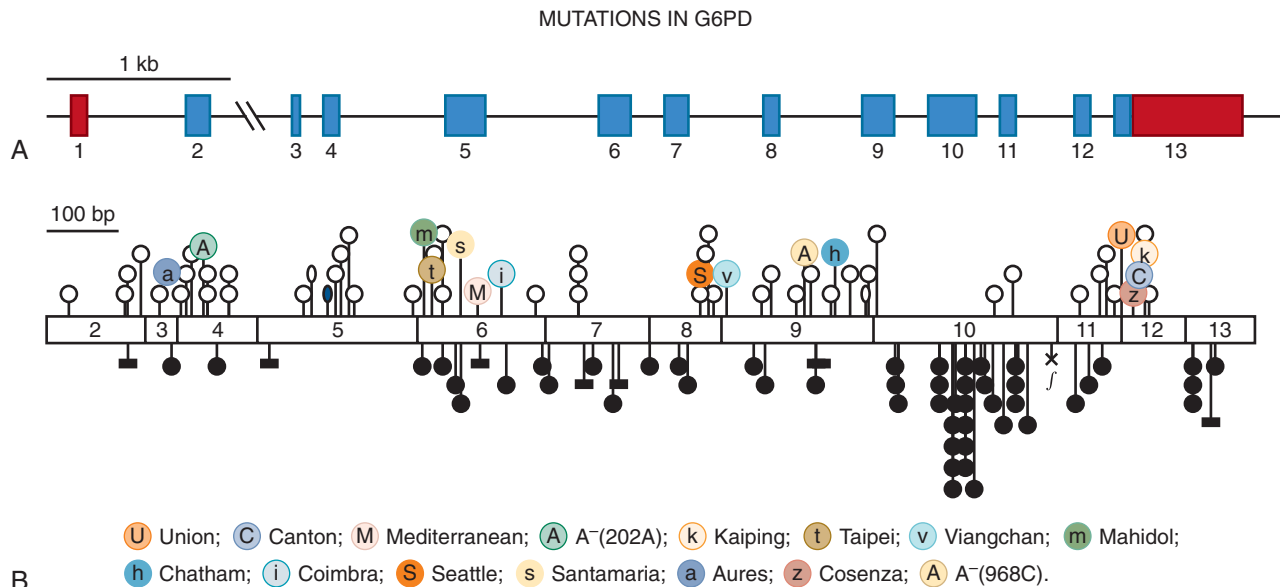
There is only one structural gene for G6PD, although a related autosomal hexose dehydrogenase also exists.[59,60] Biochemical evidence is in keeping with the notion that the G6PD protein in red cells is the same as that in other somatic cells; thus, when red cells are severely deficient in G6PD, this deficiency is also found to a greater or lesser degree in other somatic cells.[16] However, a significant difference in the metabolism of G6PD arises from the characteristic inability of mature red cells to synthesize protein. As a result, whereas in most somatic cells G6PD is subject to turnover, in red cells any G6PD molecule undergoing denaturation or proteolytic breakdown cannot be replaced (this is true, of course, not only for G6PD but also for most other red cell enzymes[61]). In normal red cells, the decay of G6PD approximates an exponential (see Fig. 17-6) with a half-life of about 60 days,[62] although it has been claimed that it may more closely approximate a two-slope curve with very fast breakdown when reticulocytes mature to erythrocytes and much slower breakdown subsequently.[63] The age dependence of red cell G6PD activity is so characteristic that it can almost be regarded as a marker of red cell age. In normal blood, reticulocytes have about five times more activity than the 10% oldest red cells.[64]


FIGURE 17-4. The human G6PD genomic gene (**A**) showing exon-intron organization and a map of many of the known mutations (**B**). All variants shown, except G6PD A, are associated with enzyme deficiency. Below the diagram are mutations associated with a severe phenotype (class I), all of which are sporadic and rare. Above the diagram mutations are associated with a mild phenotype (class II or III), many of which are polymorphic, and some of those that have been more extensively investigated are shown by *initialed lollipop symbols*. A⁻ is heterogeneous because it can result from a combination of the N126D replacement with any of three additional mutations. However, in the large majority of instances (probably more than 90%), the second mutation of G6PD A⁻ is V68M.

Molecular Basis of G6PD Deficiency

In principle, genetically determined deficiency of G6PD, like that of any other protein, might be due either to quantitative changes, such as mutations that affect the amount of the enzyme but not its structure, or to qualitative changes, such as mutations that affect the structure of the enzyme and hence its stability or catalytic efficiency. Extensive investigations of G6PD from G6PD-deficient cells, mostly carried out before the sequence of G6PD was known, revealed that (1) enzyme activity, even when severely reduced (sometimes to less than 1% of normal), is never completely absent and (2) enzymic properties (K_m, K_i, activity on substrate analogues, thermostability, etc.) are often different from those of the normal enzyme[65] (i.e., G6PD deficiency is associated with qualitative abnormalities). These data are consistent with point mutations in the coding region. In fact, from a database[66] of nearly 150 mutant alleles now known a reasonably clear pattern has emerged.

1. In nearly all the G6PD variants there is a *single amino acid replacement* caused by a single missense point mutation.
2. In a few cases (namely, G6PD Santamaria, G6PD Mount Sinai, G6PD Akrokorinthos, and the three types of G6PD A⁻), *two amino acid replacements are found*; in all these cases one of the replacements is G6PD A (N126D). Because this nondeficient G6PD variant is polymorphic in Africa, the most likely explanation is that a second point mutation has taken place in a Gd^A gene. In another case, the two mutations G6PD Cassano (Q449H) and G6PD Union (R454C) are found in tandem in G6PD Hermoupolis; because both of the former are polymorphic, the latter night have arisen through intragenic recombination.[67]
3. Three small *in-frame deletions* have been discovered: one removes a single amino acid (G6PD Sunderland),[68] one removes two adjacent amino acids (G6PD Stonybrook),[69] and one removes eight adjacent amino acids (G6PD Nara).[70]
4. Only one mutation affecting *splicing*[71] has been discovered thus far.
5. The majority of the mutations (see Fig. 17-4B) in the database[66] are *sporadic*, and most of them have been detected because they result in G6PD deficiency and CNSHA by causing sufficient loss of activity in red cells to become limiting for their in vivo survival. Sporadic variants associated with CNSHA are not likely to spread by genetic drift. However, in several instances the same variant has been encountered recurrently (for instance, we have found G6PD Tokyo in Scotland,[72] G6PD Guadalajara has turned up in Japan[73] and in Belfast,[72,74] and G6PD Nara has been observed at least three times).[75] That the same mutation may be found recurrently in people who are almost certainly not ancestrally related is not trivial; these observations corroborate the notion that there must be specific subtle constraints whereby a particular G6PD variant has a distinctly severe clinical expression but remains compatible with life.

6. *Polymorphic mutations* (Fig. 17-5). The majority of known mutations in this category again are associated with G6PD deficiency, and there is overwhelming evidence that they have become polymorphic as a result of malaria selection (see later). For these mutations we can visualize more stringent constraints; indeed, though still causing deficiency in red cells, they must not affect them so severely that the advantage with respect to malaria is outweighed. Thus, it is not surprising that nearly all the polymorphic variants fall into classes II or III and none of them cause CNSHA (class I; see Table 17-1).

7. The *pattern of G6PD mutations*, whereby null mutations (such as nonsense mutations, frameshifts, or large deletions) are conspicuously absent, is in striking contrast to that seen in other inherited disorders, such as the thalassemias, hemophilia, and muscular dystrophy. An important functional difference between these conditions and G6PD deficiency is that the former result from mutations in tissue-specific genes whereas *Gd* is a housekeeping gene. When a tissue-specific gene is totally inactivated by a mutation, it may cause severe disease but will not necessarily have interfered with embryonic development. By contrast, we know that G6PD-null mutations are lethal to the mouse embryo[15]; they probably occur in humans, but we never see them because they must be lethal in the human embryo as well. Some clue regarding what mutation can cause G6PD deficiency has come from alignment of the amino acid sequence of G6PD from 42 different organisms; there was a striking correlation between the amino acid replacements that cause G6PD deficiency in humans and the sequence conservation of G6PD.[17] Interestingly two thirds of such replacements are in highly and moderately conserved (50% to 99%) amino acids; relatively few are in fully conserved amino acids (where they might be lethal) or in poorly conserved amino acids, where presumably they simply would not cause G6PD deficiency.

8. The *biochemical mechanism of G6PD deficiency* is strongly contingent on the fact that in normal red cells, G6PD decreases exponentially as red cells age, with a half-life of about 50 days (see earlier). Because G6PD is an oligomeric globular protein, it is not surprising that many point mutations producing replacement of individual amino acids can further decrease the stability of G6PD; in fact, for most mutants, enzyme instability is the main mechanism of enzyme deficiency[6,66,76] (Fig. 17-6). The instability is most extreme when the amino acid involved is at the interface between the two subunits of G6PD; in such cases the dimer does not form or falls apart.[24] This situation applies to G6PD mutants that cause the most severe clinical phenotypes (that of CNSHA; see later). In a few cases (e.g., G6PD Orissa), altered catalytic func-

FIGURE 17-5. World map of G6PD deficiency. The *shadings* indicate the overall prevalence of G6PD deficiency in individual countries; the distribution of individual G6PD variants is shown by *colored symbols*. *(Redrawn from WHO Working Group. Glucose-6-phosphate dehydrogenase deficiency. Bull World Health Organ. 1989;67:601-611, and modified from Tan KL, Boey KW. Clinical experience with phototherapy. Ann Acad Med Singapore. 1989;18:43-48.)*

tion (instead of or in addition to protein instability) may be the main mechanism of G6PD deficiency.[77]

Epidemiology of G6PD Deficiency

The geographic distribution[78] of G6PD deficiency is rather extraordinary in two ways. First, it has a very high prevalence overall, with more than 500 million people estimated to be involved (most of them mostly asymptomatic); second, it has a high prevalence in many populations in most tropical and subtropical parts of the world because of malaria selection (see Fig. 17-5 and the last section in this chapter). Thus, G6PD is prevalent in all five continents; it has never been reported in Amerindians, and one might speculate that this is related to the fact that they have been exposed to malaria only over the past 3 centuries.

CLINICAL MANIFESTATIONS OF G6PD DEFICIENCY

The most classic manifestation of G6PD deficiency is acute hemolytic anemia (AHA); in children, however,

another syndrome of great clinical and public health importance is neonatal jaundice (NNJ). CNSHA is a much rarer manifestation of G6PD deficiency and a lifelong hemolytic process. These different clinical manifestations are discussed in turn.

Acute Hemolytic Anemia

Clinical Picture. A child with G6PD deficiency is clinically and hematologically normal most of the time, and this can be designated as a steady-state condition. However, a rather dramatic clinical picture can develop upon ingestion of fava beans (favism),[79] during the course of infection, or after exposure to certain oxidative agents (see Table 17-3). With infection or drugs the clinical picture may be more complicated than with favism; therefore, here we will describe favism as a paradigm. After a lag of hours the child may become fractious and irritable or subdued and even lethargic. Within 24 to 48 hours the child's temperature is often moderately elevated. Nausea, abdominal pain, diarrhea, and rarely vomiting may be present. In striking contrast to these relatively nonspecific symptoms, the patient or a parent will observe, within 6 to 24 hours, the telltale and rather frightening

event that the urine is discolored (Fig. 17-7). It will be reported as dark, as red, brown, or black, or as "passing blood instead of water;" it will be said, depending on experience, culture, and socioeconomic background, to resemble Coke or strong tea or port wine. At about the same time jaundice will become obvious. Physical examination may reveal little more than the signs correspond-ing to these symptoms. The child will be pale and tachycardic; in severe cases there may be evidence of hypovolemic shock or, less likely, heart failure. The spleen is usually moderately enlarged, and the liver may also be enlarged; either or both may be tender.

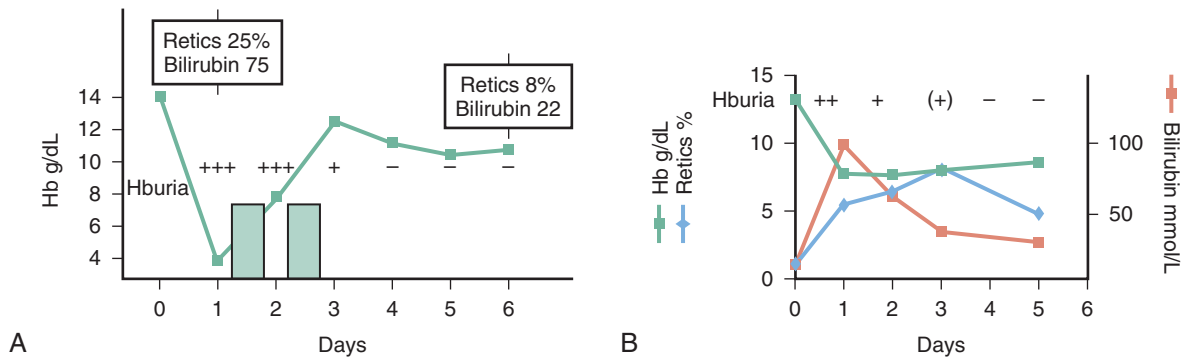
Laboratory Findings. Anemia may range from moderate to extremely severe (hemoglobin values of 2.5 g/dL have been recorded). In the absence of other preexisting hematologic abnormalities the anemia is normocytic and normochromic. The morphology of the red cells may be striking (Fig. 17-8A). There is often marked anisocytosis (reflected as a wide red cell size distribution on the electronic counter) because of the coexistence of large polychromatic cells and "contracted" cells, some of which can be frankly classified as spherocytes. There is also marked poikilocytosis with the presence of distorted red cells, "irregularly contracted" red cells, and red cells with apparently uneven distribution of the hemoglobin inside them (hemighosts).[80] Although some of these appearances are probably smearing artifacts, electron micrographic evidence suggests that in some of the cells, opposing surfaces of the membrane have become "cross-linked."[81] Probably the most characteristic poikilocytes are those in which the cell margin literally appears dented, as though a portion has been plucked out or bitten away ("bite cells"; see Fig. 17-8A). The reticulocyte count is increased and may reach peaks of 30% or greater (blood counters using immunofluorescent technology will show an elevated percentage of the immature reticulocyte fraction); this reflects a prompt and effective bone marrow response, which will take place provided that there is no preexisting or concomitant bone marrow pathology. Careful inspection of reticulocyte preparations may reveal inclusion bodies different from those normally seen in reticulocytes; these bodies are discrete, round, and 1 to 3 μm in diameter, and they usually appear to be leaning, from the interior, against the cell membrane. These inclusions are more clearly displayed by supravital staining with methyl violet and are referred to as *Heinz bodies* (see Fig. 17-8B). They consist of precipitates of denatured
FIGURE 17-6. The main mechanism of G6PD deficiency in red cells is in vivo instability of mutant enzyme. For many G6PD variants, such as the two studied here, this is essentially acceleration of a process that takes place normally with the aging of red cells in the circulation. *(Redrawn from Morelli A, Benatti U, Gaetani GF, De Flora A. Biochemical mechanisms of glucose-6-phosphate dehydrogenase deficiency. Proc Natl Acad Sci U S A. 1978;75:1979-1983.)*


FIGURE 17-7. Clinical charts of children with acute favism. **A,** Severe attack in a 21-month-old boy, who required two blood transfusions (*hatched bars*) because of life-threatening anemia after the ingestion of fava beans. The second blood transfusion was administered because of persistent hemoglobinuria (Hburia). **B,** Milder attack in a 5-year-old boy. The mother, who is a physician and knows that she is G6PD deficient, reported that the child had eaten fava beans 2 days before admission. Both children had severe G6PD deficiency (red blood cell G6PD activity less than 3% of normal). The values on day 0 are presumed. TABLE 17-2	Hemoglobinuria in Children	
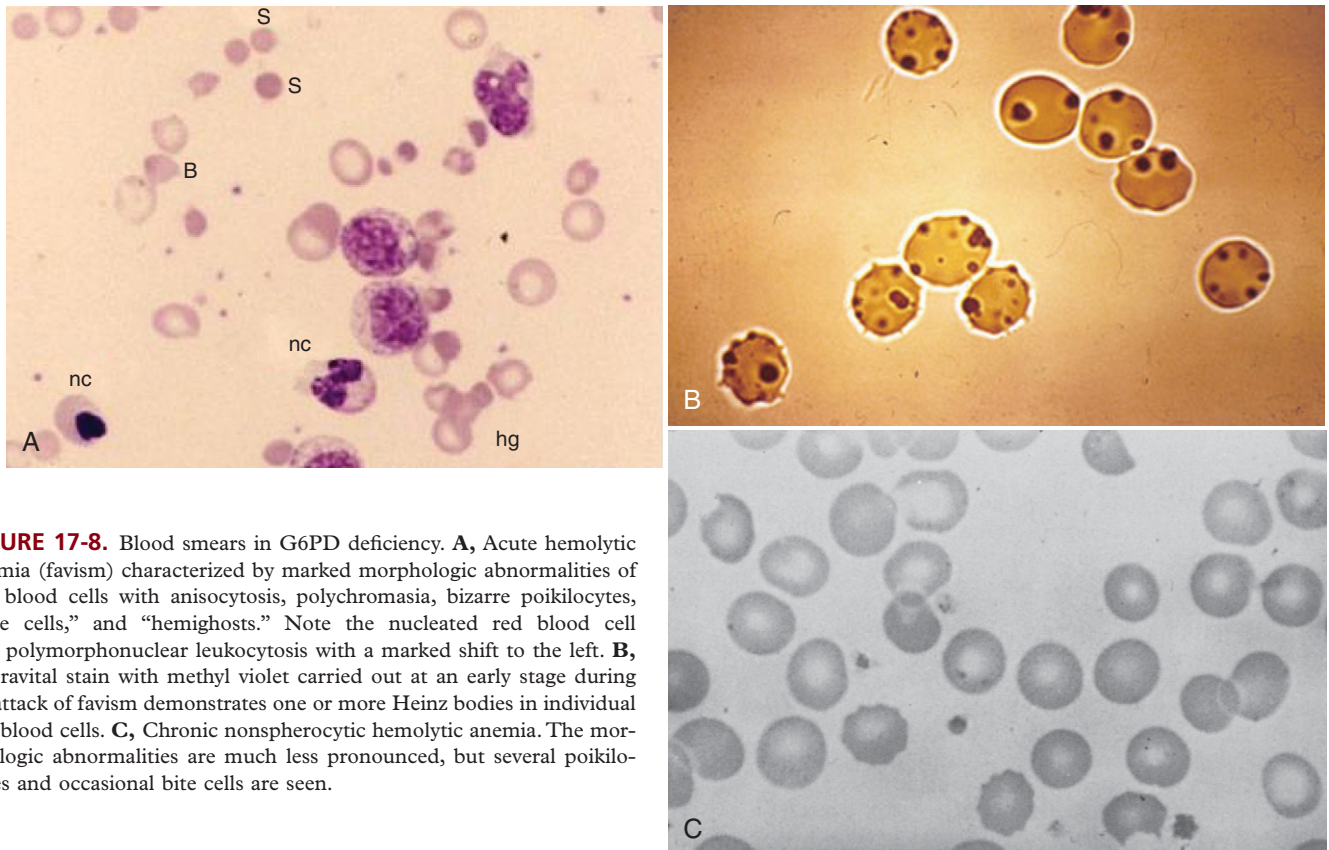
Condition	**Circumstances**	**Diagnostic Approach**
G6PD deficiency	Exposure to a trigger of hemolysis	Test for G6PD activity
Blackwater fever	Relatively rare complication of malaria	Blood slide for malaria parasites
Paroxysmal cold hemoglobinuria	Usually associated with viral infection	Test for Donath-Landsteiner antibody
Mismatched blood transfusion	Usually ABO incompatibility	Repeat crossmatch
Paroxysmal nocturnal hemoglobinuria	Tends to recur	Flow cytometry for CD59
Clostridium welchii septicemia	Burns, severe open trauma, transfusion of contaminated blood	Culture of blood or appropriate patient material


FIGURE 17-8. Blood smears in G6PD deficiency. **A,** Acute hemolytic anemia (favism) characterized by marked morphologic abnormalities of red blood cells with anisocytosis, polychromasia, bizarre poikilocytes, "bite cells," and "hemighosts." Note the nucleated red blood cell and polymorphonuclear leukocytosis with a marked shift to the left. **B,** Supravital stain with methyl violet carried out at an early stage during an attack of favism demonstrates one or more Heinz bodies in individual red blood cells. **C,** Chronic nonspherocytic hemolytic anemia. The morphologic abnormalities are much less pronounced, but several poikilocytes and occasional bite cells are seen.

hemoglobin, and they are the vivid manifestation of the oxidative insult that this protein and the cell itself has suffered. However, Heinz bodies are a very transient finding because they tend to be promptly "pinched off" by the spleen[82] (thus giving rise to bite cells) and the red cells containing them are very rapidly removed from the circulation. Haptoglobin is reduced to the point of being undetectable. In severe cases it is possible to demonstrate free hemoglobin in plasma (*hemoglobinemia*). The white blood cell count is usually moderately elevated, with a predominance of granulocytes. The platelet count may be normal, increased, or moderately decreased. The unconjugated bilirubin level is elevated, but "liver enzyme" levels are generally normal. The dark urine tests strongly positive for blood because of the presence of free hemoglobin (see the differential diagnosis of this sign in Table 17-2).

Clinical Course. In the majority of cases the hemolytic attack, even if severe, is self-limited and tends to resolve spontaneously (see Fig. 17-7B). Depending on the proportion of red cells that have been destroyed (as reflected by the severity of the anemia), the hemoglobin level may be back to normal in 3 to 6 weeks. Although the blood urea level may be transiently elevated, the development of renal failure in children is exceedingly rare, even in the presence of massive hemoglobinuria (see Fig. 17-7A).

Diagnosis. With a history of fava bean ingestion followed by hemoglobinuria (see Table 17-2), the diagnosis is almost always straightforward, and it can be made quite confidently even before obtaining the final proof that the patient is G6PD deficient (see later). If the hemoglobinuria has already subsided and the history is uncertain, one is faced instead with the much wider differential

diagnosis of AHA. A negative direct antiglobulin test will militate against autoimmune hemolytic anemia. In endemic areas it will be important to exclude malaria or the much rarer babesiosis. In hemolytic-uremic syndrome, the red cell morphology is different and there will be evidence of impaired renal function. In all cases, demonstration of G6PD deficiency will be conclusive, and in uncertain cases it will be crucial.

Pathophysiology. The clinical picture of AHA in a G6PD-deficient child is a vivid expression of the fact that as we know already, hemolysis results from the action of an exogenous factor on intrinsically abnormal red cells. Hemoglobinemia and hemoglobinuria unambiguously indicate that the hemolysis is at least in part intravascular. At first approximation we can visualize the following sequence of events: (1) an oxidative agent causes conversion of GSH to GSSG; (2) because of the limited capacity of G6PD-deficient red cells to regenerate GSH, their GSH reserve is rapidly depleted; (3) once GSH is exhausted, the sulfhydryl groups of hemoglobin and probably other proteins are oxidized to disulfides or sulfoxides; and (4) coarse precipitates of denatured hemoglobin cause irreversible damage to the membrane, and the red cells lyse.

Not all of these steps from oxidative attack to final hemolysis have been fully documented in vivo, in part because of one major difficulty: in the course of AHA the red cells sampled from the patient are obviously, at any given stage, those that have not yet hemolyzed. However, GSH depletion is a most characteristic finding when red cells are subjected to oxidative challenge,[83,84] and in one careful study it has been demonstrated that during an attack of favism, the first measurable biochemical change is a fall in NADPH, followed by a fall in GSH,[85] in keeping with stages 1 and 2 described earlier. Heinz bodies (see Fig. 17-8B) are the visible expression of stage 3. Stage 4 is less clearly defined, although studies suggest that the abnormal proteolytic activity is associated with increased intracellular calcium,[86,87] as well as binding of hemichromes (arising from denaturation of hemoglobin) to band 3 molecules.[88]

Even though intravascular hemolysis in AHA associated with G6PD deficiency is important in pathophysiology and diagnosis, a substantial proportion of the hemolysis is extravascular (as shown by the enlarged spleen). Probably the most severely damaged red cells hemolyze in the bloodstream on their own, whereas less severely damaged red cells will be recognized as abnormal by macrophages and will undergo extravascular hemolysis in the reticuloendothelial system. This process has been referred to as an example of an "innocent bystander" phenomenon[89] (although the red cells, by virtue of being G6PD deficient, are not that innocent), in which complement and immunoglobulins may be involved.[90] Finally, it is important to remember that the red cell destruction in AHA associated with G6PD deficiency is an orderly function of red cell age (see Fig. 17-6). The oldest red cells with the least G6PD are the

first to hemolyze, and the hemolytic process progresses upstream toward cells with more and more G6PD.[91] As a result, there is a selective enrichment in red cells that despite being genetically G6PD deficient, have relatively higher levels of G6PD. This phenomenon can be so marked with certain G6PD variants that patients in the post-hemolytic state are found to be relatively resistant to further challenge; thus, the patient may be in a state of compensated hemolysis.[92]

Triggers and Mechanism of Hemolysis. G6PD deficiency was first discovered by investigating a possible genetic basis for sensitivity to primaquine. Since that time, numerous other drugs have been reported as being potentially dangerous in G6PD-deficient individuals (Table 17-3). There is no obvious relationship in chemical structure among all of these substances, but they have in common the ability to stimulate the pentose phosphate pathway in red cells,[93] which must mean that they are able to oxidize NADPH, directly or indirectly. Extensive studies on the components of fava beans responsible for hemolysis have led to the identification of vicine and convicine, two β-glycosides that generate the redox aglycones divicine and isouramil.[94] These compounds, in the course of their auto-oxidation, produce free radicals, which in turn oxidize GSH and thereby activate the chain reaction of events previously outlined.[95] The drugs listed in Table 17-3, or their metabolites, act in a similar way. Cosmetic use of henna dyes in several populations, mainly in Asia, can also cause serious hemolysis.[96-99]

An intriguing feature of AHA associated with G6PD deficiency is its considerably erratic character, which is

TABLE 17-3	Drugs That Can Trigger Hemolysis in G6PD-Deficient Children*	
Category of Drug	**Definite Risk**	**Possible Risk**
Antimalarials	Primaquine Dapsone-containing combinations[†]	Chloroquine Quinine
Analgesics Sulfonamides/ sulfones	Acetanilid Sulfamethoxazole/ co-trimoxazole Dapsone[†]	Aspirin Sulfasalazine Sulfadiazine
Quinolones	Nalidixic acid Ciprofloxacin Norfloxacin Moxifloxacin Ofloxacin	
Other antimicrobials	Nitrofurantoin Methylene blue	Chloramphenicol
Other	Niridazole	Vitamin K Rasburicase Ascorbic acid Glibenclamide

*For all drugs the risk of hemolysis is dose related, as well as the severity of hemolysis. For instance, aspirin up to 20 mg/kg is probably safe; three times that dose will almost certainly cause some hemolysis.
[†]Dapsone can cause hemolysis even in non–G6PD-deficient children.
Table modified from British National Formulary, 55th edition, March 2008.

more conspicuous with certain agents than with others. For instance, it is estimated that in adults, ingestion of fava beans does not trigger AHA in more than 25% of cases, and even in the same person favism may occur on one occasion but not on another.[90] One obvious factor must be the dosage, that is, the amount of fava beans ingested (in relation to body mass). Another is the quality, with raw fava beans being more likely to cause favism than cooked, frozen, or canned fava beans. Perhaps even more important is the finding that the glycoside content is a function of the maturity of the beans, with young, small beans being much richer (as well as more tasty!). With respect to drugs, primaquine causes hemolysis regularly but aspirin does so only sometimes[100]; once again, the dosage must be important, but additional genetic or acquired factors affecting metabolism of the drug may play a role. As regards infection, the best documented precipitants are hepatitis, pneumonia, and typhoid fever, but viral infections of the upper respiratory or gastrointestinal tract may also trigger hemolysis.[101] Recently it has been reported[102] that in a group of patients who suffered major trauma in road traffic accidents, the frequency and severity of infection were significantly higher in patients who were G6PD deficient; in addition, more severe anemia occurred in this group.

Release of peroxides during phagocytosis of bacteria by granulocytes might explain the hemolytic process in bacterial infections.[103] In this respect it is possible that hemolysis has sometimes been attributed to drugs used for treating infection when it should have been blamed on the infection itself.

Treatment. A child with AHA may be a diagnostic problem that once solved, does not require any specific treatment at all, or the child may be a medical emergency requiring immediate action. The most urgent question is whether a blood transfusion is needed. It is difficult to give absolute directives, but the following guidelines may be useful[104]:

1. If the hemoglobin level is below 7 g/dL, the child should be transfused forthwith.
2. If the hemoglobin level is below 9 g/dL and there is evidence of persistent brisk hemolysis (hemoglobinuria), immediate blood transfusion is also indicated.
3. If the hemoglobin level is above 9 g/dL but hemoglobinuria persists or if the hemoglobin level is between 7 and 9 g/dL but there is no hemoglobinuria, the child is kept under close observation for at least 48 hours and transfused if either condition 1 or 2 develops.

The most important complication that may require treatment is acute renal failure, which is exceedingly rare in children.

Neonatal Jaundice

From an *epidemiologic* point of view, it is noteworthy that the frequency of NNJ varies widely in different populations; in many populations in which G6PD deficiency is prevalent, the rate of pregnancies at risk for Rhesus incompatibility happens to be low.[105,106] In addition, as rhesus-related hemolytic disease of the newborn (HDN) is disappearing thanks to the implementation of appropriate prophylaxis, one can expect G6PD-related NNJ to be generally on the increase, at least in relative terms.

Clinical Features. NNJ related to G6PD deficiency is very rarely present at birth; it has a peak incidence between day 2 and day 3.[107] There is more jaundice than anemia, and the anemia is very rarely severe.[108] For this reason the terms *HDN* and *NNJ* cannot be regarded as interchangeable, at least in the context of G6PD deficiency. The severity of G6PD-related NNJ varies from being subclinical to imposing the threat of kernicterus if not treated. Thus, prompt recognition of the problem is extremely important to avoid crippling neurologic sequelae.[109-112]

Nature of the Association between G6PD Deficiency and Neonatal Jaundice. It is not fully explained why NNJ develops in some but not all G6PD-deficient newborns. Several clinical studies have established beyond any possible doubt that the association is statistically much higher than could be expected by chance (Table 17-4).[113] However, because not *all* G6PD-deficient newborns have NNJ (Table 17-5), it is likely that genetic or environmental factors (or both) are involved in addition to G6PD deficiency and that the same factors can also, if more extreme, make the NNJ more severe. NNJ is not the prerogative of some G6PD variant because it is prevalent in widely remote parts of the world (e.g., Nigeria,[113] Sardinia,[114] Singapore,[115] China[116]) in which the *Gd* alleles underlying G6PD deficiency are different; moreover, both within Sardinia[117] and within Taiwan,[118] NNJ has been found in babies with any of several different G6PD variants. The possibility that NNJ correlates with the quantitative level of residual G6PD activity is controversial.[119,120] Specific features of erythrocytes in newborns, such as elevated levels of ascorbic acid, depressed activity of glutathione reductase,[113] and low levels of vitamin E, GSHPX, and other enzymes,[121] could contribute to the degree of jaundice. It must be noted that there is a

TABLE 17-4	Association between G6PD Deficiency and Jaundice in Newborns	
	Number	**% G6PD Deficient**
Normal	500	22.5
Mild jaundice (bilirubin 150-200 μmol/L)	38	45
Severe jaundice (bilirubin >230 μmol/L)	70	60
Admitted with kernicterus	20	78

Data collected in Ibadan, Nigeria, on consecutive babies born in or admitted to a teaching hospital; see Bienzle U, Effiong CE, Luzzatto L. Erythrocyte glucose 6-phosphate dehydrogenase deficiency (G6PD type A⁻) and neonatal jaundice. Acta Paediatr Scand. 1976;65:701-704.

Data from Kaplan M, Herschel M, Hammerman C, et al. Hyperbilirubinemia among African American, glucose-6-phosphate dehydrogenase–deficient neonates. Pediatrics. 2004;114:e213-e219.

remarkable dissociation between hyperbilirubinemia and anemia in G6PD-deficient neonates.[108,114] Indeed, in one series there was no difference in the distribution of hematocrit values in cord blood and on day 3 between jaundiced and nonjaundiced G6PD-deficient newborns, thus suggesting that to a large extent this jaundice may be of hepatic origin rather than hemolytic. In keeping with this notion, measurements of the bilirubin production-conjugation index have demonstrated that the NNJ in otherwise healthy G6PD-deficient neonates depends more on inefficient bilirubin conjugation than on hemolysis.[122] The *UDPGT1* mutation characteristic of Gilbert's disease is associated with a much higher risk for NNJ and kernicterus in G6PD-deficient babies.[123,124] In addition, environmental factors can certainly exacerbate NNJ, in some cases by causing hemolysis in individual G6PD-deficient newborns; such factors include prematurity, breast-feeding,[125] naphthalene (camphor balls) inhalation, acidosis, hypoxia, infection such as viral hepatitis,[126] oxidant drugs, and ingestion of drugs[127] or fava beans (favism in utero[128]) by the mother before delivery.

In summary, there are probably two different types of NNJ associated with G6PD deficiency: (1) a more common type (see Table 17-5) can best be visualized as a marked exaggeration of "physiologic jaundice"; this type is usually clinical benign and not greatly influenced by the environment; and (2) a rarer, frankly hemolytic type, more severe, can be visualized as AHA occurring in a newborn baby because the baby happened to be exposed to one of the same agents that could cause AHA even in an adult.

Severe NNJ can occur in girls heterozygous for G6PD deficiency.[129] In addition, in geographic areas where G6PD deficiency is very common, female newborns might be homozygous for the trait, thus behaving like a hemizygous G6PD-deficient male newborn.

Treatment. Management of NNJ associated with G6PD deficiency does not differ from that recommended for other causes. Thus, mild cases do not require treatment; intermediate cases require phototherapy; and severe cases require exchange transfusion, just as in NNJ caused by "classic" HDN. Kernicterus is still an impending threat, especially when severe NNJ is associated with anemia, hypoxia, or infection. Clinical practice guidelines for the management of hyperbilirubinemia in newborns quote: "measurement of the glucose-6-phosphate dehydrogenase (G6PD) is recommended for a jaundiced infant who is receiving phototherapy and whose family history or ethnic or geographic origin suggest the likelihood of G6PD deficiency or for an infant in whom the response to the phototherapy is poor."[130] G6PD-deficient newborns must be considered as being "*at high risk*"[125] and therefore requiring greater surveillance and more intensive treatment of hyperbilirubinemia. Specifically, it is recommended that in full-term newborns, exchange transfusion be carried out if the serum bilirubin level exceeds 15 mg/dL in the first 2 days of life or 19 mg/dL at any time in the first week of life.

Congenital Nonspherocytic Hemolytic Anemia

A small minority of children with G6PD deficiency have hemolytic anemia not only when it is triggered by an exogenous factor but even in the steady state (Fig. 17-9). These children have special G6PD mutations (class I); all of them are rare, but they are scattered worldwide, regardless of whether G6PD deficiency is endemic in the region.

The patient is invariably male and in general is evaluated because of unexplained jaundice, frequently presenting at birth (NNJ). (The only known exception is a woman heterozygous for G6PD Volendam, who had an extremely skewed X-inactivation pattern favoring, paradoxically, the X chromosome with the abnormal G6PD allele.[132]) Unfortunately, anemia recurs and the jaundice fails to clear completely, thus requiring further investigation. In other cases, NNJ may have been overlooked or forgotten and the patient is reinvestigated only much later in life (e.g., because of gallstones in a boy or in a young adult). The severity of the anemia ranges from being borderline to being transfusion dependent in different patients (Table 17-6). The anemia is usually normochromic but somewhat macrocytic because a large proportion of reticulocytes (up to 20% or more) will cause an increased mean corpuscular volume and a shifted, wider than normal red cell size distribution curve. The red cell morphology is mostly not characteristic, and

FIGURE 17-9. Clinical course of a boy with congenital nonspherocytic hemolytic anemia (CNSHA) caused by severe G6PD deficiency. Severe neonatal jaundice was the initial manifestation; subsequently, the child developed normally but required many blood transfusions. The transfusion dependence remitted after splenectomy. Currently, the patient, now in his early twenties, has had a cholecystectomy; he has moderate anemia and is still jaundiced. The patient's *Gd* mutation was characterized as G6PD Harilaou (F216L).[47,131]
TABLE 17-6	Clinical Spectrum of Chronic Nonspherocytic Hemolytic Anemia Caused by Severe G6PD Deficiency	
Patients studied	**25 (all male)**	
% With neonatal jaundice	100	
% Requiring exchange transfusion	24	
% With splenomegaly	68

Lowest hemoglobin known, range (g/dL)	3.8-9.3	
Reticulocytes, range (%)	3-51	
% Requiring multiple blood transfusion	72	

for this reason it is referred to in the negative as being "nonspherocytic." The bone marrow shows normoblastic hyperplasia, unless the increased requirement for folic acid associated with the high red cell turnover has caused it to become megaloblastic. There is chronic hyperbilirubinemia, decreased haptoglobin, and increased lactate dehydrogenase. Hemoglobinuria is rare, but hemosiderinuria may be detected sometimes. The spleen is usually moderately enlarged in small children, and subsequently it may increase in size sufficiently to cause mechanical discomfort, hypersplenism, or both.

Pathophysiology. The pattern of hemolysis in these patients is different from that described earlier for AHA associated with G6PD deficiency and instead more reminiscent of the chronic hemolysis seen in hereditary spherocytosis. However, oxidative stress caused by exposure to the same agents that cause AHA will cause acute exacerbation of hemolysis in CNSHA. Unlike the situation in thalassemia major, even in severe cases there is no

evidence of ineffective erythropoiesis. The fact that there is no hemoglobinuria, at least in the steady state, suggests that the hemolysis is mainly extravascular and therefore that its mechanism is different from that of AHA. Studies of red cell membrane proteins have revealed the presence of high-molecular-weight aggregates[133,134] consisting largely of spectrin, which seem to make the membrane abnormally susceptible to shear-induced fragmentation.[135] These abnormalities in the red cells of G6PD-deficient patients with CNSHA are not found in asymptomatic G6PD-deficient subjects, thus suggesting that whereas in the latter the reductive potential of residual G6PD is adequate in the steady state, in the former, continuous oxidation of sulfhydryl groups takes place, followed by irreversible changes in the configuration of membrane proteins. The reason why the severity of CNSHA associated with G6PD deficiency is so variable is that almost every case is due to a different mutation (see later) and each mutation will have a different effect on stability of the enzyme, on its kinetic properties, or on both.

Diagnosis. Laboratory diagnosis of G6PD deficiency is discussed next, but a special problem in relation to CNSHA is to firmly establish the causal link between the former and the latter. If the patient is, for example, a Swede of Swedish ancestry or a Japanese of Japanese ancestry, the link will be taken for granted, and this is generally justified, given the rarity of G6PD deficiency in these populations. On the other hand, if the patient is from a population in which G6PD deficiency is common, its presence in a patient with CNSHA might be a mere coincidence, and the cause of the CNSHA might be something else altogether. In such cases, while other causes of CNSHA are being ruled out, it becomes essen-

tial to characterize the G6PD of the patient. If it is a common variant known to be asymptomatic in other subjects, it can certainly be exonerated, whereas if it is a new unique variant, it is likely to be the culprit.

Treatment. In general terms, management of CNSHA associated with G6PD deficiency does not differ from that of CNSHA related to other causes (e.g., pyruvate kinase deficiency). If the anemia is not severe, regular folic acid supplements and regular hematologic surveillance suffice. It is important to avoid exposure to potentially hemolytic drugs, and blood transfusion may be indicated when exacerbations occur, mostly in concomitance with intercurrent infection. In rare patients, the anemia is so severe that it must be regarded as transfusion dependent. In these cases blood transfusion will probably be needed at approximately 2-month intervals to keep the hemoglobin in the 8- to 10-g/dL range. A hypertransfusion regimen aiming to maintain a normal hemoglobin level is not indicated (because there is no ineffective erythropoiesis in the bone marrow). However, depending on the extent of the blood transfusion requirement, appropriate iron chelation should be instituted from the age of 2 years onward and must be continued as long as transfusion treatment is necessary; sometimes the transfusion requirement may decrease after puberty.

A special problem is that of splenectomy.[72] There is no evidence of selective red cell destruction in the spleen, as in hereditary spherocytosis. However, the fact that the spleen is usually enlarged suggests that its role in hemolysis is not negligible. In practice, there are three indications for splenectomy: (1) if splenomegaly becomes a physical encumbrance; (2) if there is evidence of hypersplenism; and (3) if the anemia is severe, even in the absence of the first two indications. Splenectomy may reduce the overall rate of hemolysis (see Fig. 17-9) just enough to make a transfusion-dependent child become transfusion independent.[136] This is doubly important because it will make it possible to dispense with iron chelation. Active immunizations before splenectomy and penicillin prophylaxis after splenectomy must be started according to national guidelines such as that produced by the British Committee for the Standards in Haematology (http://www.bcshguidelines.com/pdf/SPLEEN21.pdf).

When a diagnosis of CNSHA is made, the family must be given genetic counseling, and it is advisable to establish whether the mother is a heterozygote. If she is, the chance of recurrence is 1:2 for every subsequent male pregnancy. Prenatal diagnosis should be offered; although it could be carried out on amniotic fluid cells, it would be much preferable[137] to determine the mutation involved and test for it on DNA from chorionic villi. G6PD-deficient patients with severe CNSHA (see Fig. 17-9), because its clinical manifestations are limited to blood cells, would in principle be good candidates for gene therapy by gene transfer into hematopoietic stem cells. This approach has not yet reached the stage of clinical application, but preclinical experiments have been carried out successfully in mice[138] and Rhesus monkeys.[139]

LABORATORY DIAGNOSIS OF G6PD DEFICIENCY

Although the clinical picture of favism and other forms of AHA associated with G6PD deficiency is characteristic, the final diagnosis must rely on direct demonstration of decreased activity of this enzyme in red cells. In NNJ and CNSHA, the differential diagnosis is much wider, and therefore this test is even more important. Fortunately, the enzyme assay is very easy, and numerous "screening tests" can be used as substitutes if a spectrophotometer is not available. However, a number of potential pitfalls and sources of error must be understood, and the use of commercial kits is not a substitute for such understanding. Here the value and limitations of the regular quantitative assay are discussed first, and then the use of alternatives is mentioned.

Tests for G6PD Deficiency

G6PD can be assayed by the classic spectrophotometric method,[140] which directly measures the rate of formation of NADPH through its characteristic absorption peak in the near ultraviolet spectrum at 340 nm. Red cell activity is expressed in international units (micromoles of NADPH produced per minute) per gram of hemoglobin; therefore, it is best to assay the enzyme activity and the hemoglobin concentration in the same hemolysate and work out the ratio. Because G6PD activity is much higher in leukocytes (particularly in granulocytes) than in erythrocytes, for accurate measurements it is essential to remove all leukocytes by the Ficoll-Hypaque method or by filtration through cellulose powder[141] rather than by the cruder approach of sucking off the buffy coat; however, for the purpose of clinical diagnosis of G6PD deficiency, this is not strictly necessary. In normal red cells the range of G6PD activity, measured at 30° C, is 7 to 10 IU/g of hemoglobin.

Several "screening tests" for G6PD deficiency are useful and reliable provided that they are run properly and their limitations are understood. The most popular are the dye decolorization tests,[142] the methemoglobin reduction test,[143] and the fluorescence spot test.[144] Recently, a formazan-based screening test has been developed[145] and field-tested.[146] All these methods are semiquantitative, and they are meant to classify a sample simply as "normal" or "deficient." The cutoff point can be set by following the appropriate instructions and by trial and error in the individual diagnostic laboratory; one should aim to classify as deficient any sample having less than 30% of normal activity because above this level one is unlikely to encounter clinical manifestations. Screening tests are of course especially useful for testing large numbers of samples. They are also perfectly adequate for diagnostic purposes in patients who are in the steady state but *not* for patients in the post-hemolytic period or with other complications; in addition, they cannot be expected to identify all heterozygotes. Finally, an ideal screening test ought not to give "false-negative" results

TABLE 17-7		Red Blood Cell G6PD Levels in Various Clinical Situations		
Clinical Condition	**Gender**	**Result of Screening Test**	**Result of G6PD Assay**	**Interpretation**
Normal	M or F	Normal	8.1	Normal
Normal	M	Abnormal	0.4	G6PD deficiency, steady state
Normal	F	Abnormal	2.1	Heterozygote for G6PD deficiency
Normal	F	Normal	4.9	Heterozygote for G6PD deficiency
Acute hemolysis	M	Abnormal	2.3	AHA in G6PD-deficient boy
Acute hemolysis	F	Normal	7.2	AHA in G6PD heterozygote girl
Chronic hemolysis	M	Normal	15.5	Hemolysis unrelated to G6PD deficiency
Chronic hemolysis	M	Abnormal	1.4	CNSHA, probably caused by G6PD deficiency

AHA, acute hemolytic anemia; CNSHA, congenital nonspherocytic hemolytic anemia; G6PD, glucose-6-phosphate dehydrogenase.

(i.e., it should not misclassify a G6PD-deficient subject as normal), but it can be allowed to give a few "false-positive" results (i.e., a G6PD-normal subject might be misclassified as being G6PD deficient). Ideally, every patient found to be G6PD deficient by screening should be confirmed by the spectrophotometric assay. For special purposes, formazan-based cytochemical methods are also available.[147,148]

The Effect of Red Cell Age and Selective Hemolysis. Because G6PD decreases gradually as red cells age,[61] any condition associated with reticulocytosis will entail an *increase* in G6PD activity (Table 17-7). This means that if a subject is genetically G6PD normal, in the course of hemolysis, red cell G6PD activity will now be *above* the normal range. This does not affect the diagnosis because G6PD deficiency will be correctly ruled out. However, if the subject is genetically G6PD deficient, red cell G6PD may now be raised to the extent of being near or even within the normal range, and the patient might therefore be misclassified as being G6PD normal[149] (even though at the onset of the attack the level may have been low).[150] Thus, after a hemolytic attack two circumstances concur to cause a risk of misdiagnosis: first, the older cells have been destroyed selectively; second, the marrow response has caused a sudden outpouring of young cells into the peripheral blood. (A third confusing factor may be admixture of G6PD-normal red cells if the patient has been transfused.) Although the reticulocyte count is a good warning to avoid this mistake, it must be realized that because reticulocytes turn into morphologically "mature" erythrocytes within 1 to 2 days, their count is not a sensitive index of mean red cell age; in other words, mean red cell age may be significantly younger than normal even when the reticulocyte count is normal. There are several ways to circumvent these problems. First, a G6PD level in the low-normal range (as opposed to higher than normal) in the presence of reticulocytosis is always suspicious; indeed, this finding suggests that the patient is actually G6PD deficient. Second, if the patient is suffering or is recovering from AHA, the suspicion generated from the finding just mentioned can be simply kept in store for a few weeks, when the situation will be evolving toward the steady state, and a repeat test will prove

whether the patient is indeed G6PD deficient. Third, if either the urgency of some clinical decision or academic curiosity demands a more prompt solution of the problem, the presence of severely G6PD-deficient red cells can be demonstrated either by enzyme assay of the oldest cells (fractionated by sedimentation) or by a cytochemical method (see earlier).

G6PD Deficiency in Heterozygotes. For hemolysis to be clinically significant in heterozygous girls, at least 50% of the red cells must be deficient, and therefore the G6PD level will be about 50% of normal or less. This level of deficiency can be diagnosed by a quantitative test; however, the problems associated with current or recent hemolysis outlined for male patients will be compounded in the case of heterozygous females, and they can usually be overcome by a similar approach, particularly with the use of a cytochemical test. A different matter is the biologic diagnosis of heterozygosity, regardless of immediate clinical implications, as may sometimes be required for appropriate genetic counseling. In cases of "extreme phenotypes" (sometimes referred to as arising from "imbalanced lyonization"), the G6PD-deficient red cells may be so few that the only way to identify heterozygous G6PD deficiency will be by DNA analysis, for which the underlying mutation must be known or identified for the purpose. A special situation involves heterozygotes for G6PD variants associated with CNSHA. In the authors' experience, the mothers of (male) patients with this condition are often G6PD normal, either because the variant in the offspring is due to a de novo mutation[151] or because the mother is a heterozygote but is phenotypically normal, presumably because somatic selection has favored the hematopoietic progenitor cells with the normal G6PD allele.[48]

Molecular Analysis of the G6PD Gene. In the vast majority of cases, the family history, the clinical course, and a G6PD assay are sufficient to establish the diagnosis of conditions associated with G6PD deficiency. In special cases (see the previous section for heterozygote diagnosis) and particularly in the case of CNSHA, identification of mutations in the G6PD gene can be carried out, with reference to the large numbers of mutations already

known (see Human Gene Mutation Database, http://www.hgmd.cf.ac.uk/ac/gene.php?gene=G6PD). Furthermore, in this way new mutations are still likely to be discovered.

GENOTYPE-PHENOTYPE CORRELATIONS

A rigorous definition of a polymorphic allele is one with a frequency higher than can be accounted for by recurrent mutation; however, for convenience, a conservative practical criterion is any allele with a frequency of at least 1% in at least one population. By this criterion there are 26 well-mapped *Gd* polymorphic alleles (see Figs. 17-4B and 17-5) already known.[66] The ratio of subjects having G6PD deficiency associated with CNSHA to those having "simple" G6PD deficiency varies in different populations. For instance, in Japan, where G6PD deficiency is, on the whole, very rare, the majority of patients with G6PD deficiency have been reported to have CNSHA.[152] This suggests that CNSHA, caused by rare sporadic variants, many of which may result from recent mutations, reflects the intrinsic mutation rate of the human *Gd* gene, which is likely to be uniform throughout the world; in contrast, "simple" G6PD deficiency almost always results from common variants that have arisen many generations ago and spread through biologic selection.

The three variants mentioned previously, G6PD A$^-$, G6PD Mediterranean, and G6PD Mahidol, are probably those for which clinical expression has best been characterized.[153] Although the former is often quoted as having fewer clinical manifestations than the others, the differences are marginal, and they are unlikely to be relevant with respect to patient management. The severity of hemolysis and whether it is "self-limited" depend on the offending agent, on its dose, and on the time course of exposure probably more than it depends on the G6PD variant involved. Notably, favism has been unambiguously documented with G6PD A$^-$.[154-156]

In terms of clinical expression, the demarcation between class I variants and all others is, by definition, much more clear-cut. Indeed, one of the outstanding questions in the biochemical genetics of G6PD is why a particular variant can cause CNSHA rather than just AHA. In certain cases the level of residual enzyme activity is not the whole answer—qualitative differences are also important, as first suggested by Kirkman and Riley.[157] The most likely way in which a structural change can significantly alter the function of G6PD, *given the same level of deficiency*, is by affecting the binding of one of the main ligands (i.e., G6P, NADP, NADPH). For instance, G6PD Mediterranean and G6PD Coimbra both have mutations near the G6P binding site, and both have *increased* affinity for G6P. Perhaps because of this, although they are both severely deficient, they belong to class II and not to class I. G6PD Orissa, the main polymorphic variant in tribal Indian populations[158] also belongs to class II despite having *decreased* affinity for

NADP. Thus, the affinity for G6P appears to be of greater importance. Indeed, comparison of the distribution of K_m^{G6P} values of class I variants with that of class II and III variants shows that they are significantly lower in the latter group.[8]

However, in most cases the main factor responsible for causing CNSHA is a very low level of residual activity in red cells, which in turn is due to marked in vivo instability. It is quite remarkable that although G6PD mutations as a whole are evenly spread throughout the gene's coding sequence, the majority of class I mutations are clustered in exons 10 and 11 (see Fig. 17-4B). The three-dimensional model of the human G6PD dimer has, at long last, provided a reasonable explanation for this finding.[66,159] Indeed, these two exons encode the protein region that constitutes the interface between the two identical subunits of the enzyme. As a result, any mutation in this region causes the respective amino acid replacements in the two subunits to be quite near each other in the dimer structure, thus potentially increasing their deleterious effects. Even more important, because there is no covalent link between the subunits, it stands to reason that any interference in the shape of the interface surfaces may affect their mutual fit and therefore dramatically destabilize the active form of the enzyme. Defects in protein folding have been studied in detail for certain G6PD variants.[160,161]

G6PD DEFICIENCY AND PREVENTIVE MEDICINE

Because NNJ and AHA are the most common manifestations of G6PD deficiency, it is most important to consider how they can be prevented. The first step is to identify G6PD-deficient individuals, which is where screening is most pertinent. Of course, whether population-wide screening is both desirable and feasible depends primarily on the prevalence of G6PD deficiency in any particular community; this will determine the cost-benefit ratio. If screening is done at all, it is best done on cord blood. Once a subject is known to be G6PD deficient, the two main implications are the risk for NNJ and the importance of avoiding exposure to agents that can cause AHA. NNJ cannot be prevented as yet, but awareness of G6PD deficiency must entail surveillance for NNJ until at least day 4 and special recommendations with respect to factors, such as naphthalene, that can cause it or make it worse. By contrast, at least one type of AHA, namely, favism, is completely preventable (Fig. 17-10). Prevention of infection-induced hemolysis is obviously more difficult. Prevention of drug-induced hemolysis is possible in most cases by choosing alternative drugs, but it may be difficult when none are available. The most common problem is the need to administer primaquine for the eradication of malaria caused by *Plasmodium vivax* or *Plasmodium malariae*. In these cases, administration of a lower dosage for a longer time is the recommended
FIGURE 17-10. Control of favism in a community. The data show the decrease in the number of yearly admissions for favism in the children's department of the main city and university hospitals in Sassari, northern Sardinia. During the 10-year period intervening between the two sets of data, two preventive measures were adopted: (1) education through the media and (2) screening of all newborns for G6PD deficiency. Note the dramatic reduction in the incidence of favism in boys and the more modest decrease in girls. The data suggest that (1) preventive measures are effective; (2) the increased proportion of girls can be attributed to failure of the screening method used to pick out many of the heterozygotes; and (3) in view of (2), the dramatic reduction observed in boys can perhaps be credited to screening more than to the educational campaign. *(Courtesy of Professor Tullio Meloni, Sassari, Sardinia.)*

approach. Hemolysis will still occur, but under appropriate surveillance it will be of an acceptably mild degree.

A special problem in prevention is what to do about new drugs, the hemolytic potential of which is unknown. Although in vitro methods to test drugs in this respect do exist,[162,163] such tests are unfortunately not routinely carried out before drugs are released on the market, so their hemolytic potential will become apparent only from clinical observation. Recently, a combination of dapsone and chlorproguanil, used as an antimalarial in several African countries,[164,165] has been withdrawn from the market because of life-threatening hemolytic complications.

G6PD DEFICIENCY IN NONERYTHROID CELLS

As mentioned earlier, because nucleated somatic cells have the capability to synthesize G6PD constitutively, they are affected less than red cells by G6PD deficiency.[166] For instance, subjects with G6PD Mediterranean have less than 5% G6PD activity in red cells but about 30% of normal in granulocytes; subjects with G6PD A⁻ have about 12% G6PD activity in red cells but nearly normal activity in granulocytes. On the other hand, if deficiency results from a drastic change in catalytic efficiency or in substrate affinity, deficiency may be more universal. In practice, the only well-documented pathologic effect is expressed in granulocytes. Very few of the class I G6PD variants cause not only CNSHA but also granulocyte dysfunction, mainly in the way of impaired killing of phagocytosed bacteria (an example is G6PD Barce-

lona).[167] Patients with these variants have increased susceptibility to bacterial infection, particularly with *Staphylococcus aureus*. Recently, in a group of patients who suffered major trauma in road traffic accidents, Spolarics and colleagues[102] made the interesting observation that the frequency and severity of infection were significantly higher in patients who were G6PD deficient; thus, neutrophil function may be affected in extreme situations, even in the common type of G6PD deficiency (the patients in the clinical study all had G6PD A⁻). The mechanism whereby G6PD deficiency impairs phagocytosis is a defect of the oxidative burst caused by a shortage in NADPH supply, similar to that observed in chronic granulomatous disease, in which one of the components of the cytochrome-b_{245} system is defective.[168] Functional abnormalities have also been demonstrated in macrophages from G6PD-deficient mice.[169]

Erythrocytes are not the only non-nucleated cells in the body. Another example is in the eye lens, and juvenile cataracts have been reported occasionally in subjects with G6PD deficiency.[170,171] Whether G6PD deficiency is more generally associated with a higher frequency or earlier onset of cataracts appears to still be controversial.[172-175]

G6PD DEFICIENCY COEXISTING WITH OTHER DISORDERS

In areas where G6PD deficiency is common, it is not infrequent that it may be encountered in the same patient together with another condition, whether a hematologic or a nonhematologic condition.

Association with Other Hematologic Diseases. The combination of G6PD deficiency with the sickle cell trait has been no more frequent than could be expected by chance.[176,177] Several studies have shown that there are no significant differences in a variety of clinical and hematologic parameters between two otherwise comparable groups of patients with sickle cell anemia, those with and without G6PD deficiency,[149,178-180] but it must be borne in mind that acute intravascular hemolysis superimposed on chronic severe extravascular hemolysis is an added risk with this association. The combination of G6PD deficiency with the β-thalassemia trait has been found to cause a significant increase in mean corpuscular volume,[181] which remains, however, below the normal range. Association of G6PD deficiency with thalassemia major is unlikely to be a problem because patients with the latter condition are treated with regular blood transfusions or with bone marrow transplantation. However, the association may be significant in patients with various forms of thalassemia intermedia syndromes (e.g., hemoglobin E–β-thalassemia).[182]

Occasionally, G6PD deficiency has been observed in association with much rarer red cell abnormalities, such as pyruvate kinase deficiency,[183,184] congenital dyserythropoietic anemia type II,[185-187] and hereditary elliptocytosis.[188] In these cases the two abnormalities seem to produce only additive clinical effects, but in at least one family G6PD deficiency was synergistic with hereditary spherocytosis in causing moderately severe chronic hemolytic anemia.[189]

Association with Nonhematologic Diseases. Several studies have reported variable degrees of association between diabetes and G6PD deficiency.[190-196] It now appears clear that diabetic ketoacidosis does not trigger hemolysis[197]; on the other hand, downregulation of G6PD has been reported in some West African patients with type 1 diabetes predisposed to ketoacidosis.[198] Apart from the fact that hepatitis can precipitate hemolysis in G6PD-deficient children, ribavirin, now much used in the treatment of hepatitis C, can itself cause hemolytic anemia (regardless of whether the patient is G6PD deficient). On the other hand, it has recently been shown that G6PD-deficient patients with hepatitis C can be treated safely with ribavirin and pegylated interferon.[199]

Trauma and G6PD Deficiency. Although G6PD deficiency protects against malaria, there are reports indicating that it worsens the clinical course of traumatic patients.[189] Altered cytokine response would be the underlying pathogenetic mechanism predisposing to infections in G6PD-deficient individuals.[200]

G6PD POLYMORPHISM AND MALARIA

The striking correlation between the worldwide distribution of G6PD deficiency (see Fig. 17-5) and that of

Plasmodium falciparum prompted formulation of the "malaria hypothesis" nearly half a century ago.[201,202] Since that time, numerous more detailed epidemiologic studies, which can be referred to as "micromapping,"[203] as well as clinical studies,[204] have supported the notion that G6PD deficiency confers some degree of resistance to the potentially lethal malaria parasite *P. falciparum;* and that in malaria-endemic areas, G6PD alleles associated with enzyme deficiency have therefore been subjected to positive darwinian selection.[205-207] A geographic correlation certainly does not amount to proof, but three large controlled clinical studies, all carried out in Africa, have shown concordantly that children with G6PD deficiency tend to have less severe malaria and, therefore, presumably a decreased risk of dying of malaria. It is puzzling that in one of these studies (from Nigeria[208]), increased resistance to the parasite (relative to that in appropriate controls) was significant only in heterozygous females; in another study (from Gambia and Kenya[209]), a protective effect was seen in both males and females; and in the third study (from Mali[210]), a protective effect was noted only in males. These differences might result from genetic variations (other than G6PD) in different populations, from the use of different criteria to measure the severity of malaria, from different levels of statistical power, or from any combination of these factors. However, all three studies concur in supporting the notion of malaria selection for G6PD deficiency. A more difficult issue is understanding the mechanism of this phenomenon. In vitro studies have shown that invasion of G6PD-deficient red cells by *P. falciparum* takes place normally and the parasite can multiply efficiently in G6PD-deficient red cells, at least after several cycles.[211] On the other hand, in vitro experiments have shown that parasitized red cells are recognized more promptly by macrophages when they are G6PD deficient[212]; thus, accelerated removal of parasitized red cells (suicidal infection)[213] may be the most important mechanism of protection, as it is for subjects with the sickle cell trait.[214] An additional strong argument in favor of malaria selection is the genetic heterogeneity of polymorphic Gd^- alleles in itself. Indeed, each one of these alleles, having arisen through an independent mutational event, must have increased in frequency on its own in a particular geographic area[215] where malaria was or still is endemic—a good example of convergent evolution driven by the same selective force.[216]

18 Hemoglobins: Normal and Abnormal

H. Franklin Bunn and Ronald L. Nagel

This chapter deals with the structure and properties of hemoglobin (Hb) and disorders stemming from structural abnormalities (mutations of the coding sequence) that lead to clinical manifestations. Not included are sickle cell disease and the thalassemias, which are covered in Chapters 19 and 20.

At last count (mid-2008), 983 human Hb mutations have been cataloged: 267 for the α1 gene, 314 for the α2 gene, 732 for the β gene, 79 for the δ gene, 50 for the ^{A}γ gene, and 56 for the ^{G}γ gene. Of these, 91 have high affinity for O_2 and 134 are unstable. (A list of the mutants can be found at the Globin Gene Server [http://globin.cse.psu.edu], a website founded by Ross Hardison and initially based on Titus Huisman's database.)

NORMAL HEMOGLOBIN A: STRUCTURE AND FUNCTION

Overall Hemoglobin Structure

The major Hb molecule in adults is a tetramer formed by four polypeptide chains, two α chains (141 amino acids long) and two β chains (146 amino acids long). The primary structure (amino acid sequence) is illustrated in Table 18-1. Each of these chains is attached to a prosthetic group heme formed by protoporphyrin IX and complexed with an iron molecule. All globins consist of eight helices and interconnecting loops (nonhelical), except for α Hb subunits, which lack the D helix because of deletion of five consecutive residues. Each chain is formed by helical regions and nonhelical regions (which allow for bending) that fold into a tightly globular protein.

α Chains of Hemoglobin (Tertiary Structure)

The α chains have the general architecture of myoglobin (Fig. 18-1) but are shorter and contain 141 rather than 153 amino acids as a result of the absence of six residues from the C-terminal portion and six from the D helix. The D helix in myoglobin and in the β subunit of Hb is required for retention of heme.[1]

The deletion of the D helix in the α chains has no explanation. Disappearance of the nonhelical C-terminal

*The α and α-related (δ) subunits are shown at the left. The β and β-related (δ, γ, and ε) chains are at the right. The amino acids' relationship to the eight globin helices (A to H) is also shown. Thus, A16 is the 16th amino acid in the A helix. Interhelical elbows are named for the two adjacent helices (e.g., AB1 is the first amino acid between helices A and B). The N- and C-terminal residues are labeled NA and HC, respectively. The residues are aligned to maximize the homology between subunits, which causes some gaps.

Modified from Bunn HF, Forget BG. Hemoglobin: Molecular, Genetic, and Clinical Aspects. Philadelphia, WB Saunders, 1986.

FIGURE 18-1. Myoglobin structure. The myoglobin molecule consists of eight stretches of helix that surround the heme group to form a pocket. Single letters signify a helix and double letters a corner or bend (nonhelical regions). The heme pocket is formed by helices E and F. Helices B, G, and H are at the bottom, and the CD corner closes the open end. Histidine side chains interact with the heme from both sides. *(From Dickerson RE, Geis I. Hemoglobin: Structure, Function, Evolution, and Pathology. Menlo Park, CA, Benjamin/Cummings, 1983, p 26.)*

residues could be related to the important bond between Arg-α141 and Tyr-α140 and the appropriate receptor, which are important for the conformational changes involved in the transformation from oxygenated (oxy) to deoxygenated (deoxy) forms (see later discussion), a central feature of the tetramer structure-function relationship. The additional C-terminal residues in myoglobin might strain these critical molecular interactions and make the conformational change impossible.

The differences between α chains and myoglobin could also be derived from the need for α chains to bind several different β-like chains (γ, δ, and ε), with varied requirements for generation of the quaternary structure. Specifically, generation of a quaternary structure implies changes in the character of the residues involved in subunit contact. That is, residues that are polar in myoglobin (because they are in direct contact with the solvent) might be buried in an intersubunit contact in several of the Hbs and hence have to be replaced by hydrophobic amino acids. For example, in residue B15, a lysine in myoglobin is a leucine in human α chains, whereas residue C1, a histidine in myoglobin, is a phenylalanine.[1,2]

β Chains of Hemoglobin (Tertiary Structure)

Human β chains, which contain 146 residues, are also shorter than myoglobin. The general architecture of the chain and its secondary and tertiary structure complies closely with the myoglobin fold.[3-5]

Two small structural differences with myoglobin are apparent: disappearance of two residues from the junction of the A and B helices, thereby making the AB elbow sharper, and six residues missing from the C-terminal sequence (as in the α chains). The reason for the change in the AB elbow is not understood. The critical bonds involving His-β142 and Tyr-β145 might be incompatible with the presence of the nonhelical terminal residues found in myoglobin. In the β chains, changes of charged to hydrophobic residues can also be observed in areas of the sequence involved in subunit interaction.

The Tetramer (Quaternary Structure)

The Hb molecule is a tetramer formed by two α chains and two β chains and has a total molecular mass of 64.5 kd.

How Do the Two Pairs of Chains Generate a Tetramer? The arrangement of the two types of chains in the tetramer conforms to a 222 symmetry. This designation means that the structure can be characterized by three twofold axes of symmetry perpendicular to each other (Fig. 18-2). To understand this symmetry, consider the upper half (the dark pair of chains) in the vertical axis. If you rotate these two chains 180 degrees, they will coincide perfectly with the light-colored pair of chains, an arrangement called a twofold or diad axis of symmetry, hence the three "2"s. Of course, α chains are not identical to β chains. Therefore, in an actual Hb molecule this symmetry is only approximate. A homotetramer of β chains (β_4 or HbH), observed in a severe form of α-thalassemia, exhibits perfect 222 symmetry in the oxygenated tetramer because all the chains are truly identical.

How Do the Four Chains Interact? The tetramer $\alpha_2\beta_2$ exhibits several types of subunit interactions, but the weakest contact occurs between identical chains, that is, in the $\alpha_1\alpha_2$ or $\beta_1\beta_2$ interfaces. Strong interactions occur in contacts between the dissimilar pair of chains, that is, in the interfaces $\alpha_1\beta_1$ or the equivalent $\alpha_2\beta_2$.

The next level of complexity is the contact between these two pairs of unlike chains. This contact occurs in two areas on the surface of these dimers: the $\alpha_1\beta_2$ contact (see Fig. 18-2) and the equivalent $\alpha_2\beta_1$ contact, which is called the sliding contact. Conversely, the $\alpha_1\beta_1$ dimer has areas of interaction between the α and β chains that are called packing contacts. These dimers are strong and can be broken only with very high concentrations of urea or certain salts, and they remain as such throughout the conformational changes of Hb.

The sliding contact, in contrast, is weaker and has strategically located hydrogen (H^+) bonds and salt bridges that can be broken and reformed elsewhere to allow mobility of the two surfaces, a phenomenon indispensable for conformational changes (see next section). When the tetramer dissociates, $\alpha_1\beta_1$ dimers are generated. About 20% of the surface area of the subunits is consumed in subunit-subunit interactions, 60% of which are involved in packing contacts and 35% in sliding contacts.[6]

Oxygen Binding of Hemoglobin and Structure-Function Relationships

Hb carries O_2 from the lungs to the capillaries and carbon dioxide (CO_2) in the reverse direction. In addition, mammals need to adapt to sudden changes in oxygenation requirements; therefore, they require modulation of the O_2-carrying capacity of Hb. Functions of Hb are summarized as follows:

1. Cooperative O_2 binding that is allosterically regulated
2. pH-dependent oxygen binding (Bohr effect)

FIGURE 18-2. The four chains of hemoglobin, front view: $\alpha_1\beta_2$ contacts (the $\alpha_2\beta_1$ contacts are identical on the back side of the molecule). The perpendicular pseudoaxis is indicated by *dashes*. Only the carbons of the main chains are shown. The side chains involved in contact between subunits are indicated by *numbers* in large *circles*. *(From Dickerson RE, Geis I. Hemoglobin: Structure, Function, Evolution, and Pathology. Menlo Park, CA, Benjamin/Cummings, 1983, p 36.)*

3. Allosteric effectors (2,3-diphosphoglycerate [2,3-DPG], H^+, and CO_2) that modulate O_2 affinity

Allostery and Cooperativity

Hemoglobin Binds Oxygen Allosterically. The myoglobin molecule, being a monomer, binds O_2 as predicted by mass action; a plot of the partial pressure of O_2 (Po_2) versus O_2 saturation can be described as hyperbolic. In contrast, the Hb tetramer, with four hemes, binds O_2 with a sigmoidal curve (Fig. 18-3). Binding of O_2 by myoglobin can be described at equilibrium by the simple relationship

$$y = K_a Po_2/(1 + K_a Po_2),$$

where y is the fractional saturation of the myoglobin molecule with O_2, K_a is the association constant, and Po_2 is the partial pressure of O_2.

For the Hb molecule, binding of O_2 is different, and at equilibrium this reaction can be described by the formula

$$y = K_a Po_2^n/(1 + K_a Po_2^n),$$

where n is the Hill coefficient, an empirical number that is an index of the sigmoidicity of the curve and an index of the extent of cooperativity. The Hill coefficient is approximately 3 for Hb, whereas it is equal to 1 for myoglobin.

What Is Cooperativity? Cooperativity underlies the sigmoid shape of the O_2 equilibrium curve of Hb. The initial portion of the curve has a low slope, which reflects a low affinity for O_2 by Hb at the beginning of the loading process. That is, when Hb is totally deoxygenated, it has rather poor avidity for O_2 (see Fig. 18-3). As loading proceeds and Hb binds more O_2 molecules, the slope of

the reaction begins to change rapidly and becomes steep. Hence, the affinity for O_2 becomes much higher. Thus, the initial molecules of O_2 that bind a deoxy-Hb tetramer change the avidity of the protein for O_2. This property, called cooperativity, ensures that the Hb tetramer, after it begins to accept O_2, promptly and readily binds the remaining heme groups. Consequently, if we measure the distribution of O_2 in all the Hb molecules in a solution that contains enough O_2 to oxygenate only half the hemes available, most Hb molecules would either not be oxygenated at all or would be entirely oxygenated, with a small compartment of partially oxygenated Hb.

The Molecular Basis of Cooperativity. The generally accepted basis of cooperativity is the two-state (or concerted) model of Monod, Wyman, and Changeaux[7] (the MWC model). The model is based on two fundamentally different conformations: one for oxygenated Hb and another for the deoxygenated molecule. In its strictest form, this model does not accept meaningful intermediate conformations, only two extreme ones. It predicts that the molecule of Hb will bind two or three molecules of O_2 at low affinity (deoxy conformation) and then, suddenly, the molecule will flip to the oxygenated conformation, thereby drastically increasing the O_2 affinity of the molecule as a whole. Perutz and colleagues[8-11] were very successful in accommodating the MWC model to their structural analyses (Fig. 18-4).

Formally, the two-state model can be defined by two quantities: c, which represents the difference in activity between the two enzyme states but, in the special case of Hb, corresponds to the ratio of the O_2 affinity constants between the two conformation states (K_a oxy/K_a deoxy = c). The second quantity, the allosteric constant L, is the fraction of Hb molecules in the T state. The rest are R structures. L defines the equilibrium constant for the conformational change itself between the two states: T

FIGURE 18-3. Oxygen equilibrium curves of sperm whale myoglobin (Mb) and hemoglobin (Hb) in human red cells. At pH 7.4 and 37° C, oxygen saturation of the red cells is 98% at the arterial blood partial pressure of O_2 (Po_2) (100 mm Hg) and 75% at mixed venous blood Po_2 (40 mm Hg), so oxygen corresponding to a saturation difference of 23% is transported by circulating red cells. *(After Imai K. Allosteric Effects in Haemoglobin. Cambridge, England, Cambridge University Press, 1982.)*

FIGURE 18-4. Two-state model of binding of oxygen and other ligands to hemoglobin. *R* stands for the relaxed or high-affinity conformer, and *T* stands for the tense or low-affinity conformer. *X* stands for the ligand. Each chain is in the R state (*sphere*) or the T state (*square*). Notice that when the tetramer is liganded in two of the hemes, it tends to adopt (switches to) the T conformer.

for tense, the nonaccepting or low-affinity state (the deoxygenated conformer in the case of Hb), and R for relaxed, the accepting or high-affinity state (the oxygenated conformer in the case of Hb). The significant switch in conformation occurs in Hb somewhere between the binding of two and three molecules of O_2. Under physiologic conditions of pH, the presence of effectors, and osmolarity, at full saturation only 1 in 3 million Hb molecules has the T structure. The results of recent analyses argue convincingly that the two-state MWC model of Perutz defines the fundamental function of Hb and, in addition, casts doubt on the interpretation of some of the experiments that seem to contradict this model.[12,13]

Why Is the Hemoglobin Tetramer of Higher Organisms Allosteric? Allosterism makes Hb a molecule with lower affinity for O_2 than for myoglobins or the isolated Hb chains. Allosteric effectors such as 2,3-DPG and H^+ ions modulate the reduced affinity by lowering K_T (the association constant for the T state) and raising the L constant. K_R (association constant of the R state) and L at full O_2 saturation are not modified.[8]

What Are the Structural Events Underlying Cooperativity? The critical differences between the R and T conformers involve the areas of contact between the $\alpha_1\beta_1$ and $\alpha_2\beta_2$ dimers. The intersubunit areas of contact in the $\alpha_1\beta_1$ and $\alpha_2\beta_2$ dimers are essentially immobile during the conformational change because these dimers move as a unit. These events are pictured in Figure 18-5.

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

FIGURE 18-5. The $\alpha_2\beta_2$ dimer is seen in a side view. The *dotted areas* depict the packing contacts that hold the dimer together. The sliding contacts with the $\alpha_1\beta_1$ dimer are depicted by areas of *gray stippling*. *(From Dickerson RE, Geis I. Hemoglobin: Structure, Function, Evolution, and Pathology. Menlo Park, CA, Benjamin/Cummings, 1983, p 38.)*

Three regions sustain the major changes during the R-to-T conformational change, which consists of a 15-degree rotation of the $\alpha_1\beta_1$ dimer with respect to the $\alpha_2\beta_2$ dimer around a pivot passing through the terminal portions of the H helix in both chains. These movements exclusively involve the residues that touch each other in the $\alpha_1\beta_2$ areas of contact (Fig. 18-6). One movement involves pivotal sliding of the two dimers with respect to each other, with the contact involving the β FG corner moving farther away from the pivotal axis. This is called the switch region. Another movement involves the FG corner of the α chains contacting the C helix of the β chains, but the contact is less affected because the α FG corner is much closer to the pivotal axis. This is called the flexible joint. In addition, a change is seen in the set of salt bridges between the H helix (C-terminal portion of the β chain) and the C helix of the α chain and between the C-terminal portion of the α chains and the C helix of the β chain. These contact points have no particular name but are referred to here as the C-terminal changes. Detailed residue interactions are depicted in Figure 18-6.

All these H bonds and salt bridges are broken in the oxy conformer, thus providing one of the most important sources of the difference in free energy between the T and R states in Hb.

What Triggers the Conformation Change at the Level of the Heme Molecule? The iron in deoxy-Hb is slightly out of the plane of the heme molecule (domed configuration) because the pyrrole rings are also slightly pyramidal. The angle between the heme plane and iron is 8 degrees in the α heme and 7 degrees in the β heme. The His F8 axis is 8 degrees off center, and the Val FG5 is in contact with the vinyl side chain of pyrrole 3 (Fig. 18-7). When the ligand binds the sixth coordinating position of the iron, significant steric stresses are introduced, particularly between the heme and the proximal histidine, the ligand and the heme, and the heme and Val FG5. To relieve this strain, the histidine moves 8 degrees to become perpendicular to the heme, thereby significantly decreasing doming of the iron (the angle between iron and the heme molecule falls to 4 degrees). In addition, FG5 is displaced in the direction of His F8. The configuration around the heme has now changed to the oxygenated or R state, and a chain of events involving the critical interactions in the $\alpha_1\beta_2$ area of contact follow.

What Is the Conformational Micropath between the Heme and the Globin? In the α chain, displacement of His F8 to straighten up its 8-degree tilt in the liganded heme requires that the F helix move with it. This displacement of the F helix, along its axis, is accompanied by a shift downward, which moves it closer to the heme. The heme shifts toward the interior of the heme pocket. The changes in the F helix are propagated along the E and G helices, but the rest of the α chain is left unchanged. In the β subunit, the changes are similar, except that the

FIGURE 18-6. Front view of hemoglobin showing extensive subunit interactions between the FG corners and C helices in the $\alpha_1\beta_2$ contacts. The area outlined in **A** is enlarged in **B**. Important interaction regions from top to bottom are the β-chain C-terminal, the switch region, the flexible joint, and the β-chain terminal. *(From Dickerson RE, Geis I. Hemoglobin: Structure, Function, Evolution, and Pathology. Menlo Park, CA, Benjamin/Cummings, 1983, p 43.)*

FIGURE 18-7. The protoporphyrin IX heme structure consists of four pyrrole rings with the following side chain replacements: two methyl and two propionic acids in pyrrole 1 and 4 and two methyl and two vinyls in pyrroles 2 and 3. Iron is tetracoordinated by the nitrogens of the pyrrole rings. *(From Dickerson RE, Geis I. Hemoglobin: Structure, Function, Evolution, and Pathology. Menlo Park, CA, Benjamin Cummings, 1983, p 55.)*

heme also tilts around a pyrrole 2-4 axis. In both heme niches, Val FG5 moves closer to the vinyl side chains; this van der Waals contact breaks the critical H bonds between Val98 and Tyr145 in the β chain and between Val98 and Tyr140 in the α chain. The rest of the H bonds and salt bridges described earlier for the C-terminals become weakened to the point of breakage, which releases the molecule from the T state (closed and low affinity) to the R state (open and high affinity).

Allosteric Effectors: Protons, 2,3-Diphosphoglycerate, and CO_2

Oxygen Binding Is pH Dependent. The Bohr effect describes pH-dependent changes in O_2 affinity. Within the physiologic range, the lower the pH, the lower the affinity or the higher the partial pressure of O_2 at which Hb is half saturated (P_{50}). That is, an increased concentration of protons favors a low-affinity state in Hb. Deoxy-Hb binds more protons than the oxy conformer does, which means that in the absence of a buffer, oxygenation is accompanied by a drop in pH (Haldane effect). The enhanced ability of deoxy-Hb to bind protons endows blood with very high buffering capacity. In the microcirculation, CO_2 from respiring tissue readily enters red cells and dissociates into bicarbonate anions and protons. The protons then bind to deoxy-Hb. When the blood reaches the lungs, Hb is reoxygenated and the Bohr protons are expelled; they recombine with bicarbonate, and CO_2 is exhaled.

All the features described in the previous paragraph are the consequence of H^+ ions acting as allosteric effectors: H^+ binds more avidly to the deoxy conformer (T state) than to the oxy conformer (R state). The so-called Bohr protons (protons released during oxygenation) originate primarily from breakage of the C-terminal bonds during ligand binding (see Fig. 18-6).

Seventy-five percent of the Bohr effect is derived from differences in the pK of the following residues when the molecule changes from the oxy to the deoxy conformation: (1) the two terminal histidines of the β chains (β146 His) account for approximately 40% of the Bohr protons as determined by Perutz and associates,[14-17] (2) the α amino groups of the two N-terminal residues (Val1) of the α chains account for approximately 25% of the Bohr proteins, and (3) α122 His contributes about 10% of the Bohr protons.[18]

Recently, individual pK values of the 24 histidyl residues of HbA have been measured.[19] Among these surface histidyl residues, β146 His has the biggest contribution to the physiologic Bohr effect. The sum of the contributions from 24 surface histidyl residues accounted for 86% of the alkaline Bohr effect at pH 7.4 and about 55% of the acid Bohr effect at pH 5.1. The results of this study support the presence of a global electrostatic network for regulation of the Bohr effect in the Hb molecule.

Hemoglobin Binds CO$_2$ While It Is Unloading O$_2$ and Releases CO$_2$ When It Is Binding O$_2$. Hb is designed to bind CO_2 after delivering O_2 to tissues, thereby helping dissipate the increase in concentration of CO_2 by delivery of this metabolic end product to the lung alveoli. This exchange is facilitated because CO_2 is an allosteric inhibitor of Hb and thus decreases the O_2 affinity of the molecule.

CO_2 binds to Hb by forming carbamates with the α amino groups of the α chains. Through this new negative charge, CO_2 can bind Arg141 in the absence of Cl^- ions. This bond stabilizes the T conformer and decreases O_2 affinity of the molecule.[20] The reaction is

$$Hb—NH2 + CO_2 \rightarrow Hb—NH—COO^- + H^+.$$

Although CO_2 also binds the α amino groups of the β chains, thus helping transport more of this end product, the reaction does not contribute to allosterism. The β-chain carbamate reaction favors the deoxy conformer by the production of H^+, but this effect is counteracted by the reduction in positive charges in the central cavity, an event that favors the R state. Binding of CO_2 to hemoglobin contributes much less than the Bohr effect to the buffering capacity of blood.

Other Allosteric Effectors That Modulate the O$_2$ Affinity of Hemoglobin. Benesch and Benesch[21] discovered the effects of 2,3-DPG on the function of Hb after they noticed, while examining tabular data in preparation for a lecture to medical students, that this intraerythrocytic organic phosphate was almost equimolar to the Hb tetramer ($\approx$5 mM). Oxygen equilibrium measurements in the presence and absence of 2,3-DPG readily demonstrated that this effector drastically displaced the P_{50} of Hb to the right, thereby making Hb less avid for the ligand.

Independently and simultaneously, Chanutin and Curnish[22] realized that these substances have an important biologic effect on the red blood cell. Their discoveries were followed by the finding that inositol pentaphosphate, a higher-level polyphosphate than 2,3-DPG and a more powerful effector, has the same function as 2,3-DPG but at lower concentration in the red cells of birds. Finally, in some fish, red cell adenosine triphosphate (ATP) and guanosine triphosphate seem to be the physiologic O_2 modulators.

In an allosteric model, the effector must bind differentially to each of the conformational states. For an effector to be an inhibitor (a molecule that decreases the activity of the molecule—in this case O_2 affinity), it must bind more strongly to the T form. Biochemical[23] and crystallographic[24] studies have demonstrated that 2,3-DPG binds to the central cavity of Hb, that is, the space surrounding the true diad axis of symmetry between the two β chains (ββ) (Fig. 18-8). The displacement of the β chains away from each other by 7 Å in deoxy-Hb makes this single site in the tetramer capable of accommodating the highly negatively charged 2,3-DPG molecule, whereas the tighter ββ interaction in oxy-Hb does not allow the effector to penetrate the central cavity. The five negative charges of 2,3-DPG bind to complementary positive charges on the β chains to form salt bridges just under the edge of the ββ central cavity. The globin residues involved in the binding are the two N-terminals of the β chains, the two β143 histidines, and one of the two β82 lysines. The purpose of this effector is to modulate the O_2 equilibrium curve according to physiologic requirements. For example, in anemia, synthesis of 2,3-DPG increases, thereby favoring the release of O_2 and partially compensating for the decrease in the number of O_2 carriers.

Red Cell Oxygen Transport

The O_2 equilibrium of red cells depends on the following factors: (1) the intrinsic O_2 affinity of the Hb molecule (determined in solutions stripped of phosphate), (2) intraerythrocytic pH, (3) the intraerythrocytic concentration of 2,3-DPG, (4) temperature, and (5) the partial pressure of CO_2 (PCO_2).

Intraerythrocytic pH. The Bohr effect of whole blood is essentially identical to that of Hb in solution. For normal blood (37° C and 40 mm Hg CO_2), the log P_{50}-to-pH ratio is close to 0.5. Intracellular pH is approximately 0.2 unit below extracellular pH, as determined by the concentration of permeant anions, chloride and bicarbonate, and the major impermeant anions, Hb itself and 2,3-DPG.

FIGURE 18-8.
chains around the 2,3-diphosphoglycerate (DPG) binding site. This top view of the central cavity in human deoxyhemoglobin shows the positive charges lining the DPG site: two each from the N-terminal (Val-β1), from His-β2, from Lys-β82, and from His-β143. The DPG molecule, with its five negative charges, sits in the middle of this ring of positive charges. The fetal γ chain loses two of its eight positive charges by substituting Ser for His at β143, thereby decreasing the affinity for DPG. *(From Dickerson RE, Geis I. Hemoglobin: Structure, Function, Evolution, and Pathology. Menlo Park, CA, Benjamin/Cummings, 1983, p 44.)*

Concentrations of solutes inside and outside the red cell follow the Gibbs-Donnan relationship, which requires electroneutrality and due consideration of differences in activity coefficients in the two compartments. As Hb and 2,3-DPG, which are negatively charged at pH 7.4, are trapped inside the red cell, the erythrocyte Cl^- concentration has to be decreased, thus accounting for the 0.7 ratio between intracellular and extracellular Cl^-. Calculation of the Gibbs-Donnan equilibrium predicts the observed 0.2-unit difference in pH between the inside and outside of the red cell, which suggests that no significant participant is missing in this phenomenon.

2,3-Diphosphoglycerate. The normal mean level of red cell 2,3-DPG is 12.8 µmol/g of Hb for males and 13.8 µmol/g of Hb for females.[25] Children younger than 5 years and elderly patients have increased and decreased levels, respectively.[26,27] This amount of 2,3-DPG makes organic phosphate almost equimolar with Hb in red cells, whereas in other cells it exists in very small concentrations.

Metabolically, 2,3-DPG is generated by the Rapoport-Luebering shunt from 1,3-DPG by 2,3-DPG synthase or mutase. Its level depends on its rates of synthesis and hydrolysis. The rate of synthesis is complex and depends on the amount of the substrate 1,3-DPG generated by glycolysis, which in turn increases directly with pH, and on the amount of 1,3-DPG entering the shunt. The alternative pathway for 1,3-DPG, and the most energetic, is conversion into 3-phosphoglycerate

and generation of an ATP molecule. This alternative is probably greatly affected by the activity of the synthase, which is stimulated in direct proportion to the red cell pH and is under end-product inhibition by the concentration of 2,3-DPG.

Hypoxia has a marked impact on these relationships, and the consequences of acidosis and alkalosis are described in Figure 18-9.

Temperature. The P_{50} of blood is almost doubled by an increase of $10°$ C (between $20°$ C and $30°$ C), an appropriate response to hypothermia and hyperthermia. Cold decreases metabolic requirements and reduces the need for O_2. During fever, metabolism is increased dramatically, and an increase in the delivery of O_2 is required.

Oxygen Transport to Tissues. The fundamental relationship that describes delivery of O_2 to tissues is the Fick equation:

$$Vo_2 = 1.39(Q)(Hb)(Sao_2 - Svo_2)$$

where Vo_2, milliliters of O_2 delivered by a liter of blood to tissues per minute, is the product of three independent variables: (1) blood flow (Q) in liters per minute; (2) the amount of O_2 carried by that flow, which is the product of 1.39 (the amount of O_2 in milliliters that a fully saturated gram of Hb is capable of carrying) and Hb in grams per liter; and (3) extraction of O_2 at the level of the tissues, which is the difference between the fractional saturation of arterial blood (Sao_2) and the fractional saturation of mixed venous blood (Svo_2).

The consequence of this analysis is that when regulation of O_2 release is desired, it is done in the following independent ways: (1) *blood flow* (Q)—this in turn is affected by cardiac output and the luminal size and distribution of vessels in the microcirculation; (2) *hemoglobin concentration*—red cell mass is the balance between erythropoiesis and red cell destruction and is actively regulated by erythropoietin as a response to hypoxia detected in the postarterial side of the renal circulation by a detection system that is described in Chapter 6; and (3) *oxygen extraction by tissues* ($Sao_2 - Svo_2$)—this parameter depends on the shape of the O_2 equilibrium curve, as discussed earlier, and on tissue Po_2. The determinants of tissue Po_2 and its regulation are poorly understood.

Nitric Oxide Binding

Chemistry and Physiology

In addition to oxygen, heme in its reduced (ferrous) form binds readily to two other important gaseous ligands, carbon monoxide (CO) and nitric oxide (NO). The affinity of Hb for NO is 100 times higher than that for CO and 20,000 times higher than that for O_2.

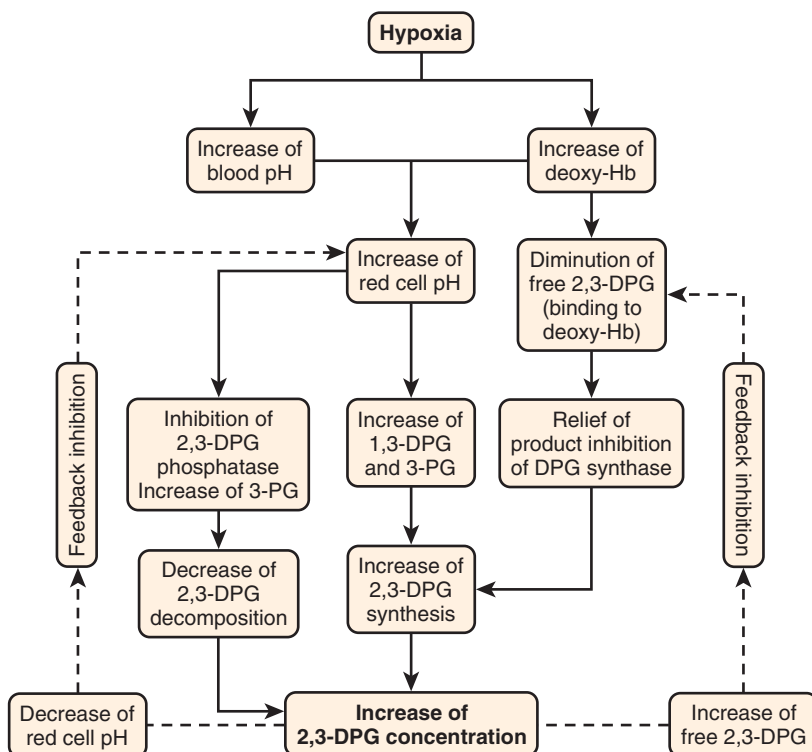
During the past 2 decades there has been an explosive accumulation of information on the biologic properties of NO, which include, *primus inter pares*, its role as a potent vasodilator. The biologic activity of NO is mediated by activation of a soluble guanylyl cyclase to produce cyclic guanosine monophosphate (cGMP). This second messenger is involved in many cellular functions. The NO formed by the action of NO synthase


FIGURE 18-9. Effect of hypoxia on red cell pH and 2,3-diphosphoglycerate (2,3-DPG). *(After Bunn HF, Forget BG. Hemoglobin: Molecular, Genetic, and Clinical Aspects. Philadelphia, WB Saunders, 1986.)*

diffuses out of its cell of origin and affects only nearby target cells (because NO has a short half-life); it binds the heme group of cytosolic guanylate cyclase and activates this enzyme by breaking the iron–proximal histidine bond.

The steady-state level of blood NO reflects a balance between the production of NO by NO synthase and binding or scavenging of NO by Hb (bound at the heme level). It is likely that most NO bioactivity involves direct cell-to-cell interactions rather than mediation by blood NO. Nevertheless, two hypotheses have proposed in which Hb plays a central and catalytic role in the regulation of hypoxic vasodilation, an important adaptation against tissue ischemia. Stamler and colleagues[28] have shown that the oxidized nitrosyl derivative of NO (NO$^+$) can form adducts with the sulfhydryl groups on cysteine residues, including the highly conserved β93 Cys on Hb, which lies in close proximity to the subunit's heme pocket. These investigators propose that the SNO adduct of Hb enables release of NO into the microcirculation, where it dilates blood vessels.[28-31] NO, produced in pulmonary arteries and arterioles, binds to the reactive β93 Cys in oxy-Hb to form the SNO derivative. As blood passes through the microcirculation, unloading of oxygen to tissues results in formation of the deoxy or T-state Hb, which precludes binding of NO to β93 Cys. The NO is thus ejected and diffuses out of the red cell into the lumen of the arteriolar and precapillary resistance vessels, where it functions as a vasodilator. The more hypoxic the tissue, the more NO that is released, thereby enhancing flow and maximizing oxygenation. As deoxygenated blood returns to the lungs, the increase in oxy-Hb allows re-formation of the SNO adducts, thus completing a dynamic and physiologically appropriate cycle. More recently, Stamler's group[32] has reported that the SNO-Hb generated from NO associates predominantly with the red blood cell membrane and principally with cysteine residues in the Hb binding, cytoplasmic domain of band 3, the anion channel in the red cell membrane. The authors postulate that the interaction with band 3 promotes the deoxygenated structure in SNO-Hb, which facilitates transfer of NO to the membrane. Although this model has enormous appeal, it remains highly controversial because of methodologic challenges in measuring extremely small in vivo levels of SNO-Hb and the rate of flow through the microcirculation, as well as difficulties reconciling the release and transit of NO or NO-like species from the red cell with what is currently known about the chemistry of Hb binding to NO.[33] Although the concept of SNO-Hb is attvactive, the in vivo significance of this phenomenon has been challenged by a recent report[34] showing that mice expressing human Hb in which β93 Cys has been mutated to alanine have normal circulatory dynamics and unimpaired vasodilation in response to hypoxia.

Gladwin and his group have proposed an alternative, but equally controversial model of how Hb may function catalytically in the mediation of hypoxic vasodilation.[35]

These investigators reason that plasma contains low to sub-micromolar concentrations of nitrite which could be a stable biologic reservoir of NO. They demonstrated a significant arterial-venous drop in the level of plasma nitrite in forearm blood flow studies even after abolishing endogenous production of NO, which is a known source of plasma nitrite.[36] These investigators went on to demonstrate that infusions of nitrite induce vasodilation along with binding of hemoglobin heme to NO.[37] The fact that this effect was maximal when red cell Hb was half saturated with oxygen led these investigators to conclude that an oxygen-dependent conformational change in Hb was required for maximal nitrite reductase activity[38] and that Hb may therefore mediate hypoxic vasodilation by serving as both the oxygen sensor and the requisite enzyme for regulated production of NO. This process apparently does not involve SNO-Hb because mutants with other residues replacing β93 Cys have even greater nitrite reductase activity.

Both the SNO model and the nitrite reductase model are heuristic but difficult to fully comprehend. The red cell is such a vast sink for NO that it is difficult to imagine how biologically significant amounts of NO or some other nitrogenous product can be released unless there is exquisite compartmentalization at the red cell membrane.

Clinical Relevance

In addition to red cell Hb, free Hb in plasma may also have an important impact on NO biology and pathogenesis of disease. Hb is released into plasma by both intravascular and extravascular hemolysis. Gladwin and colleagues at the National Institutes of Health have obtained results suggesting that sickle homozygotes with a relatively high degree of hemolysis appear to be more likely to have pulmonary hypertension, ankle ulcers, priapism, and early mortality.[39,40] In contrast, those with a comparatively low degree of hemolysis are more likely to have vaso-occlusive episodes, including acute pain crises. They hypothesize that enhanced hemolysis may have an impact on sickle cell pathogenesis by virtue of NO metabolism. Red cells that are prematurely destroyed in the circulation release arginase, which can lower the availability of arginine, a substrate required for the biosynthesis of NO via NO synthase. In addition, free Hb in plasma diffuses readily to the surface of endothelial cells and is capable of scavenging the NO that is released from these cells. These two processes can lead to a relative deficiency in NO that results in enhanced vasomotor tone, as well as activation of platelets that may independently accentuate vaso-occlusion.

The utility of the degree of hemolysis as an independent index of prognosis in sickle cell disease depends on how readily sickle homozygotes can be segregated into two groups of high versus low hemolytic rate. If these groups are readily separable, such laboratory assessment could be useful in helping assign prognostic risk to a given sickle patient. In a recent comparison of

a group of 223 sickle cell patients with priapism and a group of 979 controls who lacked this complication, those with priapism indeed had a somewhat higher rate of hemolysis, but the difference between the two groups was small.[41] The laboratory parameter that was most statistically significant in distinguishing between those with and without priapism was the white blood cell count. However, in all these measurements there is a very high degree of overlap between the two groups. Results such as this suggest that hemolysis may not segregate sufficiently into discrete subgroups to make it useful for assessing prognosis.

OTHER NORMAL HEMOGLOBINS

Hemoglobin F

In 1866, Korber[42] discovered that the red cells of newborns are resistant to alkaline denaturation. This was the first suggestion that these cells contain Hb that is different from normal adult Hb. The composition of this fetal Hb (HbF) is $\alpha_2\gamma_2$.

The γ chains are different from the β chains in 39 or 40 positions in the sequence.[43] γ Chains are the product of two genes placed in tandem between the ε and pseudo-β genes in the β-like globin cluster on chromosome 11. The only difference between the two gene products is the presence of glycine in position γ136 in the $^G\gamma$ gene, the left gene, and the presence of alanine in the same position in the $^A\gamma$ gene, to the right. A common polymorphism is found in the $^A\gamma$ gene, with threonine replacing isoleucine at position 75.[44] The striking similarities in the protein sequences are reflected at the nucleotide level, where the homology between the two genes is high. Smithies and associates[45] were the first to point out that this is a consequence of gene conversion, a mutational event in which sequences upstream replace sequences downstream, particularly in tandem genes, and homogenize them in the process. This phenomenon was demonstrated in the Bantu haplotype linked to the β^S gene.[46]

One interpretation of this phenomenon is that considerable selective value is placed on the sequence of γ chains and on the structure of HbF. This is not surprising because HbF is present throughout most of fetal life (though mostly during the last two trimesters), and abnormalities could easily cause fetal death.

Sequence Differences between γ and β Chains

The 39 differences include 22 on the surface of the molecule (see Table 18-1). Four critical substitutions are in the $\alpha_1\beta_1$ area of contact (the packing contact). This is the strong contact that dissociates only under extreme conditions such as very low or high pH.

Nevertheless, two of these substitutions, Thr112 and Try130, in the $\alpha_1\gamma_1$ contact could be involved in the alkaline resistance of HbF, as well as in its decreased dissociation to monomers. In the β chains, position β112 is a Cys and β130 is a Tyr. Both these residues ionize at alkaline pH, which could promote dissociation of the dimer into monomers. Thr and Tyr are polar but not ionizable. No sequence changes affect the $\alpha_1\beta_2$ area of contact (sliding contact), which is critical for the ligand-dependent conformational changes.

Protein Conformation

Crystallographic studies of HbF at 2.5-Å resolution show almost complete isomorphism between HbA and HbF.[47] The only difference is in the N-terminal portion. This change increases the distance of 2,3-DPG from γ2 His, which may contribute to the reduction of the effect of 2,3-DPG on HbF.

Ligand Binding

The red cells of newborns (containing mostly HbF) have higher O_2 affinity than adult red cells do (P_{50} of $\approx$15 mm Hg versus $\approx$26 mm Hg in adults), but the O_2 affinities of neonatal and adult red cell hemolysates are indistinguishable.[48] This finding suggests that HbF and HbA have identical O_2-binding properties but that the red cells contain effectors that interact differently with HbF.

2,3-DPG exhibits decreased binding to HbF.[49] The structural basis for this finding is replacement of β143 His (phosphate binding site in the central cavity) with a serine residue at γ143. This substitution abolishes an important binding site. Secondary effects arise from displacement of the N-terminal portion of the γ chains, which inhibits the binding of phosphates with γ2 His. In addition, HbF molecules that are acetylated at the γ-chain N-terminal are incapable of binding 2,3-DPG.[23]

The effect of Cl^- is also altered.[50] This anion binds at the 2,3-DPG site in the central cavity. At low NaCl concentrations (up to 0.05 mol/L), HbF has lower affinity for O_2 than HbA does. At higher Cl^- concentrations, the differences disappear. This effect is not well understood but might have to do with the diminution of positive charges in the central cavity; therefore, the binding affinity for anions and the destabilizing effect on the T state are reduced. The increased stability of the T state induced by the absence of anion-neutralizing positive charges would favor low ligand affinity.

Binding of CO_2 to HbF is drastically decreased.[51] Fewer carbamates are formed at the N-terminal over a range of P_{CO_2} values. The γ-chain N-terminal amino acid has a pK_a of 8.1, which is much higher than the pK_a of β chains (6.6). Under physiologic conditions, 90% of the γ sites are protonated and unable to bind CO_2.

The alkaline Bohr effect (relationship between high pH and ligand affinity) is increased by 20% in HbF-containing red cells.[52] This seems to be an effect of Cl^- because in isolated HbF at low anion concentrations, HbA and HbF have an identical Bohr effect and the Bohr effect of HbF increases pari passu with the Cl^- concentration. A plausible explanation is that binding of Cl^- at low

pH to β143 His stabilizes the R state. The absence of this Cl⁻ site in γ chains would lower the low-pH Bohr effect because it is a situation that favors the T state. As a consequence, the alkaline Bohr effect is favored in HbF.

Physiology of Hemoglobin F–Containing Red Cells

How do the aforementioned properties of HbF benefit the fetus and newborn? Perhaps the main feature of the fetal circulation, as opposed to the circulation in postnatal life, is that O_2 loading is accomplished under more difficult circumstances in the fetus (liquid-liquid interface) than in the neonate (gas-liquid interface). On the positive side, the tissues of the fetus have a high metabolic rate; therefore, the limitation may be on loading sufficient O_2 rather than delivery of O_2 because a significant difference between the Po_2 of blood and that of tissue is likely to exist in the fetus. This explains why the O_2 affinity of HbF-containing red cells is increased, a situation that favors uptake of O_2 in the placenta. Indeed, in nearly all mammals, fetal red cells have higher O_2 affinity compared with maternal red cells.

The Bohr effect accounts for 40% of the normal fetal gas exchange.[52] In addition, in the fetus, an increased Bohr effect can modulate delivery of O_2 to tissues (if needed), even in the absence of 2,3-DPG. About 50% of the delivery to tissues is accounted for by the increased Bohr effect. Finally, the increased Bohr effect could also explain the paradox observed[53] in which mothers with high-affinity Hb variants do not have pregnancy complications or fetal morbidity. The advantage of HbF is not limited to the difference in P_{50} with HbA. If the difference in affinity is erased, as in patients with high-affinity Hb, the enhanced Bohr effect can make up at least some of the difference.

As noted earlier, γ chains are synthesized by two sequence-identifiable genes. Additional heterogeneity arises from N-terminal acetylation of 10% to 15% of the γ chains of newborns. Acetylation is common in proteins that have N-terminal alanine, serine, and to a lesser extent, glycine residues.[54] Hb needs to have its N-termini free for functional reasons; therefore, it is not surprising that acetylation has been largely excluded by selection. In the case of HbF, it contributes to the decrease in 2,3-DPG binding, apparently a welcome feature. Acetylation occurs after synthesis, probably early in the process, and involves catalytic transfer of the acetyl moiety from acetyl coenzyme A to the protein by acetyltransferase. Hb Raleigh (β1 [NAI] Val→acetylatable alanine) is 100% acetylated. Cat Hb, in which the β1 residue is serine, is also 100% acetylated (and does not interact with 2,3-DPG[55]).

Laboratory Determination of Hemoglobin F

The best methods of determining the level of HbF in the hemolysate depend on its concentration. For normal levels (0.1% to 1.5% of total Hb), immunologic assays are best. For levels between 1.5% and 40%, alkaline denaturation is accurate. For levels greater than 40%, high-performance liquid chromatography (HPLC) is probably the best method, although it can also be used at lower concentrations. A method of enriching HbF by chromatography or isoelectric focusing, followed by HPLC, allows this technique to be applied to all concentrations of HbF. Disposable columns for determination of HbF in hemolysates that contain no HbA (such as red cells from patients with HbSS or HbCC disease) are also available and produce reasonably accurate results.

HbF is unevenly distributed among red cells in normal subjects and in those with most medical conditions except for some forms of hereditary persistence of HbF.[56] Immunologic techniques that allow identification of red cells containing HbF (F cells and F reticulocytes) and measurement of the average amount of HbF per cell have become powerful tools for the study of HbF expression.[57-59] About 0.5% to 7% of red cells are F cells in normal adults.

Agar electrophoresis at pH 6.4 (available as a kit) offers an additional method to isolate or identify HbF. Hbs are subjected to a combination of chromatography and electrophoresis in agar. The agar matrix interacts with the central cavity of Hbs,[60] and Hbs with abnormalities in that region (such as HbF) tend to migrate faster (or slower) than their electrophoretic mobility would predict at pH 6.4. Therefore, when an Hb with anomalous electrophoretic mobility in agar is compared with cellulose acetate (pH 8.6), a mutation of the central cavity should be suspected. Hb Hope is an example of this phenomenon.

Medical Conditions Apart from Hemoglobinopathies Associated with High Hemoglobin F

Newborns have between 65% and 95% HbF. This amount decreases progressively during the first year of life. The normal adult level is approached by 1 year of age and is achieved by 5 years.

Pregnancy is accompanied by a modest increase in HbF in the second trimester. Hydatidiform moles are associated with particularly high HbF values. Although maternal pregnancy hormones have been implicated, the mechanism of this elevation is not clear.[61]

Some conditions (besides hemoglobinopathies) retard downregulation of HbF in the first 5 years of life. Such conditions include prematurity, trisomy 13, and maternal diabetes.[62] Acceleration of the decrease in HbF is observed in patients with Down syndrome and those with C/D translocations.

Hemolytic anemias, acute bleeding, and treatment with hydroxyurea or arabinocytidine can all be associated with higher than normal values of HbF. This phenomenon has been interpreted to mean that under these conditions, early progenitors are rushed through development while they retain their HbF program because the reduction in the number of cell divisions precludes their downregulation.

Invariably, juvenile chronic myeloid leukemia, Diamond-Blackfan anemia, and Fanconi's anemia are accompanied by significant elevations of HbF. Erythroleukemia, paroxysmal nocturnal hemoglobinuria, kalaazar, preleukemia, and recovery from marrow aplasia are also associated with variable elevations of HbF. The highest levels are found in patients with Di Guglielmo's disease (erythroleukemia). Many conditions, including solid tumors, occasionally cause increased levels of HbF.[62-64]

Mutations in the $^G\gamma$ Genes

Variants of the $^G\gamma$ Gene. Fifty-six variants with a single amino acid substitution in the $^G\gamma$ gene have been described. Of these, two are unstable: HbF Poole ($^G\gamma130$ [H8] Trp→Gly), which is significantly unstable, and HbF Xin Jin ($^G\gamma119$ [GH2] Gly→Arg).[65] A mutation at the same site, but not the same amino acid as in Hb Poole, has also been identified in β chains (Hb Wien [β130 Try→Asp]).

Also found in HbF is the equivalent of M Hbs in the β chains: HbF-M Fort Ripley, which has a cyanotic phenotype in the newborn and corresponds to substitution of the proximal histidine, γ92 (F8) His→Tyr. It is perfectly equivalent to Hb Hyde Park. The other mutation, HbF-M Osaka,[66] involves the distal histidine, γ63 (E7) His→Tyr, and is equivalent to HbM Saskatoon. Newborns with α-chain substitutions of the proximal or distal histidines have the same cyanotic phenotype as that of adults, with the cyanosis appearing early in the neonatal period.[67,68]

Finally, one high-affinity variant has been described: HbF Onoda[69] ($^G\gamma146$ [HC3] His→Tyr).

Hemoglobin A$_2$

HbA$_2$ is present both in the neonatal period and during the rest of an individual's life and is a product of the combination of α chains with δ chains ($\alpha_2\delta_2$). The δ gene is expressed at a very low level. HbA$_2$ represents about 2.4% of the Hbs present in normal hemolysates. The δ gene resides in the cluster of β-like genes between the pseudo-β gene and the β gene.

δ Gene

The δ gene arose from a duplication of the β gene about 40 million years ago (although one cannot exclude the possibility that gene conversion could have erased differences of an older gene). The δ gene also exists and is expressed at low levels in New World primates (1% to 6%). In some Old World primates, the δ gene is present but not expressed. The δ gene is absent in other mammals. In any case, the distribution among animals suggests that this was the last globin gene to emerge in the β-like gene cluster. Its relatively recent appearance (or recent gene conversion) explains why the δ chain exhibits only 10 sequence differences from the β gene.

The low level of transcription of the δ gene might be the consequence of changes in the 5′ flanking region. Of the three CCAAT box-like sequences, none is perfectly conserved. Instability of δ-mRNA may also contribute to poor expression of the δ gene.

Functional and Structural Aspects

HbA and HbA$_2$ have similar ligand-binding curves, although the latter has slightly higher O$_2$ affinity. The Bohr effect, cooperativity, and the response to 2,3-DPG are identical.

Among the differences are that the fact HbA$_2$ is more thermostable because of a change at Arg-δ116. This Arg forms a salt bridge with Pro-α114, thereby increasing the stability of the $\alpha_1\alpha_1$ packing contact even further. Another difference is that HbA$_2$ binds to the red cell membrane better than HbA does.[70]

The low levels of HbA$_2$ and the multiple functionally abnormal mutations found in primate δ-like genes have been suggested as reasons for the lack of functional importance of this minor component. According to this view, the δ gene is condemned to the biologic trash heap of history as a pseudogene. This conclusion presupposes that the only functional role of any Hb is to carry O$_2$. If so, HbA$_2$ is clearly useless. Alternatively, the increased binding of HbA$_2$ to the membrane could indicate another role for this Hb. It is necessary to know what proteins in addition to band 3 are capable of binding this Hb and whether such binding has any functional role. The finding of an HbA$_2$ polymorphism in the Dogon region of the Republic of Mali (see later) stimulates this thinking.

