Hematopoietic stem cell transplantation (HSCT) has become an accepted treatment of a wide variety of diseases, including hematologic malignancies, bone marrow failure syndromes, immunodeficiency disorders, congenital hematologic defects, and some solid tumors. HSCT generally begins with the administration of high doses of chemotherapy, total body irradiation (TBI), or both to destroy malignant cells and sufficiently immunosuppress the recipient so that the graft will not be rejected. Patients are profoundly immunocompromised as a result and are at risk for opportunistic infections. These infectious risks, together with other complications such as graft rejection, graft-versus-host disease (GVHD), and primary disease recurrence, have been the main barriers to success in HSCT. However, advances in understanding the biology and immunology underlying transplantation, coupled with improvements in supportive care and clinical management of complications, have made HSCT an increasingly efficacious modality for a broadening range of indications.

HISTORY AND OVERVIEW

Infusion of bone marrow in an effort to restore hematopoiesis was first reported in 1939: a patient with aplastic anemia was treated by regular transfusions, as well as the infusion of a small aliquot of fraternal bone marrow.[1] Subsequently, Jacobson and colleagues demonstrated that shielding the spleen from radiation allowed mice receiving lethal doses of radiation to recover normal hematopoiesis.[2,3] Ultimately, such experiments made it clear that hemato-poietic reconstitution of irradiated animals originated from elements in the bone marrow or spleen.[4] These hematopoietic stem cells (HSCs) were also shown to function after cryopreservation and thawing.[5] Investigators subsequently demonstrated that animals did well if histocompatible HSCs were infused but suffered from GVHD if given cells from a histoincompatible donor.[6] Better understanding of the biology of the immune response coupled with the observation that administration of methotrexate was effective for both prophylaxis and treatment of GVHD[7] provided both the theoretical and practical tools necessary for HSCT to be studied in humans.

The first attempt at human bone marrow transplantation (BMT) was carried out in 1957 by E. Donnall Thomas, whose body of work in this area was later recognized by a Nobel Prize. These first experiments were performed in patients with advanced hematologic malignancies and demonstrated that chemotherapy followed by intravenous marrow infusion could result in a transient graft, although all patients subsequently died of progressive disease.[8] In 1959, lethal doses of TBI and bone marrow from an identical twin were used to transplant two patients with advanced acute lymphoblastic leukemia (ALL).[9] Hematopoiesis was established within weeks, although again both patients relapsed and died.

The first successful allogeneic HSCT procedures were performed in 1968 and 1969, with the survival of three patients who underwent transplantation for congenital immunodeficiencies.[10-13]

HSCT is currently used for a variety of malignant and nonmalignant disorders in which replacement of HSC-derived populations of cells provides or restores normal hematopoiesis or other marrow-derived elements. In malignant diseases, infusion of previously collected HSCs abrogates myelosuppression as the dose-limiting toxicity of chemotherapy regimens. Although bone marrow was initially considered the only source of pluripotent HSCs, more recently it has become clear that other sources exist. For example, self-renewing HSCs can be collected from umbilical cord blood (UCB). The low absolute number of HSCs circulating in peripheral blood can be increased after chemotherapy by the administration of hematopoietic growth factors and collected as mobilized peripheral blood stem cells (PBSCs). Exploration of the potential for cell populations derived from tissues such as the liver, nervous system, and muscle to provide HSCs has been initiated.[14-18]

Reinfusion of a patient's own HSCs after the administration of high-dose chemotherapy, radiation therapy, or both is referred to as autologous HSCT. Both tumor contamination and preexisting damage to HSCs from previous therapy limit its application in cases of malignant disease. Moreover, the lack of an allogeneic immunologic response against any residual or recurrent tumor may further have an impact on success. In the case of congenital or acquired benign hematologic conditions, stem cell abnormalities prevent autologous HSCT from being a meaningful option for most patients. Thus, autologous transplants are used mostly for the treatment of lymphomas or solid tumors. Allogeneic HSCT is the infusion of HSCs from a related or unrelated donor. Complications of allogeneic HSCT, such as graft rejection and GVHD, are generally more common or severe with increasing histoincompatibility between the donor and host, and a histocompatible sibling, if available, remains the preferred donor. However, it is estimated that only 15% to 40% of patients will have a matched related donor.[19,20] Available alternatives include HSCT from a related donor that is mismatched[21,22] or from donors in the unrelated donor pool,[23-25] including unrelated UCB collections.[26-28]