Mutational Events Involving the δ Gene

Nearly 80 amino acid substitutions, all resulting from single base changes, have been described in HbA$_2$. This might be the tip of the iceberg because these substitutions are difficult to detect. Two mutations, HbA$_2$ Wrens (δ98 [FG4] Val→Met)[71] and HbA$_2$ Manzanares (δ121 [GH4] Glu→Val),[72] are unstable. HbA$_2$ Canada (δ99 [G1] Asp→Asn)[73] has very high affinity for O$_2$, but because of its low level, no erythrocytosis is present.

A common mutation, found mostly among African Americans and Africans, is HbA′$_2$, also called HbB$_2$ (δ16 [A13] Gly→Arg). In Africa, it has been described in samples from different geographic locations, one of which is Ghana. HbA′$_2$ has been found at polymorphic rates in one of the castes in the Dogon region of the Republic of Mali. Haplotype analysis of the Mali β-like gene cluster demonstrates that all unrelated persons carrying this mutation have the same haplotype. Samples from unrelated African Americans with this mutation also demonstrate haplotype homogeneity. Hence, it is possible that HbA′$_2$ arose in Africa unicentrically and was distributed to other regions of Africa by gene flow.

An interesting set of mutational events involves unequal crossover between the δ gene and the β gene. Such crossover generates Hbs with portions of δ chains and portions of β chains. They are called Lepore-type Hbs after the first family described. The first three exam-

ples of this type of event were characterized in heterozygotes by low levels of the Lepore-type Hb (about 20%), electrophoretic migration similar to that of HbS, and a thalassemic phenotype (microcytosis, hypochromia, and hemolytic anemia). In homozygotes for this condition, severity varies from transfusion dependency to moderate anemia. Groups at risk are principally Italians, Greeks, and Yugoslavians (the latter being the most severely affected), but examples have been found in Turkish Cypriots, inhabitants of Papua New Guinea, African Americans, Indians, and Romanians.

Hb Lepore Hollandia, Hb Lepore Baltimore, and Hb Lepore Washington-Boston (the first described)[74-76] have different lengths of the δ sequence in the N-terminal portion of the hybrid chain and complementary portions of the β chains at the C-terminal end. All have a total of 146 amino acids. The more recently described Lepore-type Hb, Hb Parchman, is a patchwork in which a segment of the β sequence is located in the center of the chain. The location of the crossover is uncertain because with only 10 amino acid differences between the δ and β chains, there are too few informative sites.

If a Lepore-type unequal crossover occurs, an anti-Lepore Hb molecule is also generated, but finding it depends on its prevalence and luck. HbP Nilotic is the anti-Lepore of Lepore Hollandia. Hb Lincoln Park is probably the same with an added deletion at position δ137. Hb Miyada and HbP Congo could be anti-Lepores of Lepore Hbs that are yet to be found. Electrophoretically, HbP Congo, HbP Nilotic, and Hb Lincoln Park migrate like HbS, whereas Hb Miyada and Hb Parchman migrate like HbC.

Variation of Hemoglobin A₂ Levels with Other Clinical Conditions

Levels of HbA$_2$ are elevated in a number of conditions; in some instances this feature is of diagnostic value. The most common and important clinical instance is β-thalassemia (see Chapter 20). HbA$_2$ is also elevated in sickle trait, in blood from patients with SS disease, particularly SS disease with α-thalassemia, and in acquired conditions such as megaloblastic anemia and hyperthyroidism. HbA$_2$ may also be elevated in patients with malaria. Elevation of HbA$_2$ is not due to an increase in the synthesis of δ chains but is a consequence of the preferential assembly of δ with α chains, particularly if β chains are in short supply.[77] Decreased levels of HbA$_2$ are found in α-thalassemia, δβ-thalassemia, and δ-thalassemia and in hereditary persistence of HbF, either because the δ gene is deleted or because the α chains are more avid for γ or β chains than for δ chains. A decrease in HbA$_2$ is also seen with iron deficiency, but it returns to normal after iron therapy.

Embryonic Hemoglobins

At 4 to 14 weeks of gestation, the human embryo synthesizes three distinct Hbs in yolk sac–derived primitive nucleated erythroid cells: $\zeta_2\varepsilon_2$ (Hb Gower-1), $\zeta_2\gamma_2$ (Hb Portland), and $\alpha_2\varepsilon_2$ (Hb Gower-2).[78] ζ- and ε-globin chains are expressed before the γ- and α-globin chains. After establishment of the placenta, at 14 days of development, embryonic Hbs are replaced by HbF, but ζ- and ε-globin chains can be found in definitive fetal erythrocytes.[79] At 15 to 22 weeks of gestation, 53% of fetal cells contained ζ-globin chains and 5% had ε-globin chains. At term, cord blood contained 34% and 0.6% of ζ- and ε-globin chain–positive cells, respectively. Erythrocytes from normal adults do not contain embryonic globins.

Developmental timing of the synthesis of embryonic Hbs has been studied in embryonic erythroid cells.[80] Embryonic, fetal, and adult globins are synthesized in vivo and in cultures of erythroid burst-forming units in the yolk sac (where primitive erythropoiesis occurs) and in liver cells (site of definitive erythropoiesis). Similarly, the adult α-globin gene and the corresponding embryonic α-like chains (ζ-globin gene) are coexpressed in the earliest murine erythrocyte progenitors.[81] From these studies and from the recent finding of embryonic Hb in cord blood, it appears that embryonic globin is expressed in both primitive and definitive erythroblasts, though in vastly different quantities. These results are compatible with the notion that the switch from embryonic to fetal globin synthesis represents a time-dependent change in programs of progenitor cells rather than a change in hemopoietic cell lineages.

Embryonic Hbs obtained from an in vitro expression system in the absence of any effector of Hb function, including Cl⁻, all have O$_2$ affinity and ligand-binding rates similar to those of HbA.[82] In the presence of organic phosphates, the O$_2$ affinity of $\zeta_2\varepsilon_2$ and $\alpha_2\varepsilon_2$ is lowered, though to a lesser extent than for normal HbA. This demonstrates that ε-globin chains do bind 2,3-DPG, but less than β chains do. Hb Portland binds organic phosphates even less well, which is not surprising because its central cavity is formed by γ-globin chains (see earlier discussion).

Decreased rates of O$_2$ dissociation from embryonic Hbs appear to be responsible for the high O$_2$-binding affinity of the embryonic proteins.[83] The pH dependence of the O$_2$ dissociation rate constants also accounts for the rather unusual Bohr effects characteristic of embryonic Hbs. In $\alpha_2\varepsilon_2$ (Hb Gower-2),[84] the tertiary structure of the α-globin chain is unchanged from that of HbA and HbF.

Crystallographic data on the CO form are available for $\alpha_2\varepsilon_2$ (Hb Gower-2).[85] When compared with the structures of HbA and HbF, the tertiary structure of the α-globin chain is unchanged. The ε-globin chain has a structure very similar to that of the β-globin chain, with small differences in the N-terminal and A helix.

The most distinct difference in Hb Gower-2 and HbA is a shift of the N-terminal and the A helix, similar to that seen in HbF. The α helix moves into the central cavity as a consequence of complex disruption of the N-

terminal region. This shift may explain the decrease in binding of 2,3-DPG to Hb Gower-2.

Finally, embryonic ζ- and ε-globin subunits assemble with each other and with adult α- and β-globin subunits into Hb heterotetramers in both primitive and definitive erythrocytes. The use of complex transgenic knockout mice that express these Hbs at high level has allowed functional characterizations of these hybrids.[86] The exchange of ζ chains for α chains increases P_{50} and decreases the Bohr effect, thereby increasing O_2 transport capacity. In comparison, the exchange of ε chains for β chains has little impact on these parameters. Hb Gower-1, assembled entirely from embryonic subunits, displays an elevated P_{50}, a reduced Bohr effect, and decreased 2,3-DPG binding in comparison to HbA. The data support the hypothesis that Hb Gower-2, assembled from reactivated ε-globin in individuals with hemoglobinopathies and thalassemias, would serve as a physiologically acceptable substitute for deficient or dysfunctional HbA. In addition, the unexpected properties of Hb Gower-1 make a primary role for it in embryonic development unlikely.

Mutations Affecting Embryonic Hemoglobins

The most common mutation producing lethal hydrops fetalis is the Southeast Asian (–/SEA) double α-globin gene deletion.[87] Erythrocytes from adults heterozygous for the (–/SEA) deletion have minute amounts of embryonic ζ-globin chains detectable by anti–ζ-globin monoclonal antibodies. The majority of subjects are of Chinese, Filipino, or Laotian ancestry. The (–/SEA) double α deletion was the only abnormality in two thirds of these individuals. In others, this deletion was combined with α-globin or β-globin mutations or coincidental iron deficiency. Four other samples from (–/SEA) heterozygotes produced negative results with this immunologic assay. Anti-ζ–negative samples included deletions of the total α-globin region (–/Tot), single α-globin deletions, and a variety of β-globin mutations; normocytic samples with normal α genes also produced negative results. Benign triplicated ζ-globin genes were detected as well. Anti-ζ immunobinding testing provides rapid, simple, and reliable screening for the (–/SEA) double α-globin deletion, although it does not detect the (–/Tot) total α-globin deletions.

PATHOPHYSIOLOGY OF HEMOGLOBIN ABNORMALITIES

Nearly 1000 mutant human hemoglobins have been reported. Those involving the δ and γ subunits have been mentioned in earlier sections of this chapter. Because HbA ($\alpha_2\beta_2$) constitutes about 97% of Hb within the red cell after infancy, the most common and most important human Hb mutants pertain to either the α or the β subunit.

Assembly of Mutant Hemoglobins

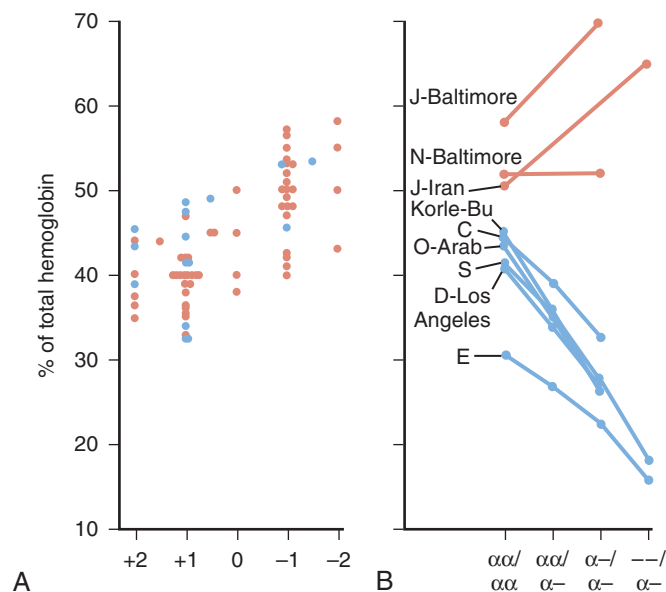
The composition of normal and mutant Hbs in the red cells of heterozygotes provides insight into the assembly of human Hbs.[88,89] The great majority of β-chain mutants are synthesized at the same rate as β^A and have normal stability. Therefore, heterozygotes would be expected to have equal amount of normal and mutant Hb. However, measurements of the proportion of normal and abnormal Hbs in heterozygotes have revealed unexpected variability. Figure 18-10 shows a comparison of stable β-chain mutants. Positively charged mutants, such as Hbs S, C, D Los Angeles, and E, account for significantly less than half of the total Hb in heterozygotes and are reduced further in the presence of α-thalassemia. In contrast, many of the negatively charged mutants are present in amounts exceeding that of HbA. In two heterozygotes who had a negatively charged mutant (HbJ Baltimore or HbJ Iran) in conjunction with α-thalassemia, the proportion of the mutant Hb was found to be increased further. Analysis of the proportion of β-chain mutant in heterozygotes suggests that alterations in surface charge contribute to different rates of assembly of the Hb tetramer. This hypothesis is supported by in vitro mixing experiments on normal and mutant subunits showing that when α chain is present in limiting amounts (mimicking α-thalassemia), negatively charged mutants are


FIGURE 18-10. A, Effect of charge on the proportion of abnormal hemoglobin in individuals heterozygous for 72 stable β-globin variants. Each data point represents a mean value for a given variant. The *blue points* (•) denote measurements of Huisman[90] by high-resolution chromatography. Substitutions involving a histidine residue were scored as a change of one-half charge. The "–1" group differs significantly from the "+1" group ($P < .001$) and from the "0" group ($P < .05$). **B,** Effect of α-thalassemia on the proportion of six positively charged β-chain variants (*blue dots*) and three negatively charged variants (*orange dots*). *(Data from Bunn HF, McDonald MJ. Electrostatic interactions in the assembly of haemoglobin. Nature. 1983;306:498-500; Rahbar S, Bunn HF: Association of hemoglobin H disease with Hb J-Iran (beta 77 His----Asp): impact on subunit assembly. Blood 1987;70:1790-1791.)*

formed much more readily than positively charged mutants.[91,92] This electrostatic model of Hb assembly has clinical implications. Differences in rates of assembly explain not only the low proportion in HbS–sickle C (SC) disease (see later) but also the differences in levels of HbA_2[89] and HbF[93,94] that accompany certain hematologic disorders.

The majority of human Hb mutants were discovered as an incidental finding, unassociated with any hematologic or clinical phenotype. However, a number of α- and β-globin mutants are associated with distinct clinical phenotypes, which fall into four broad categories: mutants with high oxygen affinity resulting in erythrocytosis, unstable mutants causing congenital Heinz body hemolytic anemia, low–oxygen affinity mutants and the M Hbs causing cyanosis, and mutants associated with a thalassemia phenotype.

High–Oxygen Affinity Hemoglobins: Erythrocytosis

Structural Defects

Mutations resulting in changes in the primary structure of the α or β chains can lead to changes in oxygen affinity. An example is shown in Figure 18-11. Increases in the O_2 affinity of Hb result from various mechanisms. In most instances, the changes in O_2 affinity are in concordance with our understanding of the structure-function relationships of Hb. In a few instances, the known alterations in the primary structure are not sufficient to explain the observed effect, given the state of our knowledge.

The mutations that generate high-affinity Hbs can arise from single point substitutions, double point substitutions (although some of these substitutions could be crossover events between two mutated chains), deletions, additions, frameshift mutations, and fusion genes.

The molecular mechanisms of ligand high-affinity Hb mutants can be grouped into four categories. (For more detailed information, see the article by Wajcman and Galacteros[94]).

1. Alterations in the switch region, the flexible joint, or the C-terminus in the $α_1β_2$ area of contact that favor the R (or oxy) state, either by stabilizing this conformer or by destabilizing the T (or deoxy) state; examples include Hb Bethesda (β145 [HC2] Tyr→His)[95] and Hb Kempsey (β99 [G1] Asp→Asn).[96]
2. Alteration of the $α_1β_1$ area of contact with disruption of the overall architecture of Hb that favors the R state. Examples include Hb San Diego (β109 [G11] Val→Met)[97] and Hb Crete (β129 [H7] Ala→Pro).[98]
3. Reduction in heme-heme interaction by restraining of quaternary conformation because of a tendency to aggregate or polymerize. In Hb Porto Alegre (β9 [A6] Ser→Cys), the additional cysteine sulfhydryl results in disulfide cross-linking and increases oxygen affinity.[99,100]
4. Mutations that decrease the affinity of Hb for 2,3-DPG; examples include Hb Providence (β82 [EF6] Lys→Asn→Asp)[101] and Hb Old Dominion (β143 [H21] His→Tyr).[102]

Identification of High–Oxygen Affinity Hemoglobins

In 1966, an 81-year-old patient complaining of mild angina was found to have erythrocytosis, an abnormal band in his Hb on electrophoresis, and red cells with increased O_2 affinity.[103] The abnormal Hb proved to be a Leu→Arg substitution in residue 92 of the α chains. Discovery of the first carrier of Hb Chesapeake opened a new chapter in the study of hemoglobinopathies because it demonstrated that a variant of this molecule could generate a distinct clinical syndrome. Discovery of this and other high-affinity Hbs has been useful in elucidation of the molecular mechanisms underlying the function of normal Hb.

Is the mild angina seen in the Hb Chesapeake pedigree a characteristic of carriers of high-affinity Hbs? Other members of the same pedigree and a large number of carriers of high-affinity Hbs generally have had no clinical consequences.

Patients with high-affinity Hbs have normal white cell and platelet counts and do not have splenomegaly. They sometimes have a family history of "thick blood," but a significant number of high-affinity Hbs are new mutations; that is, no abnormal Hb is found in parents or siblings.

The differential diagnosis of erythrocytosis is outlined in Box 18-1. Erythrocytosis should not be confused with polycythemia, in which numbers of white cells and platelets are elevated and splenomegaly is usually present. Diagnosis of the conditions in Box 18-1
FIGURE 18-11. Oxygen equilibrium curves of red cells from a healthy person (A/A) and those from a person heterozygous for Hb Hiroshima (Hiroshima/A). Oxygen pressure is plotted against oxygen saturation. *Vertical dotted lines* mark the typical Po_2 of the lungs (100 mm Hg) and the tissues (40 mm Hg). *Horizontal dotted lines* mark oxygen extraction (lungs minus tissues) in normal red cells (22.5%) and the reduction observed in high-affinity red cells (12.5%).

Box 18-1	**Differential Diagnosis of Erythrocytosis**

A. Primary increase in erythropoiesis (low plasma erythropoietin levels)
   1. Polycythemia vera
   2. Mutations of the erythropoietin receptor
B. Secondary increase in erythropoiesis (appropriately high erythropoietin levels)
   1. Hypoxemia related to
      a. Chronic pulmonary disease
      b. Right-to-left cardiac shunts
      c. Sleep apnea
      d. Massive obesity (pickwickian syndrome)
      e. High altitude
   2. Red cell hemoglobin defects
      a. High–oxygen affinity hemoglobins
      b. Absence or decrease in 2,3-diphosphoglycerate mutase
      c. Some cases of congenital methemoglobinemia
      d. Chronic carbon monoxide poisoning (smoking and work-related exposure)
C. Secondary increase in erythropoiesis (inappropriately high erythropoietin levels)
   1. Erythropoietin-producing neoplasms
   2. Erythropoietin-producing renal lesions
   3. Defects in oxygen sensing
      a. von Hippel-Lindau mutant (Chuvash polycythemia)
      b. Prolyl hydroxylase 2 mutants
      c. Hypoxia-inducible transcription factor-2α mutants
D. Idiopathic familial erythrocytosis

is facilitated by measurement of blood erythropoietin levels. Hypoxia of pulmonary or cardiovascular origin can be excluded by analysis of arterial blood gases. Affected patients characteristically have low Po_2 values and low O_2 saturation. Patients with red cells that have an altered capacity to transport O_2 have normal arterial Po_2.

Individuals with increased O_2 affinity can be investigated further by comparing the oxygen binding of phosphate-free hemolysates at physiologic pH and temperature with that of the red cells. The hemolysates identify intrinsic defects in the Hb molecule; study of intact red cells identifies other red cell factors (such as 2,3-DPG) that alter the O_2 affinity of otherwise normal Hb. Deficiency of 2,3-DPG mutase results in red cells with high O_2 affinity, normal O_2 affinity of the red cell hemolysate, and a very low 2,3-DPG concentration.[104] In all these cases the absorption spectrum of the hemolysates is normal.

Methemoglobin (Met-Hb) (such as that seen in congenital or toxic methemoglobinemia) and carboxy-Hb (secondary to CO poisoning)[105] can be identified by spectrophotometric examination of the red cell hemolysate. Several gas-measuring apparatuses are available in hospitals (e.g., the IL CO oximeter) that can give an accurate reading of Met-Hb and carboxy-Hb concentrations in whole blood.

Finally, many individuals with familial erythrocytosis have normal O_2 affinity, regardless of whether red cells or hemolysate is used. The inheritance pattern may be either dominant or recessive. Affected individuals may exhibit clubbing.[106] Two interesting groups of patients have erythrocytosis unrelated to Hb variants or enzyme abnormalities: erythropoietin receptor mutations and erythrocytosis caused abnormal oxygen sensing.

Erythropoietin Receptor Mutations. A number of families have been encountered in which erythrocytosis is inherited in an autosomal dominant manner as a result of truncation of the cytosolic portion of the erythropoietin receptor, which eliminates the negative regulatory domain of the receptor. The truncation does not allow the physiologically appropriate shutoff of the signaling cascade induced by erythropoietin binding and receptor dimerization. This leads to inappropriate erythropoietin signaling, increased red cell formation relative to plasma levels of erythropoietin, and high Hb levels.

Oxygen Sensing Mutations. In addition to mutations of globin, red cell enzymes, and the erythropoietin receptor, familial erythrocytosis can also be caused by inherited defects in the oxygen-sensing pathway leading to enhanced production of erythropoietin. Normally, erythropoietin mRNA expression is driven by the hypoxia-inducible transcription factor (HIF). In normoxic cells, HIF is markedly suppressed by proline hydroxylation of the HIF α subunit, thereby enabling it to bind to von Hippel-Lindau (VHL) protein, which mediates ubiquitylation of HIF-α and destruction in the proteasome.[107] A sizable population living in the Chuvash district of central Russia has autosomal recessive erythrocytosis because of a mutation in the VHL gene.[108] In addition, familial erythrocytosis with increased expression of erythropoietin may also be due to mutations in the prolyl hydroxylase 2 gene[109,110] and the HIF-2α gene.[111,112]

To summarize, in the identification of high-affinity Hb variants, the following points should be remembered:

1. Normal results on electrophoresis do not exclude the diagnosis of a high-affinity Hb.
2. A P_{50} value useful for diagnosis of a high-affinity Hb cannot be a value "calculated" from Po_2 data. (One has to be able to directly measure Hb saturation and Po_2 to obtain a useful P_{50} value. Types of apparatus such as the Hem-o-Scan are adequate for this purpose.)
3. Plasma erythropoietin levels are diagnostically useful.

Pathophysiologic and Clinical Aspects of High–Oxygen Affinity Hemoglobins

Most patients with high-affinity Hbs and erythrocytosis have a benign clinical course and no apparent complica-

tions. Although the first high-affinity Hb was identified in the course of a workup for angina, this association was probably fortuitous.

Patients with Hb Moke have been reported to have symptoms and to have benefited from phlebotomy and the transfusion of normal blood, but this is the exception and not the rule.[113] In a significant number of these patients, erythrocytosis is diagnosed during routine hematologic examination or when the pedigree of a propositus is examined. There are generally no physical findings, except occasionally a ruddy complexion. Hb and hematocrit levels are only moderately increased.

The most pressing reason to identify these high-affinity Hbs early and accurately is to avoid submitting the patient to unnecessary invasive diagnostic procedures and inappropriate and often dangerous therapeutic interventions. Some have undergone several courses of radioactive phosphorus (^{32}P) treatment based on a mistaken diagnosis of polycythemia vera. As a general rule, any patient suspected of having polycythemia vera who is about to undergo a serious therapeutic intervention should have a whole blood O_2 equilibrium measurement.

In patients who have had a physiologically significant high-affinity Hb all their lives, reasonable compensation is probably present throughout their lives. The reduced delivery of O_2 to tissues is compensated for primarily by increases in erythropoietin-induced red cell mass and also probably by increases in blood flow and changes in perfusion patterns in selected regions.

Erythropoietin-mediated increases in red cell mass respond to hypoxic stimuli.[114-116] Patients with several high-affinity Hbs and erythrocytosis have had normal urinary erythropoietin levels that dramatically increased when they were phlebotomized to a normal red cell mass. This effect was not observed in patients with idiopathic familial erythrocytosis. Patients with high-affinity Hbs have normal O_2 consumption, normal arterial Po_2 values,[114] slightly reduced mixed venous Po_2 values in some instances, and slightly decreased resting cardiac output. More important, these numbers change significantly after phlebotomy or measured exercise, with marked increases in cardiac output and lowering of mixed venous Po_2. The compensatory mechanisms might include increased perfusion efficiency. For example, patients with Hb Malmo have been shown to have increased myocardial blood flow, and patients with Hb Yakima have increased cerebral blood flow.

Following childbirth of women with high affinity mutants, no increase in morbidity or mortality in the infant or mother is observed, thus suggesting that compensatory mechanisms other than the differences in O_2 affinity between HbF and HbA (the former has lower affinity) must operate in pregnancies in which the mother's Hb has higher O_2 affinity than that of HbF.[117]

Why do the levels of Hb vary among carriers of the same high-affinity Hb? Charache and colleagues[117] observed that carriers of Hb Osler had the same O_2 affinity as patients with Hb McKees Rocks but that Hb levels were significantly higher (by more than 4 g/dL) in male carriers of the former. When O_2 transport was assessed in these two groups, only a small decrease in mixed venous Po_2 was observed. This could be a consequence of better O_2 extraction by carriers of Hb McKees Rocks; as a result, they do not require as much of an increase in red cell mass as needed for those with Hb Osler.

These results imply that epistatic (modifier) genetic effects might be operating, thus making the extent of increase in red cell mass variable according to a person's genetic makeup. Charache and colleagues[117] have pointed out that adaptation to hypoxia at high altitude is also different in different ethnic groups. Among the Sherpas of Nepal, a lower hematocrit value, no chronic mountain sickness, and a normal O_2 equilibrium curve are found, whereas in the populations adapted to the Andes (Quechuas and Aymaras), a higher hematocrit value, chronic mountain sickness, and right-shifted O_2 equilibrium curves are observed. These findings suggest that adaptation might involve a choice among several possible strategies (with potential differences in success) according to the different genetic background.

Should carriers of high-affinity Hbs undergo phlebotomy? The preceding discussion suggests that patients with high-affinity Hbs have a reasonable compensation for their abnormality with correction of O_2 delivery to tissues despite increases in blood viscosity; therefore, no intervention is needed. Results of exercise studies before and after phlebotomy in patients with Hb Osler showed no need for phlebotomy.[118] Nevertheless, as mentioned earlier, there are reports of individual patients who have benefited from the procedure. Perhaps, in some patients other factors interfere with the normal compensation for a high-affinity Hb and the increased viscosity may become a burden. These are exceptional patients, and prudence dictates a conservative approach and review of the patient's condition at 6-month intervals during the first few years after diagnosis. In older patients, attention to coronary status is recommended.

Conditions of low ambient Po_2 (e.g., unpressurized airplane cabins or living or climbing in mountains) do not represent a risk to patients with these high-affinity Hbs. In fact, they are better equipped than the average person to handle such situations because their Hbs bind O_2 avidly.[118a]

Low–Oxygen Affinity Hemoglobin Mutants: Cyanosis

Carriers of some low–O_2 affinity Hb variants have a slate gray color of their skin and other teguments. Cyanosis can be present from birth in the α-chain mutants and from the middle to the end of the first year of life in the β-chain mutants. This differential pattern results because α chains are expressed from the second trimester of fetal life whereas β chains begin to be synthesized in the perinatal period and do not reach significant levels until

about 6 months of age. Cyanosis caused by abnormal Hbs has to be distinguished from other more common causes, particularly pulmonary and cardiac disorders.

Many fewer low-affinity than high-affinity Hbs are described. They can be classified as resulting from the following three structural perturbations, which are discussed at length later:

1. Alterations in the switch region, the flexible joint, or the C-terminal of the $\alpha_1\beta_2$ area of contact that favor the T state, either by stabilizing this conformer or by destabilizing the R state. Examples include Hb Kansas (β102 [G4] Asn→Thr), Hb Beth Israel (β102 [G4] Asn→Ser),[119] and Hb Bruxelles (β42 [CD1] Phe→0).[120,121]

2. Steric hindrance of the heme resulting in decreased affinity for ligands. An example is Hb Chico (β66 [E10] Lys→Thr).

3. Alteration of the $\alpha_1\beta_1$ area of contact with disruption of the overall architecture of the Hb that favors the T state. Examples include Hb Yoshizuka (β108 [G10] Asn→Asp) and Hb Presbyterian (β108 [G10] Asn→Lys). Affected carriers usually have mild anemia and no cyanosis.

Hb Beth Israel[119] was found in a person of Italian descent, but the abnormal Hb was not detected in his parents. The propositus exhibited clinically apparent cyanosis involving his fingers, lips, and nail beds.[119] He had been severely disciplined in the past for constantly having "dirty hands," and the abnormal skin color was not noticeable to him or his parents. The cyanosis was detected by a surgeon about to perform a herniorrhaphy. As shown in Figure 18-12, whole blood P_{50} was 88 mm Hg (normal is 26 mm Hg), and arterial blood was only 63% saturated despite a normal P_{O_2} of 97 mm Hg. Red cell 2,3-DPG was mildly elevated (20 mmol/L). The hemolysate showed low O_2 affinity and a normal Bohr effect. The molecular mechanism involved here is the same as that in Hb Kansas: the amino acid replacement at the $\alpha_1\beta_2$ interface destabilizes the R quaternary structure.

Pathophysiologic Considerations

Low-affinity Hbs generally deliver more O_2 to tissues. The difference between O_2 binding at 100 mm Hg (lungs) and 40 mm Hg (tissues) in a low-affinity curve can be twice as high as that of a normal O_2 equilibrium curve. However, the increase in oxygen extraction is not monotonic with the increase in P_{50}. Hence, patients with moderately right-shifted red cell O_2 equilibrium curves (P_{50} of 35 to 55 mm Hg) could be "anemic." Less oxygen-carrying capacity is needed because of the enhanced oxygen unloading (see the Fick equation, discussed earlier). However, no anemia should be expected in patients with severely right-shifted curves ($P_{50} \approx$ 80 mm Hg). Findings in patients with Hb Kansas, Hb Beth Israel, Hb Titusville, and Hb Seattle confirm this analysis. Clinically apparent cyanosis is observed in
FIGURE 18-12. Oxygen equilibrium curves of normal red cells (*triangles*) and red cells from a patient heterozygous for Hb Beth Israel before (*open circles*) and after (*closed circles*) depletion of 2,3-diphosphoglycerate (2,3-DPG). The P_{50} for Hb Beth Israel–containing cells was 88 mm Hg (normal, 27 mm Hg). The patient's cells depleted of 2,3-DPG had a P_{50} of 55 mm Hg. Normal red cells subjected to the same procedure had a P_{50} of 16 mm Hg. The heterozygous patient's red cells have a biphasic or triphasic curve composed of the oxygen affinity curves of normal hemoglobin (particularly the bottom portion of the composite patient curve), the abnormal hemoglobin Beth Israel (top of the composite curve), and probably hybrid molecules containing one β Beth Israel chain and one normal β chain (intermediate portion of the curve). (*After Nagel RL, Joshua L, Johnson J, et al. Hemoglobin Beth Israel: a mutant causing clinically apparent cyanosis. N Engl J Med. 1976;295:125.*)

carriers with markedly right-shifted curves ($P_{50} >$ 50 mm Hg).

The effect of the right-shifted curve on the level of 2,3-DPG is of interest. In erythrocytes, 20% of the conversion of 1,3-DPG to 3-phosphoglycerate is done indirectly through the formation of 2,3-DPG. The level of red cell 2,3-DPG rises in conditions associated with hypoxia. This effect is related to the decrease in O_2 saturation of red cells and is independent of the presence of hypoxia per se; therefore, it applies to the low-affinity Hbs despite the absence of tissue hypoxia.

Desaturation increases intraerythrocytic pH as a result of deoxy-Hb binding more protons than oxy-Hb does (Bohr effect). This slight red cell alkalosis stimulates two enzymes involved in 2,3-DPG synthesis: phosphofructokinase, which controls the overall glycolytic rate, and 2,3-DPG mutase, which directly controls the rate of 2,3-DPG synthesis. In addition, high pH inhibits 2,3-DPG phosphatase. Hence, increased pH simultaneously increases the synthesis of 2,3-DPG and decreases its destruction. Finally, relief of end-product inhibition may also be involved. Red cells with low-affinity Hb have an increased proportion of deoxy-Hb and will bind more 2,3-DPG, thereby decreasing free 2,3-DPG and thus inhibiting 2,3-DPG mutase[25] (see Fig. 18-9).

Identification of Low–Oxygen Affinity Hemoglobin Variants

The presence of a low-affinity Hb should always be considered in patients with cyanosis, particularly when cardiopulmonary causes can be ruled out. In patients with cyanosis of unknown origin, it is advisable to perform electrophoresis of Hb and measure whole blood P_{50} before expensive or risky invasive diagnostic procedures are undertaken. The search for low-affinity Hbs as the explanation for anemia is less compelling because the yield is very low and the tests are not cost-effective. Nevertheless, if other investigations prove to be fruitless, unexplained normocytic anemias can be explored with the aforementioned tests.

A simple "bedside" test (even able to be performed at the bedside) to distinguish low-affinity Hbs and cardiopulmonary cyanosis from methemoglobinemia, the presence of M Hbs, and sulfhemoglobinemia is to expose blood from the patient to pure O_2. This will turn the purple deoxy-Hb in normal venous blood and that of patients with low-affinity Hbs to the bright red color of oxy-Hb. In contrast, the blood of patients with methemoglobinemia, sulfhemoglobinemia, or M Hbs retains its abnormal color despite exposure to O_2.

M Hemoglobins: Cyanosis

Description and Pathophysiologic Features of the M Hemoglobins

Horlein and Weber[122] described a family with congenital cyanosis caused by abnormal red cells 1 year before Pauling's discovery of HbS. The defect was autosomal dominant and was produced by red cells with an abnormal pigment that was similar to Met-Hb. The genetic defect resided in the globin and not in the heme, based on recombination experiments in which the patients' globin was bound to normal heme and the patients' heme to normal globin. The amino acid substitutions characterizing three of these M Hbs were determined by Gerald and Efron.[123] About the same time, the Japanese[124] solved the problem of hereditary nigremia (kuroko or "black child") observed in the Shiden village of the Iwate prefecture for more than 160 years. They found a brownish colored Hb in the hemolysate of a patient with this condition, which was later called Hb Iwate.

In the M Hbs, each mutated globin chain (α or β) creates an abnormal microenvironment for the heme iron in which the equilibrium is displaced toward the oxidized or ferric state. The combination of the iron (Fe^{3+}) and its abnormal coordination with the substituted amino acid generates an abnormal visible spectrum that resembles but is different from Met-Hb (oxidized heme iron in a normal globin chain). The strength at which the abnormal hemes are locked into this situation differs from one M Hb to another.

In four of the five known M Hbs, the distal or proximal histidine that interacts with the heme iron is replaced by tyrosine, either in the α chains or in the β chains. In the fifth, HbM Milwaukee-I, Val-β67 (E11) is replaced by a glutamic acid whose longer side chains can reach and perturb the heme iron.

Several molecular abnormalities are associated with the M Hbs. They can be classified into the following categories.

Weak Heme Attachment. X-ray crystallographic studies of deoxy-HbM Hyde Park (β92 [F8] His→Tyr) showed a loss of 20% to 30% of the heme.[125] Others detected a minor component (5%) in the hemolysate of these patients that migrated between HbA₂ and HbA Hyde Park.[126] The α chains of the abnormal component were normal, but only one of the two β^{HP} chains contained heme.

In this context, the mutation in Hb Auckland (α97 [F8] His→Asn) is particularly interesting.[127] This mutation, which involve the proximal histidine, does not lead to methemoglobinemia, as do other mutations of the proximal histidine, but to instability and accelerated heme loss. The clinical picture is a mild compensated hemolytic anemia but not methemoglobinemia.

Binding of the Iron to the Remaining Histidine and to the Newly Introduced Tyrosine. In β^M chains (Hb Hyde Park) and α^M chains (HbM Iwate), the proximal F8 histidine is replaced by tyrosine. Crystallographic analysis of HbM Hyde Park showed that the Tyr must be accommodated by movements of the F helix, which appears to be largely destabilized.[125]

The findings in HbM Iwate (α87 [F8] His→Tyr) are the opposite. Here, crystallographic studies[125] show that the E helix of the α chains is displaced toward the heme plane by about 2 Å, which enables the heme iron to bind to the distal histidine (α58 [E7]).[128-130]

The distal histidines (E7) are substituted by tyrosines in the β^M chain of HbM Saskatoon (β63 [E7] His→Tyr) and the α^M chain in HbM Boston (α58 [E7] His→Tyr). In HbM Boston, as illustrated in Figure 18-13, the tyrosine surprisingly fills the fifth coordinating position of the heme iron despite the presence of a normal proximal histidine.[131] This bond moves the plane of the heme sufficiently to make interaction between the proximal histidine and the heme iron impossible. No crystallographic data are available on HbM Saskatoon.

Finally, HbM Milwaukee-I is unique among the M Hbs in that it is not a mutation of the proximal or distal histidines but a mutation of a nearby residue (67Val [E11]). When substituted by Glu, it perturbs the heme iron and generates an M Hb (defined as a variant having an abnormal Met-Hb–like spectrum). Other mutations at that site, such as Hb Bristol (Asp) or Hb Sidney (Ala), are unstable or have low affinity but do not generate an abnormal ferric state of the heme iron. The carboxylic group of the new glutamate in β^M Milwaukee occupies
FIGURE 18-13. Schematic depiction of the crystallographic findings in HbM Boston (**A,** α58 [E7] His→Tyr) and HbM Milwaukee-I (**B,** β67 [E11] Val→Glu) versus those of normal hemoglobin. *(A, After Pulsinelli PD, Perutz MF, Nagel RL. Structure of hemoglobin M Boston, a variant with a five-coordinated ferric heme. Proc Natl Acad Sci U S A. 1973;70:3870. B, after Perutz MF, Pulsinelli PD, Ranney HM. Structure and subunit interaction of haemoglobin M-Milwaukee. Nature. 1972; 237:259.)*

the sixth coordination position of the iron, and the proximal histidine maintains its role in binding iron at the fifth coordinating position.[132] This situation, of course, stabilizes the abnormal ferric state of HbM Milwaukee-I.

Oxygen-Binding Properties and R→T Transition of M Hemoglobins. HbM Milwaukee-I, HbM Hyde Park, and HbM Boston all adopt a deoxy or deoxy-like conformation upon deoxygenation of the two normal chains (despite the fact that the abnormal chains cannot deoxygenate). This finding helps us understand the function of normal Hb; that is, after two hemes become deoxygenated, the molecule as a whole adopts a deoxy conformation (T state).

HbM Milwaukee-I, HbM Saskatoon, and HbM Hyde Park adopt the R state when the two normal chains are oxygenated. Nuclear magnetic resonance studies on HbM Milwaukee-I[133] also support a conformational change when the normal hemes are oxygenated. In contrast, HbM Iwate is in the crystallographic T-configuration state when the normal hemes are in the ferric state. This explains its decreased affinity. The molecule does not shift to the R state when the normal hemes are liganded and remains in the low-affinity T state. Similarly, in HbM Boston the deoxy-Hb crystal remains intact after oxygenation, thus suggesting that no conformational change has occurred.[131]

The reason that HbM Boston and HbM Saskatoon have different properties (despite their common substitution of the distal histidine) is that the former does not

change conformation when oxygenated and the latter does. Why β chains differ from α chains when their distal histidine is substituted has not been resolved.

Iron Oxidation and Spectral Characteristics. The fundamental characteristic of the M Hbs is that their hemes are stabilized in the abnormal ferric state. Hence, they exhibit an abnormal visible spectrum that can easily be distinguished from that of normal methemoglobin A. This characteristic separates these variants from Hb mutants that have a tendency to form normal Met-Hb, such as Hb Saint Louis,[134] Hb Bicêtre,[135] HbI Toulouse,[136] and Hb Seattle,[137] all of which are unstable.

Clinical Aspects and Diagnosis

The predominant clinical feature associated with M Hb carriers is cyanosis.[138-148] The skin and mucosal membranes may be brownish or slate colored, more like the coloration seen in methemoglobinemia, but not as blue-purple as the much more common cyanosis due to increased deoxyhemoglobin. The distinction is subtle and might not be apparent without contrasting the two conditions simultaneously. The reason for the difference is that the color of the skin is induced by Hb molecules that have an abnormal Met-Hb state rather than by the presence of more than 5 g/dL of deoxy-Hb. The cyanosis is present from birth in individuals with α-chain abnormalities and from the middle of the first year in those with β-chain mutants. In addition, a mixture of the abnormal pigment and increased desaturation of the normal chains are observed in the low-affinity M Hbs (HbM Boston and HbM Iwate).

Affected persons apparently have normal life expectancy and no dyspnea or clubbing. A mild hemolytic anemia (with an increased reticulocyte count) has been observed in HbM Hyde Park and can be explained by instability of the Hb induced by partial loss of the hemes.

The possibility of M Hb should be considered in all patients with abnormal homogeneous coloration of the skin and mucosa, particularly when pulmonary and cardiac function is normal. The diagnosis can be reinforced by observing an abnormal brown coloration of a blood sample. To distinguish this coloration from that caused by Met-Hb, the addition of potassium cyanide to the hemolysate is useful. Hemolysates containing Met-Hb turn red; those containing M Hb often change color more slowly. The rate of color conversion varies among the M Hbs. A recording spectrophotometer is required for definitive diagnosis.

Electrophoresis is of limited value because the oxy forms are not separable from normal Hb by cellulose acetate. Agar electrophoresis is preferable.

Perhaps the greatest hazard for carriers of M Hb is misdiagnosis and the risk of expensive and hazardous workups. A 1-week-old infant underwent a Blalock procedure because of misdiagnosis of pseudotruncus arteriosus. When the family study was completed many years

later, the father and child were identified as carriers of HbM Boston.

Unstable Hemoglobin Variants: Congenital Heinz Body Hemolytic Syndrome

Some Hb mutants have substitutions that alter the solubility of the molecule in the red cell.[149] The intraerythrocytic precipitated material derived from the unstable abnormal Hb is detectable by a supravital stain as dark globular aggregates called Heinz bodies (HBs). These intracellular inclusions reduce the life span of the red cell and generate a hemolytic process of varied severity called congenital HB hemolytic anemia.

Structural Abnormalities Involved in Unstable Hemoglobins

Substitutions in the primary sequence can lead to alterations in the tertiary or quaternary structure and result in a globin polypeptide chain or a Hb tetramer that is relatively unstable and tends to precipitate inside the red cell. The structural alterations leading to this event can be classified as follows.

Mutations That Weaken or Modify Heme-Globin Interactions. Binding of heme to globin is important not only for the O_2-binding properties of the molecule but also for its stability and solubility. Such mutations include the following:

1. Substitutions that introduce a charged side chain into the heme pocket where a nonpolar side chain existed previously: examples are Hb Boras, Hb Bristol, Hb Olsted, Hb Himeji, and others
2. Deletions involving residues that directly interact with heme, such as Hb Gun Hill
3. Nontyrosine substitutions of the proximal histidine (F8), such as Hb Saint Etienne (also known as Hb Istanbul), HbJ Altgeld Gardens, Hb Mozhaisk, Hb Newcastle, Hb Iwata, and Hb Redondo (also known as Hb Ishehara)
4. Nontyrosine substitutions of the distal histidine (E7), such as Hb Zurich and Hb Bicêtre

Hb Zurich (β63 [E7] His→Arg) is an interesting mutation that deserves special mention.[150] Substitution of an arginine for the distal histidine in the β chains makes the space available for ligand binding around the iron much larger, thereby fundamentally changing some of its interactions with ligands.

Carriers of Hb Zurich exhibit an increased affinity for CO because of the increased space in the heme pocket. This is a protective mechanism of sorts. It does not allow the abnormal β chain to become ferric, which would increase its instability. Smokers with Hb Zurich have high levels of carboxy-Hb, but carriers who are nonsmokers also have abnormal carboxy-Hb levels. Because of the partially protective effect of carboxy-Hb

Zurich, hemolysis is less severe in smokers than in nonsmokers with this abnormal Hb.[150]

Carriers of Hb Zurich are especially susceptible to hemolytic crises induced by sulfanilamide. The increased aperture of the heme pocket also explains this phenomenon: sulfanilamide is capable of binding to the heme and producing Met-Hb directly. Again, CO has a protective effect.

Mutations That Interfere with the Secondary Structure of the Subunits. As previously mentioned, Hb is composed of more than 75% α-helical regions, and any disruption of this secondary structure reduces the solubility of the subunit. Unstable Hb mutants can result from introduction of proline into the helical structure or substitution of glycine by a mutation in invariant positions in the bands. About 15% of mutations responsible for unstable Hbs involve the introduction of a proline residue.

Hb Brockton (β138 [H16] Ala→Pro)[151] is associated with moderate anemia. It cannot be separated from HbA by standard electrophoretic procedures. Crystallography showed that the tertiary structure was disrupted in the vicinity of the mutated residue. Its molecular instability is probably the result of breakage of a buried hydrogen bond that normally links Ala-β138 with Val-β134, a task that the proline side chain cannot accomplish.

Hb Singapore (α141 Arg→Pro) is an unusual exception in which the introduction of a proline is not accompanied by instability. The reason is that the substituted residue is the last amino acid of the α chain, Arg141, and no disruption of an α helix takes place.

Mutations That Interfere with the Tertiary Structure of the Subunits. Hb is a globular protein, quite tightly bound, which means that the α-helical regions must be folded into a solid sphere. This design places enormous constraints on its three-dimensional structure. Substitutions of the sequence can occur with no change in solubility as long as (1) no charged residues (hydrophilic) are allowed to point inward, (2) no bulky side chains are allowed to substitute for less bulky residues inside the molecule, and (3) loss of critical nonpolar residues from the surface of the subunit is avoided. The latter includes hydrophobic residues that are located on the surface and serve to prevent water from invading the interior of the molecule.

Mutations That Affect Subunit Interactions: Interference with the Quaternary Structure. These mutations involve the introduction of charged residues into the interior or the loss of intersubunit contact hydrogen bonds or salt bridges in the $\alpha_1\beta_1$ contact. Normal oxy-Hb tetramer readily dissociates at the $\alpha_1\beta_2$ interface into αβ dimers. In contrast, breakdown of $\alpha_1\beta_1$ dimers normally occurs to a vanishingly small extent but is a great threat to the molecule because it generates Met-Hb and consequent instability. Dissociation of $\alpha_1\beta_1$ dimers generates monomeric α and β chains, which uncoil and loosen their

heme-globin interaction, thereby favoring Met-Hb formation. Several unstable Hb mutations involve residues located in the $\alpha_1\beta_1$ area of contact: Hb Philly,[152] Hb Peterborough,[153] Hb Stanmore,[154] HbJ Guantanamo,[155] and Hb Khartoum.[156]

Hyperunstable Hemoglobins. This term was coined by Ohba[157,158] to characterize unstable Hbs that are either barely detectable or undetectable in hemolysates. These Hbs are presumably synthesized normally but are rapidly destroyed in bone marrow, thus creating a phenotype closer to thalassemia than to the hemolytic anemia normally associated with unstable Hbs. Hb mutants associated with a thalassemic phenotype are discussed in a later section.

Clinical Characteristics of the Congenital Heinz Body Hemolytic Anemias

Anemia is the centerpiece of the syndrome, but its intensity varies widely among patients, depending on the Hb variant.

Unstable Hbs are uncommon mutational events generally limited to a single pedigree. One exception is Hb Köln (β98 [FG5] Val→Met), which has been detected in many different pedigrees and geographic locations. The time at which anemia appears depends on the chain affected. One of the α-chain mutants, Hb Hasharon (α47 [CE5] Asp→His), which is found predominantly among Ashkenazi Jews, produces significant hemolysis in newborns but is milder in adults.[159,160] In some carriers it produces a mild anemia, whereas no hemolysis is observed in other carriers within the same pedigree. Epistatic effects of other nonlinked genes are probably involved here.

Unstable γ-chain variants, such as HbF Poole, cause significant hemolysis in the first 3 months of life[65] that is ameliorated by the emergence of β chains at the end of the first year.

Patients with unstable Hb may have hemolytic crises associated with bacterial or viral infections or exposure to oxidants. Pyrexia and transient acidosis contribute to hemolysis because they increase Hb denaturation. Drugs (e.g., sulfonamides) have been directly implicated in hemolytic crisis associated with Hb Zurich, Hb Hasharon, Hb Shepards Bush, and Hb Peterborough. The crises are generally self-limited, and stopping the administration of all drugs is prudent. Patients are also susceptible to parvovirus B19–induced aplastic crises.

Patients with unstable Hbs can have characteristically dark urine or pigmenturia. The color change is not due to bilirubin but rather to the presence of dipyrrole methylenes of the mesobilifuscin group.[161] These compounds probably arise from nonenzymatic catabolism of heme. Fluorescent dipyrroles may also be present in HBs.[162]

The absence of pigmenturia does not exclude the diagnosis of unstable Hb because not all mutants exhibit pigmenturia. In addition, the extent of hemolysis does not correlate with pigmenturia because significant pigmenturia is seen with both Hb Köln (severe hemolytic anemia) and Hb Zurich (little hemolysis).

Congenital HB hemolytic anemias related to unstable Hbs are generally mild and do not require therapy except for supportive and preventive measures, including administration of folic acid to ensure that the overworked marrow does not become deficient in this nutrient, prevention and prompt treatment of infections, avoidance of pyrexia with the use of aspirin, and avoidance of oxidant drugs such as acetaminophen. In patients with more severe disease, hydroxyurea may be effective in lowering the hemolytic rate.[163]

The question of splenectomy arises for patients with more severe hemolysis. There is little doubt that the spleen plays an important pathophysiologic role in the destruction of HB-containing red cells. Nevertheless, this needs to be balanced with the role of the spleen in the susceptibility to pneumococcal infections early in life and the need to use antipneumococcal vaccines after splenectomy in childhood. There is additional concern that splenectomy may promote the development of thrombosis and pulmonary hypertension.[164] Splenectomy is beneficial, on balance, for patients with the most severe unstable hemoglobinopathies, and partial correction of the anemia has been achieved.[165] Nevertheless, the success of the splenectomy cannot be ensured.

Identification of Unstable Hemoglobins

Elements in the differential diagnosis of unstable Hbs consist of the following:

1. HBs spontaneously present in blood (less often) or induced by 24-hour incubation of a sterile sample in sterile saline and stained by supravital pigments
2. Abnormal Hb electrophoresis (sometimes a smeared band is observed); normal results are not diagnostically useful
3. Positive tests for heat or isopropanol stability

All these tests are useful and should be pursued because the results of any one of them could be negative. The heat and isopropanol stability tests are the least likely to be negative.

Because the spleen removes HBs efficiently, many patients with unstable Hbs lack HBs before splenectomy, and the differential diagnosis includes autoimmune hemolytic anemias and other disorders with nonspecific red cell morphology, such as glycolytic and other red cell enzyme defects, Wilson's disease, paroxysmal nocturnal hemoglobinuria, hereditary xerocytosis, and (very rarely) erythropoietic porphyria.

The differential diagnosis of an unstable hemoglobinopathy in an adult is the same as that for other causes of congenital HB hemolytic syndrome and acquired forms of HB hemolytic anemia (acquired methemoglobinemia, chemical and drug oxidants, and other conditions). In rare instances, several of these entities interact with each other to the detriment of the patient.[166]

Smear and Heinz Body Preparation. The blood smear reveals nonspecific abnormalities, including anisocytosis and sometimes hypochromia and microcytosis. Basophilic stippling is often prominent and is a useful clue to the diagnosis because it is uncommon in other hemolytic anemias, except for the rare pyridine 5′-nucleotidase deficiency. Howell-Jolly bodies and normoblasts may also be observed in the peripheral blood of splenectomized patients.

Detection of HBs requires the use of methyl blue or crystal violet supravital stains. HBs appear as irregular pale purple inclusions, singly or a few together. They are 2 µm in diameter or smaller and often appear to be attached to the membrane.[161] Sometimes HBs are apparent in fresh blood, but usually sterile incubation of the blood for 24 hours in the absence of glucose is required to elicit HBs. A sample of normal blood should always be run as a control. After splenectomy, red cells with HBs occur more often and are easier to detect. Indeed, in occasional patients HBs can be detected only after splenectomy.

Electrophoresis. Electrophoresis of Hb can demonstrate an abnormal component, but many times the unstable Hb appears as a diffuse band. This alteration is probably related to the partial denaturation of Hb molecules during electrophoresis (as a result of the heat generated) or during manipulations of the hemolysate. Occasionally, only precipitated material at the origin is observed. Many unstable Hbs are not detectable by electrophoresis.

Heat Stability Test. The heat denaturation test, which consists of incubation of a hemolysate for 1 or 2 hours at 50° C, is a simple and reliable procedure.[165,166] Normal hemolysates are stable under these conditions, and the presence of an unstable Hb is signaled by the appearance of a visible precipitate. Some abnormal Hbs, such as Hb Hasharon, precipitate at temperatures higher than 50° C. Irrespective of incubation temperature, controls are indispensable. Normal Hb begins to precipitate at about 55° C.

Other laboratory procedures are available. The isopropanol test[167] is used in many laboratories, but it gives false-positive results when the sample contains more than 5% HbF. HbF does not interfere with zinc acetate precipitation.[168] Mechanical agitation can also reveal the presence of unstable Hbs.[169]

Pathophysiology of the Heinz Body Hemolytic Syndrome Produced by Unstable Hemoglobins

Thermostability of Hemoglobins. When heat-unstable Hbs were related to the presence of an HB hemolytic anemia, the conceptual framework for understanding this syndrome was generated. Homeothermic mammals and birds have relatively thermostable Hbs. If a hemolysate is incubated for 1 or 2 hours at 50° C, little protein precipi-

tation occurs. This property is observed even among reptile Hb, though to a lesser degree. In amphibians and fish, the thermostability of Hb decreases substantially.

The molecular basis of thermostability is not clear. Perutz and Raidt[170] suggested that the thermostability of proteins, including Hb, is based on electrostatic interactions and salt bridge formations. Others[171] contend that hydrophobic interactions are critical, and some claim that both electrostatic and hydrophobic interactions are contributory.[172] Most of the evidence comes from structural analysis of proteins obtained from thermophilic and mesophilic bacteria[173] or from comparison of amino acid sequences in the Hbs of organisms living at different temperatures.[174]

Other contributions to thermostability come from the strength of the heme-globin bonds. Heme exchange between Hb and albumin and between Hbs decreases considerably when the Met-Hb heme is ligated with cyanide.[175] Cyanomethemoglobin has a stronger heme-globin attachment than Met-Hb does and is more similar to liganded Hb. Deoxy-Hb has an even tighter bond.

Denaturation of Hemoglobin and Hemichrome Formation. HBs, one of the hallmarks of the hemolytic syndrome generated by unstable Hbs, are the product of Hb denaturation. HBs probably contain a significant amount of heme-depleted globin chains.[172,176] The precipitated material is hemichromes.[177-180] As shown in Figure 18-14, these hemichromes are derivatives of the low-spin forms of ferric Hb that have the sixth coordination position occupied by a ligand provided by the globin: a hydroxyl group (—OH) or an unprotonated histidyl (reversible hemichrome) or a protonated histidyl (irreversible hemichrome).[181] Irreversible hemichromes seem to be an indispensable stage in the formation of HBs, and both α and β chains are present.[182]

Anemia with the Unstable Hemoglobins That Generate Heinz Body Hemolytic Syndrome. The primary cause of the anemia is the reduced life span of the red cells that contain HBs. Evidence indicates that HBs, at least in part, adhere to the cytosolic side of the membrane[183] by hydrophobic interactions and not through covalent bonds.[184,185]

Unstable Hbs generate considerable amounts of hemichromes, some of which bind to the negatively charged cytosolic domain of band 3,[186-189] a transmembrane protein that functions as the primary anion exchanger in the red cell. It is not surprising that these red cells exhibit decreased deformability, a characteristic that will condemn them to be preferentially trapped in the spleen, the organ that maintains red cell quality control.[190] It is possible that HB-containing red cells are pitted initially. The term *pitting* refers to the mechanism by which HBs and a portion of the overlying plasma membrane are excised from the cells during their passage through the spleen. This manipulation converts red cells

Reversible hemichromes　　　　　　Irreversible hemichromes
FIGURE 18-14. Diagrammatic representation of the structure of hemichromes showing the proximal histidine below the plane of the heme and the distal histidine above the plane. One or both of the histidines can be substituted. *(After Peisach J, Blumberg WE, Rachmilewitz EA. The demonstration of ferrihemochrome intermediates in Heinz body formation following the reduction of oxyhemoglobin A by acetylphenylhydrazine. Biochim Biophys Acta. 1975;393:404.)*

progressively into spherocytes through loss of membrane, which produces a rigid remnant that will eventually be eliminated from the circulation.

Other sources of membrane damage come from peroxidation and cross-linking of membrane proteins. These are probably related to the presence of free heme and iron and to free radicals generated during the formation of Met-Hb and denaturation of Hb.[191-194] Other evidence of membrane alteration is the presence of abnormal potassium (K^+) efflux in some of these cells.[190,195]

Another determinant of the anemia in patients with unstable Hbs is the O_2 equilibrium curve. The level of 2,3-DPG is generally normal,[196] but some variants have high or low O_2 affinity. As discussed earlier, persons with high-affinity unstable Hbs tend to have less anemia than those with low-affinity unstable Hbs. Finally, several unstable Hbs coexist with α- or β-thalassemia: the α-chain mutants Hb Suan-Dok and Hb Petah Tikva coexist in *cis* with α-thalassemia, and the β-chain mutant Hb Leiden coexists in *cis* with β-thalassemia.

Hemoglobin Mutations with Abnormal Assembly: Dominant Thalassemia Syndrome

The dominant thalassemia syndrome includes mutations in the coding region of the globin genes that lead to a significant deficit in synthesis and that are clinically manifested as autosomal dominant thalassemia. Examples include Hb Indianapolis (β112 [G14] Cys→Arg)[197] and Hb Manhattan (β109 [G11] → −G→ frame shift).[197]

Clinical Picture and Diagnosis

The dominant thalassemia syndrome is characterized by significant anemia, often transfusion dependent, by splenomegaly, and by a blood smear with prominent hypochromia, microcytosis, and basophilic stippling.[198] The reticulocyte count is often high. Inclusion bodies are frequently observed in erythrocyte precursors with supravital staining, which is why some authors call this syndrome "inclusion body thalassemia." The bone marrow shows considerable erythroid hyperplasia and evidence

of ineffective erythropoiesis. Finally, the full-fledged thalassemic syndrome is found in members of different generations in the same pedigree, often in one of the parents or progeny of the propositus. Although the syndrome is similar to thalassemia intermedia, an astute clinician can exclude this diagnosis when the intensity of the disease in the parents or descendants is equal to that seen in the propositus. Thalassemia intermedia usually results from homozygosity or double heterozygosity for much milder defects; hence, the parents or progeny have much milder disease. Nevertheless, lack of parental involvement does not exclude the diagnosis because the mutation can arise de novo. A clinical picture of thalassemia in a patient with an ethnic origin not associated with β-thalassemia should also increase suspicion of the clinician for this syndrome.

Electrophoresis might not reveal an abnormal band because the abnormal Hb either is synthesized at an extremely low level, is rapidly catabolized, or both.

Highly unstable α-globin variants, in contrast to β-globin variants, are usually phenotypically apparent only when they interact with other α-thalassemia mutations. A child with clinical and hematologic features consistent with those of β-thalassemia intermedia nonetheless had a DNA analysis that excluded β-globin gene mutations. Instead, the propositus had a novel deletion (β37 [C2] Pro→0 [Hb Heraklion]) in the $α_1$-globin gene in *trans* to a common Mediterranean nondeletional α-thalassemia mutation.[199] This deletion results in severe instability of the variant Hb, which interacts with the α-thalassemia mutation and causes a relatively severe dyserythropoietic anemia—an alternative phenotype associated with the highly unstable α-chain variants. The dyserythropoietic marrow is due to the premature destruction of early red cell precursors.

Pathophysiology

The molecular basis of the dominant thalassemia syndrome involves several types of changes: (1) single point mutations (substitutions and deletions) affecting, in particular, exon 3; (2) exon 3 chain length shortening (premature termination) or elongation (frameshift mutation leading to an altered stop codon); and (3) amino acid

replacements in α-globin that impair binding to α-globin stabilizing protein (AHSP). Such mutations include Hb Groene Hart (α119 [H2] Pro→Ser) and Hb Diamant (α119[H2]Pro→Leu).[200] For more information on AHSP, see Chapter 20.

What causes the severity of the phenotype of dominant thalassemia? The answer lies in the notion that in dominant thalassemia, the abnormal chain is synthesized at close to the normal rate but is rapidly destroyed because it cannot assemble into tetramers; inclusions are created and free radicals are generated as a result of oxidation of the heme groups to metheme.

Clinically Important Interactions among Mutant Hemoglobins

Hemoglobin C

HbS (β6 [A3] Glu→Val), HbC (β6 [A3] Glu→Lys), and HbE (β26 [B8] Glu→Lys) are the three most prevalent abnormal Hbs in humans. HbS and sickle cell disease are discussed in Chapter 19. HbE, which confers a mild thalassemia phenotype, is discussed in detail in Chapter 20.

The unique pathogenetic feature of HbC is its capacity to induce erythrocyte dehydration. In CC disease (homozygous state for the HbC gene), this pathologic change results only in mild hemolytic anemia. In SC disease, in which equal levels of HbS and HbC coexist, HbC accentuates the deleterious properties of HbS and produces a clinically significant disorder, though milder than sickle cell anemia.[201]

Origins, Selection, and Distribution of the Hemoglobin C Gene

HbC is the product of the β^C-globin gene generated by a <u>G</u>AG→<u>A</u>AG (Glu→Lys) substitution in codon 6 of the β-globin gene. The β^C mutation occurred originally among ethnic groups in Burkina Faso (previously Upper Volta). HbC reaches its highest rate of occurrence in central western Africa, and occurrence of the gene decreases concentrically outward from this region. It is also found in western Africa, west of the Niger River, and exclusively in areas where HbS is also present.[201]

The HbC gene exists at polymorphic rates (>1%), thus suggesting that its presence confers selective advantage to the carrier. Modiano and collaborators,[202] in a large case-control study performed in Burkina Faso on 4348 Mossi subjects, found that HbC is associated with a 29% reduction in the risk for clinical malaria in HbC heterozygotes (AC) ($P = .0008$) and a 93% reduction in HbC homozygotes (CC) ($P = .0011$). These findings establish the fact that HbC is selected for in malaria caused by *Plasmodium falciparum*. Balanced polymorphism[203] explains the selective advantage of the HbS trait and is based on the advantage of heterozygotes and the disadvantage of homozygotes. It does not seem to apply

to HbC because both heterozygotes and homozygotes have some level of advantage, and surprisingly, that of homozygotes is stronger. These findings, together with the limited pathologic changes in the AC and CC genotypes versus those of the severely affected SS and SC genotypes and the low occurrence of the β^S gene in the geographic epicenter of HbC, also support the hypothesis that in the long term and in the absence of malaria control, HbC interferes with the lysis of parasitized red cells in the late schizont state, thereby impairing the dispersion of merozoites.[204]

Properties of Hemoglobin C–Containing Erythrocytes

The erythrocytes of HbCC homozygotes have microcytic and hyperchromic target cells, microspherocytes, and cells with crystalline inclusions.[201] Target cells, a diagnostically useful feature, are presumably the consequence of the greater surface-to-volume ratio of HbCC red cells, which in turn is a consequence of their reduced water content (see later).

Red cell life span is shortened to approximately 40 days in HbCC disease. However, this is at least three times as long as the life span of cells in sickle cell anemia.[205]

Scanning electron microscopic examination of cells isolated from density gradients showed intracellular HbC crystals.[206] Freeze-fracture preparations, followed by electron microscopy, also showed intracellular crystals.[207] Circulating crystals can be detected in unperturbed wet preparations from individuals with HbC disease, but they are rare. Together, these observations are consistent with early reports of an increase in intraerythrocytic crystals in patients with HbC disease after splenectomy.[208]

Why do red cells that contain HbC crystals not induce vaso-occlusion? The answer to this riddle is that the crystal forms of oxy-HbC and deoxy-HbC differ. HbC crystals in the red cells of splenectomized patients with CC disease were found to be in the oxy state and melted after deoxygenation.[209] Moreover, when cells from venous and arterial blood were fixed and counted, there was a significant difference in the mean percentage of crystal-containing cells in the arterial circulation versus the venous circulation (1.6% ± 0.22% versus 1.1% ± 0.23%). Hence, the oxy-HbC crystals melt before they can do any damage to the microcirculation.

Effect of Hemoglobin C on Cell Density

A high mean corpuscular hemoglobin concentration (MCHC) and low intracellular water content are characteristics of HbC-containing cells. Red cell density is directly related to the MCHC. Cells in both HbC trait and HbC disease are denser than normal.[210,211] The average MCHC in CC disease, SC disease, HbC trait, and HbA cells is 38, 37, 34, and 33 g/dL, respectively. Cells in all four of these genotypes have a narrow density distribution such that the youngest and lightest cells differ from the oldest and most dense cells by only 3 to

4 g/dL. In contrast, cells in sickle cell anemia have a very wide density distribution. The reticulocytes of individuals with CC and SC disease and HbC trait are denser than normal reticulocytes. This implies either that these cells are denser than normal when they first enter the circulation or that their density changes within their first 24 hours in the circulation when they are still recognizable as reticulocytes.

Increased volume-regulated loss of red cell K^+ and water makes an HbC-containing cell dehydrated and more dense than normal.[210,211] This single feature may be responsible for all the abnormalities that have been detected in erythrocytes that contain high levels of this Hb.

Binding of Hemoglobin C to Cell Membranes

Like HbS, HbC interacts more strongly with the erythrocyte membrane than HbA does. This interaction has been studied by using changes in the fluorescence intensity of a membrane-embedded probe, the fluorescence of which is quenched when it is approached by Hb.[212-214] The cytoplasmic portion of band 3 was implicated as the binding site for both HbA and HbC.

In HbC, substitution of a charged lysine residue for β6 glutamic acid causes a very different pathophysiologic condition than the hydrophobic β6 valine present in HbS does. Whereas deoxy-HbS polymerizes, oxy-HbC has an increased tendency for intraerythrocytic crystallization, which along with cell dehydration caused by the HbC-induced loss of K^+ and water, is the basis of the pathophysiology of HbC disease, particularly the hemolytic process. As discussed later, similar mechanisms contribute to the pathologic changes in HbSC disease, with the addition that here, the presence of intraerythrocytic HbC induces a reduction in volume by loss of water and K^+, thereby increasing the tendency of HbS to polymerize.

HbC crystals are most likely to form in cells with low HbF content.[209] When the cells of individuals with CC disease are density fractionated, cells of the highest density have the lowest HbF content. In this dense cell fraction, no F cells contained HbC crystals. HbF inhibition of HbC crystallization might contribute to the potentially beneficial effects of hydroxyurea in HbSC disease in individuals who have an increase in HbF in response to treatment with this drug (see later).

Vaso-occlusive episodes are not a feature of HbC disease despite the presence of intraerythrocytic HbC crystals because as mentioned earlier, oxy-HbC crystals will melt when HbC cells approach the microcirculation in which Po_2 is low.

Pathophysiology of Hemoglobin SC Disease

Why is SC a "Disease"? Individuals who are compound heterozygotes for HbS and HbC have a disorder with clinical manifestations that are very similar to those of SS disease, though less severe. A critical question is why SC patients have significant morbidity whereas individuals with sickle trait have virtually no significant pathology. Three explanations have been proffered:

1. HbC enhances the polymerization of HbS (like HbO Arab, see later). Indeed, early in vitro studies suggested that this might be the case.[215-217] However rigorous mixing experiments of deoxygenated solutions of pure HbS and HbC under carefully controlled solvent conditions showed that the polymerization was identical to comparable mixtures of HbS and HbA.[218,219] Thus there must be another explanation for why HbSC is a disease whereas sickle trait is not.
2. The higher intracellular Hb concentration in SC red cells than in AS red cells leads to enhanced polymerization. As stressed in Chapter 19, the rate of polymerization of sickle Hb is exquisitely dependent on the intracellular Hb concentration. It has long been appreciated that SC red cells have a higher MCHC than AS red cells do. More recent studies of SC and CC cells by density gradients revealed that the presence of HbC results in dehydration, thus making red cells denser.[210,218]
3. SC red cell contain a higher proportion of HbS than HbAS red cells do. Patients with HbSC disease generally have about 50% HbS and 50% HbA. In contrast, individuals with sickle trait have about 35% to 40% HbS and 60% to 65% HbA. The higher amount of HbS in SC red cells can be explained by the importance of electrostatic attraction in the assembly of Hb tetramers within the developing red cell (see earlier, Assembly of Mutant Hemoglobins).[89] In AS cells, positively charged α subunits have a substantially higher rate of combination with $β^A$ subunits that have a strong negative charge than they do with $β^S$ subunits, which have a weaker negative charge. In contrast, in SC red cells the positively charged α subunits bind more readily to $β^S$ subunits than to $β^C$ subunits, which have an even weaker negative charge.[91]

Careful quantitative assessment of the second and third contributors, the intracellular Hb concentration and the fraction of HbS, indicated that they each contribute about equally to HbS polymerization and to the pathogenesis of HbSC disease.[218]

Cellular Factors Accounting for the Pathophysiology and Severity of SC Disease. Rarely, crystals may be observed in Wright- and vital dye–stained smears and in wet preparations from fingerstick blood samples.[210] When α-thalassemia is present with SC disease, the typical crystals are absent. The red cells of all patients with SC disease exhibit heavily stained conglomerations of Hb that appear marginated with rounded edges as opposed to the straight-edged crystals. Such cells have been called "billiard ball" cells. Both crystals and billiard ball cells are found in the densest fraction of cells from individuals with SC disease and represent aggregation of Hb distinct from the polymerization of HbS. An

enlarged, infarcted, and perhaps abnormally functioning spleen might fail intermittently in its pitting function and thus allow Hb crystals and aggregates to remain in the cell.

Regardless of the α-globin gene haplotype, the blood of patients with SC disease has additional abnormally shaped cells that are strikingly apparent on scanning electron microscopic examination. Typical are "folded cells," some of which have a single fold and resemble—to the gastronomically inclined—pita bread or a taco. These are most likely the cells that Diggs called "fat cells" because in Wright-stained smears they appear as wide bipointed cells. Other misshapen cells are triconcave triangular cells with three dimples, very much like those seen in acute alcoholism that Bessis termed "knizocytes." One remarkable shape was the "triple-folded cells" that appeared as two pita breads stuck together. These bizarre shapes are the product of an increased surface-to-volume ratio, which provides an excess of surface for the cytosol volume. Excessive surface is resolved largely by membrane folding.

Cation Content. The cation content of SC disease red cells is intermediate between that of normal and that of CC disease cells.[211] Oxygenated SC disease cells exhibit a volume-stimulated potassium efflux similar to that observed in sickle cell anemia and CC disease.[211] This transporter appears to be chloride dependent and stimulated by *N*-ethylmaleimide[220]; it is found in the young cells of normal control subjects and individuals with sickle cell anemia and SC disease. It is inhibited by deoxygenation through modulation of cytosolic magnesium (Mg^{2+}).[221-223]

SC disease cells also exhibit a diminished change in cell volume in response to variations in the osmolarity of the suspending medium, which is likely to be due to the volume-regulated potassium efflux. Volume-regulated K^+ efflux should have an adverse impact on the pathophysiology of disease because any increase in MCHC will aggravate HbS polymerization.

Correction of SC Disease. SC disease cells share the increased red cell density characteristics of all cells containing HbC. Because of the increased MCHC, the intracellular HbS concentration is raised to a level at which polymerization occurs under physiologic conditions. Reducing the MCHC in individuals with SC disease to normal levels of 33 g/dL by osmotically swelling SC cells results in normalization of many of the polymerization-dependent abnormal properties of these cells[206]: increased Hb-oxygen affinity (reduced in SC disease), a reduction in the viscosity of deoxygenated erythrocyte suspensions (increased in SC disease), a decrease in the rate of sickling (similar to that in sickle cell anemia), and a reduction in the deoxygenation-induced K^+ leak (greater than that observed in sickle cell anemia). At an osmolarity of 240 mOsm/L, SC cells become biconcave discs. This is a welcome feature of the rehydration of SC disease cells

because the discoid shape is indispensable for normal deformation of red cells in the microcirculation.

Better knowledge of the transport physiology and genetics of red cells could reveal interventions that can cure SC disease by changing the hydration status of SC cells.[224]

Hemoglobins O Arab, S Oman, and S

HbO Arab (β121 [GH4] Glu→Lys) is of special interest because double heterozygotes for HbS and HbO Arab have significant hemolytic anemia and red cells denser than normal, with some as dense as the densest cells found in sickle cell anemia. As with HbD Los Angeles (D Punjab) (β121 [GH4] Glu→Gln), HbO Arab copolymerizes with HbS, and as a result, compound heterozygotes have clinical manifestations similar to those of HbS disease. HbO Arab, having the same charge as HbC, is more strongly bound than HbS and is even more tightly membrane bound than HbC.[225] This suggests that both electrostatic charge and the protein conformation in the vicinity of the charged groups play a role in membrane binding.

All red cells from patients homozygous for HbO Arab were denser than normal red cells, as is observed for patients homozygous for HbC, and red cell density was strongly influenced by the presence of α-thalassemia, which resulted in an average red cell density slightly greater than that of normal (HbAA) red cells. Patients heterozygous for HbO Arab but without α-thalassemia had denser red cells, similar to those seen in patients with sickle cell disease, with some cells of normal density but with most cells being very dense.

Reticulocytes in patients homozygous for HbO Arab were found in the densest density fraction. Cation transport in patients homozygous for HbO Arab is abnormal, with enhanced K^+-Cl^- cotransport activity leading to red cell dehydration. The similarity of the charge and consequences of the presence of both HbC and HbO Arab, which are the products of mutations at opposite ends of the β chain, raises the possibility that this pathologic change is the result of a charge-dependent interaction of these Hbs with the red cell membrane or its cytoskeleton and that this abnormality is present early in red cell development.[77]

HbS Oman has two mutations in the β chains. In addition to the classic $β^S$ mutation, it contains a second mutation in the same chain (β121 [GH4] Glu→Lys) that is identical to the HbO Arab mutation. An informative pedigree of heterozygous carriers of HbS Oman segregates into two types of patients: those expressing about 20% HbS Oman and concomitant −α/α α-thalassemia and those with about 14% HbS Oman and concomitant −α/−α α-thalassemia.[225] Higher expressers of HbS Oman have a sickle cell anemia clinical syndrome of moderate intensity, whereas lower expressers have no clinical syndrome. In addition, higher expressers exhibit a unique form of irreversibly sickled cells shaped like a "yarn and

knitting needle," in addition to folded and target cells. The C_{SAT} (solubility of the polymer) of HbS Oman is identical to that of HbS Antilles, another supersickling Hb whose carriers express the abnormal Hb at 40% to 50%, with a clinical picture very similar to that of HbS Oman. Because the level of expression is so different and the clinical picture is so similar and on the basis of C_{SAT} values of the hemolysates, it was concluded that HbS Oman produces pathologic changes beyond its sickling tendencies. There is increased association of HbS Oman with the red blood cell membrane, the presence of dense cells by isopyknic gradients, the presence of folded cells, and accelerated K^+-Cl^- cotransport in red cells expressing more than 20% HbS Oman. Hence, the pathologic effect of heterozygous HbS Oman is the product of the sickling properties of the Val-β6 mutation, which are enhanced by the second mutation at β121, in addition to further enhancement by a hemolytic anemia induced by the mutation at β121. It is likely that the additional hemolysis results from the abnormal association of the highly positively charged HbS Oman (three charges different from normal Hb) with the red cell membrane.

19 | Sickle Cell Disease

Matthew Heeney and George J. Dover

HISTORY

Sickle cell anemia was first described in a West Indian dentistry student, Walter Clement Noel, by Herrick and Irons in 1910.[1,2] Sydenstricker and colleagues described the first cases in children, recognized the association with hemolytic anemia, and introduced the term *crisis* to describe periodic acute episodes of pain.[3] The pathologic basis of the disorder and its relationship to the hemoglobin molecule were defined in 1927 by Hahn and Gillespie.[4] Shortly after the application of moving-boundary electrophoresis to the separation of sickle from normal hemoglobin by Pauling and co-workers,[5] Neel[6] defined the genetics of the disorder and clearly distinguished sickle trait—the heterozygous condition (AS)—from sickle cell anemia—the homozygous state (SS). Further understanding of the molecular basis of the disorder was made possible by the finding that normal human hemoglobin is composed of two pairs of globin subunits: one pair that is invariant, the α chain, and another pair that is variable, the ε, γ, δ, or β chain. The relative ease with which sickle hemoglobin (HbS) could be isolated by chromatography or zone electrophoresis techniques led to Ingram's application of tryptic digestion, high-voltage electrophoresis, and paper chromatography to isolated HbS, with the result that the amino acid substitution in HbS is now known to be a valine instead of a glutamic acid in the number 6 position of the β chain. The α chain is normal.[7] The chemical nomenclature for HbS is therefore $\alpha_2\beta_2^{Glu6 \to Val}$. (See Fig. 19-1 for an overview of pathophysiology of the β^S mutation.) Excellent reviews of the history of sickle cell anemia are available.[8]

PATHOPHYSIOLOGY

Hemoglobin S Mutation

Origins. The sickle gene is a common mutant that in the heterozygous state provides some protection to infants who might otherwise succumb to cerebral falciparum malaria. The frequency of the sickle gene in a population parallels the historical incidence of malaria. Whereas the average incidence of the sickle gene among American blacks is approximately 8%,[9] its frequency is much higher in inhabitants of certain areas of Africa. Polymorphic sites around globin DNA and their linkages to the β^S gene indicate that this mutation may have developed independently and spontaneously at least five times.[10-12] However, analysis of nuclear and mitochondrial DNA from African populations suggests that a single mutation may have occurred 50,000 years ago.[13] In Africa, there are four major sickle haplotypes, each associated with a particular geographic region: "Senegal" (Atlantic West Africa), "Benin" (Central West Africa), "Bantu" (also called "CAR" for Central African Republic), and Cameroon.[11,14] The Benin type is found not only in Benin but also in Ibadan,[15] Algeria,[12] Sicily,[16] Turkey,[17] Greece, Yemen,

and southwest Saudi Arabia.[15] In North American sickle cell patients of African heritage, 50% to 70% of chromosomes are Benin, 15% to 30% are Bantu-CAR, and 5% to 15% are Senegal.[18,19] In Africa, virtually all patients in a region are homozygous for a given haplotype. Nagel and co-workers documented the different hematologic characteristics of the different homozygote groups.[20,21] Benin and Senegalese individuals have higher levels of fetal hemoglobin (HbF) and fewer dense cells than Bantu-CAR people do. The Senegalese have a high proportion of $^G\gamma$ HbF. In contrast to what is found among Africans in Africa, African Americans are mainly heterozygotes. Less common β^S-linked haplotypes are usually recombinations of the common haplotypes occurring 5′ to the β-globin gene.[22,23] When patients identified in hospital-based clinics are studied, these haplotypes may be associated with overall clinical severity—Bantu-CAR being the most severe and Senegalese the least.[24]

A different haplotype is found in India and parts of Saudi Arabia.[15] In the Eastern oases of Saudi Arabia, the African haplotypes are not seen, but a unique "Arabian-Indian" haplotype is found. This haplotype is also noted in patients from Orissa and Poona, India. Patients from these regions have long been recognized as having mild disease and elevated levels of HbF.[25-28] In contrast, in Riyadh, Saudi Arabia, all patients with sickle cell anemia are from southwest Saudi Arabia and Yemen and are homozygous Benin.

Interaction with Malaria. Heterozygotes with HbS, HbC, HbE, α- and β-thalassemia, and glucose-6-phosphate dehydrogenase (G6PD) deficiency are protected from malaria relative to the normal population.[29] The physiologic basis for the influence of malaria on the sickle gene (so-called balanced polymorphism) is not well understood. It may be due to increased phagocytosis of infected red blood cells (RBCs),[30,31] failure to grow within RBCs,[32] decreased RBC invasion of the parasite because of RBC rigidity,[33] or reduced bioavailability of nitric oxide (NO).[34] Transgenic mice expressing HbS are partially protected from malaria.[35] Interestingly, protection against *Plasmodium falciparum* in inhabitants of Kenya is lost with coinheritance of HbAS and α-thalassemia (negative epistasis).[36]

The Hemoglobin S Polymer

Polymer Structure. In 1927, Hahn and Gillespie[4] showed that sickling, the change from a biconcave disc to the sickle form, was dependent on deoxygenation. Harris[37] subsequently demonstrated that cellular sickling was associated with the formation of "tactoids" of HbS, which appeared as the hemoglobin became deoxygenated. Electron micrographs of sickled red cells[38-41] reveal long, thin bundles of HbS fibers that run parallel to the long axis of the cell or the abnormal protuberances. The ultrastructure of HbS fibers, as detailed by electron microscopy and image reconstruction, reveals a complex
FIGURE 19-1. Pathophysiology of sickle cell disease. The β^S mutation, A→T in the sixth codon, results in an abnormal globin with valine instead of glutamic acid in the sixth position. That hydrophobic valine is exposed when the globin tetramer assumes the deoxy confirmation and tends to burrow into the hydrophobic pocket of nearby β chains. Polymerization of hemoglobin S tetramers occurs rapidly and leads to increased red rigidity. The inherent instability of the HbS polymer leads to oxidative damage (O_2^-) of the red cell membrane (*red dashed lines*). In the area of red cell membrane damage, phosphatidylserine (PS) becomes exposed on the outer surface of the membrane, which activates the coagulation system and leads to hypercoagulation. Membrane damage also leads to increased influx of Ca^{2+} into the cell, which activates the Gardos channel (*tan vertical bars*) and leads to the efflux of K^+ and Cl^-. To compensate for the loss of K^+ and Cl^-, water exits the cell and the cell becomes more acidic (influx of H^+Cl^-). Acidosis then activates the K^+-Cl^- cotransporter (K:Cl), thereby leading to further efflux of K^+ and Cl^- and more dehydration and intracellular acidosis. Some intravascular hemolysis occurs as a result of red blood cell (RBC) membrane damage, which leads to free hemoglobin tetramer binding to plasma nitric oxide (NO). Depletion of plasma NO leads to vasoconstriction, which along with increased RBC rigidity and increased adherence of sickled RBCs to vessel walls, leads to decreased blood flow, hypoxia, and vascular injury and localized damage to endothelial cells (lightning bolt). Endothelial damage leads to expression of adherent proteins on the surface of the endothelial cells (★★★, VV), thus increasing adherence of red and white blood cells to the vessel wall. Endothelial injury and hypoxia lead to vascular injury and acute and chronic inflammation. This ultimately results in organ damage. Each SS patient has a unique environment (e.g., exposure to infections) and unique genetic makeup (e.g., increase in fetal hemoglobin because of genetic modifiers of the hemoglobin switch) that can modify the severity of the disease and thereby make the clinical severity of SS disease extremely variable.

solid-core structure 21 nm in diameter and composed of 14 filaments arranged as seven pairs of double filaments[42,43]—an inner pair with six peripheral pairs.[44] Each filament pair is half-staggered along the fiber axis and has an inherent polarity (three pairs of one polarity and four pairs of the other polarity).[45-48] The radius of the HbS fibers are polymorphic and related to the helical pitch of the double filaments.[49]

The detailed crystal structure suggested by Wishner, Love, and colleagues[50,51] identified several critical intermolecular contact sites: Asp β73, and Glu β121. A topographic map of the HbS fiber at the level of specific amino acids was proposed by Edelstein.[52] Three classes of intermolecular contacts are evident in this model. Contacts along the axis of the filament are made by α and β chains and include the following residues in which mutants affect fiber formation: β121 (O Arab), β16 (J

Baltimore), β17 (J Amiens), β19 (D Ouled Rabah), β22 (G Coushatta), α16 (I), and α116 (O Indonesia). The lateral contacts between filaments of a pair are largely between β chains and include the primary sickle mutation β6. For each hemoglobin tetramer, one chain contributes the β6 mutation, whereas the other contributes a critical receptor region around the Phe β85 residue. In this critical receptor region lie residues where mutants affect fiber formation: β73 (Korle Bu), β66 (I Toulouse), β83 (Pyrgos), and β87 (D Ibadan). Within the acceptor pocket, the mutant valine closely contacts four different hydrophobic residues (β70, β73, β84, and β85), and in addition to the hydrophobic interaction, water molecules are present near the mutant valine and form hydrophilic interactions in the lateral contact region.[53] Contact between filament pairs is largely through α chains. α-Chain mutations (J Mexico α54, Sealy α47, Winnipeg

α75, Stanleyville II α78, Sawara α6, Anantharaj α11, and G Philadelphia α68) that occur at sites critical for inter-pair associations also influence fiber formation. With resolution of the crystalline structure of HbS to 2.0 Å, this model has been confirmed.[54]

Polymer Formation. Polymerization of deoxy-HbS is a highly complex process that results in the formation of gelled, aggregated HbS tetramers in equilibrium with hemoglobin tetramers in solution. Pertubations in oxygen levels,[55,56] temperature,[57-59] pH,[60] ionic strength,[61] 2,3-diphosphoglycerate (2,3-DPG),[60,62] and carbon monox-ide[63-65] affect the formation of HbS gels. This polymerization of HbS is the basic feature that leads to the viscosity changes, distortion of cell morphology, sludging, and organ infarction that are identified as the clinical mani-festations of sickle cell disease (SCD). Although data from various techniques differ somewhat, a representa-tive kinetic model was proposed by Hofrichter, Ross, and Eaton[57,63] and expanded by Ferrone[66] (Fig. 19-2).

The kinetics of HbS polymerization can be explained by a double-nucleation mechanism. Gelation is initiated by a process called "homogeneous nucleation" in which single deoxy-HbS molecules aggregate. Aggregation of a few molecules is thermodynamically unstable, but once a certain number of molecules aggregate, termed the *critical nucleus*, the addition of further molecules pro-

duces a more stable aggregate or polymer. Thus, homo-geneous nucleation is very highly dependent on the concentration of deoxy-HbS molecules. The second nucleation phase, termed *heterogeneous nucleation*, takes place on the surface of preexisting polymer. Recent data suggest that the same intermolecular contacts between the mutant valine and its receptor on the surface of the polymer are responsible for heterogeneous nucleation and cross-linking between strands.[67] As polymerization progresses, more surface area becomes available and therefore the reaction becomes autocatalytic.

The result of this double-nucleation mechanism is a measurable *delay time* between the initiation of polymer-ization and the exponential rise in polymer formation. The delay time varies as the 30th power of the hemoglo-bin concentration:

$$1/t_d = K(C/C_s)^n$$

in which t_d = delay time, C = hemoglobin concentration, C_s = hemoglobin solubility, and $n = 30$ (the number of hemoglobin tetramers in the "critical polymer"). Because n is so large, small changes in hemoglobin concentration have a profound effect on the delay time. For example, decreasing the mean corpuscular hemoglobin concentra-tion (MCHC) from 32 to 30 g/dL will increase the delay time threefold.[68] Gelation is also exquisitely sensitive to changes in temperature and pH. A change from 38.5° C to 37° C or an increase in intracellular pH of 0.03 would also double the delay time.

The phenomenon of delayed gelling of HbS in solu-tion is also seen in red cells containing HbS.[69,70] The distribution of observed delay times within intact RBCs is consistent with the distribution of MCHC in cells. The double-nucleation hypothesis provides for the formation of a network of polymers termed a *domain* that is non-uniformly distributed within the cell. Rapid deoxygen-ation leads to the formation of multiple small domains of polymer and little morphologic deformation of the cell. On the other hand, slow deoxygenation results in large, aligned polymers, which causes significant distor-tion of cell morphology.[71,72]

A kinetic model of HbS gelation that incorporates the concept of a critical delay time has led Eaton and co-workers to propose that polymerization kinetics plays an important role in the pathophysiology of SS disease.[73,74] Oxygenation and deoxygenation of cells in the circulation take place in a time frame that is of the same order of magnitude as the sickling and unsickling of HbS in vitro. Cells exposed to the high P_{O_2} of the lungs are quickly "degelled" because HbS gels melt in less than 0.5 second when exposed to oxygen. The cells contain little polymer-ized HbS while in the oxygenated environment of the arterial circulation. As the cells enter the capillary circu-lation, oxygen saturation decreases rapidly, as does hemo-globin solubility. The red cell spends an average of 1 second in the capillary circulation, although this is highly variable. If the delay time is less than 1 second, the cell will sickle and occlude the capillary. If the delay time is

FIGURE 19-2. Model of the polymerization and alignment of deoxy-hemoglobin S. *(Adapted from Hofrichter J, Ross PD, Eaton WA. Super saturation in sickle cell hemoglobin solutions. Proc Natl Acad Sci U S A. 1976;73:3035-3039; and Ferrone FA, Hofrichter J, Eaton WA. Kinetics of sickle hemoglobin polymerization; II A double nucleation mechanism. J Mol Biol. 1985;183:611-631.)*

prolonged, sickling will not take place in the capillary and obstruction will not occur. If the transit time through the capillary is shortened and is less than the delay time, occlusion will not occur. This is presumably the situation in the myocardium, in which sickling and infarction do not occur because of the extremely short transit time despite the high oxygen extraction. Factors such as low pH, high hemoglobin concentration, and high ionic strength, which shorten the delay time in vitro, also affect in vivo sickling. Patients who become hypoxic, acidotic, dehydrated, and febrile are likely to experience vaso-occlusive episodes. The hypertonic renal medulla and the acidotic, high-hematocrit environment of the spleen make these organs prime targets for sickling.

Relatively little is know about the uniformity of the depolymerization process within RBCs. It is likely that depolymerization occurs from both the ends and sides of polymer fibers.[75] Failure of complete depolymerization in the passage through the oxygentated environment of the lungs (1 to 3 seconds) may lead to the residual polymer observed by Noguchi and associates.[76] Using nuclear magnetic resonance, they measured the quantity of HbS polymer in AS and SS red cells under varying conditions related to MCHC and oxygenation[77,78] and found polymer formation and impaired erythrocyte deformability at oxygen saturations above the level at which cells appear to morphologically sickle.[79] They proposed that the amount of HbS polymer present at equilibrium in SS patients is the major factor determining clinical severity[80,81]; however, this relationship was not confirmed by others.[82] Important variables that affect the HbS polymer fraction (HbF, 2,3-DPG levels, oxygen saturation, and pH) are heterogeneously distributed within subsets of red cells, and these factors along with other factors, such as membrane abnormalities and red cell–endothelial interactions, are likely to play a role in the variable clinical severity of SCD.

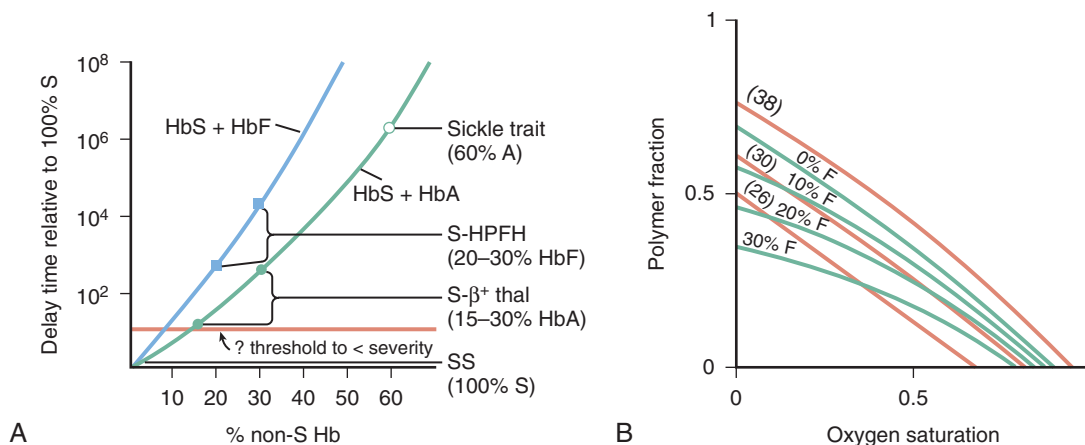
Interactions of Hemoglobin S with Hemoglobin A and Hemoglobin F. Study of the interaction with other hemoglobins supports a rational basis for understanding the clinical manifestations of the various sickle syndromes and provides a rationale for therapy. Investigators have extensively studied mixtures of HbS with HbF or HbA to determine the effects on gelation[83-88] and solubility.[89-91] In these studies the nonideal behavior of concentrated hemoglobin solutions[58,92] was considered—the bulky hemoglobin molecules take up much of the solution volume, thus making the *effective* concentration of hemoglobin higher than the *measured* concentration. Kinetic data show that HbA and HbF have a profound, dose-related effect in which delay time is increased and the HbS polymer content in cells is decreased (Fig. 19-3). The effect of HbF is considerably greater than the effect of HbA. Sunshine and others demonstrated that when compared with pure HbS solutions (as seen in sickle cell anemia), mixtures with 15% to 30% HbA (as found in S–β+-thalassemia) have delay times that are 10 to 10^2 times longer, mixtures with 20% to 30% HbF (as found in S–hereditary persistence of fetal hemoglobin [HPFH]) have delay times that are 10^3 to 10^4 times longer, and mixtures with 60% HbA (as found in sickle trait) have delay times that are 10^6 times longer.[83,85] HbA and HbF also increase the solubility of HbS, with HbF being more effective than HbA. Studies of the composition of the gels and supernatant of these mixtures demonstrate that asymmetric hybrids of HbS and HbA ($\alpha_2\beta^S\beta^A$) are readily incorporated into the gel. In mixtures of HbF and HbS in which the concentration of HbF is less than 40%, very little if any HbF is incorporated into polymer, thus suggesting that asymmetric hybrids of HbS and HbF ($\alpha_2\beta^S\gamma$) and HbF ($\alpha_2\gamma_2$) are not incorporated into polymer under most physiologic conditions.[84,86,89-91] HbA has a lesser effect on HbS solubility than HbF does because the asymmetric hybrids readily copolymerize with HbS.[93]


FIGURE 19-3. **A,** Effect of increase in concentrations of fetal hemoglobin (HbF) and adult hemoglobin (HbA) on delay time of polymerization of sickle hemoglobin (HbS). **B,** HbS polymer formation as a function of oxygen saturation for different levels of HbF (0%, 10%, 20%, 30%) at hemoglobin concentration of 34 g/dL and for concentrations of 26, 30, and 38 g/dL of pure HbS. S-HPFH, HbS and hereditary persistence of HbF; thal, thalassemia. (*A, Based on the work of Sunshine HR, Hofrichter J, Eaton WA. Requirement for therapeutic inhibition of sickle hemoglobin gelation. Nature. 1978;275:238-240; **B,** based on Noguchi DT, Torchia DA, Schechter AN. Intracellular polymerization of sickle hemoglobin. Effects of cell heterogeneity. J Clin Invest. 1983;72:846-852.*)

Crowding of hemoglobin molecules can reduce the effect of HbF replacement at hemoglobin concentrations higher than 30 g/dL.[94] Replacement of HbS by 20% HbF at hemoglobin concentrations above 30 g/dL will increase the delay time only by 10 times, *not* by the 1000 times predicted at concentrations of hemoglobin lower than 30 g/dL.

Membrane Damage

The basic pathophysiology of sickle cell anemia is directly related to polymerization of HbS. Secondary effects of the primary lesion may modulate clinical expression of the disease. Alterations in the red cell membrane because of structural damge from HbS polymerization or oxidative damage as a result of unstable HbS may be important determinants of disease severity for several reasons (see Fig. 19-1). First, the membrane is the structure most intimately associated with the abnormal gene product and is therefore vulnerable to damage. Second, the membrane is largely responsible for maintaining the environment in which this abnormal product resides. Third, the membrane is the face that the red cell presents and is recognized by proteins in plasma, by other cells in the circulation, by the vascular endothelium, and by the reticuloendothelium.

Mechanism of Membrane Damage. In normal cells, HbA has been shown to bind to membranes[95,96] at or near the cytoplasmic portion of band 3 protein[97,98] and with relatively low affinity to phospholipids on the inner surface of the memebrane.[99] Hemoglobin at physiologic concentrations stabilizes the configuration of spectrin heterodimers.[100] HbS and β^S-globin bind to membranes more readily than HbA does.[101-103] Evans and Mohandas demonstrated that membrane-associated HbS was a major determinant of erythrocyte rigidity.[104] In these experiments, normal deformability was found when normal hemoglobin was reconstituted in sickle or normal membrane ghosts, but abnormal deformability was associated with reconstitution of sickle or normal red cell membranes with HbS. In one study, membrane rigidity was associated with the presence of a small amount of a high-molecular-weight spectrin-hemoglobin complex in the membrane.[105]

HbS is inherently unstable[106,107] and has an increased tendency to denature and form small aggregates—"micro–Heinz bodies." These bodies attach with high affinity to the cytoplasmic portion of band 3 protein at or near the HbA binding site.[108] Such binding on the inside surface of the membrane is translated into changes on the outside surface because both band 3 protein and glycophorin (the major bearers of the cell's antigens and charge) are found to be clustered above the micro–Heinz bodies.[109] Clustering of band 3 protein is associated with deposition of specific anti–band 3 protein antibodies on the cell,[108,110] a process linked to normal cell senescence[111,112] and perhaps contributing to the short life span of SS cells.[113] Ankyrin is also abnormally clustered around the denatured HbS and, like band 3 protein, may be damaged in the process.[109] In addition, the hydrophobic surface of the Heinz body sequesters lipid, spectrin, band 3, ankyrin, and protein 4.1 inside the cell and may contribute to the reduced surface area of such cells.[114]

HbS has an increased tendency to auto-oxidize and form methemoglobin, thereby generating superoxide and losing heme.[115] In fact, sickle cells generate twice the normal amount of the potent oxidants superoxide, peroxide, and hydroxyl radical.[116] Iron in different compartments (denatured hemoglobin, free heme, hemichromes, and nonheme iron) is found bound to various sites in the sickle red cell membrane. This iron serves as a catalyst for the production of highly reactive hydroxyl radicals, which leads to oxidative damage of the various components of the membrane.[117,118]

Membrane Deformability. As sickle cells are deoxygenated and fill with polymerized hemoglobin, they become less deformable.[118-122] However, even fully oxygenated cells have abnormal rheologic properties.[123] Using the ektacytometer, Clark and colleagues studied the deformability of SS red cells and showed that decreased deformability was directly related to increased MCHC and that correcting the elevated MCHC restored normal deformability.[124] By means of a high-shear/hemolysis assay, normalization of the tendency to hemolyze was noted when MCHC was corrected, except in the most dense fraction, where normalization was incomplete.[125] This incomplete normalization suggests that severe cellular dehydration itself may contribute to the development of a membrane lesion. Using micropipette techniques to measure membrane deformability, two studies[126,127] have shown that MCHC is the major contributor to cell rigidity but that irreversible membrane changes as a result of dehydration also increase membrane rigidity.

Membrane rigidity is further evidence that a structural membrane lesion is present. The finding that the cytoskeleton of irreversibly sickled cells (ISCs) was permanently distorted led several investigators to analyze the various components. Abnormalities in the cytoskeleton of ISCs include aberrant cross-linking of actin,[128] dissociation of spectin tetramers,[129] and clustering of band 3 protein and glycophorin.[130] Disordered mobility of the cytoskeleton relative to the overlying membrane may relate to decreased binding of normal ankyrin to sickle protein 3[131] or to binding of normal spectrin to sickle ankyrin.[132] With the use of newer proteomic techniques, four groups of proteins appear to be increased in sickle RBC membranes: actin accessory proteins, components of lipid rafts, scavengers of oxygen radicals, and protein repair participants.[133] All these observations support the hypothesis that membrane rigidity is due to cytoskeletal damage associated with HbS polymer formation and oxidative damage.
FIGURE 19-4. Oxygenated peripheral blood smears from individuals with sickle cell anemia (**A**), hemoglobin SC disease (**B**), sickle-β⁰-thalassemia (**C**), homozygous hemoglobin C (**D**), and hemoglobin SD disease (**E**).

Hemoglobin Concentration. Sickle cell individuals have more light cells (reticulocytes) and more dense cells (MCHC >37 mg/dL) than normal individuals do (Figs. 19-4 and 19-5). The vaso-occlusive nature of these dense cells was reported by Kaul and colleagues, who showed that cells separated by density (and therefore MCHC) from patients with sickle cell anemia obstruct flow in an artificially perfused capillary system in proportion to their MCHC.[134] Although early reports suggested that the percentage of dense cells decreases during vaso-occlusive crises,[135] there is no correlation between the percentage of dense cells and the frequency or onset of crises.[136] The decreased MCHC associated with α-thalassemia leads to a more uniform distribution of red cell densities and a decreased percentage of dense cells.[137,138] Paradoxically, individuals with HbSC have milder clinical disease but more dense cells than do individuals with homozygous sickle cell anemia (see Fig. 19-5).[139]

The heterogeneity of red cell shape and density in sickle cell anemia is due partially to the heterogeneous distribution of HbF in a subset of red cells called F cells.[140] Because HbF interferes with HbS polymerization, F cells survive longer in the circulation than do cells with no HbF,[141] and the relative proportion of F cells in the densest cell fractions is very low.[137,142] The densest cell fraction in SS contains the oldest non–HbF-containing RBCs, ISCs, and young reticulocytes poor in HbF that dehydrate rapidly.[143]

Shape Changes (Sickling) in Red Blood Cell. The time course of cellular events associated with oxygenation and deoxygenation has been investigated by Hahn and associates,[143a] who studied cells from patients with SS disease under physiologic time and oxygen conditions.
FIGURE 19-5. Typical distribution patterns of cell volume and hemoglobin concentration in different sickle syndromes. Note that in SS disease, the cells fall below and above the normal (*shaded*) range of both volume and concentration. The large (microcytic) cells are low-density reticulocytes. The dehydrated population is enriched in irreversibly sickled cells and is low in HbF. In S-thalassemia (S thal) syndromes, the entire volume curve is shifted toward the left, and few dense cells are seen. In SC disease, the microcytes are often spherocytic, very dehydrated cells. Nl, normal.

They described two categories of cells—a fraction of dense cells (MCHC >36 g/dL) that exhibited reversible polymerization and shape change (reversibly sickled cells [RSCs]) and a fraction of very dense cells (MCHC of 44 g/dL) that exhibited reversible polymerization but irreversible shape change (ISCs). Changes in the rheology of the cells paralleled the appearance of polymers in cytoplasm a considerable time before any detectable distortion of cell shape.

RSCs have normal shape and normal viscosity when oxygenated. The vaso-occlusive complications of SCD may be due to the "Trojan horse performance" of these RSCs, which are able to slip into the microvasculature because of their normal rheologic properties when oxygenated and then become distorted and viscous as they become deoxygenated in the vessel.

ISCs are slender, elongated cells with blunt ends that are visible on an oxygenated peripheral blood smear in SCD (see Fig. 19-4). These cells are extremely dense, have little HbF to dilute their concentrated HbS, and survive in the circulation for only a few days.[142] In 1968, Dobler and Bertles[143] demonstrated unpolymerized hemoglobin in an oxygenated ISC. In the Hahn studies,[143a] ISCs underwent hemoglobin polymerization and depolymerization upon deoxygenation and reoxygenation. When compared with the RSC fraction, however, polymerization took place sooner, was much more highly aligned, and took longer to disappear upon deoxygenation. Onishi and Horiuchi demonstrated that in vitro formation of ISCs is correlated with the maximum linear distortion of red cell diameter under deoxygenated conditions, thus suggesting that the length of HbS polymer fibers in SS cells contributes to irreversible membrane damage.[144] ISCs can be formed in vitro by prolonged deoxygenation,[145] by incubation of red cells in a high-calcium buffer,[146] and by repeated oxygenation-deoxygenation cycles.[122] Reversible oxidative damage to β-actin and loss of ubiquitination of α-spectrin lead to ISC membrane skeleton formation. The result is a membrane cytoskeleton that is "locked" because it cannot disassemble or reassemble.[147] Antioxidants can reduce the formation of ISCs in vitro.[148] As detailed earlier, ISCs vary widely from patient to patient and correspond well with hemolytic rate[149] and spleen size[150] but poorly with vaso-occlusive severity.

Ion Transport and Volume Control. The abnormal cation permeability of a sickled red cell is characterized by calcium loading, potassium depletion, increased acidosis, and dehydration, which enhances the tendency for HbS polymerization (see Fig. 19-1). In 1955, Tosteson and colleagues[151,152] showed that HbS polymer formation with deoxygentation causes reversible potassium loss and sodium gain in SS cells. Because this cation flux was reversible with reoxygenation, by itself it could not explain the dehydration associated with ISCs and other very dense SS red cells. The abnormal water and cation movement across the sickle cell membrane has been

shown to be associated with a variety of pumps, channels, and leaks involving potassium (K^+), sodium (Na^+), chloride (Cl^-), calcium (Ca^{2+}), and magnesium (Mg^{2+}). Although the pathogenesis of these pathways remains incompletely understood, they are undoubtedly related to the physical distortion associated with sickling,[125-127,151-157] young cell age,[158-160] oxidant damage,[161-163] and the hemoglobin mutation itself.[164-166] At least two major channels are responsible for the dehydrating process: the Gardos channel and the K^+-Cl^- cotransporter (KCC). Several investigators noted that ISCs and other dense sickle RBCs had increased concentrations of Ca^{2+},[167,168] and this was later shown to be partially due to the high concentrations of Ca^{2+} found in endocytic vesicles in sickle RBCs.[169] The molecular basis for how HbS polymerization leads to influx of Ca^{2+} is still unknown. SS reticulocytes exposed to deoxygenation and HbS polymerization accumulate sufficient Ca^{2+} to activate the Gardos channel,[170] a Ca^{2+}-sensitive, K^+-selective channel. Cl^- and HCO_3^- are also lost via parallel voltage-sensitive pathways. Loss of KCl and $KHCO_3$ results in osmotically driven water loss. The activated Gardos channel leads to rapid RBC dehydration to a much greater extent than other transporters do. The Gardos channel has been shown to be inhibited by clotrimazole, an imidazole antimycotic agent in vitro,[171] in the SAD mouse model for SCD in vivo,[172] and in a short-term study in patients with SCD.[173]

A second pathway involved in RBC dehydration is the KCC. The KCC pathway is stimulated to lose K^+, Cl^-, and water when (predominantly young) sickle cells are exposed to a low pH environment, as might occur in areas of poor perfusion.[174] The KCC pathway is also activated by deoxygentation of hemoglobin[148,175] and by low levels of Mg^{2+}.[176,177] Acid activation of the KCC is exaggerated in SS reticulocytes and may be due to sulfhydryl oxidation.[178] Genes for four KCC isoforms have been identified. The 1, 3, and 4 isoforms of KCC are present in SS and normal RBCs, but SS RBCs may have N-terminal splicing variants of these isoforms.[179] The KCC pathway is inhibitable by magnesium in vivo,[176,177] and Mg^{2+} is depleted in sickle erythrocytes, possibly through abnormal Na/Mg exchange.[180] Two preliminary studies demonstrated the effectiveness of oral magnesium in the prevention of cellular dehydration in a mouse model of SCD[181] and in patients,[182,183] and clinical trials are under way.

Lew and Bookchin reviewed the evolution of our knowledge of ion transport pathology in SS dehydration and proposed a multistep dehydration model that leads to the formation of ISCs from SS reticulocytes.[184] HbS polymerization in SS reticulocyes distorts the RBC membrane, which results in the influx of Ca^{2+} sufficient to activate the Gardos channel, thereby leading to loss of K^+, Cl^-, and HCO_3^-. These losses result in dehydration and acidification predominantly through reentry of H^+ and Cl^-. Subsequently, acid-stimulated KCC channels lead to further loss of K^+ and Cl^- and acidification and

dehydration of the cell. In the acidic state, the KCC pathway would remain active in both the oxygenated and deoxygenated state.[158] This model explains how reticulocytes may rapidly become ISCs.

External Membrane Interactions

Increased Red Cell Adhesion to Endothelium. More than 15 years ago, investigators first discovered that sickle erythrocytes have an abnormal propensity to stick to vascular endothelial cells,[185,186] an adhesive force that results from numerous attachment sites[187] that can withstand the detaching forces found in low-shear vascular beds.[188] This observation has taken on increased importance in conceptualizing the pathophysiology of SCD. As cells flow through vessels of critical dimension, an increased tendency to linger at the endothelial surface will increase the odds that polymerization and obstruction will occur (see Fig. 19-1). Support for this hypothesis comes from studies that suggest a correlation between adhesiveness and clinical severity.[189,190]

A variety of RBC adhesion molecules are found on SS RBCs, especially SS reticulocytes. The adhesion process can alter or even dislodge endothelial cells. Such circulating cells may have left behind areas of exposed subendothelium. SS RBCs bind to three subendothelial extracellular matrix proteins, laminin, thrombospondin, and fibronectin.[191] SS red cells show the highest affinity for laminin because of two isoforms of the protein that bear the Lutheran blood group antigens (B-CAM and LU).[192,193] Adhesion proteins to thrombospondin on SS reticulocytes include CD47 and VLA-4 (very late antigen 4). Mature SS RBCs retain CD47 receptors but not VLA-4. CD44 is the adhesion protein found on RBCs that binds to fibronectin. VLA-4 ($\alpha_4\beta_1$ integrin) also binds to the endothelial protein vascular cell adhesion molecule 1 (VCAM-1).[191]

Perhaps more significantly, a variety of agonists can activate SS RBC adhesion properties. Protein kinase C can activate adhesion to fibronectin and thrombospondin.[194,195] Activation of signaling pathways within the RBC involving adrenergic receptors, cyclic adenosine monophosphate (cAMP), and protein kinase A also increases RBC adhesion.[196-199] SS RBCs are more responsive than normal RBCs to these agonist, possibly because of higher levels of signaling transduction proteins found in younger RBCs. Endothelial cells differ in their repertoire of surface molecules—for example, CD36 is expressed on microvascular but not large vessel endothelium.[200] Endothelial cells also express differing amounts of surface molecules and become more or less adherent, depending on environmental stimuli. Cytokines such as interleukin-18 and tumor necrosis factor[201] promote endothelial adherence, largely as a result of upregulated VCAM-1 expression. Infected endothelial cells become adhesive by a variety of mechanisms. Herpesvirus-infected cells attract sickle red cells because of increased Fc receptor expression.[202] Endothelial cells exposed to Sendai viral double-stranded RNA become adhesive through upregulated VCAM-1.[203] In transgenic sickle mice, the anti-inflammatory agent dexamethasone inhibited hypoxia-induced endothelial cell activation of NFκB, VCAM-1, and intercellular adhesion molecule 1 (ICAM-1), whereas blocking antibodies to VCAM-1 and ICAM-1 blocked RBC- and leukocyte-mediated vaso-occlusion.[204]

Circulating endothelial cells from patients with SCD exhibit an activated phenotype displaying ICAM-1, VCAM-1, E-selectin, P-selectin, and tissue factor.[205,206] Increased production of endothelial-derived adhesion molecules (VAM-1, ICAM-1, and E-selectin) was seen in 10 adult SS patients during acute sickle cell pain crises.[207] Furthermore, in a cohort of 160 adult patients in steady state, soluble levels of VCAM-1, ICAM-1, and E-selectin were elevated and independently associated with pulmonary hypertension (PHT) and mortality.[208]

Membrane Lipid Orientation and Coagulation Defects. Normally, the phospholipids of the red cell membrane are partitioned with amino phospholipids (phosphatidylserine [PS] and phosphatidylethanolamine [PE]) sequestered on the inner (cytoplasmic) surface and with sphingomyelin and phosphatidylcholine (PC) exposed on the outer surface (see Fig. 19-1). This asymmetry is not unique to the red cell and probably reflects a general structural pattern that keeps the amino phospholipids from activating soluble coagulation factors. This asymmetry is maintained by the interaction of spectrin[209] with the phospholipids and by a specific adenosine triphosphate (ATP)-dependent translocation process.[210] In RSCs, PS and PE flip back and forth from the inner leaflet to the outer leaflet during oxygenation and deoxygenation. Although early studies suggested that PS was permanently stuck to the outer leaflet in deoxygenated sickle cells,[211] later studies suggested that small amounts of PS accumulate on the outer surface of subpopulations of sickle cells[212] where the lipid bilayer is uncoupled from the cytoskeleton and when the cell is depleted of ATP.[213] Exposure of PS or PE on the outer surface during sickling may lead to increased phagocytosis by PS-binding proteins secreted by macrophages,[214] and these proteins may bind to specific PS receptors on certain enthothelial cells.[215] Alteration of the fatty acyl groups in PC results in changes in cell shape and deformability of SS cells, thus suggesting that the species composition of PC can affect membrane permeability and cellular deformability.[216] Both plasma and SS RBC membrane are deficient in certain long-chain polyunsaturated fatty acids. This deficiency is correlated with steady-state hemoglobin levels and may be affected by dietary intake.[217]

Abnormal lipid asymmetry accelerates clotting in vitro,[218] and PS-positive sickle RBCs (not PS-positive platelets) are correlated with markers of thrombin generation (prothrombin fragment F1.2, thrombin-antithrombin complexes) and fibrin degradation (D-dimers and plasmin-antiplasmin complexes).[219] Another marker of thrombophilia is the reduction in protein C and protein

S.[220] Platelet activation is also present in the steady state. In addition, microparticles from endothelial cells, platelets, monocytes, and red cells are seen in the steady state and increase during crises.[221] These microparticles are associated with increased hemolysis and activation of the procoagulant system.[222]

A growing body of evidence suggests that procoagulant and anticoagulant proteins and platelets play an important role in adhesion of sickle RBCs to endothelium. von Willebrand factor,[223-225] platelets,[226] and thrombospondin[227,228] increase RBC adhesiveness. Platelet-activating factor increases sickle red cell adherence to endothelium, and this interaction can be selectively blocked by an anti–$\alpha_V\beta_3$ integrin antibody, thus suggesting a potential therapeutic strategy.[229] Hence, abundant data support the view that SCD is a "hypercoagulable state."[230] It is unclear whether the hypercoagulable state is a consequence or a cause of vaso-occlusion, and large well-controlled trials of anticoagulants have not been conducted.[230]

Hemolysis

RBC life span is shortened in SS disesease to approximately 8 to 21 days. Hemolysis is both extravascular and intravascular. Extravascular hemolysis is enhanced by externalized PS on SS RBCs, which is recognized by macrophages with receptors specific for PS.[214] The membrane changes found in SS RBCs are similar to those seen in nucleated cells undergoing apotosis (externalization of PS, annexin binding to and blebbing of the membrane along with cell shrinkage). These changes are accentuated by accumulation of intracellular Ca^{2+} secondary to oxidative stress.[231] Approximately 30% of the total hemoglobin is released intravascularly, with approximately 4 micromoles of plasma hemoglobin being present during steady state.[232]

Nitric Oxide Depletion. NO is produced by endothelial cells from L-arginine by isoforms of the enzyme NO synthetase (NOS). NO increases intracellular cyclic guanosine monophosphate (cGMP), which decreases smooth muscle calcium concentrations and leads to muscle relaxation, vasodilation, and increased regional blood flow.[233] NO also suppresses platelet aggregation,[234] reduces expression of endothelial cell adhesion molecules,[235] and reduces the secretion of procoagulant proteins.[236] NO levels may be depleted in patients with SCD for several reasons. Sickle cell patients have low arginine levels[237] and high plasma arginase levels.[238] NO reacts with oxyhemoglobin and deoxyhemoglobin to produce nitrate, methemoglobin, and iron nitrosylhemoglobin (reviewed by Reiter and colleagues[239]). Free plasma hemoglobin consumes NO 1000 times more rapidly than intracellular hemoglobin does.[240] Reiter and associates have shown that SS patients have elevated levels of plasma free hemoglobin, that plasma from SS patients consumes NO, and that SS patients with elevated plasma free hemoglobin
FIGURE 19-6. Factors leading to and the results of nitric oxide depletion. Intravascular hemolysis leads to elevated levels of plasma arginase and free plasma hemoglobin. Increased reactive oxygen species results from denatured HbS, oxidative damage to red cell membranes, tissue ischemia/reperfusion injury, and increase expression of endothelial xanthine oxidase, reduced endothelial nicotinamide adenine dinucleotide phosphate oxidase, and uncoupled endothelial nitric oxide synthetase.

have reduced forearm blood flow responses to infusion of an NO donor, nitroprusside[239] (see Fig. 19-1). The reactive oxygen species that are elevated in sickle cell patients for multiple reasons also reduce NO.[116,117,241] Work by Gladwin and co-workers has led to the hypothesis that SCD leads to depletion of NO and thereby a "hemolysis-induced endothelial dysfunction syndrome" characterized by PHT, priapism, leg ulcers, stroke, renal insufficiency, and esophageal dysmotility.[242,243] Furthermore, hemolysis-induced NO depletion may play a role in the SS metabolic hypercoagulable state[244] (Fig. 19-6).

Acute and Chronic Inflammation

Several lines of evidence suggest that the HbS mutation leads to an acute and chronic inflammatory state. Markers of inflammation, including increased levels of white blood cells (WBCs), platelets, C-reactive protein, and fibrinogen, all increased at steady state and during crises.[245,246] Increased adherence of SS RBCs, neutrophils, and platelets to vascular endothelium may initiate local inflammatory responses. Hypoxia, increased proinflammatory cytokines (interleukins 1, 2, 4, 6, and 8; tumor necrosis factor-α), and infections may activate vascular endothelium and leukocytes, which in turn can further increase adhesion molecules on both circulating cell surfaces and endothelial cell surfaces[246] (see Fig. 19-1).

White Blood Cells. There has been increasing evidence that circulating WBCs, particularly neutrophils, play a role in the pathogenesis of SS disease. Baseline WBC counts in SS individuals are elevated. The degree of elevation is directly related to early mortality[247] and an increased frequency of acute chest syndrome (ACS)[248] and is a predictor of clinical severity in infants.[249] Elevated WBCs in the normal population appear to be genetically determined,[250] but in SS patients it is also associated with elevated levels of granulocyte-macrophage colony-stimulating factor (GM-CSF).[251] Polymorphonuclear neutrophils (PMNs) show enhanced adhesion

to endothelium during crises.[252] Activation of neutrophils is seen in the stready state and during vaso-occlusive crises.[253] In a transgenic sickle mouse model, PMNs are involved in reperfusion inflammation after hypoxia. This reperfusion injury can be abated by blocking PMN adherence with an antibody to P-selectin.[254] Thus, elevated level of PMNs in blood and the adhesiveness of PMNs to endothelium may reduce blood flow and, in association with sickled erythrocytes, can cause microvascular occlusion and crisis.[255]

Genetic Modifiers

Any analysis of the pathophysiology of SCD must address the remarkable heterogeneity in clinical severity that is observed in individuals homozygous for the sickle mutation. With completion of the human genome map, several important concepts have emerged. First, there is remarkable genomic heterogeneity between individuals, including single nucleotide polymorphisms (SNPs), varying length of tandem repeat sequences, and previously underappreciated structural variation in the genome.[256-258] Second, coexistence of the sickle mutation with variations in multiple genes whose interactions are associated with common complex disorders (stroke, hypertension) may be responsible for some variation in the severity of SCD. Third, known mutations in nonglobin genes associated with other single-gene disorders (G6PD gene in G6PD deficiency, uridine diphosphate-glucuronosyl-transferase 1A [UGT1A] in Gilbert's disease) may explain some of the heterogeneity in the phenotype of SCD. New technology now allows scanning of the whole genome or large genomic regions in large numbers of SS individuals with and without common subphenotypes (stroke, ACS, elevated HbF levels), which has resulted in identification of genes that might contribute to that phenotype. Finally, newer appreciation of how the environment has led over evolutionary time to the selection of more favorable variations in proteins continues to enlighten our understanding of susceptibility to certain acquired diseases (malaria).

Glucose-6-Phosphate Dehydrogenase. G6PD deficiency is a single-gene variant common in black populations that also protects against malaria. There is no increased incidence of G6PD deficiency in SCD.[40,259,260] In a survey of 801 SS males, G6PD deficiency did not cause more hemolysis or increased anemic episodes.[259] Episodes of accelerated hemolysis of G6PD-deficient SS red cells have been described.[260] Because of the large population of very young G6PD-rich cells, this accelerated hemolysis is likely to be due to the enzyme abnormality only when the population is shifted toward the oldest cells, that is, during an aplastic episode. Recently, the common type A variant of G6PD deficiency has been associated with increased septic complications and anemia in African Americans trauma patients,[261] thus suggesting that individuals with SS disease and G6PD

deficiency may have a poorer prognosis in this setting or with sepsis.

α-Thalassemia. Homozygous HbSS disease with accompanying α-thalassemia has been well described.[137,262-270] The diagnosis is based on the following criteria: (1) hemoglobin electrophoresis showing no HbA, normal HbA_2, and predominantly HbS; (2) microcytosis without iron deficiency; (3) both parents with the S trait, one with the typical AS α-thalassemia picture (microcytosis and HbS concentration <35%); (4) elevated Hb Bart's (γ_4) detectable in cord blood; and (5) α-gene mapping showing a total of two or three α genes. Approximately 30% of American blacks have three α genes, and approximately 2% only have two α genes. α-Thalassemia in U.S. SS disease patients is usually due to the α-thal-2 haplotype, a deletion of approximately 3.7 kilobases (kb) involving the entire α_2 gene.[269] There has been considerable interest in these patients because α-thalassemia has an effect on some of the hematologic features of sickle cell anemia and may provide insight into the pathophysiology of the disease. The primary effect of α-thalassemia is to decrease the cellular content of HbS, which increases the surface-to-volume ratio and results in a reduced MCHC that prolongs the delay time for HbS polymerization. Patients with α-thalassemia tend to have smaller, lighter cells with a higher hemoglobin level and fewer reticulocytes.[262,269-271] Although the hematologic parameters of sickle cell anemia are clearly improved by coexisting α-thalassemia, the vaso-occlusive severity is not obviously different. One study[262] indicated that leg ulcers and ACS were less frequent with α-thalassemia, but this finding was not confirmed by others.[267] Avascular necrosis (AVN) of the femoral head was increased in sickle cell anemia with α-thalassemia. α-Thalassemia does not protect children with SS disease from strokes.[272] Mears and co-workers have suggested that α-thalassemia is associated with increased life expectancy.[273] α-Thalassemia not only reduces mean corpuscular volume (MCV) and MCHC but also decreases the percentage of dense cells and ISCs.[137,274] The cells of patients with α-thalassemia and SS disease are more deformable and have fewer cation fluxes and a greater ratio of membrane surface area to volume.[264] Differences in hemoglobin values between children with SS disease with four and two genes is not apparent until after the age of 4 years,[275] but the microcytosis and elevated red cell counts are present at birth.[276] Steinberg has recently summarized the effects of α-thalassemia in SS disease.[277]

Hemoglobin F Production. HbF levels in sickle cell anemia may vary over a 60-fold range from 0.5% to 30%. Because of the known ameliorating effect of HbF in reducing HbS polymerization, the origin of this marked variability has been of great interest. Because HbF is heterogeneously distributed among the red cells of SS individuals, the percentage of HbF is the result of three independent processes: the number of cells produced

that contain HbF (F cells), the amount of HbF per F cell, and the variable preferential survival of F cells over non-F cells in the circulation.[141] Early investigators suggested that different "threshold" levels of HbF (between 10% and 20%) were necessary to ameliorate the clinical severity of SS disease.[278,279] In a natural history study, Platt and co-workers showed that any increment in HbF above 4% was associated with reduced pain crises[280] and that HbF levels greater than 9% were associated with decreased mortality.[247]

Three broad categories of genetic mutations that increase HbF in association with HbS have been described. Large deletions of the γδβ-globin gene region resulting in δβ-thalassemia or pancellular HPFH are rare in the general sickle cell population (see Chapter 20 for more details on these deletions). HbS–pancellular HPFH patients represent a unique syndrome in which one finds between 24% and 34% HbF distributed in all red cells, no anemia, minimal microcytosis (MCV of 78.8 μm^3), and no clinical disease.[281-283]

A second group of mutations that increase HbF in SCD are linked to the β-globin gene region and are termed *nondeletion HPFH*.[284-287] Some linked mutations may be associated with single nucleotide substitutions in the promoter regions of the γ genes; however, such mutations are quite rare in the general SS population.[288] HbF is usually distributed heterogeneously in these disorders, but some have been associated with a pancellular distribution. Another type of linked nondeletion mutation that may increase HbF (^{G}γ-C158→T) is associated with the Senegal and Arab–Indian (Saudi) β-globin haplotypes.[20,25-28] These haplotypes are found commonly in genetic isolates in Western Africa, in Shiite Saudi Arabians, and in the Orissa region of India.[289-292] Among U.S. patients with sickle cell anemia, less than 10% have one chromosome with either of these haplotypes and less than 2% are homozygous for the Senegal haplotype.[18,19]

A third group of genetic disorders that influence HbF levels in patients with SS disease are not linked to the β-globin region.[293-295] A third of full siblings each with SS disease have significantly different genetic programs for production of HbF.[295] Because both siblings inherited the same γδβ-globin regions from their sickle trait parents, the HbF program must be separate from the γδβ-globin region. After Myoshi and associates[296] noted that HbF (defined by F-cell levels) in normal blood donors was inherited in an X-linked pattern, it was shown that F-cell production in sickle cell patients was inherited by a diallelic gene on the short arm of the X chromosome, Xp22-23, termed the F-cell production (FCP) locus.[297] The FCP locus accounted for 40% of the variation in HbF levels in sickle cell anemia patients and one form of β-thalassemia in Sicily.[298,299] However, twin studies of normal individuals by Thein and colleagues have not detected an X-linked locus[300] but suggested a locus on chromosome 8 that may interact with β-globin haplotypes. Thein has localized another genetic locus that controls F-cell levels in normal white individuals and in an Asian-Indian kindred to chromosome 6q22.3[301] and

recently has identified a potential role for the gene *cMYB* in regulation of HbF levels in this population.[302] Steinberg and colleagues, using haplotype mapping of SNPs, have recently shown in 1311 SS individuals that 6q22.3-23.2, the *TOX* gene on chromosome 8, and Xp22.2-22.3 are involved in baseline HbF levels.[303] They also showed that these same regions on chromosomes 6 and 8 and loci on chromosomes 1, 12, 13, and 14 were involved in the change in HbF levels in response of SS patients to hydroxyurea. BCL11A on chromosome 2, along with the C-MYB region on chromosome 6, has been associated with HbF levels in a genome-wide association study of thalassemia and SS patients in the Cooperative Study of Sickle Cell Disease (CSSCD).[304] In addition to these disorders, it has been shown that α-thalassemia is associated with decreased HbF levels in SS disease. The differences in HbF levels among SS patients with or without α–thalassemia may be indirectly related to the lowered MCHC of the SS-thalassemia red cells. Preferential survival of F cells over non-F cells is less in SS–α-thalassemia because the non-F cells in α-thalassemia have less cation loss and a lower MCHC, which reduces HbS polymerization and results in a longer life span.[137,263]

Genetic Modifiers of Clinical Subphenotypes. It is likely that networks of genes that respond to or modulate hemolysis, vasoregulation, inflammation, cell adhesion, hemostasis, and oxidative stress play roles in the severity of SS disease (Table 19-1; see also Fig. 19-1). As knowledge of the genes involved in these various pathways has increased, numerous investigators have used candidate gene approaches to study the association of genetic modifiers with clinical complications in SS disease. The studies published thus far on large cohorts of SS patients who have been rigorously phenotyped are most likely to yield the best evidence for genetic modifiers. However, by definition, the candidate gene approach will not identify unknown networks of genes or unknown genes in a defined pathway involved in the clinical phenotype. Association between a genetic variant and a phenotype does not necessarily mean causality. Association studies alone may identify SNPs within a gene, but this association may indicate that the gene is involved or that genes in linkage disequilibrium with the SNP are involved. In addition, studies that look at large number of genes or numerous polymorphisms in a single gene are likely to lead to false-positive associations. Finally, most associations, albeit statistically significant, have shown relatively small effects (<5% of the variation), thus suggesting that a large number of genes are likely to be involved in any one clinical subphenotype.

The hemolysis associated with the sickle mutation leads to release of free hemoglobin, scavenging of NO, and increased oxidative stress. Clinical phenotypes associated with increased hemolysis in SS disease include stroke, priapism, PHT, and leg ulcers.[317] Interestingly, priapism,[318,319] leg ulcers,[320,321] and PHT[322] are seen to a lesser extent in other hemolytic anemias. Among the so-called hemolytic phenotypes, certain common genetic

ADCY6, adenylate cyclase 6 gene; ADRB2, beta-adrenergic receptor gene; ANXA2, annexin A2; AQP9, aquaporin 9; BCL11A, B cell lymphoma 11A gene; BMP, bone morphogenetic protein; BMPR, bone morphogenetic protein receptor; ERG, Ets (transcription factor)–related gene; GPM6B, golli-myelin basic protein gene; HBS1l-MYB, intergenic region of the gene for HBS1L (a G-protein/elongation factor) and the *MYB* oncogene; IGF, insulin-like growth factor; IGFR1, insulin-like growth factor receptor gene; IL4HR, interleukin-4 receptor gene; KL, Klotho; LDLR, low-density lipoprotein gene; MAP2K1, mitogen-activated protein kinase 2 gene; SELP, soluable P-selectin gene; SMAD, signaling mediators and antagonists of the transforming growth factor-beta (TGF-beta); TEK, tyrosine kinase receptor gene; TGF-β, transforming growth factor β; TNF, tumor necrosis factor; TOX, thymocyte selection–associated HMG box protein gene; UGT1A1, Uridine diphosphate-glucuronosyltransferase 1A1; VCAM-1, vascular cell adhesion molecule 1.

modifiers appear. Polymorphisms of Klotho (KL), a gene that encodes a membrane protein that regulates many vascular functions, including expression of vascular endothelial growth factor and release of NO by endothelium,[323] is associated with priapism[324] and leg ulcers.[315] KL may also participate in bone metabolism and is associated with an increase risk for osteonecrosis of the hip or the shoulder (or both) in SS patients.[312]

Several subphenotypes (stroke,[306] leg ulcers,[315] osteonecrosis,[312] PHT,[325] and bacteremia[314]) are associated with genes in the transforming growth factor β/bone morphogenic protein (TGF-β/BMP) pathway. BMPs, including *BMP6*, are pleiotropic secreted proteins structurally related to TGF-β and activins. BMP6 and SAND (a transcription factor activated by BMP6) are involved in inflammatory processes[326] and are important for bone formation.[327] The TGF-β/BMP pathway also consist of genes that play a role in cell proliferation, tissue repair, immune surveillance, and inflammation.[328,329]

Some genes have been implicated in similar disorders in the normal population and in patients with SCD: polymorphisms in P-selectin (SELP) are associated with an increased risk for stroke in the normal population[330]

and in SCD patients,[306] BMPR2 is associated with both familial and sporadic PHT in normal individuals[331] and in SCD,[325] and polymorphisms of UGT1A are associated with hyperbilirubinemia in normal persons (Gilbert's syndrome)[332] and with higher bilirubin levels and gallstones in sickle cell patients.[310]

Ultimately, identification of genetic modifiers should lead to detection of sickle cell individuals at increased risk for a particular complication. Because it is likely that multiple factors are involved, few studies have been robust enough to test the predictability of their findings in a general SS population. Sebastiani and colleagues analyzed 114 individuals (7 with and 107 without stroke) not included in their original study of genetic modifiers of stroke in SS disease. The polymorphism associated with six SNPs in five genes (ANXA2, BMP6, SELP, TGF-β3, and ERG) gave an overall predicted accuracy of 98.2%.[306] Reproduction of these findings has not yet been performed.

DIAGNOSIS

The Fetus. The ability to perform prenatal diagnosis for sickle cell anemia has progressed rapidly in the past 3 decades. In 1978, Kan and Dozy[333] described DNA polymorphisms around the β-globin gene that were in linkage disequilibrium with the β^S gene, thereby leading to the first DNA-based method for prenatal diagnosis. Identification of the A→T substitution in codon 6 responsible for the glutamic acid–to-valine change in β-globin can be detected by alteration of a site of a specific restriction enzyme, by homologous synthetic oligonucleotides that detect a single base substitution, and by polymerase chain reaction amplification of DNA.[334-340] With the advent of polymerase chain reaction amplification of specific DNA sequences, sufficient DNA can be obtained from a very small number of fetal cells, thereby eliminating the necessity for culture of fetal fibroblasts.[341,342] Chorionic villus biopsy offers an alternative to amniocentesis for obtaining fetal cells as early as 8 to 10 weeks' gestation.[343,344] Preimplantation genetic diagnosis of single blastomeres by single-cell polymerase chain reaction followed by standard in vitro fertilization has led to the birth of unaffected twins to a couple both with sickle trait.[345]

The Newborn. A newborn with sickle cell anemia is not generally anemic and is asymptomatic because of the protective effect of HbF. The "sickle prep" and solubility tests are unreliable during the first few months of life. Because recognition of the disease in a newborn can lead to prevention of mortality and morbidity, it is now recommended that all newborns at risk be screened for sickle cell anemia. Screening combined with comprehensive follow-up care was first begun by Pearson in New Haven and Serjeant and colleagues in Jamaica in the 1970s.[346,347] Present screening methodologies include acid and alkaline electrophoresis, high-performance liquid chromatography, and isoelectric focusing. These

tests can be performed on cord blood or on a dried blood specimen blotted on filter paper. False-negative screening results with these methods have been reported in infants who received perinatal transfusions before screening.[348] Diagnosis can also be performed by polymerase chain reaction amplification of DNA extracted from filter paper.[349] Universal screening versus targeted screening of newborns of parents "at risk" has been shown to identify more infants with disease and prevent more deaths and is cost effective in areas in which sickle trait occurs in 7 to 15 per 1000 births.[350,351]

The Older Child. After the first few months of life, as β^S-globin production increases and HbF declines, the clinical syndrome of sickle cell anemia emerges (Table 19-2). Although at 1 week of age the hemoglobin level of SS infants is statistically lower than that of AA infants, the overlap between the two groups is considerable and

does not diverge much before the second month of life.[346] Anemia and reticulocytosis are usually evident by 4 months of age.[346] ISCs are frequently absent from the peripheral blood of young children, and the morphology is typical of that of normal newborns—target cells, fragments, and poikilocytes. By 3 years of age, the typical peripheral blood smear is seen, including ISCs, target cells, spherocytes, fragments, biconcave discs, Howell-Jolly bodies, and nucleated red cells. The amount of HbF decreases with age, as in normal children, but it occurs much more slowly.[346,352]

CLINICAL MANIFESTATIONS

The clinical manifestations of SCD are extremely variable. Some patients are entirely asymptomatic, whereas others are constantly plagued by painful episodes. Most

patients fall between these extremes and have relatively long asymptomatic periods punctuated by occasional clinical crises. The complex nature of the clinical variability from patient to patient and from time to time in each patient has been prospectively studied on a large scale by the CSSCD under the auspices of the Sickle Cell Disease Branch of the National Heart, Lung, and Blood Institute (NHLBI).[353,354]

Sickle Cell Crisis

The term *sickle cell crisis* was defined by Diggs[355] as "any new syndrome that develops rapidly in patients with sickle cell disease due to the inherited abnormality." There are three categories of sickle crisis—vaso-occlusive, sequestration, and aplastic—and they are covered individually in the next few sections. The best perspective on how these acute events play out in a typical group of children comes from a report by Gill and colleagues describing the experience of almost 700 infants monitored for 10 years as part of the CSSCD.[356] The age at first event is displayed in Figure 19-7.

Vaso-occlusive Sickle Crises

Vaso-occlusive crises are acute, often painful episodes caused by intravascular sickling and tissue infarction. In a prospective study of children with SS disease moni-

tored since birth in Jamaica, painful crisis was the first symptom in more than a fourth of the patients and the most frequent symptom after the age of 2 years.[357] Painful episodes are such a prominent manifestation of the disease that African tribal names for SCD are onomatopoeic repetitive descriptions of pain, such as "chwechweechwa" (Ga tribe), "nwiiwii" (Fante tribe), "nucdudui" (Ewe tribe), and "ahotutuo" (Twi tribe). Tribal names translate as "beaten up," "body biting," and "body chewing."[358] Vaso-occlusive episodes are the major clinical manifestations of SCD and occur most commonly in the bones, lungs, liver, spleen, brain, and penis. Frequently, the differential diagnosis is very difficult because there is no definitive objective hallmark of a vaso-occlusive crisis.

Painful Crisis. The most common acute vaso-occlusive crisis is acute pain. Virtually all patients with SS disease experience some degree of acute pain. For many, these episodes are mild and are handled entirely at home, school, or work. Little is known about the extent or nature of pain-coping activities that go on outside the medical environment, but diary studies suggest that it is enormous. The "tip" of the pain "iceberg" is made of episodes that drive patients to seek medical attention. These episodes vary widely among patients[280] (Fig. 19-8) and represent the most common reason for patients to
FIGURE 19-7. visit outpatient offices and emergency departments and be admitted for inpatient care. Despite the fact that there is variation in how or why individual patients decide to seek attention for a given episode of pain, epidemiologic evidence strongly indicates that patients with higher rates of medical attention for pain have lower levels of HbF, higher WBC counts, higher steady-state hemoglobin concentrations, and higher mortality.[247,280] Some studies have suggested that infections, changes in climate,[359,360] and psychological factors may precipitate pain episodes, although commonly no precipitating factors can be identified. These patients typically have a rapid onset of deep, gnawing, throbbing pain, usually without any abnormal physical or laboratory findings but sometimes accompanied by local tenderness, erythema, warmth, and swelling. The underlying pathology is bone marrow ischemia, sometimes leading to frank infarction with acute inflammatory infiltrates.[361-363] The most frequently involved areas are the lumbosacral spine, knee, shoulder, elbow, and femur. Less often, the sternum, ribs, clavicles, calcaneus, iliac crest, mandible, and zygoma are involved.[358] Joint effusions during acute episodes are particularly common in the knees and elbows. Typically, aspiration yields straw-colored fluid, usually with a "noninflammatory" profile. Rarely, sterile purulent exudates are found.[364] Given the range of marrow involvement and inflammatory response, it is not surprising that the patients with the most inflammation mimic the findings of osteomyelitis and those without findings are at risk of being considered malingerers.

Even in patients with measurable signs of inflammation, the diagnosis of infarction is favored over osteomy-

elitis. The results of one study suggest that acute long bone infarction is at least 50 times more common than osteomyelitis.[365] In this study of 41 acute long bone infarcts, 38% affected the humerus, 23% affected the tibia, and 19% affected the femur. All patients experienced local tenderness, with swelling in 85%, joint findings in 68%, and local heat in 65%. Fourteen percent appeared "toxic," 21% had a temperature higher than 39° C, and 43% had a temperature lower than 38° C. The total WBC count ranged between 7200 and 43,000 cells/mm³, with a mean of 17,000. The mean sedimentation rate was 30.5 mm/hr, with a range of 3 to 66. Although various radionuclide scans have been suggested as a way of distinguishing between infarction and infection,[366-370] in many studies[371-373] such investigations were inconclusive. Magnetic resonance imaging (MRI) of patients with SS disease shows decreased intensity of short relaxation time/echo time pulse sequence imaging as a result of hyperplastic marrow that converts to high intensity on long relaxation time/echo time images in painful crises,[363] but no definitive series has compared infarction with infection. Therefore, despite the progress made in the development and use of imaging techniques, a definitive diagnosis of osteomyelitis in SCD still relies more on clinical assessment together with positive cultures from blood or bone obtained by aspiration or biopsy than on any single imaging modality.[374]

Except for a positive blood or tissue culture, no laboratory test can differentiate acute infection from a painful crisis.[362,375] Needle aspiration and culture of the highly suspicious area are critical in isolating the organism and should be done before initiating empirical antibiotic

therapy. The aspirated fluid may be quite purulent, even in the patients with sterile infarcts. In most series, the most common organism causing osteomyelitis is *Salmonella*,[376] although *Staphylococcus*, *Streptococcus pneumoniae*, and gram-negative enteric bacilli are also common.[377] Initial empirical antibiotic therapy should be chosen to cover these possibilities. Treatment failures are seen when anything but the most aggressive antibiotic regimens are used.

As described earlier, episodes of acute bone pain and impressive signs of inflammation may be difficult to distinguish at outset from osteomyelitis. More common and just as challenging are the evaluation and management of severely painful episodes in patients without signs of inflammation. Some of these patients will show laboratory evidence of acute inflammation such as elevated C-reactive protein,[37] of fibrinolysis such as elevated D-dimers,[379,380] or of red cell trapping such as loss of dense cells.[381] These measurements are not helpful in the management of individual cases, nor should they be used in an attempt to "validate" an individual patient's report of symptoms. In a research setting, these measurements, done on large numbers of patients with and without symptoms, provide clues to potential innovative therapeutic interventions. For example, the common finding of elevated acute phase reactants stimulated a trial of methylprednisolone for treating acute bone pain.[382] This preliminary work showed that a short course of high-dose corticosteroid decreases the duration of severe pain but results in more "rebound" attacks after treatment is discontinued. Similarly, despite the fact that previous trials of aspirin therapy were not encouraging,[383] there is significant interest in the role of platelets,[384,385] soluble procoagulants,[206] anticoagulants,[386,387] and endothelial cells[254] in precipitation or propagation of vaso-occlusion to reopen this potential line of treatment.

In children younger than 5 years, the small bones of the hands and feet are frequently affected, and in contrast to most episodes of bone pain in older children, physical findings are common. This painful dactylitis ("hand-foot syndrome") is typically the first clinical manifestation of SCD. A young child cries with pain; refuses to bear weight; and has puffy, tender, and warm feet or hands, or both. The child may appear acutely ill, be febrile, and have an impressive leukocytosis. At the onset of soft tissue swelling, bony changes are not generally apparent on radiographs. After 1 to 2 weeks, subperiosteal new bone, irregular areas of radiolucency, cortical thinning, or complete destruction of bone can be seen. All the bone changes are usually reversible but may persist for as long as 8 months.[388,389] A rare complication, permanent shortening of the digits after hand-foot crisis, has been reported.[390] Dactylitis before 1 year of age is a strong predictor of overall severity (stroke, death, high pain rate, or recurrent ACS) by 10 years of age,[249] although recent single-institution evidence suggests that dactylitis is not a strong predictor of subsequent pain or ACS.[391] In addition to dactylitis, the risk for severe disease is further increased if the child has also experienced an episode in which the hemoglobin content dropped below 7 g/dL or the baseline WBC count is elevated (or both).[249]

Acute Chest Syndrome. ACS is an acute illness with lung injury characterized by any combination of chest pain, fever, or respiratory symptoms and accompanied by a new pulmonary infiltrate on a chest radiograph. The diagnostic criteria most commonly include radiographic evidence of a new segmental pulmonary infiltrate *and* one or more of the following: fever, tachypnea, cough, new-onset hypoxia, increased work of breathing (intercostal retractions, nasal flaring, accessory muscle use), or chest pain.[392] The term "acute chest syndrome" was introduced by Charache and co-workers[393]; it reflects the difficulty of establishing a definitive etiology and emphasizes the fact that in individual patients, knowing the specific etiology is less critical for management than being able to assess the magnitude and pace of the lung injury.

The critical pathophysiology is that only deoxygenated HbS polymerizes and that reoxygenation eradicates the polymer. The lung is the critical organ that protects the arterial side of the circulation from the sludge of sickle polymers. When the lung is injured, underventilated, or inflamed, protection is inadequate, and downstream tissues, including the injured lung itself, become increasingly susceptible to sickling and ischemia. In fact, when flow is eventually restored, reperfusion injury may occur, as suggested by the study by Kaul and Hebbel, who found that cycles of oxygenation/deoxygenation cause classic P-selectin–inhibitable movement of inflammatory cells to tissue in a sickle mouse model.[254]

Although some patients, particularly adults, are initially seen with a full-blown picture of chest pain, hypoxia, and abnormal x-ray findings, frequently the diagnosis becomes clear only days into an event that starts as a fever without source, abdominal pain, or extremity pain. The diagnosis of ACS can be very difficult to make. Children younger than 4 years often have few signs at initial evaluation: 35% to 40% have a normal lung examination, 30% to 40% have no tachypnea, and 30% to 50% have no tachycardia.[394] Radiographic evolution often lags behind clinical progression. In one series, only 36% of patients had abnormal radiographic findings on evaluation, although abnormal findings eventually developed in all.[395]

Vichinsky and associates demonstrated that almost half of all patients in whom ACS develops were initially admitted for other reasons, frequently with vaso-occlusive pain.[392] Opioid analgesics and pain in the spine, ribs, and abdomen can lead to hypoventilation with decreased tidal volume, development of atelectasis, and ventilation-perfusion (V/Q) mismatch. The subsequent hypoxemia results in further intrapulmonary sickling. Secretory phospholipase A_2 (sPLA2) and serum C-reactive protein have been proposed as possible laboratory predictors of the development of ACS.[396-398] Elevated sPLA2 as a trigger for simple transfusion appeared to reduce the risk

of ACS developing in comparison to standard therapy in one small uncontrolled trial.[399]

ACS is a leading cause of morbidity and mortality. It represents the second most common acute complication (pain episode is first), with a rate of 12.8 cases per 100 patient-years,[248] and the most common condition at the time of death.[247,392] The highest incidence is found in children 2 to 4 years of age (25.3 per 100 patient-years in sickle cell anemia) and lowest in adults (8.8 per 100 patient-years in sickle cell anemia).[248] Patients who have not experienced an episode of ACS have longer life expectancy than do those who have, and those with a higher level of HbF and lower steady-state leukocyte count have a lower attack rate for ACS.[248] Hydroxyurea therapy lowers the attack rate in adults by about 50%.[400] Asthma appears to be a risk factor for ACS.[401-406]

Vichinsky and colleagues prospectively studied 671 episodes of ACS.[392,407] The most common causes were fat/bone marrow emboli and bacterial (*Chlamydia*, *Mycoplasma*), viral, or mixed infection. In contrast to patients with infection, those with bone marrow emboli were more likely to have an associated episode of bone pain, chest pain, abnormal neurologic symptoms, and fall in platelet count.[407]

Bacterial pneumonia was rare overall, but more common in children than adults, in whom it was associated with bacteremia in 58% of cases of *S. pneumoniae* and 18% of cases of *Haemophilus influenzae*.[394] Regardless of etiology, ACS is always accompanied by some degree of localized sickling and lung ischemia; in 16% of cases no precipitating embolus or pathogen was identified. Overall, the prognosis is poor. Thirteen percent of patients required mechanical ventilation, new abnormal neurologic findings developed in 11%, and 9% of patients who were 20 years or older died. In general, the death rate from ACS is four times higher in adults than children.[394]

There was a considerable change in blood counts at initial evaluation in patients with ACS. Hemoglobin dropped an average of 0.7 g/dL, and WBC counts increased an average of 69%. The mean Po_2 was 71 mm Hg, with a fifth of patients having a Po_2 of less than 60 mm Hg. Because the hemoglobin-oxygen dissociation curve varies among patients and because the shallow portion of the curve is between a Po_2 of 50 and 100 mm Hg, transcutaneous oxygen saturation measurements are not sufficient unless there are enough simultaneous direct measurements of arterial Po_2 to detect trends.[408] In one study, all children with SS disease and ACS had transcutaneous saturation measurements below 96% or only 3 points below their steady-state values.[409] Given that it is not unusual for a transcutaneous measurement to vary by as much as 3 points with slight differences in positioning of the probe, it is unwise to place too much reliance on single measurement in isolation. Unfortunately, no clinical findings are reliably predictive of the degree of hypoxia.[394]

Several important therapeutic principles emerged from the Vichinsky study.[392,394] First of all, bronchodilator therapy was remarkably effective in 20% of the patients with wheezing or pulmonary function tests indicating obstruction at initial evaluation (61% of all the patients). This is consistent with the observation that measurable airway hyperactivity has been documented in as many as 73% of children with SS, even without a history of asthma.[410] Second, red cell transfusion improved oxygenation. Simple transfusion was used in 68% of patients and appears to be as effective as exchange transfusion—although the study was not designed to test this hypothesis. It may be that the efficacy of simple transfusions relates to the fact that ACS is typically associated with a 0.5- to 1.0-g/dL decrease in hemoglobin at initial evaluation. Third, the prominence of *Chlamydia* and *Mycoplasma* underscores the importance of including macrolide antibiotics in the initial broad empirical therapy.

Optimal management of patients with ACS requires vigilant monitoring and considered judgment. A few guidelines are presented here, but they should not substitute for consultation and collaboration with a clinician experienced in managing this complex problem. All patients with ACS must be managed in the hospital, in a setting where they can have frequent monitoring of vital signs and arterial blood gases. Oxygen therapy is critically important in hypoxic patients. Broad-spectrum antibiotics, including a macrolide, should be used empirically after careful culturing while keeping in mind the prevalence of *Chlamydia*, *Mycoplasma*, *S. pneumoniae*, and *H. influenzae*. A trial of bronchodilator therapy should be instituted, especially in patients with a history of obstructive lung disease or those who exhibit wheezing on examination. A Po_2 of less than 75 mm (or a 25% decrease from baseline if the patient is chronically hypoxic) carries a poor prognosis.[386] Simple transfusion should be considered early for those with persistent or worsening hypoxia (Po_2 <75 mm Hg or a 25% decrease from baseline). Exchange transfusion is indicated if the hematocrit is high, the hypoxia is worsening, or the patient is deteriorating rapidly despite simple transfusion. Because the splinting and atelectasis associated with chest pain may exacerbate or even cause ACS, analgesic therapy should not be withheld from patients with chest pain but should titrated with extreme caution to analgesic effect. These patients may hover on the brink of hypoventilation from either too little or too much analgesia. Compulsive continuous monitoring of oxygen saturation and the respiratory rate monitoring and pain evaluation are critical. Fluid overload with pulmonary edema, congestive failure, or both is easy to achieve in the setting of ACS. Once normal hydration is attained, maintenance fluids should be given. Progression to respiratory failure is not uncommon if treatment is not early and aggressive, and mechanical ventilation is sometimes required. Both high-frequency ventilation[411] and extracorporeal membrane oxygenation[412,413] have been used successfully in severe cases of respiratory failure in ACS. In ventilated patients, bronchoscopy may have both diagnostic and therapeutic benefit by detection of plastic bronchitis and removal of

branching bronchial casts that can exacerbate the hypoxemia and V/Q mismatch.[414,415] Alternatively, nebulized recombinant human DNase has shown some efficacy in plastic bronchitis.[416] Preliminary evidence suggests that inhaled NO, a selective pulmonary vasodilator, may be of benefit in severe cases.[417,418] However, there have been no controlled studies confirming a role of NO therapy in the treatment of ACS.

Although most patients with ACS recover uneventfully, the course is unpredictable, and rapid, unexpected deterioration is common. Most series of ACS include a section on autopsy findings. Pulmonary postmortem findings typically include areas of alveolar wall necrosis and focal parenchymal scars.[419] In one autopsy, multiple large infarcts but no accompanying occluded vessels were found, thus suggesting that severe vasospasm may play a role in some cases.[420]

Acute Abdominal Pain. Severe acute abdominal pain is a common event that often poses a difficult differential diagnosis. The cause of this syndrome is unknown, although mesenteric sickling and vertebral disease with nerve root compression have been suggested. This type of crisis can be accompanied by guarding, tenderness, rebound, fever, and leukocytosis that are indistinguishable from an acute surgical abdomen. Frequently, the patient is the best judge and is aware of whether the pain is characteristic of a "crisis."

These patients should receive the general supportive measures described later in this chapter, with the omission of high-dose analgesics. Patients should be given nothing by mouth and be monitored closely by both medical and surgical personnel. Abdominal films, including upright views, may be helpful in identifying a perforated viscus. Usually, a patient with vaso-occlusive pain will remain stable or improve slightly with hydration and mild sedation. In extreme cases in which the clinical situation is deteriorating, emergency surgical exploration may be necessary. Simple or exchange transfusion should be done if possible before surgery.

Acute right upper quadrant pain may be a result of acute cholecystitis or intrahepatic sickling.[421,422] Abdominal ultrasonography will indentify cholelithiasis and choledocholithiasis in the hands of a skilled operator. The presence of gallstones and a clinical syndrome characteristic of cholecystitis does not necessarily mean that the symptoms are due to the stones. Many patients and their physicians have been disappointed when their "cholecystitis" returned after cholecystectomy. In a retrospective study of acute abdomen in 28 patients with SS disease,[423] the presence of gallstones on ultrasound evaluation did not predict which patients could be managed without surgery. Sickle patients with acute cholecystitis should undergo surgery only after the gallbladder has had a chance to "cool down" because postoperative management can be fraught with complications.[424] (For further discussion, see the section on the hepatobiliary system.)

Intrahepatic sickling can result in acute right upper quadrant pain from acute sickle hepatic crisis, hepatic sequestration, or sickle cell intrahepatic cholestasis (or any combination of these conditions). Acute hepatic crisis occurs in approximately 10% of patients with sickle cell anemia[422] and is commonly manifested as acute right upper quadrant pain, tender hepatomegaly, nausea, low-grade fever, and jaundice. Transaminases are rarely greater than 300 IU/L, and serum bilirubin levels are usually less than 15 mg/dL.[422,425] The crisis generally resolves within 2 weeks with intravenous hydration and analgesia. Hepatic sequestration is also manifested as sudden tender hepatomegaly; however, in contrast, it is accompanied by acute anemia but without cholestasis or transaminitis.[426,427] Treatment is to replace circulating volume by crystalloid or simple transfusion. Transfusion must be undertaken judiciously because the liver may "release" the endogenous sickle erythrocytes, which can lead to an elevated hematocrit and subsequent problems secondary to hyperviscosity. Exchange transfusion should be considered. Sickle cell intrahepatic cholestasis is a severe syndrome consisting of right upper quadrant pain, nausea/vomiting, fever, tender hepatomegaly, leukocytosis, and extreme direct hyperbilirubinemia. The spectrum of this entity includes acute liver failure with bleeding diatheses, encephalopathy, renal failure, and progression to multiorgan failure, and it is associated with high mortality.[425,428,429] These hepatic complications are not to be confused with "benign hyperbilirubinema" described by Buchanan and Glader,[421] which is characterized by marked conjugated hyperbilirubinemia, only mild transaminitis, and no liver synthetic dysfunction. This entity resolves spontaneously within 2 to 8 weeks and may represent a very mild variant of intrahepatic cholestasis.

Acute Central Nervous System Event. Acute infarction of the brain can result in a devastating stroke, which occurs in approximately 7% of children with SCD.[430,431] The incidence is estimated to be 0.7% per year during the first 20 years of life, with the highest rates in children 5 to 10 years of age.[432] This disaster may occur as an isolated event but also appears in the setting of evolving ACS, aplastic crisis, viral illness, painful crisis, priapism, or dehydration.[430,431] The most common underlying lesion is an intracranial arterial stenosis or obstruction, usually in the internal carotid and often in the proximal middle cerebral or anterior cerebral arteries.[433-435] Pathologically, these vessels, whose endothelium has presumably been chronically injured by sickle erythrocytes, show heaped-up intima with proliferation of fibroblasts and smooth muscle.[436] The lumen may be narrowed or completely obliterated by the vascular lesion, thus suggesting that *acute* sickling may simply be the "last straw" causing acute infarction in the setting of a chronic vasculopathy. Hemiparesis, focal seizures, gait dysfunction, and speech defects are the most common signs.

A careful discussion of the evaluation of a child with new neurologic symptoms is provided by Adams.[437] As

soon as cerebral ischemia is suspected and the patient is stabilized, the best initial diagnostic test is a non–contrast-enhanced computed tomography (CT) scan. Although CT may not be positive for infarction within the first 6 hours of ischemia, it can rule out hemorrhage or nonischemic causes. Diffusion-weighted MRI and fluid-attenuated inversion recovery (FLAIR) sequences are highly sensitive and provide better detail of the areas of ischemia within minutes of ischemia.[438-440] The typical findings are infarcts associated with obstruction of major vessels or distal obstruction of smaller vessels leading to infarction in the "border zone" area between the anterior cerebral and middle cerebral vessels.[441,442] Assessment of the intracranial and cervical artery vasculature by three-dimensional time-of-flight (TOF) magnetic resonance angiography (MRA) is becoming increasingly useful in the early evaluation of a patient with new symptoms[443] and is nearly as accurate as conventional cerebral angiography.[444]

The standard approach to treating a patient with acute infarction is immediate exchange transfusion (see the section on transfusion for details). If exchange transfusion is delayed, temporization by hydration with crystalloid and simple transfusion may be beneficial. There are no data on the use of recombinant tissue plasminogen activator (tPA) in sickle-associated cerebral ischemia. Patients treated by exchange transfusion usually show marked improvement in motor function, although the prognosis is considerably worse for those with multiple infarcts. After the initial exchange, a chronic maintenance transfusion program should be carried out (see "Transfusion"). In untreated patients, the mortality rate is approximately 20%, with about 70% of patients experiencing a recurrence within 3 years. In these untreated patients, more than 70% were left with permanent motor disabilities and a deficit in IQ.[430] A regular chronic maintenance transfusion program designed to keep HbS less than 30% reduces the incidence of stroke to 10% to 15%, which is a 90% reduction in stroke rate in comparison to no intervention.[434,445-448] Patients whose initial stroke was temporally unrelated to another medical event (e.g., ACS) are at higher risk for recurrent stroke while receiving regular transfusions.[449] Repeat arteriograms in patients maintained on transfusion generally, but not invariably show stabilization and smoothing of intimal lesions, whereas untransfused patients demonstrate progression of disease.[445] The appropriate duration of chronic erythrocyte transfusions for secondary stroke prophylaxis has not been firmly established. Two prospective studies documented a very high risk for recurrent stroke (60% to 70%) after discontinuation of either a short-term (1 to 2 years) or long-term (5 to 12 years) transfusion regimen.[434,450] Therefore, it is recommended that the maintenance transfusion program be continued indefinitely to prevent secondary stroke. In one informative series, liberalization of the transfusion regimen allowed the pretransfusion percentage of HbS to rise to 50% and effectively prevented recurrent infarction over 84 months

of follow-up.[451] Unfortunately, liberalization did not prevent hemorrhage—two patients died, one of intraventricular and one of subarachnoid bleeding. Though clearly beneficial, indefinite maintenance transfusion carries the risks of allosensitization,[452] autoantibody formation,[453] transfusion-borne infections, and the certain problem of iron overload. Bone marrow transplantation in patients with strokes can be curative,[454] although parenchymal brain disease may progress.[455] Hydroxyurea treatment to increase HbF and as an alternative to chronic transfusion[456] effectively prevented secondary stroke in a single institution,[457] and a prospective randomized trial is under way.[458]

Application of newer techniques for noninvasive assessment of the brain and its vasculature has focused attention on two new areas—identifying children at high risk for stroke and identifying children with "asymptomatic" brain disease. Adams and associates demonstrated that children with abnormally increased blood flow in their intracerebral arteries as measured by transcranial Doppler (TCD) had a relative risk of stroke of 44 (95% confidence interval, 5.5 to 346).[459] A systematic study of MRI findings in asymptomatic children with SCD revealed that unanticipated infarcts are highly predictive of subsequent clinical stroke.[460] However, in older children (mean age of 11 years) without evidence of previous central nervous system (CNS) disease, abnormal TCD and MRI findings are often discordant, thus indicating that these tests may be measuring different aspects of CNS pathology in these subjects.[461] MRI has revealed that as many as 17% of children older than 6 years have evidence of silent infarcts,[462] and in one study of 36 asymptomatic children 7 to 48 months of age, the incidence was 11%.[463] These silent infarcts are associated with impaired performance on psychometric tests that measure fine motor skills and cognitive ability.[464,465] Older children (>6 years) with silent infarcts were more likely to have a history of seizures, low hemoglobin level, and high WBC count (>11.8 × 10^9/L).[462] In a study of 392 children monitored prospectively up to 10 years, an elevated WBC count, dactylitis, and low hemoglobin content (<7 g/dL) before the age of 2 years were associated with adverse outcomes, including strokes.[249] In other studies, low hematocrit,[466] ACS,[467] and hypertension[468] have been associated with silent infarcts, clinical strokes, or both. In the multicenter prospective Stroke Prevention Trial in Sickle Cell Anemia (STOP) of 130 asymptomatic children with abnormal Doppler flow measurements (>200 cm/sec), subjects were randomized to transfusions or standard care. The study was terminated early when it was shown that only 1 of 63 transfused children versus 11 of 67 had strokes, a 92% decrease in the relative stroke rate in the treated group.[469] The NHLBI issued a Clinical Alert suggesting that children between the ages of 2 and 16 years be screened with Doppler and that transfusion therapy be considered for those with abnormal Doppler studies. A second randomized, controlled clinical trial (STOP 2) tested whether chronic transfusions for primary

stroke prevention based on abnormal TCD findings could be safely discontinued after at least 30 months in children who had not had an overt stroke and who exhibited reversion to low-risk TCD flow measurements (<170 cm/sec) with chronic transfusion therapy. After 79 of a planned 100 children were randomized, the trial was also terminated early because 16 of 41 subjects randomized to stop transfusion achieved an end point (14 reversions to high-risk TCD findings without stroke and 2 ischemic strokes) versus 0 of 38 in those maintained on chronic transfusion treatment.[470] The NHLBI issued another Clinical Alert recommending continuation of transfusion and acknowledging the need for alternative therapy to transfusion for primary stroke prophylaxis. These observations suggest that TCD or MRI (or both) should be used to screen older children with poor school performance or evidence of other risks factors. Clinical trials under consideration or under way include transfusions,[471,472] hydroxyurea,[456,473] and bone marrow transplantation[474] in younger children with MRI evidence of silent infarcts or abnormal intracranial Doppler flow measurements.

Not all acute focal neurologic events in patients with sickle cell anemia are infarcts. Intracranial hemorrhage is the other major category of sickle-related CNS events, although the incidence may be higher in adults than in children.[467] These events are manifested as a sudden severe headache, sometimes with neck pain, vertigo, syncope, nystagmus, ptosis, meningismus, or photophobia. Many of these episodes are subarachnoid hemorrhages from small bleeding aneurysms that probably arise as a result of intimal damage during childhood. Multiple aneurysms with extensive collaterals (similar to moyamoya disease) have been found incidentally during angiographic evaluation of children with stroke.[436] Many risk factors for hemorrhagic stroke have been proposed, but few have been rigorously evaluated exclusively in children. Risk factors include increasing age, low steady-state hemoglobin concentration, high steady-state leukocyte count,[467] previous ischemic stroke,[475] moyamoya,[476] cerebral aneurysms,[477] ACS,[150] acute hypertension, transfusion,[478] and recent corticosteroid use.[479] Although mortality in some series approaches 50%,[430] some describe more successful aggressive neurosurgical approaches to these bleeding lesions[480-482] and suggest that angiography should be performed to identify patients with surgically amenable lesions.

Priapism. Priapism occurs in males of all ages. In a Jamaican study of 104 males aged 10 to 62 years, 42% reported at least one episode of priapism, with a median age at onset of 21 years.[483] A long-term follow-up of patients in Los Angeles determined that priapism develops in about 7% of SS and approximately 2% of SC males, with a median age at onset of about 22 years.[24] A questionnaire survey administered to 98 patients younger than 20 years in Dallas found the mean age at the initial episode to be 12 years, with an average number of episodes per patient of 15.7 and an 89% actuarial probability of experiencing priapism by 20 years of age.[484] Prolonged sexual arousal, fever, cold exposure, nocturnal tumescence (rapid eye movement [REM] sleep), full bladder, dehydration, alcohol, cocaine, and testosterone therapy have all been implicated as triggers.[485-487] Several genetic polymorphisms[324,489] (see "Genetic Modifiers") and particularly high hemolytic rates[317,482] have also been associated with a risk for priapism. Because early intervention and treatment may prevent irreversible penile fibrosis and impotence, to prevent embarrassment, patients and parents should be educated in advance of its occurrence to treat prolonged priapism as a urologic emergency.

Four clinical entities are described: stuttering priapism, with short (less than 2 to 3 hours), often multiple episodes; acute prolonged priapism (more than 24 hours), which can persist for weeks; chronic priapism, a painless induration that may last for years; and acute-on-chronic priapism, with acute painful episodes complicating chronic induration. Sexual dysfunction was reported by 46% of patients with a history of priapism.[483] In general, young patients with brief episodes restricted to the corpora cavernosa ("bicorporal priapism") are less likely to become dysfunctional,[490,491] whereas adults with involvement of the corpora cavernosa and corpus spongiosum ("tricorporal priapism") tend to have prolonged episodes and a better than 50% chance of becoming impotent.[492] Urinary retention requiring catheterization may complicate such acute episodes. Patients with tricorporal involvement are also particularly susceptible to acute severe neurologic complications and overall increased morbidity—even those treated by exchange transfusion.[493,494] They should be monitored closely for early neurologic symptoms, especially headache.

Diagnostic studies such as technetium scans, MRI, Doppler flow studies, measurements of corporal pressure, hemoglobin electrophoresis, and blood gases are currently being used in a variety of settings to help define the anatomy and potential prognostic features of priapism. As yet, they have not had an impact on clinical decision making in individual patients.[495-497]

A consensus on treatment of priapism has not been reached; no controlled clinical trials have been conducted to guide therapy.[498] Short episodes of acute priapism usually occur on awakening and can be managed at home. Patients should be instructed to urinate frequently, perform some vigorous exercise, increase fluid intake, soak in a warm tub, and take analgesics. If the episode does not resolve within a few hours, the patient should appear for medical treatment with intravenous fluid and analgesics. If the episode persists beyond 4 hours, intracavernosal aspiration and instillation of an α-agonist should be performed and repeated.[499,500] Although the role of RBC transfusion is somewhat controversial,[501] priapism may respond to simple red cell transfusion.[490] Exchange transfusion may produce results in 6 to 8 hours,[502,502] but most do not show signs of detumescence

for 24 to 48 hours and some do not respond at all.[504] Use of intracorporal and oral α-adrenergic agents has been tried successfully in a small experimental group in Paris in both the acute and chronic setting,[500] and in one group of patients with stuttering priapism in Jamaica, stilbestrol was helpful in preventing recurrences.[505] Numerous therapeutic options have been attempted, including diethylstilbestrol, gonadotropin-releasing hormone analogues, various adrenergic agonists, and hydroxyurea.[498,506]

Surgical shunting procedures should be considered for patients who have not shown any signs of detumescence 12 to 24 hours after corporal irrigation, transfusion, or both, particularly if they are postpubertal. Historically, these procedures have carried a high complication rate with subsequent penile deformities and impotence. In fairness, it is difficult to determine how much of any observed adverse effects are related to the procedure and how much to the priapism itself. The most conservative shunt is Winter's procedure or one of its modifications, whereby a needle or scalpel is inserted through the glans into one of the corpora and the viscous blood is aspirated. This temporarily allows drainage of cavernous blood into the systemic circulation and has been used successfully in SS disease patients.[507] Intermittent compression with a blood pressure cuff is critical to limit refilling. Anecdotal evidence suggests that penile implants to correct impotence may be more easily inserted soon after an impotence-causing episode.[508,509]

Splenic Sequestration

One of the leading causes of death in children with sickle cell anemia is an acute splenic sequestration crisis.[510] Children with SS disease who have not yet undergone autosplenectomy, as well as older patients with SC disease or S–β-thalassemia,[511] may have sudden, rapid, massive enlargement of the spleen with trapping of a considerable portion of the red cell mass. Patients suddenly become weak and dyspneic, with a rapidly distending abdomen, left-sided abdominal pain, vomiting, and shock. The tempo of this crisis may be so fast that the patient dies before reaching the hospital. On physical examination, there may be profound hypotension with cardiac decompensation and massive splenomegaly. The hemoglobin concentration is at least 2 g/dL lower than baseline and is accompanied by a brisk reticulocytosis with increased nucleated red cells and moderate to severe thrombocytopenia.[510] This complication has been described as early as 8 weeks of age.[512]

Emond and colleagues described the natural history of acute sequestration crisis in a cohort of 308 children with SS disease in Jamaica.[513] Eighty-nine patients experienced 113 attacks, with 67 children having their first attack before the age of 2 years. There were 13 fatalities, 10 of which occurred before the age of 2. The most frequently associated clinical problem was upper respiratory tract infection and ACS. Sixteen percent of the patients had positive blood cultures. Recurrences are frequent and develop in 49% of survivors of the first attack. A parental education program directed toward teaching parents the technique of spleen palpation and the urgency of seeking medical attention for an enlarged spleen and pallor led to an increase in the incidence of cases (from 4.6 to 11.3 per 100 patient-years of observation) and a decrease in the fatality rate (from 29.4 to 3.1 per 100 events).

Therapy consists of emergency restoration of intravascular volume and oxygen-carrying capacity by the immediate transfusion of packed red cells. Once normal cardiovascular status is restored, patients improve rapidly. The spleen usually shrinks within a few days, and the thrombocytopenia resolves. Care must be taken to not transfuse to baseline hemoglobin levels because with improvement, the spleen releases the endogenous erythrocytes and a relative erythrocytosis with hyperviscosity may result. Recurrence of sequestration is common, usually within 4 months of the initial episode. To eliminate recurrence, some have recommended elective splenectomy after the first significant episode[514]; others, concerned with postsplenectomy sepsis, have suggested splenectomy after two episodes of sequestration.[510] Emergency splenectomy during acute sequestration is not indicated.

Kinney and co-workers' review of splenic sequestration from Duke University strengthens the position of those who favor elective splenectomy for children who have had one episode of acute sequestration.[515] In this series of 23 patients, 4 underwent early splenectomy, 7 were observed carefully, and 12 were placed on a maintenance transfusion program. Of those treated by transfusion, two were well and still receiving transfusions, three had recurrences while still receiving transfusions, four experienced recurrence within 3 months of the last transfusion, and only three remained well at 11 months (3.9 years after the last transfusion). Fourteen percent of children became alloimmunized, and non-A, non-B hepatitis developed in 1. Eventually, 14 of the 23 patients underwent splenectomy. All were immunized against pneumococcus and were prescribed penicillin for prophylaxis. None had experienced a life-threatening infection 65.6 patient-years later. Serjeant's group has demonstrated in a 22.5-year follow-up study that postspenectomy children in Jamaica are not at greater risk for infection than a matched control group of SS patients.[516]

Rao and Gooden described a subacute form of sequestration in 11 patients characterized by increased spleen size, a 25% drop in hematocrit, less than 100,000 platelets, and elevation in the reticulocyte count above the patient's baseline. All responded to chronic transfusion programs, but seven patients had recurrent episodes after transfusions were stopped and eventually required splenectomy.[517]

Sequestration can also take place in the liver. Tender hepatomegaly, increased anemia, reticulocytosis, and hyperbilirubinemia are the usual clinical features,[421,426,427] but because the liver is not as distensible as the spleen,

there is rarely pooling of red cells significant enough to cause cardiovascular collapse.

Aplastic Crisis

The clinical characteristics of the aplastic crisis of SCD have been well characterized.[518-520] In the normal steady state, a patient with sickle cell anemia can compensate for the decreased red cell survival (15 to 50 days) by increasing bone marrow output sixfold to eightfold. Temporary cessation of bone marrow activity because of suppression by intercurrent viral or bacterial infection causes the hematocrit value to fall as much as 10% to 15% per day with no compensatory reticulocytosis. The short-lived HbF-poor cells are the first to disappear from the circulation, whereas the high-HbF–containing cells linger. This natural selection of HbF-containing cells accounts for the apparent increase in the percentage of HbF during aplastic episodes.

Patients usually exhibit pallor and fatigue but no jaundice and have laboratory evidence of severe anemia below baseline with associated reticulocytopenia. Spontaneous recovery is generally heralded by a markedly elevated nucleated RBC count, followed in 1 or 2 days by a brisk reticulocytosis. Spontaneous recovery usually occurs within 7 to 10 days and may require no therapy, but some patients are extremely ill when initially seen, and many require short-term hospitalization and erythrocyte transfusions. This recovery phase, with the characteristic anemia, nucleated red cells, reticulocytosis, and occasional hyperbilirubinemia, is probably responsible for most cases referred to as "hyperhemolytic crisis."

In 1981, two groups linked transient aplastic crisis to parvovirus.[521,522] The Jamaican group subsequently documented the epidemiology and follow-up of parvovirus in a cohort of infants identified at birth—308 with sickle cell anemia and 239 controls.[523,524] They made a number of important observations: (1) the frequency of infection (about 40%) did not differ between sickle and control groups, (2) 20% of infections in the sickle group did *not* result in significant aplasia, (3) 100% of aplastic episodes were associated with parvovirus, (4) no patient had recurrent aplasia, and (5) 45% of infected patients maintained elevated parvovirus-specific IgG after 5 years. In a more recent series of aplastic episodes, approximately 70% were associated with positive diagnostic tests for parvovirus.[525] The secondary attack rate of siblings with SCD is 50% to 60%, so siblings with SCD should be monitored for evolving aplastic crisis when acute parvovirus B19 infection is diagnosed in another sibling. Parvovirus B19 has also been implicated as the etiologic agent in erythema infectiosum (fifth disease),[526,527] although frequently the classic rash of fifth disease is absent.[527,528] Parvovirus B19 infection has been related to several other sickle cell complication as well, including acute splenic sequestration,[529] hepatic sequestration,[530,531] ACS,[392] glomerulonephritis,[532,533] and stroke.[534] Many sickle patients will be seropositive for parvovirus B19 without a history of an aplastic event, thus suggesting

that many infections are subclinical.[535] Since then, the relationship between parvovirus and erythropoiesis has been studied in detail. The virus specifically retards late erythroid precursor differentiation[536] and is responsible for temporary erythroid aplasia in a broad array of hemolytic anemias.[528]

Infections

Infection is the most common cause of death in children with sickle cell anemia.[537-539] In one study, the risk of acquiring sepsis or meningitis was greater than 15% in children younger than 5 years, with an associated mortality of approximately 30%.[540] In young children, the risk for pneumococcal sepsis appears to be 400 times greater than that of normal children, and *H. influenzae* sepsis appears to be two to four times as common.[541] These two reports date from the period before the licensing of conjugated vaccines for *S. pneumoniae* and *H. influenzae*. In general, the organisms responsible for infection are primarily encapsulated bacteria and are not unusual pathogens (Table 19-3), but the infections that they cause in such patients are more frequent and severe.

The major risk factor for this increased vulnerability to infection is splenic dysfunction. The spleen normally serves two separate immunologic functions: (1) clearance of particles from the intravascular space and (2) antibody synthesis. Both functions are impaired in sickle cell anemia.

During the first year of life, "functional asplenia," the inability to clear particulate matter from the blood, develops in patients with sickle cell anemia.[542] This is heralded by the appearance of red cells with Howell-Jolly bodies and irregular surface characteristics (pits). When the percentage of "pitted" red cells exceeds 3.5%, the spleen is generally considered nonfunctional.[543] Splenic dysfunction occurs early in life, with 50% of 2068 children with SS disease having greater than 3.5% "pitted" red cells by 2 years of age. Dysfunction occurred less rapidly and less commonly in children with HbSC and S–β-thalassemia. Despite palpable splenomegaly, children with elevated numbers of pitted RBCs have no splenic uptake of technetium 99m (^{99m}Tc) sulfur colloid and are susceptible to the most serious infectious complication of asplenia and pneumococcal sepsis.[544] Repeated infarction results in a nonpalpable, fibrotic, often calcified spleen that may be visualized on a ^{99m}Tc-diphosphonate bone scan.[545] Splenic infarction in young children with SS disease appears to be an insidious process—usually without much in the way of symptoms. In older children and adults, however, especially those with HbSC and S–β-thalassemia, severe left upper quadrant pain often accompanies the infarction. Transfusion,[546] hydroxyurea,[547,548] and bone marrow transplantation[549] can correct the splenic phagocytic defect, although these treatments are not indicated for splenic dysfunction per se.

Children with functional asplenia fail to respond to intravenously administered antigen,[550] even when phago-

TABLE 19-3	Bacteremia and Associated Acute Events in a Cohort of 694 Children with Sickle Cell Anemia (SS) and Hemoglobin SC Disease Monitored Prospectively from Infancy					
Organism	Patient	Total No. Cases	Isolated Bacteremia	Acute Chest Syndrome	Meningitis	Bone/Joint

Data from Gill FM, Sleeper LA, Weiner SJ, et al. Clinical events in the first decade in a cohort of infants with sickle cell disease. Blood. 1995;86:776.

cytic function of the spleen has been restored by transfusion. As in other asplenic individuals, however, these children do respond normally to intramuscularly administered polysaccharide and conjugated pneumococcal vaccine.[551-553]

Levels of serum immunoglobulins are normal or increased in children with sickle cell anemia.[552,554,555] However, the serum is deficient in heat-labile opsonizing activity[556] because of an abnormality in the properdin pathway[557,558] that is specific for the phagocytosis of pneumococci. There is increased activation of complement via the alternative pathway[559] and no intrinsic defect in the complement system.[560] Opsonic activity can be reconstituted in vitro by addition of only the $F(ab')_2$ fragments of capsular antibodies to *S. pneumoniae*.[561] This abnormal opsonic activity and associated functional asplenia may partially explain the propensity for pneumococcal infections.

Boggs and co-workers[562] have demonstrated that the chronic leukocytosis of SCD is a reflection of a shift of granulocytes from the marginating to the circulating pool with a high granulocyte turnover rate. Neutrophil chemotaxis is normal to slightly reduced, and no specific abnormality in neutrophil oxidative metabolism has been found in patients with SS disease.[563-565] There is evidence to suggest that the phagocytic function of neutrophils toward *Candida albicans* may be reduced in some individuals with sickle cell anemia and is correlated with the severity of SCD.[566] Epidemiologic studies have also shown a positive correlation between chronic leukocytosis and early mortality[247] and frequent chest syndromes.[248]

Recurrent pneumococcal infections have been described in sickle cell patients.[567] In one series, patients with serious invasive bacterial infections were 4.8 and 15.8 times more likely to have a second or third infection,

thus suggesting that a subgroup of SS patients have an increased susceptibility to infection.[568]

Treatment. Because of the increased incidence of serious bacterial infections in patients with sickle cell anemia, the index of suspicion for infection should always be high. In general, the higher the temperature[569] and leukocyte count,[570] the higher the probability of a serious bacterial infection. Unfortunately, however, the wide variability in the temperature and laboratory values of bacteremic children does not permit accurate prediction of whether an individual febrile child is bacteremic. The following are guidelines for empirical evaluation and treatment of a febrile child younger than 12 years:

- Perform a complete blood cell count, urinalysis, chest radiography, and cultures of blood, urine, and throat.
- "Toxic" children, or those with temperatures higher than 39.9° C, should be treated with parenteral antibiotics promptly, before radiographs are taken or the results of laboratory tests are available. These children should be admitted to the hospital.
- Lumbar puncture should be performed on "toxic" children and those with any signs of meningitis.
- Nontoxic children with temperatures below 40° C, but with infiltrates on the chest radiograph, a WBC count higher than 30,000/mm³ or lower than 500/mm³, a platelet count less than 100,000/mm³, hemoglobin below 5 g/dL, or a history of sepsis should be treated parenterally and admitted to the hospital.
- Nontoxic children with temperatures below 40° C, a normal chest radiograph, normal leukocyte count, and reliable parents can be treated with a long-acting antibiotic (e.g., ceftriaxone, 50 to 75 mg/kg, parenterally),

observed over a period of hours, and be discharged home for follow-up evaluation the next day and a possible repeat empirical antibiotic dose.[571]

- Empirical antibiotic selection should be based on the ability to kill both pneumococcus and *H. influenzae* and to penetrate the CNS. In areas where β-lactamase–producing *H. influenzae* or penicillin- and cephalosporin-resistant pneumococci are regularly encountered, these issues should be factored into the choice of drug.
- If children do well and culture results remain negative after 24 to 48 hours, antibiotics can be discontinued.
- Documented sepsis should be treated parenterally for a minimum of 1 week.
- Bacterial meningitis should be treated for a minimum of 10 days parenterally or for at least 1 week after the cerebrospinal fluid has been sterilized.
- Patients with infiltrates on the chest radiograph should have cultures of sputum, blood, and stool and be treated as described for ACS. Because of the high incidence of pneumococcal, chlamydial, and mycoplasmal pneumonia, patients should be treated with an appropriate antipneumococcal agent and macrolide antibiotic. *M. pneumoniae* infection may be manifested as a lobar infiltrate,[572] and the presence of a positive cold agglutinin, albeit nonspecific, should be an indication for a macrolide. A stool culture positive for *Salmonella* may be the only evidence of *Salmonella* pneumonia. In most cases, no bacterial confirmation will be available, and the patient should receive at least a 1-week course of antibiotics to cover pneumococci, *H. influenzae*, and atypical organisms (e.g., *M. pneumoniae*).

Despite advances in laboratory and imaging techniques, the diagnosis of osteomyelitis in SCD is often very difficult to distinguish from aseptic bone infarct and still relies heavily on clinical assessment.[374] Patients with clinical findings that are highly suggestive of osteomyelitis should undergo needle aspiration and culture of the lesion. After obtaining material for culture, children who appear acutely ill should be started on antibiotics. The antibiotic regimen chosen should include agents effective against *Salmonella* and *Staphylococcus aureus*. Antibiotics should be discontinued or modified when culture reports are available.

Prevention. Attempts at preventing pneumococcal disease in patients with sickle cell anemia have focused on prophylactic antibiotics and vaccines. Prophylactic penicillin was first shown to be effective in the prevention of pneumococcal disease by John and associates,[573] who used monthly intramuscular injections of long-acting penicillin. However, if penicillin prophylaxis was discontinued after 3 years of age, an increase in pneumococcal infections was noted. Gaston and co-workers, in a blinded placebo-controlled clinical trial in the United States, showed that 84% of the pneumococcal infections in children younger than 5 years could be prevented with oral penicillin.[574] As a result of this landmark study, aggressive

universal newborn screening programs have been organized throughout the United States so that all children with sickle cell anemia can be identified and started on penicillin prophylaxis by 8 weeks of age. If penicillin is discontinued after 5 years, patients do not have a higher incidence of infections than those who remained on prophylaxis,[575] and there are conflicting data regarding the increased risk for penicillin-resistant pneumococcal colonization while on prophylaxis.[576,577] Our approach to prophylaxis is as follows:

- Give prophylaxis to all newborns with SS, S–β-thalassemia, and SC disease. (Some practitioners prefer not to treat infants with SC disease because their splenic dysfunction typically appears later in life.)
- Start as early as possible—optimally by 8 weeks of age.
- Prescribe penicillin, 125 mg orally twice a day, until 3 years of age. At age 3, increase the dose to 250 mg orally twice a day. Penicillin can be stopped after 5 years of age without resulting in an increased incidence of infection.
- Prescribe erythromycin ethyl succinate, 10 mg/kg orally twice a day, for patients allergic to penicillin.
- Educate families on the importance of compliance and early recognition of signs of infection.
- Polyvalent pneumococcal vaccine has been shown to be effective in eliciting a normal antibody response, increasing pneumococcal opsonizing activity, and reducing the incidence of pneumococcal disease.[553,559,578] Both heptavalent conjugated and 24-valent polysaccharide pneumococcal vaccines are commercially available. The 24-valent vaccine includes 90% of the common serotypes of pathogenic pneumococci. Children younger than 2 years respond relatively poorly in general to this vaccine,[579] and 2-year-old children respond poorly to two common pneumococcal serotypes, 6A and 19.[580] Revaccination after 4 years improved protective levels of antibody without serious adverse reactions in children.[581] The newer heptavalent vaccine, when given in repeated doses to children younger than 1 year, is effective in mounting antibody titers to the capsular antigens that it includes, increases opsonizing activity, and is recommended for all children, including sickle patients.[553,582,583] *H. influenzae* conjugated vaccine is immunogenic in children with SCD and should be given at the same schedule used for normal infants.[584,585]

Even though prophylactic penicillin and new vaccines are clearly effective in preventing some overwhelming infections, several children have been documented to have fatal pneumococcal sepsis who were vaccinated and had been prescribed oral penicillin.[586] Although penicillin-resistant pneumococci were not demonstrated in patients receiving prophylaxis, multidrug-resistant pneumococci appeared to emerge in patients treated for longer than 5 years.[576] These examples underscore the need for physicians to emphasize the importance of compliance

and to continue to have a high index of suspicion of sepsis in a febrile child with SCD.

Chronic Organ Damage

Cardiovascular System. Abnormal cardiac findings are present in most patients with sickle cell anemia[587-590] and are primarily the result of chronic anemia and the compensatory increased cardiac output.[591] On physical examination, the most common findings are systolic ejection murmur, S_3, split S_1, suprasternal notch thrill, and diastolic murmur.[587] Cardiac findings may closely resemble the findings in rheumatic valvular disease or congenital cardiac anomalies. Frequently, echocardiography is necessary to diagnose abnormal cardiac structure. Cardiomegaly is present in most patients, with electrocardiographic findings of left ventricular hypertrophy seen in about 50% of patients.[588]

In view of the fact that the hallmark of SCD is vaso-occlusion, it is remarkable that myocardial infarction is an extremely rare event.[588,592,593] In one review of the postmortem literature in SCD, including examination of 153 hearts, only four infarcts were reported.[592] Despite the high oxygen extraction in the coronary circulation, blood in the coronary sinus contains no more sickled forms than blood in the general circulation does,[593] presumably because of the short transit time through the coronary vessels.[591] Atherosclerosis is virtually absent in this population, seen in one study in none of the 100 hearts of patients (55 of whom were 16 to 47 years old, with a median age of 30) examined at autopsy.[592] This is in marked contrast to a Vietnamese study,[595] in which atherosclerosis was found in 45% of 105 battle casualties. When injected at autopsy, a sickle cell heart has normal patent coronary arteries, frequently of larger caliber than seen in normal hearts.[596] The cause of this apparent protective effect against atherosclerosis is unknown but may involve genetic or dietary factors or anemia itself.

The most comprehensive prospective examination of cardiac function in an unselected population of patients with sickle cell anemia was done as part of the CSSCD.[597] One hundred ninety-one steady-state patients 13 years and older underwent echocardiography, and all of the measurements were done centrally by an investigator without access to other patient data. After appropriately adjusting for body surface area, the left and right ventricles, aortic root, and left atrium were noted to be larger than normal. Significant wall thickening was found only in the septum. The left ventricular dilation correlated with hemoglobin and age, thus suggesting that the major cardiac findings are indeed related to the years of increased stroke volume in compensation for the anemia and abnormal rheology. The finding of normal left and right ventricular function suggests that if a specific "sickle myocardiopathy" exists, it is rare. As discussed in the section on chronic lung disease, patients with cor pulmonale and right ventricular dysfunction have a high mortality rate.

PHT is a common complication in adult patients with SCD, with a reported prevalence of approximately 20% to 40%.[598-601] Multiple retrospective studies report significantly increased mortality in SCD patients with PHT when compared with those without PHT.[599,601,603] Castro and colleagues demonstrated that SCD patients with PHT confirmed by right heart catheterization had a median survival of 25.6 months whereas patients without PHT had greater than a 70% survival rate at the end of a 10-year observation period.[603] A more recent study of 195 SCD patients reported a significantly higher mortality rate in adult patients with PHT (defined as a tricuspid regurgitant jet velocity >2.5 m/sec on echocardiography) than in those with no PHT after a median follow-up of 18 months.[601] Markers of hemolysis (increased lactate dehydrogenase, bilirubin, reticulocyte count) resulted in increased risk for adult PHT.[601,604] Intravascular hemolysis leads to increased plasma hemoglobin and arginase and is associated with indicators of reduced NO bioavailability (also see the section on NO depletion), subsequent endothelial dysfunction, and PHT.[317] The prevalence of elevated TR jet velocity in children appears similar to that in adults[605-607]; however, the significance of the finding and the prognostic implications remain to be established in this age group.[608]

Arrhythmias are rare under usual conditions, although in one study, during the first hour of therapy for painful crisis, 80% of patients had arrhythmias—67% atrial and 60% ventricular. These arrhythmias were not clinically significant and probably represented response to pain.[609]

Blood pressure in steady-state patients with sickle cell anemia (and to a lesser extent, SC disease) is lower than in a race-, gender-, and age-matched normal population (Table 19-4).[468] This finding may be related to the tendency to lose sodium and water in urine. This study demonstrated that high blood pressure is a risk factor for stroke and early mortality and that the diagnosis of high blood pressure depends on knowing the "normal values" for this population (see Table 19-4). Blood pressures above the 90% percentile in this population overlap with the normal range in a normal population, and a steady-state blood pressure of 140/90 is ominous. Such patients should be considered candidates for antihypertensive therapy.

Renal System. Hyposthenuria, hematuria, nephrotic syndrome, and uremia are the major renal complications of SCD.[610] In addition, production of erythropoietin in response to anemia may be lower in older patients with SS disease, possibly because of primary renal disease.[611]

Hyposthenuria[612,613] develops early in childhood and, as is the case with functional asplenia, may be temporarily reversed by transfusion.[614,615] The hypertonic environment of the renal medulla promotes sickling even at normal Po_2,[616] which leads to decreased medullary blood flow and derangement of the countercurrent multiplier. Abnormality of the countercurrent multiplier may be the

Data from Pegelow CH, Colangelo L, Stunberg M, et al. Natural history of blood pressure in sickle cell disease. Am J Med. 1997;102:171-177.

mechanism for hyposthenuria, or as suggested by Buckalew and Someren,[610] it may be due to decreased flow to nephrons in patients with long loops of Henle and preservation of flow to nephrons with short loops. The obligatory water loss results in a tendency toward dehydration and invalidates the use of urine volume or concentration as an indicator of the patient's state of hydration. Nocturia and enuresis are common complaints of these patients, who excrete large volumes of dilute urine.[617] Urinary sodium losses may be high and result in significant hyponatremia.[618] A renal tubular acidification defect,[619,620] as well as hyporeninemic hypoaldosteronism[621] and impaired potassium excretion,[622] has been identified. In one review, de Jong and Statius van Eps emphasized that renal-vasodilating prostaglandins are increased in sickle cell patients, thereby leading to a compensatory increase in renal blood flow, glomerular filtration rate, and proximal tubular activity.[623]

Although hematuria is usually mild, bleeding is occasionally severe enough to cause significant blood loss.[624] Papillary necrosis is generally the underlying anatomic defect.[625] Maintenance of high urinary flow with increased fluid intake will eliminate clots from the bladder and decrease medullary osmolality. Urinary alkalinization and diuretics may be beneficial. ε-Aminocaproic acid has been suggested for stopping severe hematuria that is refractory to transfusion,[626] but it must be used cautiously because of the risk of ureteral or pelvic clotting and obstruction. In patients with long-standing hematuria, supplemental iron may be necessary to prevent iron deficiency. Hematuria may also be the initial symptom of a renal tumor. A surprisingly high incidence of renal medullary carcinoma has been reported in adults and children with sickle cell anemia and sickle trait.[627,628]

Uremia is a rare complication in children with SCD that may follow a symptom complex of nephrotic syndrome[629] and glomerulonephritis. The nature of the glomerular lesion is unknown but may represent a response to iron deposition,[630] an antigen-antibody complex,[631] or mesangial phagocytosis of fragmented sickled cells.[632,633]

Recently, parvovirus infection, with or without an antecedent aplastic crisis, has been associated with acute glomerulonephritis.[532,533] Proteinuria in SCD frequently progresses to nephrotic syndrome[634] and ultimately to renal failure,[633,635] which is a common cause of mortality in adults with SCA.[247,636] Microalbuminuria, as manifested by a ratio of albumin to creatinine of greater than 20, is seen in more than 40% of adults and in a similar percentage of children 10 to 18 years of age with SCD.[637] Recently, a study of 442 children with SCD monitored for 10 years showed that proteinuria occurred in 6.2% and increased to 12% in teenagers. Proteinuria was associated with lower hemoglobin levels, higher MCV, higher WBC counts, and more clinically severe disease.[638] A study of 381 adults with SCD demonstrated that 7% had elevated serum creatinine levels and 26% had proteinuria.[639] Ten patients with proteinuria underwent renal biopsy, and the glomerular lesions showed perihilar focal segmental sclerosis and glomerular enlargement, similar to findings in an animal model with glomerular hypertension and efferent arteriolar vasoconstriction. To test the animal analogy, these patients were treated with enalapril, an angiotensin-converting enzyme (ACE) inhibitor that has been shown to decrease efferent arteriolar constriction. In all treated patients, the level of proteinuria fell during treatment and returned toward abnormal after discontinuation.

The predictive value of microalbuminuria has not been fully elucidated in children but has been suggested by some.[637,640] Serum cystatin C may be a better screen for the glomerular filtration rate than creatinine is in sickle cell anemia because it appears to rise according to the degree of albuminuria and before significant elevation in serum creatinine is detected.[641]

Treatment of microalbuminuria[642] or proteinuria[639] with ACE inhibitors can be effective, but long-term therapeutic benefits for the prevention of progressive glomerular disease have not yet been demonstrated.[643] Addition of hydroxyurea to ACE inhibitors may further improve renal function.[644]

Bakir and associates estimated that nephrosis develops in 4% of adult SS patients and that in two thirds of these patients, renal failure eventually develops.[633] Renal failure can be managed by peritoneal dialysis, hemodialysis, and transplantation. Renal transplantation can be successful in patients with end-stage sickle nephropathy, but 3-year allograft and patient survival is significantly decreased when compared with other patient populations.[645]

Hepatobiliary System. Liver and biliary tract abnormalities are common in SCD[646,647] and are the result of cholelithiasis, hepatic infarction, and transfusion-related hepatitis.

Bilirubin stones are common.[648,649] Two large series have studied the incidence of gallstones as detected by ultrasound in children with SS disease.[650,651] The percentage of gallstones in 226 patients aged 5 to 13 selected randomly from a group of children with SS disease identified at birth was 13%,[646] a value lower than that found in a survey of clinic patients studied by Sarnaik and associates.[650] In this report, the incidence of gallstones was 12% by 2 to 4 years of age.[650] With advancing age, the incidence increased gradually and reached 42% in the 15- to 18-year-old age group. Fourteen of the 226 patients were noted to have "sludge" in the gallbladder and had ultrasonograms repeated up to 2 years later. Stones developed in four, four had no further evidence of sludge, and six remained unchanged. Comorbid Gilbert's syndrome (UGT1A genotype) significantly increases serum bilirubin levels in children with SCD and the likelihood of requiring early cholecystectomy.[310] Evidence is good that children tolerate elective cholecystectomy with little morbidity if they are prepared properly for surgery.[424,652,653] Laparoscopic cholecystectomy has been particularly effective in reducing postoperative hospital stay in children with SCD.[654] In contrast, operating during the acute phase carries a significant risk of complication.[424,655]

Intrahepatic sickling can result in massive hyperbilirubinemia,[421] elevated liver enzyme values, and a painful syndrome mimicking acute cholecystitis[422] or viral hepatitis[648] (see "Acute Abdominal Pain"). Fulminant hepatic failure with massive cholestasis and rapidly progressing hepatic encephalopathy and shock has been described as a rare, often fatal complication of SCD that may be amenable to exchange transfusion.[425,656,657]

A review of postmortem liver findings in 70 SCD patients examined at Johns Hopkins Hospital[658] revealed hepatic necrosis, portal fibrosis, regenerative nodules, and cirrhosis in adults, thought to be a consequence of recurrent vascular obstruction and repair. In contrast, 19 liver biopsy specimens from symptomatic patients with SS disease failed to show necrosis and more often showed evidence of acute or subacute infection.[659]

Eyes. Tortuosity and sacculation of conjunctival vessels are noted in more than 90% of patients with SCD. These lesions are best seen in the lower temporal area, disappear after exchange transfusion, and are curiously related to the ISC count in peripheral blood.[660] They have no deleterious effect on the eye.

Retinopathy is classified as either proliferative or nonproliferative. Nonproliferative retinopathy probably results from retinal arteriolar infarction with adjacent hemorrhage and requires no therapy. Depending on the duration, layer, and extension of the hemorrhage, the result can be a salmon patch, schism cavity, vitreous hemorrhage, or black sunburst.[661] In two patients with documented acute arteriolar occlusion, salmon patches developed in a matter of hours to days, with atrophic schism cavities evolving in 3 to 4 months.[662] In older patients, angioid streaks are common, but the cause is unknown.[663,664]

The more serious complication is proliferative retinopathy, which has been classified by Goldberg[665] as stage 1, peripheral arteriolar occlusions; stage 2, arteriolar-venular anastomoses; stage 3, neovascularization; stage 4, vitreous hemorrhages; and stage 5, retinal detachment. Because these lesions may progress to blindness, laser therapy to occlude the feeding vessels of advanced proliferative lesions has been advocated. Unfortunately, photocoagulation carries the risk of neovascularization of the choroid[666] and retinal breaks,[667] complications that can result in blindness. The dilemma of choosing potentially blinding therapy for a potentially blinding lesion is complicated by the observation that some proliferative lesions heal spontaneously by autoinfarction. In one study of untreated retinopathy in Jamaica, 567 eyes were observed for 8 years.[668] Proliferative retinopathy was initially present in 12% of the eyes and developed in another 8% during follow-up. Blindness resulted in 12% of the eyes with retinopathy. In the original group of eyes with retinopathy, progressive retinopathy developed in 30%, 10% underwent spontaneous regression, and the remaining 30% showed a mix of regression and progression. In another prospective Jamaican study, treatment of retinopathy was compared with no treatment.[669] No statistical difference in visual acuity between the two groups was reported. Macular ischemia and color blindness have been reported to be prevalent in patients with SS disease without evidence of retinal lesions on ophthalmologic examination.[670,671]

Rarely, acute painless loss of vision is the result of central retinal artery occlusion. Although such lesions may resolve spontaneously, exchange transfusion has been recommended for bilateral disease.[672]

Blunt trauma to the eye may result in hyphema (bleeding into the anterior chamber). Because the conditions in this chamber overwhelmingly favor sickling, any hemoglobin-containing red cell will sickle and may cause obstructive glaucoma and blindness. Common medical treatments that might be considered in nonsickle patients may promote sickling and should be avoided (e.g., hyperosmotic/diuretic agents, carbonic anhydrase inhibitors). Initial topical β-adrenergic antagonists (e.g., timolol) or

α_2-adrenergic agonists (e.g., brimonidine) may be effective,[673] but a low threshold for surgical evacuation of anterior chamber blood should be observed so that vision is preserved.[674] This condition is one of the true ocular emergencies that occurs in patients with sickle trait or SCD.

Skin. Leg ulcers do not usually occur in childhood. In adolescence and adulthood, ulcers may constitute a crippling symptom. This skin lesion is seen with other chronic hemolytic anemias such as hereditary spherocytosis, thalassemia, elliptocytosis, and pyruvate kinase deficiency[675] and therefore may not represent vaso-occlusion. Ulceration may result from increased venous pressure in the legs caused by the expanded blood volume in the hypertrophied bone marrow.[676] In tropical areas in which shoes are not generally worn and insect bites are common, leg ulcers are frequent.[677] In Jamaica, leg ulcers typically start in the 10- to 20-year-old group and eventually appear in 75% of adults. Koshy and colleagues[678] reported data from the CSSCD regarding leg ulcers in sickle cell patients. Leg ulcers appear to be less frequent in individuals with two α genes than in those with three or four genes. Leg ulcer frequencies appear to decrease consistently with increases in HbF production.[678] Venous outflow is decreased in the lower extremities of patients with leg ulcers when compared with patients without ulcers, thus suggesting that venous incompetence may contribute to the development or failure of these lesions to heal.[679] In addition, low steady-state hemoglobin values and markers of a high hemolytic rate are associated with an increased incidence of leg ulcers and may be associated with decreased NO bioavailability and endothelial dysfunction.[315,680]

Chronic lesions become a major source of morbidity and have a profound negative impact on educational achievement and employment.[681] Usually present over the medial surface of the lower part of the tibia or just posterior to the medial malleolus, they begin as a small depression with central necrosis and, if unattended, widen to encircle the entire lower portion of the leg. Débridement, scrupulous hygiene, topical antibiotics, bed rest, and elevation of the leg are the mainstays of therapy. In some patients, protection of the ulcer by the application of a soft sponge-rubber doughnut and low-pressure elastic bandage seems to be beneficial. One report suggested that an RGD peptide matrix designed to mimic the normal matrix was beneficial.[682] Close attention to improved venous circulation with the use of above-the-knee elastic stockings may prevent ulceration. If ulcers persist despite optimal care, transfusion therapy may be implemented and consideration given to split-thickness skin grafts. Transfusion therapy is sometimes effective, but in many patients the ulcers either do not heal or recur after discontinuation of this therapy. Oral zinc sulfate may promote healing of leg ulcers,[683] and peripheral vasodilator therapy appears to be ineffective.[684]

Ears. Sensorineural hearing loss at both ends of the auditory spectrum was found in a substantial number of sickle cell patients in Jamaica.[685,686] In a U.S. study, 12% of children with SS disease had high-frequency sensorineural hearing loss.[687] Interestingly, although there was no increased otitis media or meningitis in the affected group, five of the six children with CNS disease had abnormal hearing. The pathology of the auditory apparatus appears to be sickling in the cochlear vasculature with destruction of hair cells.[688]

Skeleton. Skeletal changes in SCD are common[364,374,689,690] and are due to expansion of the marrow cavity and repeated bone infarction. The expanded marrow is best seen on radiographs of the thickened calvaria with a wide diploic space. Overgrowth of the anterior part of the maxilla may lead to severe orthodontic and cosmetic problems. Vertebrae are generally flattened, with a characteristic biconcave deformity called "codfish vertebrae." In older patients, vertebral disease may cause chronic back pain. These individuals need to be treated as other patients who have chronic back disease: appropriate exercises, braces, bed rest, muscle relaxants, and moral support.

The major chronic bone complication of SCD is AVN. Indeed, the most common cause of AVN of the femoral head in children is SCD. As shown in (Fig. 19-9), the incidence is relatively low in children, with an estimated prevalence of 3% in children younger than 15 years.[691] The incidence is remarkably increased in patients with SS disease and coexistent α-thalassemia.[692] Patients at highest risk for complications were those with the highest rates of painful crises and those with the highest hematocrits. The recent discovery of SNPs in several genes related to bone metabolism may affect the natural history of AVN.[312] The pathophysiology of AVN is unknown but is hypothesized to be related to sludging in marrow sinusoids, marrow necrosis, healing with increased intramedullary pressure, necrosis of the articular surface, bone resorption, and eventually, epiphyseal collapse.[692,693] The diagnosis is made radiographically, classically with a spectrum of findings from subepiphyseal lucency and a widened joint space to flattening or fragmentation and scarring of the epiphysis. Although roughly half of the patients in whom AVN was diagnosed on the basis of screening radiographs were asymptomatic, significant chronic pain and limited joint mobility plagued the others. MRI can identify changes of AVN earlier than conventional films can.[691,694] Managing osteonecrosis of the femoral head in young adults is a challenging problem with limited treatment options and often disappointing outcomes. Strict bed rest is helpful in a minority of patients,[695] with little or no evidence to support the use of chronic transfusion therapy. Injection of cement[696] and core decompression[697] have been used successfully in some series. It is possible that these procedures might be helpful in patients with very early disease. A randomized prospective study of hip core decompression versus phys-
FIGURE 19-9. Incidence of osteonecrosis of the femoral head per 100 patient-years by genotype. *(Data from Milner PF, Kraus AP, Sebes JI, et al. Sickle cell disease as a cause of osteonecrosis of the femoral head. N Engl J Med. 1991;325: 1476-1481.)*

ical therapy for the treatment of early femoral head osteonecrosis revealed clinical improvement in both groups but one not more effective than the other.[698] Despite interventions to preserve the femoral head, progression is frequent and may result in the need for total hip replacement arthroplasty in severely compromised patients. In the study of Milner and colleagues, 17% of patients underwent hip replacement, 30% of replaced hips required surgical revision within 4.5 years, and more than 60% of patients continued to have pain and limited mobility postoperatively.[692] The epidemiology of AVN of the humeral head is virtually identical to that of the femur.[699] In general, however, patients are less symptomatic, and shoulder arthroplasty was exceedingly rare.

Lungs. In contrast to ACS, chronic lung disease has been difficult to define and quantitate. In older children, lung volumes are reduced[700,701] in comparison to those of the normal white population but are appropriate when compared with those of a black control population.[702] Others report an early restrictive and obstructive pulmonary function pattern in steady-state children with SCD.[703,704] Resting arterial Po_2 in asymptomatic children with SCD is typically 65 to 85 mm Hg (normal, >87 mm Hg). There are large alveolar-arterial Po_2 differences with room air (27 to 42 mm Hg; normal, <16 mm Hg) and on 100% O_2 (186 to 246 mm Hg; normal, <86 mm Hg). These values are consistent with increased pulmonary shunting of 12% to 16% (normal, <7%).[702] The decreased membrane-diffusing capacity observed can be explained on the basis of anemia alone and does not suggest a substantial element of pulmonary vascular occlusion. No definitive profile of pulmonary function in SCD has emerged, although 90% of adults from the CSSCD had abnormal pulmonary function test results, with 74% showing a restrictive pattern.[705] In one survey of adults, fatal progressive pulmonary disease may have been related to history of previous chest syndromes[706]; however, the relationship between acute episodes of chest syndrome and chronic lung disease has

been difficult to establish reproducibly. There appears to be an emerging link between obstructive lung disease and the pathogenesis of ACS, particularly in children.[404,410,707,708] An increase in obstructive lung disease was documented in adult patients who had two to four episodes of ACS versus patients with no history.[709] In another study, patients with SS disease were found to have abnormally small lungs, but this abnormality was not related to episodes of ACS.[710] In a study of infants 3 to 30 months of age, restrictive lung disease was present in 3 of 12 infants and was not related to a history of ACS.[711] These studies suggest that subtle subacute damage to the lungs proceeds even in the absence of acute disease. Hydroxyurea therapy[400] reduces the incidence of recurrent ACS but does not lead to improved pulmonary function. In 24 patients with a history of chest syndromes studied after bone marrow transplantation, 22 showed no improvement and 2 had worse pulmonary function after transplantation.[712]

Central Nervous System. Abnormal neurologic findings in SCD were discussed earlier. Kral and co-workers found that children with SCD perform more poorly on measures of neurocognitive functioning with increasing age or lower hematocrits.[713] In addition, TCD ultrasonography was the only radiologic measure that could predict neurocognitive outcome after controlling for age and hematocrit. Changes on CT and MRI may antedate the neurologic dysfunction and represent subclinical infarcts.[440,441,446,714] It is now clear that cognitive functioning and fine motor skills are impaired in sickle cell patients with silent infarcts as diagnosed by MRI.[464,715] Because abnormal Doppler or MRI studies, or both, can be seen in children with decreased neurocognitive performance, these radiologic studies are being considered as screening tools to select very young patients for experimental therapies that may prevent further CNS damage.

Growth and Development. The birth weight of infants with sickle cell anemia is normal.[716] Subsequently, a

pattern of delayed growth emerges. Detailed anthropomorphic measurements of Jamaican children revealed decreased limb length, sitting height, and skinfold thickness, along with increased anteroposterior chest diameter,[717] possibly related to cardiomegaly.[718] Height and weight growth curves (Fig. 19-10) for individuals with SCD in the United States were generated as part of the CSSCD, sponsored by the Sickle Cell Disease Branch of the NHLBI.[719] The important features of these curves are that they are different from those for normal black controls, that weight is more affected than height, and that patients with sickle cell anemia and S–β^0-thalassemia experience more delay in growth than do patients with HbSC disease and S–β^+-thalassemia. In general, by the end of adolescence, patients with SCD have caught up with controls in height but not weight. The reason for this poor weight gain is not understood but is likely to represent increased caloric requirements of elevated resting energy expenditure related to anemia, increased bone marrow activity, and cardiovascular compensa-

tion.[720] In a second large prospective study in Jamaica, both height and weight were significantly lower than that of age- and sex-matched controls as early as 2 years of age.[721] Zinc deficiency has been suggested as a cause of poor growth in children with SS disease[722,723] but has not been confirmed.[724] Levels of vitamins A, B_6, and D have been discovered to be lower than those of ethnically matched children and may relate to morbidity.[725,726] Growth hormone deficiency is a rare and reversible cause of growth delay.[727] In general, growth hormone levels and growth hormone stimulation studies appear to be normal in children with SS disease who have impaired growth.[728] A review of nutritional studies in patients with SS disease is available,[729] and one study has suggested that hyperalimentation may be useful in some patients.[730]

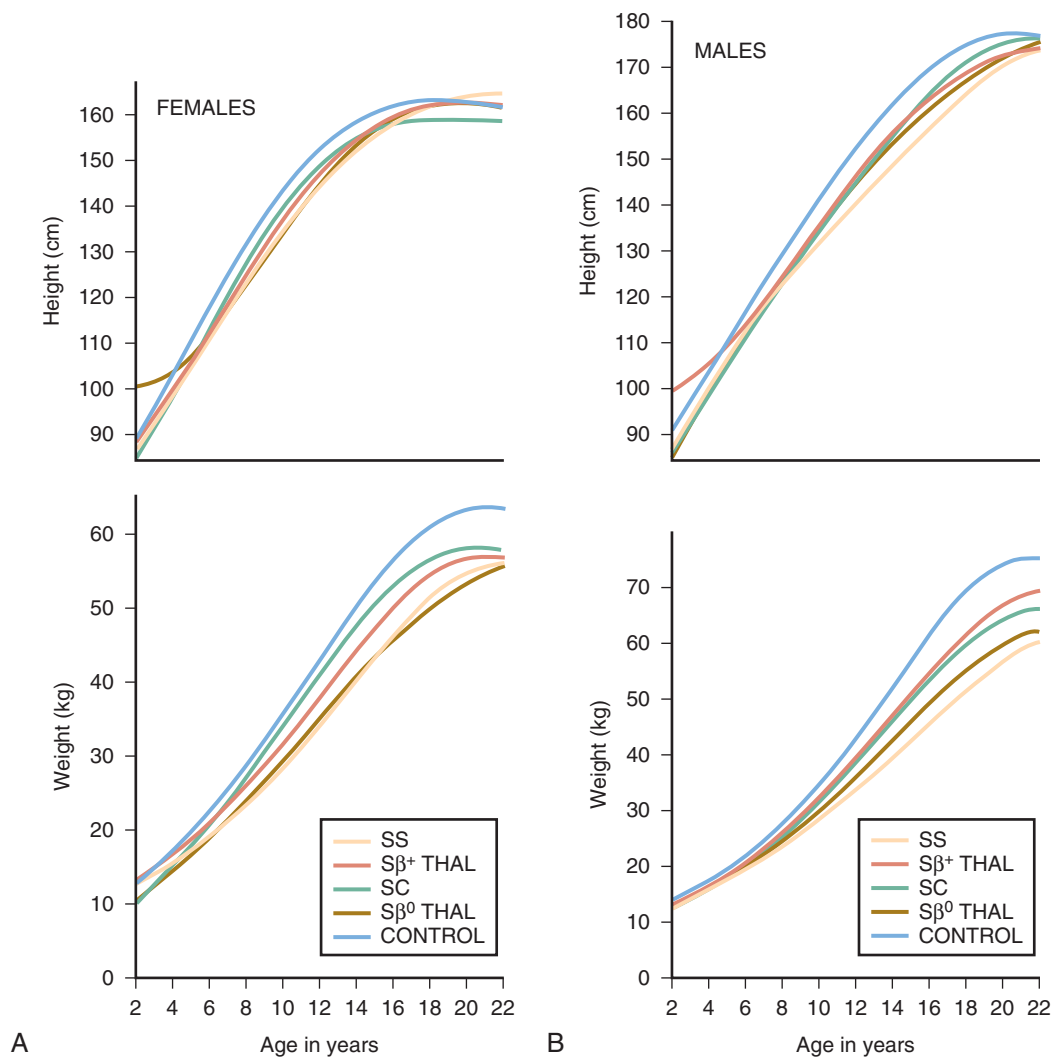
Sexual development is also delayed in patients with SCD.[719] Such delay is found in both males and females and follows the same pattern as height and weight in other hemoglobinopathies. The estimated median age of attainment of Tanner stage for each hemoglobinopathy is


FIGURE 19-10. Height and weight growth curves for females (**A**) and males (**B**) 2 to 22 years of age according to type of hemoglobinopathy. Shown are the 50% curves. listed in Table 19-5. For females (regardless of hemoglobinopathy), menarche status is a function of age and weight. This normal relationship between menarche and weight suggests that in females, delayed sexual maturity is constitutional. This finding has been confirmed in a careful analysis of female fertility in Jamaica, which revealed no difference in the interval between sexual exposure and pregnancy between patients and controls.[731] Most males do undergo delayed sexual maturation, also suggesting constitutional delay. However, among males there does seem to be evidence of decreased fertility, with abnormal sperm motility, morphology, and number.[732] Transient primary hypogonadism[733] and hypothalamic hypogonadism responsive to clomiphene[734] have also been described.

Psychological Aspects. As in any chronic disease, patients require strong, sympathetic support. Most patients with sickle cell anemia handle their illness very well. In one study,[735] patients did not differ from controls in personal, social, or total adjustment. Interestingly, acute anxiety was less frequent in patients than in controls, although patients did demonstrate lower self-concept. Another study pointed out the pitfalls of interpreting excessive fatigue as depression in these children.[736] Problems of particular concern to patients are coping with chronic pain, inability to keep up with peers, fears of premature death, and delayed sexual maturity. Discussion of prenatal diagnosis and selective abortion, particularly in a patient's own family, increases doubt about self-worth. These issues need to be addressed openly and frankly and with appropriate psychological support. Self-help groups for patients and families are gaining in effectiveness and popularity throughout the country.

Mortality. Leikin and colleagues from the CSSCD examined mortality in children with SCD.[737] They found that the peak incidence of death was between 1 and 3 years of age and that it was generally due to infection. The overall mortality rate was 0.5 per 100 patient-years, and for patients with SS disease, the probability of surviving to 29 years of age was about 85%. For those with SC disease, the probability of surviving to 20 years was about 95%. Quinn and associates from the Dallas Newborn Cohort reported an overall survival rate of 86% and a death rate of 0.59 per 100 patient-years for children with SS disease monitored from birth through 18 years of age.[539] The Dallas cohort also showed trends of decreasing sickle-related mortality, increasing mean age at death, and a smaller proportion of deaths related to infection than noted in the CSSCD[356] and Jamaican[738] cohorts.

As shown in Figure 19-11, when the data on deaths in children from the CSSCD are combined with the data on adults, it appears that the median age at death was 42 years for males with SS disease, 48 years for females with SS disease, 60 years for males with SC disease, and 68 years for females with SC disease.[247] Among adults, those with the lowest levels of HbF, highest steady-state WBC counts, and highest rates of pain and chest syndrome had the highest risk of dying at an early age. There is an age-related pattern in mortality rates: a peak in patients younger than 5 years and a gradual increase starting in late adolescence. Younger patients die primarily of pneu-

mococcal disease and less often of acute splenic seques-tration, ACS, or stroke.[537,739] Older patients die of ACS, during pain crises, of chronic organ system failure from cancer and other specific diseases of adults, and suddenly without obvious cause.[247] It is encouraging that coinci-dent with the widespread use of prophylactic penicillin in young children, aggressive treatment of pulmonary disease and infection, careful selection of patients for transfusion therapy, and thoughtful comprehensive care have led to improvement in survival.[740]

Much is known about the risk factors for early mor-tality in patients with sickle cell anemia. Those with a higher level of HbF have a longer life expectancy,[247] as do whose with a low rate of pain crisis,[247] low rate of ACS,[248] no hand-foot crisis before 1 year of age,[249] no severe anemia before 2 years of age,[247,249] low baseline WBC count,[249] and low blood pressure.[468]

APPROACHES TO THERAPY

Replacement of the Defective Gene

The most direct approach to reduction of HbS polymer is to replace the defective globin gene with a normal gene. Bone marrow transplants from sickle trait or normal siblings have been performed in more than 200 patients.[712,741-747] After preparation with various regimens and prophylactic treatment of graft-versus-host disease, the overall survival rate was 93%, the event-free survival rate was 82%, and SCD recurred in just 11% of 147 patients receiving HLA-identical sibling marrow trans-plants.[748] More recently, among 87 consecutive patients treated with myeloablative regimens, the addition of antithymocyte globulin reduced the rate of rejection from 23% to 3%.[746] Newer nonmyeloablative regimens have not yet proved successful in SS patients.[749] Transplant complications have included CNS hemorrhage (particu-larly in patients with a history of stroke), hypogonadal function, graft rejection, and acute or chronic graft-versus-host disease.[746,747,750,751] Prophylactic anticonvul-sant treatment and maintenance of a high platelet count may result in reduced CNS morbidity. The restoration of splenic function in successful transplant recipients holds out hope that other chronic organ dysfunction may improve with this approach.[549,752] In a recent summary of 53 children with SS disease undergoing bone marrow transplantation, growth was not impaired in younger chil-dren, but diminished growth occurred in patients who received transplants near or during the adolescent growth spurt.[745] Selecting patients for this high-risk therapy is particularly problematic because of the unpredictability of the clinical course, the paucity of sibling matches,[753] and parental concern.[754] Availability of unrelated or sibling cord blood stem cells may offer an increased donor pool for transplantation.[755,756] More specific "gene therapy," such as random insertion of a normal β gene or "correction" of the abnormal gene product in hema-topoietic stem cells, remains a long-term goal. However, awareness that random insertion of normal genes into donor stem cells might lead to insertional mutagenesis and malignant transformation has tempered enthusiasm for this approach.[757] Transplantation of embryonic stem cells or induction of pluripotent stem cells from donor fibroblasts after homologous recombination has replaced the human β^S gene with a normal human β-globin gene has led to correction of the sickle mutation in transgenic mice.[758,759]

Reduction of Polymer Formation

Stimulation of Hemoglobin F Production. As noted in the section on interactions of HbS with HbF, increasing the amount of HbF will increase the delay time and solu-bility of HbS. In SCD, both 5-azacytidine[760-763] and hydroxyurea[764-767] have been used successfully to increase HbF in adult SS individuals. Recombinant erythropoie-tin with hydroxyurea has inconsistently increased HbF above levels obtained with hydroxyurea alone.[768,769] Butyric acid analogues also increase HbF production in sickle cell patients, some thalassemia patients, and normal individuals.[770-772] Charache and colleagues demonstrated that daily hydroxyurea treatment of adult sickle cell patients increases HbF levels from pretreatment mean levels of 4% to 16% without clinically significant bone marrow toxicity.[766] In addition to increasing HbF, hydroxyurea has been noted to reduce the proportion of dense cells and increase the MCV and mean corpuscular hemoglobin (MCH) of sickle cells.[760,763-765] On the basis of epidemiologic data that an increase in HbF from 4% to 16% could decrease vaso-occlusive crises by 50%,[280] a multicultured double-blind prospective clinical trial of daily hydroxyurea treatment of SS adults was under-taken.[400] This trial was terminated early when it was obvious that vaso-occlusive crisis, chest syndromes, and transfusions were reduced by almost 50% in the hydroxy-urea-treated group versus controls. However, increases in HbF alone did not predict the decrease in painful crises seen in the controlled trial of hydroxyurea in adult SS patients.[400] Multiple factors such as perturbation of WBC or cytokine levels, changes in RBC adherence to vascular endothelium (see Fig. 19-1), or alteration of NO/intra-vascular hemoglobin equilibrium may also play a role in the hydroxyurea-related decrease in crises.[773,774]

A long-term follow-up of patients taking hydroxy-urea revealed an impressive 40% reduction in mortal-ity.[775] However, there has been variable acceptance of hydroxyurea therapy in adults with SS.[776] Hospitalization for neither pediatric (<18 years) nor adult (>18 years) sickle cell patients has decreased from 1996 to 2004, thus indicating that on a population basis, hydroxyurea has not reduced hospital admissions.[777]

Small-scale trials of hydroxyurea therapy in children demonstrated that the drug can be given safely,[456,778-781] and 5- and 10-year follow up studies in SS children con-tinue to demonstrate its ability to increase HbF with

minimal side effects.[782] It is noteworthy that in the only large study of 122 SS children in which maximum tolerated doses (MTDs) were obtained in the same fashion as in the adult MSH study,[400] very few if any nonresponders were noted. Hydroxyurea therapy at MTDs was well tolerated and demonstrated sustained hematologic efficacy with apparent long-term safety.[783]

Infants with SS diseases tolerate prolonged hydroxyurea therapy and exhibit sustained hematologic benefits, fewer ACS events, improved growth, and possibly preserved organ function.[548] However, previous data suggesting than an elevated WBC count, dactylitis, and anemia predicted more severe later outcomes in children younger than 4 years[249] was not confirmed in a second cohort of patients.[391] Thus, predicting clinical severity in very young children remains problematic. Recent data indicate that children taking hydroxyurea have decreased TCD velocities, which suggests that the drug may reduce the risk for stroke in young children.[784,785] These data leave open the possibility that the first efficacy trial of hydroxyrea in infants with SS disease should be directed toward prevention of CNS disease in this vulnerable age group.