Specific conditioning regimens used to prepare patients are reviewed in the next section. In brief, the preparative regimen must reduce or eliminate tumor burden or recipient hematopoietic cells (or both) and provide sufficient immunosuppression to permit engraftment. After conditioning, HSCs are infused intravenously into the host; the day of HSC infusion is termed day 0. Neutrophil engraftment occurs approximately 10 to 24 days after infusion, with red cell and platelet recovery somewhat more delayed. A number of peritransplant and post-transplant complications influence not only survival but also quality of life after transplantation (Box 9-1).

Box 9-1	Complications of Bone Marrow Transplantation

SHORT TERM

Graft rejection
Infection
Bleeding
Acute graft-versus-host disease
Veno-occlusive disease of the liver
Idiopathic pneumonitis
Side effects of radiation therapy, chemotherapy, and
   immunosuppressive therapy (e.g., pancytopenia
   mucositis)

LONG TERM

Late graft failure
Chronic graft-versus-host disease and its sequelae (e.g.,
   bronchiolitis obliterans)
Pulmonary disorders
Infection
Altered intellectual and growth development in children
Endocrine dysfunction
   Hypothyroidism
   Growth retardation (children)
   Pubertal delay, gonadal failure
   Sexual dysfunction (both sexes)
Complications secondary to radiation therapy (e.g.,
   cataracts, radiation nephritis)
Complications secondary to immunosuppressive therapy
   (e.g., aseptic necrosis of bone)
Dental problems
Psychosocial problems
Increased risk for second malignancies

There is a risk of early graft rejection and late graft failure. Early complications of HSCT are due to profound pancytopenia, regimen-related toxicity, immunologic reaction of the graft against host tissues (acute GVHD [aGVHD]) if the transplant is allogeneic, and protracted immune incompetence. Late complications of HSCT are due to chronic end-organ damage from drug and immune insults and ongoing or de novo manifestations of immune dysregulation such as poor immune function or chronic GVHD (cGVHD). Each of these factors and complications is considered in detail later.

Given these obstacles, the evolution of HSCT into a practical and curative therapy has been dependent on a number of important advances, including improved appreciation of the human histocompatibility system and development of more exact methods to establish the degree of histocompatibility between the donor and recipient. The ability to deliver the preparative regimen with greater accuracy, as illustrated both by improvements in TBI dosimetry and strategy and by the ability to monitor busulfan pharmacokinetics, has significantly

decreased regimen-related toxicity. Early and aggressive use of antibiotics, antifungal agents, and antiviral agents has improved survival during the early neutropenic period and during the period of profound and persistent immunosuppression after engraftment. Advances in transfusion support, such as viral screening, irradiation of blood products, and the availability of leukopheresed platelet products, have had enormous impact. Nutritional and other supportive therapies, including the ability to establish long-term vascular access with indwelling lines, has significantly changed the experience and comfort of HSCT recipients. Although HSCT was originally offered only to the rare patient with end-stage disease, improved outcomes because of these and other advances have markedly increased the situations in which the HSCT can provide benefit.

CONDITIONING REGIMENS

The term *conditioning regimen* refers to the preparative drugs or radiation (or both) that are administered to an HSCT recipient before the graft is infused. The purpose of conditioning is threefold: first, to eradicate all malignant cells; second, to be sufficiently immunosuppressive to prevent the immune system of the recipient from rejecting incoming allogeneic cells; and third, to induce enough marrow aplasia that the donor HSCs have a competitive advantage in reconstituting hematopoiesis. Regimens that are capable of achieving all three goals are usually associated with significant toxicity. Therefore, a major goal in HSCT is the development of conditioning regimens that provide an optimal balance between effective myeloablation and manageable toxicity.