Decreased Cell Hemoglobin S Concentration. Because polymerization of HbS is exquisitely concentration dependent, reduction of the MCHC by swelling the cell with water has been considered as a therapeutic maneuver. Two approaches have been tried: lowering plasma osmolarity and increasing intracellular cations. The first approach was used by Rosa and colleagues,[786] who successfully reduced the duration and frequency of painful crises by lowering the MCHC with dietary salt restriction and desmopressin. Subsequently, others have found this therapy too difficult to maintain, neurologically toxic, and ineffective.[787-789] The second approach has been used primarily in vitro and has focused on the property of various membrane-active agents to increase intracellular cations. Some of the interesting agents include the antibiotics monensin[790] and gramicidin[791]; the calcium channel blockers nitrendipine, nifedipine, and verapamil[792]; and the peripheral vasodilator cetiedil.[793] As discussed previously, preliminary evidence suggests that blocking the Gardos channel with oral clotrimazole[171] and blocking K^+-Cl^- cotransport with oral magnesium[182,183] may decrease the HbS concentrations by preventing dehydration and could therefore prove to be useful therapies. Dipyridamole has been observed to block sickling-induced cation fluxes in vitro, but no trials have been reported.[794]

Increased Hemoglobin S Solubility. The most straightforward approach to preventing polymerization of HbS is to attack the β6 valine, the key to fiber formation. Unfortunately, this is an extremely unreactive residue, so efforts to increase the solubility of HbS have hinged on the importance of the other intermolecular contacts. Reagents that increase deoxy-HbS solubility by noncovalent interactions with HbS have been recognized. Chang and colleagues[791] compared the effects of 15 antisickling agents on HbS solubility, oxygen affinity, and cell sickling. Urea is an effective agent but requires concentrations greater than 200 µM, too high for in vivo use. The best studied covalent modifier is cyanate, but clinical trials have not been promising. Unfortunately, despite the encouraging clinical and in vitro data, this compound is not usable because of significant neurotoxicity[795] and cataract formation.[796] A major problem with covalent reagents is that they interact with a wide variety of functional groups found in many molecules other than hemoglobin.

Decreased Dwell Time. Any manipulation that would allow a cell to traverse a vessel faster than its delay time will prevent occlusion of that vessel. Therapy aimed at reducing endothelial adherence has thus far not been successful.[797] Rodgers and co-workers[798] showed that microcirculatory flow in patients with SCD has an unusual periodic pattern indicative of abnormal vasomotor control. Recent work indicates that free plasma HbS binds NO, thereby reducing the ability of NO to maintain vasodilation.[242,243] Efforts to increase NO with hydroxyurea,[773,774,799] arginine therapy,[800,801] or inhaled NO[802] could possibly lead to less vasocontriction and increased dwell time (see Figs. 19-1 and 19-6).

Routine Health Maintenance

Patients with sickle cell anemia should be monitored on a routine basis (Table 19-6). Regular visits along with routine laboratory studies when the patient is well help establish both the individual's steady-state normal values (e.g., hemoglobin, reticulocytes, WBCs, differential, platelet count, erythrocyte sedimentation rate, chest film, electrocardiogram) and baseline physical findings (e.g., icterus, cardiomegaly, murmurs, organomegaly). These baseline data are extremely helpful in sorting out problems when the patient is ill.

Careful evaluation of the interval history may provide insight into factors that provoke painful crises. Continuing education of patients and families on how to avoid and treat painful episodes will reduce the morbidity and hospitalization rate and promote the patient's sense of independence. Education should also include genetic counseling of the parents so that they understand the risks of SCD in future pregnancies.

Careful attention is paid to routine immunization schedules; all patients should receive the complete schedule of conjugated pneumococcal, conjugated *H. influenzae*, and hepatitis B vaccines. Prophylactic penicillin should be given to all children younger than 5 years.[574] Most important, the patient and family should be educated about the importance of early detection and treatment of infection.

Although folic acid, 1 mg/day, is recommended for prevention of folate deficiency in adults, no definite advantage has been seen in children.[803] Iron deficiency is

extremely rare because of the hemolysis-induced increased absorption of gastrointestinal iron. Iron supplements are used only when iron deficiency is documented or when blood loss is chronic (e.g., hematuria).

Specially trained ultrasonographers can use TCD according to the STOP criteria to screen children with sickle cell anemia and S–β^0-thalassemia to identify those at increased risk for primary stroke. Children with internal carotid or middle cerebral blood flow greater than 200 cm/sec benefit from prophylactic maintenance transfusion to prevent stroke.[469] The ideal age range and frequency of TCD screening have not been determined yet[804]; however, the NHLBI recommends screening approximately every 6 months in patients 2 to 16 years of age, when the risk for stroke is highest.

Ophthalmologic examinations should be started at school age and repeated every few years unless retinopathy is discovered. For patients with retinopathy, more frequent follow-up and fluorescein angiography are nec-

essary to establish the tempo of the lesion and to determine appropriate therapy.

Regular dental care is critical in preventing the intraoral lesions that might predispose to infections such as mandibular osteomyelitis.[805]

Birth control options should be discussed as with any adolescent patient. Barrier methods and low-dose estrogen oral and depot injectable contraceptives can be used safely.[806,807]

Management of Painful Crises

Most painful crises can be successfully treated at home by increased fluid intake and oral analgesics. If the pain is too severe for oral analgesics or if the patient cannot maintain adequate fluid intake, the episode must be treated at the hospital. Hospital management of painful crisis includes hydration and analgesia. In dehydrated patients, the intravenous fluid rate is usually one and a

half times maintenance; however, some cannot tolerate this expansion of intravascular volume. Frequent monitoring of vital signs during fluid administration is essential to prevent iatrogenic cardiac failure. Serum electrolyte levels must be checked early and intravenous solutions adjusted appropriately. Though theoretically sound, the use of intravenous bicarbonate has not been shown to be effective.[808] Face mask oxygen is of little therapeutic value unless the patient is hypoxic. Furthermore, Embury and colleagues have shown that continuous oxygen inhalation can suppress erythropoiesis, with reticulocyte counts falling within days.[809] In addition, painful crisis may result from rebound marrow activity after the abrupt discontinuation of oxygen therapy or cessation of transfusion programs.[810]

Analgesia must be sufficient to control the pain. Analgesics and other adjuvants may be combined to optimize efficacy/safety. "Standard doses" may not be adequate to "capture" an individual patient's pain, especially if not opioid naïve on initial evaluation, so dosing should be titrated to relief. Although opioid dependence or enhanced opioid-seeking behavior may be a problem for rare patients, overestimation of the incidence of this unusual situation must not affect the decision to control severe pain.[811] It is very unfortunate that subtle misconceptions interfere with providing appropriate pain relief. In one study, standardized patients with a chief complaint of pain who gave histories of frequent pain crises were given less opioid by nurses than were identical patients whose scripts included a history of infrequent pain episodes.[812]

One should choose opioids with side effects, drug interactions, serum half-lives, and previous efficacy in mind. Changes in the route of administration (intravenous, oral, transdermal) require adjustments for equianalgesic dosages. Serial intramuscular injections should be avoided because they can lead to the formation of sterile abscesses. High-dose meperidine may cause seizures, particularly in the setting of compromised renal function, in which toxic levels of normeperidine accumulate.[813] At the onset of inpatient therapy for severe pain, regular dosage intervals based on half-life should be used and not an "as-needed" dosage strategy. This approach may avoid the recurrence of pain and anxiety as a result of delay in obtaining the next dose of medicine after being requested. Continuous intravenous opioid therapy in children has been successfully used,[814] but ACS may be precipitated by respiratory depression.[815] Perhaps an optimal approach is the use of patient-controlled analgesia[816,817] initiated in the emergency department[818] to provide adequate pain relief at a lower total opioid dose.[819]

Hypoventilation is the most serious side effect of opioid therapy and must be carefully avoided by careful monitoring of oxygen saturation, aggressive use of incentive spirometry,[820] and use of oxygen when the patient is hypoxic. In one study, epidural anesthesia was successfully used to alleviate pain and maintain or improve oxygenation.[821] Constipation and urinary retention are common problems that should be remedied early. Sometimes it is virtually impossible to make a patient entirely comfortable with safe doses of opioids. This frustrating situation needs to be approached with care and sensitivity, with involvement of every member of the patient care team.[822,823] The addition of nonsteroidal anti-inflammatory agents is helpful to some patients. Others have benefitted from adjuncts such as acupuncture,[824] biofeedback, and hypnosis.[825] For the rare patient who is incapacitated by recurrent episodes of pain and who spends more time in the hospital than out, chronic outpatient opioid therapy may be useful.[826] Although transfusion (even exchange transfusion) is rarely effective for acute pain, a brief maintenance program may facilitate completion of a school year or an important project at work; however, this must be tempered by risks of allosensitization, iron overload, and blood-borne infection. Hydroxyurea is effective at decreasing the frequency of recurrent painful crises, but its favorable effect may be delayed by months or until MTDs are reached.[393]

Transfusion

Transfusions improve the oxygen-carrying capacity and decrease the proportion of erythrocytes that carry HbS. Although transfusion is typically not used for the treatment of chronic anemia or acute painful crises, it is often necessary for associated comorbid conditions.[827] Current transfusion practices include episodic or chronic regimens, depending on whether the reduction in risk for severe clinicopathologic sequelae from SCD (e.g., stroke or recurrent ACS) outweighs the risks inherent in a chronic transfusion regimen.

Episodic transfusions (simple or exchange) are used primarily to treat acute complications of SCD. Simple transfusion is possible when the anticipated post-transfusion hemoglobin level will not exceed 10 to 11 g/dL. Exchange transfusion (either by manual technique or automated erythrocytapheresis) is reserved for complications that are either life threatening or pose risk for irreversible tissue damage (e.g., stroke, severe ACS) or when initial simple transfusion was ineffective. The primary goal of exchange transfusion is to reduce the HbS concentration rapidly to less than 30% of the total hemoglobin content without increasing blood viscosity or expanding the blood volume, thereby reducing potential cardiovascular strain. In centers in which an automated cell separator is available, a two-volume exchange transfusion can be efficiently accomplished in less than 90 minutes.[502,503] Episodic transfusion is indicated for the management of symptomatic episodes of acute anemia (e.g., aplastic crisis triggered by parvovirus infection), severe/progressive ACS, acute stroke, splenic sequestration, and priapism unresponsive to medical therapy, as well as perioperatively. As discussed previously, simple transfusion is preferred instead of exchange transfusion in the preoperative setting.

Chronic transfusion therapy is implemented when the ongoing risk of morbidity from sickle cell complications outweighs the risks inherent in recurrent blood exposure. In a chronic regimen involving simple or exchange methods, transfusions are usually scheduled every 3 to 4 weeks, with the goal of maintaining the HbS level between 30% and 50%. Chronic transfusion therapy has been indicated for primary stroke prevention in high-risk children identified by TCD and for prevention of recurrent stroke in children who have already experienced an overt stroke. Limited-duration regular transfusions may be indicated for reducing the frequency and severity of ACS, complicated pregnancy, prolonged hematuria, and chronic vaso-occlusive complications (e.g., nonhealing leg ulcer). Sickle trait blood should not be used.

Chronic transfusion regimens in SCD may increase risk for the transfusion-associated complications of allosensitization, infection, and progressive iron overload. Transfusional iron accumulation is ultimately unavoidable, though often clinically undetected and undertreated. Excess iron is deposited in multiple organs, including the liver, heart, pancreas, endocrine glands, and skin, with potential for organ damage. There is no physiologic mechanism for iron removal, but fortunately, parenteral deferoxamine[828,829] and oral deferasirox[830] are effective chelators if adhered to chronically. Serial assessment of serum ferritin levels may provide insight into ongoing iron balance in SCD,[831,832] but because infections and vaso-occlusive crises also increase ferritin levels, it is a suboptimal predictor of liver iron burden and liver fibrosis. However, high liver iron levels were not associated with as much liver disease as expected from similar data in thalassemia.[833]

In children who have received multiple transfusions, the rate of alloimmunization is between 7% and 20%.[834-837] The likelihood of alloimmunization is related to the number of transfusions, racial differences between the common donor and recipient erythrocyte phenotype, and as yet unknown genetic factors that control the responsiveness of the recipient to transfused antigens.[452] Opinions and practices differ in regard to the utility of preventing sensitization with the use of expensive antigen-matched cells as opposed to providing these cells after sensitization occurs.[838,839] The most common antibody-provoking antigens are K, C, E, S, Fy[a], Fy[b], and Jk[b]. Ideally, patients with SS SCD should receive antigen-matched red cells beyond ABO and D to include C, E, and Kell to reduce the hazard of sensitization,[839] and such a strategy has been demonstrated prospectively to reduce sensitization.[840] Some suggest further extension of phenotype matching,[841,842] but the added expense and relative scarcity of the required random donors make this impractical.[839] Potential benefits from attempting to prevent allosensitization include prevention of complications from the first delayed transfusion reaction and possibly the prevention of autoantibodies that appear in the same context. Clinically significant autoantibodies do occur in about 10% of patients with SCD, and the inci-

dence appears to be higher in those with alloantibodies.[837,842,843] In 183 children the incidence of autoantibodies was 7.6%, and when associated with C3 on the red cells, the autoantibodies resulted in hemolysis.[453]

Preparation for Surgery

Children with SCD have an increased likelihood of undergoing surgical procedures, in particular, cholecystectomy, splenectomy, and joint replacement. The CSSCD found that 7% of all deaths in patients with sickle cell anemia were related to surgery.[247] In 1079 surgical procedures on 717 patients of all genotypes, the mortality within 30 days of the procedure was 1.1% (12 deaths); however, no deaths were reported in children younger than 14 years.[844] That same series illustrated comparable complication rates in the SS and SC groups and suggested that patients undergoing regional anesthesia were at higher risk for complications than those undergoing general anesthesia.[844]

The CSSCD "natural history" study did not definitively address the important question of the effectiveness of preoperative transfusion. In a review of records from Dallas Children's Hospital, pulmonary complications were particularly common in patients undergoing laparotomy, thoracotomy, or tonsillectomy and adenoidectomy who were not transfused preoperatively (9/29) when compared with those who underwent transfusion for these procedures (0/8).[845] More recently, Vichinsky and collaborators in the Preoperative Transfusion in Sickle Cell Disease Study Group reported the findings of a prospective, multi-institutional study that randomized more than 600 preoperative HbSS patients to receive either simple transfusion designed to increase the total hemoglobin concentration to 10 g/dL or exchange transfusion designed to decrease the HbS percentage to less than 30 and increase total hemoglobin to 10 g/dL.[846-850] Several key points emerged from that study:

- There was no significant difference between the two transfusion strategies in terms of complications; both strategies reported a high 30% postpartum complication rate. Transfusion-related complications were twice as common (14%) in the exchange transfusion arm as in the simple transfusion arm (7%).
- The most common and serious complication was ACS, which occurred in 10% of procedures in both arms. The average time at onset was postoperative day 3, the average length of the episode was 8 days, 11% of the patients required intubation, and two died.
- Those in a higher surgical risk category—history of pulmonary disease, occurrence of ACS, and increased frequency of hospitalization—were at higher risk for complications.

These data suggest that at minimum, a simple transfusion designed to raise the preoperative hemoglobin level to 10 g/dL should be administered to all patients with HbSS disease.

In addition to transfusion, perioperative morbidity can be minimized safely by careful collaboration between the hematologist, anesthesiologist, and surgeon during the perioperative period. Those with previous pulmonary dysfunction or a history of multiple hospital admissions should receive a minimum of overnight maintenance intravenous hydration and be monitored as high-risk patients. During the procedure and in the postoperative period, all patients should have compulsive attention paid to oxygenation, hydration, maintenance of warm body temperature, acid-base balance, and positioning that does not impair circulation.[844,851-856] Choice of an anesthetic agent is not as critical as the care with which it is delivered.[853]

Management of Pregnancy

Although many women with SCD have normal pregnancies, pregnancy can be associated with serious problems for both the mother and fetus. Pregnant women should be monitored closely and collaboratively by obstetricians and hematologists experienced in high-risk pregnancies. Maternal complications may include an increase in the frequency and severity of painful crises, an increase in the severity and frequency of chest syndrome, exaggeration of physiologic anemia of pregnancy, toxemia, and death.[857] Because of sickling in the placenta, fetal complications can include spontaneous abortion, prematurity, and intrauterine growth retardation. Some authors have suggested that pregnancy outcome could be improved further if mothers are prophylactically transfused,[858,859] but no significant benefit of transfusions to the mother or fetus during pregnancy was demonstrated in the only prospective trial.[860] Hepatitis, alloimmunization, and hemolytic transfusion reactions[860,861] have been reported in transfused pregnant sickle patients. Therefore, transfusion therapy is not recommended prophylactically and is reserved for acute, severe, or persistent complications.[862,863] With modern obstetric management, regular prenatal care, and better nutrition, maternal mortality has been reduced to less than 1% and perinatal deaths have declined to less than 15%.[864,865]

OTHER SICKLE SYNDROMES

Sickle Cell Trait: $\alpha_2\beta_2$, $\alpha_2\beta_2^{Val6}$

Sickle cell trait is a benign condition that is not associated with increased morbidity or mortality.[866-870] There is no associated anemia, abnormal morphology, or decreased red cell survival. Most individuals have approximately 40% HbS and 60% HbA. A population with 28% to 35% HbS has been identified and shown to have accompanying α-thalassemia.[871] Decreased levels of HbS can also be seen in patients with iron[872] and folate[873] deficiencies. Growth, behavior, educational achievement, and pregnancy risks in children with sickle trait are entirely normal.[874-876] Black American professional football players

have the same incidence of sickle trait as the general black population does.[877] In a retrospective study of sudden death during physical training in the U.S. Armed Forces, Kark and colleagues noted a 1 in 3200 incidence of sudden death among sickle trait recruits, a frequency 27 times greater than that in non-HbS controls.[878] All deaths were associated with strenuous physical exertion, and risks increased with age. After this report, modifications in basic training for all recruits have been recommended, but follow-up data are not yet available. A subsequent prospective study of 25 sickle trait recruits and non-HbS controls revealed no difference in exercise tolerance or physical conditioning after 7 weeks of basic training.[879] Several authors have stressed that these data do not justify restriction of sickle trait men from the armed services or organized sports.[880-882] Although anecdotal reports of various severe vaso-occlusive episodes in those with sickle trait appear in the literature, they are extremely rare and not clearly due to sickle trait. However, Eichner has reviewed the sudden death of nine college athletes with sickle trait and summarized findings that distinguished sickling from more common heat-related illnesses.[883] Postmortem findings of intravascular sickling are not evidence that the sickling had occurred before death. Under certain extreme conditions, however, sickling and even death may occur in individuals with sickle trait. Such conditions include severe pneumonia,[884] unpressurized flying, and exercise at high altitudes.[885,886] The risk associated with routine aviation in individuals with sickle trait has been overstated.[887] Careful general anesthesia does not carry great risk for a person with sickle trait,[888,889] but tourniquet surgery[853] and deep hypothermia should be avoided. The most consistent abnormality found in sickle trait is an inability to concentrate urine.[890] Persistent hematuria in sickle trait individuals has been associated with papillary necrosis of the kidney[891] and rarely renal medullary carcinoma.[627] Traumatic hyphema in sickle trait is a medical emergency because in the hypoxic conditions of the anterior chamber of the eye, HbAS red cells will sickle and lead to increased intraocular pressure.[892] Sickle trait women in one prospective study showed an increased risk for preeclampsia, and their infants had a minimal decrease in gestational age and birth weight but no increased infant mortality.[893] Previous retrospective and case-control studies have provided conflicting data regarding differences in birth weight or gestational age at birth.[894-897] Patients in whom sickle trait is diagnosed but a clinical and laboratory phenotype consistent with a sickling disorder develops should be considered for molecular globin diagnostics to ensure accuracy of the diagnosis.[898,899]

SC Disease: $\alpha_2\beta_2^{Val6}$, $\alpha_2\beta_2^{Lys6}$

Hemoglobin SC disease is a mild chronic hemolytic anemia associated with variable degrees of vaso-occlusive complications. As described in Table 19-2, the patient typically has a hemoglobin concentration of 10 to 12 g/

dL, a reticulocyte count of 1% to 13%, and a relative microcytosis for the degree of reticulocytosis. The peripheral blood smear (see Fig. 19-4) is more characteristic of HbC than HbS and reveals impressive target cells and rare, if any ISCs. The clinical course is quite variable, with some patients severely affected at an early age and others entirely asymptomatic and identified only as adults on routine screening. Hemolysis is less severe in SC disease than in SS disease[900] and therefore results in a higher hematocrit in patients with SC disease.

The major complications of HbSS disease are not as common in SC disease but have been reported to include recurrent painful bone crises, painful abdominal crises, gallstones, pulmonary infarction, priapism, and CNS infarction.[901-904] As shown in Figure 19-7, the pattern of clinical events is different in SC disease, with most events occurring not only less frequently but also later in life. Certain complications appear to be more common in the SC disease population: eye disease,[665,902,905-907] AVN of the femoral heads, renal papillary necrosis,[908] and pregnancy-related problems.[909] Splenomegaly is found in approximately 60% of patients with SC disease and has been associated with splenic infarction[910] and splenic sequestration,[911] particularly at high altitudes. Although infection is not as common in SC disease as in SS disease,[912] splenic hypofunction and an increased risk for pneumococcal and *H. influenzae* sepsis are found in SC disease.[913] Pneumococcal and *H. influenzae* vaccines are indicated in SC disease, and the use of prophylactic penicillin is recommended.

Patients with SC disease clearly have more sickling complications than do individuals with sickle trait, who are essentially free of sickling complications. One would therefore assume that mixtures of HbS and HbA are less likely to polymerize than mixtures of HbS and HbC. Interestingly, Bunn and associates[914] have shown that such is not the case because the kinetic and equilibrium behavior of mixtures of HbS and HbA is essentially identical to the behavior of mixtures of HbS and HbC. One can resolve this apparent paradox by considering how the hemoglobin mixtures are packaged in SC and AS cells. There are two major factors that explain why SC cells sickle more readily than AS cells do: (1) there is more HbS in an SC cell, and (2) an SC cell has a higher MCHC. Because the charge and affinity for β-globin differs between β^S-globin and β^C-globin, individuals with SC disease usually have 50% HbS and 50% HbC, whereas those with sickle trait typically have 60% HbA and 40% HbS.[908] The increased HbS content of SC cells results in an approximately sevenfold increase in the rate of polymerization.[915] The increase in MCHC in SC disease, which is quite obvious on density separation of SC red cells[139,914,916] (see Fig. 19-5) and even C trait red cells,[915] is probably due to activation of the KCC system by the positively charged HbC molecules.[917] The cellular dehydration and microcytosis associated with HbC has been well characterized by Brugnara and colleagues[918] and Ballas and associates.[916]

Hemoglobin SC and α-Thalassemia

One patient with HbSC and α-thalassemia trait has been described.[919] This 7-year-old child had the following laboratory values: hematocrit, 25.8%; hemoglobin, 7.9 g/dL; MCV, 53 μm³; MCH, 16.2 pg; MCHC, 30.6 g/dL; reticulocytes, 7.2%; HbS, 50.5%; HbC, 47.7%; and HbF, 1.8%. One parent had 27% HbS with an MCV of 71 μm³; the other had 24% HbC with an MCV of 57 μm³. This patient, like many patients with SC disease, was relatively asymptomatic. Of interest is that her hematocrit level and reticulocyte count are compatible with a considerable degree of hemolysis.

SO Arab: $\alpha_2\beta_2^{Val6}$, $\alpha_2\beta_2^{Lys121}$

SO$_{Arab}$ double heterozygotes are quite rare and have a relatively severe disorder with chronic hemolytic anemia and vaso-occlusive episodes.[920] As seen in Figure 19-4, the O Arab mutation lies within the area critical to axial contact in the HbS fiber. Routine cellulose acetate electrophoresis at pH 8.6 does not distinguish between HbC and HbO$_{Arab}$. Citrate agar electrophoresis at pH 6 does separate HbC from HbO and should be performed for patients who appear to have HbSC disease on cellulose acetate electrophoresis but who have particularly severe symptoms.[921]

SD: $\alpha_2\beta_2^{Val6}$, $\alpha_2\beta_2^{Glu121}$

SD double heterozygotes have severe hemolytic anemia with a peripheral blood smear comparable to that seen in HbSS. These rare patients have severe vaso-occlusive complications,[922-924] thus illustrating, as in those with HbO$_{Arab}$, the critical nature of the β121 contact site. HbD migrates with HbS on cellulose acetate electrophoresis at alkaline pH and can be distinguished from HbS on citrate agar electrophoresis at acid pH. HbD is suspected when a hemoglobin appears to be HbS on cellulose acetate electrophoresis but gives a negative "sickle prep." Identification of a parent with HbD is important socially because it may become difficult to explain how a child has "SS disease" and only one parent has a positive sickle prep.

S Korle Bu: $\alpha_2\beta_2^{Val6}$, $\alpha_2\beta_2^{Asn73}$

Hemoglobin Korle Bu is a rare hemoglobin mutant.[925] It is mentioned here only because it illustrates an important pathophysiologic point. Korle Bu participates poorly in sickling.[926] This mutation interferes with lateral contact between HbS fibers by blocking the critical receptor area for β^{Val6}. S Korle Bu double heterozygotes are entirely symptom free.

Hemoglobin C Harlem (C Georgetown): $\alpha_2\beta_2^{Val6,\ Asn73}$

Hemoglobin C$_{Harlem}$ (also known as C$_{Georgetown}$) has two substitutions on the β chain: the sickle mutation β^{Val6} and

the Korle Bu mutation β^{Asn73}.[927] Patients with these mutations are asymptomatic. Patients doubly heterozygous for HbS and HbC_{Harlem} have clinical crises resembling SS disease.[927,928]

Hemoglobin S Antilles: $\alpha_2\beta_2^{Val6, \ Ile23}$

HbS Antilles also has two substitutions on the β chain: the sickle mutation β^{Val6} and a second mutation β^{Ile23}.[929] This mutation results in hemoglobin with low oxygen affinity that in heterozygotes for HbA and HbS Antilles, results in mild hemolytic anemia and the presence of 5% to 7% ISCs. A transgenic mouse with HbS Antilles and the HbD mutations (see earlier) exhibits many of the clinical features of SS disease.[930]

Sickle–β-Thalassemia

Patients heterozygous for HbS and β-thalassemia have clinical severity that depends on the output of the thalassemic β gene.[511,931,932] If no HbA is produced ("S–β^0-thalassemia"), the clinical course is comparable (see Table 19-2 and Fig. 19-9) to that of homozygous sickle cell anemia. Electrophoresis shows mostly HbS with slightly elevated HbA_2 and variable amounts of HbF. Features that distinguish these patients from those with sickle cell anemia are that they may be of Mediterranean origin, have microcytosis, and often have splenomegaly. One parent will have classic sickle trait, whereas the other will have β-thalassemia trait. The hemolytic rate is lower, and the patients tend to have a slightly higher hematocrit and lower reticulocyte count. Their peripheral blood morphology is notable for target cells, microcytosis, and generally fewer ISCs than in sickle cell anemia. If there is output from the β-thalassemia gene ("S–β^+-thalassemia"), patients tend to have a milder clinical course, comparable to that of SC disease. Electrophoresis in these patients shows predominantly HbS, elevated HbA_2, variable amounts of HbF, and HbA. Features that distinguish these individuals from those with sickle cell anemia are HbA, microcytosis, splenomegaly, and a relatively benign clinical course. The ameliorative effects of HbA (see Table 19-2 and Figs. 19-5 and 19-9) are apparent. These patients can be distinguished from individuals with sickle trait because of a higher percentage of HbS than HbA, microcytosis, hemolytic anemia, abnormal peripheral morphology, and splenomegaly. α-Thalassemia with HbS–β^0-thalassemia results in higher hemoglobin levels, lower reticulocyte counts, and increases in MCV and MCHC.[271]

Hemoglobin C Disease: $\alpha_2\beta_2^{Lys6}$

Homozygous HbC disease is a mild disorder characterized by hemolytic anemia, microcytosis, and splenomegaly.[933-938] The tendency of HbC to aggregate and crystallize[939-941] is probably responsible for the characteristic target morphology of the stained and dried red cell in homozygous C disease and in HbC trait, although these crystals are not likely to be directly responsible for the hemolytic anemia. In HbC trait, target cell formation and mild microcytosis are the only manifestation of the anomaly. Hemolytic anemia is not present.

The basis of the aggregation and crystal formation of HbC cells is not precisely understood. It is thought that the substantial charge difference between HbC and HbA is in some way responsible for the tendency toward aggregation of C molecules, which leads to local increments in hemoglobin concentration in excess of its solubility.[938] The structure of these crystals has been examined by x-ray diffraction analysis.[939-941]

The hemolytic anemia of homozygous HbC disease is probably due to the fact that these cells are dehydrated. Brugnara and colleagues have demonstrated that CC red cells have decreased water and cation content associated with a large efflux of potassium.[918] As discussed in the previous section on membrane abnormalities, this volume-dependent potassium efflux is regulated by the KCC pathway.

The Thalassemias

Melody J. Cunningham, Vijay G. Sankaran, David G. Nathan, and Stuart H. Orkin

FIGURE 20-1. Geographic distribution of thalassemia.

The thalassemias are a heterogeneous group of inherited anemias caused by mutations affecting the synthesis of hemoglobin.[1-3] Milder forms are among the most commonly seen genetic disorders, whereas the less often seen severe forms lead to significant morbidity and mortality worldwide (Fig. 20-1).

Study of the thalassemias traces the history of the application of recombinant DNA methods to analysis of inherited diseases and underscores how naturally occurring mutations in humans illuminate genetic principles. Here, the genetics of hemoglobin genes are reviewed as background for discussion of the molecular basis of the thalassemia syndromes, their clinical phenotypes, prenatal diagnosis, and current management.

HUMAN HEMOGLOBINS: COMPOSITION AND GENETICS

Normal hemoglobins are tetramers of two α-like and two β-like globin polypeptides. The predominant hemoglobin in normal adult red blood cells is hemoglobin A (HbA), $\alpha_2\beta_2$.[4,5] The α- and β-globins contain 141 and 146 amino acids, respectively. In addition to HbA, adult red cells normally contain two minor hemoglobins: HbA$_2$ ($\alpha_2\delta_2$) and fetal hemoglobin (HbF) ($\alpha_2\gamma_2$). The γ and δ polypeptides are related to β but differ in their primary amino acid sequences; hence they may be referred to as β-like

globins. HbA$_2$ normally accounts for 2% to 3.5% of the total hemoglobin. Though a minor component in adult red cells, HbF is the predominant hemoglobin in fetal red cells during the latter two trimesters of gestation. Because it does not bind 2,3-diphosphoglycerate, its affinity for oxygen is higher than that of HbA.[6] As such, HbF enhances the fetus' ability to extract oxygen from the placenta. HbF constitutes a small fraction of the total hemoglobin in adult red cells (0.3% to 1.2%), in which it is largely restricted to a small subset of circulating erythrocytes (0.2% to 7% of the total cells) referred to as F cells.[7,8] Production of HbF in normal adults appears to be largely genetically controlled as demonstrated by studies in twins and families.[9-13] During the first trimester in utero, embryonic hemoglobins with differing subunit composition are found in the yolk sac–derived macrocytic (or primitive) red cells.[1]

The genes that encode the globin polypeptides are organized into two small clusters.[2,4,5,14,15] The α-like genes are located near the telomere of the short arm of chromosome 16 (16p13.3), whereas the β-like genes reside on chromosome 11 at band 11p15.5.[16,17] A schematic diagram of the human globin genes and the composition of the various hemoglobins are shown in Figure 20-2.

The α-globin gene cluster contains three functional genes, ζ, α_2, and α_1, oriented in a 5′-to-3′ direction along the chromosome.[2,15,18,19] ζ-Globin, encoded by the ζ gene, is found in two embryonic hemoglobins, Hb

FIGURE 20-2. Chromosomal organization of the globin genes and their expression during development. The *blue boxes* indicate functional globin genes, whereas the *yellow boxes* indicate pseudogenes (see text). The $\Theta 1$ globin gene is depicted by a *brown box* and is expressed at very low levels compared with the adult α-globin genes. The scale of the depicted chromosomal segments is in kilobases of DNA. The switch from embryonic to fetal hemoglobin occurs between 6 and 10 weeks of gestation, and the switch from fetal to adult hemoglobin occurs at about the time of birth.
Gower-1 ($\zeta_2\varepsilon_2$) and Portland ($\zeta_2\gamma_2$).[20] The duplicated α-globin genes (α_1 and α_2) encode identical polypeptides. DNA sequence analysis has revealed three additional globin gene–like sequences in the cluster: pseudo-ζ (ζ_1), pseudo-α_1, and pseudo-α_2.[2,15] Although they resemble the functional genes, sequence differences in coding or critical regulatory regions render these genes inactive; hence they are referred to as pseudogenes.

Five functional genes, ε, $^G\gamma$, $^A\gamma$, δ, and β, are present within the β-like cluster and are arranged in a 5′-to-3′ direction as they are expressed during development.[21-24] The product of the embryonic ε gene is found in the embryonic hemoglobins Hb Gower-1 ($\zeta_2\varepsilon_2$) and Hb Gower-2 ($\alpha_2\varepsilon_2$). The fetal γ genes are duplicated but encode globins differing only at amino acid 136; $^G\gamma$-globin and $^A\gamma$-globin contain a glycine or alanine residue, respectively. $^G\gamma$- and $^A\gamma$-globins are both found normally in HbF ($\alpha_2\gamma_2$). The δ-globin gene encodes a polypeptide differing in only 10 of 146 residues from β, and yet it is expressed at a very low level in adult red cells (<3% of β). The poor expression of δ-globin is attributed to differences in critical regulatory sequences[25] within the gene that appear to inhibit messenger RNA (mRNA) processing[26] and the inherent instability of δ mRNA.[27] Only a single functional β-globin gene is present in the cluster. β-Globin is the predominant β-like globin in adult red cells, in which HbA ($\alpha_2\beta_2$) accounts for more than 95% of the total hemoglobin.

The relative synthesis of individual globin chains and the major sites of erythropoiesis during development are depicted in Figure 20-3.[1,4,28-30] Embryonic hemoglobins are expressed nearly exclusively in primitive nucleated red cells differentiating in the yolk sac blood islands. HbF production commences during the next wave of erythropoiesis in the fetal liver. Fetal liver–derived red cells lose their nuclei as terminal maturation occurs, whereas the primitive, yolk sac–derived cells remain nucleated. The transition from HbF to HbA coincides approximately with the switch from fetal liver to bone marrow erythropoiesis. Despite this correlation between the site of erythropoiesis and the hemoglobins expressed, careful analysis of tissues derived from experimental animals and human fetuses has shown that embryonic hemoglobins are synthesized in the liver as well as the yolk sac and HbFs are produced in the bone marrow as well as the liver. The developmental switches in hemoglobin expression are related to the time of gestation rather than the anatomic site of erythropoiesis per se.

Globin Gene Structure

The globin genes were among the first eukaryotic genes to be isolated by recombinant DNA cloning methods in the late 1970s. Subsequent work has provided the entire DNA sequences of the human α- and β-globin gene clusters and extensive sequences of other vertebrate globin complexes. These data have been invaluable in determining the mutations underlying thalassemia syndromes and in manipulating gene regulatory regions.

Intervening Sequences or Introns

A remarkable finding was made on initial study of the globin genes: the coding region, rather than being organized in a single continuous unit, is interrupted by noncoding DNA known as intervening sequences (IVSs), or introns. The majority of eukaryotic genes contain one or more introns. As indicated in Figure 20-4, globin genes are interrupted at two positions. The discontinuous nature of the coding region of globin genes poses a formidable problem for the formation of mRNA that must be translated into globin polypeptides on cytoplasmic ribosomes. Transcription of a globin gene generates a precursor mRNA containing introns. Formation of mature mRNA is accomplished by post-transcriptional
FIGURE 20-3. Sites of erythropoiesis and pattern of globin biosynthesis during development. Nucleated megaloblasts are produced predominantly in the yolk sac. They are replaced by macrocytic fetal red cells produced in the liver and subsequently in the spleen and bone marrow. The height of the *shaded area* approximates the proportion of circulating red cells produced by each organ. Globin biosynthetic measurements were made to obtain the data shown in the lower part of the figure through incubation of intact cells in the presence of radioactive amino acids followed by globin chain separation. *(Redrawn from Weatherall DG, Clegg JB. The Thalassemia Syndromes. Oxford, Blackwell Scientific, 1981, p 54.)*
FIGURE 20-4. Structure of the human α- and β-globin genes. Untranslated (UT) regions, exon, and intervening sequences (IVS, introns) are depicted by green, salmon, and blue boxes, respectively.

processing, termed RNA splicing. The pathway of RNA processing is depicted in Figure 20-5.

RNA splicing must be executed with exquisite precision for functional mRNA to be generated. Because translation of mRNA proceeds by the reading of triplets (codons), excision of introns needs to be accurate to the nucleotide; otherwise, shifts in the reading frame of the translated polypeptide will result. RNA processing is guided by specific sequences, known as splice site consensus sequences, located at the 5′ and 3′ boundaries of the introns. The donor site, which marks the 5′ end of the intron, generally conforms to the sequence 5′ (C/A)AG′*GT*(A/G)AGT, where the prime sign indicates the position of splicing and GT is an essentially invariant dinucleotide at the 5′ end of the intron. The acceptor site, which defines the 3′ end of the intron, usually fits the consensus 5′ (T/C)$_n$N(C/T)*AG*′G, where *n* is 11 or greater, N is any nucleotide, the prime sign indicates the site of splicing, and AG is an essentially invariant dinucleotide. Excision of introns generally occurs between the dinucleotides GT and AG, the GT-AG rule.

Conserved Features of Mature Globin mRNA

Sequences of human globin genes represented in processed globin mRNA include additional segments located before (5′) and after (3′) the coding region. These untranslated regions are depicted in Figure 20-5. In addition, the mature mRNA is modified at both termini. At the 5′ end a methylated guanylic acid (m⁷G) cap structure is present. A variable number of adenylic acid residues are added at the 3′ end and constitute a poly(A) tail. The 5′ cap structure appears to be important for efficient initiation of mRNA translation, whereas the poly(A) tail contributes to mRNA stability. Overlapping the beginning of the mRNA sequence in genomic DNA are sequences that aid in directing the initiation of transcription to the proper site. In some eukaryotic genes these sequences conform to an initiator (Inr) consensus element.[31] The human β-globin gene has been shown to possess an Inr element that is functional in transcription reactions performed in vitro.[32]

Polyadenylation at the 3′ end of mRNA precursors depends on a signal in the 3′-untranslated region, generally AAUAAA (AATAAA in genomic DNA). The mechanism of modification of the 3′ end is complex and involves not only polyadenylation but also cleavage of the precursor RNA because the primary RNA transcript extends several hundred nucleotides past what becomes the position at which the poly(A) tail is added.

Translation of mRNA into a polypeptide proceeds by the reading of triplets (codons) on cytoplasmic ribosomes. The first AUG codon (specifying methionine) present in the mRNA specifies the start site for translation of the mRNA into protein and is embedded in a sequence context (the Kozak consensus sequence, typi-
FIGURE 20-5. Expression of the β-globin gene. Transcription of the gene generates the precursor RNA, which is processed by RNA splicing to form messenger RNA.

cally CC[A/G]CC*ATG*G) that signals the binding of translation initiation factors and ribosomes to the RNA. Usually, the amino-terminal methionine residue is removed from the growing polypeptide chain even before its synthesis is completed. Termination of polypeptide chain translation is directed by the termination codons UAA, UAG, or UGA. Mutation of these codons allows continued translation into the 3′-untranslated sequences of mRNA, as occurs in selected α-globin chain variants associated with α-thalassemia (see later).

As briefly reviewed earlier, the formation of functional mature mRNA demands extraordinary precision and depends on highly conserved sequence elements. As exemplified by the thalassemia syndromes, point (or other) mutations in these signals lead to reduced or absent polypeptide chain synthesis, the hallmark of thalassemia. Mutations causing thalassemia involve all phases of gene expression, including gene transcription, RNA splicing, integrity of the coding sequence, 3′ polyadenylation, and translation initiation (see later).

Regulation of Globin Gene Expression

Globin genes in all vertebrates are expressed in a tissue-specific and developmentally programmed manner. Their transcription is activated only within developing erythroid precursor cells. Moreover, individual globin genes are expressed at different developmental stages. Hence, within the genes of the β cluster, globins are expressed at the embryonic (ε), fetal (γ), or adult (β and δ) stages, whereas within the α cluster, embryonic (ζ) and adult (α) chain expression is seen. A central problem posed by the organization of the globin gene clusters is how these patterns of tissue- and developmental-stage specificity are achieved. Current findings suggest that interactions between regulatory regions and their chromatin-bound proteins located near the genes (the proximal regulatory elements) and more distant control regions provide the means by which transcription is orchestrated in globin gene clusters.

Proximal Regulatory Sequences and Transcription Factors

Several conserved sequence elements (motifs) in the 5′-flanking sequences of globin genes comprise the promoter, a region required for accurate and efficient transcription of genes by RNA polymerase II.[33-36] Promoters of vertebrate globin genes are similar in overall configuration and subset of motifs present but differ in their detailed organization and sequences. Promoters generally cooperate with more distant regulatory elements termed enhancers to stimulate transcription.[37-39] As discussed later, globin gene promoters appear to interact in a synergistic fashion with very powerful distant elements known as locus control regions (LCRs).

The TATA (or ATA) box is a motif seen in nearly all promoters, including those of the globin genes. The TATA box, typically located 20 to 30 base pairs (bp) upstream from the transcription start site, constitutes the binding site for a general transcription factor, the TATA-binding protein (TBP).[40-42] Binding of TBP to the TATA box is the first step in the assembly of a basal transcription complex (often termed TFIID) that includes many additional proteins (such as TFIIA, TFIIB, TFIIE/F, and TFIIH) and RNA polymerase II.[36] Mutations within the TATA box, as occur in some types of β-thalassemia,[43-49] decrease the binding of TBP to the promoter and decrease transcription.[40,41,50]

DNA sequence motifs located upstream of the TATA box bind proteins that interact with the general transcription machinery through protein-protein contacts with the TFIID complex and other associated proteins.[35,37,38,42] These promoter-bound proteins may either increase (activate) or decrease (repress) the rate of transcription.

A relatively small set of motifs are consistently present in globin gene promoters, including the CCAAT box, the CACC box, and GATA consensus sequences. Each motif may be viewed as a potential binding site for one or multiple transcription factors, which are either tissue restricted or ubiquitous in their cellular distribution.

Transcription factors are typically viewed as modular proteins made up of two domains that fulfill different functions: a DNA-binding domain responsible for sequence-specific DNA recognition and an activation (or repression) domain or domains that interact with components of the basal complex to modulate transcription. Additionally, some transcription factors may function to recruit activities that modify the histones around which DNA is wrapped to make chromatin. These modifications can indirectly alter the activity of the basal transcriptional complex. It is currently believed that transcriptional specificity is achieved by functional cooperation and interaction between cell-restricted and general transcription factors. As background for understanding globin gene control, the presently characterized erythroid-enriched transcription factors are reviewed here. For additional discussion of these proteins, readers are referred elsewhere.[51,52]

The consensus motif (A/T)GATA(A/G), the GATA motif, is found in the promoter region of most vertebrate globin genes and binds an abundant erythroid-restricted transcription factor, GATA-1. GATA motifs have been identified in the regulatory elements of virtually all erythroid-expressed genes, consistent with the notion that GATA-1 should serve a critical role in erythroid gene expression. As noted later, multiple GATA sites are also present within distant regulatory elements. The essential role of GATA-1 in erythroid development was formally demonstrated through gene targeting experiments in mouse embryonic stem cells. Disruption of the single X-chromosome GATA-1 gene in totipotent embryonic stem cells prevents their development into normal erythroid cells. Naturally occuring hypomorphic mutations of GATA-1 in humans have been shown to cause β-thalassemia or disrupt normal erythroid development.[53-58] The GATA-1 protein is a member of a small family of related "GATA factors" that are distinguished by a novel zinc-finger DNA-binding domain. In addition to merely specifying DNA recognition, this domain also mediates protein-protein interactions. Accordingly, GATA-1 is able to interact physically with other GATA-1 molecules or with other types of zinc-finger proteins, including the ubiquitous CACC- or GC-binding factor Sp1, the transcription factor erythroid Krüppel-like factor (EKLF), and a specific cofactor called FOG-1 (for friend of GATA-1)[59,60] (see later). It is envisioned that through its multiple physical interactions GATA-1 cooperates with other transcription factors, perhaps bound to DNA at distant sites, to program erythroid-specific transcription.

CACC motifs, which are represented by diverse sequences within globin and other gene promoters, bind a variety of transcription factors. Many CACC sequences

are recognized by Sp1, a ubiquitous zinc-finger activator protein.[61] A particular CACC motif, CCACACCCT, is found in the adult β-globin gene promoter and is recognized with high affinity by the erythroid-specific protein EKLF. The functional relevance of this binding site has been established through naturally occurring mutations that lead to β-thalassemia (see later). In addition, gene targeting (or knockout) experiments in mice have formally established that EKLF is necessary for efficient β-globin transcription in vivo.[62]

A third erythroid transcription factor, known as NF-E2, binds to an extended motif—(T/C)TGCTGA(C/G)TCA(T/C)—that is found within some distant regulatory elements (see later) and a small subset of erythroid promoters, but not within globin gene promoters. NF-E2 is a heterodimer of two polypeptides of the basic domain–leucine zipper (or b-zip) class of transcription factors.[63,64] One subunit of NF-E2 is tissue restricted, whereas the other is ubiquitous. Although NF-E2 is essential for globin gene expression in mouse erythroleukemia cells in tissue culture,[65,66] its role in vivo appears to overlap that of one or more unknown factors that may act through the same target sites in DNA.[67]

Locus Control Regions and Chromatin Domains

How is globin gene transcription activated and developmentally controlled? Inspection of the DNA sequences of globin gene promoters in the early 1980s failed to provide substantive insight. Initial attempts to dissect control elements involved introducing globin genes into the germline of mice by oocyte injection but were plagued by low-level and erratic transgene expression. Nonetheless, it was possible to show that stage specificity was imparted by the human β- and γ-globin gene promoters. For example, when the human β-globin promoter is introduced into transgenic mice, it directs gene expression only in adult erythroid cells,[68-71] whereas the human γ-globin promoter is active only in embryonic erythroid cells (mice do not have an HbF stage).[72,73]

These early globin gene regulation studies suggested that critical regulatory elements required for high-level expression were missing from the immediate vicinity of the genes themselves. When sensitivity to digestion by the enzyme DNase I was used as an indicator of chromatin structure in the mid-1980s, regions of extreme sensitivity (hypersensitivity sites [HSs]) were identified far upstream (≈30 to 50 kilobases [kb]) of the adult human β-globin gene[74,75] (Fig. 20-6). Four subregions were delimited; they are present in the chromatin of erythroid but not nonerythroid cells. An additional site located even further upstream was found in all tissues. In a formal test of their functional relevance, the HSs were linked to a human β-globin and introduced into the germline of mice. Remarkably, transgenic mice then expressed the human β-globin gene at a level equivalent to that of the endogenous mouse β gene.[76] Further studies showed that the transgene is expressed not only in a tissue-specific manner but

DNase I hypersensitive sites
FIGURE 20-6. Schematic representation of the human β-globin gene locus. The *yellow boxes* depict the core DNase I hypersensitive subregions of the locus control region. The individual globin genes are indicated with their stage of expression.

also in a copy number–dependent fashion, independent of the chromosomal site of integration. These HSs comprise an essential distal regulatory domain, now referred to as the LCR (see elsewhere[51,52] for more detailed history and discussion).

Other globin gene clusters also contain erythroid-specific DNase I HSs. A segment of extreme DNase I hypersensitivity (known as HS-40) located far upstream of the human α-globin genes serves as an enhancer for the α locus. HS-40, however, does not display the full properties of an LCR because it does not direct copy number–dependent transgene expression.[77] Nonetheless, the in vivo relevance of both the β-LCR and HS-40 is underscored by the discovery of patients with thalassemia who have specific deletions in these regions (see later).

The human β-LCR, HS-40, and analogous regions studied in other species are composed of cores, each encompassing a DNase I HS. Cores are approximately 200 to 300 bp in length. Remarkably, within the cores three major protein-binding sites are consistently found: GATA, AP-1 (NF-E2), and CACC sequences. The position-independent activity of the β-LCR correlates best with the presence of GATA and CACC motifs, particularly within the subregion known as HS-3. Enhancer activity of the LCR, particularly within subregion HS-2, requires the NF-E2 motif. The protein-binding motifs within the LCR are also found in globin and other erythroid-expressed gene promoters. To date, no protein-binding sites unique to LCR elements have been identified. Hence, the distinctive properties of the LCR (or HS-40) appear to reflect the synergistic interactions of more typical transcription factors rather than the action of a new set of regulatory proteins.

The discovery of distant control elements, marked by DNase I hypersensitivity, emphasizes the relationship between chromatin structure and globin gene regulation, an association solidified by the unraveling of a rare syndrome, α-thalassemia with X-linked mental retardation.[78] This condition results from mutations in a gene designated *XH2* (or *ATR-X*) that encodes a member of the helicase superfamily.[79] Such proteins, which are often involved in DNA recombination and repair and in the regulation of transcription in *Drosophila*, yeast, and mammals, appear to influence transcription in a global manner by altering chromatin structure.

Regulation at a Distance: Globin Gene Switching

How do LCR sequences influence globin gene transcription over large distances (>50 kb)? How are the individual globin genes developmentally regulated? Two formal possibilities have been considered. On the one hand, the LCR might merely provide an environment conducive for activation of the downstream globin genes. The globin genes would be autonomously regulated; that is, the developmental profile of their expression would be intrinsic to the individual genes (and presumably determined by their promoters). The "influence" of the LCR is most simply viewed as reflecting physical association of the LCR with globin genes brought into apposition by chromosomal looping. On the other hand, sequential activation of the particular genes might depend (at least in part) on competition of each gene for influence of the LCR such that only one gene-LCR interaction would be productive on a single chromosome at any time. The outcome of the competition would be dependent on the array of proteins bound not only at each promoter but also at specific sites in the LCR. Data in favor of both autonomous and competitive mechanisms of regulation have been obtained (see Orkin[51] for detailed discussion).

The human embryonic ζ- and ε-globin genes appear to be largely autonomously regulated. LCR-containing transgenes are expressed during embryonic erythropoiesis (the yolk sac stage) and then extinguished during the fetal liver stage. The information required for shutoff is contained near the globin genes, and competition by adjacent globin genes is not required. Shutoff is hypothesized to reflect the action of repressors, or silencer proteins, that bind the gene promoters. Motifs within the human ε-globin promoter involved in silencing bind GATA-1 and a ubiquitous factor, YY1.[80]

The competitive model of gene regulation is based on experiments in chicken red blood cells that demonstrate competition between the chicken β- and ε-globin gene promoters for a single enhancer located between the genes.[81] In the chicken it has been proposed that an adult stage–specific factor (NF-E4) favors interaction of the β promoter with the enhancer to the exclusion of the ε promoter. In an analogous fashion, data suggest that the human β-globin gene may be negatively regulated in a competitive fashion by the γ-globin gene. Whereas the γ gene is largely autonomously regulated, the β-globin gene is silenced in the embryonic and early fetal stage by a linked γ gene (a γ gene in *cis* to β). Shutoff of the γ gene, presumably as a result of repressors (or silencers), allows the adult β-globin to be expressed. It has been suggested that a protein complex known as the stage-selector protein (SSP), which binds to a site in the proximal γ promoter, serves a function analogous to that proposed for chicken NF-E4 and tips the balance to γ-globin transcription at early stages.[82] Of interest, both NF-E4 and SSP complexes appear to contain the ubiquitous transcription factor CP2.[82] Although other models are theoretically

possible, the capacity of the LCR to act at a distance in regulating activation of globin genes is most compatible with the formation of physical contacts between the LCR (or subregions thereof) and their associated proteins with regulatory elements neighboring the genes themselves. Stage-specific and competitive regulation would therefore reflect engagement of the LCR with genes one at a time. LCR-gene interactions probably have intrinsic stabilities and off-rates such that a single erythroid cell might express more than one globin over time, even from a single chromosome. Experiments examining nascent human globin RNA along the β-gene complex tend to support such models and lend credence to the notion that chromosomal looping brings the LCR and individual genes in apposition. Evidence for LCR interactions with the proximal promoter regions of both the β- and α-globin genes has recently been directly demonstrated by using novel in vivo biochemical approaches.[83-85] Dynamic interactions between the β-LCR and the γ- and β-globin genes appear to underlie the reciprocal expression of these genes in erythroid cells and provide hope that subtle alterations in the nuclear environment may facilitate reactivation of γ-globin genes in patients with hemoglobinopathies such as sickle cell anemia or β-thalassemia.

CLASSIFICATION OF THE THALASSEMIAS

The hallmark of thalassemia syndromes is decreased (or absent) synthesis of one or more globin chains. The designation α- and β-thalassemia refers to deficits in α- and β-globin production, respectively. The α- and β-thalassemias include clinical syndromes of varying severity (Table 20-1). Knowledge of molecular genetics provides a framework in which to consider their clinical heterogeneity.

TABLE 20-1	Clinical Classification of the Thalassemias
Silent carrier (α or β)	Hematologically normal
Thalassemia trait (α or β)	Mild anemia with microcytosis and hypochromia
HbH disease (α-thal)	Moderately severe hemolytic anemia, icterus, and splenomegaly
Hydrops fetalis (α-thal)	Death in utero caused by severe anemia
Severe β-thalassemia (Cooley's anemia)	Severe anemia, growth retardation, hepatosplenomegaly, bone marrow expansion, and bone deformities
Thalassemia major	Transfusion dependent
Thalassemia intermedia	No regular transfusion requirement

thal, thalassemia.

Because the structural gene for α-globin is duplicated on chromosome 16, each diploid cell contains four copies of the α-globin gene. The four α-thalassemia syndromes—silent carrier, α-thalassemia trait, HbH disease, and hydrops fetalis (see Table 20-1)—reflect the inheritance of molecular defects affecting the output of one, two, three, or four of the α-globin genes, respectively. More than 30 different mutations affecting one or both α-globin genes on a chromosome have been described. Some mutations abolish expression of an α-globin gene (α^0), whereas others reduce expression of the gene to a variable degree (α^+). Within the four general categories of α-thalassemia there is marked genetic and clinical heterogeneity. Heterogeneity arises because the syndrome in any given individual may represent a combination (or so-called interaction) of 2 of the 30 or more mutations that have been described.

The β-thalassemias also include four clinical syndromes of increasing severity—silent carrier, thalassemia trait, thalassemia intermedia, and thalassemia major (see Table 20-1).[1,3,86,87] In contrast to the α-thalassemias, the four classes of β-thalassemia are not correlated with the number of functioning genes. Because a single functional β-globin gene resides on each chromosome 11, a diploid cell normally has two β-globin genes. The clinical heterogeneity of the β-thalassemias represents the diversity of specific mutations that variably affect β-globin gene expression. Almost exclusively, these mutations involve the β-globin gene rather than an unlinked genetic determinant. Many mutations eliminate β-gene expression (β^0), whereas others cause a variable decrease in the level of β-gene expression (β^+).[3,87] The capacity of individual patients to synthesize γ-globin modulates the clinical severity. Such is the case because the severity of thalassemias is determined by the degree of globin chain imbalance rather than by the absolute level of either α- or β-globin synthesis per se.[88-92] Substantial synthesis of γ-globin in the marrow cells of individuals with β-thalassemia lessens the extent of chain imbalance and therefore improves red cell production.[93-95] Particular mutations of the β-globin gene in β-thalassemia appear to affect γ-globin gene expression directly. However, some individuals with otherwise severe β-thalassemia may coinherit additional genetic determinants that enhance the synthesis of HbF. Coincident inheritance of an α-thalassemia mutation also reduces chain imbalance in patients with homozygous or heterozygous β-thalassemia.[96] Clinical severity in any individual patient represents the outcome of these complex genetic interactions.

Origin of Thalassemia Mutations: The Influence of Malaria

Mutations causing thalassemia have arisen spontaneously. The nearly exclusive distribution of lethal red blood cell disorders, such as thalassemia, sickle cell disease, and glucose 6-phosphate deficiency, in tropical and subtropi-

cal regions led Haldane in 1949 to propose that the heterozygous carrier state for these conditions confers a selective advantage in locations where malaria is endemic.[97] The incidence of these genes in a population is determined by the balance between premature death of homozygotes and increased fitness of heterozygotes. The frequency of β-thalassemia mutations is high (>1%) in regions such as the Mediterranean basin, northern Africa, Southeast Asia, India, and Indonesia but uncommon in northern Europe, Korea, Japan, and northern China.[3,98,99] The incidence of β-thalassemia trait may exceed 20% in some villages in Greece.[100] α-Thalassemia is perhaps the most common single gene disorder in the world.[2] The frequency of α+-thalassemia alleles ranges from 5% to 10% in the Mediterranean basin,[101] 20% to 30% in portions of West Africa,[102] and 68% in the southwest Pacific.[103] The incidence of α-thalassemia is less than 1% in Britain, Iceland, and Japan.[104,105] Although the incidence of malaria and the rate of occurrence of thalassemia are not always inversely correlated, the anomalies and inconsistencies seem to be the result of genetic drift, migration, and demographic changes that have occurred in the last 10,000 years.[106]

Additional epidemiologic studies have provided further evidence for the validity of the "malaria hypothesis" in both α- and β-thalassemia.[103,107-114] Siniscalco and associates[107] showed that β-thalassemia is uncommon in inhabitants of the mountainous areas of Sardinia, where malaria is rare, as compared with the incidence in coastal populations. In Melanesia, α-thalassemia is correlated with malaria across both latitude and altitude.[103] β-Thalassemia in Melanesia is also associated with malarious coastal regions.[111] A study by Williams and colleagues found that children with α-thalassemia trait appear to have a higher incidence of malaria in childhood that appears to confer subsequent immunity to more severe malarial infections.[115] Follow-up studies in other populations have demonstrated that although α-thalassemia does not confer a reduced risk of malarial infection, it does dramatically reduce the incidence of severe malarial complications.[116,117]

The cellular mechanisms responsible for the selective advantage of thalassemia heterozygotes remain incompletely defined. Cultured erythrocytes containing high concentrations of HbF retard the growth and development of *Plasmodium falciparum*.[118] β-Thalassemia heterozygotes have a delayed disappearance of HbF in the first year of life.[1] This might provide protection from potentially fatal cerebral malaria early in life as the passive immunity acquired in utero wanes. Until recently, however, investigators were unable to document decreased invasion or growth of *P. falciparum* in red cells from thalassemia heterozygotes except under conditions of unusual oxidant stress.[99,119] Using modified tissue culture conditions, Brockelman and associates[120] and, more recently, Pattanapanyasat and colleagues[121] demonstrated decreased parasite multiplication in the red cells of β-thalassemia heterozygotes. They theorized that *P. falciparum* resistance

was a consequence of the inability of the parasite to acquire sufficient nutrients from the digestion of hemoglobin in thalassemic red cells. In one study, red cells with α- and β-thalassemia trait bound greater levels of antibody than control cells did. This could lead to greater removal of parasitized red cells and hence provide protection.[122] Recent studies have suggested that parasitized red cells from α-thalassemia heterozygotes may have altered membrane properties that more readily allow binding of antibody to the red cell and may promote more effective antimalarial immune responses.[123] Erythrocytes from individuals with HbH disease also appear to inhibit *P. falciparum* in vitro.[120,124] Recently, it has been suggested that rosette formation, the binding of uninfected red cells to *P. falciparum*–infected red cells, is decreased in thalassemia because of reduced red cell size and that such impaired rosette formation may hinder the development of cerebral malaria by lessening sequestration.[125]

The difficulty in documenting the cellular mechanism of *P. falciparum* resistance in thalassemic erythrocytes in vitro suggests that the heterozygote advantage may be small. The high mortality associated with malaria in endemic regions is a powerful selective force that may be sufficient to amplify a small increase in fitness.

Classes of Mutations That Cause Thalassemia

Thalassemia is the consequence of mutations that diminish (or abolish) production of either the α or β chain of hemoglobin. Molecular cloning, DNA sequencing, and functional analysis of cloned genes have provided the tools with which to dissect the thalassemia syndromes. This analysis has revealed remarkable heterogeneity in the specific alterations in DNA that lead to these clinical syndromes.

Typically, single nucleotide mutations associated with thalassemia interfere with one of the critical steps in mRNA production (Fig. 20-7 and Table 20-2). Base substitutions alter promoter function, RNA processing, or mRNA translation or modify a codon into a "nonsense codon" that leads to premature termination of translation or substitution of an incorrect amino acid. Insertion or deletion mutations within the coding region of the mRNA create "frameshifts" that prevent the synthesis of a complete, normal globin polypeptide. Large deletions within the α- or β-globin clusters may remove one or more genes and alter regulation of the remaining genes in the cluster. The phenotype that results from the diverse mutations found in thalassemia is determined by the degree of inactivation of the affected gene or genes and the extent of associated increases in expression of other genes within the cluster.

Mutations Affecting Gene Transcription

Point mutations within promoter sequences recognized by transcription factors tend to reduce the affinity with

FIGURE 20-7. Location of various classes of point mutations that cause β-thalassemia with respect to important structural elements present in the β-globin gene. *(Adapted from Kazazian HH Jr, Boehm CD. Molecular basis and prenatal diagnosis of beta-thalassemia. Blood. 1988;72:1107-1116.)*
1. PROMOTER: DNA sequences required for accurate and efficient initiation of transcription.

2. EXONS: DNA that specifies the amino acid sequence of the polypeptide.

3. INTRONS: DNA that interrupts the coding sequence of the gene.

4. ENHANCER: DNA sequences that increase promoter activity at a distance and independent of orientation relative to coding sequence.

5. CAP SITE: Position where transcription of gene into RNA begins.

6. TRANSLATION INITIATION SITE: Position where translation of mRNA into protein begins.

7. SPLICE DONOR SITE ⎫ Sequences required for precise and efficient
8. SPLICE ACCEPTOR SITE ⎭ removal of RNA transcribed from introns.

9. RNA CLEAVAGE/POLYADENYLATION SIGNAL: Sequence that specifies the 3' end of the RNA transcript and the addition of the poly(A) tail.

FIGURE 20-8. Point mutations in the β-globin gene promoter. The sequences of conserved motifs within the promoter and their distance from the transcription start site are indicated. A single base substitution at the indicated positions results in β⁺-thalassemia.

which these proteins bind. Typically, this leads to reduced gene transcription. Analysis of the promoter for the β-globin gene in patients with β-thalassemia has identified a variety of mutations clustered in the ATA and CACC motifs (Fig. 20-8; see also Table 20-2).[3,40-46,126-129] These mutations are associated with preservation of some β-globin expression and hence are customarily associated with the phenotype of thalassemia intermedia. The C→T substitution at position −101, which results in a particularly mild defect, is associated with the "silent carrier" phenotype in heterozygous carriers.[126,204] Although the CCAAT box is highly conserved in globin genes, no mutations within this motif have been identified in thalassemia. Rare mutations in transcription factors that result in thalassemia have been

detected, and exceedingly rare families have been identified in which a thalassemia mutation is unlinked to the globin clusters (see the section on mutations not linked to the globin gene clusters that alter globin gene expression).

Mutations of the ATA box presumably reduce binding of TBP and therefore lead to decreased transcription initiation. Substitutions in the CACC motifs decrease the affinity of binding by several transcription factors, including the erythroid-specific factor EKLF and the ubiquitous protein Sp1. Studies showing that mice engineered to lack EKLF suffer lethal β-thalassemia at the fetal liver stage have established EKLF as a β-globin activator protein in vivo.[62,205] Human β-thalassemias resulting from mutation of a single CACC motif are presumably mild

*The position specifies the location in the gene at which the point mutation occurs. Positions are specified with reference to the start site for transcription (Cap site), the position within the intron (intervening sequence [IVS]), or the position of the codon.

[†]When more than one ethnic group is indicated, the mutation has had more than one origin.

[‡]Loss (−) or gain (+) of a restriction enzyme site with mutation is indicated; the remainder of the mutations can be detected with allele-specific oligonucleotides (see the section on direct detection of thalassemia mutations).

We are grateful to Drs. Halg Kazazian and Titus Huisman and colleagues for providing us with their detailed lists of β-thalassemia point mutations. (From Kazazian H. The thalassemia syndromes: molecular basis and prenatal diagnosis in 1990. Semin Hematol. 1990;27:209; and Huisman TH. Beta-thalassemia repository. Hemoglobin. 1990;14:661, by courtesy of Marcel Dekker, Inc.)

because of the presence of one normal CACC motif within the promoter.

In addition to the protein-binding sites in the promoter, proper transcription depends on sequences surrounding the start site of transcription (known as +1). These sequences often display functional activity in in vitro assays and herald the binding of specific protein complexes to this type of element, termed the Inr. Mild β-thalassemia has been associated with a base substitution (A→C) at +1. Recently, this substitution has been shown to impair the β-globin Inr.[32] The proteins that mediate this effect are unknown.

A novel mechanism by which transcription at the α-globin locus can be disrupted has recently been described and serves as a paradigm for a new class of mutations that can cause human disease. Higgs and colleagues found a variant single nucleotide change upstream of the α-globin genes that creates a binding site for the transcription factor GATA-1.[206] This in turn produces a novel promoter that competes with the endogenous α-globin promoters for interaction with upstream enhancer elements such as HS-40. As a result of this mutation, α-globin gene synthesis is reduced and α-thalassemia results. This mutation is present in approximately 4% of the Melanesian population.

RNA Processing Defects in Thalassemia

The importance of RNA splicing for the formation of functional mRNA cannot be overemphasized. As discussed earlier, removal of introns must be precise to the nucleotide for a continuous, translatable mRNA to be generated from an mRNA precursor. As soon as introns were discovered, it was hypothesized that mutations affecting RNA splicing would probably be involved in the thalassemia syndromes. Apart from its role in constructing a functional mRNA, RNA splicing also appears to be a determinant of mRNA stability[207,208] and is possibly coupled to RNA transport from the nucleus to the cytoplasm.[209]

Mutations That Alter Splice Junctions or Splice Consensus Sequences

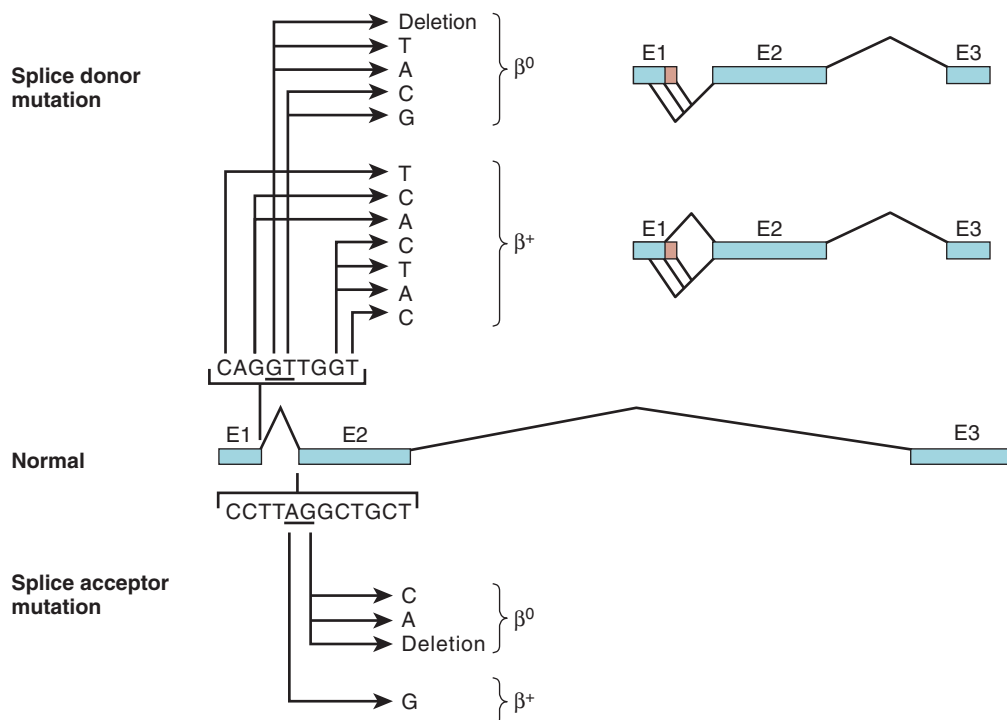
Mutations at the 5′ donor site (GT)[129,131-138] or at the 3′ splice acceptor site (AG)[3,46,135,136,139,140,210] abolish proper splicing of the pre-mRNA transcript and result in α^0- or β^0-thalassemia (Fig. 20-9; see also Table 20-2). Substitutions at other sites within the splice junction consensus sequence have varied effects; because some correctly spliced RNA is produced, albeit a reduced amount, a β^+-thalassemia phenotype ensues.[110,128,129,133,134,141-148,211]


FIGURE 20-9. Examples of abnormal splicing that result from alterations in the splicing consensus sequences. The three β-globin gene exons are symbolized by *blue boxes*, the normal splicing pattern is illustrated by *lines* that project above the exons, and the splice donor and splice acceptor sequences of the first intron are shown. Mutations in the invariant GT dinucleotide of the splice donor site abolish normal splicing of the first intron and result in β⁰-thalassemia, whereas mutations elsewhere in the consensus sequence preserve some normal splicing and cause β⁺-thalassemia. Changes in the splice donor site are associated with abnormal splicing from three cryptic splice donors (*lines* that project below the exons); one site is within the first intron and results in the addition of intron sequences to exon 1 (*brown boxes*). Similarly, changes in the invariant AG dinucleotide of the splice acceptor sequence are associated with β⁰-thalassemia, whereas a mutation in an adjacent nucleotide causes β⁺-thalassemia.

Mutations within the splice site or the splice site consensus sequences favor improper processing of the mRNA precursor. These secondary splicing events, which are not seen under normal circumstances, occur at positions that resemble splice site consensus sequences. Splicing at these "cryptic" sites generates aberrantly processed, nonfunctional globin mRNA (see Fig. 20-9). Mutations within the β-globin IVS-1 splice donor site activate two cryptic donor sites in exon 1 and a third site in IVS-1,[129,136,212] whereas mutation in the IVS-2 splice donor activates a cryptic donor site in IVS-2.[137] Mutation of the IVS-2 splice acceptor site activates an upstream cryptic splice acceptor at position 579 in IVS-2.[46] These incorrectly spliced mRNA molecules suffer either insertions or deletions in the coding region and also shifts in the translational reading frame downstream of the cryptic splice site. The polypeptide synthesized beyond this point bears no resemblance to the globin chain and is often prematurely shortened by a termination codon encountered in the new reading frame.

Mutations within Exons That Create an Alternative Splice Site

RNA from β-thalassemia genes with mutations in the IVS-1 donor splice site may be processed via a cryptic splice donor site GTG*GT*GAGG in exon 1 (codons 24 through 27). Four independent mutations have been identified that activate this cryptic site in the presence of a normal IVS-1 splice donor site (Fig. 20-10; see also Table 20-2).[87,150-152] These mutations appear to enhance the ability of the cryptic site to compete with the normal site for binding of the splicing complex. A T→A mutation at codon 24 is "silent" at the translational level, yet approximately 80% of RNA transcripts are spliced at this incorrect site; hence, mild β+-thalassemia ensues. Two mutations—GAG→AAG in codon 26 and GCC→TCC in codon 27—lead to amino acid replacements that produce the hemoglobin variants HbE and Hb Knossos, respectively, in normally processed mRNA. Because a proportion of transcripts are aberrantly spliced, mild β+-thalassemia results. An analogous mutation in codon 19 produces β+-thalassemia with the hemoglobin variant Hb Malay.[149] These represent mutations that lead to thalassemic hemoglobinopathies.

Mutations within Introns That Create an Alternate Splice Site

Mutations within β-globin IVS-1 may create a new splice acceptor sequence (Fig. 20-11; see also Table 20-2).[153-155] In the first of this class of mutations to be characterized, a G→A substitution at position 110 (19 nucleotides upstream of the normal intron/exon boundary), the majority of globin mRNA precursors are spliced at this alternate site.[153,154,213,214] Because the incorrectly spliced mRNA contains 19 nucleotides from IVS-1, a shift in the reading frame leads to premature termination of translation. A T→G mutation at position 116 of IVS-1 creates a new acceptor site that is used exclusively, thereby leading to little or no normal β-globin mRNA production and to β0-thalassemia.[155]

Three mutations in IVS-2 create new donor sites and activate an upstream cryptic donor site located 579 nucleotides from the exon 2–IVS-2 boundary (see Table 20-2 and Fig. 20-11).[129,143,156] The consequence of these mutations is the insertion of a fourth "exon" derived from sequences within IVS-2. Although the normal donor and acceptor sites are unaffected, little or no correctly spliced β-globin mRNA may be produced.[129,143,156]

RNA Cleavage and Polyadenylation Defects

Proper cleavage at the 3' end of the pre-mRNA and subsequent poly(A) addition depend on the integrity of the AAUAAA signal in the 3'-untranslated region. The importance of the polyadenylation signal for efficient production of globin mRNA was first demonstrated in α-thalassemia.[157,158,215] An AAUAAA→AAUAAG mutation in the α2 gene reduces the efficiency of cleavage-polyadenylation of precursor RNA and leads to "run-on" transcripts that terminate downstream of the gene (see Fig. 20-13). Mutations in the AAUAAA element have also been described in β-thalassemia,[128,159,160] in which the presence of elongated in vivo transcripts has been demonstrated.[159] The transcripts appear to terminate at the next AAUAAA signal, which is present approximately 900 nucleotides downstream of the normal cleavage site. These mutations lead to a moderate reduction in the level of β-globin mRNA and a β+ phenotype.

FIGURE 20-10. Mutations that create an alternate splice donor site in the first exon decrease but do not abolish the occurrence of normal splicing (pattern that projects above the exons) and are associated with splicing from the new site in the first exon (pattern that projects below the exons). Three of these mutations lead to the incorporation of a different amino acid into the β-globin chain derived from the decreased quantity of correctly spliced β-globin mRNA and generate variant hemoglobins.

Mutations Affecting mRNA Translation Initiation

Translation begins at an AUG codon that usually lies within the consensus sequence (GCC)GCC(A/G)CC*AT*GG.[216] Substitutions within the AUG codon abolish translation, whereas those in other positions of the consensus often result in less efficient initiation of translation.

Four mutations in α-globin genes alter the consensus sequence and impair translation (see Table 20-2). Three of them affect the AUG initiator.[161-163] No globin polypeptide is produced because the next downstream initiator is in a different reading frame. The fourth α-globin mutation in this class, found on a chromosome in which one α-globin gene was deleted, alters the consensus sequence by the deletion of 2 bp and reduces mRNA translation to 50% of normal.[164,165] Two AUG initiator mutations of the β-globin gene have been described, and both are of the β^0 type (see Table 20-2).[3,160]

Premature Termination (Nonsense) Mutations

Nucleotide substitutions within the coding region are innocuous if they occur in the third position of a codon and do not alter the amino acid inserted during translation. Substitutions that alter codons from one amino acid to another lead to hemoglobin structural variants. Some substitutions change a triplet coding for an amino acid to a stop codon (UAG, UUA, or UGA). Such chain termination (or nonsense) mutations abort mRNA translation and lead to the synthesis of a truncated polypeptide. Moreover, nonsense mutations also reduce the amount of stable mRNA generated, which is a reflection of coupling between mRNA biogenesis and mRNA translation (Fig. 20-12).[217]

Chang and Kan[167] described the first nonsense mutation in β-thalassemia in which a lysine codon at amino acid position 17 was converted to a stop codon (AAG→UAG). Although no β-globin chains were produced in vivo, complete translation of the abnormal mRNA could be achieved in a cell-free extract capable of protein synthesis by the addition of a "suppressor" tRNA that inserts a serine at the UAG codon.[218] Several other nonsense mutations causing thalassemia have been described (Fig. 20-13; see also Table 20-2).[133,145,168-172] In addition, single or dinucleotide insertions or deletions have been observed that alter the translational reading frame and introduce a premature stop codon as a consequence.[3,128,143,146,149,173-180,219] Two termination mutations have been described in the α-globin genes, one that introduces a stop codon[166] and the other a frameshift.[172] In addition, frameshift mutations have been described that result in abnormal elongation of globin chains (see the section on unstable β-globin chains).

mRNA molecules with termination mutations often do not accumulate to a normal level in vivo.[215,220] The extent of this effect is variable and depends on the specific mutations; deletion of the third nucleotide (C) from codon 41 (Fig. 20-14) leads to complete absence of globin mRNA,[221] whereas a single substitution in the β39 codon allows the accumulation of roughly 5% to 10% of the normal amount of globin mRNA.[220] The basis for the quantitative deficiency in these mRNA species is of considerable interest. Some data suggest that such mutations lead to intranuclear degradation of abnormal globin RNA and suggest a link between mRNA translation and nuclear RNA processing or nuclear to cytoplasmic transport of mRNA.[222,223] Experimental studies in tissue culture systems have shown that the deficiency in β-globin mRNA accumulation is specific for nonsense mutations and is not observed with missense mutations[217]; a suppressor tRNA that allows the abnormal mRNA molecule to be translated completely will correct the quantitative deficiency in globin mRNA.[223] Recent work from a number of investigators has begun to unravel the molecular machinery that mediates this phenomenon, which has been termed nonsense-mediated decay and appears to play an important role in normal physiology, as well as pathologic states.[224]

Termination Codon Mutations

UAA is the normal termination codon for both α- and β-globin mRNA translation. The 3′-untranslated regions are 109 and 132 nucleotides for α- and β-globin mRNA, respectively. A single nucleotide substitution in the termination codon could either create another stop codon (UAG) or permit incorporation of an amino acid at this position and translation of the otherwise untranslated 3′ sequences until the next in-frame stop codon. Four termination codon mutations involving the α_2 gene have been reported (see Table 20-2).[182-187] These mutants differ only in the specific amino acid incorporated at the terminator codon position (Fig. 20-14). Translation terminates in each instance at a UAA codon in the polyadenylation signal (AA*UAA*A) downstream, and a 172–amino acid polypeptide is produced. The first of these elongated α chains to be described was found in Hb Constant Spring.[182,183] The α chain in this hemoglobin has a glycine substituted at codon 142. Hb Constant Spring produces an associated thalassemia phenotype because of a marked reduction in α_2-globin mRNA stability.[225-227]

Mutations that give rise to elongated β-globin chains have also been described. Hb Tak is a 157–amino acid product of a β-globin mRNA molecule containing two inserted nucleotides in the terminator codon 147.[187] An analogous elongated β-globin with 157 amino acids found in Hb Cranston reflects a dinucleotide insertion in codon 147, but red cells containing Hb Cranston are morphologically normal.[228] The mechanism by which the β^{Tak} mutation causes thalassemia has not been elucidated.

Mutations Affecting Globin Chain Stability

Hemoglobin Assembly

Shortly after synthesis is completed, α- and β-globin chains bind a heme moiety and rapidly associate into

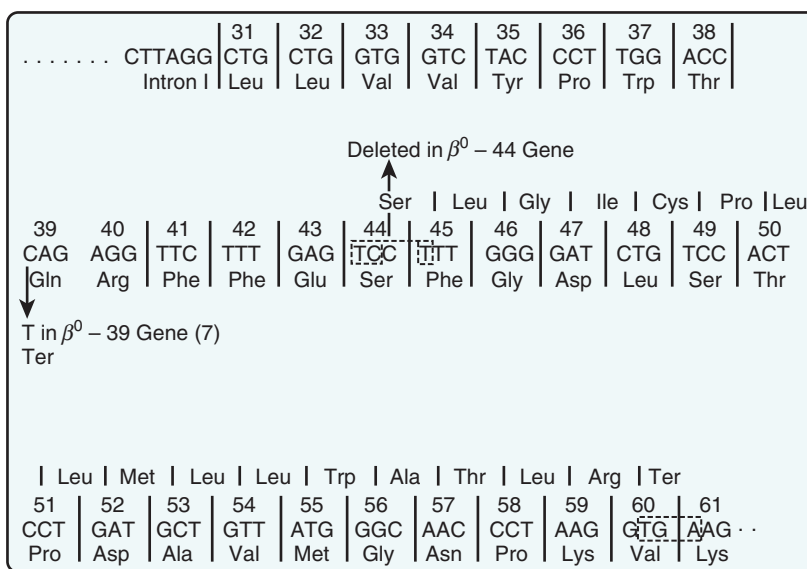
FIGURE 20-11. Mutations within introns that create a new splice site. Three mutations in the second intron create a new splice acceptor site (the invariant GT is underlined) and activate the identical cryptic splice donor site located just upstream. Abnormal splicing from these sites (pattern that projects below the exons) leads to the creation of a fourth exon (*brown boxes*) derived from sequences within the second intron. Two mutations in the first intron create a new splice acceptor site with the conserved AG dinucleotide, and abnormal splicing from this site (pattern that projects below the exons) adds sequences from the first intron to the beginning of the second exon.
FIGURE 20-12. Two of the several thalassemia mutations that destroy gene function by the introduction of a premature translation termination codon in β-globin mRNA. The numbers above the individual codons refer to the position of the encoded amino acid in the β-globin. Replacement of C with T in codon 39 introduces the terminator UAG in β-globin mRNA. Another β⁰ gene has a deletion of the third nucleotide (C) in codon 41. This results in a shift in the reading frame of the mRNA; the new amino acid sequence is shown above the line. This new reading frame has an in-phase terminator (UGA) in a position corresponding to codon 60 to 61. *(Redrawn from Nienhuis AW, Anagnou NP, Ley TJ. Advances in thalassemia research. Blood. 1984;63: 738-758.)*


FIGURE 20-13. RNA cleavage and polyadenylation occur 15 to 20 bp downstream from the AAUAAA polyadenylation signal. Mutational analysis in the rabbit β-globin gene has established that sequences located downstream from the polyadenylation site, called the G/U cluster, are also required for efficient cleavage and polyadenylation. Individual point mutations at one of several nucleotides within the AAUAAA polyadenylation signal result in β⁺-thalassemia. The same A→G mutation in the last position that causes β-thalassemia has been observed in the α₂-globin gene and results in α⁺-thalassemia.
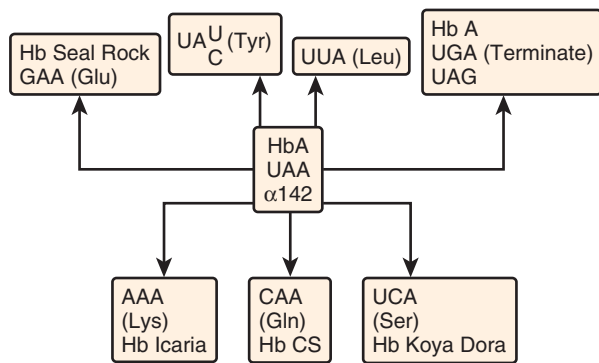

FIGURE 20-14. Point mutations in the terminator codon of the α-globin gene that lead to the synthesis of elongated α-globins. The normal terminator, UAA, of α-globin mRNA is shown in the *center*. Each of the nine possible single nucleotide substitutions is depicted; two would result in the formation of another terminator codon, whereas the other seven would lead to insertion of an amino acid at this position and continued synthesis of the globin chain. Four such mutations have been described; the mutation that causes the synthesis of Hb Constant Spring (CS) is the most common. (*Adapted from Weatherall DJ, Clegg JB. The Thalassemia Syndromes. Oxford, Blackwell Scientific, 1981, p 578.*)

FIGURE 20-15. Schematic representation of the α- and β-globin chains and the location of residues involved in different hemoglobin functions (*black vertical bars*). Heme contact sites and $\alpha_1\beta_2$ contacts are concentrated in the second exon (*blue*), whereas $\alpha_1\beta_1$ contacts are principally located in the third exon (*salmon*). DGP, diphosphoglycerate. (*Adapted from Eaton WA. The relationship between coding sequences and function in haemoglobins. Nature. 1980;284:183-185. $\alpha_1\beta_1$ dimers in a noncovalent reaction that is nearly irreversible under physiologic conditions.[229] The majority of the heme contact points are present in the portion of the globin chains encoded by exon 2, whereas most $\alpha_1\beta_1$ contacts are located within the exon 3 domain (Fig. 20-15).[6,230] These dimers may then reversibly associate with other dimers to form the hemoglobin tetramer. Formation of the $\alpha_1\beta_1$ dimer, therefore, is the principal controlling step in the assembly of hemoglobin.

Hemoglobin assembly is an important determinant of the final hemoglobin composition of the erythrocyte.[229,231,232] The rate constant of dimer formation depends greatly on the surface electrostatic charge of the subunits.[229] α-Globin has a net positive surface charge, whereas β-globin has a net negative surface charge. The other normal β-like globin chains, γ-globin and δ-globin, dimerize with the α chain at a lower rate. δ-Globin has a lower net negative surface charge than β-globin does, and the significant structural differences between γ- and β-globin presumably account for the differing dimerization rates. When β-globin chains are in limited supply (i.e., β-thalassemia), HbA_2 and HbF levels may rise because of enhanced dimerization with α chains, independent of changes in the production of δ and γ chains. In α-thalassemia or iron deficiency, HbA_2 and HbF levels will fall because of competition with β chains for the limited number of α chains. Similarly, β-chain variants may have decreased (β^S and β^E) or increased ($\beta^{Baltimore}$) affinity for α chains based on their net surface charge. The net hemoglobin composition of the cell is determined by these simple rules of competition based on the relative affinity of hemoglobin subunits.

An efficient, energy-dependent proteolytic system is present in erythrocytes that rapidly degrades free globin chains while leaving chains incorporated into dimers or tetramers unaffected.[229] Changes in globin chain structure that result from amino acid substitutions, premature chain termination, or chain elongation may slow or block the formation of stable $\alpha_1\beta_1$ dimers and lead to rapid degradation of the globin chain. In some instances, as discussed later, mutations may also enhance association of the free globin chain with the cell membrane and thereby promote oxidative damage to the membrane and shortened red cell survival.

Recently, an erythroid-specific protein called AHSP (for α-hemoglobin–stabilizing protein) has been identified that appears to act as a chaperone for free α-globin chains. In the absence of this protein mice exhibit mild hemolytic anemia as a result of α-globin precipitation.[233] When this protein is absent in the presence of a β-thalassemia mutation in mice, a much more severe thalassemic phenotype occurs.[234] However, it is currently not clear whether variation in the structure or expression of this gene in humans causes phenotypic variability in patients with β-thalassemia. One study has suggested that this was not the case in patients with HbE–β-thalassemia in Thailand.[235] Another study has suggested that expression levels of this gene vary in humans and that such levels may correlate with the severity of β-thalassemia.[236] Further studies will need to be conducted to better understand whether AHSP plays a role as a modifier gene in β^+-thalassemia.

During hemoglobin biosynthesis it is also important that the globin chains not be produced in excess of heme. A protein called heme-regulated inhibitor kinase (HRI) appears to mediate this function by inhibiting globin chain translation when an erythroid precursor is deficient in heme.[237] When HRI is absent in mice with a β-thalassemia mutation, the thalassemic phenotype is exacerbated and lethality of the mice results.[238]

Unstable α-Globin Chains

One such unstable variant was identified on sequencing of a mutant α-globin gene (see Table 20-2).[192] The α[Quong Sze] variant, which contains a Leu→Pro substitution at position 125, is so unstable that the mutant globin chain cannot be detected by biosynthetic studies in intact cells or by conventional hemoglobin electrophoresis.[193] The α[Quong Sze] chain appears to be stable once it is incorporated into the hemoglobin tetramer. Three other similar unstable α-globin chain mutations have been described (see Table 20-2).[188-191]

Unstable β-Globin Chains

Several unstable β-globin chains have been associated with thalassemia (see Table 20-2). Five mutations lead to amino acid substitutions in the β-globin chain.[194-198] Frameshift mutations in the third exon result in the synthesis of an elongated β-globin chain with a novel carboxy-terminal.[3,197,199-203] A premature termination mutation in exon 3 has also been described.[201-203] Many of the unstable β-globin chain mutations in exon 3 are associated with a dominantly inherited form of thalassemia (see the section on dominant β-thalassemia).[197,198] Thein and associates[201] proposed that alterations in β-globin structure in exon 3 interfere with $\alpha_1\beta_1$ dimer formation yet may permit binding of heme to the mutant globin chain through contacts in the exon 2 domain. These free, heme-associated β chains may be more resistant to proteolysis and associate with the cell membrane, where they form "inclusion bodies" and induce oxidative damage.

Thalassemic Hemoglobinopathies

The mutations described in this section, taken together with the RNA-processing mutants HbE, Hb Knossos, and Hb Malay and the termination mutant Hb Tak, include a distinctive set characterized by structural changes in the hemoglobin molecule and a thalassemia phenotype. These mutations are often referred to as "thalassemic hemoglobinopathies" (see the section on thalassemic hemoglobinopathies)[239] and are characterized clinically by a syndrome of ineffective erythropoiesis. Other globin variants may be associated with mild hypochromia, microcytosis, and chronic hemolysis because of instability and degradation of hemoglobin tetramers and are discussed in detail in Chapter 18. Because thalassemia is the consequence of an imbalance in α- and β-globin chains, these variants are not considered part of the spectrum of thalassemia.

Identification, Characterization, and Ethnic Distribution of β-Thalassemia Mutations

The hemoglobin disorders serve as a paradigm for the molecular analysis of genetic disease. Study of β-thalassemia was aided by the introduction of now widely used methods for identifying and characterizing mutant alleles. Accordingly, the identification of β-thalassemia mutations in many ethnic groups is nearly complete.[3,136]

In this section we briefly outline molecular techniques that have been applied to the characterization of β-thalassemia mutations. An understanding of these methods is important not only because they are broadly used in the study of other genetic diseases but also because they are directly relevant to strategies for genetic screening and prenatal diagnosis of β-thalassemia.

Haplotype Analysis

The first several β-thalassemia mutations were identified by cloning and sequencing β-globin genes isolated from individuals with β-thalassemia major.[130,137,153,154,167,170,219,240-243] Because certain mutations are extremely common, a nondirected strategy is inefficient since β genes with common mutations will be repeatedly studied. For example, 95% of the β-thalassemia alleles on the island of Sardinia contain the codon 39 nonsense mutation.[244]

To facilitate the search for new β-thalassemia mutations, Orkin, Kazazian, and their colleagues[129,245,246] introduced the concept of haplotype analysis to the study of thalassemia. Naturally occurring, genetically neutral, nonselected sequence differences among individuals constitute polymorphisms, which are estimated to occur roughly once every 100 bp.[247] These sequence differences are heritable, and those residing close to one another on a chromosome tend to be inherited together, a property known as *linkage*. A subset of polymorphisms will alter the cleavage site for a restriction enzyme or create a site where one did not exist. Therefore, when DNA from unrelated individuals is digested with a restriction enzyme and analyzed by Southern blotting, polymorphisms in the restriction enzyme digest pattern may be observed and are referred to as restriction fragment length polymorphisms (RFLPs).[248] Within the 60 kb of the human β-globin cluster, more than such 20 RFLPs are known[5,249]; at least 13 have been identified in the α cluster.[2,250] The pattern of these RFLPs (each based on the presence [+] or absence [−] of a restriction enzyme cutting site) along the chromosome defines a haplotype of associated or linked polymorphisms. Seven RFLPs were used initially to define nine distinct haplotypes (I through IX) of the β-gene cluster in the analysis of thalassemia mutations in Greek and Italian populations from the Mediterranean basin (Fig. 20-16).[129]

Close inspection of these haplotypes revealed a nonrandom association of restriction digest patterns within the β-gene cluster (Fig. 20-17).[245,251] The pattern of restriction sites 5′ of the δ-globin gene is inherited as a

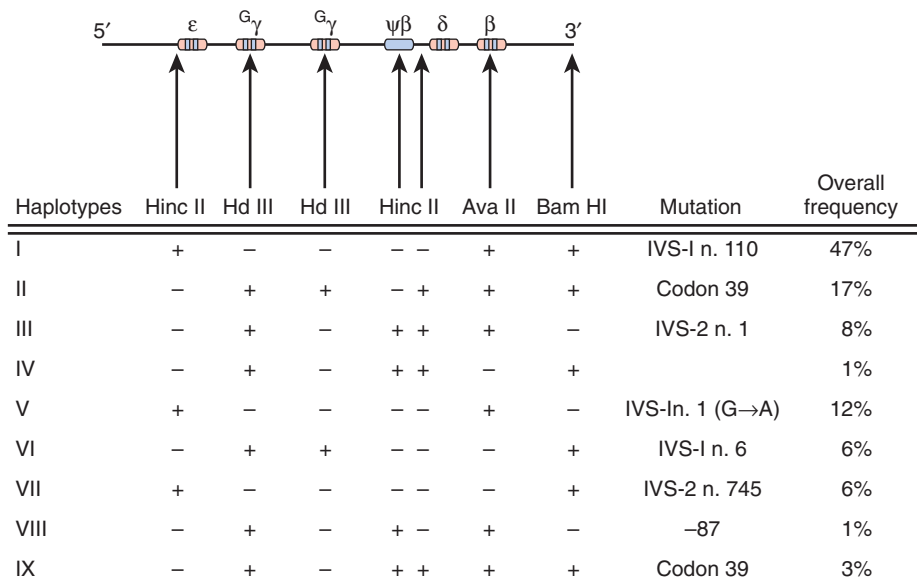
Haplotypes	Hinc II	Hd III	Hd III	Hinc II	Ava II	Bam HI	Mutation	Overall frequency
I	+	−	−	− −	+	+	IVS-I n. 110	47%
II	−	+	+	− +	+	+	Codon 39	17%
III	−	+	−	+ +	+	−	IVS-2 n. 1	8%
IV	−	+	−	+ +	−	+		1%
V	+	−	−	− −	+	−	IVS-In. 1 (G→A)	12%
VI	−	+	+	− −	−	+	IVS-I n. 6	6%
VII	+	−	−	− −	−	+	IVS-2 n. 745	6%
VIII	−	+	−	+ −	+	−	−87	1%
IX	−	+	−	+ +	+	+	Codon 39	3%


FIGURE 20-16. Linkage of chromosomal haplotypes to specific β-thalassemia mutations in Mediterranean populations. A haplotype is defined by the sequential pattern of restriction enzyme sites (present "+" or absent "−") along a chromosome. In this example, seven restriction enzyme sites were used to classify nine haplotypes. Overall frequency refers to the prevalence of the specific haplotype as found in all individuals, with or without thalassemia. IVS, intervening sequence. *(Adapted from Orkin SH, Kazazian HH Jr, Antonarkis SE, et al. Linkage of beta thalassaemia mutations and beta-globin gene polymorphisms with DNA polymorphisms in the human beta-globin gene cluster. Nature. 1982;296:627-631. Reprinted by permission from Nature, copyright © 1982, Macmillan Magazines Limited.)*
FIGURE 20-17. Restriction endonuclease sites for which restriction fragment length polymorphisms (RFLPs) have been identified in the β-globin gene cluster. A recombinational hot spot has been identified between the two brackets; the RFLP enclosed in each bracket must often remain associated during recombination (see text).

group, whereas restriction sites downstream (including the β-globin gene) track as another set. In all populations only a few haplotypes predominate.[252] The full spectrum of haplotypes is derived from random association over evolutionary time between the 5′ and the 3′ subhaplotypes, presumably reflecting the presence of a recombination "hot spot" lying between these regions.[137,251,253,254]

The generation of haplotypes appears to be an ancient event predating racial dispersion. Consequently, a specific haplotype may be found in diverse ethnic and racial groups from different geographic locations. The introduction of malaria as a selective pressure for certain random mutations is a more recent phenomenon. A mutation leading to thalassemia would be under positive selection and amplified within a population; accordingly, the mutation would be expected to be found on the haplotype background in which it originated in that ethnic group. Several conclusions can be derived from the study of different racial groups.[87] Within a single population both normal and thalassemia β-globin genes are found on the same haplotype, but specific thalassemia mutations tend to be linked to a single haplotype. Individual thalassemia mutations are generally restricted to a single population (see Table 20-2). In circumstances in which specific mutations are found in different populations, the identical thalassemia mutation may have occurred and

been selected for independently and will be found on a different haplotype background.[47,141,255] This observation has provided a sound genetic basis for the belief that thalassemia has had multiple distinct origins throughout the world. In circumstances in which a specific mutation is found on more than one haplotype within a population, the 3′ subhaplotypes (where the β-globin gene resides) may be identical, whereas the 5′ subhaplotypes differ because of recombination between the two subhaplotypes (for an example, see codon 39 mutation, see Fig. 20-16). By this mechanism, specific mutations can be distributed to new haplotypes within an ethnic group, and an independent origin of the mutation need not be invoked.

New thalassemia mutations were identified by cloning thalassemia β-globin genes from distinct haplotypes within a population, thereby avoiding the likelihood of repeated cloning of the same common mutation.[129] In this way, the great diversity of thalassemia mutations was elucidated.[139]

Direct Detection of Thalassemia Mutations

Restriction Enzyme Analysis

Several thalassemia mutations fortuitously result in the creation or destruction of a restriction enzyme cleavage

site within the α- or β-globin gene. The change in the restriction digest pattern can be detected in a Southern blot of digested genomic DNA or can be visualized directly when the analysis is performed on DNA amplified by polymerase chain reaction (PCR) (see later).[256-258] A list of mutations that alter restriction enzyme sites is provided in Table 20-2. Although approximately 50% of the common thalassemia mutations in Mediterranean populations may be detected in this manner, this approach is of less utility in other groups.[3,139]

Allele-Specific Oligonucleotide Hybridization and Polymerase Chain Reaction

Specific synthetic oligonucleotide probes approximately 19 nucleotides in length extend the capacity to detect specific thalassemia mutations directly in genomic DNA or in DNA amplified by PCR.[258,259] Single nucleotide mismatches between a probe of this length and a target DNA sequence destabilize hybridization.[260] To study a given mutation or allele, two probes are generally used, one identical in sequence to the normal gene and the other identical to the mutant sequence. To facilitate detection of a mutation, probes are generally designed to position the difference in the center of the probe. In Southern blots, such probes can be shown to be highly specific for cloned DNA fragments containing particular mutations. When the target is DNA amplified by PCR, probes with low specific activity or nonradioactive probes can be used to detect the presence or absence of the mutation.[261-264] Although there are many β-thalassemia mutations, relatively few predominate in each ethnic group (see the section on ethnic distribution). Hence, a small panel of oligonucleotides can be used to identify the majority of potential mutations in any given population.[265,266]

The introduction of PCR in 1985[267] and subsequent modification of the procedure with the use of thermostable Taq polymerase[268] have revolutionized molecular biology and the ease with which specific mutations can be identified in DNA.[269,270] Application of PCR to the analysis of thalassemia facilitated the rapid identification of several new and quite rare mutations.[137] Several features of the PCR method are of particular relevance.[268-270] First, only minute quantities of relatively impure genomic DNA are required as starting material; in fact, the DNA of a single cell may be sufficient. Fragments ranging from 50 to several thousand base pairs can be rapidly amplified more than 10^6-fold in vitro. Second, the product of PCR, double-stranded DNA, can be readily subcloned, subjected to restriction enzyme analysis,[257,258] hybridized to allele-specific probes,[261,264] or directly sequenced.[130] As discussed earlier, the combination of PCR with restriction enzyme analysis or oligonucleotide hybridization lessens the need to work with high–specific activity radioactive probes to detect mutations. Third, the technique is easily automated. Finally, the analysis, including DNA sequencing if required, can be completed within several days of obtaining tissue for DNA preparation.

Ethnic Distribution

Determining the incidence of specific β-thalassemia mutations in different ethnic groups is particularly relevant to strategies for prenatal diagnosis of thalassemia.[3] Nearly complete surveys of thalassemia mutations have been performed in Greek and Italian,[246] Asian Indian,[208,271] American black,[43,145] Sardinian,[244] Chinese,[272,273] Lebanese,[209] Turkish,[274] Spanish,[275] Sicilian,[181] Thai,[168] Kurdish Jewish,[128] and Japanese[198] populations. From these studies, several general conclusions can be drawn. First, in each ethnic group a small subset of mutations (as few as four or six) constitute more than 90% of the mutant alleles. This is particularly striking on the island of Sardinia, where the codon 39 nonsense mutation accounts for 95% of the β-thalassemia genes and a codon 6 frameshift represents another 4%.[244] Second, the remaining 5% to 10% of mutant alleles in an ethic group are divided among a larger number of rarer alleles. For example, four alleles account for 90% of the β-thalassemia genes in Chinese, and 11 rare alleles account for the remaining 10%.[3,272] Third, several mutations appear to have originated independently in different ethnic groups and are present on different haplotype backgrounds as discussed earlier. For example, the IVS-2 no. 1 (G→A) mutation is present in Mediterranean, Tunisian, and American black populations[134,136,138]; the IVS-1 no. 5 (G→C) substitution is present in Asian Indians, Chinese, and Melanesians.[111,133,143] Finally, as a consequence of the large number of mutations present in each population, most individuals with severe β-thalassemia are genetic compound heterozygotes for two different thalassemia mutations.

Mutations That Affect β-Globin Gene Regulation

Deletions within the β-globin gene cluster often lead to thalassemia. Many of these deletions are associated with a significant increase in the level of HbF, a finding that distinguishes them from the common varieties of β-thalassemia. Ordinarily, heterozygous carriers of β-thalassemia have an increase in the level of HbA_2 (to >3% of total hemoglobin) and, at most, a slight increase in the level of HbF. Before detailed molecular analysis was available, these conditions were broadly grouped into two categories, hereditary persistence of fetal hemoglobin (HPFH) and δβ-thalassemia[4,276,277] (Table 20-3). HPFH heterozygotes have normocytic, normochromic red cells, whereas δβ-thalassemia heterozygotes have hypochromic and microcytic cells. Many HPFH heterozygotes have high levels of HbF (up to 30%) with a uniform or pancellular distribution in circulating erythrocytes, whereas in δβ-thalassemia heterozygotes, the amount of HbF is less abundant and it is present in an uneven or heterocellular distribution among red cells. In rare individuals homozygous for either condition, only HbF is found. HPFH

homozygotes have normal or slightly elevated total hemoglobin concentrations, their red cells are slightly hypochromic and microcytic, and globin synthesis is modestly imbalanced.[278,279] Thus, these mutations are appropriately considered along with the thalassemia mutations.

Deletion mutations of the β-globin gene cluster represent in vivo experiments of nature useful in developing and validating experimental models of gene regulation. Multiple regulatory elements are present within the cluster, and the clinical phenotypes observed with specific deletions relate to removal of one or more such regulatory elements. More than 30 deletion mutations have been described (Table 20-4 and Fig. 20-18)[293]; they vary greatly in size from a few hundred base pairs of the β-globin gene to more than 100 kb with loss of the entire cluster. In addition to deletion mutations, significant elevations of HbF in adults may arise as a result of single base substitutions within the γ-globin gene promoters (Table 20-5). Such mutations, also classified as nondeletion HPFH, appear to enable the γ-globin genes to "capture" the influence of the LCR at the adult stage. Individuals with these HPFH mutations have HbF values ranging from only slightly elevated to more than 20%, which can be distributed in either a heterocellular or pancellular fashion.

HPFH and δβ-thalassemia mutations are uncommon, and individuals who inherit these mutations are asymptomatic or have mild disease. Their importance relates to the insight that they provide into globin gene regulation and the role of HbF in modulating disease severity in patients with severe β-thalassemia or sickle cell anemia.

Isolated point mutations of the δ-globin gene, similar to those in β-thalassemia, may lead to "δ-thalassemia." This is a benign condition with no clinical significance that when inherited with a β-thalassemia mutation may lead to a normal- or low-HbA$_2$ thalassemia phenotype in heterozygotes.[374,375]

Crossover Globins: Hemoglobin Lepore and Hemoglobin Kenya

Deletion mutations in the α- and β-globin gene clusters arise through unequal homologous recombination or through nonhomologous (illegitimate) recombination. In contrast to the α-globin cluster, in which there are blocks of tandem duplicated sequences (see later discussion), the only directly repeated homologous segments of DNA in the β cluster are the globin genes themselves. Hence, mutations arising from homologous, but unequal crossover in the β-globin cluster are relatively uncommon and usually involve two globin genes directly (Fig. 20-19).

FIGURE 20-18. **A,** Organization and chromatin structure of the human β-globin cluster. The expressed genes are shown as *salmon boxes* and the single pseudogene in the cluster as a *blue box*. The *arrowheads* in the line figure indicate the location and orientation of Alu repetitive DNA sequences, whereas the *green boxes* represent members of the L1 family of repetitive DNA. The *salmon downward arrows* mark developmentally stable, erythroid-specific hypersensitive sites that constitute the locus-activating region (LAR) flanking the cluster. The true boundaries of the "active" chromatin domain established by these sites are unknown and extend beyond the cluster. Hypersensitive sites are also found over the promoters of the expressed genes (*blue downward arrows*). The location of the three enhancers in the cluster are marked by letters: A, hypersensitive site II enhancer; B, 3′ $^A\gamma$ enhancer; C, 3′ β enhancer. **B,** The methylation pattern of the locus at different stages of ontogeny is depicted. *Blue circles* show an unmethylated site, *salmon circles* show a totally methylated site, and *circles with blue and salmon* show the degree of site methylation. The coordinates refer to distance in kilobases. *(Adapted from Stamatoyannopoulos G, Nienhuis AW. Hemoglobin switching. In Stamatoyannopoulos G, Nienhuis AW, Leder P, Majerus PW [eds]. The Molecular Basis of Blood Diseases. Philadelphia, WB Saunders, 1987, p 79.)*

Two crossover hemoglobins, Hb Lepore and Hb Kenya, are associated with thalassemia.

In 1958, Gerald and Diamond[376] identified a minor hemoglobin component by starch gel electrophoresis in the blood of parents of a patient with thalassemia major. Structural analysis revealed that the hemoglobin was composed of α-globin and a heretofore undescribed globin consisting of fusion of the 80 to 100 amino-terminal amino acids of δ-globin with the carboxyl portion of β-globin.[304,305,307,377] This "chimeric" globin polypeptide, named Lepore after the family in which it was first described, arose from an unequal, homologous recombination event between the δ-globin and β-globin genes (Fig. 20-19). It is poorly expressed because transcription of the fusion gene is under control of the γ-gene promoter. Other Lepore-type globins have been characterized in which the relative contribution of the δ and β genes to the fusion protein varies as a result of a different point of crossover. Homozygotes for Hb Lepore have 90% HbF and approximately 10% Hb Lepore, but no HbA or HbA$_2$, whereas heterozygotes have mainly HbA, 2% to 4% Hb Lepore, and 3% to 5% HbF.[378,379] In heterozygotes, red cells have a very heterogeneous HbF content. Anti-Lepore globins with the amino-terminal sequence of β-globin and the carboxyl sequence of δ-globin have also been described (see Fig. 20-19).[380-383] Individuals with anti-Lepore genes also have two normal δ- and two normal β-globin genes; consequently, their red cells lack any stigmata of thalassemia. The anti-Lepore globins are produced in very low amounts, perhaps because of sequences within the large intron of the δ-globin gene that may reduce mRNA production.[26]

Hb Kenya, another important crossover hemoglobin, contains a non–α-globin composed of amino sequences of γ-globin and carboxyl sequences of β-globin[334-336,384] (see Fig. 20-19). Molecular analysis demonstrated that the ^{A}γ-globin gene was involved in the crossover. The crossover occurred approximately at the position of amino acid codon 100. Hb Kenya was first observed in an individual who was heterozygous for a β^S gene. This patient had an increased level of HbF (up to 6%) that was uniformly distributed in all his red cells. The HbF was entirely of the ^{G}γ type. Hb Kenya accounted for 17% to 20% of the total hemoglobin. Individuals who are heterozygous for Hb Kenya without HbS are clinically well. Approximately 10% Hb Kenya and 6% to 10% HbF of the ^{G}γ type are found homogenously distributed in their red cells, in contrast to the distribution of HbF with the Lepore-type deletion.[336] It was originally hypothesized that the deletion removes a regulatory element that suppresses γ synthesis in adult life, thereby leading to a pancellular or uniform increase in HbF in the red cells of individuals with the Kenya fusion gene.[385] Even before discovery of the LCR and other regulatory elements within the β cluster, this hypothesis was disproved by analysis of several other deletion mutations (see later). Current models of hemoglobin switching posit that increased expression and pancellular distribution of the ^{A}γβ fusion gene and the adjacent ^{G}γ gene result from deletion of the adult-stage δ- and β-globin genes and their promoters, which serves to eliminate competition

for the LCR. In addition, the deletion repositions an enhancer 3′ to the β-globin gene immediately downstream of the γ-globin genes and may also contribute to their increased expression.

Silent Deletions

Deletions that eliminate a single γ-globin gene or the δ-globin gene are unlikely to result in a phenotype that would be detected in hematologic screening. Thus, few of these mutations have been detected and described. A clinically silent deletion of the ^{A}γ-globin gene was identified through extensive molecular screening of chromosomes in Melanesians.[280] A 7.2-kb deletion involving the δ-globin gene but not the γ- or β-globin gene was reported in Corfu $(δβ)^0$-thalassemia in *cis* to the G→A substitution at IVS-1 position 5.[281] Homozygotes for the IVS-1 position 5 mutation ordinarily exhibit a mild β+-thalassemia intermedia phenotype with 10% to 20% HbA,[146] but homozygotes for Corfu $(δβ)^0$-thalassemia display the clinical phenotype of $β^0$-thalassemia intermedia with 100% HbF. This has been interpreted as evidence that sequences in the deleted region are important in activating the β-globin gene and potentially in suppressing γ-gene expression. Subsequently, however, the identical deletion was identified in *cis* to a normal β-globin gene.[282] In this circumstance, the deletion leads to failure of δ-globin gene expression but has no demonstrable effect on expression of the γ- and β-globin genes on the same chromosome. Recent work has suggested that this deletion may increase γ-gene expression in *cis* to the deletion but that translation of the γ gene may be limiting in certain settings, thus helping explain the discrepancy between carriers of the deletion and homozygotes.[283] Nonetheless, the basis for the lack of β-gene expression in Corfu $(δβ)^0$-thalassemia remains unresolved.

$β^0$-Thalassemia Deletion Mutations

Several deletions remove the β-globin gene and are associated with typical high-HbA$_2$ $β^0$-thalassemia (see Table 20-4). Interestingly, deletions that remove the promoter region are associated with somewhat higher HbF levels than usually seen in $β^0$-thalassemia heterozygotes (e.g., see Oner and colleagues[386]). The HbF is distributed in a heterocellular pattern. In contrast, a 0.6-kb deletion at the 3′ end of the β gene that spares the β-globin promoter, seen in Asian Indians, is not associated with an increased level of HbF in heterozygotes.[133,240-242,284] One explanation for the different phenotypes relates to the possibility that an intact β-gene promoter may interact productively with the LCR and thereby effectively compete with an incompletely silenced γ-globin gene at the adult stage. Removal of the promoter may alleviate competition and favor persistent γ-globin expression.

δβ-Thalassemia

Individuals heterozygous for these deletions generally have 5% to 15% HbF composed of both ^{G}γ- and ^{A}γ-globins and distributed in a heterocellular fashion (see Table 20-4). The erythrocytes are typically hypochromic and microcytic.[1] The level of HbA$_2$ is characteristically low in comparison to the modest elevations observed in most individuals with β-thalassemia trait. Homozygotes for these deletions produce only HbF yet exhibit a mild $β^0$-thalassemia intermedia phenotype with hemoglobin levels of approximately 10 g/dL. The most common of these deletions is referred to as the Sicilian type.[285,294,295,387] The deletion extends from within the δ-globin gene to just beyond the β-globin gene (see Table 20-4).

The 5′ breakpoint junctions of δβ-thalassemia deletions generally lie between the pseudo-β gene and the δ-globin gene. Located within this region are moderately repetitive sequences known as Alu sequences.[388] Although the function of such sequence elements is unknown, their preservation in δβ-thalassemia deletions and their deletion in HPFH encouraged speculation that the Alu elements might be involved in modulating HbF production during development.[308,385] Based on analysis of additional deletion mutations, this hypothesis may not be likely (see Table 20-4). For example, the 7.2-kb Corfu deletion removes both Alu elements and the δ-globin gene, but it has not been associated with increased γ-gene expression.[281,282] As described earlier (see the section on silent deletions), more recent work suggests that γ-gene transcription may be increased in *cis* to the deletion.[283] However, the Japanese type of deletion, which also removes the Alu elements, is associated with a heterocellular distribution of HbF and thalassemic red cell indices.[300,301] The increase in HbF expression may be more appropriately explained by the deletion of local δ- and β-globin gene regulatory elements, which leaves the γ-globin genes to interact with the LCR unopposed by competition from the adult genes.

^{A}γδβ-Thalassemia

The phenotype of these deletions in heterozygotes is identical to that of δβ-thalassemia: hypochromic microcytic red cells with low levels of HbA$_2$ and moderately increased ^{G}γ-HbF levels (5% to 15%) with a heterocellular distribution (see Table 20-4). Homozygotes have $β^0$-thalassemia intermedia with 100% ^{G}γ-HbF. The 5′ breakpoints in these instances lie between the two γ genes or within the body of the ^{A}γ gene, thereby resulting in silencing of the ^{A}γ gene together with the δ and β genes.[308-312,314-316,389,390] The 3′ end points of several of these deletions have been precisely mapped. Other deletions are very large and extend well beyond the boundary of the β-gene complex (see Table 20-4). One interesting mutation of this type, the Indian form (see Table 20-4), has two deletions, one involving the γ gene and the second involving a portion of the δ and β genes and intragenic DNA. The segment of DNA between the two deletions is inverted such that the 5′ ends of the γ and δ genes come to be adjacent but in an inverted orientation.[308,309]

γδβ-Thalassemia

The diagnosis of γδβ-thalassemia should be considered in newborns with hemolytic disease associated with hypochromic red cells. In adults, it is also a cause of normal-HbA$_2$, normal-HbF β-thalassemia trait. The syndrome was first identified in a newborn with microcytic, hemolytic anemia.[391] Heterozygous β-thalassemia associated with normal levels of HbA$_2$ and HbF was identified in the father and many relatives. Decreased γ- and β-chain synthesis was demonstrated in the infant's reticulocytes. The anemia was self-limited; as the baby grew older, the hemolytic anemia disappeared and the phenotype of simple heterozygous β-thalassemia developed in the child.

The syndrome of γδβ-thalassemia results from large deletions within the β-globin gene cluster (see Table 20-4). They can be divided into two categories: extremely large deletions that remove the entire β-globin gene cluster or all of the structural genes[323-325] and deletions such as the Hispanic, English, Dutch, and Anglo-Saxon forms in which the structural genes are left intact but the LCR elements are removed.[312,317-322] The remaining genes on the chromosome are not expressed and are found in inactive chromatin that is methylated and resistant to nuclease digestion. Study of these deletions has provided the most convincing evidence that the LCR is required in normal erythroid cells for transcription of the β-like globin genes in vivo. Homozygous γδβ-thalassemia is expected to be incompatible with survival and has not been observed.

β-Thalassemia Mutants Unlinked to the β-Globin Complex

Until recently, the mutations characterized in β-thalassemias resided within or near the β-globin gene itself or the β-globin locus. In principle, defects in *trans*-acting regulatory factors could lead to failure of proper β-globin gene expression. Two examples are now known.

Mutation of the xeroderma pigmentosum disease (XPD) helicase gene, which encodes a component of the general transcription factor TFIIH, results in β-thalassemia in association with trichothiodystrophy. Patients with specific mutations in *XPD* have typical features of β-thalassemia trait, including reduced levels of β-globin synthesis. Inadequate expression of diverse, highly expressed genes is presumed to be the direct consequence of an abnormality in TFIIH.[392]

Mild β-thalassemia trait in association with thrombocytopenia was reported as an X-linked trait in a rare family.[393] Linkage studies demonstrated that the gene mutated in this family resides on the short arm of the X chromosome, near the Wiskott-Aldrich syndrome (*WAS*) gene and the erythroid/megakaryocytic transcription factor GATA-1 gene.[331] Subsequently, it was shown that affected boys in this family have a specific amino acid substitution in the amino zinc finger of GATA-1 that subtly alters its interaction with DNA and leaves its physical interaction with the cofactor FOG-1 intact.[58] How this change in the properties of GATA-1 leads to a slight imbalance in globin gene expression is unknown. Presumably, interactions of the regulatory elements of the LCR and β-globin complex are affected by the manner by which GATA-1 binds to DNA. More recently, similar mutations have been found in other patients. In one case, β-thalassemia was present along with an elevation in HbF to nearly 60%.[56] This patient also had features of erythropoietic porphyria and mild thrombocytopenia. However, another patient with a similar mutation had features of only gray platelet syndrome, and β-thalassemia was not present.[57] These phenotypic differences may be due to modifier loci that vary with the genetic background of these different patients.

Hereditary Persistence of Fetal Hemoglobin

Individuals heterozygous or homozygous for mutations that enhance HbF are asymptomatic. They are identified incidentally in routine screening programs or during investigation of family members with hematologic disease because of interaction of these variants with other mutations in the β-globin gene cluster. Homozygotes for deletion forms of HPFH have normal hemoglobin concentrations, but their red cells are slightly hypochromic and microcytic.[278,279] Minimal globin chain biosynthetic imbalance may be seen. No symptoms or physiologic impairment has been associated with the exclusive production of HbF despite its high oxygen affinity.

Hereditary Persistence of Fetal Hemoglobin Deletion Mutations

Several deletions produce the HPFH phenotype of increased levels of HbF in otherwise normal red cells (Table 20-5).* The 5′ breakpoints lie between the ^{A}γ-globin gene and the δ-globin gene, and in all cases (with the exception of Hb Kenya), an enhancer 3′ to the ^{A}γ gene is unaffected by the mutation. Two of the deletions (HPFH-1 and HPFH-2) are very large and extend beyond the 3′ end of the cluster (see Table 20-4). The Kenya mutation is also included in this category because of the pancellular distribution of HbF that is characteristic of this mutation.

Heterozygotes for these deletions produce up to 30% HbF containing both ^{G}γ and ^{A}γ chains in a pancellular distribution. Differences in the relative percentages of ^{G}γ and ^{A}γ chains can be detected between different types of HPFH deletions (see Table 20-4). Heterozygotes have normocytic red cells. The red cells of homozygotes

contain HbF exclusively. The higher oxygen affinity of HbF may lead to slightly elevated hemoglobin levels in such individuals. Although homozygotes are clinically well, the α-globin–to–γ-globin chain biosynthetic ratio may be slightly imbalanced, and mild microcytosis and hypochromia may be observed. This suggests that γ-chain synthesis occurs at levels below the output of the normal β-globin gene on these chromosomes.

Several hypotheses have been put forward to account for the increased expression and pancellular distribution of HbF in the deletion HPFH syndromes, particularly when compared with the moderate increase and heterocellular distribution in δβ-thalassemia. Sequence analysis has confirmed that the γ-globin genes linked to the HPFH-1 deletion do not contain additional mutations responsible for the increased HbF expression.[396] As discussed earlier, deletion of postulated inhibitory sequences[297,385] has not been substantiated by the effects of other mutations that remove similar elements. Because several mutations extend far beyond the 3′ end of the β-globin cluster, it has been suggested that introduction of a distant enhancer into the locus might lead to activation of the γ genes. Some evidence is consistent with this model. Sequences located immediately 3′ of the HPFH-1 deletion breakpoint and translocated into the cluster by the deletion event display transient enhancer activity when tested in erythroid cell lines.[298] In addition, the DNA in the vicinity of this enhancer is hypomethylated and nuclease sensitive in normal erythroid cells and contains a long open reading frame,[298,397] thus suggesting that the enhancer may belong to a distinct gene that is also transcribed in erythroid cells. RNA transcripts from this putative gene have been detected in erythroid cell lines.[398] In Spanish δβ-thalassemia, which exhibits a deletion nearly identical to that in HPFH-1, the 3′ breakpoint is located approximately 9 kb downstream of HPFH-1, and therefore the putative distant enhancer is not imported into the locus.[298]

In another type of deletion HPFH observed in an Italian family, a 12.9-kb deletion removes the δ- and β-globin genes and brings the enhancer 3′ of the β-globin gene closer to the γ-globin genes.[333] Analogous to the comparisons between HPFH-1 and Spanish δβ-thalassemia, deletions similar in size and location to the 12.9-kb Italian HPFH deletion that remove the 3′ β enhancer result in δβ-thalassemia rather than HPFH.[332] The

TABLE 20-6	α-Thalassemia Syndromes		
Syndrome	Clinical Features	Hemoglobin Pattern	α-Globin Genes Affected by the Thalassemia Mutation
Silent carrier (α-thal-2)	No anemia, normal red cells	1-2% Hb Bart's (γ_4) at birth; may have 1-2% Hb Constant Spring; remainder HbA	1
Thalassemia trait (α-thal-1)	Mild anemia, hypochromic and microcytic red cells	5-10% Hb Bart's (γ_4) at birth; may have 1-2% Hb Constant Spring; remainder HbA	2
Hemoglobin H (HbH) disease	Moderate anemia; fragmented, hypochromic, and microcytic red cells; inclusion bodies may be demonstrated	5-30% HbH (β_4); may have 1-2% Hb Constant Spring; remainder HbA	3
Hydrops fetalis	Death in utero caused by severe anemia	Mainly Hb Bart's; small amounts of HbH and Hb Portland also present	4

Kenyan deletion also brings the 3′ β-globin gene enhancer closer to the γ-globin genes. Though distributed in a pancellular pattern, the level of HbF is lower in the Kenyan deletion than in the other HPFH syndromes. It is noteworthy that it is also the only deletion mutation that does not spare the 3′ $^A\gamma$-globin enhancer.

Nondeletion Hereditary Persistence of Fetal Hemoglobin Mutations

Individuals with these mutations exhibit elevated levels of HbF with normal red cell indices and are identified through hemoglobin screening programs or by study of families in which a segregating high-HbF allele modulates the severity of sickle cell disease or β-thalassemia.[93,94] (The role of nondeletion HPFH mutations in modifying the course of sickle cell disease is discussed in more detail in Chapter 19.[141]) In many instances, single base changes have been discovered within the promoter region of either the $^G\gamma$- or $^A\gamma$-globin gene.[338-340,342-350,352-363,367,399] These mutations are postulated to alter the binding of nuclear regulatory proteins and lead to a more favorable interaction of the promoter with the LCR at the adult stage.[349,350,400-405] Typically, only increased expression of the γ-globin gene in which the mutation is found occurs. In instances of the nondeletion HPFH syndrome, no mutation has been characterized. As discussed in a later section, the Swiss HPFH determinant may segregate with the X chromosome.[12]

The level of HbF observed in patients with this syndrome varies greatly and ranges from 1% to 4% in Swiss HPFH[12,368] to 30% in the −175 T→C substitution found in either the $^G\gamma$- or $^A\gamma$-globin gene.[352-354] Similar to the deletion forms of HPFH, the HbF may be found in either a heterocellular or a pancellular distribution (Table 20-6 and Fig. 20-20). The −158 C→T substitution in the $^G\gamma$-globin gene is associated with a normal level of HbF in otherwise normal heterozygotes but with a high level of HbF in the presence of erythropoietic stress.[356-362] For example, in Saudi Arabia, patients with sickle cell anemia often have high HbF levels (25% or greater) and mild disease, whereas their parents with sickle cell trait have normal or only slightly elevated levels.[356] Identification of individuals with this mutation (or polymorphism) has been aided by the finding that it is linked to a rare sub-haplotype.[357,358] The −158 HPFH substitution also improves the clinical course of β-thalassemia. A Chinese individual homozygous for the −29 promoter mutation has transfusion-dependent β-thalassemia,[47] yet black patients homozygous for the same mutation who coinherit the −158 HPFH mutation in the $^G\gamma$ promoter have mild β-thalassemia.[46,95]

Confirmation that the base substitutions in the promoter region are the cause of increased γ-chain synthesis rather than associated random DNA polymorphisms is based on several lines of evidence (reviewed by Ottolenghi and co-workers[406]). As mentioned earlier, they are generally associated with overexpression of the gene in which the mutation is found and typically represent the only sequence change. None of the mutations listed, with the exception of the −158 mutation, have been observed in individuals with normal HbF levels. Haplotype analysis in some pedigrees of patients with HPFH has demonstrated that the HPFH determinant is linked to the β-globin cluster. The British type of nondeletion HPFH is quite informative in this regard. The gene has been tracked through three generations, and three homozygous individuals have been observed.[342-344,407] Haplotype analysis using restriction enzyme polymorphisms has established linkage of the British HPFH phenotype to the β-globin gene locus.[343] More than 90% of the γ chains are of the $^G\gamma$ type, and there is an associated mutation at −198 of the $^G\gamma$ gene.[343] Even the three homozygotes, with approximately 20% HbF, have heterogeneous distribution of HbF among their red cells. Two homozygotes for −117 $^A\gamma$ HPFH have also been described, and they had 24% HbF in a pancellular pattern.[408] More recent transgenic experiments unequivocally demonstrate that the single base substitutions seen in

FIGURE 20-20. A, Immunofluorescent staining of erythrocytes with antibody directed against HbF shows the distribution of HbF in a heterocellular pattern. **B,** Immunofluorescent staining of erythrocytes with HbF distributed in a pancellular pattern. *(Courtesy of Dr. George Stamatoyannopoulos.)*
HPFH lead to enhanced γ-globin expression into adult life.

An interesting aspect of this syndrome is a balanced α-globin–to–non–α-globin chain synthetic ratio, even in homozygotes,[408] which implies that increased γ-globin synthesis is offset by decreased β-globin synthesis.[363] Expression of the β gene in *cis* to the mutation may be reduced by 20% to 30%.[338,353,354,367,409] It has also been observed that HbA$_2$ levels are uniformly low in the nondeletion HPFH syndromes and generally correlate inversely with HbF levels.[1] The reduction in δ- and β-globin gene expression in *cis* to the HPFH mutations is compatible with models of competitive regulation of β-globin expression by the linked γ-globin gene.

Mutations That Alter α-Globin Gene Regulation

In contrast to the β-globin cluster, in which single nucleotide substitutions are the most common cause of thalassemia, large deletions within the α-globin cluster are the predominant basis of α-thalassemia. The overall impairment in α-globin chain synthesis that results from defects in the α-globin cluster is determined by the number of genes inactivated (either by deletion or mutation), the type of lesion (deletion or mutation), and whether the lesion affects the α$_2$ or α$_1$ gene.

The α-globin cluster on chromosome 16[16,410,411] contains three functional genes (ζ, α$_2$, and α$_1$), an expressed gene of no apparent significance, and three pseudogenes[2,15] (see Fig. 20-2). Transcription of the genes depends on the integrity of the distant regulatory element HS-40. An α-thalassemia deletion mutation (αα^{RA}) has been reported that removes a large segment of DNA upstream of the ζ$_2$ gene but spares the remainder of the cluster.[412] In heterozygotes, no expression of the ζ- or α-globin genes from this chromosome is detected in heterozygotes. These findings are formally analogous to those in Hispanic and English γδβ-thalassemias (see Table 20-4),[317,318] in which upstream LCR elements of the β-globin cluster are deleted.

The two human α-globin genes are thought to have been generated through a gene duplication event that occurred approximately 60 million years ago.[413] The nucleotide sequences of the α$_2$ and α$_1$ genes have remained remarkably similar and represent an example of concerted evolution[414-416] in which the two genes have exchanged genetic information through crossover fixation and gene conversion events. The coding regions of the two genes are virtually the same and encode identical polypeptides.[4149-417] The genes differ only in minor respects within IVS-2, whereas the sequences diverge significantly in the 3′-untranslated region.

The α-globin genes are expressed in embryonic, fetal, and adult-stage erythroid cells. Initially it was believed that the two α genes were expressed at similar levels, but subsequent RNA analysis relying on sequence differences in their 3′-untranslated regions revealed that α$_2$ RNA predominates over α$_1$ RNA by a ratio of 3:1.[225,418-420] Because the two α-globin mRNA molecules have the same intrinsic stability, the higher level of α$_2$ RNA reflects increased transcription of the α$_2$ gene. "Transcriptional interference" of the α$_1$ gene by the upstream α$_2$ gene has been proposed as an explanation for this observation.[421] Ribosome-loading studies suggest that α$_2$ and α$_1$ tran-

scripts are translated at equivalent rates.[422] Systematic characterization of the expression of α-globin structural variants at both the α_2 and α_1 loci has confirmed that the α_2 gene has a predominant role in α-globin chain production.[418,419] A direct prediction of this model is that mutations altering the α_2 gene would result in a greater deficiency of α-globin chain production than would mutations of the α_1 gene. Clinical support for this prediction is provided by study of Sardinian patients with HbH disease who are heterozygous for one chromosome with a deletion of both α genes (–/) and a chromosome with a nondeletion mutation affecting the initiator codon of either the α_2 gene ($\alpha^T\alpha$/) or the α_1 gene ($\alpha\alpha^T$/).[162] Patients with the mutation in the α_2 gene (–/$\alpha^T\alpha$) have clinically more severe disease. Consistent with its predominance, the α_2 gene is involved in the majority of the reported mutations of the α-globin genes (see Table 20-2).

Deletion Mutations within the α-Globin Gene Cluster

Mutations That Remove One α-Globin Gene

The two α-globin genes are embedded in highly homologous, tandem repeated sequence blocks (called X, Y, and Z) that are separated by nonhomologous segments (Fig. 20-21).[18] Unequal, homologous recombination through the X and Z blocks generates a chromosome with a single α-globin gene and another with three α-globin genes. Homologous recombination in the small Y box has not been observed. The most common type of deletion in this class removes 3.7 kb as a result of misalignment of the Z boxes and is known as "rightward deletion." The products of this crossover are the $(-\alpha^{3.7}/)$[423,424] and $(\alpha\alpha\alpha^{anti-3.7}/)$ haplotypes.[425,426] The $-\alpha^{3.7}$ products may be further subdivided into types I, II, and III by the precise location of recombination within the Z box.[416] Unequal crossover events through the X box leads to "leftward deletion" of 4.2 kb of DNA and the $-\alpha^{4.2}$ chromosome[406] and its triplicated antitype.[427,428] The incidence of the observed recombination products appears to reflect the size of the homologous target sequence within the boxes because $-\alpha^{3.7I}$ (1436 bp) is the most common, followed by $-\alpha^{4.2}$ (1339 bp), $-\alpha^{3.7II}$ (171 bp), and $-\alpha^{3.7III}$ (46 bp).[2,414,415,429] Unequal α-gene recombination through the X and Z boxes has been reproduced in both prokaryotic and eukaryotic experimental systems with episomal vectors.[18,430,431]

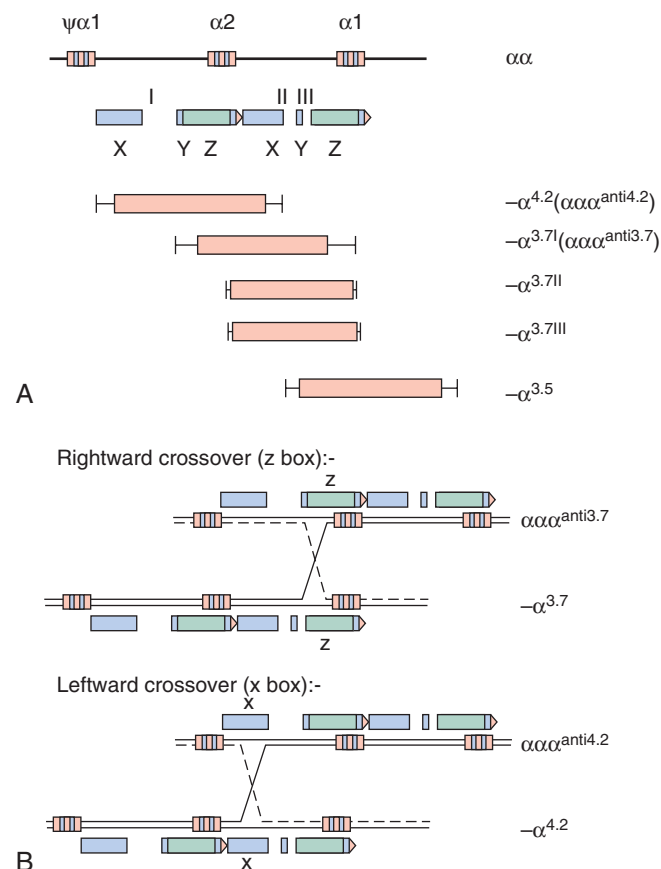
The $-\alpha^{3.7I}$ deletion is extremely common and is seen in all populations in which α-thalassemia is prevalent, whereas the $-\alpha^{4.2}$ deletion is most common in Asian populations.[2,15] Frequencies of up 80% to 90% for the single-deletion chromosome have been reported in some populations.[103] The association of these mutations with a variety of α-globin cluster haplotypes and α-globin variants in different populations suggests that they have arisen through numerous independent mutational events.[103,432]


FIGURE 20-21. **A**, Deletion mutations that give rise to α-thalassemia. The two α-globin genes are embedded in a duplicated segment of DNA with homologous (X, Y, and Z boxes) and nonhomologous (I, II, and III) regions. The extent of specific mutations that delete a single α-globin gene are indicated by *salmon boxes* and the limits of the breakpoints as *solid lines*. These deletions and the reciprocal chromosomes containing three functional α-globin genes result from misalignment and unequal recombination mediated by the homologous blocks. **B**, Unequal crossover through the Z box deletes 3.7 kb of DNA and produces the $\alpha^{3.7}$ chromosome and its antitype, whereas recombination through the X box produces the $-\alpha^{4.2}$ chromosome and its antitype. The $-\alpha^{3.7}$ deletion can be further subdivided (I to III) by the exact location within the Z box where recombination occurs (see **A**). *(Redrawn from Higgs DR, Vickers MA, Wilkie AO, et al. A review of the molecular genetics of the human alpha-globin gene cluster. Blood. 1989;73:1081-1104.)*

Deletion of one α-globin gene does not affect expression of the ζ-globin gene[433] but has unanticipated consequences on expression of the remaining α-globin gene. The α_1 gene that remains on the $-\alpha^{3.7}$ chromosome is expressed approximately 1.8 times more often than the α_1 gene on a normal chromosome.[419] Individuals homozygous for the leftward deletion ($-\alpha^{4.2}/-\alpha^{4.2}$), who carry two copies of the α_1 gene, express more α-globin than the anticipated 25% of normal.[434] Homozygotes for the $-\alpha^{3.7III}$ deletion ($-\alpha^{3.7III}/-\alpha^{3.7III}$), who carry two α_2 genes, express less than the anticipated 75% of normal.[434] The increased expression of the α_1 gene on the $-\alpha^{3.7}$ and $-\alpha^{4.2}$ chromosomes may be secondary to release of transcriptional interference from the upstream α_2 gene,[421] whereas

the lower expression of the α_2 gene in the $-\alpha^{3.7III}$ deletion remains to be explained. An important consequence of this observation, however, is that common mutations that delete the α_2 gene ($\alpha^{3.7I}$ and $\alpha^{4.2}$) may lead to increased expression of the remaining α_1 gene and to a less severe clinical phenotype than predicted from expression studies of the native α-globin genes.[434] Single nucleotide substitutions that inactivate the α_2 gene do not affect α_1 expression and consequently lead to a more severe clinical phenotype than single gene deletions do.[2,15]

Triplicated α-gene chromosomes are observed in populations in which the $\alpha^{3.7I}$ and $\alpha^{4.2}$ chromosomes are present. The third gene is expressed and leads to a slight increase in the α-chain–to–β-chain ratio in homozygotes for the triplication, but this is generally of no clinical consequence.[435,436] However, if a triplicated α-gene chromosome is coinherited with a β-thalassemia gene, thalassemia intermedia may be seen.[437,438] A unique deletion that removes the α_1 gene and some downstream sequence was recently described as a cause of α-thalassemia and appears to be due to a novel biologic mechanism.[439] As a result of the deletion, a promoter in the antisense orientation is brought into close proximity to the remaining α_2 gene. Antisense transcripts are created and appear to cause methylation of DNA and silencing of the chromatin in the region, thus attenuating transcription of the intact α_2 gene. Recent work in both yeast and human cells has begun to delineate the mechanisms that may be responsible for this phenomenon, which may normally play a major role in physiologic gene regulation.[440]

Mutations That Remove Both α-Globin Genes

Illegitimate, nonhomologous recombination within the α-globin cluster results in partial or complete deletion of both α-globin genes and generates an α^0 chromosome.[2,412,441-445] (Note that the term α^+ and α^0 may refer to the expression of α-globin from a single gene or may refer to the presence or absence of an intact α-globin gene on a chromosome.) In some circumstances, the ζ-globin gene may also be encompassed by the deletion. The boundaries of many of the deletions that have been characterized are summarized in Figure 20-22. The geographic distribution of these lesions is more restricted than that of the α^+-thalassemia deletions, the most common being the $-^{SEA}$ (Southeast Asia) and $-^{MED}$ (Mediterranean) deletions, thus suggesting that they are rare genetic events. Theories concerning the mechanisms of these deletions are summarized elsewhere.[2]

Homozygotes for α^0 chromosomes ($-/-$) suffer from hydrops fetalis, whereas individuals heterozygous for an α^+ chromosome and an α^0 chromosome ($-/-\alpha$ or $-/\alpha^T\alpha$) exhibit HbH disease. Increased expression of minute quantities of ζ-globin into adulthood may accompany some of the mutations in which the ζ gene is left intact by the deletion.[433] Sensitive radioimmunologic assays for the presence of ζ-globin chains in heterozygous adult carriers of these mutations have been devised,[446] and they may prove useful in areas such as Southeast Asia, where the incidence of the $-^{SEA}$ chromosome is as high as 3%.[447]

Mutations Not Linked to the Globin Gene Clusters That Alter Globin Gene Expression

Acquired Hemoglobin H Disease

A particularly severe, acquired form of HbH disease has been described in elderly men with clonal myeloproliferative disorders.[448-451] In this setting, levels of HbH approaching 60% may be seen.[426] Extremely low α-chain–to–β-chain synthesis ratios and low α-globin mRNA levels have been documented in bone marrow

FIGURE 20-22. Deletion mutations that give rise to α^0-thalassemia. The organization of the α-globin cluster is shown. Expressed genes are represented by *salmon boxes*, whereas pseudogenes are shown as *blue boxes*. Two hypervariable regions (HVRs) are indicated as *zigzag lines*. Coordinates are in kilobase pairs (kb). The extent of each deletion is defined by a *salmon box* and the uncertainty of the breakpoints by *blue boxes*. The designation of the genotype is indicated to the right of each deletion. *(From Higgs DR, Vickers MA, Wilkie AO, et al. A review of the molecular genetics of the human alpha-globin gene cluster. Blood. 1989;73:1081-1104.)*

cells from affected individuals.[449,450] Residual α-globin mRNA expression may be derived from nonclonal erythroid cells. A bimorphic population of cells is present on examination of the peripheral blood smear. The manifestations of hemolytic disease caused by HbH may increase and decrease with the clinical course of the myeloproliferative disorder.[449]

Available evidence suggests that the absence of a positive regulatory factor in the clonal population or the presence of an inhibitory factor is responsible for the lack of α-globin gene expression. Extensive molecular analysis of the α-globin gene cluster in patients with acquired HbH disease indicates that it is structurally intact and hypomethylated in these individuals.[449,450] Human α-globin gene expression can be detected in somatic cell hybrids derived by fusion of bone marrow cells from patients with acquired HbH disease to murine erythroleukemia cells,[452] thus further suggesting that the transcriptional defect is not linked to the α-globin cluster. Additional study of this unusual condition may provide important information about factors regulating the α-globin gene cluster.

X-Linked α-Thalassemia Associated with Mental Retardation Syndrome

Rare instances of α-thalassemia occurring in individuals of Anglo-Saxon origin with phenotypically normal parents first drew attention to a new syndrome.[453] Further investigation revealed the commonly seen association of profound mental retardation, facial anomalies, and genital abnormalities.[78] Important recent studies demonstrated mutation of the *AH2* gene, a member of the DNA helicase superfamily and presumed global transcriptional regulator, as the underlying basis of this syndrome.[79]

Silent β-Thalassemia

Hematologically normal "silent carriers" of β-thalassemia are identified through family studies.[1,6,454-457] Some instances of "silent" β-thalassemia may be attributed to mutations that cause a very modest reduction in β-globin gene expression—the −101 promoter mutation[126,130] and the +1 cap site mutation[133]—or attributed to the inheritance of triplicated α-globin gene chromosomes.[437,438] In an Albanian family in which the father was a silent carrier, the mother had high-HbA$_2$ β-thalassemia trait, and two children had β-thalassemia, the silent carrier determinant did not appear to segregate with either of the paternal β-globin gene clusters.[458] Subsequently, a number of reports of families in which a β-thalassemia mutation appeared to be unlinked to the β-globin complex have been reported.[459-461] These rare instances of unlinked β-thalassemia may be due to mutations in *trans*-acting factors. However, all these patients did not have the syndromic features seen in those with the previously characterized *trans*-acting regulatory factor mutations (see the section on β-thalassemia mutants unlinked to the β-globin complex). Thus, new insight may be gained from genetic analysis of these rare cases.

Swiss Hereditary Persistence of Fetal Hemoglobin

Ordinarily, HbF constitutes less than 1% of the total hemoglobin in normal adult erythrocytes and is restricted to a subpopulation of erythrocytes (F cells) that represent between 3% and 7% of the total number of red cells.[7,8] Both the percentage of F cells present in the circulation and the amount of HbF per F cell are under genetic control, and evidence suggests that the determinants are not linked to the β-globin gene cluster.[462]

In the Swiss type of nondeletion HPFH (see Table 20-5), HbF is distributed in a heterocellular fashion with levels of HbF of 0.8% to 3.4% in heterozygotes.[1,12,93,368,462] Interpretation of earlier studies of Swiss HPFH was complicated by the small size of the pedigrees, overlap of HbF levels in heterozygotes and normal subjects, varying age of the research subjects (HbF levels tend to fall with age), and concomitant inheritance of β-globin gene alleles that can also influence HbF levels.

Several studies have been published in which linkage analysis clearly demonstrates that the HPFH determinant segregates independently from the β-globin gene cluster. In the first, a large Sardinian pedigree,[463,464] and the second, a large Asian Indian pedigree,[465] nondeletion HPFH and β^0-thalassemia genes were segregating in each family. Studies of normal individuals in Japan with Swiss HPFH in which the F-cell percentage rather than the HbF level was used to define HPFH have suggested that the "high–F-cell trait" segregates as an X-linked determinant.[12] A recent study has also localized a genetic determinant for HbF production to the long arm of chromosome 6 in a large HPFH pedigree.[13] An additional locus for HbF production has been found on chromosome 8 in the Asian Indian pedigree just described and also in a European twin study.[466] Further mapping of these HPFH determinants may provide important insight into the mechanisms regulating hemoglobin switching. There is substantial evidence from the results of twin and family studies that HbF and F-cell levels are genetically controlled.[9-11] Traditional approaches have used linkage analysis in an attempt to find genetic determinants that modulate HbF levels, but it is likely that complex trait analysis will be necessary to delineate putative common variants that have an effect on HbF.[467] Recently the analysis of HbF-regulating variants using genetic association studies has led to initial insight into genes unlinked to the β-globin locus that alter fetal hemoglobin levels. Two regions harboring genetic variants have been found in the course of whole-genome association studies in nonanemic Caucasian populations[467a,467b]. One region is found on chromosome 6 and is in an intergenic region between the genes *HBS1L* and *cMYB*.[467a-467c] The other region is found on chromosome 2 and is within an intron of the zinc-finger transcription factor *BCL11A*[467a,467b]. How these particular variants lead to changes in fetal hemoglobin levels remains to be uncovered. Interestingly, the variant in *BCL11A* on

chromosome 2 also appears to ameliorate the severity of β-thalassemia in a cohort of patients from Sardinia.[467a]

CLINICAL HETEROGENEITY OF THALASSEMIA SECONDARY TO DIVERSITY OF MUTATIONS

In the previous sections, the extraordinary array of mutations associated with the clinical syndrome of thalassemia has been described. In populations in which thalassemia is prevalent, different types of mutations that affect genes of either the α-globin, β-globin, or both globin clusters may coexist. Frequently, patients are compound heterozygotes for these mutations. The relative degree to which globin chain synthesis is impaired reflects this genetic heterogeneity and determines the clinical phenotype. In the following clinical description of the thalassemia syndromes, we emphasize such genetic interrelationships.

α-Thalassemia

Nomenclature and Genetics of α-Thalassemia

α-Thalassemia is divided into four clinical subsets that reflect the extent of impairment in α-globin chain production: silent carrier ($-\alpha/\alpha\alpha$), α-thalassemia trait ($-\alpha/-\alpha$ or $-/\alpha\alpha$), HbH disease ($-/-\alpha$), and hydrops fetalis ($-/-$) (see Table 20-6). Before the introduction of molecular analysis, these syndromes were classified on the basis of red blood cell parameters (hemoglobin level, mean corpuscular volume [MCV], mean corpuscular hemoglobin [MCH], globin biosynthetic ratio, presence of inclusions, and HbH [β_4] levels), as well as the manner in which they interacted genetically to produce different phenotypes. Much of this early work relied on the study of Asian populations in which α-thalassemia is particularly common.[1]

The silent carrier state for α-thalassemia, in which a single α-globin gene on a chromosome is inactivated, has traditionally been designated α-thalassemia-2. Homozygosity for α-thalassemia-2 or heterozygosity for an allele causing more severe disease in which both α-globin genes are inactivated leads to α-thalassemia trait, also termed α-thalassemia-1. According to the historical nomenclature, HbH disease reflects heterozygosity for α-thalassemia-2 and α-thalassemia-1, whereas hydrops fetalis results from homozygosity for α-thalassemia-1.

Advances in molecular characterization of the α-globin gene cluster have clarified the genetic basis of these phenotypes. Weatherall and colleagues proposed a more informative nomenclature for these mutations.[1,2] Each chromosome may be designated as α^+ or α^0 to indicate the presence or absence of any α-globin chain production derived from that chromosome. This is referred to as a haplotype and should be distinguished from use of the term haplotype in describing the linkage of DNA polymorphisms on a chromosome. Haplotypes are further subdivided by the status of each α-globin gene

on a chromosome. As discussed previously, mutations may be of the deletion or nondeletion type. Normal individuals are designated ($\alpha\alpha/\alpha\alpha$) to indicate the presence of four active α genes, two on each chromosome 16, with the first position corresponding to the α_2 gene and the second position to the α_1 gene. Deletion of a single α-globin gene on a chromosome is designated ($-\alpha/$), whereas deletion of both genes is indicated as ($-/$). Further refinement of this nomenclature includes a designation of the specific mutation; for example, ($-^{SEA}/$) signifies the α^0 deletion mutation that is common in Southeastern Asian populations (see Fig. 20-22), and ($-\alpha^{3.7}/$) symbolizes the α^+ rightward α-gene deletion that is extremely common in the American black population (see Fig. 20-22). Nondeletion mutations in a haplotype are designated in this scheme by a superscript T ($\alpha\alpha^T$) and can be more precisely described by symbols for the specific mutation and the gene affected. For example, ($\alpha^{CS}\alpha$) designates a chromosome bearing the Constant Spring chain termination mutation affecting the α_2 gene (see Table 20-2), and ($\alpha^{QS}\alpha$) designates a chromosome bearing the α gene with a substitution in codon 125 that leads to the synthesis of an unstable globin (see Table 20-2). This shorthand nomenclature is extremely useful when a patient's genotype is known in detail and has simplified description of the many genotypes that interact to generate the heterogeneous clinical syndromes.

At least 30 mutations that may inactivate one or both α-globin genes are known; thus, the different combinations of chromosomes bearing α-thalassemia mutations number more than 200. The number of occurrences of the different genotypes and haplotypes define the spectrum of disease observed in a given ethnic group. For example, severe forms of α-thalassemia (HbH disease and hydrops fetalis) are uncommon in blacks. In this group the single-deletion chromosome is very common,[468,469] whereas chromosomes with two defective α genes are quite rare. In some circumstances the phenotype of HbH disease is not readily related to genotype. Indeed, there is a significant spectrum of disease severity in individuals from the Southeast Asian area with the same genotype ($-\alpha^{3.7}/-^{SEA}$).[432] The observed phenotype may be further complicated by the inheritance of another hemoglobin disorder (β-thalassemia) or the influence of environmental factors such as iron or other nutritional deficiency.

Silent Carrier

The silent carrier state, or the α-thalassemia-2 defect, is due to the presence of a mutation affecting only one α-globin gene. Most often this occurs because of a deletion mutation ($-\alpha/\alpha\alpha$). Patients who are silent carriers for α-thalassemia have three rather than four functional α-globin genes.[424,470] Thus, the impairment in α-globin synthesis is very mild. There is significant overlap of their globin biosynthetic ratio with both that of normal subjects and that of individuals with only two functional α-globin genes (Fig. 20-23). Similarly, the mean MCV of patients with three functional genes is slightly lower than
FIGURE 20-23. Biosynthetic α-globin–to–β-globin ratio in various forms of thalassemia. Peripheral blood cells were incubated with [^{14}C]leucine for 2 hours in autologous plasma. The globin chains were isolated by ion exchange chromatography. The specific activity of the chains and the ratio of their radioactivities were then calculated. *(Redrawn from Nathan DG. Thalassemia. N Engl J Med. 1972;286:586-594. Copyright 1972, Massachusetts Medical Society.)*

that in normal subjects, but significant overlap between the two groups exists.[2] Despite these differences that become apparent on comparison of groups with different numbers of α-globin genes, there is no reliable way to diagnose silent carriers of α-thalassemia by hematologic criteria. Diagnosis has been reported by detection of small amounts of Hb Bart's in cord blood,[1] but additional studies indicate that this approach is unreliable in ascertaining the presence of the silent carrier state.[471,472] However, a more recent U.K. study using high-performance liquid chromatography (HPLC) and genotyping to verify α-globin genotype on fresh cord blood samples demonstrated HPLC to be a reliable technique for determining the silent carrier state.

Silent Carrier Variant: Hemoglobin Constant Spring

Some silent carriers og α-thalassemia produce small quantities of slowly migrating hemoglobins (Fig. 20-24) that contain elongated α-globin chain variants resulting from termination codon mutations (see Table 20-2 and Fig. 20-14).[182-186] The original elongated α-chain variant, Hb Constant Spring, was named for the small Jamaican town in which the Chinese family in whom these hemoglobins were first discovered resided.[183] The family had three children with HbH disease; each had a small amount of the abnormal hemoglobins. One parent had typical thalassemia trait, whereas the other had normal red cells but, in addition, had approximately 1% of the abnormal hemoglobin. Similar slowly migrating hemoglobins have been found in other racial groups in Thailand and Greece.[473] Individuals homozygous for the α^{CS} mutation (α^{CS}α/α^{CS}α) have a clinical syndrome similar to HbH disease, although their erythrocytes contain Hb Bart's (γ$_4$) rather than HbH and the degree of anemia and the extent of abnormalities in red cell indices are milder than those in most patients with HbH disease.[474] Compound heterozygotes for the α^0 and α^{CS} haplotypes (–/α^{CS}α) exhibit typical HbH disease.

α-Thalassemia Trait

Two genotypes (–/αα and –α/–α) that reflect inactivation of two α-globin genes are associated with α-thalassemia trait. Substitution mutations that affect the predominant α$_2$ gene (α^{T}α/αα) may also lead to α-thalassemia trait.
FIGURE 20-24. Hemoglobin electrophoresis. **A,** Starch gel electrophoresis at pH 8.6; 1, normal; 2, HbH disease with Hb Constant Spring. **B,** Agarose electrophoresis at pH 8.6; 1, normal; 2, β-thalassemia trait with increased HbA$_2$; 3 and 4, homozygous β-thalassemia with different relative amounts of HbA and HbF. **C,** Starch gel electrophoresis at pH 8.6; 1, Hb Lepore trait; 2, sickle cell trait. "O" indicates the origin. The anode is at the top of the figure.

The extent of the observed changes in red cell indices mirrors the reduction in α-globin production seen with each genotype, with the (–α/–α) genotype being less affected than the (–/αα) genotype. α-Thalassemia trait is characterized by marked microcytosis and hypochromia of red cells in conjunction with mild anemia and erythrocytosis (see Table 20-6). Levels of HbA$_2$ and HbF are generally normal or low. Diagnosis of this condition is typically made by family studies or by exclusion of iron deficiency and β-thalassemia trait. The incidence is particularly high in Asian populations and less in African, Mediterranean, and American black populations. Even in the neonatal period, the red cells appear hypochromic and microcytic. The proportion of Hb Bart's may be as high as 1% in the blood of normal newborns, but levels of 4% to 6% are attained in infants who are later shown to have α-thalassemia trait[1] (see Table 20-6). Beyond the

neonatal period, biochemical markers such as HbA$_2$ and HbF in β-thalassemia are not particularly helpful in confirming the diagnosis of α-thalassemia trait. The one exception occurs in circumstances in which the expression of ζ-globin is increased because of deletion of both α-globin genes on a chromosome.[433,445,475] In Southeast Asia, where the $-^{SEA}$ allele is common, a sensitive radioimmunoassay allows detection of ζ-globin chains in adult carriers of this mutation.

Measurement of the β-to-α biosynthetic ratio has little place in the routine diagnosis of α-thalassemia trait. Although detection of impaired α-globin synthesis has been reported,[476,477] measurement is technically difficult because these individuals have a low reticulocyte count and the measured values overlap with those found in normal individuals (see Table 20-6). Iron deficiency may raise the measured β-to-α biosynthetic ratio, thus further complicating interpretation.[478-481] Consequently, in most patients the diagnosis of α-thalassemia trait is established by red cell morphology and parameters, coupled with exclusion of β-thalassemia trait and iron deficiency. Gene deletions responsible for deficient α-globin production can be demonstrated by restriction endonuclease mapping; this technique may be applied when an accurate diagnosis is critical. Newer technology allows PCR detection of deletion[482] and triplication[483] of α genes, and it has the same level accuracy as the more cumbersome Southern blotting and DNA hybridization with φζ-globin gene probe.

Hemoglobin H Disease

Genetics

HbH disease occurs in individuals who have only a single fully functional α-globin gene. the genotypes leading to HbH disease are diverse.[2] Most common is heterozygosity for the single- and double-deletion chromosomes ($-$/$-$α). As a result, HbH disease is observed most often in Southeast Asia ($-^{SEA}$/$-α^{3.7}$) and the Mediterranean basin ($-^{MED}$/$-α^{3.7}$), where the incidence of both the α$^+$ and α^0 haplotypes is significant. Nondeletion mutations may also interact to cause HbH disease. As discussed earlier, the α$_2$ genes are responsible for the production of approximately 75% of the total α-globin chains. Mutations that decrease expression from the α$_2$ gene ($α^Tα$/) result in an α+ haplotype that produces fewer α-globin chains than a deletion α+ haplotype ($-α$/) does. Thus, homozygosity for mutations in both α$_2$ genes ($α^Tα$/$α^Tα$) is phenotypically equivalent to deletion of three genes and is associated with HbH disease and not α-thalassemia trait.[2,15] Consistent with this observation, nondeletion α+-thalassemia haplotypes that are paired with α^0-thalassemia haplotypes ($-$/$α^Tα$) lead to more severe HbH disease than does the interaction of the deletion α+ haplotypes ($-$/$-α$).

Hemoglobin Pattern

Anemia of moderate severity characterized by hypochromia, microcytosis, striking red cell fragmentation (Fig. 20-25), and the presence of a fast migrating hemoglobin,
FIGURE 20-25. Peripheral blood smear from a patient with HbH disease.

HbH (β$_4$), on electrophoresis (see Fig. 20-24) may be shown to represent an α-thalassemia syndrome by measurement of the β-to-α biosynthetic ratio.[476,484,485] Incubation of peripheral blood reticulocytes with [^{3}H]leucine and subsequent chromatographic resolution of the globins indicate that such patients have a twofold to fivefold excess of β-chain synthesis (see Table 20-6 and Fig. 20-23). These excess β chains form HbH, which accounts for 5% to 30% of the total hemoglobin in patients with HbH disease.[486] In approximately 50% of individuals with HbH disease in Southeast Asia, small quantities of Hb Constant Spring are found (see Fig. 20-24). HbH disease may be suspected in anemic neonates in whom all the red cells are severely hypochromic. At birth, patients with HbH disease also have large amounts of Hb Bart's (γ$_4$). In patients with HbH disease and an intact spleen, incubation of peripheral blood cells in brilliant cresyl blue produces many small inclusions in most red cells (Fig. 20-26). The dye induces precipitation of HbH by a redox reaction. In contrast, large and usually single preformed inclusions (Heinz bodies) may be visualized with methyl violet in the red cells of splenectomized patients (see Fig. 20-26).[91,487] These inclusions are composed of precipitated β-globin rendered insoluble by hemichrome formation or by interaction of β-globin sulfhydryl groups with the red cell membrane.[91,488]

Pathophysiology

HbH exhibits no Bohr effect or heme-heme interaction and thus is not effective for oxygen transport under physiologic conditions.[489] Consequently, patients with appreciable amounts of HbH have a more severe deficit in functional hemoglobin and oxygen-carrying capacity than the measured hemoglobin concentration might suggest. Red cells containing HbH are sensitive to oxidative stress, thus accounting for the enhanced red cell destruction that may occur with the administration of oxidant drugs such as sulfonamides.[490] As erythrocytes age and lose their capacity to withstand oxidant stress, precipitation of HbH occurs and leads to premature destruction of circulating red cells.[91] Hence, HbH is primarily a hemolytic disorder.[487,491] Inclusions of HbH are
FIGURE 20-26. Red cell inclusions in HbH disease. **A,** Inclusions induced by incubation of peripheral blood in 1% brilliant cresyl blue and 0.4% citrate for 30 minutes at 37° C (patient not splenectomized). **B,** Preformed inclusions in the peripheral blood of a splenectomized patient stained by a new methylene blue reticulocyte stain.

rarely seen in bone marrow cells,[492] and erythropoiesis is fairly effective.[491]

Clinical Features

Typical patients with HbH disease live quite normally. Generally, the anemia is moderate with a hemoglobin concentration of 7 to 10 g/dL, although occasional patients may have hemoglobin levels as low as 3 to 4 g/dL.[1] The complications of HbH disease are related to chronic hemolysis. Jaundice and hepatosplenomegaly are commonly present. Folic acid deficiency, pigment gallstones, leg ulcers, and increased susceptibility to infection are also observed. Hemolytic episodes may be precipitated by drugs or infection. Iron overload is uncommon but may occur in patients receiving transfusions and those older than 45 years.[493] Development of the characteristic thalassemic facies, which reflects expansion of marrow space equivalent to that seen in patients with severe β-thalassemia, is rare. Usually, only moderate bone marrow erythroid hyperplasia is evident.[481]

Therapy

Consistent with the benign course of HbH disease, treatment is primarily supportive. Therapy includes supplementation with folic acid, avoidance of oxidant drugs and iron salts, prompt treatment of infectious episodes, and judicious use of transfusions. Splenectomy should be contemplated in patients with HbH disease only if hypersplenism is present as reflected by leukopenia, thrombocytopenia, and worsening anemia or the development of a transfusion requirement in a patient whose condition was previously stable. Thrombocytosis after splenectomy may be complicated by a clotting diathesis, recurrent pulmonary emboli, and pulmonary hypertension, particularly in patients with severe HbH disease and a fairly normal hematocrit.[493-495] The use of measurements of red cell survival and splenic sequestration by ^{51}Cr labeling of red cells is controversial in making a clinical decision regarding splenectomy because the label binds selectively to β-globin chains and may, by virtue of selective removal of HbH inclusions from red cells in the spleen, give a falsely high index of splenic destruction.[496] Other studies,

however, suggest that results from the ^{51}Cr technique may be valid.[497]

Other Hemoglobin H Syndromes

Syndrome of α-Thalassemia with Mental Retardation

Patients with a syndrome characterized by mental retardation and a form of α-thalassemia that cannot be explained by simple mendelian inheritance of an α-thalassemia gene have been described.[453,498] In rare patients, the mutation arises as a de novo event in a paternal germ cell. These patients can be divided into two distinct syndromes (deletion and nondeletion) on the basis of their clinical features and the results of molecular analysis of their α-globin gene clusters.

Patients have been described with extensive deletions involving chromosome band 16p3.3 or, alternatively, with deletions resulting from unbalanced chromosome translocations that also lead to aneuploidy in a second chromosome. Patients with deletion mutations exhibit mild to moderate mental retardation and a broad spectrum of dysmorphic features. Other rare patients are characterized by more severe mental retardation and a uniform pattern of dysmorphic features, including genital abnormalities, but no detectable deletions involving the α-globin gene cluster.[78] Such patients fall into the category of the syndrome of X-linked α-thalassemia with mental retardation. As noted earlier, the affected gene is a putative global regulator (XH2).[79]

Although these disorders are seen rarely, they may be under-recognized. This is particularly true of ethnic groups in which α-thalassemia is uncommon, and the mild hematologic findings in patients who do not inherit a second α-thalassemia gene might be overlooked. Infants with uncharacterized mental retardation should be studied with techniques suitable for detection of a deficiency in α-globin synthesis.

Acquired Hemoglobin H Disease

HbH is also found rarely in the red cells of patients with erythroleukemia or a myeloproliferative syndrome.[448-450]

The disorder may be clonal and displays a striking male predisposition (85% of confirmed instances).[453] The clinical features manifested by these patients are those of their primary disorder; the finding of HbH is incidental to the outcome of the disease, although striking red cell abnormalities and active hemolysis may be present. The genetic mechanism of this syndrome appears to involve abnormal regulation of α-gene expression because of a mutation affecting a distant genetic locus (see earlier).

Hydrops Fetalis

Genetics

Homozygosity for the α^0 haplotype (–/–) leads to hydrops fetalis, a disorder that is particularly common in Southeast Asia where the α^0 haplotype is seen frequently. In rare infants from Greece and Southeast Asia, hydrops fetalis has been shown to result from the interaction of α^0 haplotypes with nondeletion α^+ haplotypes.[499-501]

Hemoglobin Pattern

The birth of stillborn infants to parents with α-thalassemia trait reflects the most severe form of α-thalassemia.[502,503] Because of the inability to synthesize any α-globin, their blood contains only Hb Bart's (γ_4), HbH (β_4), and small amounts of Hb Portland ($\zeta_2\gamma_2$) within red cells displaying morphologic changes characteristic of severe thalassemia.[504,505]

Pathophysiology

Although the hemoglobin concentration averages 6.2 g/dL, both HbH and Hb Bart's have high oxygen affinity and no subunit cooperativity. Therefore, a hydropic infant has very little functional hemoglobin. Viability in utero is maintained by the presence of small quantities of Hb Portland 1 and 2.

Clinical Features

Generally, affected infants are delivered stillborn at 30 to 40 weeks' gestation or die shortly after delivery at term.[447,504] Infants are grossly edematous or hydropic as a result of congestive heart failure induced by severe anemia. The blood smear is characterized by large hypochromic macrocytes and numerous nucleated red cells. At autopsy, extensive extramedullary hematopoiesis and placental hypertrophy are seen. A high incidence of toxemia of pregnancy and postpartum hemorrhage is observed in mothers of hydropic infants,[481,506] presumably as a consequence of the massive placenta. Hence, early recognition of the disorder in at-risk pregnancies by prenatal diagnosis should lead to consideration of termination of the pregnancy.

Therapy

At least five infants born prematurely with hydrops fetalis have survived with the use of chronic transfusion regimens.[507,508] Intrauterine transfusion of fetuses with hydrops fetalis should also be considered if treatment after delivery is contemplated.[509] Marrow transplantation may be considered if the affected infant is delivered safely.

Mild β-Thalassemia

Silent Carrier

A silent carrier state for β-thalassemia was recognized through the study of families in which affected children had a more severe β-thalassemia syndrome than a parent with typical β-thalassemia trait.[1,6,454-457] A study of the "normal" parent often revealed mild microcytosis or a slight impairment in β-globin synthesis on radiolabeling of the globin chains in peripheral blood reticulocytes. Characteristically, silent carriers of β-thalassemia have normal levels of HbA_2. These silent carriers must be distinguished from individuals whose red cells have all the stigmata of β-thalassemia trait but have normal levels of HbA_2. Several patients who are homozygous for the silent carrier β-thalassemia gene have been described.[1] Anemia is moderate (hemoglobin concentration of 6 to 7.0 g/dL), and these patients rarely require transfusion. Hepatosplenomegaly may be significant. HbF values range from 10% to 15%, and the HbA_2 level is elevated to the range normally seen in individuals with thalassemia trait.

The silent carrier state of β-thalassemia appears to be a distinct clinical and biochemical entity. The underlying molecular defects cause only a modest reduction in β-globin synthesis. Two point mutations in the β-globin gene region have been linked to the silent carrier phenotype. The −101 promoter mutation appears to be a common cause of silent β-thalassemia in the Italian population[204] and has been observed in Bulgarian and Turkish individuals,[126] whereas the +1 cap site Inr mutation is associated with a silent carrier phenotype in an Indian family.[133] As noted earlier, rare instances of silent β-thalassemia secondary to mutations unlinked to the β-gene cluster have been reported.

β-Thalassemia Trait

Genetics

In 1925, Rietti[510] described Italian patients with mild anemia whose red cells exhibited increased resistance to osmotic lysis. A similar syndrome was later recognized in American patients of Italian descent by Wintrobe and co-workers,[511] who noted that both parents of a patient with Cooley's anemia also had this syndrome. Detailed analysis of several pedigrees by Valentine and Neel[512] and others[513,514] established the fact that this form of thalassemia occurs in individuals who are heterozygous for a mutation that affects β-globin synthesis. Expression of one β gene is impaired by mutation, whereas the other gene is normal.

Hemoglobin Pattern

Characteristically, HbA_2, HbF, or both are elevated in patients with β-thalassemia trait, although normal levels

are observed occasionally. The relative amounts of HbA_2 or HbF have been used to classify thalassemia trait, which has relevance to the molecular lesion in certain instances and also to the severity of the disease in homozygous offspring.

Globin Biosynthetic Ratio

In peripheral blood reticulocytes, the measured β-to-α biosynthetic ratio varies from 0.5 to 0.7, as predicted for inactivation of a single β gene (see Fig. 20-23). However, when bone marrow cells are incubated with [^{3}H]leucine, the measured β-to-α biosynthetic ratio is often 1:1 in patients with heterozygous β-thalassemia.[515-519] The capacity of bone marrow cells to degrade free α-globin by proteolysis may explain why it is difficult to demonstrate unbalanced synthesis of β- and α-globin chains in the marrow cells of heterozygotes. The measured β-to-α ratio is approximately 0.5 in pulses of 10 to 20 minutes, but if the incubation of bone marrow cells is prolonged, proteolysis apparently destroys the excess newly synthesized α-globin.[520,521] Fractionation of bone marrow cells after incubation in [^{3}H]leucine demonstrated that proteolysis is most efficient in the earliest erythroid cels, namely, proerythroblasts and basophilic erythroblasts.[521] The impairment in β-globin synthesis becomes easier to detect as erythroid cells mature, thus accounting for the reduced β-to-α biosynthetic ratio that is usually found in peripheral blood reticulocytes.

δ-Globin Synthesis

Among inherited anemias, the elevation in HbA_2 level is unique to β-thalassemia. The absolute quantity of HbA_2 present in red cells is a complex function of the inherent capacity for δ-globin chain synthesis and factors regulating rates of hemoglobin dimer and tetramer assembly. As discussed earlier, δ-globin is normally expressed at a low level, approximately 2.5% that of β-globin. The level may be reduced further by mutations that affect δ-globin expression. Heterozygous[522,523] and homozygous[524] states have been described. δ-Thalassemias reflect point mutations that completely silence the already defective δ-globin genes.[282,374,375,457,525-527]

In heterozygous β-thalassemia, the observed increase in HbA_2 represents a relative as well as an absolute increase in the quantity of HbA_2 per red cell from the normal level of 0.6 to 0.7 pg to 1.0 pg.[1] The increased amount of HbA_2 contains δ-globin chains derived from the δ gene adjacent to the mutant β gene, as well as from the δ gene on the opposite chromosome. This has been inferred from the study of β-thalassemia heterozygotes who also have a variant δ chain.[528] The increase in the HbA_2 level can be accounted for by enhanced incorporation of δ-globin chains into hemoglobin dimers as a consequence of deficient β-globin chain production (see earlier discussion on hemoglobin assembly).[229]

Environmental factors also influence the absolute level of HbA_2. Iron deficiency leads to a decrease in the level of HbA_2, which may become normal in thalassemia

heterozygotes and therefore mask the diagnosis of β-thalassemia trait. In such instances, the level of HbA_2 becomes elevated with iron repletion.[529] An increase in the level of HbA_2 may be seen in acquired megaloblastic disorders associated with either folic acid or vitamin B_{12} deficiency.[529]

Clinical Features

Peripheral blood smears from patients with β-thalassemia trait are shown in Figure 20-27. Microcytosis, hypochromia, targeting, basophilic stippling, and elliptocytosis may be striking features, although the red cells may be nearly normal in occasional patients. The bone marrow is characterized by mild to moderate erythroid hyperplasia; red cell survival is modestly decreased, and slight ineffective erythropoiesis is present.[530] Inclusions in bone marrow cells and peripheral red cells are rare. Similar hematologic parameters appear to characterize Thai, Chinese, Greek, British, and Italian populations with β-thalassemia trait,[531-534] whereas African Americans appear to have a milder syndrome.[535] Hepatomegaly and spleno-
FIGURE 20-27. Peripheral blood smears from patients with heterozygous β-thalassemia (**A**) and homozygous β-thalassemia (**B**) after splenectomy.

megaly have been reported in 10% to 19% of Italian and Greek patients but are less common in other groups.[533,534] Iron or folic acid deficiency, pregnancy, or intercurrent illness may exacerbate the anemia in patients with thalassemia trait.

Therapy

No therapy is required for thalassemia trait, but genetic counseling is imperative. The homozygous offspring of two individuals with high-HbA$_2$ β-thalassemia trait usually have transfusion-dependent anemia and thalassemia major, but they may sometimes have a thalassemia intermedia phenotype. The precise nature of the mutation or mutations in homozygous individuals is one factor in determining the clinical phenotype.

β-Thalassemia Trait Phenotypes

High-A$_2$ β-Thalassemia

This is the most common form of β-thalassemia trait. HbA$_2$ levels vary from 3.5% to 8.0%, whereas the HbF level varies from less than 1% to 5%.[1,531-535] The vast majority of single base mutations resulting in β-thalassemia (see Table 20-2) lead to typical high-HbA$_2$ β-thalassemia trait. Although individual mutations variably reduce β-globin synthesis, efforts to differentiate the effect of specific mutations in heterozygous individuals have largely been unrewarding.[1,533,536,537] In blacks, β^0 and β$^+$ mutations can often be distinguished in individual families by the rate of occurrence of double heterozygotes for a β-thalassemia mutation and the β^S mutation. In this population, MCV and MCH values are higher in β$^+$ heterozygotes than in β^0 heterozygotes, but circulating hemoglobin concentrations are nearly equivalent.[535,538] The common mutations found in American blacks, most notably residing in the ATA box of the promoter (see Table 20-2), only modestly impair β-globin gene expression,[46,146] which perhaps accounts for the relatively mild phenotype of many individuals with heterozygous or homozygous β$^+$-thalassemia in this population.

δβ-Thalassemia

Individuals heterozygous for these mutations have increased levels of HbF (5% to 15%) and low HbA$_2$ levels. This phenotype is most often generated by deletions that remove most or all of the coding sequences of the δ- and β-globin genes (see Table 20-4). The propensity of these deletion mutations for enhancement of the expression of γ-globin genes contributes to a relatively mild phenotype in homozygous individuals or those in whom a δβ-thalassemia deletion is inherited along with a thalassemia allele with a typical substitution mutation.

High-A$_2$, High-F β-Thalassemia

A distinct variant of β-thalassemia trait has been described in which the level of HbA$_2$ is elevated and the level of HbF is also elevated (5% to 20%).[287,288,539] This form of

thalassemia trait is associated with deletions of the β-globin gene that leave the δ and γ genes intact (see Table 20-4).

Normal-A$_2$ β-Thalassemia

This form of β-thalassemia trait should be distinguished from the silent carrier state. Although both are characterized by low or normal HbA$_2$ levels, the red cells in individuals with normal-HbA$_2$ β-thalassemia are characteristically hypochromic and microcytic,[456,540] in contrast to silent carriers, whose red cells appear near normal.[453,455] Individuals who coinherit this type of β-thalassemia allele from one parent along with a high-HbA$_2$ β-thalassemia allele from the other usually have severe transfusion-dependent β-thalassemia.

This phenotype is thought to represent coinheritance of mutations (usually deletions) that decrease β- and δ-gene function. The mutations in the δ-globin gene may be present on the same chromosome or on the opposite chromosome from the β-thalassemia gene.[282,374,3759,457,525-527]

Differential Diagnosis of Thalassemia Trait

In clinical practice, thalassemia trait must be distinguished from iron deficiency (see Chapter 12 for additional discussion of the differential diagnosis of microcytosis and iron deficiency). Frequently, the differential diagnosis may be suspected from red blood cell indices; mild erythrocytosis and marked microcytosis are characteristic of thalassemia trait (Table 20-7).[548-550] The red cell count is usually decreased in patients with iron deficiency, whereas red cell volume may be normal or decreased, depending on whether the iron deficiency anemia is acute or chronic,[551-554] but red cell volume is rarely as low as in thalassemia trait. The mean corpuscular hemoglobin concentration (MCHC) is usually normal in thalassemia trait, whereas the MCHC may be low in a subset of cells in iron deficiency; in both syndromes the hypochromic appearance of the red cells reflects their small size, diminished hemoglobin content, and high surface-to-volume ratio. The red cell distribution width (RDW), a parameter available in modern automated cell counters, was originally believed to distinguish between iron deficiency and other causes of microcytosis.[555,556] However, the RDW is also increased in the thalassemias and other hemoglobinopathies and is not a useful independent discriminator.[557-561] The absence of stainable iron in a bone marrow specimen is highly suggestive of iron deficiency, but the presence of iron does not necessarily exclude an iron-responsive anemia.

Several formulas have been developed to assist in the diagnosis of thalassemia trait during the assessment of microcytic hypochromic anemia (Table 20-8).[552,562,563] None of the discriminant functions are infallible. Nonetheless, the Mentzer index[552] is useful as an office screening test. More accuracy in separating thalassemia trait from iron deficiency may be achieved with the England and Fraser function,[563-565] but when both conditions exist

simultaneously, all indices are subject to error. Additional discriminant functions and automated protocols have been proposed that may also prove useful.[566-568] Free erythrocyte protoporphyrin, often incorporated into the initial workup of hypochromic microcytic anemia in childhood to screen for lead exposure, is an additional useful test for patients suspected of having thalassemia trait.[569,570] This technique has been especially helpful in evaluating newly arrived Southeast Asian refugees to the United States.[571] Of course, measurement of transferrin saturation or ferritin may also be used to verify or exclude the diagnosis of iron deficiency. The ratio between microcytic (MCV <61 fL) and hypochromic (MCHC <28 g/dL) erythrocytes is a helpful parameter. A ratio greater than 1.0 is highly suggestive of thalassemic trait, whereas a ratio less than 1.0 is mostly associated with iron deficiency.

In office practice the distinction between thalassemia trait and iron deficiency generally depends on examination of peripheral blood smears and, above all, the patient's clinical history, as well as measurement of red cell indices in the parents. It is worth remembering that patients with thalassemia trait are not immune to iron deficiency. In these patients, iron deficiency may mask increases in the levels of HbA₂ and HbF that would otherwise suggest a diagnosis of β-thalassemia.

After iron deficiency is excluded, differential diagnosis between α- and β-thalassemia trait depends on measurement of HbA₂ and HbF levels (see Table 20-7) and rarely if ever on measurement of the α-to-β biosynthetic ratio in peripheral blood reticulocytes. In patients with microcytosis, hypochromia, and erythrocytosis but without evidence of iron deficiency or altered HbA₂ and HbF levels, α-thalassemia is the most probable diagnosis. When both α- and β-thalassemia coexist, changes in the levels of HbF and HbA₂ characteristic of β-thalassemia trait may not be present[96] (see later). Molecular genetic analysis and family studies are often necessary to define these complex interactions.

Severe β-Thalassemia

Historical Perspective

It was not until Thomas Cooley, a Detroit pediatrician, first described the clinical entity that was to bear his name that thalassemia major was recognized as a distinct disease.[572,573] Cooley recognized similarities in the appearance and clinical course of four children of Greek and Italian ancestry. These children exhibited severe anemia (hemoglobin concentration of 3 to 7 g/dL), massive hepatosplenomegaly, and severe growth retardation. In addi-

tion, bone deformities, such as frontal bossing and maxillary prominence, gave the patients a characteristic facies. Deformities of the long bones of the legs were also commonly seen and thought to reflect severe osteoporosis. Thalassemia major, or "Cooley's anemia," was and is far more common in Greece and Italy than in the United States, and descriptions of the disease in these countries soon followed Cooley's original report.[574]

Autopsy studies revealed extraordinary expansion of bone marrow at the expense of bony structures. Extramedullary hematopoiesis was often a striking feature and appeared as either isolated massive hepatosplenomegaly or hepatosplenomegaly in association with intrathoracic or intra-abdominal masses.[573-575] Children were also noted to have significant iron deposition in almost all organs, the significance of which was not initially appreciated.[575] Before regular blood transfusion regimens were used, these changes progressed inexorably and were invariably fatal during the first few years of life. Patients died of the effects of their anemia: congestive heart failure, intercurrent infection, or complications resulting from all too commonly seen pathologic fractures.

Initial transfusion regimens were mainly palliative; transfusions were recommended only when the anemia interfered significantly with a patient's ability to function on a daily basis. In defense of this regimen, we must realize that the pathophysiologic basis of the disease was not understood and that clinicians first attempted to minimize the transfusional iron administered because they feared that the iron, seen ubiquitously in these patients at autopsy, might itself be the cause of the disease.[575] Palliative transfusion therapy enabled affected individuals to live somewhat longer than patients not receiving transfusions, but the bone deformities and severe anemia forced them to lead markedly restricted lives.

In an attempt to improve the quality of life of these patients, trials using routine transfusion schedules to maintain hemoglobin levels of 8.5 g/dL or greater were initiated.[576-578] The condition of patients improved dramatically, with fewer overt side effects of anemia and more normal growth.[579,580] Clinical improvement proved transient, however, because regular transfusions led to the complications of chronic iron overload, including growth retardation from endocrine disturbances, diabetes mellitus, and delayed sexual maturation. Death invariably ensued in the second or early third decade of life, most often as a result of iron-induced cardiac arrhythmias or intractable congestive heart failure.[581]

Pathophysiology

Imbalance in Globin Biosynthesis

That severe β-thalassemia was caused by impaired production of β-globin was established in the mid-1960s by direct measurement of globin biosynthesis in reticulocytes.[582-586] Soon thereafter, impaired production of α chains was demonstrated in the α-thalassemia syn-
FIGURE 20-28. Supervital stain (methyl violet) of the peripheral blood cells from a patient with homozygous β-thalassemia after splenectomy.

dromes.[476] Decreased hemoglobin production is reflected in the peripheral blood smear by hypochromia, microcytosis, and target cells (which are a sign of the severe impairment in total hemoglobin production), as well as by teardrops, fragments, and microspherocytes (see Fig. 20-27). Red cell fragmentation is a direct consequence of unbalanced globin chain synthesis. Excess α chains, which have no complementary non–α chains with which to pair, form insoluble inclusions, demonstrable on methyl violet staining of the peripheral blood of asplenic patients with β-thalassemia (Fig. 20-28). In nonsplenectomized individuals, these inclusions are difficult to demonstrate because they are efficiently removed during the passage of red cells through the splenic sinusoids, where fragments and teardrops are generated (Fig. 20-29).

α-Globin inclusions in the erythrocytes and nucleated erythroid cells of patients with thalassemia major were first demonstrated by Fessas and associates[587-589] and by Nathan.[590] The incidence of the inclusions parallels the degree of impairment in β-globin synthesis. Inclusions have several deleterious effects on erythroid cells and are believed to lead to severe ineffective erythropoiesis. Intranuclear α-globin inclusions, visualized with electron microscopy, have been hypothesized to interfere with cell division.[591,592] Intracytoplasmic inclusions oxidize and mechanically damage cell membranes, interfere with mitochondrial function, and permit the ingress of calcium ions, which perturb the internal monovalent cationic environment and thereby contribute to the intramedullary death of erythroid cells. Moreover, α inclusions reduce red cell deformability and very likely interfere with egress from the bone marrow spaces, as well as from the tortuous vasculature of the spleen. The combined effects of ineffective erythropoiesis and severe anemia account for the extraordinary marrow expansion seen in patients with thalassemia major. In fact, these individuals have a nonfunctional cell mass that approximates the 10^{15} tumor cells present in patients with fatal leukemia and is associated with a profound hypermetabolic state that includes fever, wasting, and hyperuricemia.[590]
FIGURE 20-29. Phase-contrast microscopy of a wet preparation of scrapings from the spleen of a patient with homozygous β-thalassemia. Note the chain inclusion bodies (*black arrowheads*) within teardrop-shaped red cells, inclusions being pulled out, or "pitted," from the red cell by reticuloendothelial cell action (*lower left*), and inclusions free in the splenic pulp (*white arrowhead*).

The Red Cell Membrane

Numerous membrane abnormalities of thalassemic erythrocytes have been described.[488,490,593] Many are attributable to oxidative damage from excess globin chains and the association of heme and iron with the cell membrane after the degradation of precipitated hemoglobin chains.[488,594] Other abnormalities may result from selective interaction of excess α or β chains with the membrane cytoskeleton. After oxidation, globin chains, as well as trace metals such as iron and copper, generate free oxygen radicals that foster oxidative injury to the membrane.[595] Peroxidation of lipids in the red cell membrane is reflected by altered membrane lipid composition and distribution; polymerization of membrane components caused by lipid peroxidation leads to excessive calcium influx, monovalent cation loss and dehydration, decreased cell deformability, and increased rigidity of the phospholipid bilayer.[90,91,596] Similar changes are observed in normal red cells forced to engulf excess α chains.[597] The reductions observed in the level of serum and red cell vitamin E, a natural antioxidant, may result from accelerated consumption secondary to oxidant stress. The abnormal lipid distribution may contribute to enhanced clearance by macrophages. Increased binding of autologous immunoglobulin G (IgG) with an α-antigalactosyl specificity, originally proposed to reflect a decrease in sialic acid content of the membrane, may also promote clearance of thalassemic red cells from the circulation. The increased calcium content of thalassemic red cells is a hallmark of membrane damage.

Electrophoresis of red cell membrane proteins readily demonstrates an increased association of globin chains with the red cell membrane (up to 11% of total protein), and similar findings can be reproduced in nonthalassemic erythrocytes by exposure to experimental oxidative stress.[598] The α- and β-globin chains interact differently with components of the cytoskeleton.[599-601] The specificity of these interactions may contribute to the different phenotypic manifestations of the disorders. Membrane protein 4.1 of β-thalassemia erythrocytes has a diminished capacity to enhance the binding of spectrin to actin. In HbH disease, protein 4.1 appears to be normal, but binding of spectrin to inside-out vesicles is decreased, potentially because of oxidative damage to ankyrin promoted by binding of HbH to protein band 3, with which ankyrin interacts. Spectrin binding is normal in β-thalassemia erythrocytes.

Schrier and colleagues[602] reported differences in the rheologic properties of erythrocytes obtained from patients with HbH disease and β-thalassemia intermedia. Erythrocytes from both groups had a normal surface area but decreased cellular volume and increased membrane rigidity that resulted in decreased cellular deformability under conditions of hypertonic osmotic stress. Although HbH erythrocytes exhibit an increase in mechanical stability and a decrease in cell density, β-thalassemia erythrocytes are prone to cellular dehydration and have markedly decreased mechanical stability. In a murine model of β-thalassemia, these cellular abnormalities correlated with the extent of α-globin associated with the membrane; small increases in β-globin chain expression

through the introduction of a β-globin transgene resulted in a marked decrease in membrane-associated globin and significant reversal of the rheologic abnormalities.[603] Thus, the slight improvements in chain synthetic balance that accompany increased expression of γ-globin or decreased expression of α-globin may result in dramatic improvements in membrane integrity in patients with β-thalassemia. More detailed understanding of the red cell membrane abnormalities in thalassemia may facilitate the development of novel therapies in the future.

Genetic Heterogeneity

In current hematologic parlance, the term *thalassemia major* refers to patients with severe β-thalassemia who require regular blood transfusions to sustain life. In the vast majority of such patients, both β-globin genes are affected by a thalassemia mutation; hence, they are described as homozygous β-thalassemics, although in the United States most are actually double heterozygotes. In other patients who also appear to be homozygous for β-thalassemia mutations based on family studies, a hemoglobin concentration of 6 to 10 g/dL is maintained without blood transfusions except during periods of infection, surgery, or other stress.[1,604] Such patients are said to have *thalassemia intermedia*. Thalassemia intermedia is a clinical term that describes the transfusion status of the patient. The term *Cooley's anemia* is still often used and applied somewhat indiscriminately to individual patients with either the major or intermedia clinical syndrome. Although other acquired and genetic modifiers exist, disease severity in the β-thalassemias is most directly related to the degree of imbalance between α- and total non–α-globin synthesis. Three major factors emerge as important determinants of the biosynthetic ratio in individual patients: the nature of the specific mutation or mutations, the presence of abnormalities in the α-globin cluster that increase or decrease α-globin expression, and the genetic capacity for synthesis of HbF. Proteolysis of excess α chains, evident on comparison of the α-to–non-α biosynthetic ratio by short- and long-term incubation of bone marrow cells[515-519] (see earlier), is also likely to modulate disease severity, although no meaningful quantitative studies of this mechanism have yet appeared. Recently, a chaperone of free α-globin chains has been described (see earlier discussion).

Nature of Specific Mutations

The capacity for production of β-globin chains in an individual with thalassemia is directly determined by the specific mutations involving the β-globin gene. Because several different mutations are commonly found in populations with a high incidence of β-thalassemia, most American patients with clinical homozygous β-thalassemia are heterozygous for two different mutations. The effect of specific mutations may range from total loss to only a mild impairment in β-globin synthesis, and thus the potential interactions based on the many different mutations are extraordinary. Indeed, disease severity may

be viewed as a continuum, the extremes of which have been shown to correlate with specific mutations.

Mutations in the IVS-1 splice donor site (see Table 20-2 and Fig. 20-11) provide a particularly illustrative example of the variable consequences of specific mutations on β-chain synthesis. These mutations lead to either a complete block in correct splicing of β-globin mRNA or merely a reduction in the abundance of normal mRNA. Patients homozygous for a mutation in the conserved GT splice junction dinucleotide and who have not coinherited an α-thalassemia gene or a determinant that increases HbF synthesis display severe transfusion-dependent β⁰-thalassemia.[129,133-135] Substitution of C or T at position 5 of the splice donor consensus sequence results in severe β⁺-thalassemia,[111,133,143-145] whereas substitution of A at the same position results in a more mild phenotype.[146] The T→C substitution at position 6 is also associated with mild β⁺-thalassemia.[129]

Dominant β-Thalassemia

In rare circumstances, the heterozygous state of β-thalassemia may be associated with severe disease rather than typical thalassemia trait. Several pedigrees with severe heterozygous β-thalassemia characterized by splenomegaly, cholelithiasis, and leg ulcers have been described.[605,606] A striking association has been noted between mutations involving exon 3 of the β-globin gene and these unusual cases of dominantly inherited β-thalassemia.[197,201] Third-exon mutations typically lead to the production of an unstable β-globin chain. A subset of third-exon β-thalassemia mutations are associated with the presence of inclusion bodies in the normoblasts of affected heterozygotes (see Table 20-2)[199-203] and were first reported as "inclusion-body β-thalassemia," originally defined as a dominantly inherited dyserythropoietic anemia.[607,608] The inclusion bodies, which may contain both α-globin and β-globin, represent an aggregation of precipitated α-globin and unstable β-globin chains with the cell membrane, where they presumably potentiate oxidative damage. The dominantly inherited β-thalassemias are relatively rare and are found in ethnic groups from non-malarious regions.[197,201] Presumably, there is little selective pressure for these mutations because of the decreased fitness of heterozygous individuals.

Increased production of α-globin chains above normal levels may exacerbate the chain imbalance in β-thalassemia heterozygotes; coinheritance of triplicated α-globin gene chromosomes is another potential cause of severe heterozygous β-thalassemia, and patients usually have the phenotype of thalassemia intermedia.[437,438,6-9-611]

Interaction with Genetic Determinants That Increase Hemoglobin F Synthesis

Deletions within the β-globin gene cluster and mutations in the γ-globin promoters are sometimes associated with increased expression of γ-globin (see earlier discussion). Relatively small, genetically determined heterocellular

increases in HbF ameliorate the clinical course of thalassemia,[93,94,343,356,463,539] thereby raising the prospect that pharmacologic augmentation of γ-chain production may be of particular benefit in the management of thalassemia (see later).

Readily demonstrated in thalassemic patients is an apparent amplification of the capacity for HbF synthesis during erythroid maturation. In the earliest erythroid precursor cells, γ-globin may be synthesized at a level less than that of β-globin and at only a small percentage of that of α-globin, yet the final proportion of HbF in patients not receiving transfusions may be quite high.[1,90] This occurs because the subset of cells expressing γ-globin have less overall globin chain imbalance and therefore preferentially survive in both bone marrow and peripheral blood. Hence, measurement of steady-state HbF levels provides an imperfect measure of the capacity for γ-globin synthesis in individual patients. More accurate assessment of the HbF program is achieved by measurement of the HbF accumulated in progenitor-derived erythroid colonies produced in vitro.[612]

Interaction of α- and β-Thalassemia Mutations

Because the clinical severity of α- and β-thalassemia correlates with the degree of imbalance in the production of α and non-α chains, coinheritance of α- and β-thalassemia mutations would be anticipated to yield syndromes of intermediate severity.[613-619] This principle has been validated by clinical experience.[96,620,621] One striking example is the influence of the number of functional α genes in individuals with β-thalassemia trait in Sardinia.[96] As shown in Table 20-9, MCV and MCH improve in a stepwise fashion as α-globin production decreases and the α-globin–to–β-globin ratio approaches 1, but they then deteriorate as the ratio decreases to less than 1. This analysis provides conclusive evidence that the degree of chain synthesis imbalance determines the red cell phenotype. Thus, a higher incidence of α-gene deletions (−α/αα or −α/−α) has been found in patients with thalassemia intermedia than in those with thalassemia. Further evidence for the effect of α-gene number on clinical phenotype is the occurrence of thalassemia intermedia in a subset of individuals doubly heterozygous for β-thalassemia and triplicated α genes (ααα/αα)[437,551,609-611] or severe β-thalassemia trait in individuals also heterozygous for triplicated α genes.[600,601,622-628] Individuals heterozygous for β-thalassemia but homozygous for triplicated α genes invariably have thalassemia intermedia.

Clinical Features and Laboratory Values on Initial Evaluation

Severe β-thalassemia is most often diagnosed between 6 months and 2 years of age when the normal physiologic anemia of the newborn fails to improve. γ-Globin production is not impaired in utero; therefore, only when β-globin becomes the predominant β-like globin does anemia ensue. Occasionally, the disease is not recognized until 3 to 5 years of age because prolonged HbF synthesis compensates for the lack of HbA. When first seen, affected infants usually display pallor, poor growth, and abdominal enlargement from hepatosplenomegaly.

Children with severe β-thalassemia are readily distinguished from those with other congenital hemolytic anemias. At initial evaluation, patients who have not received transfusions show 20% to 100% HbF, 2% to 7% HbA$_2$, and 0% to 80% HbA (see Fig. 20-24), depending on the precise genotype. Consistent with severe ineffective erythropoiesis and splenomegaly, the reticulocyte count is characteristically low (often<1%), whereas the nucleated red cell count is elevated. Erythrocytes are severely microcytic (MCV of 50 to 60 μm^3) with a hemoglobin content as low as 12 to 18 pg/cell. HbF can be shown to be heterogeneously distributed among the red cells either by the Betke-Kleihauer acid elution technique or by anti-HbF fluorescent staining (see Fig. 20-20).

Bone marrow examination reveals marked erythroid hyperplasia, often with an erythroid-to-myeloid cell ratio of 20:1 or greater. Before the onset of hypersplenism, the accelerated rate of hematopoiesis may also be reflected by elevated white cell and platelet counts in peripheral blood. The serum iron value is markedly elevated, but total iron-binding capacity is usually only slightly increased, thereby resulting in a transferrin saturation of 80% or greater. Serum ferritin levels are generally elevated for age.

If laboratory parameters fail to establish the diagnosis of thalassemia, demonstration of a mild microcytic and hypochromic anemia, indicative of the presence of thalassemia trait in both parents, will allow the diagnosis to be made with confidence. If the diagnosis remains in doubt, it can be confirmed by globin genotyping.

TABLE 20-9   Effect of Successive α-Globin Gene Deletion on Hematologic Parameters in a Homogeneous Population with β-Thalassemia Trait

Group/Genotype	Hb (g/dL)	MCV (mm³)	MCH (pg)	HbA₂ (%)	HbF (%)	Ratio
αα/αα (n = 20)	12.4 ± 1.2	66.2 ± 3.7	21.2 ± 1.2	4.8 ± 0.7	1.4 ± 1.3	2.2 ± 0.3
α−/αα (n = 12)	12.8 ± 1.3	67.3 ± 3.4	22.1 ± 1.1	5.2 ± 0.7	1 ± 0.3	1.3 ± 0.1
α−/α− (n = 4)	14.1 ± 1.1	76 + 3.4	24.8 ± 1.4	4.8 ± 0.6	1.3 ± 0.7	0.8 ± 0.1
α−/−− (n = 4)	11.7 ± 0.8	54.7 ± 2.5	18.4 ± 0.8	4.6 ± 0.2	—	0.5 ± 0.05

Complications

The etiology of the complications of thalassemia is multifactorial and variable and depends on the genotype, other known and unknown phenotypic modifiers, and availability and adherence to therapy. The pathophysiology of the complications stems from ineffective and extramedullary hematopoiesis and treatment-related side effects, including transfusional iron overload, transfusion-associated infections, and chelation. In addition, more recently recognized but not fully understood is the increased risk for clinically evident and silent thromboses leading to pulmonary hypertension and overt portal vein thromboses. The complications of thalassemia in a large group of North American patients have recently been reviewed.[629]

Bones

To appreciate the full spectrum of bone changes in severe β-thalassemia, one must examine patients who receive transfusions rarely.[572,573] Bone disease in such patients is primarily related to erythroid expansion and not to iron overload or abnormalities in vitamin D metabolism.[630,631] Maintenance of nearly normal hemoglobin levels results in suppression of erythropoiesis and tends to reverse the bone abnormalities,[600,601,622-628,632-634] but osteoporosis is common even in patients who receive regular transfusions.[635-638] Some clinics report a high incidence of vertebral compression fractures.[637] A recent review of more than 700 patients with thalassemia syndromes reported an overall fracture prevalence of 12.1% that ranged from 2.5% in very young patients to 23% in those older than 20 years. Therapy with excessively high doses and sometimes even standard doses of deferoxamine may also lead to metaphyseal dysplasia.[639-641]

Radiologic abnormalities may be present during the first 6 months of life but are not usually marked until about 1 year of age.[642] In the small bones of the hands and feet the trabecular pattern is coarse, cystic abnormalities are present, and the bones are tubular in appearance. The long bones of the extremities exhibit thinning of the cortices and marked dilation of the medullary cavities. Accordingly, they become extremely fragile and prone to pathologic fractures.[643] The skull is also classically involved, with marked widening of the diploic space and arrangement of the trabeculae in vertical rows, which tends to give a "hair on end" appearance to the skull radiograph (Fig. 20-30). Other radiologic abnormalities in the skull include failure of pneumatization of the maxillary sinuses and overgrowth of the maxilla. These changes lead to maxillary overbite, prominence of the upper incisors, and separation of the orbits—changes that contribute to the classic "thalassemic facies."

Other bone changes caused by medullary overgrowth include widening of the ribs with notching and the development of masses of extramedullary hematopoietic tissue, which may appear as tumors in the chest and mediastinum. The vertebrae are square with coarse trabeculae.

The aforementioned osteoporosis and associated bone pain may be relieved by calcitonin therapy,[644] but the role of vitamin D and calcium supplementation in the prevention of osteoporosis in patients with thalassemia has not been established. Controlled randomized studies have revealed the potential value of bisphosphonate therapy to improve bone denisty as measured with bone density scans.[645]

Gallbladder

Calcium bilirubinate gallstones secondary to excessive excretion of the products of heme catabolism are common in older patients.

Iron Deposition

Most longitudinal studies of iron overload have used serum iron, iron-binding capacity, and ferritin as noninvasive measures of stored iron. As mentioned earlier, these parameters are easily perturbed by the effects of other diseases (e.g., hepatitis) or are highly variable (iron/iron-binding capacity). Some clinics still rely on the measurement of ferritin.[646] The relationship between serum ferritin and body iron stores as measured by quantitative assay of liver iron remains poor. In a recent study using superconducting quantum interference device (SQUID) technology, only 25% of the variance in body iron could be explained by the variance in serum ferritin.[647] This confirms the earlier studies of Brittenham and co-workers.[648] The poor correlation between serum ferritin and total body iron in thalassemic patients receiving many transfusions[649] can perhaps be improved somewhat by measuring the glycosylated form.[650] Grading of stainable iron in liver biopsy samples also offers a rough assessment of parenchymal iron stores. Biopsy also provides a view of histology, as well as direct chemical measurement of iron. It should be mentioned that excessive fibrosis may cause a false reduction in tissue iron content as estimated by measurements on biopsy material. Thus, there is no true "gold standard" of liver iron content. Only serial measurements of ferritin and an imaging signal in which patients serve as their own control provide a practical approach to analysis of the course of treatment.

Computed tomography (CT) has been used to demonstrate iron overload in patients with thalassemia by detection of increased density of the liver.[651-654] CT scans have also shown increased density of the spleen, pancreas, adrenal glands, and lymph nodes in the abdomens of these patients[655] while also offering another assessment of extramedullary hematopoiesis[656-658] and bone abnormalities.[659] Repeated CT examinations involve substantial radiation doses. Magnetic resonance imaging (MRI) has become the favored repeated imaging approach for iron assessment in the liver because of x-ray dosage considerations. The procedure is not always suitable for small children because it requires cooperation, but recent applications have provided reproducible and clinically useful results within the range of hepatic iron content
FIGURE 20-30. Radiologic abnormalities in a patient with homozygous β-thalassemia who receives blood transfusions rarely (thalassemia intermedia). **A**, Skull radiograph illustrating the typical "hair on end" appearance of the diploë and failure of pneumatization of the frontal sinus. **B**, Abdominal film illustrating the coarse trabeculation and osteoporosis within the vertebrae. Multiple calcified gallstones are also seen. **C**, Severe osteoporosis, pseudofractures, thinning of the cortex, and bowing of the femur. **D**, Degenerative arthritis affecting the tibiotalar joint in particular is reflected by loss of the cartilage space and sclerosis in the adjacent bone.

expected in thalassemic patients.[6592,660] T2* MRI is now used in thalassemia centers for assessment of cardiac iron content because it is a technique uniquely suited to capturing data from a moving organ. Though yet to be validated in patients by an independent measurement, it is useful clinically and in therapeutic research.[661,662] This technology has demonstrated that iron is removed more slowly from the heart than from the liver and has allowed enhanced chelation strategies to remove lethal iron from the heart.[663]

Determination of hepatic magnetic susceptibility with SQUID technology has been proved to have excellent correlation with direct measurement of hepatic iron by biopsy,[542,543] but it is very expensive, highly complex, generally unavailable, and poorly reproducible from center to center. It will probably be abandoned as a clinical tool.

Pathophysiology of Iron Deposition. The original pathologic description of thalassemia[544,575] was concerned

with conditions extant in the untreated state and is not relevant to conditions seen in patients today who receive transfusions chronically and thus become iron overloaded. In countries in which transfusion is widely available, patients demonstrate few of the stigmata that characterized the disease during the first few years of life in patients who do not receive transfusions. Depending on the level of hemoglobin maintained, most patients fortunately no longer have difficulty with the marked erythroid hyperplasia that causes extensive medullary expansion and its consequent pathologic changes.[576] However, patients are now confronted with consequences of the chronic iron overload that accompany routine transfusion therapy.[664] In a study of British Cypriot patients at autopsy, Modell[665] found evidence of marked iron deposition in the liver, pancreas, thyroid, parathyroid, adrenal zona glomerulosa, renal medulla, heart, bone marrow, and spleen. Such parenchymal iron loading and the accumulation of "free" or non–transferrin-bound iron in blood remain the major causes

of morbidity and mortality in patients with severe β-thalassemia.

Although the contribution of transfusional iron to iron toxicity is easily appreciated, anemic thalassemic patients also have markedly enhanced gastrointestinal iron absorption,[666] particularly patients with thalassemia intermedia, such as those with HbE–β-thalassemia.[545,667] This seems paradoxical because one might expect suppression of iron absorption in the presence of iron overload. In normal individuals, a portion of dietary iron presented to the gut lumen is transported across the brush border of the gut epithelium and is available for transfer to the plasma iron transport protein transferrin. The individual's iron status should then determine the amount of iron eventually presented to the serum pool.[668] The observation that anemic patients with thalassemia major bypass the ferroportin mechanism in intestinal epithelial cells (see Chapter 12) and thereby display increased iron absorption is at least partially understood.

Calculations by Modell and Berdoukas[669] suggested that the kinetic requirement of the expanded bone marrow for iron to make new red cells exceeds the rate at which the reticuloendothelial system is able to salvage iron from senescent red cells and replenish the erythron with iron. On this basis they argue that the bone marrow is relatively iron deficient on a kinetic basis, thereby leading to enhanced gastrointestinal absorption. Increased absorption is variable[666] (range, 2% to 40%) and appears to be directly related to erythroid activity[670,671] measured by either morphologic observation of patient bone marrow[672] or enumeration of nucleated red cells in peripheral blood.[666] Experimental studies in animals suggest that hypoxia, even in the absence of increased erythropoiesis, may increase iron absorption.[673]

Hepcidin and ferroportin are pivotal to the increased iron absorption in the presence of ineffective erythropoiesis (see Chapter 12 for further details). It was first discovered that elevated hepcidin mediates iron retention by macrophages and causes internalization of ferroportin on the intestinal brush border, which leads to failure of intestinal absorption. Conversely, hepcidin levels fall in response to iron deficiency, hypoxia, erythropoietin, or ineffective erythropoiesis, thus explaining the increase in intestinal iron absorption in thalassemic syndromes.[674,675] That hepcidin remains inappropriately low suggests that the erythroid drive is a more potent regulator than the iron overload. A decrease in erythroid drive via transfusions upregulates hepcidin.[675,676] The signaling molecule between erythroid drive and downregulation of hepcidin is being actively investigated. A recent study in the murine model demonstrated that inappropriately low hepcidin levels dominate the pathophysiology of iron loading early in life and upregulation of ferroportin mediates the absorption in later life.[676] This has yet to be studied in humans. Concomitant mutations in the *HFE* gene also increase iron overload in thalassemia.[677,678]

With most modern transfusion regimens, iron absorption is significantly decreased but iron loading is increased as transfused red cells become senescent and their iron is deposited in the reticuloendothelial system. Reticuloendothelial cells relinquish iron directly to transferrin. Although the erythron usually claims most of this circulating iron, a certain amount is also delivered to other cells according to their individual needs. Cellular uptake may normally depend on the number of transferrin receptors on the cell membrane.[679] As iron accumulates in the body, individual tissues, particularly the liver, accelerate their production of apoferritin molecules to store the iron in a nontoxic form as ferritin or hemosiderin.[680,681]

Apoferritin production can be monitored by measurement of the serum ferritin concentration via radioimmunoassay. In patients receiving multiple transfusions[682] and in patients with increased gastrointestinal iron absorption who do not receive transfusions,[683] serum ferritin levels correlate well with total body iron stores during the first several years of iron loading, but less well later.[684] Serum ferritin is an acute phase reactant, as well as a product of hepatocellular damage. Infection, congestive heart failure, and hepatitis may elevate serum ferritin levels. Thus, in patients with marked iron overload, the serum ferritin level correlates poorly with liver iron concentration. Patients with thalassemia intermedia have severe hepcidin deficiency, which leads to hyperabsorption of dietary iron, as well as depletion of iron in macrophages. It has been suggested that this is the basis of the lack of correlation between liver iron content and serum ferritin levels in thalassemia intermedia.[685]

The human body is extremely conservative in its handling of iron (see Chapter 12). Under normal conditions, iron is always found in the presence of a chelating protein with a high affinity constant. Serum transferrin binds iron with an association constant of 10 to 20 mol/L.[686-688] When transferrin arrives at its surface receptor, the complex is transferred to the "labile iron pool"[689] by receptor-mediated endocytosis.[541,688,690,691] This pool supplies iron to cytosolic proteins. The remaining iron is directed to apoferritin for storage as ferritin. When ferritin molecules accumulate, the protein moiety is apparently cleaved, with smaller hemosiderin granules remaining but with greater iron concentrations.[547] Theoretically, these storage forms of iron are inert and do not exert any pathologic damage. However, accumulated hemosiderin granules appear to cause release of hydrolytic enzymes from lysosomes that are toxic to the cell.[692,693]

As iron stores increase from both transfusions and gastrointestinal absorption, transferrin becomes saturated with iron to greater than 90%. In parallel, a circulating pool of non–transferrin-bound or free serum iron is found in iron-overloaded individuals.[546,694-698] Its source is uncertain but presumably reflects expansion of the intracellular labile iron pool, and it is thought to be particularly cardiotoxic.

Cell damage probably occurs as a result of iron-related catalysis leading to oxidation of membrane components.[699,700] Unbound iron induces lipid peroxidation in vitro.[701-703] Peroxidation of mitochondrial membranes and hepatocyte microsomes has been demonstrated in vivo in rats overloaded with iron by parenteral or oral administration[704] and in the spleens of thalassemic patients.[705] Lysosomal leakage of hemosiderin and hydrolytic enzymes may also occur.[706,707] Cultured rat myocardial cells have been used to study the effects of iron deposition.[708] Peroxidation of membrane lipids induces functional abnormalities in cultured myocardial cells that are exacerbated by ascorbic acid (see later), corrected in part by the antioxidant vitamin E, and markedly suppressed by chelation with deferoxamine.[709]

Further evidence in support of the free radical hypothesis stems from measurement of substances that defend against free radical attack. Vitamin E, a potent antioxidant, is decreased in the serum and red cells of iron-overloaded thalassemic patients.[488,710] Both vitamin E levels[711] and total serum antioxidant activity bear strong inverse correlations to the degree of iron overload.[712] Perhaps most intriguing is a correlation between superoxide production in resting neutrophils and serum ferritin in patients receiving multiple transfusions. The observed superoxide generation approaches five times normal in some patients.[713] It should be emphasized, however, that replacement therapy with vitamin E has little or no value in thalassemia. Elimination of iron by chelation is the only way to prevent iron-induced oxidative damage.

Indirect data also suggest that the route of accumulation (i.e., gastrointestinal absorption versus parenteral red cell transfusion) may be an important determinant of iron toxicity.[714,715] Attention must be paid to the contribution of gastrointestinal iron absorption.[666,672] Experiments in rats suggest that oral iron loading leads to more global hepatocyte damage than parenteral loading does.[704] Patients with hereditary hemochromatosis and thalassemia intermedia who do not receive transfusions sustain parenchymal damage entirely from gastrointestinal absorption.[672,716,717] On the other hand, extensive transfusion in patients with hypoplastic anemia is associated with a lower incidence of cirrhosis.[714] Nonetheless, the view that reticuloendothelial iron derived from transfused red cells is innocuous is overly simplistic. There are no reasons to believe that transfusion protocols, designed to maintain a normal hemoglobin level and reduce gastrointestinal iron absorption, will be free of the complications of iron overload.

Clinical Consequences of Iron Deposition. Patients with thalassemia major have traditionally died of the cardiac complications of iron overload.[581] Recurrent pericarditis, distinguished by characteristic pain, fever, and a friction rub, may be the initial manifestation of myocardial iron deposition and occasionally requires pericardectomy to relieve constriction. Ventricular tachycardia and fibrillation or severe refractory congestive heart failure are often fatal.[718]

Cardiac iron deposition has been studied in autopsies of patients with transfusional hemosiderosis and idiopathic hemochromatosis.[719,720] Patients with a history of transfusion of more than 100 units of red cells without chronic blood loss generally exhibit significant cardiac iron deposition. Cardiac hemosiderosis is not observed unless significant iron accumulation has occurred in other organs. Cardiac iron deposits that are grossly visible at autopsy indicate that the patient experienced cardiac dysfunction during life, but severe cardiac dysfunction may also occur in the absence of significant deposits of cardiac hemosiderin.[720,721] Therefore, iron toxicity must be due to a small, highly reactive intracellular iron pool or to the labile pool of non–transferrin-bound iron in plasma. Prevention of cardiac dysfunction therefore requires a reduction in the iron load and persistent presence of a chelator in the blood. Preliminary data suggest that deferiprone, a chelator approved in Europe but not in the United States, removes iron from the heart more effectively than deferoxamine does.[722] In vitro data demonstrate better access to and removal of iron from rat cardiac myocytes by both deferiprone and deferasirox than by deferoxamine.[723] In a gerbil model of iron overload, deferiprone and deferasirox have similar capacity to remove iron from myocytes.[724] The clinical significance of these observations remains to be confirmed.

Cardiac disease in thalassemia and particularly thalassemia intermedia after splenectomy may be unrelated to cardiac iron deposition but instead be due to pulmonary hypertension secondary to platelet activation together with the circulation of erythrocyte membrane fragments and the induction of an hypercoagulable state.[725-727]

Gross anatomic cardiac changes attributable to iron loading include dilation of the atrial and ventricular cavities and overall thickening of the muscle layer resulting in a twofold to threefold increase in heart weight. Microscopic evaluation suggests that iron is first deposited in the ventricular myocardium and later in conduction tissue.[719] Thus, intracavitary endomyocardial biopsy is not useful in these patients as a means of evaluating cardiac iron deposition.[728,729] Supraventricular arrhythmias correlate well with the extent of iron deposition in the atrial myocardium but may occur in its relative absence. Cardiac abnormalities seem to be a function of both the quantity of iron deposited per fiber and the absolute number of fibers affected. Link and colleagues[730] have shown that myocardial cells in culture take up iron if there is no physiologic or pharmacologic chelator present. As iron loading takes place, peroxidation products accumulate and contractility and rhythm are disturbed.[709] This in vitro model parallels concepts developed from clinical findings.

Noninvasive Studies of Cardiac Function. Echocardiography, radionuclide cineangiography, and 24-hour

recording of cardiac rhythm have been used to assess the effects of iron deposition in the heart and evaluate the results of chelation therapy.[731] In general, echocardiography may reveal alterations in cardiac anatomy but little change in cardiac function until clinically evident cardiomyopathy develops.[732-734] Low-dose dobutamine echocardiography is thought by some to be more helpful.[735] Radionuclide cineangiography offers the ability to observe dynamic cardiac function during exercise and may reveal changes in function before the appearance of clinical disease.[734,736-738] Twenty-four-hour recordings of cardiac rhythm in patients with iron overload have demonstrated marked disturbances in most patients older than 12 years regardless of clinical symptoms.[731] As previosuly mentioned, T2$\star$ MRI can be used to assess cardiac iron. It demonstrates that patients with high cardiac iron content are at substantial risk for sudden cardiac decompensation. However, patients with high liver iron and low cardiac iron are also at risk, and liver and cardiac iron correlate poorly, largely because the kinetics of iron flux are different in the two organs. Serial MRI assessment of *both* liver and cardiac iron are required for careful follow-up of thalassemic patients. Box 20-1 summarizes the clinical course of patients before the onset of aggressive chelation programs. The efficacy of future transfusion and chelation programs must be assessed in this context. Considerable data have recently demonstrated the bene-

fits of chelation therapy, both for prophylaxis and for treatment of cardiac disease in patients with iron over-loading (see later).

Hepatic Abnormalities. Liver enlargement, long viewed as a hallmark of thalassemia, is prominent with contemporary transfusion regimens only in patients older than 10 years. Hepatomegaly is due to progressive engorgement of hepatic parenchymal and phagocytic cells with hemosiderin deposits rather than extramedullary hematopoiesis.[739] Hepatic iron stores correlate very well with total body iron stores.[740] In addition, iron deposition induces intralobular fibrosis.[741,742] Intercurrent episodes of hepatitis may lead to marked liver dysfunction and contribute to the development of fibrosis and cirrhosis.[743-745] Liver enzyme levels are rarely elevated in the absence of hepatitis. The concentration of total bilirubin in patients receiving adequate transfusion therapy is seldom greater than 2 mg/dL, 50% or less of which is typically indirect. Recent data clearly demonstrate that chelation therapy reduces the liver iron concentration[740,746-748] and forestalls iron-induced liver damage. Progressive liver disease in patients receiving appropriate therapy is often due to viral hepatitis.[749] A recent study demonstrated the value of interferon and ribavirin in the management of hepatitis C in patients with thalassemia.[749a] Despite expected increases in transfusion requirements because of ribavirin-induced hemolysis, patients tolerated the therapy, the degree of inflammation as measured by alanine transaminase and hepatic biopsy decreased, and the molar efficacy of deferoxamine improved.

Endocrine Abnormalities. Endocrine disorders commonly associated with thalassemia in the United States today are generally thought to be caused by chronic iron loading.[664,669,750,751] Most of the pathologic changes develop slowly and are not usually apparent until the second decade of life. In patients not receiving transfusions, these abnormalities develop more slowly.

Growth and Development. Growth retardation, historically considered a typical finding in thalassemia major,[750] is generally associated with moderate retardation in bone age. Patients undergoing chronic transfusion therapy may be spared growth retardation,[752] which is seen in more than 50% of patients and then not until the second decade of life.[669] Growth retardation is less evident in patients receiving chelation therapy,[752,753] although excessive amounts of deferoxamine can also impair growth.[754,755] Alternative causes should be sought in young thalassemic children who are receiving adequate transfusion therapy and still exhibit significant growth retardation.

Growth retardation may also be associated with evidence of endocrine dysfunction. Impaired growth hormone production has been reported in some patients[756-758] but not confirmed in others.[759] Treatment with growth hormone may accelerate the growth rate, but final height may not be changed.[760] A subset of patients

BOX 20-1	**Cardiac Disease in Patients with Iron Overload**

STAGE I (<100 UNITS TRANSFUSED)

Asymptomatic
Echocardiogram: slight left ventricular wall thickening
Radionuclide cineangiogram: normal
24-Hour electrocardiogram: normal

STAGE II (100-400 UNITS TRANSFUSED)

Asymptomatic or mild fatigue
Echocardiogram: left ventricular wall thickening; left ventricular dilation but normal ejection fraction
Radionuclide cineangiogram: normal at rest but no increase or fall in ejection fraction with exercise
24-Hour electrocardiogram: atrial and ventricular premature beats

STAGE III

Palpitations and/or congestive heart failure
Echocardiogram: decreased ejection fraction
Radionuclide cineangiogram: normal or decreased ejection fraction at rest but a fall in ejection fraction during exercise
24-Hour electrocardiogram: atrial and ventricular premature beats, often in pairs or runs

Adapted from Nienhuis AW, Griffith P, Strawczynski H, et al. Evaluation of cardiac function in patients with thalassemia major. Ann N Y Acad Sci. 1980;344:384-396.

with normal growth hormone production have low serum levels of somatomedin,[761] a factor produced by the liver in response to growth hormone that promotes cartilage growth. Failure of adrenal androgen production may also contribute to growth failure.[762] Thyroid deficiency is an additional factor that may potentially contribute (see later). A thorough search for endocrine dysfunction is warranted in patients with growth retardation because a favorable response to specific replacement therapy may be anticipated.

Puberty. Puberty will occur normally in many patients with β-thalassemia who receive appropriate treatment and is typically seen in those with the least growth retardation. Sexual maturation is variably observed in other patients and is retarded in patients whose transfusion and chelation therapy is inadequate.[763] Failure of patients receiving transfusions to mature sexually may be the first indication of iron toxicity. Breast development in females tends to begin normally, but menarche is frequently delayed until the late teenage years. In many female patients who progress through puberty normally, secondary amenorrhea will develop as a result of progressive iron accumulation.

Failure of patients to develop sexually is not usually related to primary end-organ unresponsiveness.[764,765] Although males tend to have low baseline testosterone levels, the response to treatment with human chorionic gonadotropin is generally normal.[765] Moreover, spermatogenesis correlates directly with the stage of sexual maturation of the patient.[766] Gonadotropins, on the other hand, have been implicated in a number of studies as the primary cause of dysfunction in the hypothalamic-pituitary-gonadal axis.[765,767-770] Although defective ovarian function has been described in some patients,[771] patients who fail to attain puberty or who have experienced regression of secondary sexual characteristics demonstrate blunted responses to luteinizing hormone–releasing factor (LHRF) and follicle-stimulating hormone. Prolactin levels respond normally to thyroid-releasing factor stimulation. Failure of sexual maturation therefore appears to most often be related to hypothalamic-pituitary axis dysfunction, and the anterior pituitary is often loaded with iron.

Although one report suggested preservation of normal gonadotropin production in young patients receiving large amounts of chelation therapy,[766] modification of transfusion schedules and chelation therapy has not yet been found to preserve normal function in many patients. This is a problem of increasing severity as the long-term clinical prognosis for patients improves. In approaching such patients, Modell and Berdoukas[669] have likened the attainment of puberty as a trophy in a race between a patient's physical growth and iron overload. Patients with a constitution that favors tall stature and a rapid growth rate and whose transfusion programs and chelation regimens are adequate are likely to attain puberty. Those who do not require transfusion in the first year of life may also have an advantage. Constitutionally short children and those whose transfusion and chelation regimens are inadequate often fail to "win the race."

For patients with delayed puberty, initial efforts should be devoted to assessment of nutritional status, general health (i.e., presence of hepatitis), and the adequacy of transfusion and chelation therapy. In addition, attention should be paid to the availability of calcium for growth (see later). For those receiving maximal therapy who have delayed puberty and also biochemical evidence of hypothalamic-pituitary axis dysfunction,[772,773] pulsatile gonadotropin-releasing hormone infusions have been used to artificially induce puberty and growth (Chaterjee B: personal communication),[774] although this approach may or may not be successful.[769] More conventional treatment regimens include testosterone or estrogen supplementation after the age of 14 or 15 for those in whom puberty was not achieved or in whom secondary hypogonadism has developed, either clinically or based on loss of response to LHRF.