The first human BMT by Thomas and colleagues in 1957[9] and a subsequent experience using unrelated donor marrow to treat victims of a radiation accident in Belgrade in 1959[29] established the basic principle of TBI-based conditioning. Work initiated by Santos, Owens, and Sensenbrenner in the 1960s first demonstrated the effectiveness of cyclophosphamide as a conditioning agent.[30] TBI combined with cyclophosphamide has remained the standard conditioning regimen for the last 30 years. More recently, the alkylating agent busulfan has become more widely used as an alternative to TBI, in part because of limited access to costly radiation facilities.[31]

The wide range of indications for HSCT has led to considerable variation in the design of conditioning regimens. For example, high relapse rates after HSCT stimulated attempts to increase the antileukemic efficacy of conditioning regimens by using other high-dose chemotherapy agents in place of or in addition to cyclophosphamide. In contrast, the problem of graft failure/rejection in patients receiving grafts that are T-cell depleted or from genetically disparate donors has led to regimens that increase recipient immunosuppression. Patients with aplastic anemia or severe combined immunodeficiency

(SCID) have preexisting marrow aplasia or immunosuppression, and thus conditioning regimens in these diseases do not require the same degree of myelosuppression as regimens for patients with intact immune function. Similarly, patients with benign hematologic diseases have no need of the antileukemic effect of conditioning, and therefore specialized myeloablative regimens have been developed specifically for these conditions.[32] In addition, as autologous HSC support for high-dose chemotherapy became more common, many new conditioning regimens were developed with an emphasis on potential antitumor effects. Although individual studies demonstrated acceptable or even favorable outcomes related to some of these changes, no consensus on optimal recipient preparation for either autologous or allogeneic stem cell transplantation (SCT) has emerged. More recently, alternative concepts regarding the relative roles of conditioning regimens and the donor immune system in achieving recipient hematopoietic ablation have been applied in preclinical and clinical studies of nonmyeloablative transplantation. Some key issues are highlighted later.

Total Body Irradiation. Several parameters associated with TBI can be adjusted to deliver different amounts of radiation and different degrees of end-organ effect. Total dose, dose rate, fraction size, interfraction interval, and shielding are among the TBI parameters most manipulated in SCT. An ideal schedule would maximize malignant cell killing, hematopoietic ablation, and in the case of allogeneic SCT, immunosuppression while limiting acute and chronic toxicity. In principle, a higher total dose, higher dose rate, and larger fraction size are associated with greater hematopoietic ablative effect (and therefore potentially greater antileukemic efficacy) and with better immunosuppression. Fractionation, or division of the total dose of radiation over time, usually in a twice-daily schedule, theoretically yields improved tolerance of nonhematopoietic tissues and leads to decreased acute toxicity and reduced late effects, but it carries the risk of decreased antileukemic efficacy. However, a series of studies from the 1980s support the use of fractionated radiation, and this remains the standard today.[33,34] Studies from Seattle demonstrated decreased relapse as the total radiation dose increased, but lung, liver, and kidney toxicity was limiting.[35,36] The parameters total dose, fractionation, dose rate, and schedule have largely been extrapolated to pediatric HSCT from adults.[37,38]

Busulfan. Developed in the mid-1970s, busulfan (BU)/cyclophosphamide (CY) rapidly became an established regimen for patients with acute myelocytic leukemia (AML) undergoing either allogeneic[39] or autologous SCT.[40-42] The original regimen, called BU/CY4 (big BU/CY: BU, 4 mg/kg/day for 4 days, followed by CY, 50 mg/kg/day for 4 days) was joined by BU/CY2 (little BU/CY, in which the CY was delivered as 60 mg/kg/day for 2 days),[41-45] and this regimen has been used in patients with acute lymphoblastic leukemia (ALL) or chronic myelog-

enous leukemia (CML).[46,47] The BU/CY regimen has been used extensively in pediatric patients, particularly those with nonmalignant diseases,[48-53] in an attempt to avoid radiation-mediated toxicity.

Total Body Irradiation versus Busulfan. Several randomized studies and meta-analyses have compared BU/CY with TBI-based regimens.[54-62] Overall, the results are similar, although they suggest that both relapse rates and hepatic veno-occlusive disease (VOD) may be less frequent in the TBI-containing regimens. Even though recent data support these observations, variability of the chemotherapy component of TBI-based regimens and potential differences in the antileukemic efficacy of BU/CY4 and BU/CY2 regimens[63] render definitive generalizations difficult. Reports of decreased bioavailability, increased volume of distribution, and increased clearance rate of busulfan in children raise the question of how to interpret studies in which such data are unavailable.[64-67] Alternative busulfan dosing, based on plasma levels, has been suggested,[68,69] and studies comparing "optimal" BU/CY with CY/TBI have not been performed. Busulfan-containing regimens have often been reported to result in greater toxicity than TBI-based regimens; thus, increases in the busulfan dose may further increase regimen-related morbidity.[54,55,57,60,70,71] Monitoring of busulfan pharmacokinetics has generally, but not always demonstrated an association of increased area under the curve with increased VOD.[68,72] Individualizing busulfan dosing may possibly increase the benefit-risk ratio, and the recent availability of an intravenous form of busulfan with more dependable pharmacokinetics now makes such individualization feasible.[73-76]