Thyroid Gland. Even though iron deposition in thyroid parenchymal tissue is often extensive, dysfunction is usually limited to primary subclinical hypothyroidism.[775] In one large series in which simultaneous serum thyroxine and thyroid-stimulating hormone (TSH) levels were obtained in 31 thalassemic patients, mean thyroxine levels were significantly lower (6.2 versus 9.5 μg/dL) and TSH levels were significantly higher (3.2 versus 1.0 μU/mL) than those in age-matched control subjects.[767] In a longitudinal study, serum thyroxine levels declined, whereas TSH secretion increased. Although the means were significantly different, individual patients with thalassemia could not be reliably distinguished from control subjects. Androgen replacement in males may correct abnormalities in thyroid function.[776]

Adrenal Gland. In the adrenal gland, pathologic changes in patients with thalassemia are historically characterized by iron deposition limited primarily to the zona glomerulosa,[544] the site of mineralocorticoid production. Iron deposition in the zona fasciculata may also occur.[669] In one series, normal aldosterone production in response to salt deprivation was achieved only at the expense of a marked increase in serum renin.[761] Basal morning adrenocorticotropic hormone (ACTH) levels measured in prepubertal thalassemic patients were 3 to 10 times normal.[777] Basal glucocorticoid production and response to ACTH and insulin provocation are generally normal in younger patients, although older patients often demonstrate a blunted provocative response.

Pancreas. Diabetes mellitus, a common and often under-recognized complication of thalassemia, is due to both pancreatic hypoproduction[778] and (at least in some patients) insulin resistance.[779] Even in patients between

5 and 10 years of age whose iron burden is approximately 5 to 20 g, fasting blood glucose levels are significantly elevated.[777] When glucose tolerance tests are performed, as many as 50% of thalassemic patients have "chemical diabetes"; the majority of these patients have normal or elevated circulating insulin levels.[779,780] Insulin resistance may predate the onset of glucose intolerance, as revealed by the euglycemic clamp method.[781] In contrast, thalassemic patients who have not received transfusions display accelerated insulin clearance and normal tissue sensitivity.[782] As symptoms of diabetes become evident, insulin output decreases, as occurs in most patients with juvenile diabetes. Glucose intolerance generally correlates with the number of transfusions received, age of the patient, and genetic predisposition.[783]

Parathyroid Glands. Symptomatic parathyroid disease manifested by classic tetany, hypocalcemia, and hyperphosphatemia is said to be an uncommon complication of iron overload.[767,778,783-785] However, the prevalence was 10% in one recent study. Affected patients had severe iron overloading.[786] Subclinical deficiency of parathyroid function is difficult to diagnose. The provocative use of calcium chelates to identify subclinical deficiency of parathormone has been described.[787] Patients with thalassemia major have been reported to show diminished response to a challenge. Although symptomatic parathyroid disease may be rare, more common defects may affect the mobilization of calcium for growth and the preservation of normal serum ionized calcium, which are important in patients with cardiomyopathy or arrhythmia. To complicate matters, deficiency of activated vitamin D may occur, perhaps partially as a consequence of parathormone deficiency. Symptoms of 25-hydroxytachysterol deficiency, which are relieved either by iron chelation therapy or by vitamin D supplementation, have been described in case reports.[788,789] Therefore, careful attention should be paid to calcium, phosphate, and vitamin D intake in patients with growth disturbances and cardiac disease.

Pulmonary Abnormalities

Arterial Hypoxemia and Pulmonary Hypertension. In 1981, Fucharoen and co-workers[790] reported significant arterial hypoxemia in patients with HbE–β-thalassemia, especially in those who had been splenectomized. These authors found circulating platelet aggregates in such patients and successfully used aspirin and dipyridamole to improve oxygenation. Other groups have reported hypoxemia in thalassemia major[791-800] but have related it to changes in ventilatory mechanics, obstructive airway disease, or iron deposition in the lungs. Pulmonary hypertension, possibly associated with thrombocytosis and a general hypercoagulable state,[801] may contribute to right ventricular dysfunction in these patients.[802-807] A more recent multivariate analysis demonstrated that splenectomy was significant correlated with pulmonary hypertension in patients with thalassemia syndromes. Further studies support the role of increased platelet activation as measured by P-selectin[727] and impaired nitric oxide.[808]

Therapy for β-Thalassemia

Transfusion

Choice of Transfusion Regimen. The mainstay of management of severe β-thalassemia remains blood transfusion.[809-816] Transfusion programs have several aims. By increasing the hemoglobin content, transfusions enhance the oxygen-carrying capacity of blood and thereby decrease tissue hypoxia. The concomitant fall in erythropoietin levels blunts the massive erythroid expansion associated with the anemia. Furthermore, improved tissue oxygenation and reversal of the hypercatabolic state promote more normal growth and development. Suppression of erythropoiesis is associated with decreased intestinal iron absorption. These benefits must be weighed against the prospects of excessive iron loading, particularly with more intensive transfusion protocols.

Transfusion management and the optimal maintenance level of hemoglobin have evolved. Wolman and associates[576,655] first recommended a pretransfusion hemoglobin level of 8.5 g/dL. This approach improved survival, but chronic illness, bone disease, and anemic cardiomyopathy persisted. To enhance quality of life, Piomelli and colleagues[580] suggested maintaining the hemoglobin level at greater than 10 g/dL with a mean of 12 g/dL. Such "hypertransfusion," if initiated in the first year of life, promotes normal initial growth and development, limits the development of hepatosplenomegaly, prevents disfiguring bone abnormalities, reduces intestinal iron absorption, and decreases cardiac workload.[817-820]

In 1980, Propper co-workers[821] proposed a "supertransfusion" program with a pretransfusion hemoglobin level greater than 12 g/dL and a mean of 14 g/dL to more effectively eliminate chronic tissue hypoxia. Initial studies reported that the quantity of blood required to maintain a higher hemoglobin level was no greater than that required for maintenance of a lower level because of a decrease in intravascular volume.[821-823] Further data, however, suggested that increasing the pretransfusion hemoglobin level may simply increase the quantity of transfused blood and thus increase iron loading,[669,824] and this regimen is no longer recommended.

Senescence in red cells is a function of cell age. Because the iron content of transfused erythrocytes is independent of cell age, attempts have been made to improve the "quality" of transfused blood by infusing the youngest third of red cells present in whole blood ("neocytes").[818,825] Administration of these cells would be predicted to decrease the transfusion requirement. Neocytes can be readily prepared with automated cell separa-

tors,[826-830] but 3 or more units is required to prepare the equivalent of 1 unit of blood, thus drastically increasing donor exposure for these patients. Although prolonged survival of neocytes has been documented in vivo, the observed sparing of transfusions with such therapy has been disappointing.[831-834] Similarly, methods to remove "gerocytes" (old red cells) from the recipient's circulation at the time of transfusion, though technically feasible, have not been widely applied.[833,835] These approaches should be considered experimental at present.

Although specific practices differ among clinical centers, transfusion is indicated both to correct anemia and to suppress erythropoiesis.[809] After diagnosis, a period of observation should be initiated to determine whether transfusion is required to maintain the hemoglobin level at 7 g/dL or greater. The condition of patients with thalassemia intermedia will be stable without transfusion. If the hemoglobin level falls to less than 7 g/dL, a transfusion program should be initiated to maintain the hemoglobin level at 9.5 to 11.5 g/dL. During the first decade of life, normal growth provides reassurance that the transfusion regimen is adequate. Because the rate of iron absorption parallels the number of nucleated red cells in peripheral blood,[666] adequate transfusion should suppress the nucleated cell count to less than 5 per 100 white blood cells[809]; however, in older patients who received inadequate transfusion therapy early in life, it may not be possible to achieve this level. During the teenage years, growth failure may reflect endocrine dysfunction rather than inadequate transfusions; laboratory investigation and appropriate replacement therapy are then indicated. After the epiphyses have fused and growth is complete, a hemoglobin level of 8.0 of 9.0 g/dL may be well tolerated. If the transfusion requirement exceeds 200 mL of packed red cells per kilogram per year, splenectomy should be considered (see further discussion later).[809] Our current transfusion procedure is outlined in Box 20-2.

Complications of Blood Transfusion. The primary long-term complication of blood transfusion is iron loading and the resultant parenchymal organ toxicity, as discussed earlier. Febrile reactions to leukocyte antigenic determinants and allergic reactions to plasma components are commonly encountered in patients receiving transfusions chronically. The use of prestorage leukoreduction filters has significantly decreased the rate of febrile reactions. Washing of red cells in saline to remove plasma proteins can be beneficial.[836]

Alloimmunization to minor blood group antigens occurs in 20% to 30% of patients[837-840] and may be manifested as delayed hemolysis. Rare circumstances of multiple alloantibodies may be a potentially life-threatening complication in patients with transfusion-dependent β-thalassemia because it may not be possible to find sufficient appropriately matched blood. Alloimmunization is frequently a less significant problem in patients in whom transfusion is initiated before the age of 3 years.[837-840] The

---

BOX 20-2	Guidelines for Chronic Transfusions in Patients with Thalassemia

1. Determine the blood type of the patient completely to identify minor red cell antigens before the first transfusion.
2. Keep the pretransfusion hemoglobin level between 9.5 and 11.5 mg/dL as needed for suppressing ineffective erythropoiesis and maintaining a reasonable sense of well-being.
3. Give 10 to 20 mL/kg of leukocyte-poor, washed, and filtered red blood cells at a maximum infusion rate of 10 mL/kg over a 2-hour period; transfuse more slowly in patients with heart disease.
4. Avoid raising the post-transfusion hemoglobin level to greater than 16 g/dL.
5. Choose a transfusion interval to maintain pretransfusion levels as outlined above (3 to 5 weeks, depending on individual patient needs). (*Comment*: Some patients tolerate slightly lower pretransfusion hemoglobin levels and need 5 weeks between transfusions, whereas others feel best coming every 4 weeks. Some prefer receiving fewer units and coming every 3 weeks. Some of the younger patients whose weight would require between 1 and 2 units receive a transfusion every 3 or 4 weeks and alternate between 1 and 2 units per transfusion.)
6. Pretransfusion laboratory tests include a complete blood cell count, differential, crossmatch, and red cell antibody screen.
7. Height and weight are recorded at least every 3 months.
8. Liver function (AST, ALT, bilirubin, and LDH) is evaluated every 3 months and serum ferritin every 3 to 6 months. A deferoxamine (Desferal) challenge test is performed at irregular intervals to measure the appropriate Desferal dosage and chelatable iron stores.

ALT, alanine transaminase; AST, aspartate transaminase; LDH, lactate dehydrogenase.

---

benefit of extended red cell phenotyping to minimize alloimmunization has been debated in the literature,[841,842] but crossmatching for the rhesus and Kell systems from the time of initial transfusion may decrease the incidence of alloimmunization.[839] Detailed red cell phenotyping should be performed in all patients with newly diagnosed thalassemia before transfusion. The average transfusion regimen in most centers is 12 to 15 mL of leukocyte-poor red cells per kilogram per month. Autoimmune hemolytic anemia is a rare but perilous complication of allosensitization. It must be managed aggressively to prevent dangerous iron overload.

Transmission of viral infections by transfusion remains a serious and significant problem in patients receiving transfusions chronically in countries in which the safety measures of volunteer donors, detailed donor questionnaires, and serologic and nucleic acid testing are

not used. In one study, approximately 25% of transfusion-dependent patients with thalassemia had been exposed to hepatitis B, 80% of whom had clinical evidence of hepatitis.[843] Exposure to hepatitis C, with an incidence of approximately 6% per transfusion, was nearly inevitable in thalassemic patients receiving regular transfusions, and this agent accounts for the active hepatitis seen in many older patients. Identification of the hepatitis C agent and the development of a serologic test to screen donors have greatly minimized this risk,[844,845] but the infection can lead to fibrosis, cirrhosis, and hepatic carcinoma if untreated.[846-848] Treatment with interferon alfa and ribavirin is indicated and has now been demonstrated to be safe in patients with thalassemia despite the increased rate of hemolysis and transfusion secondary to ribavirin.[749a] Some studies have suggested that iron overload inhibits a therapeutic response,[849-852] but others have shown little or no such effect.[853,854] A minority of patients with thalassemia have become infected with human immunodeficiency virus, and the rate of progression to symptomatic acquired immunodeficiency syndrome has been proportionately lower than in most infected populations.[855] Although death and complications from these illnesses are uncommon in this patient population, it is prudent to exercise precautions. The most important consideration is the use of blood products screened for the presence of potential infectious agents. Patients should be immunized against hepatitis B upon diagnosis or if they have not acquired immunity. When practical, exposure to multiple donors or units of blood should be minimized. In this regard it is important to recognize that the use of washed or frozen red cells may lead to an increase in the number of transfused units.

Splenectomy

Splenectomy may be indicated in some patients in an attempt to decrease transfusion requirements. The role of the spleen must be carefully considered in patients who are treated with transfusion, iron chelation programs, or both. The spleen serves both as a scavenger by increasing red cell destruction and iron redistribution and as a storage depot by sequestration of the released iron in a potentially nontoxic pool. Unfortunately, splenic iron may equilibrate with other iron pools throughout the body. In one uncontrolled study, three splenectomized patients exhibited cirrhosis and massive iron deposition, whereas slightly younger patients with an intact spleen had only iron deposition.[856] Risdon and colleagues,[739] however, observed no difference between splenectomized and nonsplenectomized patients with regard to pathologic changes in the liver. If the spleen acts primarily as a storage depot for excess iron, premature removal could theoretically be detrimental. On the other hand, if the splenic pool is a particular target for deferoxamine, the beneficial effects of aggressive chelation therapy might be diminished by preferential removal of iron from this relatively innocuous pool. Perhaps most important is the feasibility of achieving negative iron balance with conventional chelation regimens (see later). Eventually, an increased requirement for transfusion because of hypersplenism perturbs the balance and contributes to iron loading.[857]

Splenectomy may be indicated in the management of patients with severe β-thalassemia. Massive splenomegaly with hypersplenism causing leukopenia, thrombocytopenia, and an increasing transfusion requirement is often seen in young patients whose transfusion regimens are sporadic. Early splenectomy is often required. The development of splenomegaly is delayed in patients who are receiving a high number of transfusions.[858] Several factors should be considered in the decision to remove the spleen. Modell[669,859,860] carefully documented the annual blood requirement of splenectomized patients with thalassemia major and suggested that the spleen be removed if the observed requirement exceeds that predicted by 50%. Data from other investigators suggest that the benefits of splenectomy on iron balance are realized if the transfusion requirement exceeds 200 to 250 mL of packed red cells per kilogram per year with a minimum hemoglobin level of 10 g/dL.[857,861] Because a huge spleen, irrespective of functional hypersplenism, may account for a large fraction of the total blood volume, its removal often leads to a marked, though transient reduction in the patient's requirement for blood.[862,863] Most patients show a moderate, but significant reduction in their requirement for transfusion to the predicted 200 mL of packed red cells per kilogram per year,[859,860] and it remains stable for many years.[864]

The immediate surgical risk accompanying splenectomy is minimal for experienced practitioners, although reports of acute portal vein thrombosis are increasingly being recognized. There is some evidence that iron overload itself may inhibit the immune response.[865,866] Infections with *Yersinia* are sometimes observed in patients with iron overload.[867] The potential for overwhelming infection by *Diplococcus pneumoniae*, *Haemophilus influenzae*, or *Neisseria meningitidis*[868-870] should always be considered by the attending physician. Because removal of the spleen may blunt the primary immune response to encapsulated organisms, delay of splenectomy until after approximately 5 years of age is preferable. Patients should be immunized with polyvalent pneumococcal, meningococcal, and *H. influenzae* vaccines.[871-874] Supplemental prophylactic oral penicillin may also be used to prevent colonization by strains not covered by vaccines,[809] particularly in young children. Illnesses accompanied by high fever of uncertain cause should be treated aggressively with parenteral antibiotics until bacterial culture results are available. Patients in regions endemic for malaria should receive prophylactic treatment.[860] Infections appear to be significant causes of morbidity in HbE–β-thalassemia.[875]

Red cell survival usually increases immediately after splenectomy.[862] The peripheral blood smear may reveal increased numbers of hypochromic, microcytic, and

nucleated red cells. Platelet counts greater than 10^6 are often seen, although correction of anemia by transfusion generally results in suppression of platelet production.[494] White blood cell counts of 15,000 to 20,000 are common; the differential is usually normal.

As discussed in more detail previously, arterial hypoxemia and evidence of pulmonary vascular disease have been reported in patients with thalassemia, and it has been suggested that splenectomy may exacerbate these problems.[790,802] Accordingly, splenectomized patients should be examined carefully for these findings. Because thrombocytosis may be an inciting factor,[802,876] prophylaxis with low-dose aspirin may be considered, although effective transfusion to correct anemia is probably the best form of preventive therapy.

Chelation Therapy

Progressive iron overload is the life-limiting complication of transfusion therapy. In the absence of adequate chelation, cardiac dysfunction ends the life of a thalassemic patient receiving transfusions during the teenage years. Regular chelation with the drug deferoxamine has proved remarkably effective in reducing the iron burden of patients receiving transfusions. Cardiac disease is delayed or prevented, susceptibility to infection is reduced,[876] and life expectancy is significantly extended; nonetheless, endocrine dysfunction may develop and persist. Unfortunately, effective use of deferoxamine requires strict compliance to subcutaneous administration via a mechanical pump. The lack of oral absorption of the drug and its short serum half-life dictate this cumbersome route of administration. Recently, two oral iron chelators have been studied. Deferiprone is approved in more than 40 countries but not approved by the Food and Drug Administration (FDA) in the United States. Deferasirox was approved in the United States and many other countries in 2004. Data on each of these chelators will be reviewed.

Deferoxamine. Deferoxamine has, until very recently, been the only approved iron chelator in the United States. The drug is a hexavalent hydroxylamine with a remarkable affinity for iron. It binds metal iron stoichiometrically with a binding ratio of deferoxamine to iron of approximately 1:1. Deferoxamine enters cells, chelates iron, and appears in serum and bile as the iron chelate product feroxamine.[699]

Humans have no intrinsic mechanism for excreting excess iron. Iron available for chelation is thought to be derived from the "labile iron pool"[689]; the size of this pool is directly related to the total body iron burden.[877,878] Non–transferrin-bound plasma iron should also be available for chelation.[695,696] A fraction of reticuloendothelial iron salvaged from red cells may likewise be chelated,[879] perhaps only when stored as ferritin.[880] Urinary iron excretion appears to be proportional to marrow erythroid activity and is diminished by transfusion.[881] Net iron loss, however, is not compromised because the diminution in urinary iron excretion is balanced by increased fecal excretion of iron.[880,881] In patients with primary hemochromatosis, in whom iron deposition is seen predominantly in parenchymal cells and erythropoiesis is normal, administration of deferoxamine results primarily in enhanced fecal iron excretion.[699] Thus, the site of iron removal is influenced by the transfusion schedule, but no data are available regarding the influence of hemoglobin level on prevention or removal of cardiac iron deposits. In brief, chelation from a small labile pool that is in equilibrium with a much larger storage pool in the organs eventually reduces stored iron, but at different rates from different organs because of variations in efflux rates.

Deferoxamine Chelation Regimens. Deferoxamine is active when administered by the intramuscular, subcutaneous, or intravenous routes. After its introduction in 1962, the drug was given by the intramuscular route until the late 1970s. This regimen was only partially successful because rapid clearance from plasma via metabolism and biliary and urinary excretion[699] led to insufficient iron removal to achieve a negative net iron balance in most patients.[882] Supplemental oral administration of ascorbic acid enhanced urinary excretion (see later),[883] but just 14 to 16 mg of iron could be removed per day, even from patients with severe hemosiderosis. Adults receiving full transfusion support require removal of more than 35 mg/day to have a negative net iron balance.[882] Continuous intravenous infusion significantly enhances iron excretion,[882,884] presumably because of exchange between deferoxamine and tissue iron pools. Substantial plasma and tissue drug concentrations can be attained by continuous subcutaneous administration via a pump mechanism.[885] Iron excretion is markedly enhanced in comparison to the intramuscular route,[882,885-887] and net negative iron balance can be achieved in most patients older than 3 or 4 years with an iron burden of 4 to 5 g.[817,824,885]

A typical regimen involves the administration of 30 to 40 mg/kg of drug overnight (8 to 12 hours) at least 5 to 6 nights per week; the patient thereby avoids the need to carry the pump during the daytime hours. Obviously, such a program is a compromise in that optimal management demands drug infusion every hour of every day, a schedule met with poor compliance, particularly among teenagers. Data now show that regular use of deferoxamine, if started by the age of 3 or 4, forestalls significant iron overload. It also promotes elimination of excess iron in patients if started after a substantial transfusional iron burden has already developed.[748,888-892] It is generally agreed that treatment should be initiated by 5 years in transfusion-dependent patients; some advocate treatment by the age of 3.[812,824,893-895] It has been argued that irreversible tissue damage, particularly to endocrine glands, occurs at a very low iron burden during the first years of life. However, the toxicity of deferoxamine is most significant in patients with a low iron burden (see later). Indeed, growth retardation and other toxic effects have been documented in children younger than 3 years who

are given high doses of the drug.[664] A test infusion of deferoxamine may be used to determine whether mobilizable iron is present.[809,812]

Periodic intravenous administration allows the use of higher doses (6 to 10 g/day); local reactions at the site of administration limit the tolerable subcutaneous dose to 2.0 to 2.5 g/day. By extending the time of infusion and increasing the drug dose, iron removal can be greatly enhanced over that achievable with conventional subcutaneous therapy. Chelation with high drug doses by the intravenous route is capable of reversing established cardiac disease in some patients who continue to require transfusions (Nienhuis AW: unpublished observations, 1990).[737,813, 896,897] This regimen is most effective when instituted while the patient's heart is still compensating, either with or without cardiac medications.

Efficacy of Deferoxamine Chelation. Clinical experience has shown subcutaneous deferoxamine administration to be effective in preventing cardiac disease and prolonging the life of thalassemic patients receiving transfusions.[748,891,898-900] Life expectancy was previously approximately 16 years, with rare patients surviving into their mid-20s.[581,718,901] Since the introduction of subcutaneous deferoxamine therapy, the projected life expectancy extends into the middle of the fourth decade.[902] Several studies have also documented sparing of cardiac disease in patients receiving adequate chelation therapy.[748,891,903,904] Figure 20-31 shows a striking comparison between two groups of patients; one group received adequate chelation therapy, whereas the other group was poorly compliant. Onset of cardiac disease has been observed in the chelated group in whom negative iron balance was achieved,[903] but the dose of the drug used was relatively low.
FIGURE 20-31. Cardiac disease–free survival of patients with respect to the serum ferritin level. The *circles* depict cardiac disease–free survival of patients with less than 33% of ferritin measurements greater than 2500 ng/mL; *squares*, patients with 33% to 67% of measurements greater than 2500 ng/mL; and *triangles*, patients with more than 67% of measurements greater than 2500 ng/mL. *(From Olivieri NF, Nathan DG, MacMillan JH, et al. Survival in medically treated patients with homozygous beta-thalassemia. N Engl J Med. 1994;331:574-578. Copyright 1994, Massachusetts Medical Society.)*

Unfortunately, the cohort of patients in whom subcutaneous administration of deferoxamine was initiated in their late first decade of life after significant iron deposits had accumulated continues to exhibit endocrine dysfunction and growth retardation.[892] Glucose intolerance and diabetes are observed even in patients receiving adequate chelation therapy,[905] although the incidence is reduced.[748] There is scant evidence that deferoxamine can reverse established endocrine dysfunction. It remains to be determined whether patients in whom a regimen of subcutaneous deferoxamine is started at a very young age will fare better with respect to growth, sexual development, and endocrine function. Because this cohort of patients is just now entering their teenage years, information on this point may become available in the near future.

Toxicity of Deferoxamine. At high doses of deferoxamine, significant side effects are seen.[699,809] Local erythema may occur at the site of infusion and contribute to an inflammatory response characterized by multiple subcutaneous nodules. These local reactions can be partially suppressed by the inclusion of 5 to 10 mg of hydrocortisone in the deferoxamine solution.

Of particular concern is neurosensory toxicity observed at high doses. Several large series report a 30% to 40% incidence of high-frequency hearing loss, which may become symptomatic.[906-910] Reversal with discontinuation of the drug has been reported, although other patients have experienced persistent hearing loss. Ocular toxicity has also been reported.[906,911] Progressive visual failure with night and color blindness and field loss has also been described[912] but may be not be related to chelation therapy.[913] In fact, in one study iron dysfunction was thought to be related to failure to take deferoxamine.[914] Reversal after discontinuation of deferoxamine has also been reported.

The neurosensory complications of deferoxamine are dose related and inversely correlated with the body iron burden. Patients with heavy iron loading are relatively protected, but those with lower iron burdens who receive aggressive chelation therapy may be more susceptible to these toxic effects.[909,915,916] Administration of deferoxamine to patients with rheumatoid arthritis and normal iron stores has induced neurologic deficits, including confusion, nausea and vomiting, and coma.[915,917] These findings suggest that the toxicity is caused by free drug, which may chelate other metal irons.[910] Alternatively, deferoxamine may reduce the concentration of iron in neurosensory cells below a threshold needed for normal function. These serious complications necessitate careful monitoring of patients receiving deferoxamine. Young children and individuals from whom the majority of iron has been removed by chelation are particularly susceptible to these effects. The occurrence of complications is most likely in patients receiving continuous intravenous infusions of more than 50 mg/kg/day. Formal audiometry and ophthalmologic examination should be performed at

6-month intervals. The use of a test infusion to assess the ability of deferoxamine to mobilize iron, as advocated by Fosburg and Nathan,[809] may help in avoiding toxicity.

Deferoxamine is normally used by microorganisms to facilitate iron uptake.[699,918] *Yersina enterocolitica*, for example, uses deferoxamine in this manner.[859] Although it is associated with low virulence in humans, serious *Y. enterocolitica* infections have been reported in treated patients.[919,920] Mucormycosis has also been reported in patients undergoing hemodialysis who receive deferoxamine.[921] Of interest is the observation that iron chelators have profound in vitro effects on T-lymphocyte function.[809,922-927] Whether these effects can be put to practical use is not known.[926]

Additional rare complications have been associated with high-dose deferoxamine. Pulmonary infiltrates and respiratory insufficiency have been reported in eight patients[928,929] and in iron-loaded mice.[930] Curiously, deferoxamine also protects the developing lung[931]; therefore, the view that deferoxamine causes pulmonary toxicity in the treatment of iron overload is controversial.[932] Indeed, iron overload is thought to contribute to pulmonary disease in thalassemia,[802] although the latter is complex and probably also related to pulmonary vascular obstruction associated with chronic thrombocytosis.[803,876] Acute and chronic renal decompensation has likewise been described.[803,876,933-935] Growth failure and skeletal changes have been reported as well.[936,937]

The array of potential side effects should not obscure the finding that deferoxamine has proved to be very safe in the vast majority of patients. Many of the side effects have been seen only at higher intravenous doses or in patients with a low iron burden. Although careful follow-up is warranted, patients can be reassured that deferoxamine therapy is both remarkably effective and generally quite safe. Indeed, methods have been designed to permit chronic intravenous infusion.[938-940] The major limitation of deferoxamine use is compliance and the serious problems faced by patients and their families as they deal with this lifesaving but onerous therapy.[941-943]

Deferiprone. Deferiprone, L-1-(1,2-dimethyl-3-hydroxy-pyridin-4-one), is a bivalent iron chelator initially synthesized by Hider and colleagues.[944] It was briefly licensed to Ciba-Geigy (now Novartis) but abandoned by the company in 1993 because of its low therapeutic index in non–iron-overloaded animals, its poor stoichiometry (three molecules of drug are required for binding of each iron atom),[945] and its rapid removal from the circulation.[946,947]

Efficacy of Deferiprone Chelation. Deferiprone was first investigated in uncontrolled clinical trials by a group at the Royal Free Hospital in London.[948] These trials were followed by two studies by Olivieri, Brittenham, and their colleagues,[949,950] who measured iron stores by liver biopsy and SQUID in patients treated with deferiprone. Their initial results, published in 1995, were encouraging.[949]

The drug appeared to reduce or maintain liver iron levels in patients with thalassemia who were receiving many transfusions.[951] In a second study, hepatic iron levels were not reduced below their starting points or actually increased to a value considerably above their starting points in a substantial fraction of deferiprone-treated patients.[950] In addition, increased hepatic fibrosis appeared to have developed in some of the deferiprone-treated patients but none of the deferoxamine-treated patients (who had much lower liver iron levels on average). Other studies have confirmed that iron stores, measured by liver biopsy, are not effectively reduced by deferiprone.[952,953] The influence of the drug on hepatic fibrosis remains uncertain.[952,954,955] Recent published studies of deferiprone have been based on the level of serum ferritin as an index of effectiveness, but such studies[956-958] are unreliable. Thus far the drug has been inadequately assessed.[959] Further studies of deferiprone are warranted. The drug may play a role in shuttling iron within membranes and within intracellular pools.[960,961] More recent studies, retrospective, prospective, and epidemiologic, provide some important data suggesting that deferiprone alone or in combination with deferoxamine may provide some important cardioprotective effect.

Toxicity of Deferiprone. Administration of deferiprone is associated with severe adverse side effects, including idiosyncratic agranulocytosis in 0.5% to 1% of patients and neutropenia in up to 5% of patients. Other complications include arthropathy, zinc deficiency, gastrointestinal symptoms, and abnormal liver function test results.[962,963] Until the risk-to-benefit ratio of deferiprone is established by additional clinical trials in which iron stores are measured, compliant patients should be advised to continue an effective deferoxamine chelation program.[697,963,964]

Deferasirox. Deferasirox, known in original studies as ICL670, produced promising results in early preclinical trials[965] and was approved by the FDA in 2004. Deferasirox is a tridentate chelator in a class of compounds known as 3,5-bis-(orthohydroxyphenyl)-1,2,4-triazoles. Therefore, two molecules of desferasirox are required to bind one molecule of iron. After an oral dose the drug is promptly absorbed, persists in blood with a half-time of 8 to 16 hours, and excretes iron largely in feces.

Efficacy of Deferasirox Chelation. In short-term dose-finding clinical trials, the drug removed an amount of iron that would be expected to be delivered in a standard transfusion regimen.[966] It has been extensively studied in preclinical[967] and phase I, II,[968,969] and III[970,971] studies. The phase III study in patients with thalassemia demonstrated no inferiority to deferoxamine at only at the higher deferasirox doses of 20 and 30 mg/kg/day. Further study has demonstrated that the efficacy of deferasirox is related to ongoing transfusional iron burden and that this factor should be carefully monitored in patients.

FIGURE 20-32. Kaplan-Meier survival curves, by birth cohort, of 977 patients from seven Italian centers participating in a natural history study by Borgna-Pignatti and colleagues. Statistically significant improvements in survival were demonstrated overall (*P* < .00005) and in later cohorts (*P* = .024). *(From Borgna-Pignatti C, Rugolotto S, De Stefano P, et al. Survival and complications in patients with thalassemia major treated with transfusion and deferoxamine. Haematologica. 2004;89:1187-1193.)*

Toxicity of Deferasirox. Deferasirox has generally been well tolerated in the clinical trial setting. Mild gastrointestinal adverse events and rashes were the most common toxicities, and discontinuation of the study drug because of adverse events was rare. Mild increases in creatinine occurred, and in a small number it increased above the upper limit of normal. There were no reports of progressive or severe renal failure. Of more than 800 patients treated, none have had significant myelosuppression.[967-969]

Survival

There has been a marked improvement in the survival of patients with thalassemia major. In a cohort of U.S. patients born from 1960 to 1976, the median survival was 17.1 years. In Italy, 50% of patients died before the age of 12 years in the late 1970s. Borgna-Pignatti and co-authors[972] reported on more than 1000 patients born since 1960 and demonstrated a statistically significant improvement in survival in each of the more contemporary cohorts (Fig. 20-32).

Vitamin Supplementation

Ascorbic Acid. The role of ascorbic acid in iron metabolism and chelation therapy is complex and controversial.[699,973] Tissue deficiency of vitamin C often develops in patients with hemosiderosis because of accelerated catabolism; frank scurvy is documented in individuals with marginal dietary intake.[974-977] Administration of vitamin C significantly augments iron excretion in response to deferoxamine, particularly in patients who have vitamin C deficiency. Serum iron and ferritin levels may also rise.[881,977,978] Ascorbic acid retards the rate of conversion of ferritin to hemosiderin[979,980] and presumably allows more iron to remain in a chelatable form.

Unfortunately, ascorbic acid also enhances iron-mediated peroxidation of membrane lipids[981,982] and has been shown to increase iron-induced membrane damage in cultured myocardial cells.[709] It has also been observed that patients with iron overloads who are receiving vitamin C may experience cardiac dysfunction that is reversed when the supplementation is discontinued.[983,984]

Some investigators have suggested giving low doses of ascorbic acid (3 mg/kg) at the start of each subcutaneous infusion of deferoxamine. The chelator should be able to block the deleterious effects of ascorbic acid on lipid peroxidation of cellular organelles in vitro. Others avoid using vitamin C in patients with iron overload and argue that iron depletion can be achieved without supplemental vitamin C. Patients with significant iron burdens should be cautioned against self-administration of substantial amounts of ascorbic acid because abrupt cardiac deterioration has been observed in this setting (Nienhuis AW: unpublished observations, 1990).

Vitamin E. Deficiency of vitamin E has been noted in many patients with thalassemia major receiving transfusions chronically.[711,712,884,985,986] It may contribute to hemolysis as a result of red cell membrane damage.[488,710] α-Tocopherol has long been considered to be a potent antioxidant that protects membrane lipids from attack by free radicals formed when excess iron is present. Deficiency in the neonatal period[987] or deficiency caused by malnutrition is associated with varying degrees of hemolysis. Hemolysis and the characteristic increased red cell susceptibility to in vitro hydrogen peroxide are readily reversed by the administration of supplemental vitamin E. Of interest, supplemental iron administration increases the hemolytic rate, even in nonthalassemic patients with vitamin E deficiency.[987] In patients with iron overload, supplemental vitamin E may lessen iron-mediated cellular toxicity. One study in experimental animals suggests that vitamin E may also inhibit deferoxamine-induced urinary iron excretion.[988] Although vitamin E is used clinically, the efficacy of this therapy remains to be demonstrated.

Folic Acid. Megaloblastic anemia, which is almost invariably due to folic acid deficiency, may occur in patients with severe β-thalassemia.[989-991] In contrast, vitamin B_{12} deficiency is extremely rare in thalassemic patients.[991] Folic acid deficiency is thought to develop as a result of decreased absorption, low dietary intake, and the enormous demand of bone marrow expansion. Most patients benefit from daily folic acid administration (1 mg), although patients receiving adequate transfusions to suppress erythropoiesis and those living in countries where folic acid is added to many breads and cereals probably do not require supplementation.

Trace Metals. Trace metal deficiency associated with thalassemia or aggressive chelation therapy is not commonly observed.[699,992] Zinc deficiency (acrodermatitis

enteropathica) has been reported in a patient receiving diethylenetriaminepentaacetic acid for chelation.[993] The reversible toxic effects seen with high-dose deferoxamine chelation may reflect trace metal deficiency or intracellular chelation of a trace metal. Newer techniques to analyze trace metal concentrations may reveal subtle deficiencies; yearly screening for zinc deficiency is appropriate, but supplementation is not usually required.

Allogeneic Bone Marrow Transplantation

Successful cure of β-thalassemia by bone marrow transplantation was first reported by Thomas and associates in 1982.[994] Subsequently, a number of centers have explored the use of this modality as definitive therapy for β-thalassemia. The most extensive published experience with bone marrow transplantation in β-thalassemia is that of Lucarelli and co-workers in Italy.[995-999] The results of their early attempts to use transplantation in this patient population were discouraging.[996] The preparative regimens used were often ineffective and associated with graft failure, toxicity, and high mortality. Their recent experience is considerably more promising.[999] Patients were analyzed to identify clinically important variables predictive of transplant outcome. The probability of survival was decreased in patients with poor chelation status, hepatomegaly (>2 cm), and portal fibrosis. The probability of event-free survival was reduced in the presence of hepatomegaly. Risk factors for hepatomegaly and portal fibrosis were used to divide patients into three classes: class 1, absence of both risk factors; class 2, one risk factor; and class 3, both risk factors. However, such classification of patients may be difficult to reproduce (i.e., hepatomegaly of ≤2 cm and a history of adherence to chelation therapy). The most recent data from Lucarelli for class 3 patients younger than 17 years who received HLA-identical matched sibling donor transplants demonstrated significant improvement with the addition of hydroxyurea, azathioprine, and fludarabine to the previous regimen of cyclophosphamide and busulfan. In the 33 patients treated with the new protocol (protocol 26), the survival rate was increased to 93% and the rate of graft rejection decreased from 30% to 8%.[1000] Adults treated with protocol 26 demonstrated an improved thalassemia-free survival rate of 62% to 67%, and transplant-related mortality was decreased but still significant at 27%, down from 37%.

One of the major reasons for failure of bone marrow transplantation in patients with thalassemia may be the unpredictable pharmacologic effects of the busulfan used in most preparative regimens. Hyperabsorption of the drug is associated with hepatic veno-occlusive disease and hypoabsorption with recurrent thalassemia. Improved control of busulfan levels during induction may provide better clinical results.[1001] Whatever the event-free survival estimates, bone marrow transplantation is the only viable option for patients who cannot or refuse to adhere to a well-administered transfusion and chelation program.[1002]

On the basis of available data, bone marrow transplantation may be recommended to patients receiving adequate chelation with no evidence of liver disease. Many of these patients can be cured. Although most such patients are very young, age does not appear to be a significant variable in determining outcome. Chronic graft-versus-host disease is still a potential long-term complication of successful allogeneic transplantation. A current limitation to the general applicability of this therapy is the availability of a related, HLA-matched donor. Only one in four siblings on average will be HLA identical. Improved management of graft-versus-host disease and the development of technologies for bone marrow transplantation from unrelated donors may expand the pool of potential donors in the near future. Some encouraging results have recently been reported.[1003] The use of cord blood stem cells may also extend the donor pool.[1004,1005]

Pharmacologic Manipulation of Hemoglobin F Synthesis

The interaction between β-thalassemia and genetic syndromes that increase γ-globin synthesis has illustrated how even small increases in γ-globin production lead to a significant improvement in the effectiveness of red blood cell production in patients with thalassemia. Although steady-state production of HbF is a genetically determined trait,[12] perturbations in erythropoiesis may be associated with an increased capacity for HbF synthesis. Treatment of experimental animals or patients with a variety of cytoreductive agents, including 5-azacytidine (5-Aza), hydroxyurea, vinblastine, and cytosine arabinoside, leads to an increase in production of HbF.[1006-1016] Although the precise mechanism of action of these drugs remains incompletely defined, the increased capacity for γ-globin synthesis appears to be linked to rapid erythroid regeneration. Consistent with this hypothesis, hematopoietic growth factors that promote the expansion and maturation of erythroid precursors, including erythropoietin,[1017-1019] interleukin-3,[1018-1020] and granulocyte-macrophage colony-stimulating factor,[1018] have also been shown to enhance HbF synthesis in primate models. Of particular interest is the observation that infants delivered of diabetic mothers exhibit a delayed switch from γ- to β-globin.[1021] Levels of butyric acid derivatives are elevated in the serum of these mothers and their infants before birth. Similarly, patients with metabolic disorders associated with increased levels of short-chain fatty acids also have elevated HbF levels.[1022] Infusions of sodium butyrate or α-aminobutyric acid into fetal sheep markedly delay the perinatal switch,[1023] whereas infusions in primates lead to activation of the γ gene (McDonagh KT, Bodine DM, Nienhuis AW: unpublished observations).[1024,1025] It has been proposed that butyrate, propionate, or the metabolite acetate promotes increased γ-globin expression by acetylation of histones and alteration of chromatin structure, but other mechanisms cannot be excluded.[1026,1027] A flurry of articles have described the

results of treatment of patients with sickle cell anemia with butyrate or its derivatives.[1028-1033] One patient[1029] had a sustained increase in hemoglobin, and healing of leg ulcers without an increment in circulating hemoglobin has also been observed.[1032] A recent report cited a sustained increase in HbF in sickle cell anemia.[1034,1035] Caution must be exercised, however, because high doses of butyrate are associated with neurotoxicity in simians.[1036]

The most extensive experience with pharmacologic manipulation of HbF synthesis in patients has involved administration of hydroxyurea to patients with sickle cell disease (Dover GJ: personal cummunication).[1012,1037-1041] In this population, the majority of patients appear to respond to the drug with a twofold or greater increase in HbF levels over their baseline. In many patients, HbF levels between 10% and 15% of total hemoglobin are seen. This increase reflects both augmented production and enhanced survival of HbF-containing cells. The clinical results in patients with sickle cell anemia are impressive as described in Chapter 19. However, the results in patients with thalassemia have been disappointing thus far.[1014]

A response to 5-Aza has been seen in several patients with thalassemia[1007,10427,1043] (Fig. 20-33). The dramatic increases in HbF levels associated with administration of this drug may result from a combination of cytotoxicity and inhibition of postsynthetic methylation of DNA.[1043-1047] Global demethylation of DNA, including the γ-globin gene, is observed after the administration of 5-Aza. Despite its effectiveness, the use of 5-Aza in the treatment of hemoglobinopathies has been limited by concerns about its known carcinogenic potential,[1048-1050] as well as the demonstrated effectiveness and safety of current treatment strategies involving transfusion and chelation. Because response to the drug is short-lived, chronic therapy would be required.

Treatment of β-thalassemia with busulfan (Myleran) has been reported in two patients in China.[1051] Combinations of agents, notably erythropoietin and hydroxyurea, often enhance HbF production in experimental animals[1019,1052] and have shown promise in preliminary trials in sickle cell patients (Rodgers GP: personal communication). Undoubtedly, the response of individual patients to these medications will be influenced by their endogenous, genetically determined capability for γ- and β-chain synthesis.[1053,1054]

Gene Therapy

As a result of advances in molecular biology, treatment of hematologic disease through the introduction of new genetic material into bone marrow stem cells is a goal for the foreseeable future.[1055-1058] Application of somatic gene therapy to the treatment of hematologic diseases requires improved efficiency of gene delivery, regulated and sustained expression of the introduced genes, and biologic studies demonstrating expression of the foreign gene. Although active research is ongoing, experimental shortcomings in all these aspects presently preclude the use of gene therapy for the management of thalassemia or sickle cell anemia.

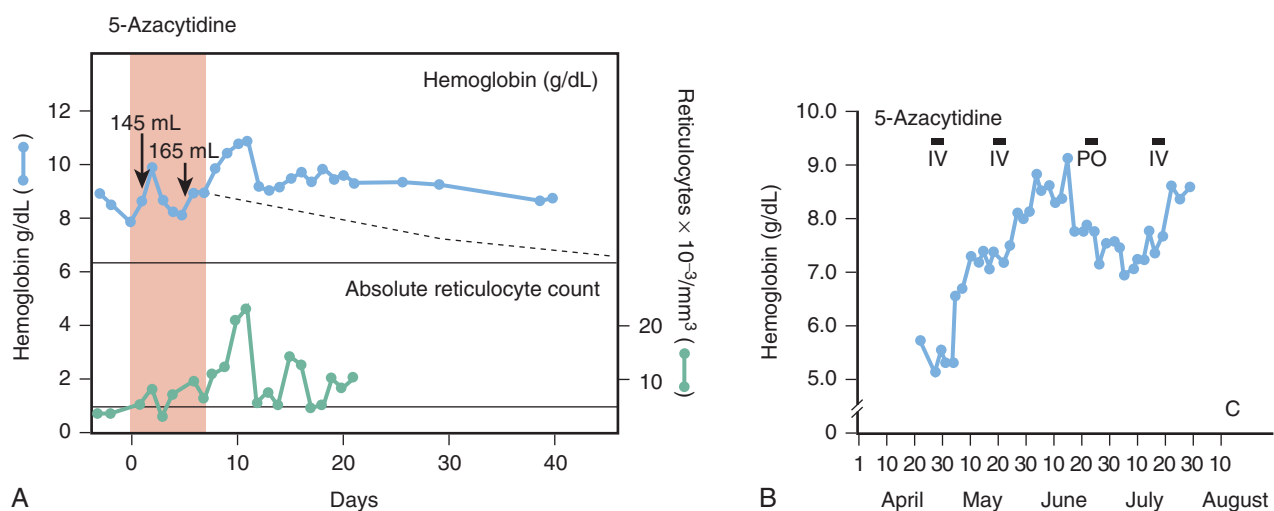
Correction of thalassemia by gene transfer will necessitate the introduction of a normal β-globin gene into pluripotent hematopoietic stem cells.[1055-1057] Experimen-


FIGURE 20-33. **A,** Effects of 5-azacytidine on erythropoiesis in a patient with severe homozygous β-thalassemia after a single administration of the drug by continuous infusion over a period of 7 days. Two small blood transfusions were administered on days 2 and 5. The *dashed line* indicates the projected hemoglobin concentration and reticulocyte count in this patient without treatment based on clinical records. **B,** Effects of sequential courses of treatment with 5-azacytidine in a patient with β-thalassemia who had severe cardiomyopathy and alloimmunization. *(A, Adapted from information appearing in Ley TJ, DeSimone J, Anagnou NP, et al. 5-Azacytidine selectively increases gamma-globin synthesis in a patient with beta thalassemia. N Engl J Med. 1982;307:1469-1475. Reprinted by permission from The New England Journal of Medicine; B, from Dunbar C, Travis W, Kan YW, Nienhuis A. 5-Azacytidine treatment in a beta zero-thalassaemic patient unable to be transfused due to multiple alloantibodies. Br J Haematol. 1989;72:467-468.)*

tal studies in mice have demonstrated that retroviral vectors are capable of transferring foreign sequences to hematopoietic stem cells.[1059,1060] Expression of transferred genes has been more problematic but has been improved with use of a new vector containing a portion of the LCR, which has led to 17% to 33% HbF.[1061] The efficiency with which primate (or human) stem cells are infected by retroviral vectors appears to be lower than that observed in murine cells. Nonetheless, transfer of foreign sequences to long-term repopulating hematopoietic cells of primates and humans has been demonstrated.[1062]

For treatment of β-thalassemia (or sickle cell anemia) it will be necessary to express the transferred gene at high levels in erythroid cells. This has been a challenge in the field, but vectors that incorporate elements of the LCR have recently been generated. Lentiviral vectors containing such elements have been constructed. Indeed, it has become possible to achieve long-term correction of both sickle cell anemia and β-thalassemia in mouse models with these viruses.[1063-1065] A phase I human gene therapy trial has been initiated in France for thalassemia and sickle cell disease, but clinical data are not yet available.[1066]

Interaction of Thalassemia with Globin Structural Variants

In geographic areas in which thalassemia mutations and structural variants of α- and β-globin genes are both commonly seen (such as Africa and Southeast Asia), compound heterozygotes with a thalassemia mutation and a structural variant are common.[1] In such double heterozygotes, disease may be more or less severe than that seen in individuals who are heterozygous for only the structural variant. For example, heterozygotes for a β[S] gene have 30% to 45% HbS and are usually clinically well, whereas patients with a β[S] gene and a β-thalassemia mutation (in the *trans* β gene) have 60% to 95% HbS and may have a severe sickling disorder. Individuals with a β[S] gene and α-thalassemia trait generally have less HbS than those with sickle trait[1067,1068] and are asymptomatic.[1069,1070] The interaction of α- and β-thalassemia mutations and the HPFH mutations with the β[S] gene are described in detail in Chapter 19.

Hemoglobin E–β-Thalassemia

This syndrome is particularly common in Southeast Asia, where as many as 4000 to 5000 patients may reside in Thailand alone.[1071,1072] As a result of immigration from Southeast Asia, HbE–β-thalassemia is now a commonly encountered form of transfusion-dependent thalassemia in certain areas of the United States.[1073,1074] Double heterozygotes not receiving transfusions have hemoglobin levels of 2.3 to 7 g/dL, depending primarily on the output of the β-thalassemia gene. Because α-thalassemia is common in Southeast Asia, more complex phenotypes may be observed.[1075] Nucleated red blood cells are found

on the peripheral blood smear, whereas they are absent in patients homozygous for β[E]. HbE and HbA$_2$ account for 50% to 70% of the total hemoglobin (5% HbA$_2$ by HPLC).[1074,1076] Small quantities of HbA are found in association with a β[+]-thalassemia gene. Patients with HbE–β-thalassemia usually require transfusions and exhibit the clinical features of thalassemia major. In areas where intensive treatment is unavailable, the disease resembles classic thalassemia major, with patients exhibiting massive hepatosplenomegaly, hypersplenism, severe skeletal disease, and death from infection in childhood. Iron loading occurs as a result of either transfusion or enhanced intestinal absorption.[1077] Proper treatment is the same as that recommended for thalassemia major or intermedia, depending on the requirement for regular blood transfusion. Recent work has also suggested that there are different compensatory responses in HbE–β-thalassemia as patients get older, and this may have important implications in the management of this disease.[1078] These alterations in the compensatory responses of older patients are also likely to be applicable to patients with other forms of β-thalassemia.

Hemoglobin C–β-Thalassemia

The β[C] gene, which encodes a variant β chain with a lysine→glutamic acid substitution at position 6,[1079] is common in blacks of West African origin. The only hematologic consequence of simple heterozygosity for the β[C] gene is increased target cells on the peripheral smear. Double heterozygotes with a β[C] gene and β-thalassemia genes exhibit moderately severe hemolytic anemia with splenomegaly. The peripheral blood smear reveals hypochromia and microcytosis with many target cells. HbC accounts for 65% to 95% of the total hemoglobin, depending on whether the thalassemia mutation is of the β[+] or β[0] variety. In the black population the disease is generally mild because of the prevalence of mild β-thalassemia genes (see earlier),[535] whereas in Italian,[1080] North African,[1081] and Turkish patients,[1082] the disease is more severe, particularly in those who have a β[0]-thalassemia mutation.

Thalassemic Hemoglobinopathies

As discussed in detail in earlier sections, several variant polypeptides can be described as thalassemic hemoglobinopathies. With the exception of HbE and the elongated α-chain variants, these mutations are very uncommon. Interest in these mutations arises from the unique mechanisms by which they produce the thalassemia phenotype.[239,1083] The most common thalassemic hemoglobinopathy is HbE disease.

Hemoglobin E Disease

As described earlier, the β[E] mutation activates a cryptic splice site in exon 1 (see Fig. 20-10). Because the correct splice site is less efficiently used, production of functional β-globin mRNA that codes for the variant decreases.[142] The incidence of the β[E] gene is extraordinarily high in

some populations (≈30% in Laos, Cambodia, and Thailand).[1071,1084] The occurrence of the gene in immigrants from Southeast Asia to the United States reflects these origins.[1074]

In the heterozygous form, patients are largely asymptomatic with a hemoglobin level of 12 g/dL or greater, no reticulocytosis, an MCV of 74 ± 10.6 μm³, and an MCH of 25 ± 2.5 pg. The peripheral blood smear is distinguished by mild microcytosis and occasional target cells. Hemoglobin electrophoresis reveals HbE comigrating with HbA$_2$ in the range of 19% to 34%. The α-to-β biosynthetic ratio is usually 0.8 or greater, hence the mild nature of HbE trait.

Patients with homozygous HbE disease are also asymptomatic.[1072,1076] The hemoglobin level is rarely less than 10 g/dL, and significant reticulocytosis is uncommon. The red cells, however, are markedly microcytic (MCV of 50 to 66 μm³) and hypochromic (MCH of 20.1 pg). Target cells and occasional coarse stippling are evident on the smear. HbE accounts for 90% or more of the total hemoglobin, with varying levels of HbF.

The differential diagnosis of microcytic anemia in the Southeast Asian population initially requires the exclusion of iron deficiency. When present, electrophoresis will identify HbE. However, its level may be diminished in the presence of α-thalassemia or iron deficiency because the affinity of normal β chains for α-globin exceeds that of β^E chains. Interaction of α-thalassemia mutations with the β^E gene is usually seen because of the high incidence of each in the Southeast Asian population.[1075]

PRENATAL DIAGNOSIS OF THALASSEMIA

The morbidity and mortality associated with severe forms of thalassemia prompted efforts to develop effective prenatal diagnosis more than 2 decades ago. For the vast majority of β-thalassemias, for which point mutations are usually responsible, early efforts focused on determination of globin chain synthesis in fetal blood cells obtained by aspiration of placental vessels or direct visualization of fetal vessels.[1085-1087] The risk associated with fetal blood sampling at 18 to 20 weeks' gestation proved to be acceptably low when performed by experienced personnel (fetal loss rate of ≈3%; error rate of <0.5%) such that between 1975 and 1985, more than 7900 pregnancies were studied.[1088] As molecular methods and the knowledge of mutations leading to thalassemia improved, strategies for prenatal detection of these conditions evolved.

Successful prenatal diagnosis of α-thalassemia of the hydrops fetalis variety by solution hybridization methods to detect deficiency of α-globin genes in amniotic fluid cell DNA was first reported by Kan and associates in 1975.[1089] Southern blot analysis rapidly supplanted this approach for the detection of gene deletion in either the α- or β-thalassemias.[1090,1091] Detection of mutations in DNA rapidly became the preferred strategy for prenatal diagnosis as mutations became defined in the β-thalassemias.[3] The introduction of PCR methods further facilitated the detection of mutations and also permitted the use of nonradioactive tests.[1092] Coupled with chorionic villus biopsy, accurate and safe diagnosis can be accomplished within the first trimester of pregnancy. More recently, noninvasive methods consisting of examination of fetal erythrocytes in maternal plasma[1093] and analysis of nucleic acids in maternal plasma[1094] have provided promise for detection of severe thalassemia syndromes, without risk to the fetus.

Besides molecular biology, prenatal diagnosis of thalassemia has relied on identification of couples at risk, widespread public education, and genetic counseling. In countries in which the incidence of β-thalassemia is high and the burden of disease to the overall population great,

FIGURE 20-34. A decrease in the birth rate of infants with thalassemia major in Great Britain and several Mediterranean regions after the introduction of effective prenatal diagnosis. *(Adapted from Modell B, Bulyzhenkov V. Distribution and control of some genetic disorders. World Health Stat Q. 1988;41: 209-218. By permission of the World Health Organization.)*
such as on the island of Sardinia and in Greece, intensive prevention programs have been established and have proved to be extraordinarily successful. For example, the birth of children with β-thalassemia in these area has been reduced by more than 90% in recent years[1095-1100] (Fig. 20-34). These results represent major achievements in the prevention of genetic disease and paradigms for other disorders.*

21 | The Phagocyte System and Disorders of Granulopoiesis and Granulocyte Function

Mary C. Dinauer and Peter E. Newburger

Phagocytic leukocytes are bone marrow–derived cells that have the capacity to engulf and digest particulate matter. Phagocytes are essential for the host response to infection and injury and are equipped with specialized machinery enabling them to seek out, ingest, and kill microorganisms. Other functions include the synthesis and secretion of cytokines, pyrogens, and other inflammatory mediators, as well as the digestion of senescent cells and debris. These functions are important for resolution of injury and wound repair, as well as for linking innate to adaptive immunity.

The phagocyte system has two principal limbs: granulocytes (neutrophils, eosinophils, and basophils) and mononuclear phagocytes (monocytes and tissue macrophages). Both limbs participate in innate immunity and initiation of acquired immune responses. Neutrophils, the rapid effector cells of the innate immune system, circulate in the bloodstream until encountering specific chemotactic signals that promote adhesion to the vascular endothelium, diapedesis into tissues, and migration to sites of microbial invasion or tissue injury, where they release chemotactic signals to attract and activate inflammatory monocytes, dendritic cells, and lymphocytes. Mononuclear phagocytes also function as resident cells in certain tissues, such as the lung, liver, spleen, and peritoneum, where they perform a surveillance role. Both granulocytes and mononuclear phagocytes dispose of target cells and particles by engulfment and sequestration within intracellular vacuoles, followed by the release of digestive lysosomal enzymes and bactericidal antibiotic proteins from storage granules and the generation of highly reactive oxidants from the respiratory burst pathway.

This chapter is divided into three major sections. The first describes the normal distribution, structure, and function of granulocytes and mononuclear phagocytes. The second section reviews the clinical disorders associated with deficient or excessive phagocytic number. The third focuses on disorders of phagocyte function, including both intrinsic phagocyte defects and conditions secondary to other disease processes.

FIGURE 21-1. Neutrophil maturation. Neutrophil maturation and control of granule protein biosynthesis are achieved by the sequential and combined action of specific transcription factors, including PU.1, the CCAAT/enhancer-binding protein (C/EBP) and acute myelogenous leukemia (AML) families, CDP, Myb, and GATA-1. The granules formed at any given stage of maturation will be composed of the granule proteins synthesized at that time. The different subsets of neutrophil granules are the result of differences in the biosynthetic windows during maturation and not the result of specific sorting between individual granule subsets. When the formation of granules ceases, it is believed that secretory vesicles will form. It cannot be ruled out that post-transcriptional control occurs, so biosynthesis of proteins may not always be a precise reflection of the corresponding mRNA levels. BC, band cell; MB, myeloblast; MC, myelocyte; MMC, metamyelocyte; MPO, myeloperoxidase; PMC, promyelocyte; Segm., segmented cell (mature neutrophil). *(Adapted with permission from Borregaard N, Cowland JB. Granules of the human neutrophilic polymorphonuclear leukocyte. Blood. 1997;89:3503-3521.)*

PHAGOCYTE DISTRIBUTION AND STRUCTURE

Regulation of Myelopoiesis

Granulocytes and monocytes are produced in the bone marrow in a complex, highly regulated, dynamic process that requires both specific hematopoietic growth factors and an appropriate bone marrow microenvironment. As reviewed in Chapter 6, multipotent, self-renewing hematopoietic stem cells give rise to lineage-restricted progenitor cells that divide and further differentiate in bone marrow before release into the intravascular compartment. Transcription factors of the PU.1 and CCAAT/enhancer-binding protein (C/EBP) families play promi-

nent roles in normal myelopoiesis (Fig. 21-1). PU.1 is important for the development of early myeloid precursors and is absolutely essential for subsequent differentiation of the monocyte/macrophage lineage.[1,2] Early steps in the differentiation of granulocytes are dependent on C/EBPα, whereas C/EBPε activity is required for terminal maturation beyond the metamyelocyte stage.[2] Cytokines that promote the proliferation and differentiation of neutrophils and monocytes from primitive precursor cells include interleukin-3 (IL-3), IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage colony-stimulating factor (M-CSF), and granulocyte colony-stimulating factor (G-CSF).[3-5] The latter two cytokines are relatively specific for the mono-

cyte and neutrophil lineages, respectively. During infection, activated macrophages release cytokines, such as IL-1, IL-6, and tumor necrosis factor (TNF), that activate stromal cells and T lymphocytes to produce additional amounts of colony-stimulating factors and increase the production of myeloid cells. IL-5 plays an important role in inducing eosinophil differentiation,[6-8] and IL-3 is the principal cytokine inducing human basophil growth and differentiation.[9] In addition to their regulatory role in hematopoiesis, hematopoietic growth factors can act on mature myeloid cells and stimulate their functional activities. For example, circulating phagocytes become "primed" to undergo an enhanced respiratory burst on exposure to GM-CSF.[10]

Myeloid differentiation also appears to be modulated by transcriptional repressors such as Gfi 1 and retinoic acid receptors.[11-14] The participation of retinoic acid in myeloid development was originally surmised from its ability to induce differentiation of myeloid leukemia cell lines and leukemic promyelocytes in patients with acute promyelocytic leukemia[15] (see Chapter 11, Myeloid Leukemia, Myelodysplasia and Myeloproliferative Disease in Children, in *Oncology of Infancy and Childhood*).

Granulocytes

Neutrophils

The neutrophil life span is traditionally divided into the bone marrow, circulating, and tissue phases. Approximately 14 days are spent in the bone marrow, where proliferation and the early stages of neutrophil differentiation are followed by the final stages of maturation and retention in a large, nonmitotic storage pool that is many-fold larger than the circulating and tissue neutrophil populations (Table 21-1).[16-19] Once released into the bloodstream, neutrophils have a half-life of 6 to 10 hours and move between the circulating and marginated pools in a reversible fashion. Neutrophils then exit by diapedesis between endothelial cells into tissue sites of infection or inflammation. Once in tissues, neutrophils are believed to live for another 1 to 2 days before undergoing apoptosis and engulfment by macrophages.[20-22]

Myeloblasts are the earliest morphologically recognizable granulocyte precursor in marrow and are identified by their relatively undifferentiated appearance consisting of a large, oval nucleus, several prominent nucleoli, and few or no granules in gray-blue cytoplasm on Wright-stained preparations. This stage of neutrophil differentiation is followed by the promyelocyte and myelocyte stages, which are distinguished by the appearance of distinct neutrophil granule populations[23] (Table 21-2). Azurophilic, or primary, granules are formed during the promyelocyte stage and contain myeloperoxidase (MPO), bactericidal peptides, and lysosomal enzymes. The subsequent myelocyte stage is distinguished by the formation of peroxidase-negative specific, or secondary, granules containing lactoferrin. No further cell divisions occur after the myelocyte stage. The metamyelocyte, band, and mature neutrophil exhibit progressive nuclear condensation, accumulation of glycogen, and accumulation of tertiary gelatinase-rich granules and secretory vesicles marked by alkaline phosphatase.[24,25]

TABLE 21-1	Neutrophil and Monocyte Kinetics	
	Transit Time Range (hr)	**Total Cells (× 10⁹/kg)**
NEUTROPHILS		
Marrow mitotic compartment		
Myeloblast	23	0.14
Promyelocyte	26-78	0.51
Myelocyte	17-1266	1.95
Postmitotic marrow maturation and storage compartment		
Metamyelocyte	8-108	2.7
Band	12-96	3.6
Neutrophil	0-120	2.5
Total storage		8.8
Vascular compartment		
Circulating neutrophils	4-10	0.3
Marginated neutrophils	4-10	0.4
Total blood neutrophils		0.7
Tissue compartments	0-3 days (?)	Not known
Neutrophil turnover rate	1.6 × 10⁶/kg/day	
MONOCYTES		
Marrow mitotic compartment: promonocyte	≈160	0.006
Postmitotic marrow compartment: monocyte	24	0.10
Vascular compartment	36-104	0.024
Tissue compartment	Days-months	Not known
Blood monocyte turnover rate	6 × 10⁶/kg/day	

Neutrophil and monocyte kinetics based on references in the text.

TABLE 21-2   **Content of Human Neutrophil Granules and Secretory Organelles**

Primary: Azurophil Granules	Secondary: Specific Granules	Tertiary: Gelatinase Granules	Secretory Vesicles
MEMBRANE	**MEMBRANE**	**MEMBRANE**	**MEMBRANE**
CD63	CD11b/CD18 (Mac-1)	CD11b/CD18 (Mac-1)	Alkaline phosphatase
CD68	CD15 antigens (Lewis X)	CD67	CD10
Presenilin-1	CD66	Cytochrome b_{558}	CD11b/CD18 (Mac-1)
Stomatin	CD67	Diacylglycerol-deacylating enzyme	CD13
V-type H$^+$-ATPase	Cytochrome b_{558}	Formyl peptide receptor	CD14
	Formyl peptide receptor	Leukolysin (MMP-25)	CD16 (FcγIIIR)
	Fibronectin receptor	NRAMP-1	CD35 (complement receptor type 1)
	G protein α subunit	SCAMP	CD45
	Laminin receptor	SNAP-23, -25	CD67
	NB-1 antigen (CD177)	Tumor necrosis factor receptor	Chemokine receptors
	Rap1, Rap2	Urokinase-type plasminogen activator (uPA) receptor	Cytochrome b_{558}
	SCAMP	V-type H$^+$-ATPase	Decay-accelerating factor
	SNAP-23, -25	VAMP-2	Ig (G, A, E) FcR
	Stomatin		Formyl peptide receptor
MATRIX	Thrombospondin receptor		Leukolysin (MMP-25)
Acid β-glycerophosphatase	Tumor necrosis factor receptor		SNAP-23, -25
Acid mucopolysaccharide	Urokinase-type plasminogen activator (uPA) receptor		Tumor necrosis factor receptor
α$_1$-Antitrypsin	VAMP-2		V-type H$^+$-ATPase
α-Mannosidase	Vitronectin		VAMP-2
Azurocidin/CAP37/ heparin-binding protein			
Bactericidal/permeability-increasing protein (BPI)			
	MATRIX	**MATRIX**	**MATRIX**
β-Glycerophosphatase	β$_2$-Microglobulin	Acetyltransferase	Plasma proteins
β-Glucuronidase	Collagenase (MMP-8)	β$_2$-Microglobulin	
Cathepsins	Gelatinase (MMP-9)	Gelatinase (MMP-9)	
Defensins	hCAP-18	Lysozyme	
Elastase	Heparanase		
Lysozyme	Histaminase		
Myeloperoxidase	Lactoferrin		
N-acetyl-β-glucosaminidase	Lipocalin (NGAL)		
Proteinase-3	Lysozyme		
Sialidase	Plasminogen activator		
Ubiquitin-protein conjugate	Vitamin B$_{12}$–binding protein (transcobalamin I)		

See text for references.

On Wright-stained blood smears, a mature neutrophil is 10 to 15 mm in size and has a multilobed, polymorphic nucleus with highly condensed chromatin and yellow-pink cytoplasm containing numerous granules, as well as clumps of glycogen. The mean lobe count is usually slightly less than three. Circulating neutrophils appear round with some cytoplasmic projections and surface ruffling. A scaffold of cytoskeletal filaments, composed of largely actin microfilaments and microtubules,

plays a key role in mediating neutrophil locomotion on surfaces, phagocytosis, and exocytosis.[26-28] Microtubules radiate from the centriole in the perinuclear cytoplasm near the Golgi region, whereas actin tends to be located more peripherally, where it forms an organelle-excluding meshwork. Actin is associated with a variety of actin-binding proteins (ABPs) that regulate the structure of this meshwork and link the actin cytoskeleton to the plasma membrane.[27]

The morphologic changes seen with neutrophil differentiation are accompanied by temporally coordinated changes in gene expression and protein synthesis (see Fig. 21-1).[29-31] Transcription and translation of mRNA for MPO and cathepsin, which are both primary granule constituents, are restricted to myeloblasts and promyelocytes.[31-34] In contrast, expression of secondary granule proteins, such as lactoferrin and transcobalamin I, occurs in myelocytes and metamyelocytes.[33,34] Gelatinase expression occurs even later in maturation and is first detected in bands and bone marrow neutrophils.[34] The leukocyte β integrin subunit CD11b is first detectable in myelocytes and increases throughout the later stages of neutrophil differentiation.[31] The gp91[phox] subunit of the respiratory burst oxidase complex is expressed relatively late in neutrophil maturation,[24] consistent with the observation that respiratory burst activity is not detected until the metamyelocyte stage.[35]

A mature neutrophil, previously thought of as an "end-stage" cell, retains the capacity for inducible gene expression and protein synthesis even after release from the marrow cavity.[36-39] For example, cytokines induce neutrophil expression of mRNA transcripts encoding respiratory burst oxidase components, Toll-like receptor 2 (TLR2), and IL-8.[40,41] Mature neutrophils also synthesize and secrete a variety of cytokines, including IL-1, IL-6, TNF-α, GM-CSF, M-CSF, and IL-8, which may promote recruitment and activation of both phagocyte and lymphocyte populations in the inflammatory response.[39,42] In some cases, increased cytokine synthesis is regulated by activating translation of preformed mRNA transcripts.[43]

Abnormalities in Neutrophil Morphology

Upon neutrophil activation by inflammatory signals, granule fusion can result in vacuolization and toxic granulation (prominent azurophilic granules). These morphologic changes reflect a nonspecific response to inflammation and do not necessarily indicate the presence of bacterial infection. Large azurophilic granules are also seen in the Alder-Reilly anomaly, an autosomal recessive trait, but neutrophil function does not appear to be affected. Döhle bodies can be seen in normal neutrophils at times of infection. These inclusions represent strands of rough endoplasmic reticulum that are retained from a more immature stage and stain bluish because of their high content of RNA and ribosomes. Döhle bodies in granulocytes and monocytes, in combination with leukopenia, giant platelets, and variable thrombocytopenia, characterize the May-Hegglin anomaly. This autosomal dominant syndrome, like the very similar Fechtner and Sebastian syndromes, is caused by mutations in the gene encoding nonmuscle myosin heavy chain-9.[44]

Neutrophil hypersegmentation can be a sign of vitamin B$_{12}$ or folate deficiency. Hypersegmented neutrophils, with a mean of four lobes, also occur as a rare autosomal dominant trait that is not associated with disease. Nuclear hyposegmentation is seen in Pelger-Huët anomaly, an autosomal dominant trait caused by mutations in the gene encoding the lamin B receptor, an integral protein of the nuclear envelope.[45] Typically, the nucleus is bilobed (often described as pince-nez) but has mature, coarse, densely clumped chromatin. The nucleus remains round in the rare homozygote. Pelger-Huët anomaly must be distinguished from neutrophil band forms and from the acquired or "pseudo"–Pelger-Huët anomaly, which can be seen in myeloproliferative disorders. Bilobed neutrophil nuclei are also seen in a rare functional disorder of neutrophil maturation—specific granule deficiency (SGD). In this disorder the pink-staining specific granules are absent in peripheral blood neutrophils. Giant granules representing defective membrane targeting of proteins in secretory lysosomes are seen in the neutrophils of patients with Chédiak-Higashi syndrome (CHS), most prominently in the bone marrow. SGD and CHS are discussed in more detail in the section "Disorders of Granulocyte and Mononuclear Phagocyte Function" later in this chapter.

Neutrophil Granule Biosynthesis and Classification

The numerous intracellular granules and vesicles in a neutrophil's cytoplasm function as storage pools for cell surface receptors and as reservoirs of sequestered digestive and microbicidal proteins. Many compounds are multifunctional. For example, cathepsin G, defensins, and azurocidin are both antimicrobial and chemotactic for monocytes and T cells, which helps amplify the inflammatory response and link innate to adaptive immunity. The older classification of granules as either peroxidase positive (azurophilic or primary) and peroxidase negative (specific or secondary) has proved to be too simplistic.[24,38,39,46] A current classification of neutrophil granules is shown in Table 21-2, which summarizes the composition of their membranes and luminal (matrix) contents.

Azurophilic (primary) granules are defined histochemically by the presence of MPO, an enzyme in the oxygen-dependent killing pathway. This green heme enzyme lends its color to collections of mature neutrophils (pus) or myeloid leukemia cells in the bone marrow or extramedullary tumors ("chloromas"). Azurophilic granules also contain defensins and bactericidal/permeability-increasing (BPI) protein, cytotoxic polypeptides that participate in oxygen-independent killing of microbes. Other components of the azurophilic granule matrix include neutral serine proteases, such as cathepsin and elastase, and other digestive enzymes.

Specific (secondary) granules, which are uniquely found in neutrophils, are classically identified by their content of lactoferrin, an iron-binding protein that also has direct bactericidal activity. Specific granules contain additional antibiotic substances as well, including lysozyme, lipocalin (also known as neutrophil gelatinase–associated lipocalin [NGAL]), a bacterial siderophore–binding protein, and the metalloproteinases collagenase and gelatinase. The membranes of secondary

granules contain a major proportion of the neutrophil's supply of flavocytochrome b_{558}, the electron carrier of the respiratory burst oxidase.[47,48] Specific granule membranes also contain a pool of receptors for adhesive proteins, TNF, and chemotactic formyl peptides.

Although specific granules contain collagenase and some gelatinase, most of the neutrophil's store of gelatinase is localized to the matrix of gelatinase (tertiary) granules, which also contain the membrane-associated metalloproteinase leukolysin (MMP-25). Tertiary granules are formed relatively late in neutrophil differentiation and are smaller and more easily mobilized for exocytosis than secondary granules are. Secretory vesicles are formed in bands and mature neutrophils by endocytosis of the plasma membrane and serve as an important store of leukolysin, as well as the adhesive protein Mac-1 (CD11b/CD18) and many other membrane receptors (see Table 21-2).

The generation of different classes of granules largely reflects the sequential synthesis of granule proteins during granulopoiesis ("targeting by timing") (see Fig. 21-1).[24,38,39,46] As mentioned earlier, expression of primary, or azurophilic, granule proteins is restricted to myeloblasts and promyelocytes.[31-34] Expression of specific and gelatinase granule matrix proteins occurs later in granulopoiesis and requires the transcription factor C/EBPε. Specific and gelatinase granules are absent in neutrophils from C/EBPε-nullizygous mice generated by gene targeting.[49] The phenotype of C/EBPε-nullizygous mice is similar to that seen in the rare inherited disorder SGD, and mutations in the C/EBPε coding sequence have been

reported in several affected patients (see later in this chapter).[50,51]

Neutrophil Cell Surface Receptors

The primary function of a mature neutrophil is to move rapidly into tissue sites to destroy invading microbes and clear inflammatory debris. To respond to inflammatory stimuli, the neutrophil is equipped with an array of cell surface receptors for adhesive ligands, chemoattractants, and cytokines that can be divided into groups based on their structure and major intracellular signaling pathway to which they are linked (Table 21-3). Many of these surface proteins are pattern recognition molecules such as TLRs and formyl peptide receptor,[52,53] a reflection of the neutrophil's role in the innate immune response. The signal transduction cascades triggered upon binding of ligand to neutrophil receptors are complex and probably redundant.[54-56] A common early event downstream of neutrophil receptor binding is activation of phospholipase C, which hydrolyzes the membrane phospholipid phosphatidylinositol 4,5-bisphosphate (PIP_2) to generate two important second messengers, diacylglycerol and 1,4,5-inositol triphosphate (IP_3),[57,58] which in turn cause the release of calcium from intracellular stores and activate protein kinase C. Changes in intracellular calcium concentration are important for neutrophil degranulation and secretion and for phagolysosome fusion during phagocytosis.[59] Activation of phosphatidylinositol 3'-kinase (PI3K) is another common early event that catalyzes the phosphorylation of PIP_2 to generate a third important lipid messenger, phosphatidylinositol 3,4,5-

---

TABLE 21-3   Receptors in Neutrophils

Receptor Grouping	Examples	Structural Characteristics
G protein linked	fMLP, C5a, PAF, LTB, IL-8, chemokines	Seven-transmembrane–spanning domains (serpentine); linked to heterotrimeric GTP-binding proteins
Membrane tyrosine kinases	PDGF	Integral membrane protein, intrinsic tyrosine kinase activity; ligation leads to receptor dimerization and cross ("auto") phosphorylation
Tyrosine kinase linked	FcγRIIA, GM-CSF	FcγRII is a member of the immunoglobulin family of receptors The GM-CSF receptor is an 84-kd transmembrane protein related to receptors for IL-2 and IL-6 Ligation of receptor activates cytosolic tyrosine kinases
GPI linked	FcγRIIIB, DAF, CD14	Receptors with no transmembrane or intracellular domains. May associate with a partner receptor to mediate signal transduction
Adhesion molecules	β₂ Integrins L-selectin	β-Integrins are heterodimers with relatively long cytoplasmic tails L-selectin has an extracellular lectin-binding domain and a very short cytoplasmic tail Ligation results in potentiation of the oxidative burst and phagocytosis in adherent cells, calcium signaling, actin cytoskeletal changes, and upregulation of gene expression
Ceramide linked	TNF	Single-membrane-spanning glycoproteins; ligation activates membrane-bound sphingomyelinase with generation of ceramide, which in turn activates a 96-kd protein kinase

DAF, decay-accelerating factor; fMLP, N-formyl-methionyl-leucyl-phenylalanine (formyl peptide); GM-CSF, granulocyte-macrophage colony-stimulating factor; GPI, glycosylphosphatidylinositol; IL, interleukin; LTB₄, leukotriene B₄; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; SH2, src homology 2; TNF, tumor necrosis factor.

triphosphate (PIP$_3$). Neutrophil activation is also accompanied by alterations in the phosphorylation status of intracellular proteins, as regulated by protein kinase C, tyrosine kinases and phosphatases, and serine/threonine kinases of the mitogen-activated protein kinase (MAPK) family.[59-63] Guanine nucleotide–binding proteins play important roles in neutrophil signal transduction. Such proteins include the heterotrimeric guanosine triphosphate (GTP)-binding proteins, which are coupled to the seven-transmembrane–spanning domain (7-TMS; serpentine or heptahelical) receptors for chemokines and other chemoattractants,[64-66] and the low-molecular-weight guanosine triphosphatases (GTPases) of the Ras superfamily.[67] The latter category includes p21Ras itself, which can be activated via chemoattractant receptors,[68] and the Rho family GTPases Rho, Rac, and Cdc42, which are involved in the regulation of many neutrophil responses, including adhesion, the respiratory burst reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, and actin remodeling during migration and phagocytosis.[54] A dominant-negative form of the Rac2 GTPase has been identified in an infant with recurrent deep-seated bacterial infections and leads to multiple defects in phagocyte function.[69,70]

Eosinophils

Like neutrophils, eosinophils are compartmentalized in the bone marrow into mitotic and storage pools; they usually constitute no more than 0.3% of the nucleated bone marrow cells.[71] Eosinophils arise from a progenitor cell, the eosinophil colony-forming cell (CFC-Eo), that is committed at a relatively early stage to differentiate into eosinophils instead of neutrophils and monocytes. GATA-1 plays a critical role in the transcriptional regulation of eosinophil lineage commitment and differentiation.[72,73] Morphologic differentiation and maturation of the eosinophil parallel that of the neutrophil series, and the characteristic eosin-staining specific granules of this granulocyte lineage are prominent by the myelocyte stage. IL-3, IL-5, and GM-CSF mediate eosinophil production in the bone marrow; IL-5, IL-13, chemokines (such as eotaxins [CCL11] and RANTES [CCL5]), and leukotrienes (such as leukotriene B$_4$ [LTB$_4$]) play key roles in regulating eosinophil differentiation, chemotaxis, and functional activation.[6-8,74,75]

Once released from bone marrow, eosinophils have a half-life in the bloodstream similar to that of neutrophils.[76] After leaving the circulation, eosinophils typically localize in areas exposed to the external environment, such as the tracheobronchial tree, gastrointestinal tract, mammary glands, and vagina and cervix.[77] They are also found in connective tissue immediately below the epithelial layer. As discussed in a later section, eosinophils have both immunoenhancing and immunosuppressive functions and play a role in helminthic infection, allergy, and the response to certain tumors.[6,7,74,78] The majority of mature eosinophils reside in tissues, with an estimated blood-to-tissue ratio of 1 : 300 to 1 : 500. The life span of

tissue eosinophils is not known but may be several weeks.[77] The number of circulating eosinophils tends to be highest late at night, decreases during the morning, and begins to rise at mid-afternoon. These changes correlate inversely with the diurnal variation in adrenal glucocorticoid levels, to which circulating eosinophils are very sensitive.[79]

A mature eosinophil is slightly larger than a neutrophil, with a diameter of 12 to 17 µm. The nucleus is characteristically bilobed, although multiple lobes can be seen in patients with eosinophilia of diverse causes. The cytoplasm has prominent and morphologically distinctive granules that stain strongly with acid aniline dyes because of their high content of basic proteins.

Like the neutrophil, a mature eosinophil is endowed with the capacity for chemotaxis, phagocytosis, degranulation, and the synthesis of reactive oxidants and arachidonate metabolites.[7,77,80,81] Eosinophil cell surface membranes express a wide variety of molecules, including receptors for immunoglobulin and members of the immunoglobulin superfamily; cytokine receptors; adhesion molecules; chemokine, complement, and other chemotactic receptors; and major histocompatibility complex (MHC) class I and II and costimulatory molecules.[7,77,80]

The distinctive mature eosinophil granules are membrane-bound organelles 0.15 to 1.5 µm in length and 0.3 to 1.0 µm in width that contain a variety of enzymes and cytotoxic proteins.[7,80] These small granules are round and homogeneous by electron microscopy and include the primary granules, which develop early in eosinophilic maturation,[82] and a smaller population appearing in late eosinophils that contain arylsulfatase and other enzymes.[83] The more numerous eosin-staining secondary (specific) granules are large ovoid bodies that contain an electron-dense crystalloid core surrounded by a less dense matrix. The eosinophil major basic protein (MBP) makes up about 50% of the dense crystalloid core of the eosinophilic specific granule, along with other basic proteins rich in lysine, arginine, and phospholipids.[84,85] MBP strongly absorbs to membranes, precipitates DNA, and neutralizes heparin.[86] MBP is toxic to the schistosomules of *Schistosoma mansoni* and larvae of *Trichinella spiralis*[87] and induces the release of histamine from basophils and mast cells.[88] Hydrolytic enzymes, cathepsin, and an eosinophil-specific peroxidase are located in the matrix. Eosinophil peroxidase plays an important role in the anthelmintic function of eosinophils[89,90] and uses bromate to generate hypobromous acid from hydrogen peroxide.[91] The specific granule matrix also contains eosinophilic cationic protein and eosinophil-derived neurotoxin, two cationic proteins with ribonuclease activity.[77]

Eosinophil granule products—particularly MBP, eosinophil peroxidase, and eosinophil neurotoxin—are toxic to tissues, including the heart, lung, and brain.[7,80] These substances mediate many of the adverse clinical complications of eosinophilia and hypereosinophilic

syndrome (HES), such as Löffler's endocarditis and pneumonia.[92,93]

Both eosinophils and basophils contain a lysophospholipase in the plasma membrane and primary granules that can polymerize to form the bipyramidal hexagons known as Charcot-Leyden crystals (CLCs).[94,95] CLCs are typically found in areas of eosinophil degeneration, such as sputum from asthmatic patients, nasal mucus of patients with allergies, stool of patients with parasitic infections, and pleural fluid of patients with pulmonary eosinophilic infiltrates. The CLC lysophospholipase, whose protein sequence is distinct from that of other eukaryotic or prokaryotic lysophospholipases,[96] catalyzes the hydrolysis and inactivation of lysophospholipids generated by phospholipase A_2 and thereby prevents the generation of proinflammatory arachidonic acid metabolites. The CLC protein constitutes about 5% of the total protein in eosinophils.[77]

Basophils

Basophils, like other granulocytes, differentiate and mature in the bone marrow over a period of 7 days before their release into the bloodstream; they are not normally found in connective tissue.[97] Basophils account for approximately 0.5% of the total circulating leukocytes and 0.3% of nucleated marrow cells.[98] Mature basophils have a bilobed nucleus and contain prominent metachromatic granules that stain purple or bluish with Wright stain because of their high content of sulfated glycosaminoglycans. These granules are rich in heparin, chondroitin sulfate, histamine, and kallikrein but lack acid hydrolases, alkaline phosphatase, and peroxidase.[94,99] The heparin of basophils appears to have poor anticoagulant activity. Basophil granules also contain small amounts of MBP, as well as serine proteases. Receptors expressed on the plasma membrane of basophils include a high-affinity receptor for the Fc portion of IgE, which is an important trigger for the release of granule contents and the production of arachidonic acid metabolites in anaphylactic degranulation.[100] Hence, basophils are key effector cells in certain hypersensitivity reactions.[99] Basophils synthesize and secrete IL-4 and IL-13 and may thus mediate a link between the innate and adaptive immune systems for the generation of T_H2 responses.[99,101]

Basophils share certain morphologic and functional features with mast cells, which appear to be derived from a common marrow progenitor.[102,103] However, mast cells and basophils are distinct terminally differentiated cell lineages.[9,104] Similar to basophils, mast cells contain histamine-laden metachromatic granules, express high-affinity IgE receptors, and participate in immediate and cutaneous hypersensitivity.[94,102,105,106] However, mast cells lack receptors for IL-2, IL-3, and CD11b/CD18, which are present on basophils.[9] The c-kit receptor for stem cell factor is present on mast cells but absent on the majority of basophils.[105,107] Murine mast cells can secrete a wide variety of mitogenic or inflammatory cytokines, including many interleukins (IL-1, IL-3, IL-4, IL-5, and IL-6),

chemokines, GM-CSF, and TNF-α, that are likely to play an important role in leukocyte recruitment and inflammation.[105]

Mast cells are ordinarily distributed throughout normal connective tissue, where they are often situated adjacent to blood and lymphatic vessels, near or within nerve sheaths, and beneath epithelial surfaces that are exposed to environmental antigens, such as the respiratory and gastrointestinal tracts.[106] Mature mast cells do not circulate in the blood, although circulating mast cell progenitors have been described[102] and retain a limited proliferative capacity in the tissue compartment.[108] In contrast to monocytes and macrophages, a transformation between the circulating and tissue forms of basophils and mast cells has not been observed. The fate of basophils in tissues is unknown.

Mononuclear Phagocytes

The blood monocyte is derived from a bone marrow progenitor cell (colony-forming unit–granulocyte-macrophage [CFU-GM]) that is shared with the neutrophil and undergoes differentiation through stages as monoblasts and promonocytes in the marrow cavity. The transit time of monocytes in the marrow compartment is briefer than that of neutrophils, and the mature monocyte is released into the circulation only 24 hours after the last mitosis (see Table 21-1).[109-111] Consequently, a relative monocytosis in peripheral blood commonly precedes the return of granulocytes during recovery from bone marrow aplasia or hypoplasia. Monocyte production and differentiation are regulated by IL-3, IL-6, GM-CSF, and the more lineage-specific cytokine M-CSF.[3-5,112,113]

The monocyte may spend several days in the intravascular compartment in either circulating or marginated pools.[114] Monocytes then migrate into tissues and body cavities to participate in inflammatory processes as exudate macrophages and to replenish the resident tissue macrophages, which have a relatively long life span. At least two subsets of circulating monocytes are present in humans.[115-119] The majority are CD14+CD16− and are recruited into inflamed sites. A second subset is CD14+CD16+ and also expresses high levels of CX_3CR1, a receptor for fraktalkine, which is a transmembrane chemokine found on endothelial cells (see later in this chapter). This subset is proposed to be a source of resident macrophages in noninflamed tissue. In patients receiving allogeneic bone marrow transplants, host tissue macrophages disappear gradually and are replaced by donor macrophages approximately 3 months after transplantation.[120]

Circulating monocytes in Wright-stained blood smears are 10 to 18 μm in diameter with a convoluted surface, gray-blue cytoplasm, and an indented or kidney-shaped, foamy nucleus. However, some monocytes can be as small as 7 μm in diameter and may be difficult to distinguish morphologically from lymphocytes.[109] In contrast to neutrophils, monocytes contain a single class of

granules with lysosomal characteristics.[121] After leaving the circulation, monocytes become larger and take on the appearance of tissue macrophages characteristic of the organ in which they reside. The nucleus of macrophages is typically oval with more prominent nucleoli, and the cytoplasm stains blue because of an increase in RNA content. Monocytes and macrophages are distinguished histochemically by the presence of a fluoride-inhibitable nonspecific esterase and can be identified immunohistologically by a variety of monoclonal antibodies such as F4/80 in the mouse and anti-CD68 in human tissue.[122,123]

Monocytes and macrophages share many structural and functional features with neutrophils and are capable of sensing chemotactic gradients, migrating to inflamed sites, ingesting microorganisms, and killing them with a variety of cytocidal products. However, when compared with neutrophils, mononuclear phagocytes have a large and diverse developmental potential.[115,119,124] In addition to their protective function as phagocytic cells in host defense, mononuclear phagocytes play a central role in the adaptive immune response by presenting antigens to lymphocytes; elaborating growth factors and cytokines important for lymphocyte function, wound repair, and hematopoiesis; and participating in a variety of scavenger and homeostatic pathways.

Factors modifying the enzymatic, antigenic, and functional profile of mononuclear phagocytes are incompletely understood and involve a combination of tissue-specific signals and release of inflammatory cytokines and toxins.[115,125-127] Mononuclear phagocytes at inflammatory sites become "activated" and display morphologic alterations and a variety of enhanced functions, including more pronounced ruffling of the plasma membrane and pseudopod formation, increased capacity for adherence and migration to chemotactic factors, increased microbicidal and tumoricidal activity, and enhanced ability to release cytokines.[128]

In keeping with their broad range of activities, mononuclear phagocytes possess an assortment of cell surface receptors not found in neutrophils, including receptors for the coagulation factors VII, VIIa, and thrombin[129,130] and receptors for low-density (LDL) and very-low-density (VLDL) lipoprotein.[131] Macrophages and monocytes are also active secretory cells capable of secreting more than a hundred defined substances,[132] many of which are listed in Box 21-1. These substances include molecules important in control of microbial pathogens, such as lysozyme, neutral proteases, acid hydrolases and reactive oxidants, components of the complement cascade, and coagulation factors. Mononuclear phagocytes secrete a large array of cytokines and hormones that regulate the proliferation and function of other cells that participate in the immune response, inflammation, wound repair, and hematopoiesis. Tissue macrophages also play an important role in the clearance of apoptotic cells during embryogenesis, tissue homeostasis, and resolution of inflammation.[23,133]

Monocytes and tissue macrophages are considered to make up a "mononuclear-phagocyte system," a term that has replaced the "reticuloendothelial system." Resident tissue macrophages were formerly referred to as histiocytes, an imprecise and often loosely applied term. Tissue macrophages are widely distributed and perform specialized functions at portals of entry, such as the pulmonary alveoli, and in sterile sites, such as the bone marrow.[115]

Spleen. Macrophages are distributed in all parts of the spleen, including the germinal centers, where they are associated with lymphocytes. Splenic macrophages located in the red pulp and sinuses serve a clearance function, where sluggish blood circulation maximizes the interaction between blood elements and macrophages lining the sinus walls.

Liver. The portal circulation percolates through a labyrinthine system, the spaces of Disse, before exiting via the hepatic venous system. This hepatic circulation, though less sluggish than that of the spleen, provides considerable contact between blood and the resident liver macrophages, known as Kupffer cells, that reside within these vascular sinuses.

Lymph Nodes. As in the spleen, macrophages are present throughout all regions of peripheral lymph nodes. They are most abundant in the medullary zone close to efferent lymphatic and blood capillaries. This location is probably related to the important role that macrophages play in the presentation of antigens to T lymphocytes.[127,134]

Lungs. Pulmonary macrophages reside both in the interstitium of alveolar sacs and free within the air spaces, where they participate in the clearance of inhaled microorganisms and particulate matter. The number of lung macrophages increases in many chronic pulmonary inflammatory disorders. Pulmonary macrophages are easily seen in the lungs of smokers, where black inclusions mark the macrophage vacuoles.[135] Hemosiderin-laden alveolar macrophages can be indicative of recurrent pulmonary hemorrhage, such as seen in idiopathic hemosiderosis or Goodpasture's syndrome. Gastric aspiration to detect ingested iron-laden macrophages is a useful test for these disorders.

Bone Marrow. Macrophages are found throughout the bone marrow cavity. They are particularly abundant within hematopoietic islands and on the walls of the marrow sinuses.[136] Bone marrow macrophages may have a clearance function in normal or pathologic states of ineffective hematopoiesis.[137] The clearance function of marrow macrophages is dramatically illustrated by lysosomal storage diseases such as Gaucher's disease.[138] Large inclusions build up within marrow macrophages (as well as hepatic and splenic macrophages) because of

Box 21-1	Products Secreted by Mononuclear Phagocytes

ENZYMES

Acid ceramidase, lipase, phosphatase, DNAase, RNAase
α-Iduronidase, α-L-fucosidase, α-mannosidase, α-neuraminidase
α-Naphthylesterase
Angiotensin-converting enzyme
Arginase
Aspartyglycosaminidase
β-Glucuronidase, β-glucosidase, β-galactosidase
Cathepsins, collagenase, elastase
Leucine-2-naphthylaminidase
Lipoprotein lipase
Lysozyme
N-acetyl-β-galactosaminidase, N-acetyl-β-glucosaminidase
Phospholipase A_2
Sphingomyelinase
Sulfatases

OXIDANTS

Hydroxyl radical, hydrogen peroxide, hypohalous acids, nitric oxide, peroxynitrite, superoxide anion

BINDING PROTEINS

Avidin, apolipoprotein E, acidic isoferritins, gelsolin, haptoglobin, transcobalamin II, transferrin

COAGULATION SYSTEM PROTEINS

Factors V, VII, IX, X, XIII
Tissue factor/procoagulant activity (PCA), plasminogen activator, urokinase, thrombospondin, plasminogen activator inhibitors, plasmin inhibitors

LIPID METABOLITES

Prostaglandins E_2, F_2, I; thromboxane A_2; leukotrienes B, C, D, E; malonyldialdehyde; mono-diHETEs; platelet-activating factor

COMPLEMENT SYSTEM PROTEINS

C1, 2, 3, 4, 5; factors B, D, H; properidin; C3b inactivator

CYTOKINES AND GROWTH FACTORS

Interferons α, β, γ
Interleukin 1α, 1β, 6, 8
Tumor necrosis factor (TNF)-α
Fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β)
Colony-stimulating factors (CSFs) G (granulocyte), GM (granulocyte/monocyte), M (monocyte)
Macrophage inflammatory proteins (MIP) 1α, 1β, 2
Monocyte chemoattractent proteins (MCP) 1, 2, 3
Thymosin B_4

MATRIX PROTEINS

Fibronectin, proteoglycans, thrombospondin

OTHER METABOLITES, PEPTIDES, AND PROTEINS

Glutathione, purines, pyrimidines
Sterol hormones, including 1α-25-dihydroxyvitamin D_3

the inability of these cells to break down lysosomal contents.[139]

Other Sites. Mononuclear phagocytes associated with lymphoid cells reside throughout the alimentary tract, particularly in submucosal tissue and small intestinal villi. They are present as microglial cells in the central nervous system (CNS), where their numbers increase after injury as monocytes emigrate across the blood-brain barrier,[140] and they may contribute to the pathogenesis of the CNS manifestations of human immunodeficiency virus (HIV) infection.[141] Mammary gland macrophages released into milk during lactation have been implicated as a potential source of postnatal transmission of HIV.[142]

Dendritic Cells. Dendritic cells are specialized antigen-presenting cells with long cytoplasmic processes and are located in tissues throughout the body, except for the brain.[143] They include the Langerhans cells of the epidermis, the veiled cells in lymph, and interdigitating cells in lymph nodes. Many dendritic cells have some of the antigenic characteristics of mononuclear phagocytes and share a common progenitor cell with granulocytes and monocytes/macrophages.[119,124,143,144] Monocytes can give rise to dendritic cells in various in vitro culture systems.[143-145] Some dendritic cells are also derived from the lymphoid lineage.[119,146] Antigen presentation by dendritic cells, which have a high density of MHC class II molecules, is a particularly potent stimulus for T-cell mediation of the primary immune response.[143,146,147]

Osteoclasts. Osteoclasts are large, multinucleated mononuclear phagocytes that resorb mineralized cartilage and bone.[148,149] Rodent transplantation studies have shown that osteoclasts can be derived from granulocyte-macrophage progenitor cells.[150] Defects in osteoclast function result in osteopetrosis, a genetically heterogeneous group of disorders characterized by defective bone resorption.[149,151] The *op/op* osteopetrotic mouse mutant lacks M-CSF, which results in deficiencies of both osteoclasts and tissue macrophages.[152] However, M-CSF levels and osteoclast numbers are normal in human infantile ("malignant") osteopetrosis,[153] an autosomal recessive

disorder characterized by progressive obliteration of the marrow space.[149,151] This severe form of osteopetrosis is caused by mutations in genes encoding a vacuolar proton pump or the ClC-7 chloride channel[154,155] and is correctable by bone marrow transplantation.[151,156] Gene therapy targeting hematopoietic stem cells has shown promising results in the mouse model of the disease.[157] Administration of recombinant interferon-γ (IFN-γ), a major activator of macrophage function, can produce a clinically significant increase in bone resorption in children with infantile osteopetrosis.[158]

FUNCTION OF PHAGOCYTES

Phagocytic leukocytes play a central role in the acute phases of the inflammatory response, where they are rapidly mobilized into sites of tissue infection or injury and release an array of cytotoxic molecules to quickly eliminate the offending substance or microbe, as well as mediators that initiate an adaptive immune response. Phagocytes are also essential for normal repair of tissue injury, as evidenced by the impairment in wound healing in patients with deficits in leukocyte function or number.

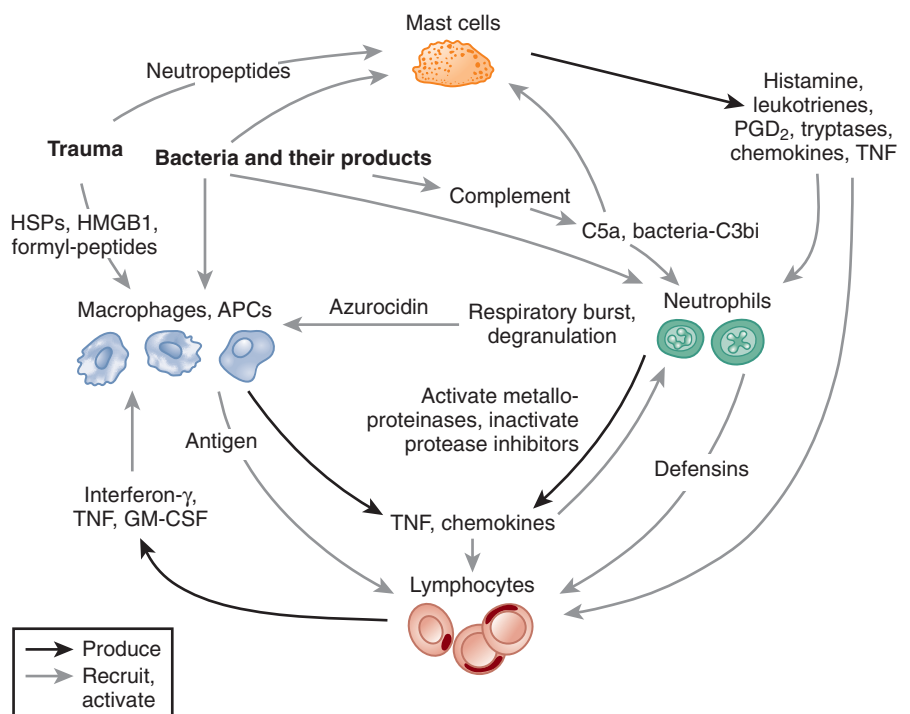
The classic signs of the inflammatory response were described by the Roman writer Celsus as "rubor et tumor, cum calore et delore," redness and swelling with heat and pain.[159] However, it was not until the late 19th century that the cellular events associated with these signs were studied by Virchow and by Cohnheim.[159] The beneficial role of phagocytes in the inflammatory process for host defense and wound healing was championed by

Metchnikov. Much of his work, for which he received a Nobel prize,[159,160] involved studies on the wandering ameboid mesenchymal cells of marine organisms such as the larval starfish, for which he coined the term "phagocyte" after the Greek word *phagein*, "to eat."

In this section the principal functions of granulocytes and mononuclear phagocytes in the inflammatory process are reviewed. Although these functions will be discussed as individual components, it is important to recognize that many occur either simultaneously or in rapid succession. Moreover, many of the cellular structures or secreted molecules participating in the inflammatory process have multiple and redundant functions. For example, phagocyte cell surface proteins that act as adhesive ligands for receptors on the vascular endothelium can also trigger phagocytosis and activation of the phagocyte respiratory burst. An overview of early events in the inflammatory process and crosstalk between different leukocyte populations is shown in Figure 21-2. Note that the proinflammatory events that are critical for the response to tissue injury and effective elimination of microbial challenge also set into motion the generation of counter-regulatory signals leading to resolution of the inflammatory response.[161,162]

Humoral Mediators of the Inflammatory Response

The acute inflammatory response reflects an ongoing collaboration between tissue macrophages and mast cells, vascular endothelial cells, and circulating phagocytes.[162,163] The release of soluble inflammatory mediators plays a

FIGURE 21-2. Early events in the response to infection accompanied by mild tissue injury. During the early inflammatory response, a variety of soluble inflammatory mediators are involved in crosstalk between different leukocyte populations and lead to their recruitment and activation. Multiple signals, generally requiring evidence of both injury and infection, are required before each population fully joins in to amplify the inflammatory process. Not shown are interactions among leukocytes, the endothelium, and the coagulation system; the generation of counter-regulatory signals that dampen the inflammatory response; and signals that regulate the subsequent transition to wound healing. APCs, antigen-presenting cells; GM-CSF, granulocyte-macrophage colony-stimulating factor; HMGB1, high–molecular group box 1 protein; HSPs, heat shock proteins; PDG$_2$, prostaglandin G$_2$; TNF, tumor necrosis factor. *(Reprinted with permission from Nathan C. Points of control in inflammation. Nature. 2002;420:846-852.)*


crucial role in activating and coordinating this process. These molecules can be generated from serum proteins (e.g., the complement-derived protein fragment C5a), secreted by endothelial cells or inflammatory leukocytes (e.g., lipid metabolites, histamine, cytokines, S100 protein), derived from invading microbes (e.g., endotoxin or formylated chemotactic peptides), or released from damaged cells (e.g., heat shock proteins [HSPs], the nuclear high–molecular group box 1 protein [HMGB1]) (see Fig. 21-2).[162,164-166]

The proinflammatory cytokines TNF-α and IL-1 have a broad range of activities in the acute inflammatory response.[55,167] Both IL-1 and TNF can cause fever and muscle breakdown and are involved in the cachexia associated with chronic infection and malignancy. The synthesis of acute phase reactants by the liver is induced by IL-6, whose synthesis and secretion are stimulated by IL-1. Proinflammatory cytokines also induce a proadhesive state on the surface of endothelium and increase the production of chemotactic cytokines (chemokines). IFN-γ is another important proinflammatory mediator that enhances the responsiveness of phagocytes to inflammatory stimuli.[126,168,169] Counterbalancing the activities of these polypeptides are IL-4, IL-10, and transforming growth factor β (TGF-β), which tend to downregulate the acute inflammatory response.[170-172]

Vasodilation and increased vascular permeability are two early responses to an inflammatory insult that are elicited, in large part, by products secreted by granulocytes and mononuclear phagocytes. Activated basophils and tissue mast cells release histamine, which leads to vasodilation of tissue arterioles and microvascular beds through H_1-type receptors.[173,174] The lipid metabolite platelet-activating factor (PAF), secreted by activated macrophages, mast cells, and endothelial cells, induces platelet degranulation and the release of additional histamine, as well as serotonin, another vasoactive amine.[175,176] Prostaglandin E and other arachidonic acid metabolites secreted by activated neutrophils and macrophages are another group of potent vasodilators.[161,175,177] Finally, vasodilation can be triggered by the release of nitric oxide (NO) from endothelial and smooth muscle cells, as well as perhaps activated macrophages, which may be particularly important in the hypotension seen in patients with gram-negative septicemia.[178,179] The increased vascular permeability that produces the edema of acute inflammation allows plasma proteins such as immunoglobulins and complement to enter tissues to promote phagocyte activation and opsonize microbes. Agents that increase vascular permeability include histamine, serotonin, PAF, and the leukotrienes LTC_4, LTD_4, and LTE_4.[175,176] Bradykinin, which is generated as a result of cleavage of Hageman factor (factor XII), also induces enhanced vascular permeability.

Chemokines and Other Chemoattractants

A wide variety of chemoattractants for neutrophils and other circulating phagocytes are generated at sites of inflammation (Table 21-4).[68,180-183] These molecules are chemically diverse and derived from many different sources in response to bacterial products and inflammatory mediators released as a result of tissue necrosis. This diversity provides functional redundancy and ensures that leukocytes will be attracted to sites of injury or infection. In addition to molecules generated by the activation of complement (C5a) or bacteria themselves (formylated peptides), many are secreted by activated phagocytes, which acts as a positive feedback loop for additional recruitment and activation of inflammatory cells.

The phospholipid PAF, released by both activated phagocytes and endothelial cells, triggers platelet activation and release of granules, in addition to being a potent chemoattractant for neutrophils and eosinophils.[175,176] Activation of phagocytes also stimulates phospholipase A_2–mediated cleavage of membrane phospholipids to generate arachidonic acid, which is then converted into a variety of eicosanoid metabolites, including the chemoattractant LTB_4.[161,184] Lipid mediators synthesized at later time points retard the accumulation of neutrophils and other leukocytes, which plays an important role in resolution of the inflammatory response. Such mediators include lipoxins, another class of eicosanoids derived from arachidonic acid, as well as the resolvins and protectins, two newly discovered families of lipid mediators generated from ω-3 polyunsaturated fatty acids.[161]

Chemokines (named for their combined *chemo*tactic and cyto*kine* properties), a family of small (8 to 10 kd) basic heparin-binding proteins, are an important group of phagocyte chemoattractants.[68,181-183,185,186] Chemokines were first discovered in the late 1980s as molecules that interact relatively specifically with subsets of inflammatory leukocytes and therefore help orchestrate the sequential influx of neutrophils, monocytes, and finally lymphocytes into an inflamed tissue site. The heparin-binding sites on chemokines can bind to negatively charged proteoglycans on endothelial cells or in the subendothelial matrix to produce locally high chemokine concentrations at an inflamed site.[180,187,188] As additional chemokines and their receptors have been identified, many other functions have emerged, including regulation of lymphoid homeostasis, hematopoiesis, and angiogenesis.[68,182,183,185] Of note, stromal cell–derived factor 1 (SDF-1, CXCl2) provides a key retention signal for neutrophils in the marrow through its interaction with the CXCR4 receptor, and mutations in the CXCR4 receptor account for myelokathexis syndrome, an inherited neutropenia (see the later section Myelokathexis and the WHIM Syndrome).[189]

Members of the chemokine family, which have a conserved structure containing two cysteine pairs, have been divided into two groups based on their disulfide sequence pattern. The CXC family, in which the first cysteine pair is separated by an intervening amino acid, include IL-8 (CXCL8), the GRO peptides (CXCL1,

CXCL2, CXCL3), and NAP-2 (CXCL7), which are all potent neutrophil activators and chemoattractants. NAP-2 is generated from the peptide CTAP-III released from platelets by proteolytic cleavage mediated by cathepsin G, a protease released from monocytes and neutrophils.[190] The IL-8 and GRO chemokines are secreted by phagocytes and mesenchymal cells (including endothelial cells) in response to inflammatory mediators such as IL-1 and TNF.[68,182,185] Fraktalkine (CX_3CL1) is unique in having three intervening amino acids between the first two cysteine residues. In addition, rather than being soluble, fraktalkine is expressed on the cell surface because it is linked via a mucin-like stalk to a transmembrane domain.[191] The other major family of chemokines is called the "CC" family because the first two cysteines are adjacent to each other. CC chemokines include two important inducers of mononuclear phagocyte migration, monocyte chemoattractant protein 1 (MCP-1, CCL2) and RANTES (CCL5).[192-194] MCP-1 is produced by a wide variety of cells, whereas RANTES is secreted by macrophages and eosinophils.[68] RANTES is chemotactic for eosinophils, basophils, memory T cells, and

monocytes,[193] and both MCP-1 and RANTES induce the release of histamine from basophils.[173,174,193]

Chemokine receptors belong to the 7-TMS, G protein–coupled receptor family, with 6 receptors for CXC chemokines and 10 receptors for CC chemokines identified to date.[68,181,183,185] Most chemokines bind to more than one receptor, and most chemokine receptors, particularly those for CC chemokines, recognize more than one chemokine. Neutrophils, monocytes/macrophages, eosinophils, basophils, dendritic cells, lymphocytes, and T cells each express a distinctive subset of chemokine receptors. According to one model, specific receptors are used sequentially in successive gradients of chemoattractants. Some transmit desensitizing rather than activating signals or even fail to signal and act instead as "decoy" receptors to downregulate inflammatory reactions.[181,183] Of note, a number of chemokine receptors are coreceptors for HIV-1, including CCR5 and CCR3, whose ligands include RANTES, and CXCR4, the major receptor for SDF-1, which is a chemoattractant for T lymphocytes, CD34+ hematopoietic progenitor cells, and neutrophils.[68,189]

In addition to their role as chemoattractants, the molecules listed in Table 21-4 induce the activation of other many other phagocyte functions on binding to their cognate cell surface receptors. Such functions include the upregulation and increased affinity of leukocyte integrin adhesion receptors to promote firm attachment to the endothelium, degranulation, and activation of the phagocyte respiratory burst.[180,182,185] The latter two responses generally require higher ligand concentrations than those that elicit chemotaxis, which can be as low as 10^{-9} mol/L.[195] Strong attachment of leukocytes to the endothelium can also be mediated by the membrane-tethered chemokine fraktalkine.

Despite the diverse chemical structures of the phagocyte chemoattractants listed in Table 21-4, all of the corresponding receptors that have been cloned to date belong to the 7-TMS family of receptors, also known as heptahelical or serpentine receptors.[67,196,197] The transduction of signals through chemoattractant receptors is mediated by binding of heterotrimeric G proteins to specific intracellular domains of the receptor.[198] Binding of ligand to the receptor promotes the exchange of GTP for guanosine diphosphate (GDP) bound to the G-protein α subunit, which in turns leads to dissociation of the β-γ subunits and their interaction with downstream signaling effectors, including enzymes that catalyze the production of important phospholipid second messengers at the cell membrane.[63] Phospholipase C generates diacylglycerol and IP_3 from PIP_2, which then activate protein kinase C and induce the release of intracellular calcium stores. PI3K is another key target of activated heterotrimeric G proteins and catalyzes the phosphorylation of PIP_2 to form PIP_3. Binding of formylated peptides to neutrophils also activates the p21ras-MAPK pathway and the Rho GTPases Cdc42 and Rac, with the latter known to play important roles in regulating the actin cytoskeleton and oxidant production.[54,199-202] Certain Gα subunits are expressed preferentially in leukocytes and are important in signaling through the phagocyte 7-TMS receptors.[203,204]

Adhesion and Migration into Tissues

The discovery that leukocytes migrate from the bloodstream into extravascular sites of inflammation, described by Cohnheim in 1867, was a major milestone in the conceptualization of the inflammatory process.[159] Cohnheim, who used intravital microscopy to study the microvasculature in the frog tongue and mesentery after tissue injury, also first proposed that inflammatory stimuli induce a molecular change in the blood vessel wall that promotes increased adherence of leukocytes, a concept that was finally proved a century later.

To move from the bloodstream into inflamed sites, leukocytes must attach to the vascular endothelium, migrate between adjacent endothelial cells in a process referred to as diapedesis, and penetrate the basement membrane. The molecular mechanisms underlying these events involve a series of sequential adhesive interactions between chemoattractant-activated leukocytes and endothelial cells that are activated by inflammatory mediators (Fig. 21-3).[6,116,180,205,206]

Leukocyte Adhesion and Migration into Tissues

The initial step in emigration from postcapillary venules is a low-affinity interaction between the neutrophil and
FIGURE 21-3. Adhesive interactions during phagocyte emigration. Under conditions of flow within postcapillary venules, leukocytes are first observed to roll along the endothelium adjacent to the extravascular site of inflammation. Subsequently, some of the rolling leukocytes adhere firmly, pass between endothelial cells by diapedesis, and then migrate into subendothelial tissue. Leukocyte rolling is mediated by multiple low-affinity interactions between selectin receptors and carbohydrate counter-receptors, and firm adhesion and diapedesis are largely mediated by integrin and immunoglobulin (Ig)-like adhesion proteins. Chemokines or other chemoattractants are important for both upregulating the cell surface expression of leukocyte integrins and triggering inside-out signaling to increase their avidity for endothelial ligands. *(Adapted with permission from Carlos TM, Harlan JM. Leukocyte-endothelial adhesion molecules. Blood. 1994;84:2068-2101.)*

the endothelium that is often referred to as "rolling" based on its appearance on intravital microscopy. This transient adherence, also called "tethering," is mediated by the upregulation of selectin expression on endothelial cells. The selectin family of adhesion molecules consists of membrane-spanning glycoproteins (Fig. 21-4) that bind to fucosylated structures such as Lewis X (Galβ1→4[Fucα1→3]GlcNac→R), sialyl-Lewis X, and other specific carbohydrates.[205,207-209] P-selectin is important for the initial steps of neutrophil adhesion to the endothelium and is stored in the Weibel-Palade bodies and alpha granules of endothelial cells and platelets, respectively. Upon endothelial cell activation by histamine, thrombin, and other inflammatory molecules, these cytoplasmic storage granules fuse with the cell membrane to rapidly increase the surface expression of P-selectin. E-selectin is expressed on endothelial cells at low levels but is upregulated by transcriptional activation and de novo protein synthesis in response to inflammatory cytokines.[210] E-selectin binds to three different ligands on neutrophils, P-selectin glycoprotein ligand 1 (PSGL-1), E-selectin ligand 1 (ESL-1), and CD44.[211] These ligands allow endothelial cells to capture neutrophils by mediating tethering, rolling, and slowing of neutrophil velocity, respectively. L-selectin is expressed constitutively on the surface of neutrophils, mononuclear phagocytes, and lymphocytes and is shed within minutes of leukocyte activation by a proteolytic cleavage event near the external membrane surface insertion site.[212,213] Circulating L-selectin may modulate leukocyte adhesion during inflammation.[214]

Rolling neutrophils can detach and return to the circulation. Others will come to a halt and, within seconds, adopt a flattened, adherent morphology and attach firmly to the vessel wall.[205] This firm attachment appears to be mediated in large part by binding of leukocyte integrin adhesion receptors to intercellular adhesion molecules (ICAMs) on the endothelium.[205,206] In addition, complement fragments are found on the endothelial surface at inflamed sites and may also function as integrin-binding sites. Activation of leukocytes by chemoattractants and other inflammatory mediators is critical to the development of these strong adhesive interactions because it leads to upregulation of the number and avidity of cell surface integrins ("inside-out signaling"). Exposure to locally high concentrations of chemoattractants may be enhanced by selectin-mediated tethering and by retention of chemokines on the extracellular matrix.[187,188]

The integrins, a large family of adhesion proteins that are glycosylated heterodimers of a noncovalently linked α and β chain, are classified into subfamilies according to the type of β subunit.[205-207,215] Many integrins mediate attachment to extracellular matrices by serving as receptors for matrix proteins. Others are involved in hemostasis, such as glycoprotein IIb/IIIa on platelets. Neutrophil β_2 and β_1 integrins appear to be involved in regulating neutrophil retention and release, respectively, from the bone marrow storage pool into the circulation.[189]

Leukocyte β_2 integrins (Fig. 21-5) play a critical role in mediating adhesive interactions in inflammation, including attachment of leukocytes to endothelial cells, and are also opsonic receptors for complement fragment C3bi-coated particles. There are four different leukocyte β_2 integrins, each with a common 95-kd β subunit (CD18) but different α subunits: CD11a (177 kd), CD11b (165 kd), CD11c (150 kd), and CD11d (160 kd) (Fig. 21-5). Lymphocyte function antigen 1 (LFA-1) is

expressed by all leukocytes, including lymphocytes. Mac-1 and p150,95 are expressed by granulocytes, mononuclear phagocytes, some activated T lymphocytes, and large granular lymphocytes.[205-207,215] Mac-1 is the most prominent β_2 integrin on neutrophils, whereas α_d β_2 is expressed particularly in tissue macrophages. Mutations in the common β subunit result in an inherited defect in phagocyte function—leukocyte adhesion deficiency type I (LAD I), as discussed in a later section. All β_2 integrins are absent in LAD I, thus indicating that the stability of each α subunit requires association with the β chain. The β subunit has a large, glycosylated extracellular domain, a single transmembrane-spanning domain, and a short cytoplasmic tail.[216] The extracellular domain has two regions that are conserved among other β subunits.[215] There are four cysteine-rich tandem repeats that appear to be important for the tertiary structure of the β subunit. Another conserved region, located near the N-terminal, is critical for maintenance of the α/β heterodimer and may bind divalent cations as well. The α subunit is also a glycosylated integral membrane protein with a single membrane-spanning segment and a short cytoplasmic tail. The external domain contains three divalent cation-binding motifs that must be occupied for ligand binding to occur. A second important extracellular domain, the I domain (for inserted or interactive domain), can coordinate divalent cations and is likewise thought to be involved in ligand binding. The intracellular domain of the α

subunit includes a conserved sequence that is critical for the modulation of integrin avidity (see later).[217] The cytoplasmic tails of both the α and β integrin subunits also interact with cytoskeletal proteins.[207,215] The endoparasite hookworm *Ancylostoma caninum* produces a heavily glycosylated protein called NIF that binds to CD11b/CD18 to inhibit neutrophil spreading and attachment to the endothelium.[218,219]

Although β_2 integrins are constitutively expressed on the neutrophil cell surface, a large pool is stored in intracellular secretory vesicles (see Table 21-2). These vesicles are rapidly mobilized upon neutrophil activation by chemoattractants and fuse with the membrane to increase the cell surface expression of β_2 integrins by about 10-fold.[180,220] Signaling through chemoattractant receptors also markedly increases the avidity of β_2 integrins for their ligands, which plays an even more important role in rapidly upregulating integrin activity and promoting firm attachment to the blood vessel wall.[205,206,215] The increased adhesiveness of the β_2 integrins appears to involve a conformational change in integrin structure upon cellular activation.

The major counter-receptors for the β_2 integrins are the ICAMs (Fig. 21-6), which are members of the immunoglobulin superfamily.[205,206,215] These transmembrane proteins contain anywhere from two to six immunoglobulin domains and are present on endothelial cells, T cells, and a variety of other cell types. ICAM-1 and ICAM-2 are of particular importance in mediating binding of neutrophils and other leukocytes to the endothelium. Endothelial cell expression of ICAM-1, which promotes increased cell-cell interactions with leukocytes at inflamed sites, increases in response to inflammatory cytokines.

Vascular cell adhesion molecule 1 (VCAM-1) is another immunoglobulin superfamily member expressed on endothelial cells that can be induced by cytokines.[206,221] VCAM-1 is the counter-receptor for the β_1 integrin very late antigen 4 (VLA-4) and appears to be important in promoting the adherence of monocytes and eosinophils during inflammation. The β_2 integrin Mac-1 (CD11b/CD18) also has an important role as an opsonic receptor for the complement fragment C3bi, as discussed later.

In addition to their role in adhesion, β_2 integrins play an important role in leukocyte activation.[222,223] Binding of ligand to integrins results in their clustering and activation of tyrosine kinase and other signaling cascades,[224] which provides costimulatory signals to enhance migration, the respiratory burst, Fcγ-mediated phagocytosis, and degranulation.

Although leukocyte β_2 integrin–mediated adhesion is clearly important for recruitment of neutrophils from the systemic microvasculature into inflammatory sites, emigration of neutrophils out of the pulmonary circulation can also be mediated by alternative pathways, depending on the inflammatory stimulus.[225] Whether the alternative pathway in pulmonary capillaries involves selectins or other adhesion molecules remains to be defined.

The final steps in emigration of neutrophils from the blood vessel lumen into inflamed tissue involves squeezing between adjacent endothelial cells (diapedesis) and penetrating the basement membrane (see Fig. 21-3). The presence of a chemotactic gradient is required to induce the directional migration of neutrophils.[187,226,227] Adhesive interactions between the β_2 integrins and endothelial cell ICAM-1 are essential for neutrophil diapedesis, whereas VCAM-1 and E-selectin can mediate the transmigration of monocytes and eosinophils.[6,116] Junctional adhesion molecule 1 (JAM-1), an immunoglobulin superfamily protein expressed at the tight junctions of resting endothelial cells and epithelial cells, facilitates leukocyte transmigration via binding to LFA-1 (CD11a/CD18).[228] Transendothelial migration of neutrophils is also dependent on homologous binding between neutrophil and endothelial cell platelet–endothelial cell adhesion molecule 1 (PECAM-1, CD31), another immunoglobulin superfamily member expressed on the surface of leukocytes, platelets, and endothelial cells, where it is localized at the junctions between cells.[229,230] Migrating neutrophils induce increases in endothelial intracellular calcium levels and changes in the actin cytoskeleton that facilitate transmigration.[231,232] Finally, chemoattractant-induced neutrophil degranulation results in the release of digestive enzymes, including collagenase, elastase, and gelatinase, which facilitate penetration of the basement membrane.[46,233]

Chemotaxis

Chemotaxis is the directional movement of a cell along a concentration gradient.[26,28,31,234,235] Defects in neutrophil cellular motility or other steps in chemotaxis can result in decreased resistance to bacterial and fungal infections, as discussed later in this chapter. The neutrophil chemotactic response occurs at chemoattractant concentrations that approximate the dissociation constants of the chemotactic factors for their receptors, which are much lower than those that elicit degranulation and activation of the respiratory burst.[29,195] Cells respond to a chemotactic gradient by constantly sensing across their surface, and bound chemotactic receptors are continuously internalized. A migrating neutrophil has a polarized appearance, with pseudopodia or lamellipodia, thin structures rich in actin filaments and lacking intracellular organelles, extending at the leading edge.[29,31] The pseudopods appear to glide forward and pull the cell body behind them. The nucleus tends to remain in the posterior half of the moving leukocyte. Migration also requires the formation of a uropod at the "tail" of the leukocyte that deattaches from the underlying matrix and retracts the rear of the cell as it moves forward.[236] Rho GTPases play an important role in establishing chemoattractant-induced polarization and migration.[54,202]

Neutrophil movement is dependent on the dynamic assembly and disassembly of filamentous actin, coordinated by various ABPs whose activity is regulated by intracellular signaling molecules.[26,28,234,235,237,238] Leukocyte motility is inhibited by the cytochalasins, which block actin assembly. Actin can exist either as a soluble monomer (globular actin) or in needle-like helical filaments (filamentous actin). Actin filaments align spontaneously in parallel bundles, but in the cell they are organized into a branching network because of the presence of actin filament cross-linkers such as ABP.[239,240] Another class of actin regulatory proteins sequesters actin monomers and can thus control the availability of globular actin for filament formation. Prophyllin and thymosin B_4 are two major actin monomer–binding proteins in neutrophils.[241] Other ABPs, such as gelsolin, cap the fast-growing barbed end of the actin filament or sever filamentous actin into shorter pieces, or both.[29,31]

Agonists acting via receptors on the cell membrane trigger the generation of second messengers that interact with ABPs to control dynamic local cycles of filamentous actin assembly.[31] For example, increased local calcium concentrations activate gelsolin, which promotes actin disassembly by cleaving actin filaments and capping its barbed ends. On the other hand, actin assembly is stimulated by the accumulation of phosphoinositols liberated from membrane phospholipids around an activated receptor. Phosphoinositols such as PIP_2 interact both with actin-sequestering proteins to liberate actin monomers and with gelsolin to uncap the barbed ends of filamentous actin. The Rho GTPases Cdc42 and Rac are important regulators of actin remodeling and are activated by binding of ligand to chemoattractant receptors.[54,201,202,234,242] Cdc42 activates proteins of the Wiskott-Aldrich syndrome protein (WASP) family, which then bind to a complex of seven proteins known as the Arp2/3 complex to nucleate assembly of new actin filaments at the leading edge of migrating cells.[234,237,243] Activation of Rac appears to be

important both for de novo actin nucleation by the Arp2/3 complex and for stimulating uncapping of existing actin filament barbed ends.[199]

During pseudopod extension in chemoattractant-activated neutrophils, new actin polymerization occurs at the site of membrane protrusion while the filamentous actin in the rear of the cell disassembles.[28,235,244] How actin assembly-disassembly results in membrane extension and the formation of pseudopodia is not fully understood but may involve localized changes in osmotic pressure as a result of alterations in actin polymerization.[29,31] Membrane movement and retraction of the rear of the cell are mediated in part by Rho GTPase–regulated contractile proteins such as myosin 1.[235,245,246]

Recognition, Opsonization, and Phagocytosis

Recognition, ingestion, and disposal of microbes, foreign particulate matter, and damaged cells constitute a major aspect of phagocyte function. To facilitate their recognition by phagocytes, these targets are coated with serum opsonins (from the Greek word meaning "to prepare for dining") that include proteolytic fragments derived from the complement cascade, as well as specific immunoglobulins. The key humoral opsonins are the proteolytic cleavage products of C3 (C3b and C3bi), which can be generated in the absence of specific immunity by the alternative and mannose-binding lectin (MBL) pathways (see later), and the opsonic antibodies IgM, IgG1, and IgG3. Targets are opsonized by the deposition of C3b and C3bi or IgG onto their surfaces via the specific (Fab) portion of the antibody. Antibacterial IgM antibodies, though not opsonic by themselves, play an important role in phagocytosis by activating complement. Opsonins are recognized by phagocyte cell surface glycoprotein receptors for immunoglobulin and C3 cleavage products, as described later. Inherited deficiencies of opsonization can result in increased susceptibility to bacterial infections, as discussed in a following section. In contrast, primary defects in phagocyte receptors for these opsonins appear to be an uncommon cause of recurrent infections.[247]

Phagocytes also have cell surface receptors capable of recognizing targets even in the absence of opsonins. These members of the "pattern recognition receptor" (PRR) family recognize broad classes of macromolecules.[248-250] PRRs include scavenger receptors that have broad binding specificity for polyanionic ligands and participate in the clearance of diverse material, including modified LDL and apoptotic cells.[248] Many PRRs detect conserved molecular structures unique to microbes that are referred to as pathogen-associated molecular patterns (PAMPs).[248-251] The mannose receptor recognizes carbohydrate structures present in a range of cells infected by bacteria, fungi, viruses, and parasites, whereas the β-glucan receptor (dectin-1) binds to β-glucan structures in zymosan and other yeast-derived particles. Mamma-

lian TLRs are an important group in the PRR family.[249,250,252] At least 12 different TLRs have been described; they recognize conserved peptide, lipid, carbohydrate, and nucleic acid structures expressed by different groups of microbes. For example, peptidoglycan and lipopolysaccharide are PAMPs associated with gram-positive and gram-negative bacteria and are recognized by TLR2 and TLR4, respectively. Binding to PRRs, which often occurs in a combinatorial fashion, activates an array of proinflammatory responses, including expression of proinflammatory cytokines and release of oxidants and reactive nitrogen intermediates. TLR signaling activates the NF-κβ and interferon regulatory factor (IRF)-dependent pathways, and genetic defects in the protein that couples TLRs to NF-κβ lead to recurrent bacterial infections.[253] Some PRRs, including the mannose receptor, scavenger receptors, and β-glucan receptor, also trigger phagocytosis.[251]

In addition to cell surface PRRs, soluble PRRs present in serum or tissues serve important roles in alerting phagocytes to the presence of microbes.[254,255] Such PRRs include the collectins (calcium-dependent lectins), which bind to oligosaccharide or lipid moieties of microorganisms to enhance their opsonization and efficiently activate phagocytes. Members of the collectin family include the lung alveolar surfactant proteins A and D and the MBL, also known as MBP.[255-257] Binding of MBL to mannose residues initiates a third pathway of complement activation (in addition to the classical and alternative pathways) by interacting with the serine proteases MASP1 and MASP2 and thereby generating opsonic C3 fragments.[254,258] MBL itself can also function as an opsonin for promoting uptake by the complement receptor CR1.[255,258]

Complement Receptors

Activation of complement C3 to generate the cleavage fragments C3b and C3bi is the dominant source of opsonins in the absence of antibodies. Four C3 fragment receptors have been described on phagocytic leukocytes (Table 21-5). The human phagocyte C3b receptor (CR1, CD35) is a high-molecular-weight, single-subunit glycoprotein that shows substantial heterogeneity in size because of the presence of four distinct alleles in the human population that encode proteins ranging in size from 160 to 250 kd. CR1 is responsible for the binding of C3b-opsonized particles and for initiating their ingestion.[258,259] CR1 also recognizes microbes opsonized with MBL.[255,256,258] The other major opsonic receptor, CR3, recognizes particles opsonized with C3bi. This receptor is the same as the β_2 integrin Mac-1 (CD11b/CD18) discussed in detail in an earlier section (see Fig. 21-5). Binding of C3bi-opsonized particles to CD11b/CD18 triggers both phagocytosis and, in neutrophils, the respiratory burst. The CR4 receptor is the same as the β_2 integrin CD11c/CD18 and, on macrophages, can also initiate phagocytosis of C3bi-coated targets. Finally, a newly discovered receptor that binds the complement

fragments C3b and C3bi, termed CRIg (complement receptor of the immunoglobulin superfamily) is expressed primarily in resident macrophages of the liver (Kupffer cells).[260] CRIg appears to play a critical role in mediating phagocytosis and clearance of C3 fragment–opsonized bacteria from the circulation, at least in mice.[260]

Immunoglobulin Receptors

Immunoglobulins are recognized by Fc receptors, which are members of the immunoglobulin gene superfamily. Fc receptors bind to the "constant domain" of the antibody molecule, these being specific to each class of immunoglobulin (IgA, IgE, IgG, and IgM).[247,261-263] The most important from the standpoint of microbial opsonization are Fc receptors that recognize IgG (Table 21-6). The Fcγ receptors include three distinct classes, FcγRI, FcγRII, and FcγRIII, which are encoded by at least eight genes that have evolved through gene duplication and alternative splicing, although not all give rise to detectable mRNA or protein.[264] The low-affinity FcγR genes (FcγRII and FcγIII families) and two of the genes for the high-affinity IgE receptor are clustered on chromosome 1q22. The high-affinity IgG Fc receptors map to other sites on chromosome 1.

Except for FcγRIIIb, which is anchored in the membrane by a glycosylphosphatidylinositol (GPI) moiety, the FcγR proteins have a single transmembrane domain. FcγRI and FcγRIIIa exist as oligomeric complexes with γ (in phagocytes) or ζ (in lymphocytes) chains that are important for both their stable expression and signaling functions.[264] These accessory chains contain YXXL immunoreceptor tyrosine activation motifs (ITAMs), which become tyrosine-phosphorylated upon receptor cross-linking to initiate downstream signaling cascades.[247,261-263] The cytoplasmic tail of FcγRIIa contains variant ITAMs, and hence this receptor does not require accessory chains for its function. There is no murine equivalent to FcγRIIa.[263] The GPI-linked FcγRIIIb must be colligated to either FcγRIIa or the β_2 integrin CR3 (Mac-1) to initiate signaling functions upon ligation.[247,261-263] FcγRIIb, expressed on monocytes/macrophages, mast cells, and lymphocytes, contains immunoreceptor tyrosine inhibition motif (ITIM) sequences and instead inhibits cellular activation upon immunoglobulin cross-linking.[261-263]

Each FcγR is expressed at different levels, depending on the type of phagocytic cell (see Table 21-6), and some FcγRII and FcγRIII family members are also expressed on lymphocytes, platelets, thymocytes, natural killer (NK) cells, and mast cells.[263,264] The FcγRI class includes the products of three highly homologous genes, denoted A, B, and C, although the protein products of the latter two have not been detected in vivo. FcγRIa receptors are expressed by monocytes and neutrophils or eosinophils stimulated by IFN-γ or G-CSF and have high affinity for monomeric IgG.[247,262,263] Members of the FcγRII and FcγRIII families have low affinity for monomeric IgG, but high affinity for clusters of IgG (e.g., several antibodies bound to the same particle) and immune complexes. Only neutrophils and IFN-γ–stimulated eosinophils appear to express FcγRIIIb, and polymorphisms in this receptor correspond to the serologically defined NA1/NA2 antigen system, which is a common antibody target in autoimmune and alloimmune neutropenia.[265,266] Polymorphisms in FcγRIIa, FcγRIIIa, and FcγRIIIb are associated with an increased incidence or severity of various autoimmune or infectious diseases.[267] For example, the 131H allele of FcγRIIa, which is the only FcγR that

mediates efficient phagocytosis of IgG2-opsonized bacteria, has been linked to a lower incidence of infections with encapsulated bacteria.[247]

Cross-linking of FcγRs can trigger a wide range of functional responses, including phagocytosis of IgG-coated microbes, blood cells, or tumor cells; ingestion of immune complexes; release of inflammatory mediators; activation of the respiratory burst; and antibody-dependent cellular cytotoxicity (ADCC). The relative roles of different phagocyte FcγR classes have not been clearly delineated, although all can function as receptors for opsonized particles or immune complexes. Binding of IgG to FcγRI and FcγRIIa activates the respiratory burst, whereas secretion of granular contents is a prominent response on binding to FcγRII and FcγRIIIb.[247,261] Although the ligand-binding domains of different FcγRs all bind IgG, the specificity of the cellular response may be governed by the unique transmembrane and cytoplasmic domains of a particular Fc receptor subtype.[261-263]

Ligation and cross-linking of FcγRs induce a cascade of biochemical signals that are initiated by activation of nonreceptor protein tyrosine kinases of the Src family, which phosphorylate ITAMs in the FcRγ chain and in FcγRIIa to recruit and activate the Syk tyrosine kinase and further amplify ITAM phosphorylation.[261,268-270] Subsequent activation of several parallel pathways, including activation of phospholipase C, PI3K, MAPK-related pathways, and other targets, leads to various cellular responses, such as actin and membrane remodeling for ingestion of particles, activation of NADPH oxidase, and release of cytokine.

Opsonization of microbes with secretory IgA antibodies is likely to be important in the clearance of microbes from the mucosal surfaces of the respiratory, gastrointestinal, and urogenital tracts. Neutrophils and monocytes have an Fc receptor for IgA (FcRα) that has close structural similarities with other members of the Fc receptor family.[271] Ligation of phagocyte FcRα can trigger phagocytosis, degranulation, and release of superoxide.[272,273] IgE antibodies can activate eosinophils and mast cells through the high-affinity FcεRI receptors.

Phagocytosis

Engagement of any of the opsonic receptors initiates phagocytosis of an opsonized particle by forming a phagocytic vacuole to enclose the particle. The molecular details of this process are incompletely understood but involve membrane remodeling and regulated assembly and disassembly of the actin cytoskeleton, in a fashion analogous to the mechanisms that result in cell movement when chemotactic receptors are engaged. FcγR-mediated phagocytosis triggers the extension of long pseudopodia that attach in a zipper-like fashion around the particle and then fuse to form the phagosome, which is then drawn into the cell.[268-270] In contrast, complement-opsonized particles attach to the cell surface only at limited points and "sink" into the cytoplasm in the absence of any pseudopod extension.[269] These

morphologic differences are associated with differences in the underlying biochemical pathways. FcR-mediated phagocytosis is sensitive to inhibitors of tyrosine kinases and requires the Rac and Cdc42 GTPases, whereas CR3-mediated phagocytosis is dependent on protein kinase C and the Rho GTPase.

Microorganisms can also enter phagocytes by nonopsonic routes, which enables them to evade the cytocidal weapons that are otherwise activated upon phagocytosis. For example, after binding to the macrophage cell surface, *Salmonella typhimurium* induces extensive membrane ruffling that leads to internalization of the bacterium into a macropinisome, or "spacious phagosome."[274] Attachment of *Legionella pneumophila* to macrophages induces the formation of a pseudopod that spirals around the bacterium to form a "coiling phagosome" that does not acidify or fuse with lysosomes. [274]

Cytocidal and Digestive Activity

Binding of ligands to phagocyte chemoattractant and opsonic receptors ultimately leads to the mobilization of phagocyte granules that contain cytotoxic and hydrolytic proteins and to the activation of enzymatic reactions that generate toxic oxygen metabolites (see Fig. 21-8). These complementary processes are designed to modify or destroy the inciting object and are often classified as oxygen-independent and oxygen-dependent pathways.

Neutrophil granules are secretory organelles that can be divided into four general classes, as discussed in a preceding section (see Table 21-2). Degranulation (also referred to as exocytosis or mobilization), or the fusion of granule membranes with the plasma or phagosome membrane, results in the transfer of granule membrane constituents to a new membrane compartment and discharge of the granule contents into the extracellular fluid or phagocytic vacuole. Microtubules and microfilaments are involved in granule translocation. Degranulation is triggered by increases in calcium concentration when neutrophils are activated through chemoattractant and other receptors. Different neutrophil granule populations have marked differences in expression of VAMP-2, a fusogenic protein involved in exocytosis; expression is highest in secretory vesicles, less in gelatinase granules, and still lower in specific granules.[39] Thus, different granule classes vary in their responsiveness to calcium, which leads to the mobilization of different granule classes, depending on the calcium concentration, which in turn is proportion to the concentration of the chemoattractant or other activating signal.[24,46,275] Secretory vesicles, whose membranes are storage pools for β_2 integrin adhesion proteins and other receptors, are mobilized with relatively low concentrations of calcium. Fusion of secretory vesicles with the plasma membrane provides a rapid means of upregulating the cell surface expression of these receptors, along with the metalloproteinase leukolysin (MMP-25), another membrane constituent of secretory vesicles. Gelatinase (tertiary) granules are also easily mobilized for exocytosis at the cell surface to release gelatinase (MMP-9). These metalloproteinases are stored as inactive proforms and become activated by proteolysis after exocytosis to facilitate the breakdown of extracellular matrix during the early phases of neutrophil migration.[25,233] At the opposite end of the spectrum, azurophilic (primary) granules, which contain cytotoxic proteins and hydrolytic enzymes, undergo only limited exocytosis and fuse primarily with phagocytic vacuoles to deliver their contents into a sequestered compartment.

Monocytes and macrophages do not have populations of cytoplasmic storage granules and secretory vesicles equivalent to those found in neutrophils. Instead, internalized phagosomes fuse sequentially with endocytic vesicles and subsequently lysosomes to form a phagolysosome, which has a highly acidic interior rich in hydrolases.[121,268,269]

Certain microorganisms can become intracellular parasites because they have developed mechanisms to prevent fusion of granules with the phagocytic vacuole or otherwise evade the phagocyte digestive and oxidative armamentarium. For example, although mycobacteria exist intracellularly within a phagosome, they produce compounds that inhibit their fusion with lysosomes.[276] *L. pneumophila* and *Toxoplasma* may inhibit acidification and lysosomal fusion.[274] Virulent strains of *Salmonella* engulfed by macrophages produce compounds that prevent translocation of the respiratory burst oxidase to the phagosomal membrane.[277] *Listeria monocytogenes* escapes the phagocytic vacuole altogether to avoid attack by lysosomal products and can survive in the cytoplasm of relatively quiescent macrophages and hepatocytes.[274] *Yersinia*, group A streptococci, *Helicobacter*, *Ehrlichia*, and *Francisella* are examples of microbes that have developed similar strategies to survive in neutrophils.[278]

In addition to delivering their antimicrobial granule contents to the interior of phagosomes, dying neutrophils are also capable of extruding web-like extracellular structures, termed neutrophil extracellular traps (NETs), composed of chromatin and granule proteins that can bind and kill microbes.[279] The formation of NETs appears to involve a novel process of cell death that is dependent on oxidants generated from neutrophil NADPH oxidase.[280]

Oxygen-Independent Toxicity

Phagocyte granules supply preformed cytotoxic and digestive compounds that play a key role in oxygen-independent killing and digestion of microbes, senescent cells, and particulate debris. In neutrophils, azurophilic (primary) and specific (secondary) granules serve as the main storage reservoir of these compounds. Oxygen-independent pathways complement those dependent on the respiratory burst (see the following section) and are also important for phagocyte antimicrobial activity under the adverse conditions of hypoxia and acidosis often encountered locally at the site of infection.

Numerous cationic antimicrobial proteins are contained within neutrophil azurophilic granules.[46,275,281,282] Defensins are small (29– to 25–amino acid residue) basic peptides that constitute more than 5% of the total cellular protein of human neutrophils, although they are absent in murine neutrophils. These peptides exert antimicrobial effects against a broad range of gram-positive and gram-negative organisms, fungi, mycobacteria, and some enveloped viruses. Defensins are also cytotoxic to mammalian cells. Defensins kill target cells by insertion into the cellular membrane and formation of voltage-regulated channels. Defensin-like peptides have also been found in small intestinal Paneth cells and in tracheal epithelium.[281,282] BPI is a 55-kd cationic protein that has potent cytotoxic effects on gram-negative bacteria.[283] BPI binds avidly to lipopolysaccharide, which leads both to bacterial killing by damaging the cell membrane and to neutralization of the endotoxin associated with the bacterial cell wall and in serum. Serpocidins are a family of 25- to 29-kd glycoproteins that are homologous to members of the serine protease superfamily; they include azurocidin (CAP37) and three serine proteases (cathepsin G, elastase, and proteinase-3).[282,284] In human neutrophils, serpocidins are even more potent than defensins in antimicrobial activity and have a broad spectrum of cytotoxicity that is, with few exceptions, unrelated to proteolytic activity. Cathepsin G, elastase, and proteinase-3 are often referred to as neutral proteases because the optimal pH for their proteolytic activity is approximately 7. Azurocidin can bind to endotoxin, which appears to account for its activity against gram-negative bacteria.[285] Azurocidin is also a potent chemoattractant for monocytes, as well as fibroblasts and T cells.[285] Exogenous administration of antimicrobial peptides is being studied as an adjunctive or alternative therapy to conventional antibiotics in a number of settings.[286]

Both azurophilic and specific granules contain lysozyme, which hydrolyzes the cell wall of saprophytic gram-positive organisms and may also assist in the nonlytic killing of other organisms.[46] hCAP-18, a member of the cathelicidin family of antimicrobial peptides, is cleaved by proteinase-3 after exocytosis. Its N-terminal region is homologous to that of other cathelicidins, whereas its 37–amino acid C-terminal fragment, termed LL-37, has additional activities, including acting as chemoattractant, as well as effects on apoptosis.[39] Specific granules also contain the iron-binding glycoprotein lactoferrin, which has direct bactericidal activity both related and unrelated to the chelation of iron compounds required for bacterial metabolism. Lactoferrin may also catalyze the nonenzymatic formation of OH· radicals during the respiratory burst (see the following section). Vitamin B_{12} (cobalamin) binding–protein has been proposed to bind an analogous family of compounds found in bacteria to exert an antimicrobial effect.[287] Lipocalin, also known as NGAL, interferes with bacterial iron utilization by binding to bacterial ferric-siderophore complexes.[46]

Azurophilic granules contain a variety of hydrolases (see Table 21-2) that have a lower optimal pH (<6), consistent with the lysosomal character of these granules. Studies using indicator dyes and biochemical techniques suggest that after a transient rise, the pH of the phagocytic vacuole falls below 6, which would enhance the activity of these enzymes upon their discharge into the vacuole.[288,289] The acid hydrolases serve primarily a digestive rather than a microbicidal function.[290] Azurophilic granules also contain MPO, which is an important enzyme in the microbicidal oxygen-dependent reactions that are described in the following section.

Inherited partial or complete deficiency of MPO, which occurs in 0.05% of the population, can occasionally result in increased susceptibility to infection (see later in this chapter). Deficiencies in other individual neutrophil granule proteins have not yet been described in humans, but gene-targeted mice lacking the neutrophil granule serine proteases elastase or cathepsin G have impaired host defense against gram-negative sepsis and fungal infections.[291,292] A few rare disorders involving defects in granule formation (SGF) or degranulation (CHS) are associated with recurrent bacterial infections. Inherited mutations in neutrophil elastase have recently been identified in patients with cyclic neutropenia and severe congenital neutropenia (SCN).[293,294] The mutant forms of elastase may have abnormal properties that exert a toxic effect on granulopoiesis.

Oxygen-Dependent Toxicity

The resting neutrophil relies primarily on glycolysis for energy and hence consumes relatively little oxygen.[295] However, within seconds after contacting opsonized microbes or high concentrations of chemoattractants, oxygen consumption increases dramatically, often by more than 100-fold. This "extra respiration of phagocytosis" was first observed in 1933,[296] but it was almost 30 years before it was appreciated that this process was insensitive to mitochondrial poisons and thus not related to increased energy demands.[297] The enzyme complex responsible for this phenomenon, referred to as the NADPH or respiratory burst oxidase, is associated with the plasma and phagolysosomal membranes and catalyzes the transfer of an electron from NADPH to molecular oxygen, thereby forming the superoxide radical (O_2^-) (Fig. 21-7).[298-301] Superoxide, though itself a relatively weak microbicidal agent, is the precursor to a family of potent oxidants that are essential for the killing of many microorganisms (Fig. 21-8; also see Fig. 21-7).[298,299,302,303] The importance of the respiratory burst to normal host defense is underscored by the recurrent and often life-threatening infections seen in patients with chronic granulomatous disease (CGD); such patients are genetically deficient in respiratory burst oxidase activity.

The respiratory burst oxidase is a multi-subunit enzyme complex assembled from membrane-bound and soluble proteins upon phagocyte activation (Fig. 21-9). Identification of the components of this enzyme has ben-

FIGURE 21-7. Reactions of the respiratory burst pathway. The enzymes responsible for reactions 1 to 9 are as follows: (1) the respiratory burst oxidase (reduced nicotinamide adenine dinucleotide phosphate [NADPH] oxidase); (2) superoxide dismutase or spontaneous; (3) nonenzymatic, Fe^{2+} catalyzed; (4) myeloperoxidase; (5) spontaneous; (6) glutathione peroxidase; (7) glutathione reductase; (8) glucose-6-phosphate dehydrogenase; (9) glutathione synthetase. Neutrophils and immunity: challenges and opportunities. Nat Rev Immunol. 2006;6:173-182.)*

efited greatly from the biochemical and molecular genetic analysis of patients with CGD. Four polypeptides, gp91^{phox}, p22^{phox}, p47^{phox}, and p67^{phox}, that are essential for respiratory burst function have been identified (Table 21-7), and mutations in the corresponding genes are responsible for the four different genetic subgroups of CGD. The oxidase subunits have been given the designation "*phox*" for *ph*agocyte *ox*idase. A fifth *phox* protein, p40^{phox}, exists in a complex with p47^{phox} and p67^{phox},[301] and though not required for enzyme activity, is important for high levels of superoxide production during phagocytosis.[304-306]

An unusual *b*-type flavocytochrome, located in the plasma membranes and specific granules of resting neutrophils, mediates electron transfer in the oxidase complex. This flavocytochrome is a heterodimer that contains a 91-kd glycosylated protein, gp91^{phox}, and a nonglycosylated subunit, p22^{phox}.[307-310] The gene for gp91^{phox}, which is the site of mutations in the X-linked form of CGD, was one of the first human disease–associated genes to be identified by positional cloning.[310]

The respiratory burst oxidase flavocytochrome has been referred to as flavocytochrome b_{558} for its spectral peak of light absorbance at 558 nm or as flavocytochrome b_{-245} in reference to its midpoint potential of −245 mV, which is the lowest reported for any mammalian cytochrome[311] gp91^{phox} in the redox center of the oxidase; it contains two heme prosthetic groups embedded within the membrane in the hydrophobic amino-terminal of the protein and a flavoprotein domain in the carboxy-terminal with binding sites for flavin and NADPH.[300,301] The p22^{phox} subunit is also an integral membrane protein and provides an important docking site for p47^{phox} during the assembly of NADPH oxidase.[312] Heterodimer formation with gp91^{phox} is essential for heme incorporation and intracellular stability of both flavocytochrome subunits.[313,314]

Based on the redox properties of flavocytochrome b_{558}, the following pathway has been proposed for transfer of electrons from NADPH to O_2 in the respiratory burst (reaction 1 in Fig. 21-7):

Membrane
FIGURE 21-9. Activation of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Shown is the assembled form of the enzymatically active NADPH oxidase, along with subunits affected in the four different genetic subgroups of chronic granulomatous disease (CGD), the approximate incidence, and the chromosomal location of the corresponding gene. Flavocytochrome b_{558}, the redox center of the enzyme, is located in plasma, specific granule, and phagolysosomal membranes. This heterodimer is composed of $gp91^{phox}$ and $p22^{phox}$, which are affected in X-linked and an autosomal recessive form of CGD, respectively. Mutations in the genes encoding two soluble regulatory proteins, $p47^{phox}$ and $p67^{phox}$, account for two autosomal recessive forms of CGD. These subunits, along with a fifth *phox* protein, $p40^{phox}$, are found in the cytosol until phagocyte activation, after which they move as a complex to the membrane to assemble the active NADPH oxidase complex. Membrane translocation of the $p47^{phox}$-$p67^{phox}$-$p40^{phox}$ complex is mediated by binding domains on 47^{phox} that are exposed by activation-induced $p47^{phox}$ phosphorylation. Another essential regulatory component of NADPH oxidase is the small guanosine triphosphatase Rac, which in its active guanosine triphosphate–bound state becomes membrane bound and associates with $p67^{phox}$. By a mechanism that involves an activation domain on $p67^{phox}$, binding of these multiple regulatory subunits activates the flavocytochrome to catalyze the transfer of electrons from cytosolic NADPH across the membrane via the flavin adenine dinucleotide and heme redox centers to molecular oxygen, thereby forming superoxide in the extracellular or intraphagosomal compartment. No cases of CGD have been reported to result from mutations in $p40^{phox}$ or Rac. *(Adapted with permission from Dinauer MC. Chronic Granulomatous Disease and Other Disorders of Phagocyte Function. Washington, DC, American Society of Hematology, 2005, pp 83–89.)*

$$\underset{-330\,\text{mV}}{\text{NADPH}} \rightarrow \underset{-256\,\text{mV}}{\text{flavin}} \rightarrow \underset{-245\,\text{mV}}{\text{heme}} \rightarrow \underset{-160\,\text{mV}}{\text{O}_2} \rightarrow \text{O}_2^-$$
The flavocytochrome spans the membrane, with NADPH being oxidized at the cytoplasmic surface and oxygen being reduced to form O_2^- on the outer surface of the plasma membrane (or the inner surface of the phagosomal membrane).[298]

The $p47^{phox}$ and $p67^{phox}$ subunits, along with the Rac GTPase, regulate NADPH binding and electron transfer in the flavocytochrome. The $p47^{phox}$, $p67^{phox}$, and $p40^{phox}$ subunits are found in the cytosol as a complex that is stabilized by intermolecular interactions that include

those mediated by Src homology domain 3 (SH3) and proline-rich SH3-binding motifs within these proteins.[300,301] Phagocyte activation induces translocation of this complex to the membrane flavocytochrome, triggered by phosphorylation of $p47^{phox}$ to expose an additional pair of SH3 domains that bind to a proline-rich target SH3-binding sequence in $p22^{phox}$.[301,312] The $p47^{phox}$ and $p40^{phox}$ subunits also contain a PX (for *phox* homology) domain for binding phosphoinositides generated by PI3K during neutrophil activation.[315–317] The $p47^{phox}$ subunit is necessary for translocation of $p67^{phox}$ to the membrane of activated neutrophils based on studies of $p47^{phox}$-deficient CGD neutrophils.[300,318] However, substantial amounts of superoxide can be generated from neutrophil membranes in vitro in the absence of $p47^{phox}$, provided that high concentrations of $p67^{phox}$ and Rac-GTP are supplied.[300] Hence, $p47^{phox}$ acts as an "adaptor" protein to mediate the translocation of $p67^{phox}$ and position it correctly in the active NADPH oxidase complex. In addition to $p47^{phox}$ and $p67^{phox}$, the active NADPH oxidase requires the GTP-bound form of the Rho GTPase Rac.[54,202,300,301] The main target of Rac-GTP is the $p67^{phox}$ subunit, which contains a Rac-binding domain created by four α-helical tetratricopeptide repeat (TPR) motifs.[319] The GTP-bound form of Rac also appears to interact with flavocytochrome *b* to further regulate enzyme activity.[320]

Oxidase assembly is triggered by receptor-mediated binding of many soluble chemoattractants (see Table 21-4), which requires higher concentrations of these molecules than needed for the initiation of chemotaxis. Binding of opsonized microbes to $Fc\gamma$ and complement receptors is another major physiologic trigger of the respiratory burst that is activated at sites of microbial contact.[321,322] The specific pathways in the signal transduction cascade leading to oxidase assembly and activation are still incompletely defined, but the two critical downstream events are phosphorylation of $p47^{phox}$ and activation of Rac to its GTP-bound state.[202,300,301] The functional oxidase complex is assembled at the plasma membrane in response to soluble agonists. During phagocytosis, additional flavocytochrome *b* for assembly of NADPH oxidase is delivered to the phagosome by the membrane fusion of specific granules, which contain the majority of the neutrophil's supply of flavocytochrome b.[24,46,275] Because release of O_2^- occurs largely at the extracellular side of the membrane, oxidants are released at sites of microbial contact or within the phagocytic vacuole, where they can interact with granule contents to potentiate their microbicidal effects.

Once formed, the O_2^- radical is first converted, either spontaneously or by means of superoxide dismutase, into H_2O_2 (reaction 2 in Fig. 21-7). Azurophilic granule–derived MPO, in the presence of halides, catalyzes the conversion of H_2O_2 to hypochlorous acid (HOCl), the active agent in household bleach (reaction 4 in Fig. 21-7). Hydrogen peroxide may also be converted to hydroxyl radical (OH·) in a nonenzymatic reaction with

O_2^- catalyzed by either iron or copper ions (reaction 3 in Fig. 21-7). Hydrogen peroxide, HOCl, and OH· are all strong oxidants that participate in microbial killing within the phagocytic vacuole.[303,323] Reactive oxidants also regulate phagocyte proteolytic activity by activating latent phagocyte metalloproteinases (such as collagenase and gelatinase) and inactivating plasma antiproteinases.[46,233] Enhanced phagocyte proteolysis at localized sites may be important for facilitating cellular migration into inflamed tissues, destruction of microbes, and removal of cellular debris.

Other enzymatic pathways related to oxidant generation include the detoxification of H_2O_2 by glutathione peroxidase and reductase (reactions 6 and 7, Fig. 21-7).[323] Glutathione is produced from γ-glutamylcysteine by the enzyme glutathione synthetase (reaction 9, Fig. 21-7). Other important antioxidant systems in phagocytes and other tissues include catalase, which catalyzes the conversion of H_2O_2 to oxygen and water, ascorbic acid, and α-tocopherol (vitamin E).[324] Generation of NADPH is important for providing a source of reducing equivalents for the glutathione detoxification pathway, as well as the respiratory burst itself. NADPH is replenished from NADP⁺ by leukocyte glucose-6-phosphate dehydrogenase (G6PD; reaction 8, Fig. 21-7) in the hexose monophosphate shunt.

A second oxygen-dependent pathway with antimicrobial effects involves the generation of NO from the oxidation of L-arginine to L-citrulline. This reaction is catalyzed by nitric oxide synthase (NOS), with molecular oxygen supplying the oxygen in NO.[325-327] There are three different NOS isoforms, two of which are constitutively expressed in a variety of tissues, including the endothelium, brain, and neutrophils. Expression of a third, high-output isoform of inducible NOS (iNOS) is mediated by inflammatory stimuli in a variety of cells, including macrophages and neutrophils, where it has a wide spectrum of antitumor and antimicrobial activity against bacteria, parasites, helminths, viruses, and tumor cells.[325-327] NO can also interact with superoxide to form peroxynitrite, which mediates tyrosine nitration of cellular and bacterial proteins.[302] High levels of iNOS-catalyzed NO production are readily elicited in normal mouse macrophages by exposure, for example, to IFN-γ and endotoxin. In human monocytes and macrophages, IFN-α/β, IL-4 plus anti-CD23, or chemokines can induce iNOS expression.[326] Expression of iNOS has been detected in a variety of inflammatory and infectious diseases in humans, including malaria, hepatitis C, tuberculosis, tuberculoid leprosy, and the dementia associated with acquired immunodeficiency syndrome (AIDS).[326] Cytokine-activated human neutrophils also exhibit inducible

production of NO, which leads to the nitration of ingested bacteria.[328]

Nonphagocyte NADPH Oxidases

The gp91^{phox}, p22^{phox}, p67^{phox}, and p47^{phox} subunits of the phagocyte respiratory burst oxidase have also been detected in endothelial cells and smooth muscle cells.[329] Expression of these components, as well as oxidant production, appears to be much lower than in phagocytic leukocytes. The physiologic significance of *phox* expression in nonphagocytic cells is controversial, but it has been speculated to play a role in intracellular signaling. Because there are many other potential sources of reactive oxidants, such as from xanthine oxidase, mitochondria, or other NAD(P)H oxidases, it has been difficult to ascribe any specific functions to vascular *phox* protein expression. However, recent studies in CGD knockout mice suggest that endothelial cell expression of these *phox* subunits may play a role in regulating inflammatory cell recruitment.[330,331]

Close homologues of the gp91^{phox} flavocytochrome subunit have recently been discovered.[332-334] This family is known as the NOX (NAD(P)H oxidase) proteins, of which there are six members in mammalian cells, in addition to gp91^{phox}, which is designated NOX2 in this classification. All NOX proteins share a similar protein structure, with transmembrane domains for heme binding and an intracellular flavoprotein domain. The other NOX proteins are expressed in various cell types, including the epithelium, smooth muscle cells, and gut, and appear capable of generating superoxide, generally at much lower levels than the phagocyte enzyme. At least some appear to be located in intracellular membranes rather than at the plasma membrane. Homologues of p67^{phox} (NOXA1) and p47^{phox} (NOXO1) that regulate several of the nonphagocyte NOXs have also been identified. The biologic functions of the nonphagocyte NOXs are under investigation and may include epithelial host defense, intracellular signaling for the regulation of cell growth and differentiation, and post-translational modification of proteins.

Specialized Functions of Mononuclear Phagocytes

Mononuclear phagocytes, particularly tissue macrophages, participate in a broad range of activities important for tissue homeostasis and repair, as well as in host defense against viruses, bacteria, fungi, and protozoa (Box 21-2).[115,126,133,134,168] From the standpoint of antimicrobial function, activated macrophages play a key role in the ingestion and killing of intracellular parasites such as mycobacteria, *Listeria*, *Leishmania*, *Toxoplasma*, and some fungi,[335] although various intracellular organisms have evolved specialized evasion mechanisms.[336] Both oxygen-dependent and oxygen-dependent systems are involved in this process, as described earlier. When

microbes (most characteristically mycobacteria, but any other organism or particle) cannot be fully ingested or killed, macrophages fuse in a cytokine-mediated process to form giant cells and granulomas.[337,338]

Activated macrophages also exhibit cytotoxicity against tumor cells, although the importance of this process in vivo remains to be determined.[339,340] Tumor cell killing can be mediated by antibody-dependent and antibody-independent processes that are highly dependent on macrophage activation. On the other hand, macrophage-mediated inflammation can contribute to tumorigenesis,[341] and tumor-associated macrophages can participate in tumor angiogenesis, invasion, and metastasis.[342,343] Osteoclasts, a specialized form of bone macrophage, cause bone resorption in osteolytic tumor metastases.[344]

IFN-γ, one of the principal macrophage-activating factors, is secreted by T lymphocytes, as well as by macrophages and neutrophils.[126,134,168,169] The cytokine induces changes in macrophage gene expression through the JAK (Janus kinase)-STAT (signal transducer and activator of transcription) pathway, elements of which are shared by many other cytokines, including IL-2, IL-6, and G-CSF.[29,345,346] Endotoxin, the bacterial lipopolysaccharide derived from gram-negative bacteria, is another important trigger of macrophage activation through pathways involving CD14 and TLRs.[126,347]

Interactions of macrophages with T and B cells are essential for the development of cellular and humoral

immunity.[147,348,349] Macrophages, particularly the specialized form of dendritic cells, are professional antigen-presenting cells that initiate and regulate NK-, T-, and B-cell responses. Macrophage production of IL-1, as well as subsequent interactions between stimulated T and B cells, leads to B-cell production of antigen-specific immunoglobulins.[349] Macrophages are also major physiologic sources of cytokines and chemokines that regulate both the innate and the adaptive immune systems.[127,147,348,350] As a source of "endogenous pyrogens," they are responsible for the production of fever in response to infection or inflammation.[351]

Macrophages participate in many aspects of wound repair.[352,353] The early phases of this process are dominated by an influx of neutrophils, followed by the migration of monocytes that differentiate into activated macrophages and, finally, the appearance of T lymphocytes. Proliferating fibroblasts secrete collagen and other matrix proteins important for wound closure and tissue remodeling, and migrating keratinocytes regenerate the epithelial surface. Both neutrophils and macrophages protect against infection and dispose of phagocytosed debris. Mononuclear phagocytes also elaborate fibroblast, epithelial, and angiogenic growth factors (see Box 21-1) that stimulate the normal progression of tissue repair and neovascularization that characterize the later phases of wound healing.[132,352,353]

Macrophages ingest and dispose of apoptotic and necrotic cells.[133,354,355] This function not only contributes to cellular processing for antigen presentation but also plays a critical role in tissue remodeling and homeostasis, embryologic development, and resolution of inflammation. A redundant and promiscuous system of receptors, including integrins, scavenger receptors, complement receptors, calreticulin, CD14, and Mer receptor, recognize and effect the uptake of apoptotic cells. Resident tissue macrophages, particularly those lining the sinusoids of the spleen and liver (formerly known as the "reticuloendothelial system"), clear senescent and antibody-bound blood cells from the circulation.[356-358]

Iron from the catabolism of hemoglobin in aged erythrocytes is incorporated into ferritin and hemosiderin, where it accounts for about two thirds of the body's store of reserve iron. Iron in this macrophage storage pool turns over and returns in a transferrin-bound form to the bone marrow for new red blood cell synthesis (see Chapter 12).[359] Sequestration of iron in macrophages leads to the anemia of chronic disease.[360]

Monocytes and macrophages contribute to the pathophysiology of atherosclerosis through the uptake, metabolism, and oxidation of LDL and VLDL by receptor-mediated endocytosis.[131,361] Macrophages in blood vessel walls that are exposed to sufficient quantities of cholesterol develop into the foam cells characteristic of atherosclerotic plaque[362] and contribute to the important inflammatory component of plaque formation and destabilization.[363]

Specialized Functions of Eosinophils and Basophils

Eosinophils and basophils, though sharing many of the functional characteristics of neutrophils and mononuclear phagocytes, participate in distinctive aspects of the inflammatory response and interact with each other in the context of certain allergic reactions. Eosinophils and mast cells are often situated beneath epithelial surfaces exposed to environmental antigens, such as the respiratory and gastrointestinal tracts, where they may be actively involved in mucosal immune responses. However, the role of eosinophils, basophils, and mast cells is better known in pathologic settings than in normal homeostasis.

Eosinophils appear to have both immunoenhancing and immunosuppressive functions (Table 21-8).[6,7,74,75] Though capable of ingesting and killing bacteria, eosinophils are not particularly efficient at this task. Rather, they possess an unusual ability to destroy invasive metazoan parasites, especially helminthic parasites. Eosinophils bind to the surface of both adult and larval helminths and inflict damage through the release of cationic granule proteins and the generation of reactive oxidants, including the eosinophil peroxidase–catalyzed formation of hypohalous acids via the action of the respiratory burst and eosinophil peroxidase.[6,7]

Eosinophil production of the lipid inflammatory mediators LTC_4 and PAF plays a role in the pathogenesis of allergic diseases.[7] PAF and LTC_4 can induce smooth muscle contraction and promote the secretion of mucus, and PAF itself is a potent activator of eosinophils. The

TABLE 21-8	Eosinophil Function
Function	**Mechanism**
Defense against helminths (both larval and adult forms)	Binding of eosinophils to surface
	Peroxidation of larval surface mediated by eosinophil peroxidase
	Toxicity to larval surface by released major basic protein
Immunosuppression of immediate hypersensitivity reactions	Engulfment of most cell granules
	Release of prostaglandin E_1/E_2 to suppress basophil degranulation
	Release of histaminase
	Oxidation of slow-reacting substance of anaphylaxis
	Release of phospholipase D to inactive mast cell platelet-activating factor
	Release of major basic protein for binding of mast cell heparin
	Release of plasminogen to reduce local thrombus formation

release of eosinophil granule contents may also contribute to localized tissue damage. Purified eosinophil MBP, for example, can cause cytopathic changes in tracheal epithelium in vitro that are similar to the changes observed in asthmatic patients.

Eosinophils may also perform an immunosuppressive function in immediate hypersensitivity reactions (see Table 21-8). IgE-activated basophils or mast cells release eosinophilic chemotactic factor of anaphylaxis, which recruits eosinophils to the site. Subsequent eosinophil degranulation releases products that can inactivate inflammatory mediators. For example, histaminase inactivates histamine, phospholipase B inactivates PAF, MBP inactivates mast cell heparin, and lysophospholipase prevents the generation of arachidonic acid metabolites.

Basophils and mast cells are central participants in a variety of inflammatory and immunologic disorders, particularly immediate hypersensitivity diseases, and may also play a role in host defense against bacterial infections. Basophils and mast cells express plasma membrane receptors that specifically bind with high affinity the Fc portion of the IgE antibody (Fcε receptors).[264] After active or passive sensitization with IgE, exposure to specific multivalent antigen triggers an almost immediate release of granule contents (anaphylactic degranulation) and the synthesis and release of newly generated chemical mediators such as LTC_4, which stimulates smooth muscle contraction, secretion of mucus, and vasoactive changes.[364] Degranulation can also be triggered in response to insect venom, radiocontrast dye, and other nonspecific agents. Recent studies on mutant mice engineered by gene targeting to lack Fcγ or Fcε receptors (or both) have shown that mast cell FcγRIII receptors are essential in activating the inflammatory response to IgG immune complexes (Arthus reaction), heretofore an unrecognized role for the mast cell.[365] Mast cells can secrete numerous mitogenic or inflammatory cytokines, including many interleukins (1, 3, 4, 5, and 6), chemokines, GM-CSF, and TNF-α, that are also likely to regulate leukocyte recruitment and inflammation in IgE-dependent reactions and immune complex injury.[107,366,367] The inflammatory cytokines and leukotrienes released from tissue mast cells have recently been recognized to play an important role in neutrophil recruitment during the acute response to bacterial infection.[368-370]

Pathologic Consequences of Phagocyte Activation and Inflammatory Response

Though normally serving a protective function, the inflammatory response can also result in damage to host tissues. The release of proteases, oxygen radicals, and proinflammatory cytokines by activated phagocytes appears to play a major role in the generation of tissue injury in a wide variety of pathologic inflammatory processes (Box 21-3).[162,233,371-373] For example, neutrophil

elastase has been implicated in the pathogenesis of emphysema in both adult smokers and individuals with α_1-antitrypsin deficiency. Neutrophil granule proteases may contribute to the joint destruction in rheumatoid arthritis and other chronic arthropathies. Neutrophils are also believed to play a key role in the systemic inflammatory response syndrome, a term that has been created to encompass the host response to both infectious (e.g., gram-negative sepsis) and noninfectious (e.g., pancreatitis, trauma) causes and can lead to organ dysfunction and tissue damage.[372] Sequestration of activated neutrophils in the pulmonary capillary bed along with subsequent release of tissue-damaging agents is an important component in the development of adult respiratory distress syndrome. Activation of the complement cascade by artificial membrane surfaces during hemodialysis and cardiopulmonary bypass can also result in neutrophil activation, intrapulmonary sequestration, and lung injury. Macrophages are integral to the pathophysiology of atherosclerosis by uptake of serum lipoproteins and contribute an important inflammatory component that influences the development and rupture of atherosclerotic plaque.[361-363] In addition to their cytotoxic effects, the oxidative products released by activated phagocytes are also mutagenic, as documented by plasmid mutagenesis, sister chromatid exchange, and transformation of cells in culture.[374] Hence, the increased risk for malignancy observed with certain chronic inflammatory states, such as ulcerative colitis or chronic hepatitis, has been postulated to be in part related to oxidant-induced carcinogenesis.

The development of anti-inflammatory interventions based on agents that block leukocyte adhesion or inhibit the action of specific proinflammatory agents has been an area of intense interest. TNF-α antagonists are now widely used for the treatment of rheumatoid arthritis, and IL-1 receptor antagonists also have efficacy in this disease.[375] Antagonists of leukocyte integrins have shown benefit in phase II and III studies for inflammatory bowel disease, psoriasis, and multiple sclerosis.[206] However,

although protective effects of monoclonal antibodies directed against either β_2 integrins, ICAM-1, or selectins were found in various animal models of inflammation, including ischemia-reperfusion injury, endotoxic shock, and acute arthritis, the results of clinical trials failed to show significant benefit.[206] The contributions of non-phagocytic cells to inflammatory tissue injury must also be kept in mind. For example, adult respiratory distress syndrome can occur in the presence of severe neutropenia.[376] Moreover, despite the adverse consequences of the acute inflammatory process, these events are also important for normal healing. For instance, the use of anti-inflammatory agents in myocardial infarction, which can decrease infarct size acutely, results in impaired healing of the myocardium and the formation of fragile scar tissue.[371] Finally, the impact of the new anti-inflammatory biologic agents on host defense must be kept in mind, particularly if being used in combination with other immunosuppressive drugs such as steroids. For example, patients receiving TNF-α antagonists have increased rates of tuberculosis and infection with endemic mycotic or intracellular bacterial pathogens.[377]

QUANTITATIVE GRANULOCYTE AND MONONUCLEAR PHAGOCYTE DISORDERS

This section reviews clinical disorders associated with disturbances in granulocyte number, with particular emphasis on syndromes in which the granulocyte abnormality is a central feature. Several disorders have now been associated with specific genetic defects, although the molecular pathophysiology leading from the gene to the phenotype often remains obscure. This section of the chapter is organized by clinical characteristics of the disorders, with genetic and functional laboratory data provided when available.

Neutropenia

Definition and Classification

Neutropenia is defined as an absolute decrease in the number of circulating neutrophils in blood. Normal neutrophil levels should be stratified for age, race, and other factors. For whites, the lower limit for normal neutrophil counts (neutrophils and bands) is 1000 cells/μL in infants between 2 weeks and 1 year of age; after infancy it rises to 1500 cells/μL. Blacks have somewhat lower neutrophil counts, with counts of less than 1500 cells/μL in 4.5% of black participants in the 1999-2004 National Health and Nutrition Examination Survey.[378] The lower limits of normal are generally considered to be 200 to 600/μL less than those in whites. This difference probably derives from a relative decrease in neutrophil release from the bone marrow storage compartment.[379-381] Falsely low white blood cell counts can result when counts are performed long after blood is drawn, after leukocyte clump-

ing in small clots, or in the presence of certain paraproteins.

Neutropenia can represent disturbances in production, shifts of neutrophils from the circulating to the marginated or tissue pools, increased peripheral utilization or destruction, or combinations of these causes. However, assays of leukokinetics and myelopoiesis are not routinely available, so mechanisms may be hard to identify. Classifications based on biochemical or functional studies are also difficult because of the paucity of neutrophils in the circulation of neutropenic patients. In general, neutropenic syndromes are broadly classified as intrinsic, or caused by defects in myelopoiesis, or as acquired and caused by extrinsic factors such as drugs, infections, or autoantibodies (Box 21-4).

The clinical significance of neutropenia depends on the level of depression of the absolute neutrophil count (ANC). Mild neutropenia, with neutrophil counts of 1000 to 1500 cells/μL, and moderate neutropenia, with counts of 500 to 1000 cells/μL, are not generally clinically significant with respect to host defense but may warrant evaluation to determine the underlying cause. Severe neutropenia refers to ANCs below 500 cells/μL, with the term "agranulocytosis" usually reserved for counts below 200 cells/μL. Children with severe chronic neutropenia can be registered with the Severe Chronic

Cyclic neutropenia
Severe congenital neutropenia (including Kostmann's
    syndrome)
Myelokathexis/WHIM syndrome
Shwachman-Diamond syndrome
Albinism/neutropenia syndromes (including
    Chédiak-Higashi)
Familial benign neutropenia
Bone marrow failure syndromes (congenital and acquired)

NEUTROPENIA CAUSED BY EXTRINSIC FACTORS

Infection
Drug-induced neutropenia
Autoimmune neutropenia
Chronic benign neutropenia (including chronic
    autoimmune neutropenia of childhood)
Neonatal immune neutropenia
Neutropenia associated with immune dysfunction
Neutropenia associated with metabolic diseases
Nutritional deficiencies
Reticuloendothelial sequestration
Bone marrow infiltration
Chronic idiopathic neutropenia (may also be intrinsic)

Types of neutropenia are listed in order of discussion in the text.
WHIM, warts, hypogammaglobulinemia, infections,
    myelokathexis.

Neutropenia International Registry (SCNIR; http://depts.washington.edu/registry/).

Symptoms of Neutropenia

The hallmark of neutropenia is increased susceptibility to bacterial and fungal infection; neutropenia by itself does not diminish host defense against viral or parasitic infections. The most frequent types of pyogenic infections in patients with significant neutropenia are cellulitis, furunculosis, superficial or deep cutaneous abscesses, pneumonia, and septicemia.[382-386] Stomatitis, gingivitis, and periodontitis may be initial signs of neutropenia that develops into chronic problems. Perirectal inflammation and otitis media (especially in younger children) occur as well. Endogenous bacteria are the most frequent cause of infections, but colonization or infection may occur with a variety of nosocomial and opportunistic organisms. The most commonly isolated organisms from neutropenic patients are *Staphylococcus aureus* and gram-negative bacteria, but almost any organisms can be isolated, particularly in hospitalized patients or those receiving frequent or prolonged courses of antibiotics. The usual symptoms and signs of local infection—such as exudates, fluctuation, ulceration, and regional adenopathy—may be less evident in neutropenic patients than in normal individuals.[387]

Susceptibility to bacterial infection, even with severe neutropenia, can be quite variable, depending on the underlying cause. For example, some patients with chronic neutropenia secondary to autoantibodies do not experience serious infections over a period of many years, even with neutrophil counts as low as 200 cells/μL, most likely because these individuals have rapid production and transit of normal neutrophils, with relative preservation of neutrophil delivery to tissues.[388] Many patients with chronic neutropenia also have normal to increased numbers of circulating monocytes, an alternative phagocyte.[389] However, the recruitment of monocytes to inflammatory sites is delayed relative to neutrophils, and monocytes are not as efficient as neutrophils in ingesting bacteria.[390,391] Thus, monocytes appear to provide only marginal protection against pyogenic organisms in severely neutropenic patients. It is likely that the humoral, cell-mediated, and tissue macrophage immune systems also play important alternative or compensatory roles preventing infection in these individuals.

Neutropenia Caused by Intrinsic Defects in Granulocytes or Their Progenitors

These disorders are also discussed in detail, with more emphasis on molecular pathogenesis, in Chapter 8.

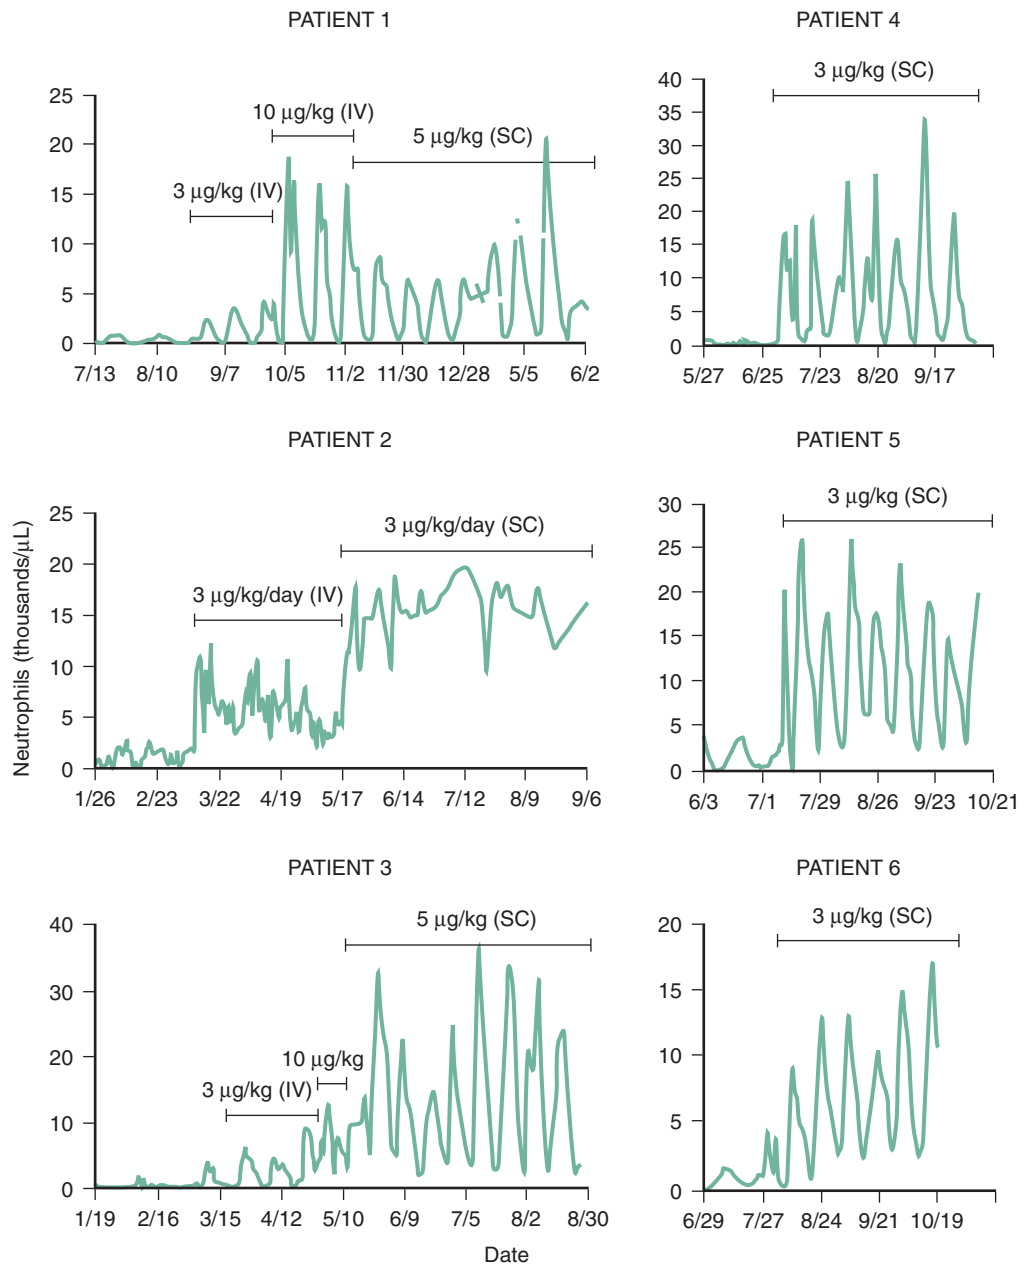
Reticular Dysgenesis

The selective failure of stem cells committed to myeloid and lymphoid development leads to reticular dysgenesis, one of the rarest and most severe forms of combined immunodeficiency.[392-397] It is characterized by severe leukopenia, including both agranulocytosis and lymphopenia; defective cellular and humoral immunity; and absence of lymph nodes, tonsils, Peyer's patches, and splenic follicles. Erythroid and megakaryocyte development is normal. Most patients have been male, but two females and several nontwin males have been reported, thus suggesting autosomal inheritance. All reported infants have died of bacterial or viral infections within the first weeks of life, except a few treated by hematopoietic stem cell transplantation (HSCT).[395,398,399]

Cyclic Neutropenia

Cyclic neutropenia is a sporadic or autosomal dominant disorder characterized by regular periodic oscillations approximately every 21 days in the number of peripheral blood neutrophils, with a nadir of less than 200 cells/μL (Fig. 21-10).[400,401] In most typical cases, reticulocytes, platelets, and other leukocytes also cycle. The frequency of occurrence of cyclic neutropenia has been estimated at 0.5 to 1 case per million population.[402] During the neutropenic nadir of each cycle, patients may suffer malaise, fever, oral ulcers, gingivitis, periodontitis, and pharyngitis associated with lymph node enlargement. Symptoms typically begin during the first year of life but may not commence until adulthood. More serious complications can occur occasionally, including mastoiditis, pneumonia, or ulceration of vaginal or intestinal mucosa. The severity of the infections tends to parallel the depth of the neutropenia, but some patients escape infections entirely during the neutropenic period. Many patients experience improvement in symptoms as they grow older. In these individuals, the cycles tend to become less noticeable as the neutrophil nadir rises to a more functionally adequate level. Although cyclic neutropenia is frequently viewed as a benign condition, 10% of patients in historical reviews have died of infectious complications.[401,403] Pneumonia and peritonitis, the latter complicated by clostridial sepsis, have been the most frequent causes of death.[400,401]

Oscillations in the rate of bone marrow production of neutrophils result in neutropenia with nadirs at intervals of 21 ± 3 days in the majority of patients, although the cycles can be as long as 28 to 36 days and as short as 14 days.[403] Neutrophil counts often fall to 0 at some time during the nadir and remain below 200 cells/μL for at least 3 to 5 days. In most patients, monocytosis occurs when neutrophil counts are at their lowest. In the recovery phase, neutrophil counts rise, often into the low-normal range, and monocyte counts drop. Oscillations are subtle in some individuals, particularly older patients, who instead have a pattern more consistent with chronic neutropenia. Oscillations in reticulocyte and platelet counts may parallel those seen for neutrophils,[401,404] hence the alternative term "cyclic hematopoiesis," but these other cell numbers range between normal and elevated levels and thus have no clinical impact. Marrow aspirates show highly variable morphology, depending on the phase of the cycle. The myeloid series may show hypoplasia with "maturation arrest" at the myelocyte

FIGURE 21-10. Cyclic neutropenia and the response to clinical administration of granulocyte colony-stimulating factor (G-CSF) in six patients. The cycling of neutrophil counts before and during therapy with various doses of G-CSF is shown. The *rectangles* represent the duration of G-CSF treatment, with the corresponding dose shown above each rectangle. Note the approximately 21-day cycle before therapy in patients 1, 5, and 6, which is characteristic of cyclic neutropenia. The cycle shortened to approximately 14 days during G-CSF therapy, whereas the peak neutrophil counts increased approximately 10-fold. *(Reprinted with permission from Hammond WP, Price TH, Souza LM, Dale DC. Treatment of cyclic neutropenia with granulocyte colony-stimulating factor. N Engl J Med. 1989;320:1306-1311.)*


stage during the declining phase of neutrophil oscillation, but normal or hyperplastic myelopoiesis during neutrophil recovery. The marrow stem cell defect in cyclic neutropenia has been demonstrated by transfer of the disorder via allogeneic bone marrow transplantation from a child with cyclic neutropenia to a sibling undergoing treatment of leukemia.[405]

Patients with both sporadic and autosomal dominant forms of cyclic neutropenia have been shown to have coding sequence mutations in the *ELA2* gene encoding neutrophil elastase, a serine protease synthesized at the promyelocyte-myelocyte stage.[293,294] This gene was discovered by linkage analysis of families with autosomal dominant cyclic neutropenia, but mutations in *ELA2* have now also been identified in approximately 60% to 80% of kindreds with SCN (see later and Chapter 8).

How mutations in neutrophil elastase result in the cyclic production of neutrophils and other blood cells is not currently well understood. Bone marrow samples from both cyclic neutropenia and SCN patients demonstrate increased apoptosis of neutrophil precursors.[406-409] Thus, expression of mutant neutrophil elastase may induce excessive apoptosis through either aberrant subcellular targeting of the protein or induction of a strong unfolded protein response.[407,408,410,411] Cycling may occur as a result of partial recovery of myelopoiesis via G-CSF production at the nadir, but with oscillation rather than homeostasis taking place because of the abnormal kinetics of the feedback loop.[412,413]

Cyclic neutropenia must be distinguished from cyclic fever without neutropenia[414] and from other causes of neutropenia. To establish the diagnosis of cyclic neutro-

penia, neutrophil counts should be monitored twice or at least once a week for 6 to 8 weeks. The genetic diagnosis can be confirmed by sequencing of the *ELA2* gene.

Management of patients with cyclic neutropenia includes careful attention to identification and treatment of infections acquired when these patents are neutropenic. In general, fevers, upper respiratory symptoms, and cervical lymphadenopathy occurring during neutropenic episodes require no specific therapy. However, the physician must remain alert to symptoms suggesting a specific infection, particularly the sometimes fatal abdominal complications. Careful attention to oral and dental hygiene is important to minimize periodontal disease and ameliorate the discomfort of mouth sores. To prevent the development of severe dental complications and because of the risk of life-threatening infections, prophylactic G-CSF (filgrastim) therapy is recommended for patients with cyclic neutropenia with nadirs consistently below 500 cells/μL. G-CSF has been very effective in improving peripheral blood neutrophil counts in this disorder, along with the signs and symptoms associated with neutropenic nadirs.[415-418] Most patients still experience cycles, and in fact the amplitude of the cycling may increase, but with shortened cycle periods and increased neutrophil counts at the nadir (see Fig. 21-8).[412,418] The dose of G-CSF required to maintain peripheral neutrophil counts in the normal range in most patients with cyclic neutropenia is usually 2 to 4 μg/kg/day, administered either daily or on alternate days.[415,417,418] Cases of myelodysplastic syndrome (MDS) or acute myelogenous leukemia (AML) have not been reported in cyclic neutropenia patients, including those treated with G-CSF.[386,406,417]

Severe Congenital Neutropenia

SCN was first described by Kostmann in 1956 as an autosomal recessive disorder associated with severe neutropenia that was identified in the population of an isolated northern parish of Sweden.[419] Other forms of SCN have since been identified with sporadic occurrence or with historical or genetic evidence of autosomal recessive or autosomal dominant inheritance.[382,417,420,421] This disorder is also discussed in detail, with emphasis on the genetics and molecular pathogenesis, in Chapter 8. Although the nomenclature is still in flux, we suggest that the term SCN (Online Mendelian Inheritance in Man [OMIM] 202700) be used to refer to the entire disorder regardless of inheritance or genotype and that Kostmann's disease (OMIM 610738) be used to refer to the autosomal recessive subtype, caused in all or most cases by mutations in the *HAX1* gene[422] (see later).

The incidence of SCN is approximately two cases per million population.[402] Affected patients generally maintain ANCs of less than 200 cells/μL, which has been documented on the first day of life in several cases.[423] Frequent episodes of fever, skin infections (including omphalitis), stomatitis, pneumonia, and perirectal abscesses typically appear during the first months of life. Infections often disseminate to the blood, meninges, and

peritoneum and are usually caused by *S. aureus*, *Escherichia coli*, and *Pseudomonas* species. Before the current era of G-CSF therapy, most patients died in the first 1 to 2 years of life,[417,424] and survivors were known to be at risk for the development of MDS and AML.[424-426]

Peripheral blood counts generally show, in addition to agranulocytosis, moderate to marked monocytosis, mild to moderate eosinophilia, and secondary changes such as anemia and thrombocytosis. G-CSF production in SCN patients appears to be normal, if not elevated.[427,428] Antineutrophil antibodies may be present, and a positive test should not be used to rule out SCN.[429]

Bone marrow examination characteristically shows a myeloid "maturation arrest" at the myelocyte stage of development, with normal to increased numbers of promyelocytes but few if any more mature forms.[382,402] The promyelocytes may have dysplastic morphology, including large size, atypical nuclei, and vacuolated cytoplasm. Marrow eosinophilia and monocytosis are common and do not change during treatment. Cellularity is usually normal or slightly decreased. Megakaryocytes are normal in number and morphology. The in vitro growth of granulocyte colonies from SCN bone marrow is defective, with few colonies formed, but most patients' bone marrow produces colonies with some capability for full maturation to neutrophils in the presence of exogenous G-CSF, thus indicating that the "arrest" is intrinsic but incomplete.[430-432]

The genetic basis of 60% to 80% of SCN cases derives from mutations in the *ELA2* gene,[293,294,433] which encodes neutrophil elastase and is also responsible for the related but distinct disorder cyclic neutropenia (discussed earlier). *ELA2*-related SCN may be sporadic or inherited in an autosomal dominant mendelian pattern, as dramatically illustrated by a series of five affected children from four families, all conceived by sperm from the same anonymous donor.[420] An additional, recently identified case of cyclic neutropenia with the identical S97L missense mutation from the same sperm donor not only confirms the autosomal dominant inheritance of *ELA2*-related disorders but also indicates that genetic background can result in the same genotype being expressed phenotypically as either SCN or cyclic neutropenia. Additional, rare cases of autosomal dominant SCN appear to arise from mutations in the *Gfi1* gene,[434] which encodes a transcriptional repressor that inhibits multiple genes involved in neutrophil maturation, including *ELA2*.[11,12]

Similar to cyclic neutropenia, the bone marrow of SCN patients shows evidence of accelerated apoptosis of neutrophil precursors.[435] As noted earlier, expression of mutant neutrophil elastase or other aberrant proteins may induce excessive apoptosis through either aberrant subcellular targeting of the protein or induction of a strong unfolded protein response.[407,408,410,411]

Mutations in most autosomal recessive SCN kindreds, including several originally studied by Kostmann,

have been identified in the *HAX1* gene,[422] which encodes a mitochondrial protein with putative functions in signal transduction and cytoskeletal control. Other rare mutations responsible for an SCN phenotype include defects in the Wiskott-Aldrich syndrome (WAS) gene[436,437] and constitutional defects (as opposed to acquired mutations—see later) in the gene encoding the G-CSF receptor.[407,438]

G-CSF, the standard treatment modality for SCN, has greatly improved both life span and quality of life for these patients.[416,417,439] Until the availability of this cytokine in the 1980s, severe neutropenia would inevitably lead to fatal infections in the majority of patients despite supportive care with prophylactic trimethoprim-sulfamethoxazole, aggressive use of antibiotics at the time of documented infections, and scrupulous attention to oral hygiene. More than 95% of SCN patients respond to G-CSF treatment with an increase in the ANC to greater than 1000/μL, along with a documented reduction in infections.[416,417,439] There is often a delay of 7 to 10 days before the rise of peripheral blood neutrophil counts at the start of treatment. In patients enrolled in the SCNIR between 1993 and 1999, more than 90% of congenital neutropenia patients responded to G-CSF treatment with rises in the ANC to greater than 1.0×10^9/L and required significantly less antibiotic therapy and less frequent hospitalization.[421] SCN patients required G-CSF doses ranging from 0.56 to 190 μg/kg/day, with mean of 10.2 and standard deviation of 19.0 μg/kg/day.[417] These doses are significantly higher than those needed for cyclic or idiopathic neutropenia.[417] The percentage of maturing neutrophils in bone marrow increases with G-CSF, although morphologically abnormal promyelocytes with vacuolized and asynchronous nuclear-cytoplasmic maturation can persist, and the number of monocytes and eosinophils in marrow and peripheral blood may remain high.[402]

Based on data from the SCNIR, a starting daily dose of G-CSF of 5 μg/kg/day is recommended, increasing gradually, if necessary, to as high as 100 μg/kg/day for at least 14 days to achieve a neutrophil count of 1000 to 2000/μL.[440] The drug is generally administered subcutaneously, but it may be given intravenously at equal dosage if clinical conditions warrant or if vehicle volumes are too high to permit comfortable subcutaneous injection. In G-CSF–refractory patients, combination therapy with stem cell factor has been reported to be effective,[402] but rarely used, because it also leads to mast cell activation with the release of histamine and anaphylactoid reactions. GM-CSF treatment results in large increases in eosinophils and monocytes, but not neutrophils.[441]

Side effects of G-CSF treatment are usually mild and include bone pain, headache, and rashes. Other common, but often asymptomatic findings include splenomegaly and osteopenia.[415,417] Splenomegaly has been reported in patients with SCN before and during G-CSF therapy.[415,417] Palpable splenomegaly, with a median spleen measurement of 2 cm below the costal margin, was recorded in

18.2% of untreated patients registered in the SCNIR. During the first year of G-CSF therapy, the incidence increased to 38.2% and remained at this level (26.7% to 44.7%) through 10 years of therapy, with no trend to progression in spleen size during therapy.[417] Of 731 SCNIR patients analyzed in 2003, osteopenia or osteoporosis was reported in 127, including 93 with SCN. Findings included abnormal bone density only (46), abnormal bone density and clinical problem (67), and clinical problem only (14). G-CSF doses in the patient group in whom osteopenia/osteoporosis developed ranged from 0.3 to 240 μg/kg/day, and there was no correlation with the dose of G-CSF, duration of treatment, or patient age or sex.[417,442] The SCNIR recommends regular monitoring of bone density. Rare patients were also found to have vasculitis or glomerulonephritis, both before and during G-CSF therapy.[417]

The SCNIR has reported thrombocytopenia (platelet count $<50 \times 10^3$/μL) in 26 patients, including 17 with SCN.[417] Seven were not receiving G-CSF, and among the 19 treated patients, 7 became thrombocytopenic concurrent with conversion to MDS/AML. Thus, development of thrombocytopenia in SCN patients requires thorough evaluation as a possible heralding sign of disease progression.

Conversion to MDS/AML and bacterial sepsis remain the most serious complications of SCN. The predilection to acute leukemia was recognized before the availability of G-CSF,[424,425] but most affected children probably died of severe infections. Now, longer survivors appear to be at increased risk for the development of MDS, which almost invariably progresses to AML,[443] whereas death from sepsis has become rarer but can still occur in G-CSF–responsive patients.

During long-term G-CSF therapy, some SCN patients acquire mutations in the G-CSF receptor gene (*GCSFR*), then myelodysplasia characterized by monosomy 7, and finally myeloid leukemia.[406,443-445] Acquired mutations in *GCSFR* have been detected in approximately 80% of SCNIR patients in whom MDS/AML developed, whereas mutations in the *FLT3*, *KIT*, and *JAK2* tyrosine kinase genes, frequently found in de novo AML, are uncommon.[445-448] Some SCN patients with *GCSFR* mutations have not progressed, including some who lost the mutated clone after discontinuation of G-CSF therapy and reacquired it upon resumption of treatment.[445-447] Cytogenetic abnormalities, particularly monosomy 7, also precede and predict leukemic conversion. For this reason, the SCNIR recommends yearly bone marrow surveillance, including karyotyping and chromosome 7 fluorescence in situ hybridization (FISH) for all SCN patients. Although clonal cytogenetic abnormalities may spontaneously remit, their appearance should be considered a strong indication for HSCT, including the use of a matched unrelated donor if necessary, because transplantation is more likely to be successful when undertaken before progression to MDS/ AML.[449,450]

Recent studies by the SCNIR and the French Severe Chronic Neutropenia Study Group[386,444] have shed light on the incidence and some of the risk factors for sepsis and MDS/AML. In the SCNIR analysis of 374 SCN patients, many monitored for 10 or more years, the cumulative incidence of death from sepsis was 8% after 10 years of G-CSF therapy, and the cause-specific hazard of death from sepsis was stable over time at 0.9% per year.[386] In contrast, the cumulative incidence of MDS/AML was 21% after 10 years of G-CSF therapy and 36% after 12 years, with the cause-specific hazard of MDS/AML increasing over time from 2.9% per year at 6 years up to 8% per year after 11.7 years of therapy. Thus, there is an increasing risk for MDS/AML as patients receive G-CSF for longer periods.

Importantly, the SCNIR analysis also identified a subgroup of SCN patients at greatest risk for MDS/AML.[386,451] The "worst responder" group, which received a G-CSF dose of 8 μg/kg/day or greater and had an ANC of less than 2188 cells/μL, had relative hazards of 3.1-fold for MDS/AML and 5.6-fold for sepsis. In the worst responder group, the cumulative incidence at 10 years was 40% for MDS/AML and 14% for death from sepsis versus 11% and 4%, respectively, for the best responder group (G-CSF dose <8 μg/kg/day and ANC ≥2188 cells/μL). However, it is notable that even the best responders were not free of the risk of MDS/AML or even death from sepsis. Although data were not available for blood counts at the time of onset of sepsis, these patients were considered G-CSF responders, generally with an ANC of greater than 1000 cells/μL, thus suggesting that granulocytes from such patients, though seemingly adequate in number, may still be limited in function.[452] For patients in the "worst responder" category—high G-CSF dose requirements and low ANC during therapy—early transplantation should be considered, depending on donor availability, but the indication is not as strong as for those already showing abnormal cytogenetics.

Notably, multiple studies have shown a higher risk for MDS/AML in patients with Shwachman-Diamond syndrome than in those with SCN, but no progression to MDS or leukemia in cyclic neutropenia.[386,443,444] The latter finding is particularly striking because as discussed earlier, most cases of cyclic neutropenia and SCN derive from mutations in the same gene, *ELA2*.

Myelokathexis and WHIM Syndrome

Myelokathexis is an uncommon form of moderate to severe chronic neutropenia characterized by granulocyte hyperplasia in the bone marrow, which contains degenerating neutrophils with cytoplasmic vacuoles, prominent granules, and nuclear hypersegmentation with very thin filaments connecting pyknotic-appearing nuclear lobes.[453-455] Comparable abnormalities can be seen in the majority of peripheral blood neutrophils. Eosinophils exhibit similar abnormal morphology, but lymphocytes, monocytes, and basophils appear normal,[454] although relative lymphopenia has been noted in some patients.[454]

Recurrent warts and hypogammaglobulinemia (low IgG and occasionally low IgM and IgA) have often been reported in patients in whom myelokathexis has been diagnosed; hence, the acronym WHIM refers to warts, hypogammaglobulinemia, infections, and myelokathexis.[456]

The recurrent sinopulmonary infections and other bacterial infections in WHIM syndrome probably reflect increased susceptibility as a result of both neutropenia and hypogammaglobulinemia. However, early deaths related to infection have not been reported, and affected patients are capable of mobilizing increased numbers of neutrophils into peripheral blood during infectious episodes.[455] Neutrophil function has generally been reported to be normal. Since the description of first patient in 1964, more than 25 cases have been reported,[455,457-459] including a kindred of six affected individuals in three generations[454] and dizygotic twin sisters.[460] The sex ratio among reported patients has a female preponderance.

The genetic basis of WHIM syndrome was discovered by analysis of four WHIM kindreds in which affected members all carried a truncating mutation in the cytoplasmic tail domain of the gene encoding chemokine receptor 4 (CXCR4),[461] a G protein–coupled receptor with a unique ligand, CXCL12, also known as SDF-1. This work indicated autosomal dominant inheritance of the WHIM syndrome. However, in other kindreds with wild-type CXCR4 genes and probably autosomal recessive inheritance, patients' lymphocytes and neutrophils displayed similar marked enhancement of G protein–dependent responses to CXCR4 ligands.[462,463] Therefore, aberrant dysfunction of the CXCR4-mediated signaling constitutes a common biologic trait of WHIM syndrome with different causative genetic anomalies. Because the interaction between CXCR4 and CXCL12 provides a key retention signal for neutrophils in bone marrow,[189] myelokathexis has been suggested to result from retention of neutrophils in the marrow ("kathexis" = retention), where they eventually undergo apoptosis, evident in their diminished expression of the antiapoptotic factor bcl-x.[458]

The neutropenia and excessive granulocyte apoptosis associated with WHIM syndrome are partially corrected by G-CSF or GM-CSF therapy, with responses typically seen within 4 to 8 hours of administration.[455,458] Immunoglobulin levels also return to normal in patients treated with G-CSF.[455]

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome, a rare multiorgan disease inherited as an autosomal recessive trait, includes clinical findings of neutropenia, pancreatic exocrine insufficiency, short stature, and metaphyseal chondrodysplasia.[464-466] The pancreatic acini are largely replaced by fatty tissue with relative sparing of the pancreatic ducts and islets.[465,466] Patients are at risk for the development of progressive bone marrow failure and eventual conversion to MDS/AML.[464] Growth failure and short

stature are usually noted during the first or second year of life, and puberty is often delayed.

Patients may be seen in infancy because of eczema, skin infections, and otitis media; pneumonia, osteomyelitis, and sepsis can also be present. Pancreatic insufficiency is typically manifested in early infancy as steatorrhea, weight loss, and failure to thrive. Later in childhood, pancreatic function may improve, thus rendering the clinical diagnosis elusive.[467] Serum levels of trypsinogen or pancreatic isoamylase are generally low, but not specifically diagnostic. Mild abnormalities of the liver, including hepatomegaly or elevated serum liver enzymes, are seen in 50% to 75% of younger patients but are usually mild and tend to resolve with age.

Common skeletal abnormalities include metaphyseal dysostosis in about 50% of affected children, most often involving the femoral head but generally asymptomatic.[465] Other anomalies include rib cage defects (shortened ribs with flared ends, costochondral thickening, and a narrow rib cage), clinodactyly, syndactyly, pes cavus, kyphosis, scoliosis, osteopenia, vertebral collapse, slipped femoral epiphysis, and supernumerary digits.[465] Skeletal radiologic findings can include "cup" deformation of the ribs, metaphyseal widening and hypoplasia of the iliac bones, and extremity shortening,[468] but these abnormalities may not be detectable until after 12 months or even several years of age.[465]

Neutropenia is the most common hematologic manifestation of the syndrome, although anemia or thrombocytopenia can also occur.[465,467,469] Neutrophil counts fall below 1000 cells/μL in approximately two thirds of patients, with no reciprocal monocytosis, but the neutropenia may be intermittent. Some patients also have a defect in chemotaxis that may contribute to the increased susceptibility to pyogenic infection.[470,471] Anemia is also seen frequently, and a fourth of patients have mild to moderate thrombocytopenia.[465,467,469] Bone marrow studies have generally shown some degree of myeloid hypoplasia,[465,467,469] but this finding is not diagnostic.

Evaluation of immune function in 11 patients with Shwachman-Diamond syndrome[472] identified varying degrees of impairment in the number or function of B cells (including low IgG or IgG subclasses, low percentage of circulating B cells, decreased in vitro proliferative responses, and diminished antibody or isohemagglutinin production), T cells (low circulating total CD3+ cells or CD3+/CD4+ ratio, inverse CD4/CD8 ratios, and low mitogen responses), and NK cells.

The diagnosis of Shwachman-Diamond syndrome may be based on a combination of neutropenia, possibly other types of cytopenia, pancreatic insufficiency, and skeletal anomalies.

Around 90% of patients who meet the clinical criteria harbor mutations in the Shwachman-Bodian-Diamond syndrome gene *SBDS*.[469,473] The majority of mutations appear to arise from gene conversion events, with an adjacent pseudogene producing a protein with diminished expression or function.[474] The SBDS protein is localized throughout the cell but shuttles into the nucleolus, the major cellular site of ribosome biogenesis, in a cell cycle–dependent manner.[475] Studies in yeast indicate that the protein may function in ribosomal RNA maturation, thus suggesting that Shwachman-Diamond syndrome may share some ribosomal pathobiologic mechanisms with other bone marrow failure syndromes.[467,469]

Treatment includes pancreatic enzyme replacement, which does not improve the neutropenia or dwarfism. Steatorrhea tends to diminish with time, although the pancreatic insufficiency persists.[476] The frequency of bacterial infections can vary between patients, but they generally respond to appropriate antibiotics. Administration of G-CSF increases the neutrophil count to the normal range[465,469] and should used in patients with persistently severe neutropenia and recurrent or life-threatening infections. However, aplastic anemia or MDS develops in up to a fourth to a third of patients, often with the acquisition of a structural chromosomal abnormality.[465,469,474] Hence, regular blood counts are recommended and bone marrow examination should be performed annually—or even more frequently in the face of evolving peripheral blood findings.[465] As is the case for SCN and other congenital bone marrow failure syndromes, there is a high risk of subsequent leukemic transformation if MDS develops. However, cytogenetic abnormalities, particularly i(7q), may be transient or unaccompanied by marrow dysplasia. Thus, criteria for HSCT in this disease remain unclear at the present time.

Albinism-Neutropenia Syndromes

This group of rare primary immunodeficiency syndromes derives from autosomal recessive defects in the biogenesis or trafficking of lysosomes and related late endosomal organelles.[477] As a result, they share varying degrees of overlap in phenotype, including defects in the formation of melanosomes (hence partial albinism), abnormal platelet function, and immunologic defects involving not only neutrophil number but also the function of neutrophils, B lymphocytes, and cytotoxic T lymphocytes.

CHS is a rare genetic disorder characterized by partial oculocutaneous albinism, giant lysosomes in many cell types, including granulocytes, and neuropathy.[478-485] Most patients have moderate neutropenia, apparently caused by ineffective granulopoiesis, and are at high risk for the development of hemophagocytic lymphohistiocytosis (HLH). CHS is described in detail in a later section of this chapter.

Hermansky-Pudlak syndrome, another rare autosomal recessive disease characterized by oculocutaneous albinism, is best known for associated platelet defects (see Chapter 29). One subtype, Hermansky-Pudlak syndrome type 2, also includes neutropenia and decreased numbers of NK cells and therefore leads to increased susceptibility to infections.[486] The *AP3B1* gene responsible for this disorder,[487] as well as for cyclic neutropenia in gray collie

dogs,[488] encodes an adapter protein involved in shuttling granule proteins, including neutrophil elastase, and thus may provide a connection to the molecular pathology of SCN.[407,488]

Griscelli's syndrome type 2 falls within the spectrum of Griscelli syndrome subtypes that share a phenotype of hypomelanosis with varying degrees of neurologic impairment and immunodeficiency.[489] The type 2 variant is characterized by neutropenia, hypogammaglobulinemia, partial albinism, and (like CHS) a predisposition to terminal lymphohistiocytic proliferation with hemophagocytosis.[490] It is caused by mutations in the *RAB27A* gene,[491] which encodes a small GTPase that serves as a key effector of granule exocytosis.[492]

Cohen's syndrome is an autosomal recessive condition that includes neutropenia, pigmentary retinopathy, developmental delay, and facial dysmorphism.[493] The gene responsible for Cohen's syndrome, *COH1*, shares homology to a yeast protein that functions in vesicular sorting and intracellular protein trafficking.

A single Mennonite family has been described with severe chronic neutropenia combined with short stature, albinism, coarse facial features, and recurrent bronchopulmonary infections with *Streptococcus pneumoniae*.[494] This syndrome is caused by defects in the endosomal adaptor protein p14, which is involved in MAPK signaling to late endosomes.[477]

Familial Benign Neutropenia

Familial benign neutropenia is characterized by mild neutropenia and no tendency for increased infections. Autosomal dominant transmission has been identified in some familial cases.[495] Familial benign neutropenia has been described in Yemenite Jews,[496] American and African blacks,[497] and Germans, French, Americans, and South Africans.[498]

Other Causes of Neutropenia Resulting from Intrinsic Defects in Myelopoiesis

Congenital or acquired bone marrow failure syndromes, including Fanconi's anemia, dyskeratosis congenita, aplastic anemia, and MDS, can occasionally be manifested as isolated neutropenia. Fanconi's anemia and dyskeratosis congenita should usually be easily recognized by other features associated with these disorders (see Chapter 8).[499]

Schimke's Immuno-osseous Dysplasia

This rare autosomal recessive syndrome with variable expressivity is characterized by spondyloepiphyseal dysplasia, focal segmental glomerulosclerosis leading to steroid-resistant nephritic syndrome and renal failure, lymphopenia with defective cellular immunity, neutropenia, and other types of cytopenia.[500,501] Vaso-occlusive processes, including cerebral and generalized atherosclerosis, are a life-limiting complication in the more severely affected patients.[502] The disorder is associated with mutations in the gene *SMARCAL1*, which encodes the swi/snf-related matrix-associated actin-dependent regulator of chromatin, subfamily a–like 1 protein,[503] although the genetics may be heterogeneous.[504] The immunodeficiency and cytopenia can be treated with HSCT[505]; neutropenia, seen in a few patients, responds to G-CSF or GM-CSF therapy.[501]

Neutropenia Caused by Extrinsic Factors

Infection

The most common cause of transient neutropenia in childhood is viral infection. Viruses commonly causing neutropenia include cytomegalovirus, Epstein-Barr virus, hepatitis A and B, HIV, influenza A and B, measles, respiratory syncytial virus, parvovirus B19, rubella, and varicella.[506-513] Neutropenia develops during the first 24 to 48 hours of the illness and may persist for 3 to 6 days. This period usually corresponds to the time of acute viremia and may relate to virus-induced redistribution of neutrophils from the circulating to the marginated granulocyte pool, sequestration, or increased neutrophil utilization after tissue damage by the viruses.[514,515] Several human viruses, including measles and herpes simplex virus, have been demonstrated to replicate in human endothelial cells and lead to the expression of receptors on endothelium for immune complexes containing IgG and C3, which might potentially promote enhanced neutrophil adhesion to the endothelium.[516,517] Acute transient neutropenia often occurs during the early stages of infectious mononucleosis[518,519] and may be related to both direct infection of progenitors[507] and accelerated destruction of neutrophils by antineutrophil antibodies.[520,521] Parvovirus B19 can cause transient neutropenia and can also be associated with prolonged neutropenia with or without the development of antineutrophil antibodies.[506,522-524]

Leukopenia is commonly seen in patients with AIDS.[508,525,526] In the pediatric AIDS population, neutropenia can be caused by antiviral drugs, vitamin B_{12} or folate deficiency, or cellular immune dysfunction.[527] Neutropenia in HIV infection can also be associated with hypersplenism and antineutrophil antibodies.[528,529]

Significant neutropenia may occur during typhoid, paratyphoid, tuberculosis, brucellosis, tularemia, and rickettsial infections.[512,513,530-532] The mechanisms responsible for neutropenia in these conditions remain ill defined. During periods of relapsing fever caused by acute vivax malaria, the apparent neutropenia may be secondary to increased neutrophil margination in the intravascular compartment.[533]

Sepsis is one of the more serious causes of neutropenia. The neutropenia in patients with bacteremia and endotoxemia may result from excessive destruction of neutrophils and depletion of the bone marrow reserve pool. This consumption can occur after the phagocytosis of microbes, from the release of metabolites of arachidonic acid, or as a result of activation of the complement system through either the alternative or classical pathway.

The resultant generation of the chemoattractant C5a induces neutrophil aggregation and leads to the formation of leukoemboli, which adhere to and damage endothelial surfaces in the pulmonary capillary bed. Complement-mediated neutropenia may also occur transiently during hemodialysis, during continuous-flow leukapheresis, and after burn injury.[534-537]

Significant neutropenia occurs most commonly in neonatal bacterial sepsis. Newborns can exhaust their neutrophil reserves during overwhelming bacterial infection because their neutrophil storage pool is small and neutrophil production is already near a maximum.[538] Septic newborns may benefit from granulocyte transfusion[539-542] or G-CSF,[543-547] but clinical trials have not yet provided compelling evidence for benefit from either modality.

Drug-Induced Neutropenia

Drug-induced neutropenia is a disorder characterized by a severe and selective reduction in levels of circulating blood neutrophils (usually to levels of less than 200 cells/μL) and is due to an idiosyncratic reaction to the offending drug (Table 21-9).[548-562] This definition thus excludes disorders in which other cell lines are perturbed (such as aplastic anemia), those in which drug administration is not a feature, and the predictable neutropenia observed with anticancer therapy. Implicit in this definition is the unpredictability of the condition. Although the majority of patients will recover, drug-induced neutropenia is a serious disorder with high morbidity (e.g., deep tissue infection and sepsis) and recent mortality rates of 5%, but most deaths occur in patients who are elderly or have metabolic complications such as shock or renal failure.[548]

Idiosyncratic reactions tend to develop more frequently in women than in men and more often in older than in younger persons.[552] Drugs reported to have been associated with agranulocytosis have been extensively reviewed.[548,549,551,554,556,560,561] The most common drug classes include antimicrobial agents, particularly sulfonamides and penicillins; antithyroid drugs; antipsychotics such as phenothiazines and clozapine; antipyretics, particularly aminopyrine; antirheumatics, including gold, levamisole, and penicillamine; and sedatives, including barbiturates and benzodiazepines (see Table 21-9).

Although the underlying mechanisms for most drug-induced neutropenia are unknown, most studies suggest that they can be classified as leading to toxic suppression of neutrophil formation or immune destruction of mature cells.[551,553,560,561] First, differences in drug pharmacokinetics can lead to toxic levels of the drug or metabolites in the marrow microenvironment. An example is the neutropenia induced by sulfasalazine. Although neutropenia can be observed in any patient taking this drug, individuals who are slow acetylators show much greater toxicity than do those who are fast acetylators.[559] Second, a susceptible patient's myeloid precursors may be abnormally sensitive to typical drug concentrations. Phenothiazines induce neutropenia by this mechanism in that myeloid precursors in the marrow are particularly sensitive to these agents.[551,561,563] The toxic damage induced by phenothiazines is manifested as a neutropenia that appears 20 to 40 days after the patient has started taking the drug. Neutropenia secondary to drug-induced myelosuppression is usually insidious in onset and may be asymptomatic. Oral mucositis may be the first clinical sign before infectious complications occur.

Drugs can also induce immune-mediated peripheral destruction of neutrophils by alternative mechanisms. In one, the drug serves as a hapten in promoting the synthesis of antibodies that are capable of destroying mature neutrophils. Aminopyrine, penicillin, propylthiouracil, and gold can cause neutropenia by this mechanism.[551,555,558,561] Alternatively, the drug can elicit the formation of circulating immune complexes that attach to the surface of the neutrophil and lead to its destruction, as in the case of quinidine. In addition, immunologic changes induced by drugs can suppress granulopoiesis. For example, activation of both cellular and humoral immune responses has been reported to impair myelopoiesis after therapy with quinidine and phenytoin, respectively.[553,561] Drug-induced immune neutropenia is characterized by an abrupt onset—often with fever, chills, and prostration—7 to 14 days after the first exposure to the drug or immediately after re-exposure.

The duration of drug-induced neutropenia is highly variable. Acute idiosyncratic drug reactions may last only a few days, whereas chronic idiosyncratic reactions may persist for months or years. By contrast, immune-mediated neutropenia usually lasts for 6 to 8 days. Once neutropenia occurs, the most important therapeutic action is, of course, to withdraw all drugs that are not absolutely essential, particularly those suspected of being myelotoxic. During recovery from drug-induced neutropenia, rebound leukocytosis accompanied by a left-shifted marrow and circulating immature leukocytes can occur. G-CSF therapy may hasten neutrophil recovery slightly, but evidence-based data to justify its routine use are lacking,[407,564,565] so the clinical indication is questionable unless the patient has a severe infection.

Autoimmune Neutropenia

Autoimmune neutropenia (AIN) can be seen as an isolated phenomenon, in association with other autoimmune diseases, or as a secondary manifestation of infection, drugs, or malignancy.[382,564,566] Many cases of chronic idiopathic neutropenia in children and adults are now recognized as being secondary to autoimmunity directed against neutrophils. In primary AIN, low circulating neutrophil counts are the only hematologic finding, and associated diseases or other factors that cause neutropenia are absent. The peak incidence of AIN occurs in infants and young children,[567,568] where it is generally a benign disorder that remits spontaneously, as discussed in the following section. Immune-mediated neutropenia

Underlining indicates drugs with the highest relative risk for neutropenia and agranulocytosis. See text for references.

is also seen in association with other disorders (Box 21-5), where it is often referred to as secondary AIN.

Patients with AIN may have highly—and rapidly—varying neutrophil counts ranging from mild neutropenia (ANC < 1000 cells/µL) to agranulocytosis (ANC < 200 cells/µL). Monocytosis is common. Bone marrow examination generally shows normal to increased cellularity with myeloid hyperplasia and normal to increased numbers of mature neutrophils, although diminished neutrophils or maturation arrest at earlier stages of differentiation can also be seen.[382,564,566] Mild splenomegaly is occasionally present. The incidence of pyogenic infection is not always related to the degree of neutropenia,[382,388] and it is usually limited to cutaneous and respiratory infections. Serious infections are generally uncommon. Spontaneous remission resolves the process in most infants but occurs less commonly in older children (see the following section).

Neutrophil-specific cell surface antigens identified as targets of autoantibodies include NA1 and NA2, NB1,

ND1, and NE1.[265,266] The NA1 and NA2 antigens are glycosylated isoforms of the neutrophil immunoglobulin receptor FcγRIIIb (CD16) (see Table 21-6), and the NB1 antigen is a 58- to 64-kd GPI-anchored membrane glycoprotein found on the plasma membrane and secondary granules.[569] Then mechanisms that trigger autoantibody production are unknown. In children, primary AIN is usually associated with NA allele–specific antibodies, but secondary AIN is associated with pan-FcγRIIIb antibodies.[570]

To detect antineutrophil antibodies, a combination of an indirect granulocyte immunofluorescence test (GIFT) and granulocyte agglutination test (GAT) appears to result in optimal sensitivity and specificity.[265,266,571] These assays detect IgG and IgM antibodies, both of which been identified in AIN. In the GIFT assay, a panel of heterologous donor granulocytes is incubated with serum or plasma from patients and controls, and bound immunoglobulins are detected by a fluorescent dye–labeled antihuman immunoglobulin antibody and

DRUG REACTION

quantitated by fluorescence microscopy or flow cytometry. The GIFT assay is analogous to the indirect antiglobulin (Coombs) test for erythrocyte antibodies. It is subject to false-positive results from anti-HLA antibodies unless they are specifically absorbed before testing. The analogous direct antineutrophil antibody test can be performed by detection of immunoglobulin bound to patient neutrophils, similarly detected by microscopy or flow cytometry. Importantly, the standard laboratory test for antineutrophil cytoplasmic antibody (ANCA) does *not* detect the antibodies responsible for AIN.

The GAT is less sensitive but is useful for detecting a subgroup of antibodies against antigens other than CD16, although these are not typical of AIN.[265,266,571] Neutrophil-binding immune complexes may also give positive results in these assays and may be important in the pathogenesis of neutropenia in Felty's syndrome.[572] Confirmatory testing of autoantibody specificity can be done by assay involving monoclonal antibody immobilization of granulocyte antigens, in which binding of patient sera to a panel of donor neutrophils is compared with binding of monoclonal antibodies of defined specificity.[571,573] Sera containing HLA antibodies requires preabsorption or other controls to determine whether there is specific antineutrophil activity. Because of the limited

sensitivity and specificity of these assays, even in combination, laboratory demonstration of antineutrophil antibodies may not always be necessary to make the diagnosis of AIN, and their interpretation depends on the specific clinical setting.

The neutropenia of AIN is presumed to primarily be due to peripheral destruction of antibody-coated neutrophils, which may be also be augmented by the deposition of C3. Phagocytosis of neutrophils in the spleens of AIN patients has been observed.[574] In some cases, antineutrophil antibodies also appear to interfere with myelopoiesis.[572,575,576] Impairment of phagocytosis, respiratory burst activity, and adhesion by neutrophil-directed antibodies has likewise been observed and may contribute to the risk of infection in AIN.[572,575,577]

Treatment of patients with immune neutropenia includes the judicious use of appropriate antibiotics for bacterial infections and antimicrobial mouthwashes and regular dental hygiene for mouth sores or gingivitis. Infections tend to be less frequent in patients with immune neutropenia than in those with the corresponding degree of neutropenia from other causes, probably because granulopoiesis is intact in most cases. Prophylactic administration of trimethoprim-sulfamethoxazole may be also helpful in the management of recurrent minor infections, although no controlled studies have addressed the efficacy of this approach.

For definitive therapy, administration of G-CSF, starting at low doses of 1 to 2 µg/kg/day, has been successful in increasing the neutrophil count to the normal range or even higher in patients with primary AIN, including secondary immune neutropenia and Felty's syndrome.[566,567,578,579] The initial response may be apparent within days of starting therapy, but up to 2 weeks may be required. Patients with a normal or high ANC during therapy may be weaned to very-low-dose or alternate-day administration of G-CSF. The incidence of bone pain appears to be higher in AIN than in hypoproductive neutropenia, probably as a result of expansion of the already hyperplastic bone marrow. Because most patients with immune neutropenia do not suffer serious infectious complications, G-CSF therapy should be reserved for those with serious or recurrent infections or multiple hospitalizations for febrile neutropenia.

Administration of intravenous immunoglobulin can result in normalization of the neutrophil count, but its efficacy is variable and often short lived.[566,567,578] Corticosteroids can raise the neutrophil count but may actually increase the risk for serious infection. Similarly, splenectomy can provide transient benefit that is offset by the risk for sepsis.