Alternative Myeloablative Regimens. The addition or substitution of a variety of chemotherapeutic agents to the backbone of CY/TBI—and less commonly BU/CY—has met with mixed success. Etoposide (VP-16), cytarabine, and busulfan have been added to or substituted for cyclophosphamide in TBI-based regimens.[58,77-84] Etoposide and melphalan have also replaced cyclophosphamide in some busulfan-based protocols.[85-88] Fluorouracil, high-dose methotrexate, doxorubicin, cisplatin, carboplatin, thiotepa, melphalan, and many other agents have been used in a variety of high-dose chemotherapeutic regimens supported by autologous SCT. Common conditioning regimens referred to by acronyms are CBV (cyclophosphamide, BCNU [carmustine], VP-16), BACT (BCNU, Ara-C [cytarabine], cyclophosphamide, 6-thioguanine), BEAM (BCNU, etoposide, Ara-C, melphalan), and CBP (cyclophosphamide, BCNU, cisplatin). In the allogeneic setting, alternative regimens have generally shown equivalent benefit in terms of disease control but often at the cost of increased toxicity. No regimen has established unequivocal superiority in terms of disease-free survival (DFS) or overall survival when compared with "standard" regimens. Given the more limited follow-up and the extraordinary diversity of diseases and

regimens, establishment of relative efficacy in the realm of autologous SCT is likely to be a complicated and prolonged process.[89-93]

Nonmyeloablative Regimens. One of the target tissues of allogeneic T lymphocytes is the hematopoietic precursors. As a result, the infusion of donor lymphocytes can be sufficient to cause marrow aplasia. Indeed, this is the basis of the marrow aplasia seen in inadvertent cases of transfusional GVHD. Observations made initially in the 1980s by the Seattle group have led to a new approach to conditioning based on the immunologic elimination of normal and malignant hematopoiesis. Because this technique minimizes the doses of conventional conditioning drugs and radiation, it has been termed "nonmyeloablative" or reduced-intensity conditioning.[94-100] Although allogeneic graft-versus–bone marrow can cause the necessary marrow aplasia and antileukemic efficacy, it does not supply the immunosuppression needed to avoid graft rejection. This is usually achieved by preinfusion conditioning with purine analogue chemotherapy, low-dose TBI, or both. A variety of agents, including lower-dose busulfan, melphalan, and cytarabine, have also been used for additional effect and partial HSC depletion.[94-96,98-100] A major advantage of this approach is that the toxicity of conventional myeloablative approaches can be reduced.[101] Comparisons of conventional and nonmyeloablative regimens have shown reduced non–relapse-related mortality, especially in older adults or patients with preexisting illnesses, in whom HSCT is associated with significant toxic death rates.[102,103] The safety and effectiveness of this approach have led to its wider application in recent years. However, the low toxicity of nonmyeloablative regimens is balanced against the increased risk of relapse in acute leukemias and the increased risk of cGVHD.[104] The indications for nonmyeloablative transplantation may therefore remain principally for slower-growing tumors. Because childhood hematologic malignancies rarely fall into this category, the use of nonmyeloablative transplantation in children has been more limited.[96,105,106] Moreover, the increased risk of graft rejection associated with standard HSCT for nonmalignant conditions such as thalassemia and sickle cell anemia have precluded the broad use of nonmyeloablative transplantation for these conditions.

SOURCES OF STEM CELLS

Selection of an appropriate source of HSCs for a patient undergoing HSCT has become a more complex undertaking in recent years. HSCs can be obtained from bone marrow, peripheral blood, or the umbilical vein of newborn infants. The majority of HSCT procedures in the pediatric setting are performed from allogeneic donors, but autologous bone marrow or peripheral blood is used as a source of transplants as well, particularly in patients with solid tumors. For each disease

entity, the clinician must consider what sources of stem cells are available and the relative risks and benefits associated with each potential stem cell source. For allogeneic donors, the principal consideration in donor selection is the genetic similarity between donor and recipient.

Typing. Genetic disparity between host and donor can lead to graft rejection or GVHD. The genes encoding the antigens most associated with these complications lie in a group of genes known as the major histocompatibility complex (MHC). In humans, the MHC maps to a region of the short arm of chromosome 6 known as the HLA system. The MHC codes for many genes, and identification and exploration of the functional importance of some of these gene products are still ongoing. Among the best characterized gene products are proteins comprising the class I and class II antigens. In humans, MHC class I molecules include HLA-A, HLA-B, and HLA-C, and MHC class II molecules are called HLA-D. There are at least five subregions, including DR, DQ, and DP, but the number of genes transcribed differs between different HLA class II haplotypes.

MHC class I antigens are present on nearly all human cells (with rare exceptions such as erythrocytes and corneal endothelium). MHC class II antigen expression is more restricted, with expression limited to "professional" antigen-presenting cells, including dendritic cells, B cells, monocytes, macrophages, and Langerhans cells. Class II antigens can also be induced on activated T cells and endothelium. MHC genes are codominantly expressed—that is, each parent contributes half the MHC antigens expressed on each cell of their offspring. MHC class I and II antigens normally function to present partially degraded products of intracellular proteins to T cells. In this way, damaged or virally infected cells can be identified by the immune system. However, in the setting of transplantation, recognition of MHC molecules by T cells is known as *alloimmunity* and is the basis for GVHD and graft rejection.

The genes of the MHC region are highly polymorphic. Matched siblings have inherited the same two copies of chromosome 6 from the parents and thus identical HLA antigens—such a pair of donors are said to be genotypically identical. However, even HLA-identical sibling transplants can be associated with GVHD. Differences in the sequences of intracellular proteins physically associated with MHC molecules are caused by polymorphisms in non-MHC genes, such as blood group antigens and cell adhesion molecules. These polymorphisms are mostly unidentified, and those that are known to elicit alloreactive T-cell responses are termed *minor histocompatibility antigens.*[107] Although these antigens may not be directly responsible for organ and bone marrow rejection, human typing studies suggest that these minor antigens contribute to the generation of GVHD.[108,109]

Historically, HLA typing was performed by using antibodies derived from postpartum sera, from persons

who have undergone transplantation or transfusion, or even from persons immunized for the purpose of generating specific serologic reagents. These antibodies were used in a standardized complement-dependent, microcytotoxicity assay with purified T or B lymphocytes as their target cell.[110] The extensive cross-reactivity among products coded by alleles of the HLA-A and HLA-B loci, known as *cross-reactive groups*, made precise delineation of MHC class I antigens by this technique difficult. In contrast, HLA-D specificities were originally defined by their ability to stimulate T-lymphocyte proliferation in a mixed leukocyte culture.[111]

The aforementioned approach, termed *low-resolution typing*, provides sufficient accuracy in the matched sibling setting. However, only approximately 30% of patients have an acceptable sibling donor, and as the infrastructure necessary to identify unrelated donors became available, high-resolution HLA typing techniques that resolve the DNA sequence of specific alleles was essential. The first attempts to use molecular genetic techniques were based on the application of restriction fragment length polymorphism analysis of genomic DNA by Southern blotting with HLA region probes. This technique soon gave way to the current technology in which sequence-specific oligonucleotide probes and, in some cases, direct sequence analysis are performed. This has also led to a great increase in the number of HLA specificities identified. This fine analysis is increasingly being used to determine the haplotypes of patients and potential donors. The implications of more exact typing within families, where the haplotypes are "conserved," are probably confined to the potential identification of differences in minor histocompatibility antigens to allow better selection between possible donors.[108,109,112] In the unrelated donor setting, high-resolution HLA matching has significantly contributed to the lower incidence of GVHD, hence improved outcomes reported in unrelated donor HSCT in the past decade.[113-115] Historically, an allogeneic donor must match the patient at five of the six major loci (A, B, DR) for a transplant to be feasible. Stem cells obtained from UCB are more permissive, and four out of six matches is acceptable. The lower incidence of GVHD when UCB is employed is probably due to the relatively low dose of cells obtained from that source. What degree of mismatching at other loci or which specific loci are most important when mismatch is inevitable has yet to be established.

Allogeneic Stem Cell