Chronic Benign Neutropenia and Autoimmune Neutropenia of Childhood

Most cases of what was termed chronic benign neutropenia of infancy and childhood are now believed to represent an AIN that has parallels to childhood idiopathic thrombocytopenic purpura.[566,567,578,580] The handful of

TABLE 21-10	Summary of Autoimmune Neutropenia of Childhood
Incidence	Most common cause of chronic neutropenia in infancy and childhood; incidence ≥1 per 100,0000 children per year
Clinical features	Median age at diagnosis, 8-11 months (range, 3-38 months). Slight female preponderance (56% F, 44% M) Relatively minor infections (otitis media, gingivitis, upper respiratory tract, skin) occur with increased frequency in some patients and respond well to antimicrobial therapy. Rare patients (usually young infants) have pneumonia or sepsis
Laboratory evaluation	Median ANC at time of diagnosis ≈200 neutrophils/µL (range, 0-500 cells/µL). Hemoglobin, platelet count generally normal. Antineutrophil antibodies can be detected in majority of patients and are often directed to the NA1 antigen (neutrophil FcγIII receptor). Bone marrow evaluation (if performed) shows normal to increased myelopoiesis, sometimes with a decrease in mature neutrophils or maturation arrest at earlier stages
Therapy	Antibiotics for acute infection; prophylactic antibiotics may be helpful in some patients with recurrent otitis media. Consider use of G-CSF in the event of serious infection or very high frequency of minor infections
Prognosis	Excellent. Although the ANC often remains below 500 cells/µL for 12 or more months, spontaneous remission occurs in almost all patients (median, 20 months; range, 6-54 months)

ANC, absolute neutrophil count; G-CSF, granulocyte colony-stimulating factor.

cases reported as "lazy leukocyte syndrome," characterized by profound neutropenia, normal-appearing bone marrow, and little increase in the peripheral blood neutrophil count in response to steroids or epinephrine,[581] are also likely to have been AIN of childhood.

AIN of childhood occurs predominantly in children younger than 3 years (Table 21-10). The median age at diagnosis is 8 to 11 months, with a range of 2 to 54 months.[566,567,578,580] There is a slight female preponderance. Although AIN of childhood is the most common cause of chronic neutropenia in the pediatric age group, it is still a relatively infrequent diagnosis, with an incidence of approximately 1 in 100,000 children per year.[385,582] However, this figure is probably an underestimate because of the generally benign course of the disorder.

The initial ANC is often in the severe range (<200 cells/µL) and may approach zero, usually with a relative monocytosis or eosinophilia, or both. Transient increases in circulating neutrophil counts can occur in response to infection. Other peripheral counts are normal for age, although mild thrombocytopenia (≥100,000 cells/µL) has been reported.[583] There is usually no family history of neutropenia.

Antineutrophil antibodies can be detected in almost all patients when a combination of immunofluorescence and agglutination assays are used, with repeated testing if necessary.[571,573,578,580] However, absence of detectable antibody does not exclude the diagnosis, and a positive result does not exclude SCN.[429] As in AIN in adults, antibodies are typically directed against neutrophil-specific antigens of the NA, NB, and ND loci. Antibody specificity to NA1, an allele of the neutrophil immunoglobulin FcγRIII receptor, is seen most commonly.[571,573,578,580] Some, but not all studies report a correlation between the strength of the antibody and the severity of clinical manifestations.[571,573,578,580] As the neutropenia resolves, antibodies gradually become undetectable. Bone marrow examination generally shows normal

to increased cellularity with myeloid hyperplasia and normal to increased numbers of mature neutrophils, although some patients with intramedullary destruction of neutrophils or their precursors may show a "maturation arrest." Some, but not all patients will manifest an increase in the peripheral neutrophil count in response to hydrocortisone or prednisone.

Bacterial infections in AIN of childhood are often increased in frequency but are mild (e.g., skin infections, upper respiratory infections, otitis media, gingivitis) and responsive to standard antibiotics.[385,575,584] Cellulitis involving the labia majora was seen in 23% of 26 girls with AIN in one series, often caused by *Pseudomonas aeruginosa*.[385] Pneumonia, sepsis, and meningitis have been reported only occasionally in infants with AIN.[575] Spontaneous remission occurs in almost all patients, with neutropenia persisting for a median duration of 20 months.[584] Children younger than 9 months at the time of diagnosis may recover normal peripheral neutrophil counts more rapidly.[583] With increasing age, spontaneous remission becomes less likely.

The diagnosis of AIN of childhood is generally straightforward if the signs and symptoms occur within the first 2 years of life, there is no history of serious infections over a period of several months of observation, and neutrophil morphology and other peripheral counts are otherwise normal. Demonstration of antineutrophil antibody is not necessary for diagnosis in a patient with the typical clinical features of childhood AIN (see Table 21-10). Because of the association of AIN with immunodeficiency syndromes (see later in this section), evaluation of immunoglobulin levels should be performed to exclude dysgammaglobulinemia or hypogammaglobulinemia. If lymphopenia or clinical signs of cell-mediated immunodeficiency are present, T-cell function should also be studied. Bone marrow examination should always be performed if hematologic abnormalities other than neutropenia are present, if the child's age falls outside the usual range for AIN of infancy, or if the patient has an

unusual or deep-seated infection suggesting poor marrow neutrophil reserve. Other laboratory tests to consider are outlined later in this section.

Febrile episodes should be managed aggressively, including the use of broad-spectrum parenteral antibiotics, in the initial period before the diagnosis of childhood AIN is established. However, once the diagnosis is definite and the patient has had no serious infections, subsequent febrile illnesses can be managed more conservatively if clinically warranted. Prophylactic trimethoprim-sulfamethoxazole can be helpful in children with recurrent otitis media and other minor infections. Administration of G-CSF results in an increased peripheral neutrophil count in childhood AIN and is the treatment of choice for the rare child with AIN who manifests very severe or recurrent major infections.[566,567,578,580] G-CSF doses of 1 to 2 μg/kg/day or less are usually effective, and responses are typically seen within days. Steroids and intravenous gamma globulin have also been used but have limited efficacy, as discussed earlier.

Neonatal Immune Neutropenia

Immune-mediated neutropenia in the newborn may be alloimmune and be due to maternal immune response to fetal alloantigens or may be isoimmune and be due to passive transfer of maternal autoantibody.

Neonatal alloimmune neutropenia, an immunologic disorder analogous to Rh hemolytic disease, results from maternal sensitization to fetal neutrophils bearing antigens that differ from the mother's. Maternal IgG antibodies cross the placenta and result in an immune-mediated neutropenia that can be severe and last from several weeks to as long as 6 months.[266,568,585] During the neutropenic phase, the infant's bone marrow demonstrates myeloid hyperplasia, usually with depletion of mature neutrophil forms.

Neutrophil antibodies are found in the serum of the mother and the infant and are frequently directed to the neutrophil-specific NA antigen system. The NA1 and NA2 antigens are two isotypes of the neutrophil FcγRIII receptor (see Table 21-6). Affected infants may be asymptomatic or can exhibit omphalitis, cutaneous infections, pneumonia, sepsis, and meningitis. Because neonatal sepsis can itself be associated with profound neutropenia, the underlying immune-mediated neutrophil destruction may not be appreciated immediately in affected newborns with sepsis.

The initial management of neonatal alloimmune neutropenia should include parenteral antibiotics, even if signs of infection are absent, because of the association of neutropenia with neonatal sepsis. Intravenous gamma globulin may sometimes be effective in increasing neutrophil counts.[586,587] Treatment with G-CSF, starting at 5 to 10 μg/kg/day intravenously, should be considered for very profound neutropenia or when serious infections develop in infants with alloimmune neutropenia.[568,588,589]

Neonatal immune neutropenia can also occur in infants of mothers with AIN. Transplacental passage of an IgG antineutrophil antibody can react with the infant's neutrophils bearing the inciting antigen and result in a profound neutropenia lasting 2 to 4 weeks.[568,590] Treatment is similar to that for isoimmune neutropenia. Leukoagglutinating antibodies directed against HLA antigens are frequently found in multiparous women and their newborn children's sera[591,592]; these antibodies are not associated with neutropenia and thus need to be distinguished from neutrophil-specific antibodies in laboratory assays.[571,585]

Neutropenia Associated with Immune Dysfunction

Primary disorders of immunoglobulin production have been associated with neutropenic syndromes.[593-595] A third of males with X-linked agammaglobulinemia have neutropenia at some time during the course of their disease.[593,595] Persistent or cyclic neutropenia is common in patients with the hyper-IgM immunodeficiency syndrome, which in many instances appears to be secondary to the formation of autoantibodies.[593,595] Immunoglobulin replacement therapy abolished the neutropenia in some, but not all of these patients.[596] AIN and other autoimmune cytopenias can also be seen in common variable immunodeficiency and isolated IgA deficiency.[593,594]

Autoimmune lymphoproliferative syndrome (ALPS), which reflects a family of defects in lymphocyte apoptosis, is characterized by lymphadenopathy, splenomegaly, and a variety of autoimmune disorders, including immune thrombocytopenia, anemia, and neutropenia.[597,598] The neutropenia associated with ALPS tends to be chronic and, because of the unique pathophysiology of the underlying disorder, represents one of the few forms of neutropenia treated by immunosuppression with corticosteroids or mycophenolate mofitil.[598,599]

Cartilage-hair hypoplasia, an autosomal recessive disorder found frequently in the Amish population, is characterized by short-limbed dwarfism, fine hair, moderate neutropenia (100 to 2000 cells/μL), and impaired cell-mediated immunity.[600,601] The disorder arises from mutations in the noncoding RNA gene *RMRP*,[602] which provides the RNA subunit of the RNase mitochondrial RNA-processing enzyme, a complex involved in multiple cellular RNA-processing events.[603] G-CSF therapy has been reported to be effective in a single patient who also had an antineutrophil antibody[604]; bone marrow transplantation has corrected both the immunologic defects and the neutropenia.[605]

Neutropenia can be seen as part of a broader spectrum of disease in a variety of other disorders of the immune system. Autoimmune disorders such as systemic lupus can be associated with antibody- or immune complex–mediated destruction of neutrophils or their precursors, as discussed earlier. G-CSF therapy is effective but may precipitate flares of the underlying disease.[606,607] Finally, in patients with HIV infection,

neutropenia is common and has multiple causes, including antiretroviral drugs, cellular immune dysfunction, ineffective hematopoiesis, antineutrophil antibodies, and hypersplenism.[526-529]

T-cell large granular lymphocyte leukemia (LGL), a clonal disorder of cytotoxic T lymphocytes most common in the elderly, is often manifested as severe chronic neutropenia, with or without accompanying anemia.[407,608] LGL-associated neutropenia, which overlaps clinically with Felty's syndrome, may derive from either immune complex– or cell-mediated mechanisms and generally responds to a combination of immunosuppressive and cytotoxic therapy for the underlying disease and G-CSF for the neutropenia.[407]

Neutropenia Associated with Metabolic Diseases

Significant neutropenia, often with a relative monocytosis, occurs in Barth's syndrome, a distinctive X-linked disorder also associated with dilated cardiomyopathy, growth retardation, and 3-methylglutaconic aciduria.[609,610] Symptoms develop in infancy or childhood in affected boys, and neutropenia can precede the development of cardiac abnormalities. Children suffering from hyperglycinemia, isovaleric acidemia, propionic acidemia, methylmalonic acidemia, and tyrosinemia may also have significant neutropenia, although clinically it is not as consequential as other features of the disorders.[611-618] The mechanisms underlying the neutropenia associated with disorders of organic acid metabolism are not known, but the finding that propionate and isovalerate impair the development of myeloid colonies in vitro suggests that altered levels of metabolites may suppress myelopoiesis in vivo.[619]

Neutrophils in patients with glycogen storage disease type IB are not only diminished in number, with neutrophil counts commonly less than 500 cells/μL,[611,612,620,621] but also functionally defective, with abnormalities reported in chemotaxis, respiratory burst activity, and bacterial killing.[612,614] There is no correlation between a given mutation in the microsomal glucose-6-phosphate gene and the clinical severity of neutropenia or systemic complications of the enzyme deficiency, thus indicating that other genes can modify the phenotype.[622] Recombinant G-CSF has been effective in correcting the neutropenia and reducing serious infections in glycogen storage disease type IB.[623] Prolonged use of G-CSF has not been associated with any increased risk for MDS/AML in this disease.[444]

Macrocytic anemia, often accompanied by neutropenia or thrombocytopenia, is a hematologic hallmark of Pearson's syndrome, a rare and fatal congenital disorder involving not only the hematopoietic system but also the exocrine pancreas, liver, and kidneys.[624] The bone marrow shows normal cellularity, but striking abnormalities include vacuolization of erythroid and myeloid precursors, hemosiderosis, and ringed sideroblasts. A mitochondrial defect related to large deletions in mitochondrial DNA, whose integrity depends on a specific DNA polymerase, probably leads to impaired hematopoiesis.[625]

Nutritional Deficiencies

Ineffective granulopoiesis is part of the megaloblastic marrow pathology observed in patients with nutritional deficiencies of vitamin B_{12} or folic acid.[626] As a reflection of the increased neutrophil turnover secondary to ineffective myelopoiesis, serum muramidase levels are often elevated.[626] Neutropenia also occurs with starvation in such conditions as anorexia nervosa[627] and marasmus in infants, as well as occasionally in patients maintained by parenteral feeding. In addition, neutropenia and marrow megaloblastosis have been observed in patients thought to have copper deficiency because these patients responded promptly to copper replacement.[628] Notably, these nutritional deficiencies do not cause isolated neutropenia; anemia is virtually universal and thrombocytopenia is an occasional additional finding.

Reticuloendothelial Sequestration

Splenic enlargement as a result of portal hypertension, intrinsic splenic disease, or splenic hyperplasia can lead to neutropenia. The usual picture is one of moderate neutropenia, usually accompanied by similar degrees of thrombocytopenia and anemia. The reduced neutrophil survival corresponds with the size of the spleen, and the extent of neutropenia is proportional to bone marrow compensatory mechanisms.[629] The neutropenia is usually mild and may be ameliorated by successful treatment of the underlying disease. Bed rest alone may lead to restoration of the neutrophil counts because of a reduction in portal pressure. In selected situations, splenectomy may be necessary to restore the neutrophil count to normal. Histiocytic disorders (see Chapter 24, Histiocytosis, in *Oncology of Infancy and Childhood*) may also cause reticuloendothelial hyperplasia leading to neutropenia and anemia secondary to the ingestion of neutrophils and red cells.[549]

Bone Marrow Infiltration

Malignancies—including leukemia, lymphoma, and solid tumors—that infiltrate the bone marrow result in a myelophthisic picture characterized by leukoerythroblastic peripheral blood smears with neutropenia, usually accompanied by other cytopenias. Tumor-induced myelofibrosis may further reduce the peripheral blood neutrophil count.[630] Neutropenia can also result from bone marrow involvement in granulomatous infections, lysosomal storage disease, or osteopetrosis.[631-633]

Chronic Idiopathic Neutropenia

Chronic idiopathic neutropenia represents a group of disorders that by definition, are poorly understood and cannot be placed in any of the aforementioned categories.[407,634] Investigation of the mechanism of neutropenia has suggested that in some cases, decreased or ineffective production of neutrophils may be the result of excessive

apoptosis, as in congenital neutropenia.[635] Overall, the clinical features, bone marrow findings, and natural history of chronic idiopathic neutropenia are variable but generally milder than those of congenital neutropenia; it is likely that many of the patients described in older studies had antibody-mediated neutrophil destruction and normal bone marrow reserve.[634,636] Treatment, when necessary, should be based on the severity of symptoms; G-CSF has proved effective at lower doses than needed for SCN and without any reported increase in risk for MDS/AML.[417]

Evaluation of Patients with Neutropenia

The basic approach to a patient with neutropenia includes a history and physical examination with emphasis on (1) related phenotypic abnormalities; (2) determination of whether bacterial infection is present (including evaluation of the gingiva and perineum); (3) evaluation of lymphadenopathy, hepatosplenomegaly, and any other signs of an underlying associated chronic illness; and (4) a history of recent infection and drug exposure. The frequency and duration of symptoms are important, and a history of periodontitis, dental abscesses, or tooth loss is particularly suspicious for significant chronic or recurrent neutropenia. The family history may reveal other individuals with recurrent infection. Unexplained deaths in children younger than 1 year and the race and ethnic background of each patient should be noted.

The duration and severity of the neutropenia and the presence or absence of significant other symptoms or physical findings greatly influence the speed and extent of laboratory evaluation. If the patient has isolated neutropenia and is asymptomatic and if other findings are absent, clinical observation for several weeks is usually the best approach. Any medications known or suspected to be associated with neutropenia should be discontinued. Any signs of an acute bacterial infection in a patient with moderate to severe neutropenia and fever call for prompt evaluation and treatment, including the use of intravenous broad-spectrum antibiotics.

Patients with persistent neutropenia should have white blood and differential counts obtained twice weekly for 6 to 8 weeks to evaluate for periodicity suggestive of cyclic neutropenia. Direct and indirect antiglobulin (Coombs) tests should be performed to evaluate for the presence of red cell autoantibodies, and serum immunoglobulins (IgG, IgA, and IgM, but not IgE) should be measured to detect associated immunoglobulin abnormalities. HIV testing is also indicated in chronic cases. Antineutrophil antibody testing, though technically imperfect, is generally included in an initial evaluation because of the frequency of AIN.

Bone marrow aspiration and biopsy with cytogenetics should be part of the initial evaluation if leukoerythroblastosis, anemia, macrocytosis, or thrombocytopenia is present and should be performed eventually if the diagnosis remains obscure despite initial testing. If SCN is suspected, bone marrow analysis with cytogenetic

screening for monosomy 7 should be performed both to establish the diagnosis and to provide a baseline before G-CSF therapy. Other laboratory tests that should be considered, depending on the clinical situation, include evaluation for collagen vascular disease, exocrine pancreatic insufficiency, and metabolic disorders (e.g., organic acidurias), as well as measurement of vitamin B_{12}, folate, and copper levels. Radiographic studies of the femoral heads, rib cage, and spine may be useful in the diagnosis of Shwachman-Diamond syndrome. Assessing the response of the peripheral neutrophil count to a single dose of corticosteroid may be useful for assessment of bone marrow reserves and, if normal, may indicate a more benign course[637] but should not relax clinical vigilance for febrile neutropenia.

Principles of Therapy for Neutropenia

Management of neutropenia depends on the underlying cause and severity of the neutropenia. The major concern in neutropenic patients is the development of serious pyogenic infection. Patients with severe neutropenia (ANC ≤ 500 cells/μL) and poor marrow reserves are at highest risk for progressive infection and septicemia. Fever may often be the only indication of infection inasmuch as local signs and symptoms of inflammation may be diminished in the face of neutropenia. Organisms involved are usually from the skin or gastrointestinal tract. Thus, febrile patients with severe neutropenia secondary to poor marrow function should be treated promptly with broad-spectrum antimicrobials after blood and other appropriate samples are obtained for culture. If the patient defervesces and blood cultures do not reveal any growth, the antibiotics should be continued for at least 2 to 3 days after the patient is afebrile. However, if the patient continues to have fevers of 38°C or higher, antimicrobial therapy should be continued despite negative blood cultures. Neutropenic patients who are febrile for more than 4 days while receiving broad-spectrum antibacterial antibiotics are at risk for fungal infection, so empirical treatment with antifungal antibiotics should be considered in this setting.[638] Neutropenic patients with documented fungal infection or gram-negative bacterial sepsis who have not responded to appropriate therapy are candidates for granulocyte transfusions.[539,639,640]

Neutropenic patients with normal to increased marrow cellularity, such as in the setting of AIN, often have a minimally increased risk of pyogenic infection and respond more briskly to appropriate antibiotics. A less aggressive course may be a reasonable approach to a febrile illness in such patients who clinically look well, even if the ANC is below 500 cells/μL. A child in whom the diagnosis of AIN of childhood has been established and fever or infection develops can generally be managed as an outpatient, unless the infection is severe.

An important component in the management of all patients with chronic or cyclic neutropenia is close attention to oral hygiene. Chronic gingivitis and periodontitis can be a persistent source of morbidity and result in tooth

loss. All patients should receive regular dental care, along with regular use of antibiotic mouthwash.

The advent of recombinant G-CSF and other hematopoietic growth factors has revolutionized the treatment of neutropenia.[407,416,417,439,564,579] As discussed in previous sections, G-CSF has been successfully used to increase the neutrophil count in a wide variety of conditions, including SCN, cyclic neutropenia, and immune-mediated neutropenia. In some cases, chronic prophylactic use of G-CSF is recommended, such as in SCN, in which patients have poor marrow production of neutrophils and a high risk for the development of serious infection. For other causes of neutropenia in which patients tend to have fewer problems with infection, such as AIN, G-CSF therapy should be reserved for specific clinical indications such as repeated or progressive infection.

Antibiotic prophylaxis, usually with trimethoprim-sulfamethoxazole, may be useful in some neutropenic patients with normal to increased myelopoiesis who do not meet the criteria for G-CSF therapy.[579] There are no evidence-based data to indicate the effectiveness of reverse precautions or neutropenic diets in chronic neutropenia patients without concurrent immunosuppression, but careful hand washing is clearly indicated (as for all patients), and common sense suggests that avoidance of environmental mold exposure[638,641] might reduce the risk for invasive fungal infection.

Neutrophilia

Neutrophilia refers to an alteration in the total number of blood neutrophils that is in excess of about 7500 cells/μL in adults (Box 21-6). During the first few days of life the upper limit of the normal neutrophil count ranges from 7000 to 13,000 cells/μL for neonates born prematurely and at term gestation, respectively.[642] A decrease to adult levels occurs within the first few weeks of life and is maintained thereafter. An increase in circulating neutrophils is the result of a disturbance in the normal equilibrium involving neutrophil bone marrow production, movement in and out of the marrow compartments into the circulation, and neutrophil destruction (see Box 21-6). Three mechanisms, either alone or in combination, largely account for neutrophilia.[17,643] First, increased numbers of neutrophils may be mobilized from either the bone marrow storage compartment or the peripheral marginating pools into the circulating pool. Second, blood neutrophil survival may be increased because of impaired neutrophil egress into tissue. Finally, the circulating neutrophil pool might be expanded as a result of (1) increased progenitor cell proliferation and terminal differentiation through the neutrophilic series, (2) increased mitotic activity of neutrophilic cell precursors, or (3) shortening of the cell mitotic cycle in neutrophil precursors. Acute neutrophilia occurs rapidly within minutes in response to exercise or epinephrine-induced reactions and has been attributed to mobilization of the marginating pool of neutrophils into the circulating

Box 21-6	Classification of Neutrophilia

INCREASED PRODUCTION

Chronic infection
Chronic inflammation
    Ulcerative colitis
    Rheumatoid arthritis
Tumors (perhaps with necrosis)

pool.[644,645] Slower onset of acute neutrophilia can occur after glucocorticoid administration or with inflammation or infection associated with the generation of endotoxin, TNF, IL-1, and a cascade of growth factors.[4,5,646,647] Maximal response usually occurs within 4 to 24 hours after exposure to these agents and is probably due to release of neutrophils from the marrow storage compartment into the circulation. Mechanisms that underlie release from the marrow pool involve interactions between neutrophils and the bone marrow stroma mediated by adhesion molecules such as β_2 integrins and by chemokines such as SDF-1 and its receptor CXCR4.[189] Glucocorticoids may also slow the egress of neutrophils from the circulation into tissue.[648] Less well understood mechanisms leading to delayed-onset acute neutrophilia have been reported after electric shock trauma, anesthesia, and surgery.[649-651]

Chronic neutrophilia is usually associated with continued stimulation of neutrophil production, possibly through perturbation of marrow feedback mechanisms. Chronic neutrophilia may accompany the prolonged administration of glucocorticoids, persistent inflammatory reactions, infection, chronic blood loss, or chronic anxiety.[652-656] Infections with pyogenic microorganisms, leptospira, and certain viruses (including herpes simplex,

varicella, rabies, and poliomyelitis) may all produce neutrophilia.[657] Significant neutrophilic leukocytosis has also been reported with both Kawasaki's disease and infectious mononucleosis.[658,659] Occasionally, extreme neutrophilia has been observed in tuberculosis, generally in seriously ill patients with widespread necrotizing inflammatory disease.[660] Chronic inflammation is frequently responsible for persistent neutrophilia, especially in patients with juvenile rheumatoid arthritis.[661] Marked neutrophilia is a hallmark of functional disorders of neutrophils caused by impaired adhesion or motility, as in patients with LAD or actin dysfunction (see later). Sustained moderate neutrophilia invariably follows either surgical or functional asplenia,[662] probably because of decreased clearance of circulating neutrophils.[18]

Congenital primary neutrophilia is rare. In a single reported family with autosomal dominant hereditary neutrophilia, affected individuals maintained absolute granulocyte counts between 14,000 and 164,000 cells/μL, along with increased leukocyte alkaline phosphatase, hepatosplenomegaly, and Gaucher-type histiocytes.[663] Neutrophilia also occurs in familial cold urticaria, in which cold exposure elicits, after about 7 hours, elevated neutrophil counts, fever, urticaria, and a rash characterized histologically by a neutrophil infiltrate.[664,665]

Leukemoid Reactions

The elevation of normal leukocytes to counts greater than 50×10^3 cells/μL is referred to as a leukemoid reaction.[666] The peripheral blood may show small proportions of immature myeloid cells, including occasional myeloblasts and promyelocytes. Leukemoid reactions need to be distinguished from chronic myelogenous leukemia (CML), which features a more extreme "left shift" and basophilia in the peripheral blood differential count, as well as the characteristic clinical, laboratory, and cytogenetics signs of a myeloproliferative disorder (see Chapter 11, Myeloid Leukemia, Myelodysplasia and Myeloproliferative Disease in Children, in *Oncology of Infancy and Childhood*). Chronic neutrophilic leukemia is a distinct, extremely rare malignant cause of mature neutrophilia, with a mean age at diagnosis of 62.5 years (range, 15 to 86) in 33 reported cases.[667]

Leukemoid reactions can be triggered by pyogenic infections, especially those secondary to *S. aureus* or *S. pneumoniae*. Leukemoid reactions can also occur with tuberculosis, brucellosis, toxoplasmosis, and inflammatory syndromes such as acute glomerulonephritis, acute rheumatoid arthritis, liver failure, and diabetic acidosis.[666] A transient myeloid myeloproliferative disorder that can be difficult to distinguish from a leukemoid reaction may develop in infants with Down syndrome[668,669] (see Chapter 11, Myeloid Leukemia, Myelodysplasia and Myeloproliferative Disease in Children, in *Oncology of Infancy and Childhood*). However, more often there is marked leukoerythroblastosis, and large numbers of circulating blast cells can be present. Although the syndrome is transient, it portends a high risk for subsequent leukemia.[670] Leukemoid reactions have also been identified in neonates with thrombocytopenia–absent radius syndrome, but without any subsequent increased risk for leukemia.[671]

Clinical States Associated with Alterations in Eosinophil Number

Eosinophilia

Eosinophil stimulation most commonly occurs after repetitive or prolonged antigen exposure, especially when the antigens are deposited in tissues and elicit hypersensitivity reactions, whether of the immediate (IgE-mediated) or delayed (T lymphocyte–mediated) type. Stimulation of eosinophilia is T lymphocyte dependent and underlies the immune response to metazoan parasites.[6,7] A very broad range of conditions can elicit an eosinophilic response (Box 21-7).

Allergy is the most common cause of eosinophilia in children in the United States.[672] Acute allergic reactions may cause leukemoid eosinophilic responses, with eosinophil counts exceeding 20,000 cells/μL, whereas chronic allergy is rarely associated with eosinophil counts of greater than 2000 cells/μL.[673] A variety of skin diseases have been associated with eosinophilia,[674] the best documented being atopic dermatitis, eczema, pemphigus, acute urticaria, and toxic epidermal necrolysis. Drug reactions often elicit eosinophilia,[675] including the potentially fatal disorder "drug rash with eosinophilia and systemic symptoms" (DRESS syndrome).[676]

Outside the United States and hence also in immigrants and returning travelers, parasitic infections are the most common causes of eosinophilia.[677-679] Infestations by certain parasites, including helminths, induce greater degrees of eosinophilia than protozoan infestations do.[7,672,674] Although some parasite antigens appear to be potent immunogens, the eosinophilia resulting from parasitic infection is not due to some unique component of the parasites themselves but rather to a tissue granulomatous response requiring the participation of intact parasites. Other parasites, such as *Giardia lamblia*, *Enterobius vermicularis*, and *Trichuris trichiura*, fail to elicit an eosinophilic response, probably because they remain localized to the intestinal tract and do not enter the systemic circulation. When parasites invade systemic organs, they may incite clinical symptoms and signs related to the involved organs, such as hepatomegaly and pulmonary infiltrates.

These features are further associated with eosinophilic leukocytosis, anemia, and hyperglobulinemia, as commonly seen in visceral larva migrans from *Toxocara canis*. The patient may be brought for medical attention because of fever, cough, and wheezing. Complications include seizures, encephalitis, myocarditis, retinal lesions (which are often difficult to distinguish from retinoblastoma), and skin nodules on the palms of the hands and

soles of the feet. Leukocyte counts may exceed 100,000 cells/μL, with marked eosinophilia persisting from months to years after resolution of the symptoms. Polyclonal hypergammaglobulinemia is frequent. Increased anti-A and anti-B titers are commonly observed because of cross-reactivity between red cell and parasitic antigens.

In contrast to viral exanthems, scarlet fever is frequently associated with modest degrees of eosinophilia. Eosinophilia is also observed in cytomegalovirus pneumonia of infancy, cat-scratch disease, infectious lymphocytosis, and occasionally, infectious mononucleosis. Many patients with acute pulmonary tuberculosis show decreased numbers of circulating eosinophils followed by an increase in eosinophils during the convalescent phase, but rare patients exhibit marked eosinophilia at diagnosis.

In general, fungal diseases do not cause eosinophilia, but important exceptions are allergic and nonallergic fungal sinusitis and rhinosinusitis, coccidioidomycosis, and allergic bronchopulmonary aspergillosis.[674,680-682] The latter two diagnoses fit into the spectrum of pulmonary eosinophilic syndromes, which also include idiopathic eosinophilic pneumonia, Churg-Strauss syndrome (a form of vasculitis), tropical pulmonary eosinophilia (caused by microfilariae and other parasites), and drug- and radiation-induced pulmonary eosinophilia.[674,683,684]

Gastrointestinal disorders may also be associated with eosinophilia.[672,685] Primary eosinophil-mediated disorders usually involve the esophagus and stomach, but they can affect any or all segments of the gastrointestinal tract. Eosinophilia can also be a secondary sign of food allergy.[686] Inflammatory bowel disease and gluten enteropathy may involve large numbers of tissue eosinophils but show little or no elevation in blood eosinophil numbers.[685,687,688] Eosinophilia is a prominent feature of several immunodeficiency disorders, especially hyper-IgE (Job's) syndrome (see later), WAS, and Omenn's syndrome.[437,689] It can also be associated with hereditary angioedema, a defect in the complement C1 inhibitor.[690,691] In approximately 10% of patients with rheumatoid arthritis, mild eosinophilia develops during the course of their disease.

Autosomal dominant familial eosinophilia has been reported in several families in which individuals displayed marked eosinophilia, but few had pulmonary, cardiac, or neurologic involvement.[692,693] The disorder has been mapped to chromosome 5q31-q33, a region that contains a cytokine cluster that includes genes encoding IL-3, IL-5, and GM-CSF.[694] However no mutations or functional polymorphisms have been identified within the promoter, exons, or introns of any of these genes, thus suggesting that the primary defect in familial eosinophilia

is located in another gene in the cluster. The disorder can be distinguished from HES (see later) by the relative absence of eosinophil activation markers and the rarity of end-organ damage.[693]

Marked eosinophilia can accompany or precede the diagnosis of malignancies, including Hodgkin's and non-Hodgkin's lymphoma, acute lymphoblastic leukemia, and a variety of solid tumors.[674,695,696] Excessive numbers of normal eosinophils may also be produced in response to the production of cytokines, primarily IL-5, by abnormal (but only sometimes clonal) T cells with aberrant immunophenotypic markers.[697] In about a third of patients undergoing chronic hemodialysis, blood eosinophilia develops without apparent cause.[698] Similarly, chronic peritoneal dialysis may cause an eosinophilic peritoneal effusion and occasionally an elevated number of eosinophils in blood.[699]

Eosinophilia can produce organ damage—particularly to the heart, lungs, and gastrointestinal tract—by infiltration and deposition of toxic granule proteins. If treatment of the underlying infection or disease is not sufficient to reduce the eosinophil count, steroid therapy generally produces a rapid decline in eosinophil production and circulating cell numbers. More recently, anti–IL-5 antibody therapy has shown promise as an alternative.[700]

Hypereosinophilic Syndrome

HES is defined as persistent eosinophilia in patients who meet the following criteria: (1) absolute eosinophil count of 1500 cells/μL or higher for longer than 6 months (or fatal termination within 6 months), (2) lack of other diagnoses to explain secondary eosinophilia, and (3) signs and symptoms of organ involvement by infiltrating eosinophils.[701] Clinical manifestations result from tissue infiltration by eosinophils and from tissue damage caused by the release of eosinophil granule products. Symptoms include nonspecific findings of fever, weight loss, and fatigue. Cardiac damage is the major cause of morbidity and mortality in HES and includes endocardial fibrosis and the formation of mural thrombi with infiltrating eosinophils (Löffler's endocarditis).[672,674,702-705] These findings can also be seen with eosinophilia of multiple other causes, including parasitic infection, drug reactions, and malignancies. Hepatosplenomegaly, pulmonary infiltrates, and skin involvement with urticarial or nodular lesions are common; neuropathies, encephalopathy, and CNS thromboembolism can also occur.

There is still controversy on the proper classification of HES in relation to chronic eosinophilic leukemia and idiopathic HES. One proposed subdivision, after elimination of reactive eosinophilias, classifies HES into clonal eosinophilias and idiopathic HES (i.e., everything else).[674,702] The clonal forms of HES can be further classified—and in many cases treatment guided—by identification of specific gene rearrangements.[674,702,703,706] The most common involve the gene encoding platelet-derived growth factor receptor α, *PDGFRA*, which forms fusion products that generate constitutively active tyrosine kinase molecules.[706,707] Fusion partners include the Fip1-like 1 gene *FIP1L1* and, less commonly, *BCR* or *CDK5RAP2*, which encodes CDK5 regulatory subunit–associated protein 2. The *FIP1L1-PDGFRA* fusion results from an interstitial chromosome 4q12 deletion that is not cytogenetically detectable. This rearrangement results in HES with a marked male preponderance and a phenotype that includes splenomegaly, elevated serum vitamin B_{12} and tryptase levels, and hypercellular bone marrow with fibrosis and increased eosinophils and mast cells. Other patients with clonal HES have rearrangements of the gene encoding the platelet-derived growth factor receptor β, *PDGFRB*, and rare cases have been reported with rearrangements of *FGFR1* and other genes.[674,702] Most importantly, patients with either of the PDGFR fusion products are likely to respond to imatinib therapy, sometimes at doses lower than those used for CML.[702,704,707]

HES can generally be distinguished from the M4Eo variant of AML (see Chapter 11, Myeloid Leukemia, Myelodysplasia and Myeloproliferative Disease in Children, in *Oncology of Infancy and Childhood*), which is characterized by myelomonocytic blasts with eosinophilia and has been referred to in the past as eosinophilic leukemia.[708] In acute leukemia, there is typically a marked increase in the number of immature eosinophils in blood or marrow (or both), infiltration of tissue by immature cells of predominantly an eosinophilic type, and secondary anemia and thrombocytopenia. The eosinophils in M4Eo leukemia have an additional granule population that stains with periodic acid–Schiff and chloroacetate esterase. Almost all patients in the M4Eo leukemia subgroup have inversion or another cytogenetically detectable abnormality in chromosome 16.[709]

Eosinopenia

Eosinopenia is not uncommon but is seldom recognized clinically because its precise diagnosis requires an absolute eosinophil count.[710] Eosinopenia may be produced by at least two mechanisms: (1) acute stress, with resultant stimulation of adrenal corticoids or release of epinephrine (or both), and (2) acute inflammatory states. The immediate eosinopenia after the administration of glucocorticoids reflects the destabilization of mRNA encoding cytokines such as eotaxins and inhibition of the cytokine-dependent survival of eosinophils.[7,711] Glucocorticoids also suppress the transcription of a number of factors involved in eosinophil production and trafficking, including IL-3, IL-4, IL-5, and GM-CSF.[7] Acute inflammation is associated with alterations in eosinophil distribution and production that resemble those observed after corticosteroid administration. At least part of this response occurs independent of adrenal corticoid release. Acute infections associated with a marked inflammatory response, including invasive bacterial and most acute viral infections, may be accompanied by eosinopenia throughout the period of the fever. Chronic infections cause a less predictable eosinophil reaction.

Basophilia and Basophilopenia

Basophils are associated with hypersensitivity reactions of the immediate type[99,101,712] (Box 21-8). Basophil levels may be elevated in allergic responses, helminth infections, and chronic inflammatory diseases.[101,713,714] Most importantly, basophil levels are increased in myeloproliferative disorders such as CML (see Chapter 11, Myeloid Leukemia, Myelodysplasia and Myeloproliferative Disease in Children, in *Oncology of Infancy and Childhood*). Basophil counts exceeding 30% can occur during the course of CML; marked basophilia often heralds a poor prognosis,[715,716] and the cells may be morphologically and functionally abnormal.[717,718] Patients with marked basophilia may have symptoms attributable to the release of biogenic amines or heparin-like material from degranulated basophils[718,719] and may benefit from the administration of antihistamines. Increased numbers of marrow basophils may occur in MDS and sideroblastic anemia.[720,721] Peripheral blood or bone marrow basophilia may also be seen with AML, usually in association with 6p or 12p chromosomal abnormalities,[722] or juvenile myelomonocytic leukemia.[718] Basophilopenia occurs in conditions that are associated with eosinophilopenia, such as during acute infection or after the administration of glucocorticoids.[723-725] Basophil counts are diminished in thyrotoxicosis and after treatment with thyroid hormones, and conversely they may be increased in myxedema.[724]

Monocytosis and Monocytopenia

The normal absolute blood monocyte count varies with the age of the patient, and this variation must be taken into account when assessing monocytosis. During the first 2 weeks of life, the absolute monocyte count is greater than 1000 cells/µL.[726] With increasing age there is a gradual decline in the monocyte count until it reaches a plateau of 400 cells/µL in adulthood. Monocytosis may therefore be defined as a total monocyte count of greater than 500 cells/µL. Given the widespread importance of monocytes, as previously described, it is not surprising that many clinical disorders give rise to monocytosis (Box 21-9). Typically, monocytosis is associated with bacterial, protozoan, and rickettsial infections; examples include subacute bacterial endocarditis, tuberculosis, syphilis, Rocky Mountain spotted fever, and kala-azar.[114,727] Monocytosis is a hallmark of juvenile myelomonocytic leukemia (see Chapter 11, Myeloid Leukemia, Myelodysplasia and Myeloproliferative Disease in Children, in *Oncology of Infancy and Childhood*) and can also be observed in malignant disorders such as preleukemia, AML, CML, lymphomas, and advanced-stage carcinomas.[727,728] Approximately 25% of all patients with Hodgkin's disease have monocytosis, although its presence does not correlate with prognosis.[726] Monocytosis has also been noted in a wide variety of inflammatory and immune disorders, including lupus, rheumatoid arthritis, sarcoidosis, and inflammatory bowel disease.[727] Finally, as discussed earlier, both relative and absolute

monocytosis occurs in some forms of severe chronic neutropenia and in patients recovering from myelosuppressive chemotherapy. Monocytopenia has been observed after glucocorticoid administration and in infections associated with endotoxemia.[729,730] In the latter case, systemic activation of complement and deposition of C5a on the surface of monocytes lead to their aggregation and clearance. In contrast to the profound granulocytopenia and lymphopenia associated with irradiation or cytotoxic chemotherapy, noncirculating monocytes and tissue macrophages are relatively resistant to these agents.[731] Decreased monocyte superoxide production, chemotaxis, and microbial killing have been reported in Gaucher's disease, which possibly contributes to the risk of infection in patients with this disease.[732-734] The defects are reversed at least partially by enzyme replacement therapy.[732]

Infantile (malignant) osteopetrosis is an autosomal recessive disease caused by failure of bone resorption and remodeling by osteoclasts, a form of specialized tissue macrophage.[148,149,151] This disorder arises in infancy and is characterized by progressive obliteration of the bone marrow space by bone and leads to progressive loss of marrow function, hepatosplenomegaly, growth retardation, and compression of cranial nerves. Autosomal recessive osteopetrosis is caused by mutations in genes encoding a vacuolar proton pump or the ClC-7 chloride channel.[154,155] Autosomal dominant osteopetrosis, a less severe form, is also caused by ClC-7 gene mutations, probably with a dominant-negative phenotype.[735] Generation of superoxide by peripheral blood leukocytes is defective in patients with autosomal recessive (malignant) osteopetrosis,[736] and recombinant IFN-γ (also used for CGD; see later) has been shown to increase bone resorption and improve hematopoietic marrow function in children with infantile osteopetrosis.[158] Infantile osteopetrosis has been treated by bone marrow transplantation,[151,156] and promising studies in a mouse model of the disease suggest that gene therapy targeted at hematopoietic stem cells might be a future therapeutic approach.[157]

DISORDERS OF GRANULOCYTE AND MONONUCLEAR PHAGOCYTE FUNCTION

Abnormalities in one or more steps of phagocyte function—adhesion, chemotaxis, ingestion, degranulation, and oxidative metabolism—are causes of inherited and acquired clinical disorders, which can be classified on the basis of the function primarily affected. Consistent with the critical role of phagocyte function in host defense, patients afflicted with these disorders often suffer recurrent, difficult-to-treat bacterial and fungal infections in the skin or mucosa, lungs, lymph nodes, or deep tissue (abscesses). Many of these disorders have characteristic clinical and microbiologic features related to the particular functional defect. As will be seen, some of the disorders manifest abnormalities in several phagocyte functions. In these instances, the primary defect is used

to classify the disorder. Finally, inherited disorders involving cytokine receptors and their signal transduction are increasingly being recognized,[737] many of which affect phagocyte function and result in recurrent infections. These disorders are described near the end of this chapter.

During the past 25 years, numerous papers have been published that describe abnormalities in phagocyte function, often associated with other diseases. In many of these reports, marginal abnormalities were noted with the use of in vitro phagocyte assays, with little evidence that the observed defects were responsible for the clinical predisposition to infection. In this section, disorders in which good correlations exist between the phagocyte abnormality and the clinical condition will be emphasized. In several of these disorders, particularly LAD and CGD, the molecular basis for the functional abnormality is well understood. Because these conditions serve as prototypes for understanding the less well characterized phagocyte disorders, the underlying biochemical and molecular genetic aspects of these conditions will be reviewed in some depth.

One final point should be emphasized. In clinical practice, most physicians encounter a number of patients who experience recurrent bacterial infections. Although it is true that nearly all patients with well-characterized phagocyte abnormalities have recurrent infections, the converse is seldom the case. Most patients with impressive histories of persistent and repeated infections do not have identifiable qualitative or quantitative phagocyte abnormalities. Therefore, the major disorders described in this section account for only a fraction of the patients with recurrent infections. This point will be discussed further in the final section describing the laboratory evaluation of phagocyte function.

Disorders of Adhesion

Leukocyte Adhesion Deficiency Type I

LAD I is a rare, autosomal recessive disorder in which phagocyte adhesion, chemotaxis, and ingestion of C3bi-opsonized microbes are impaired because of mutations in the gene for CD18, β subunit of the β_2 integrins. As a result, expression of β_2 integrins on leukocyte cell surfaces is reduced or absent.[738-741] More than 100 patients with this disorder have been described in the literature. The hallmark of LAD I is the occurrence of repeated, frequently severe bacterial and fungal infections without the accumulation of pus despite a persistent granulocytosis (Table 21-11). The clinical syndrome is heterogeneous and related to the severity of the reduction in β_2 integrin expression. A severe clinical phenotype is seen when less than 0.3% of the normal amount of β_2 integrins is present, whereas a more moderate phenotype is observed at levels of 2.5% to 11% of normal. Patients with the severe form of LAD I, which is more common, are generally seen in early infancy with neutrophilia,

TABLE 21-11	Clinical Features of Leukocyte Adhesion Deficiency Type I		
Chronic Conditions	**Acute Infections**	**Infecting Organisms**	**Other**
Persistent granulocytosis(12,000-100,000 cells/mm³)	Omphalitis	*Staphylococcus aureus*	Delayed umbilical cord separation
Gingivitis	Cutaneous abscesses and cellulitis (possibly invasive)	*Escherichia coli*	
Periodontitis	Perirectal abscesses and cellulitis (possibly invasive)	*Pseudomonas aeruginosa*

	Esophagitis		
	Erosive gastritis		
	Appendicitis		
	Otitis media		

Each list is arranged in approximate order of frequency based on reviews summarizing various series of patients with leukocyte adhesion deficiency (see text for references).

omphalitis, and delayed separation of the umbilical cord. Recurrent necrotic and indolent infections of the skin, mucous membranes, and gastrointestinal tract also occur, including perirectal abscesses, which often heal poorly. An aggressive form of gingivitis and periodontitis is characteristic, and ulcerative lesions of the tongue and pharynx can be seen. Otitis media and pneumonia are also often encountered. The majority of infections are caused by *S. aureus* and gram-negative enteric bacteria. Fungal infections occur as well, particularly *Candida albicans* and *Aspergillus* infection.

The molecular basis for LAD I was first suggested by Crowley and colleagues,[742] who found that neutrophils from a patient with this clinical syndrome lacked a high-molecular-weight membrane glycoprotein. Because the patient's neutrophils neither adhered to plastic surfaces nor underwent an oxidative burst when exposed to serum-opsonized particles, it was hypothesized that the missing glycoprotein was responsible for both adhesion and cell-particle interactions. A similar glycoprotein was also found to be missing in several other patients,[743,744] which proved to be the α subunit (CD11b) of the Mac-1 β₂ integrin (CD11b/CD18).[745] It was subsequently recognized that leukocyte β₂ integrins (see Fig. 21-5) were absent or severely deficient in LAD I.[738,739]

Deficient β₂ integrin expression impairs a variety of leukocyte adhesion-dependent activities, with neutrophil function being the most significantly affected.[739-743,746] In addition to their role in mediating adhesive interactions during neutrophil emigration and phagocytosis, signaling through β₂ integrins potentiates virtually all functional responses of adherent neutrophils, including the production of reactive oxidants and degranulation.[747] Hence, LAD I neutrophils have a profound defect in their ability to become fully activated.

One of the striking findings in LAD I is the failure of neutrophils to migrate to sites of inflammation. The initial phase of neutrophil adhesion to the endothelium (see Fig. 21-3), which is mediated by selectins and their sialylated counter-receptors, is normal in LAD. However, because of the absence or a marked deficiency of Mac-1 (CD11b/CD18) expression, LAD I neutrophils are neither able to attach firmly to the endothelium nor undergo transendothelial migration.[748] Neutrophil intravascular survival is prolonged,[749] presumably related to deficient adhesion and migration. In vitro assays of neutrophil adhesion to glass or cultured endothelial cells and neutrophil chemotaxis also exhibit marked abnormalities. An exception to these observations is neutrophil adhesion and emigration in the pulmonary capillary bed, which can be mediated by CD11/CD18-independent mechanisms under some circumstances.[225] In autopsy tissue from a patient with severe LAD I, no neutrophils were observed in infected appendiceal and skin lesions, whereas many neutrophils were seen within the alveolar spaces.[225] In contrast to neutrophils, other leukocytes (monocytes, eosinophils, and lymphocytes) express the β₁ integrin VLA-4 and are able to use this adhesion molecule to emigrate into inflammatory sites throughout the body.

Another major defect in LAD I is the inability of neutrophils and monocytes to recognize microorganisms coated with the opsonic complement fragment C3bi because Mac-1 is a major C3bi receptor.[742,746,750] Binding of C3bi normally triggers neutrophil degranulation, phagocytosis, and activation of the respiratory burst, but these responses are diminished or absent in neutrophils from patients with LAD I. Controlled experiments have consistently demonstrated, however, that these responses can be at least partially activated in LAD I neutrophils

by opsonins (e.g., IgG, C3b) that have different cell surface receptors or by soluble agonists that bypass Mac-1.[742,747]

Defects in lymphocyte functions dependent on LFA-1 (CD11a/CD18) have been observed in many LAD I patients in vitro. Such defects include proliferative responses to mitogens, NK cell function, and lymphocyte-mediated killing.[751-753] Nevertheless, most patients with LAD I manifest few, if any problems related to lymphocyte dysfunction in vivo. Cutaneous hypersensitivity reactions are normal, and patients are not generally unusually susceptible to viral infections, including varicella. However, one patient has died of an overwhelming respiratory infection with picornavirus, and one or more episodes of aseptic meningitis have been reported in three patients.[754]

Molecular Basis of Leukocyte Adhesion Deficiency

That LAD I involves a deficiency of all leukocyte CD11/CD18 integrins focused attention on the common β_2 chain (CD18) of this integrin family as the site of the molecular defect. This hypothesis has proved to be correct. Expression of leukocyte integrin α subunits is normal in LAD I, but these subunits are not transported to the cell surface because the β_2 chain is absent or contains mutations that disrupt the β_2 structure or its interaction with the α subunit.[755] More than 30 different mutations have now been characterized at the molecular genetic level in over 35 patients with LAD I, and all involve mutations in the β_2 gene, which is located on chromosome 21q22.3. A computerized database is available: http://bioint.uta.fi.[756] The mutations are heterogeneous. Many patients are compound heterozygotes for two different mutant alleles, whereas others are homozygous for a single mutant allele. About half of LAD I patients with characterized genetic defects have point mutations that result in single–amino acid substitutions in CD18, almost invariably between amino acids 111 to 361.[757,758] This protein domain is highly conserved among all β subunits and appears to be important for interaction with the α subunit. In this LAD I subgroup, approximately half exhibit a low level of CD11/CD18 cell surface expression and moderate disease, with the remainder having absent expression and the severe phenotype. mRNA splicing abnormalities resulting in either deletion or insertion of amino acids in the conserved extracellular domain of CD18 have also been described, as well as small deletions within CD18 coding sequences or nucleotide substitutions resulting in a premature termination signal.

There are several animal models of LAD I,[741] including the occurrence of a severe form of the disease in an Irish setter born of a mother-son mating[759,760] and in Holstein cattle.[761,762] In the latter case, affected calves could be traced to a common sire and have been shown to be homozygous for a point amino acid substitution in the conserved extracellular domain of CD18.[763] Finally, CD18-deficient mice have produced by gene targeting.[740,741]

Diagnosis and Treatment of LAD I

The diagnosis of LAD I should be suspected in any infant or child with unusually severe or recurrent infections or periodontitis accompanied by persistently elevated peripheral blood neutrophil counts (see Table 21-11). Although this laboratory finding may simply represent a leukemoid reaction in an otherwise immunologically normal infant, the diagnosis of LAD I should nonetheless be considered, particularly if there is a paucity of neutrophils at affected sites or delayed separation of the umbilical cord. A well infant with delayed separation of the umbilical cord and normal blood counts is very unlikely to have LAD I. Although the mean age at cord separation has been reported to be 7 to 15 days, 10% of healthy infants can exhibit cord separation at 3 weeks of age or later.[764,765] A rare cause of recurrent, deep-seated tissue infections in association with neutrophilia and poor formation of pus is mutations in the Rac2 GTPase, which leads to neutrophil signaling defects affecting chemotaxis and adhesion (see "Disorders of Chemotaxis" later in this chapter).[71,766,767]

The diagnosis of LAD I is established by flow cytometric analysis to assess cell surface expression of any of the β_2 integrin α (CD11) subunits or the shared CD18 subunit. Monoclonal antibodies to each are commercially available. Neutrophil Mac-1 deficiency is more dramatic if neutrophils are first stimulated, which normally upregulates Mac-1 cell surface expression. Though not necessary to establish the diagnosis of LAD I, in vitro functional assays of neutrophils obtained from these patients demonstrate striking defects in adherence, chemotaxis, and C3bi-mediated phagocytosis and activation of the respiratory burst. Carriers of LAD I can also generally be identified by flow cytometry because they typically express approximately 50% of the normal level of β_2 integrins on leukocyte cell surfaces.[738,768] For prenatal diagnosis of LAD I in families in which the mutations in the two CD18 alleles are known, chorionic villus or amniocyte DNA can be analyzed, and commercial testing is available. Flow cytometry on fetal blood granulocytes, which express Mac-1 by 20 weeks' gestation, has been used for prenatal diagnosis.[769,770]

Treatment of LAD I depends on the clinical severity of the disorder. In patients with the moderate clinical phenotype, who typically have some residual β_2 integrin expression, cutaneous and oral infections should be treated aggressively as they occur. The use of prophylactic trimethoprim-sulfamethoxazole appears to be beneficial. Aggressive prophylactic treatment of periodontal disease is also advisable in the form of frequent dental cleaning and the use of antimicrobial oral rinses such as chlorhexidine gluconate. Clinical management of patients with a moderate phenotype should be guided by the observation that these patients are still at risk of dying of overwhelming infection, with 75% succumbing between the ages of 12 and 32 years.[769] Patients with severe LAD I have an even grimmer prognosis, with a high incidence of death

secondary to infection before the age of 2 years, and therefore bone marrow transplantation is recommended for this group of patients.[738,771-776] Graft rejection or graft-versus-host disease can be problematic with partially compatible HLA matching.[773-775] Nonmyeloablative bone marrow transplantation for LAD I has also been reported.

Because LAD I is caused by a defect in a single gene, transfer of a normal CD18 sequence into a patient's hematopoietic stem cells via retroviral or other vectors should, in principle, correct the defect. High-level expression of the transferred CD18 sequence may not be necessary to confer substantial clinical benefits based on the observed milder course of patients with some residual β_2 integrin expression. Studies in canine LAD I suggest that restoring CD18 expression to even 10% of leukocytes will result in clinical improvement.[771,777] At present, a major obstacle in applying this approach to clinical use is the development of techniques that achieve high-level gene transfer into human hematopoietic stem cells.[771,778]

Leukocyte Adhesion Deficiency Type II

LAD II is a very rare autosomal recessive clinical syndrome similar to LAD I but is associated with defective selectin-mediated adhesion because of deficiency of sialyl-Lewis X ligands.[779-783] This autosomal recessive disease was first described by Etzioni and colleagues[779] and since reported in a total of five kindreds (four Arab and one Turkish). As in CD11/CD18-deficient LAD, these children suffered from periodontitis, recurrent cellulitis, otitis media, and pneumonia without the formation of pus despite peripheral leukocyte counts of 30,000 to 150,000 cells/µL. However, neutrophils had normal levels of CD18, and infectious symptoms were not as serious as in LAD I. Also in distinction from classic LAD I, affected children had short stature, a distinctive facial appearance consisting of a flat face and depressed nasal bridge, and severe mental retardation. All had the rare Bombay (hh) blood phenotype, a clue to the molecular defect, in which red cells express a nonfucosylated variant of the H antigen. Red cells were also secretor negative and Lewis antigen negative. The Bombay and nonsecretor phenotypes are caused by deficient formation of Fucα1→2 Gal linkages in ABO blood group core antigens, whereas the Lewis antigen–negative phenotype is due to failure to synthesize Fucα1→4 GlcNAc and Fucα1→3 GlcNAc moieties. The defect in fucose metabolism in LAD II cells results from point mutations in the Golgi GDP-fucose transporter,[782,783] which leads to generalized loss of fucosylated glycans on cell surfaces, particularly the sialylated and fucosylated tetrasaccharide SleX (CD15a) on the neutrophil. As a result, LAD II neutrophils cannot bind to E- and P-selectin receptors. The early step of neutrophil rolling on activated endothelial cells is defective in LAD II,[748,779] consistent with the role of selectin-mediated adhesion in this process (see Fig. 21-3). However, chemoattractant-induced tight adhesion and emigration of LAD II neutrophils are normal, both of which are severely impaired in LAD I.[748]

All of the Arab patients have the same nucleotide substitution in the Golgi GDP-fucose transporter mRNA, which alters an amino acid in a transmembrane domain, whereas the Turkish patient has a different nucleotide alteration that results in an amino acid substitution in a different transmembrane domain of the transporter.[782,783] The different mutations may explain why the Turkish patient had some response to oral fucose therapy consisting of increased expression of certain fucosylated ligands and improved clinical symptoms except mental retardation but the Arab children did not.[780,784,785] It is speculated that the mutation in the Turkish child leads to a decrease in transport affinity for GDP-fucose, which can be overcome by higher concentrations of fucose, whereas the mutant protein in Arab children has normal affinity for GDP-fucose but decreased transport activity.[781]

Leukocyte Adhesion Deficiency Type III

LAD III is a newly described subgroup of LAD that has been reported in a handful of patients with severe, recurrent infections similar to LAD I, as well as a severe bleeding tendency similar to Glanzmann's thrombasthenia.[786-790] First described in 1997 by Kuijpers and colleagues, almost a dozen patients have now been reported in the literature, most of whom are descendents of Turkish ancestors.[786-792] The disorder has also been termed LAD-1/variant syndrome.[791] Inheritance appears to be autosomal recessive, and it is associated with functional defects in the "inside-out" activation of multiple classes of integrins in response to G protein–coupled receptor stimulation; the defects appear to be restricted to the hematopoietic cell lineage. In addition to abnormalities in cell adhesion and platelet activation, stimulation of the respiratory burst by unopsonized zymosan is markedly reduced as a result of the integrin activation defect.[791] Rap1 GTPase is implicated in integrin activation, and a decreased level of the active form of Rap1 was reported in several LAD III kindreds.[792,793] A mouse genetically engineered to lack a blood cell–specific guanine nucleotide exchange factor, CalDAG-GEFI, which catalyzes the formation of Rap-GTP, had defective β integrin activation and manifestations similar to those of LAD III.[794] Two LAD III patients from the same region of Turkey exhibited decreased expression of CalDAG-GEFI in association with a homozygous mRNA splice junction mutation in the corresponding gene.[792] However, Rap1 activation was normal in other LAD III patients, thus suggesting that genetic defects in other signaling proteins can also be responsible for LAD III.[791] Because the clinical manifestations are typically severe, early bone marrow transplantation may be indicated for patients with LAD III.[786,790]

Acquired Disorders of Adherence

Neutrophils may exhibit decreased adhesiveness after exposure to a variety of drugs, the most common being corticosteroids and epinephrine.[645,795,796] Clinically, the

diminished adhesiveness induced by these drugs is manifested by a dramatic rise in the total neutrophil count in blood as cells from the marginated pool are quickly released into the circulating pool. Although the mechanisms by which corticosteroids alter adherence are probably complex,[797] epinephrine and other β-adrenergic agonists exert their effect indirectly by causing endothelial cells to release cyclic AMP (cAMP), which in turn impairs the ability of neutrophils to adhere.[645,798]

Adhesiveness of neutrophils can be dramatically increased in a variety of clinical conditions that have in common the formation of biologically active complement fragments: gram-negative bacterial sepsis, severe thermal injury, pancreatitis, trauma, and exposure of neutrophils to artificial membrane surfaces during hemodialysis and cardiopulmonary bypass.[799] In these various conditions, generation of complement fragments leads to activation of neutrophils and enhanced adhesiveness, possibly as a result of enhanced expression of β_2 integrins. Under these conditions, neutrophils exhibit increased aggregation with each other and become trapped within capillary beds, such as those in the lungs.[800] It is believed that the aggregated neutrophils then generate toxic oxygen radicals and release proteases that conspire to damage structural protein such as collagen and elastin.[233] Binding of viral proteins to neutrophils can depress adhesion and other neutrophil functions in influenza or HIV infection.[799]

Amphotericin B has been associated with increased neutrophil aggregation, particularly when administered in conjunction with transfusions of neutrophils that have been harvested by filtration (rather than by centrifugation).[801,802] It is possible that the enhanced aggregation is mediated by upregulation of surface β_2 integrins induced both by the amphotericin B and by the filters used to harvest the cells. Liposomal amphotericin causes substantially less in vitro aggregation of mobilized neutrophils and may therefore be easier to use in patients being treated for fungal infections who are also receiving allogeneic neutrophil transfusions.[803]

Disorders of Chemotaxis

Directed migration into sites of infection and inflammation involves a complex series of events. As reviewed in the beginning of this chapter, the generation of chemotactic signals and their binding to specific receptors on the phagocyte surface lead to the generation of intracellular second messengers. These intracellular signals, in turn, trigger changes in adhesiveness and in the actin cytoskeleton that result in adhesion to the endothelium and chemotaxis to the inflamed tissue site. Given the numerous cellular functions involved in chemotaxis, it is perhaps not surprising that impaired phagocyte chemotaxis is observed in a large number of clinical conditions.[799,804] Some of the more important syndromes are listed in Box 21-10. These disorders are classified according to the mechanisms thought to be responsible for the

Box 21-10	Clinical Conditions Associated with Impaired Neutrophil Chemotaxis

DEFECT IN GENERATION OF CHEMOTACTIC AGENTS

Familial deficiency of C1r, C2, C4
Familial deficiency of C3, C5
Other abnormalities of complement pathways (e.g., systemic lupus erythematosus, immature complement system in neonates, diabetes mellitus, C5 dysfunction, chronic hemodialysis, glomerulonephritis)

EXCESSIVE PRODUCTION OF NORMAL CHEMOTACTIC FACTOR INACTIVATORS

Hodgkin's disease
Cirrhosis of the liver
Sarcoidosis
Lepromatous leprosy

INHIBITORS OF THE NEUTROPHIL RESPONSE TO CHEMOTACTIC FACTORS

Hyperimmunoglobulin E syndrome
Localized juvenile periodontitis
Immune complex diseases (rheumatoid arthritis, systemic lupus erythematosus)
Influenza virus
HIV
IgA paraproteinemia states
Solid tumors
Bone marrow transplantation
Drugs (ethanol, antithymocyte globulin, interleukin-2)

DEACTIVATION (DOWNREGULATION) BY INCREASED LEVELS OF CHEMOTACTIC FACTORS

Wiskott-Aldrich syndrome
C5a generation in plasma (hemodialysis)
Bacterial sepsis

PHAGOCYTE DEFECTS

Neutrophil actin dysfunction
Rac2 mutation
Localized juvenile periodontitis
Neonatal neutrophils
Leukocyte adhesion deficiency
Chédiak-Higashi syndrome
Specific granule deficiency

MISCELLANEOUS DEFECTS

Hypophosphatemia
Shwachman-Diamond syndrome
Burn patients

defective chemotaxis, which are related either to abnormalities in the production or inhibition of chemotactic factors or to defects in the phagocyte itself involving adhesiveness and locomotion. In some cases, abnormal chemotaxis is one component of a disorder that involves multiple defects.

It is worth noting that in many of the reports describing defective in vitro chemotaxis of neutrophils from various clinical conditions, it is not clear whether the

increased number of infections observed clinically is due to the observed chemotactic abnormality or to medical complications of the underlying disorder (such as malnutrition or exposure to nosocomial infection). Further complicating the interpretation of these reports is that in vitro assays for chemotaxis are subject to laboratory artifacts and may not accurately reflect the in vivo extracellular environment.[805-807] Phagocyte migration to an inflamed site in vivo can be measured by the skin window technique of Rebuck and Crowley, in which a superficial dermal abrasion is produced in the patient and the appearance of inflammatory cells in the lesion is monitored over a 24-hour period.[808] Because of difficulties in standardizing the dermal lesion, variable results may be obtained with this method. Moreover, the assay can measure only the response of phagocytes to the chemotactic signals generated by this type of sterile injury.

As outlined in Box 21-10, several of the conditions associated with impaired neutrophil chemotaxis are due to complement deficiencies and other immunodeficiency syndromes (e.g., WAS). These disorders are discussed elsewhere in this text. In addition, several disorders of phagocyte function (LAD, CHS, and SGD) are reviewed in other sections of this chapter. This section focuses on clinical conditions in which there is evidence that a chemotactic defect plays a major contribution to the decreased resistance to bacterial and fungal infections.

Hyperimmunoglobulin E Syndrome

The hyperimmunoglobulin E syndrome (HIES) (see Chapter 5 in *Oncology of Infancy and Childhood*) is a relatively rare disorder characterized by markedly elevated serum levels of IgE (often greater than 2000 IU/mL), serious recurrent staphylococcal infections of the skin and lower respiratory tract, pneumatoceles, chronic pruritic dermatitis, and skeletal and dental abnormalities.[809-814] The key features of HIES are summarized in Table 21-12. Neutrophils from patients with this syndrome exhibit a variable, but at times severe, chemotactic defect.[810,815,816] This syndrome was originally known as "Job's syndrome" when it was first reported in 1966 in two red-haired, fair-skinned females who had hyperextensible joints and "cold" abscesses that lacked the usual characteristics of inflammation.[809] It is now appreciated that only a small fraction of patients with HIES have red hair or hyperextensible joints, and it may be that Job's syndrome is a variant subset of HIES. The disease can occur in both males and females and in all ethnic groups, including blacks and Asians. The mode of inheritance is variable. Many cases are sporadic. Familial patterns suggest autosomal dominant inheritance with variable expressivity, as well as, rarely, autosomal recessive inheritance.[812,813,817]

The clinical manifestations of HIES are often severe and usually become apparent during infancy. Staphylococcal furuncles on the head and neck, as well as chronic dermatitis, are seen most frequently in younger patients. The skin abscesses in HIES typically lack erythema (cold abscesses). Chronic candidiasis of the mucosa and nail beds is also frequent and can occur in children. Recurrent staphylococcal pneumonia is a common problem as patients grow older and can be complicated by the formation of persistent pneumatoceles that can become superinfected with *Haemophilus influenzae*, gram-negative

TABLE 21-12	Summary of Hyperimmunoglobulin E Syndrome
Incidence	More than 200 cases reviewed in the literature
Inheritance	Autosomal dominant with variable expressivity, sporadic forms, autosomal recessive (rare)
Molecular defect	Dominant-negative mutations in STAT3 (autosomal dominant and sporadic cases), Tyk2 kinase (autosomal recessive)
Clinical manifestations	"Cold" cutaneous skin abscesses and furuncles
	Chronic eczematoid dermatitis
	Mucocutaneous candidiasis
	Staphylococcal pneumonia, pneumatoceles
	Fungal superinfection of lung cysts
	Coarse facies
	Delayed shedding of primary teeth
	Scoliosis
	Recurrent fractures
	Hyperextensible joints
Laboratory evaluation	Serum IgE > 2500 IU/mL
	Peripheral blood eosinophilia
Differential diagnosis	Atopic dermatitis
	Wiskott-Aldrich syndrome, DiGeorge's syndrome
	Hypergammaglobulinemia
	Chronic granulomatous disease
Therapy	Prophylactic antibiotics for *Staphylococcus aureus*
	Aggressive treatment of acute infections with parenteral antibiotics
	Surgical drainage of deep infections and resection of lung cysts
	Monitoring for scoliosis and fractures
Prognosis	Generally good if managed aggressively

bacteria, or *Aspergillus*. Chronic infections of the ears, sinuses, and eyes (keratoconjunctivitis) are seen, and septic arthritis and osteomyelitis have been observed. Dental and bone abnormalities are also common features of HIES. Delayed shedding or failure to shed primary teeth occurs in the majority. Hyperextensible joints and scoliosis are frequent. Osteopenia of unknown etiology is observed many patients, and there is also an increased risk for fractures of the long bones and vertebral bodies, even in the absence of osteopenia.[812] Coarse facial features characterized by a broad nasal bridge and a prominent nose are evident in the majority of patients by the time that they reach the teen-age years. Craniosynostosis can also occur.

There is a subgroup of HIES with autosomal recessive inheritance, with 13 reported patients from six consanguineous families.[817] In addition to high IgE, eosinophilia, eczema, and recurrent pneumonia and abscesses, many patients had recurrent or chronic viral infections, including molluscum contagiosum, herpes simplex, and varicella, as well as increased susceptibility to atypical mycobacterial infection.[817,818] Pneumatoceles were not seen, in contrast to autosomal dominant HIES, nor were skeletal abnormalities, dental problems, or the characteristic facies. Significant neurologic symptoms were often present and ranged from partial facial paralysis to hemiplegia.

The molecular basis of HIES and how the immunologic abnormalities relate to the dental and skeletal defects that are the other hallmarks of this disorder have been puzzling. It has been proposed that the immunologic manifestations may reflect an underlying T helper 1 cell (T_H1)/T_H2 imbalance in T lymphocytes.[819] Skewing toward a T_H2 response might lead to abnormal regulation of IgE production and greatly reduced production of IFN-γ and TNF.[813,820,821] This putative T-cell defect may also explain the abnormal antibody responses that have recently been documented in some patients in response to various vaccines.[822] Patients with HIES produce excessive amounts of IgE directed against *S. aureus* at the expense of protective antistaphylococcal IgG.[823,824] The recurrent bacterial infections in HIES may also be aggravated by the chemotactic defect that is periodically observed in these patients.

Recent breakthrough studies have identified genetic defects in the JAK-STAT pathways in all three forms of HIES, which helps explain the pathogenesis of HIES and its multisystem manifestations. Thus, HIES can be considered a disorder of cytokine signaling. A patient with autosomal recessive HIES exhibited defects in IL-6, IL-10, IL-12, and IFN-α signaling associated with a homozygous frameshift mutation in the tyrosine kinase 2 (Tyk2) JAK family member.[818] This is consistent with the broader spectrum of infections seen in autosomal recessive HIES. In contrast, mutations in STAT3 itself account for a large proportion of autosomal dominant and sporadic forms of HIES. Missense mutations and single-codon in-frame deletions in STAT3 were identi-

fied in autosomal dominant and sporadic cases of HIES.[825,826] Many affect the DNA-binding and Src homology 2 (SH2) domains. Mutations in the DNA-binding domain can have dominant-negative effects on STAT3 signaling, which in turn interferes with cytokine signaling by the IL-6 and IL-10 pathways, but not with IL-12 and IFN-α responses.[826] Defective responses to the proinflammatory cytokine IL-6 may account for the minimal inflammatory response characteristic of HIES, and the enhanced IgE production may reflect dysregulated immune responses secondary to defects in signaling by IL-10, a negative regulator. STAT3 also influences lymphocyte IL-17 production, which is important for host defense against extracellular bacteria and may predispose to staphylococcal infections. The dental and skeletal abnormalities may be related to defects in STAT3-dependent cytokine responses in osteoblasts and osteoclasts.

The diagnosis of HIES should be considered in any child with the aforementioned clinical history. Almost all patients have peripheral eosinophilia. Markedly elevated polyclonal serum IgE, or at least a value of 2500 IU/mL, is a constant laboratory finding, although IgE levels can fluctuate over time and occasional decrease to the normal range.[812,814] Despite the impressive elevations in serum IgE (up to 150,000 IU/mL), this laboratory finding alone is not diagnostic in that comparably high serum levels of IgE can be seen in patients with atopic dermatitis. Because many patients with atopic dermatitis suffer from superficial skin infections and eczema, this disorder must be considered in the differential diagnosis of HIES. The two can be distinguished from each other by the severe and recurrent nature of the staphylococcal furuncles and the pneumonia seen in patients with HIES.

Treatment of HIES is largely supportive.[813,814] One of the mainstays of therapy for HIES is the use of prophylactic antibiotics such as dicloxacillin or trimethoprim-sulfamethoxazole. These drugs can help prevent staphylococcal infections and should be prescribed at the time of diagnosis. Pneumonia and other deep-seated infections should be treated aggressively with parenteral antibiotics. Patients with HIES are unusually predisposed to the development of pneumatoceles as a result of staphylococcal lung infections. If these lesions persist, they should be surgically resected to prevent superinfection by fungal and gram-negative organisms. Plasmapheresis has been reported to be effective in patients who are responding poorly to the aforementioned therapies. Cyclosporine or intravenous IgG infusions have also shown some success in the management of HIES.[813] Dermatitis can be treated with topical steroids. Delayed shedding of primary teeth may necessitate extraction. Patients should be carefully monitored for scoliosis, and skeletal fractures can occur after even minor trauma. If infections and their complications are managed aggressively, the prognosis for patients with HIES is good. Recombinant human IFN-γ (rIFN-γ) has been used with inconsistent results.[813]

Neutrophil Actin Dysfunction

Primary defects in neutrophil actin polymerization are exceedingly rare. The first such case, described by Boxer and colleagues in 1974, was a male infant who suffered from recurrent *S. aureus* skin infections and a cutaneous-cecal fistula complicated by *Streptococcus faecalis* sepsis.[827] Despite marked neutrophilia, sites of infections were devoid of neutrophils and healed slowly. The patient's neutrophils showed markedly diminished chemotaxis and a decreased capacity to ingest serum-opsonized particles. He underwent bone marrow transplantation with transient engraftment of normally functioning neutrophils but succumbed to infectious complications. The underlying defect in this patient appeared to involve neutrophil actin or an ABP. Neutrophils from his parents and a sibling exhibited decreased actin polymerization in vitro. Neutrophils from family members also had intermediate levels and decreased expression of the Mac-1 integrin (CD11b/CD18),[828,829] thus raising the question of whether the neutrophil actin dysfunction in the proband was a variant of LAD I. However, actin filament assembly is normal in LAD I patients.[829] Alternatively, a primary actin-associated defect might alter cell surface expression of the integrins, which have binding sites in their cytoplasmic domains for cytoskeletal proteins.[790]

Coates and co-workers reported a male infant of Tongan descent who was afflicted with severe skin and mucosal infections.[830] At the age of 2 months he was found to have hepatosplenomegaly, moderate thrombocytopenia, recurrent pulmonary infiltrates, and a lingual ulcer that grew *Candida tropicalis*. Two siblings had previously died in infancy with a similar clinical picture. Neutrophils from this patient, which had normal cell surface expression of CD11b, exhibited abnormalities in a wide range of motile behavior, including chemotaxis, phagocytosis, and spreading on glass. Morphologically, the neutrophils had thin, filamentous projections of membrane with an underlying abnormal cytoskeletal structure. Biochemical studies revealed markedly defective actin polymerization and severe deficiency of an 89-kd protein, along with a markedly elevated level of a 47-kd protein. Hence, this disorder has been referred to as neutrophil actin dysfunction with 47- and 89-kd protein abnormalities (NAD 47/89). The 47-kd protein has recently been identified as LSP1 (lymphocyte-specific protein 1),[831] which is an ABP present in normal neutrophils. Neutrophils from the patient's parents showed a partial defect in actin polymerization and intermediate abnormalities in levels of LSP1 and the 89-kd protein. These observations, along with the history of previously affected siblings, suggest that NAD 47/89 is an autosomal recessive disorder. The patient underwent allogeneic bone marrow transplantation at the age of 7 months and no longer suffers from thrombocytopenia or the neutrophil motility disorder.

Markedly impaired neutrophil chemotaxis associated with a heterozygous point mutation in β-actin was reported by Nunoi and colleagues in a female patient with recurrent infections, stomatitis, photosensitivity, and mental retardation.[832] The defect lies within a domain that binds to profilin and other actin regulatory molecules, and the mutant β-actin may interfere with normal actin function in a dominant-negative manner. Interestingly, formyl peptide–induced superoxide production was also decreased in the patient's neutrophils, thus suggesting that actin function is important for normal NADPH oxidase assembly.

Localized Juvenile Periodontitis

Localized juvenile periodontitis (LJP) is a group of disorders of unknown etiology characterized by severe alveolar bone loss localized to the first molars and incisors, with an onset around the time of puberty.[833-836] LJP appears to be an acquired disorder in some patients and a genetic disorder in others. Defective neutrophil chemotaxis has been identified in vitro in approximately 70% of LJP patients and may be due to the intrinsic variability present in in vitro chemotaxis assays (see earlier) or to a fundamental heterogeneity in this disorder.[834,837-841] For example, whereas most individuals with LJP have defective chemotaxis in response to both formyl peptides and C5a, others may have an abnormality in response to only formyl peptides.[838] Further support for the heterogeneity of LJP is provided by studies showing that factors elaborated by periodontopathic bacteria may secondarily alter leukocyte function and depress chemotaxis (e.g., *Capnocytophaga* species, *Actinobacillus actinomycetemcomitans*, and *Bacteroides* species).[842-844] Whether these factors are the same as the chemotactic inhibitors identified in the sera of some patients with LJP remains to be determined.[839,845] In the subset of patients with LJP who have abnormal chemotaxis, phagocytosis has generally been found to be abnormal, whereas degranulation (of specific granules) and superoxide generation are unaltered.[846]

The observations that LJP tends to cluster in families and that the neutrophil chemotactic activity is not restored in vitro or after the patient is treated for periodontal infection lend support to the hypothesis that some LJP patients may have an inherited disorder affecting chemotactic receptors. A 40% to 50% decrease in the total number of receptors for formyl peptides and C5a has been reported for some patients with LJP.[838,847] Preliminary studies have identified point mutations in the ligand-binding domain of the formyl peptide receptor in a few LJP patients.[836]

The diagnosis of LJP should be suspected in any adolescent with unusually severe and destructive alveolar bone loss involving the first molars and incisors. From a diagnostic point of view, it is important to bear in mind that many qualitative and quantitative neutrophil disorders are associated with periodontal disease that, at times, may be severe.[833] The differential diagnosis should include LAD, CGD, CHS, leukemia, chronic neutropenia, and cyclic neutropenia.

Neonatal Neutrophilia

Although most infants are able to defend themselves successfully against microbial challenges, they are nonetheless at increased risk for the development of severe bacterial infections—particularly sepsis, pneumonia, and meningitis caused by group B streptococci.[848] The risk of infection and the rate of mortality from pyogenic infections are even greater in premature infants. As a result, the development of innate immunity in neonates has been the subject of intense investigation for many years.[848-850] It is generally agreed that neonates have defects in various aspects of specific immunity (immune cellular cytotoxic mechanisms and cytokine generation). Defects in neutrophil adherence, chemotaxis, phagocytosis, and bacterial killing have all been reported.[849,850] Compounding these functional defects in neonates is a deficiency of antibodies directed against organisms that typically infect infants. Furthermore, neonates can easily exhaust bone marrow reserves of granulocytes and exhibit neutropenia in the midst of severe pyogenic infections, as discussed in the previous section.

The most important of the functional defects, at least from a clinical point of view, appears to be the depressed chemotactic ability of neonatal neutrophils. When compared with adult cells, directed migration of neonatal neutrophils toward a variety of chemotactic agents (C5a, formyl peptides, and bacterial extracts) is reduced by approximately 50% for the first several weeks of life.[849,851-853] The biochemical basis for the diminished chemotaxis does not appear to be related to abnormalities in the number or affinity of either the C5a or formyl peptide receptor.[849,853] Instead, there appears to be a defect in the chemotaxis-induced upregulation of cell adhesion molecules. Cell surface expression of the two subunits of the β_2 integrin Mac-1 (CD11b and CD18) was found to be normal in neonatal neutrophils but failed to increase normally after exposure to chemotactic concentrations of C5a and formyl peptides.[854,855] Fetal, preterm, and term infant neutrophils expressed levels of Mac-1 in stimulated neutrophils that were only 40% to 60% of those seen in adult cells. Total cellular Mac-1 is decreased in neonatal neutrophils.[856] Because internal membrane stores serve as an intracellular pool for Mac-1 (see Table 21-3), the overall reduction in cellular Mac-1 could explain the diminished upregulation of Mac-1 seen in neonatal cells after stimulation. Another underlying biochemical abnormality that may contribute to the chemotaxis defect is diminished polymerization of F-actin in neonatal neutrophils after stimulation.[857] Finally, Hill[849] reported that neonatal neutrophils fail to increase the intracellular concentration of free calcium to normal levels in response to chemotactic factors.

Other Disorders of Neutrophil Chemotaxis

A new syndrome of severe neutrophil dysfunction caused by a dominant-negative mutation in the small GTPase Rac2 has recently been described in a male infant born to unrelated parents. This child had recurrent, rapidly progressive soft tissue infections, including perirectal abscesses and a necrotic periumbilical infection, associated with poor formation of pus and neutrophilia.[71,766,767] Although the clinical manifestation was suggestive of LAD, expression of β_2 integrins and fucosylated cell surface proteins was normal. Marked abnormalities were seen in chemoattractant-induced neutrophil function, including F-actin formation, chemotaxis, degranulation, and the respiratory burst, along with defects in phagocytosis and L-selectin–mediated adhesion.[71,767] Responses to other agonists were normal, thus suggesting a selective defect in signal transduction. This constellation of functional abnormalities resembled those described for gene-targeted mice lacking the hematopoietic-specific GTPase Rac2.[200,201] Analysis of the Rac2 gene in this patient identified a point mutation that affects the guanine nucleotide–binding pocket. The patient was heterozygous for this mutation, which apparently exerts a dominant-negative effect on wild-type Rac2 that interferes with normal signal transduction.[71,767] Neither parent had the mutant Rac2 allele. The patient was successfully treated by HLA-matched bone marrow transplantation from a sibling. The clinical history, neutrophilia, and functional neutrophil defects in this patient are very similar to those seen in another infant described in an earlier report.[858] This patient, a female, was the first child of nonconsanguineous healthy parents, both originating from India; she suffered from chronic omphalitis and otitis media secondary to *S. aureus*, buccal candidiasis, and internal cecal fistulation that ultimately led to death from gram-negative sepsis at 8 months of age.

A recent study of 240 patients with a significant history of recurrent infection, generally requiring at least one hospitalization, identified 10 patients, all children, with consistently markedly reduced chemotactic activity in vitro that was not associated with any other neutrophil abnormalities.[859] In six of these patients, partial reduction in chemotactic activity was also seen in either the mother or a sibling. However, other than for the disorders discussed earlier, well-defined clinical entities in which defective neutrophil chemotaxis plays a predominant role in impaired host resistance to bacteria and fungi have not been established or the underlying mechanisms identified. In part, this is related to the difficulty of performing and interpreting in vitro assays of adhesion and chemotaxis, except in specialized research settings. Biochemical approaches to delineating a specific abnormality are also difficult because of the complex nature of the chemotactic response.

Disorders of Opsonization and Ingestion

Clinical disorders of recognition fall into two major categories: humoral and cellular. In the former, deficient or absent plasma-derived opsonins result in incomplete opsonization. In contrast, the cellular disorders are characterized by defective receptors for opsonins or by

abnormalities in the actin cytoskeletal system responsible for ingestion of microbes.

Humoral Disorders of Opsonization

Primary B-cell deficiencies result in decreased or absent production of immunoglobulins, most commonly IgG. Patients afflicted with these antibody deficiency syndromes suffer from recurrent infections with pyogenic bacteria such as *S. aureus*, pneumococci, and *H. influenzae*. One of the major functional abnormalities in these disorders is defective opsonization of pathogenic microorganisms. As a result, these microbes are not efficiently cleared by the host phagocytic system. A variety of clinical disorders may lead to antibody deficiency, including deficiencies in specific IgG subclasses; such disorders are discussed elsewhere in this text.

Complement deficiencies can also result in recurrent infections, particularly when they involve factors shared by both the classical and the alternative pathways. Therefore, patients with deficiencies of C1, C2, or C4 have relatively minor problems with infections because the alternative pathway remains intact. In the case of C3, on the other hand, recurrent infections are much more common because this protein is the direct precursor of two major complement opsonins—C3b and C3bi. Two forms of C3 deficiency have been described, and both are quite rare. In one, congenital deficiency of C3 is inherited in an autosomal recessive manner and has been described in around 20 patients.[860-864] Heterozygotes contain half the normal levels of C3 but do not suffer from infections. The molecular genetic basis of the C3 deficiency has been identified in several families, and the mutations are heterogeneous.[863,864] A second type of C3 deficiency is caused by unchecked catabolism of C3 as a result of the absence of a C3 protease inhibitor.[865] In both types of C3 deficiency, the majority of patients experience recurrent pyogenic infections caused by encapsulated bacteria such as pneumococci. Patients with deficiencies of the terminal complement components (C5, C6, C7, C8, or C9) are particularly susceptible to infections with meningococci or gonococci. Infections in complement-deficient individuals should be treated aggressively with antibiotics, and immunization against *H. influenzae*, *S. pneumoniae*, and *Neisseria meningitidis* may be helpful.

Approximately 5% of the population have low serum levels of MBL, also known as MBP. MBL is a serum lectin secreted by the liver and functions as a soluble PRR by binding to mannose sugars present on the surface of bacteria, fungi, and some viruses.[254,256,257] Bound MBL activates the complement cascade to mediate opsonization of a broad range of microbes with C3 cleavage products. The incidence of MBL deficiency is higher in infants with frequent unexplained infections, chronic diarrhea, and otitis media. It has been proposed that MBL serves as a primitive antibody of broad specificity to provide an important defense mechanism during the period when maternal "antibody" levels have waned yet the antibody

repertoire of the infant is still immature.[254,256,257] MBL deficiency is associated with autosomal dominant inheritance of point mutations in a collagen-like domain of the MBL polypeptide.[866-868] These mutations decrease MBL levels by interfering with normal polymerization of the MBL subunits to form the oligomeric structure required for complement activation. A polymorphism in the promoter of the MBL gene has also been described that can influence MBL levels.[254] Clinical illness associated with MBL deficiency may not be limited to infants. In a recent report, MBL deficiency was the only identifiable immune defect in four adults with recurrent infections, as well as in one patient who also had IgA deficiency.[869] The spectrum of illness included recurrent skin abscesses, chronic cryptosporidial diarrhea, meningococcal meningitis with recurrent herpes simplex, and fatal *Klebsiella* pneumonia. Three of the five adults were homozygotes for mutant MBL alleles. Decreased MBL levels are seen in some populations, such as in sub-Saharan Africa, thus suggesting that low levels of this protein may be beneficial in certain settings. For example, low levels of MBL may partially protect against mycobacterial infections.[254]

Cellular Disorders of Ingestion

Patients with LAD I show a marked abnormality in the phagocytosis of C3bi-opsonized particles because the Mac-1 β_2 integrin (CD11b/CD18) that is deficient in LAD I functions as the C3bi receptor (see Tables 21-2 and 21-4). Patients with neutrophil actin dysfunction also show abnormal ingestion because actin assembly plays a critical role in the formation of phagosomes.

A deficiency in FcγRIa has been described in four members of a Dutch family.[870] The monocytes from the affected family members did not bind IgG with high affinity. However, these individuals did not have increased susceptibility to infection despite this receptor deficiency. There is an incidence of 4 in 3377 in the French population for complete absence of FcγRIIIb, and neutrophils from affected individuals type as NA-null.[871] None of these individuals exhibit any increased incidence of infection, although infants of women with the NA-null phenotype are susceptible to alloimmune neutropenia because of placental transmission of anti-FcγRIIIb antibodies. Similar findings were also reported in a study of 21 individuals from 14 families with FcγRIIIb deficiency in the Netherlands.[247] Complete absence of the FcγRIIIb gene was found in all kindreds studied. Three of the women who had multiple pregnancies lacked antineutrophil antibodies, thus suggesting that neonatal alloimmune neutropenia does not always develop in this setting. Marked deficiency in neutrophil FcγRIIIb has also been observed in patients with paroxysmal nocturnal hemoglobinuria (PNH),[872] an acquired stem cell disorder caused by a defect in the biosynthesis of GPI membrane anchors. Because neutrophil FcγRIIIb is linked to the plasma membrane by means of a GPI anchor,[873] this receptor is unable to insert in the cell membranes in patients with PNH. Decay-accelerating factor and acetyl-

cholinesterase are likewise deficient in the membranes of patients with PNH because these two proteins are also anchored by GPI moieties. Neutrophils from patients with PNH undergo a normal oxidative burst in response to IgG-coated latex particles.[873] Hence, there appears to be sufficient redundancy in the function of Fc and complement receptors to permit normal phagocyte function in these cases of FcγRI and FcγRIIIb deficiency.

Allelic polymorphisms in FcγRIIa (131H versus 131R) and in FcγRIIIb (NA1 versus NA2) may each contribute to a subtle defect in the host response to encapsulated microorganisms. The polymorphism in amino acid 131 in FcγRIIa affects binding to IgG2, with "H" referring to "high" responder and the ability to bind to this IgG subclass. The 131H versus 131R polymorphism is seen in about equal frequencies in the white population, but it is distributed in a 3:1 ratio in Japanese and Chinese populations.[247] The FcγRIIa 131H allele is the only FcγR able to mediate efficient phagocytosis of IgG2-opsonized bacteria, and the FcγRIIa 131H/131H genotype in children was associated with a lower incidence of infections with encapsulated bacteria.[247] The NA1 polymorphism in FcγRIIIb, which affects receptor glycosylation, is associated with more efficient phagocytosis of IgG-opsonized particles than the NA2 allele is.[247,874] The allelic frequency of NA1 is approximately 0.33 versus about 0.64 for the NA2 allele in whites, but this ratio is reversed in Japanese and Chinese populations. Patients who are homozygous for both the FcγRIIa 131R and the FcγRIIIb NA2 alleles appear to be at higher risk for meningococcal meningitis.[875]

Disorders of Neutrophil Granules

Phagocytes kill microorganisms with a variety of cytotoxic compounds, as reviewed earlier in this chapter, including a host of preformed antimicrobial polypeptides that are stored within intracellular granules and released into the phagocytic vacuole upon phagocytosis. The importance of granule contents in host defense is attested to by two clinical syndromes associated with disorders of neutrophil granules, CHS and SGD.

Chédiak-Higashi Syndrome

CHS, a rare, autosomal recessive, multiorgan disease resulting from defects in granule morphogenesis, is characterized by partial oculocutaneous albinism, frequent bacterial infections, giant lysosomes in granulocytes, and (in some patients) a mild bleeding diathesis, as well as peripheral and cranial neuropathies associated with decussation defects at the optic chiasm[478-485] (Table 21-13). Ten types of oculocutaneous albinism have been described in humans, and CHS is one of the tyrosinase-positive forms that has been designated type VIB. Because granule defects also affect cytotoxic T-cell and NK-cell function, CHS is associated with HLH in the "accelerated" phase of the disease that often develops after the first or second decade of life.[482-485,876,877]

CHS is caused by a fundamental defect in granule morphogenesis that results in abnormally large granules in multiple tissues. The most extensively studied of the affected cells are neutrophils. In the early stages of myelopoiesis, some of the normally sized azurophilic granules

TABLE 21-13	Summary of Chédiak-Higashi Syndrome
Incidence	More than 200 cases described
Inheritance	Autosomal recessive
Molecular defect	Defect in granule morphogenesis in multiple tissues as a result of mutations in the *CHS1* gene, which encodes a lysosomal trafficking protein
Pathogenesis	Giant coalesced azurophilic/specific granules in neutrophils resulting in ineffective granulopoiesis and neutropenia, delayed and incomplete degranulation, and defective chemotaxis
Clinical manifestations	Partial oculocutaneous albinism
	Recurrent severe bacterial infections (usually *Staphylococcus aureus*)
	Gingivitis and periodontitis
	Cranial and peripheral neuropathies (muscle weakness, ataxia, sensory loss, nystagmus)
	HLH (accelerated phase)
Laboratory evaluation	Giant granules in peripheral blood granulocytes and in bone marrow myeloid progenitor cells
	Widespread lymphohistiocytic infiltrates in accelerated phase
Prenatal diagnosis	Demonstration of giant granules in fetal blood neutrophils or cultured amniotic cells
Differential diagnosis	Other genetic forms of oculocutaneous albinism
	Giant granules can be seen in acute and chronic myelogenous leukemia
Therapy	Prophylactic trimethoprim-sulfamethoxazole
	Parenteral antibiotics for acute infections
	Ascorbic acid (200 mg/day for infants; 6 g/day for adults)
	Steroids, cyclosporine, etoposide for HLH
	Bone marrow transplantation before or at beginning of HLH
Prognosis	Most patients die of infection or complications of HLH in the accelerated phase during the first or second decade of life unless transplantation performed. A few patients have survived into their thirties

HLH, hemophagocytic lymphohistiocytosis.

coalesce to form giant granules that later fuse with some of the specific granules to form huge secondary lysosomes containing constituents of both granule types.[878-880] In addition to this uncontrolled fusion of granules, CHS neutrophils are markedly deficient in neutral proteases,[881] including two azurophilic granule enzymes, cathepsin G and elastase.[882] In melanocytes, there are giant melanosomes that prevent the even distribution of melanin and result in hypopigmentation of the hair, skin, iris, and ocular fundus. Giant granules are also seen in other leukocytes, Schwann cells, and certain cells in the liver, spleen, pancreas, gastric mucosa, kidney, adrenal gland, and pituitary gland.[483,485] In addition, disorders similar to human CHS have been described in many mammalian species, including Aleutian mink, *beige* mice, blue foxes, cats, killer whales, and Hereford cattle.[479,480,483,484,883]

Mutations in the *CHS1* gene, believed to normally regulate lysosome biogenesis, account for most cases of CHS.[884-886] *CHS1* is located on the long arm of chromosome 1 and is homologous to the *bg* locus responsible for the granule defect in *beige* mice.[887] The *beige* gene was positionally cloned and termed LYST for its presumed function as a lysosomal trafficking regulatory protein.[884,886] The encoded CHS/LYST protein is a very large (3801 amino acids) polypeptide, and at least one of its functions may be to inhibit lysosome fusion with other intracellular membrane vesicles.[888] Frameshift and nonsense mutations have been identified in the *CHS1* gene in patients with CHS and result in truncated forms of the protein.[482,884-886,889] Patients with clinically typical CHS who lack identifiable mutations in *CHS1* have been reported, thus suggesting that additional genetic loci may be affected in some cases.[890]

Some of the most dramatic examples of the granule defect in CHS are manifested in the various blood cells and are summarized in Box 21-11. A few to a large majority of circulating neutrophils contain giant coalesced azurophil/specific granules. These giant granules are often more prominent in bone marrow than in peripheral blood because many of the abnormal myeloid precursors are destroyed before they ever leave the marrow.[891] Extensive myeloid cell vacuolization, enhanced marrow cellularity, and elevated levels of serum lysozyme all reflect this process of intramedullary granulocyte destruction. As a result, most patients with CHS have moderate neutropenia with ANCs ranging between 500 and 2000 cells/mm[3].[478,481] Monocytes are also affected in CHS and have similar, but not identical cytoplasmic inclusions that appear to be ring-shaped lysosomes.[892] Lymphocytes can also contain giant cytoplasmic granules that contribute to abnormal cytotoxic T-cell and NK-cell function (see later). Finally, CHS platelets have a decreased number of dense granules and a storage pool deficiency of adenosine diphosphate and serotonin.[893-896] This abnormality leads to a defect in platelet aggregation and an increased bleeding time manifested clinically as easy bruising, intestinal bleeding, and epistaxis. Most patients with

Box 21-11	Hematologic Manifestations of Chédiak-Higashi Syndrome

STABLE PHASE

Neutrophils
Giant, coalesced azurophilic specific granules
Vacuolization of marrow neutrophils (ineffective myelopoiesis)
Neutropenia (intramedullary destruction)
Decreased bactericidal activity
  Decreased chemotaxis in vivo and in vitro
  Delayed and incomplete degranulation

Monocytes/Macrophages
Ring-shaped lysosomes
Decreased chemotaxis

Lymphocytes/Natural Killer Cells
Giant cytoplasmic granules
Diminished natural killer function
Diminished antibody-dependent cell-mediated cytolysis

Platelets
Giant cytoplasmic granules may be seen
Normal platelet count
Increased bleeding time because of abnormal aggregation caused by storage pool deficiency of adenosine diphosphate and serotonin

ACCELERATED PHASE (HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS)
Hepatosplenomegaly
Bone marrow infiltration
Hemophagocytosis by histiocytes
Worsening neutropenia, thrombocytopenia, and anemia as a result of the first three manifestations

CHS do not have thrombocytopenia until they enter the accelerated phase of the disease (see later).

The infections usually encountered with CHS involve the skin, respiratory tract, and mucous membranes and are caused by both gram-positive and gram-negative bacteria, as well as by fungi. The most common organism is *S. aureus*. These infections are often recurrent and can be fatal. Gingivitis and periodontitis are common. The skin is also susceptible to severe sunburn, and photosensitivity in bright light is common.

The neutrophil defects are primarily responsible for the propensity to bacterial infection. In addition to the moderate neutropenia, several defects in neutrophil function lead to impaired bactericidal activity. First, chemotaxis is markedly depressed, whether measured in vivo by the Rebuck skin window or in vitro by chemotaxis assays.[481,897] The large granules appear to interfere with the ability of neutrophils to travel through narrow passages, such as those between endothelial cells. Second, degranulation is delayed and incomplete in CHS neutrophils.[898,899] Third, the marked deficiency of antimicrobial proteins such as cathepsin G probably contributes to the

diminished bactericidal potency of CHS neutrophils.[899] Finally, decreased expression of Mac-1 (CD11b/CD18) in CHS neutrophils may also play a role.[900]

Contributing to the enhanced susceptibility to infection are abnormalities in monocytes, lymphocytes, and NK cells. Monocytes, like neutrophils, exhibit decreased chemotaxis.[901] Peripheral blood CHS lymphocytes demonstrate diminished ADCC of tumor cells.[902] Perhaps most important, cytotoxic T-cell and NK-cell cytolytic function is profoundly abnormal in CHS.[877,902-904] This defect may not only contribute to the recurrent bacterial infections but also lead to the development of HLH in the "accelerated phase" of CHS, which is sometimes precipitated by a herpes-type virus such as Epstein-Barr virus or varicella.[876,877,905-907]

Patients who survive the infectious and neurologic problems of the stable phase of CHS have a high risk of progressing to the accelerated phase of the disease, now recognized to be a genetic form of HLH.[478,876,877] HLH results from uncontrolled hyperinflammation and multiorgan dysfunction and can be triggered by viral infections or other stimuli; it typically develops during the first or second decade of life in patients with CHS.[478,906] The accelerated phase is characterized pathologically by diffuse lymphohistiocytic infiltration of the liver, spleen, lymph nodes, and bone marrow, and the outcome for the patient is uniformly fatal if not treated.[906] The accelerated phase is heralded by hepatosplenomegaly, bone marrow infiltration, and hemophagocytosis leading to worsening of the neutropenia and an ever-increasing risk for infection. Thrombocytopenia likewise develops and intensifies the bleeding disorder already present in the platelets.

The diagnosis of CHS should be suspected in any child with one or more of the following findings: (1) recurrent bacterial infections of unknown etiology; (2) hypopigmentation of the hair, skin, and eyes; a white forelock can be present; (3) the presence of giant peroxidase-positive lysosomal granules in granulocytes from peripheral blood or bone marrow; (4) mild to moderate neutropenia; (5) easy bruising or nose bleeding despite a normal platelet count; and (6) unexplained hepatosplenomegaly (associated with the accelerated phase of the disease). CHS is usually manifested in infancy or early childhood but may become evident later when the child is in the accelerated phase. In some patients, the disease may be suspected on the basis of neurologic abnormalities, including ataxia, muscle weakness, decreased deep tendon reflexes, sensory loss, a diffusely abnormal electroencephalogram, and abnormal visual and auditory evoked potentials.[908,909] The physician should not be dissuaded from considering the diagnosis of CHS if the patient does not have clear-cut oculocutaneous albinism. Depending on the skin coloration in the family, the only manifestations of the albinism may be a metallic sheen in the hair (which can vary from blond to dark brown) and a lighter skin color than seen in siblings. In younger patients, there is likely to be a cartwheel distribution of pigment in the iris and an abnormal red reflex.

The diagnosis of CHS is made by finding giant peroxidase-positive lysosomal granules in blood or bone marrow myeloid cells. In some cases, relatively few abnormal granulocytes will be seen in peripheral blood, presumably because of extensive intramedullary destruction of myeloid precursors, and a bone marrow aspirate may be necessary to identify the large lysosomes. Microscopic examination of the hair reveals giant melanin granules. In the accelerated phase, biopsy of the liver, spleen, and lymph nodes reveals diffuse infiltrates of lymphohistiocytic cells. An affected fetus with CHS diagnosed by fetal blood sampling, which showed large abnormal granules in neutrophils, was also found to have significantly larger than normal acid phosphatase lysosomes in cultured amniotic and chorionic villus cells.[910] Microscopic examination of fetal hair shafts for prenatal diagnosis has also been reported.[911] This suggests that prenatal diagnosis of CHS might be accomplished with these latter techniques, which is less risky than fetal blood sampling.

The differential diagnosis for CHS includes other genetic forms of partial albinism.[477] One condition characterized by partial albinism is Griscelli's syndrome,[490] which is distinguished from CHS by the lack of giant cytoplasmic granules in neutrophils, the presence of large pigment clumps in hair shafts, and accumulation of mature melanosomes in melanocytes. HLH also typically develops in patients with Griscelli's syndrome, again secondary to defective cytolytic T-cell and NK-cell function.[877,912] Hermansky-Pudlak syndrome is another disorder marked by partial albinism, but it is characterized by platelet function defects and an associated bleeding diathesis. Giant granules resembling those in CHS can be seen in both AML and CML[913-915] and should not be confused with those seen in CHS.

Management of the stable phase of CHS primarily involves the treatment of infectious complications. Prophylactic trimethoprim-sulfamethoxazole may be beneficial. Infections should be treated vigorously with appropriate intravenous antibiotics. Treatment with high doses of ascorbic acid (20 mg/kg/day) has been reported to result in clinical improvement, as well as improved function of neutrophils in vitro (neutrophil chemotaxis or bactericidal function, or both).[916,917] Although there is some disagreement in the literature regarding the efficacy of ascorbic acid,[918] it seems reasonable to try this medication given its safety in moderate doses. NK cell function appears to remain abnormal even after ascorbate therapy.

Treatment of HLH (accelerated phase) has improved in recent years with the use of combinations of drugs that suppress the function of activated macrophages and T cells, followed by allogeneic HSCT. Regimens for HLH include corticosteroids, cyclosporine, and etoposide, and they are recommended for the accelerated phase of CHS.[876,877] In patients with moderate symptoms, corticosteroids and immunoglobulin infusions may be sufficient to induce an initial remission, although the use of etoposide should not be delayed if symptoms progress.[877]

Active therapy should be maintained until bone marrow transplantation can be performed. The only curative therapy is bone marrow transplantation with matched related or unrelated donor grafts.[876,919-925] This procedure is ideally performed before onset of the accelerated phase. Transplantation does not prevent the progressive neuropathy associated with CHS.[921]

Specific (Secondary) Granule Deficiency

SGD is an extremely rare congenital disorder of neutrophil function characterized by recurrent bacterial infections and multiple abnormalities in neutrophil structure and composition, including absent specific granules and bilobed nuclei.[926,927] Despite its rarity, SGD is an important part of the differential diagnosis in patients with suspected phagocyte immunodeficiencies and provides important insight into the transcriptional regulation of granule biogenesis and the functional roles of lactoferrin, vitamin B_{12}–binding protein, and other specific granule constituents of host defense. To date, five patients have been reported with SGD.[431,882,928-941] Inheritance appears to be autosomal recessive.[938,939,942]

The key features of SGD are summarized in Table 21-14. Clinically, patients with this disorder suffer from indolent, smoldering cutaneous infections punctuated by episodes (sometimes prolonged) of severe infections involving the lungs, ears, lymph nodes, and deeper structures of the skin. Lung abscesses and mastoiditis have been reported as complications of these infections. *S. aureus*, *P. aeruginosa*, *Proteus* species, other enteric gram-negative bacteria, and *C. albicans* appear to be the major pathogens. Further complicating the clinical course in some patients is the presence of neutropenia that is either intermittent and mild[928,930] or prolonged and severe.[431]

The clinical picture of SGD is consistent with the functional defects identified in patient neutrophils. There is a marked abnormality in chemotaxis that can be observed in vivo by the Rebuck skin window technique.[928,930,931,939] The indolent nature of some infections in SGD may be attributable to this chemotactic defect. In vitro measurements of neutrophil killing of *E. coli* and *S. aureus* show a moderate impairment despite the presence of a normal respiratory burst.[928-931,939,941] Patient neutrophils adhere normally to plastic surfaces[929,939] but exhibit slightly diminished sticking to nylon fibers and endothelial cells.[931] Degranulation of both azurophilic and (to the extent that they are present) specific granules also appears to be normal.[929,931,939]

At least three cellular compartments are affected by the underlying molecular defect or defects in SGD: the nucleus, specific granules, and azurophilic granules. Approximately half or more of the peripheral blood neutrophils in SGD have nuclei that resemble those seen in the Pelger-Huët anomaly. The nucleus has a kidney-shaped, bilobed configuration that is flawed by a series of microlobulations and clefts apparent on electron microscopy.[930,931,939] On a Wright stain of peripheral blood, neutrophils appear to be devoid of the pink-staining specific granules. By electron microscopic analysis, however, it is apparent that the specific granules are not actually absent but instead are present as empty, elongated vesicles that retain their characteristic trilamellar membrane structure and positive staining for complex carbohydrates.[930,932,934,938] Biochemical measurements of specific granule contents parallel the morphologic studies. Lactoferrin, vitamin B_{12}–binding protein, and gelatinase[943] are present at levels that are only 3% to 10% of normal.[929,931,939] Thus, there appears to be an abortive

TABLE 21-14	Summary of Neutrophil Specific Granule Deficiency
Incidence	Five cases reported
Inheritance	Autosomal recessive
Molecular defect	Protein deficiencies in azurophilic granules (defensins), specific granules (lactoferrin, vitamin B_{12}–binding protein, gelatinase), and secretory vesicles (alkaline phosphatase) suggest a common defect in regulation of the production of these proteins in myeloid cells. Eosinophil specific granules also deficient in protein contents. Mutations in the myeloid transcription factor C/EPBε identified in several patients
Pathogenesis	Recurrent infections result from the combined effect of deficiencies in microbicidal granule protein (e.g., defensins and lactoferrin) and abnormal chemotaxis, perhaps as a result of failure to upregulate surface β_2 integrins and chemotactic peptide receptors from granule stores
Clinical manifestations	Recurrent (sometimes indolent) pyogenic infections of the skin, ears, lungs, and lymph nodes that may have diminished neutrophil infiltration; onset usually during infancy
Laboratory evaluation	Absent or empty specific granule vesicles in neutrophils by electron microscopy (by light microscopy, granules appear absent)
	Bilobed nuclei resembling the Pelger-Huët anomaly are frequently seen in neutrophils
	Severe deficiency of neutrophil lactoferrin, vitamin B_{12}–binding protein, defensins, and alkaline phosphatase (by histochemical assay)
Differential diagnosis	Acquired specific granule deficiency (e.g., thermal burns or myeloproliferative syndromes)
Therapy	Prophylactic antibiotics
	Parenteral antibiotics for acute infections
	Surgical drainage or resection of refractory infections
Prognosis	With appropriate medical management, patients can survive into their adult years

and incomplete formation of normal specific granules. Azurophilic (primary) granules in this disorder are also strikingly abnormal. Although they contain a normal (if not slightly elevated) amount of MPO and are present in normal numbers, they are severely deficient in defensins.[882] In addition, there is a severe deficiency of alkaline phosphatase activity in peripheral blood neutrophils,[928,930,939] which is normally localized to secretory vesicles, and its deficiency probably represents yet another organelle abnormality in this disorder.[934] Finally, granule formation also appears to be abnormal in eosinophils. These cells are deficient in three eosinophil-specific granule proteins (eosinophil cationic protein, MBP, and eosinophil-derived neurotoxin), although the corresponding mRNA transcripts are present.[944]

In view of the multiple deficits in granule matrix contents produced after the promyelocyte stage, it had long been speculated that SGD is due to an abnormality in biosynthetic regulation of granule (and probably non-granule) proteins during granulopoiesis. This mechanism is also consistent with the observation that the SGD neutrophils are severely deficient in defensins, which are stored in azurophilic granules. In contrast to other azurophilic granule proteins that are synthesized at the promyelocyte stage, defensins are produced during the subsequent myelocyte stage, along with the specific granule matrix proteins (see Fig. 21-1).

At least some cases of SGD result from autosomal recessive mutations in a transcription factor that regulates gene expression during granulocyte differentiation. Serendipitously, mice generated with a targeted deletion in the myeloid transcription factor C/EBPε exhibit absence of neutrophil secondary granules and their matrix proteins, bilobed neutrophil nuclei, impaired chemotaxis, and increased susceptibility to bacterial infection.[49,945,946] Mutations in the C/EBPε gene have been identified in two SGD patients to date. In one case, a 5–base pair (bp) deletion resulted in a truncated, nonfunctional protein,[947] whereas a second, unrelated patient was homozygous for a nucleotide insertion in the coding sequence that also leads to the synthesis of a truncated and nonfunctional form of C/EBPε.[59] However, DNA sequencing of the C/EBPε gene in several other SGD patients has not revealed abnormalities, which suggests that SGD is a genetically heterogeneous disorder.[948]

The cellular defects just described can explain, at least in part, the clinical problems observed in SGD. The markedly abnormal specific granules and secretory vesicles, which contain intracellular stores of both β_2 integrins[949-951] and a chemotactic peptide receptor,[952] fail to support normal upregulation of these two types of receptors[936,939] and may thereby contribute to the chemotactic defect. Furthermore, the severe deficiency of key bactericidal proteins such as lactoferrin and the defensins renders the cell less efficient in killing bacteria and *Candida*. Neutropenia, when it does occur, also impairs host defense and appears to be caused by intramedullary destruction of the abnormal neutrophils, as evidenced by their ingestion by marrow macrophages.[938]

The diagnosis of SGD can be made by light microscopic examination of Wright-stained peripheral blood neutrophils. Electron microscopic studies can confirm the presence of empty specific granule vesicles. Bilobed nuclei and greatly diminished levels of alkaline phosphatase by histochemical analysis also support the diagnosis. In conjunction with these morphologic studies, biochemical and immunologic measurements of lactoferrin, vitamin B_{12}–binding protein, and defensins can be made. As discussed previously, all three of these granule proteins are severely deficient in this disorder. Acquired SGD is observed in myeloproliferative syndromes and after thermal burns.[926,953] In these acquired disorders, however, at least a few intact specific granules are still observed microscopically, and the deficiencies of the various granule enzymes are less profound.

As with other neutrophil disorders, prophylactic antibiotics appear to be beneficial based on anecdotal experience. Parenteral antibiotics should be used aggressively for acute infections. With appropriate medical management, patients can survive into their adult years. Malignant transformation of the dysmorphic myeloid cells in this disorder has not been reported.

Disorders of Oxidative Metabolism

The elimination of many pathogens requires oxygen-derived microbicidal compounds generated by the phagocyte respiratory burst pathway in response to inflammatory stimuli (see Fig. 21-7). Five clinically recognized defects have been identified in this series of reactions, including deficiencies in NADPH oxidase (reaction 1 in Fig. 21-7), G6PD, (reaction 8), MPO (reaction 4), glutathione reductase (reaction 7), and glutathione synthetase (reaction 9).

Chronic Granulomatous Disease
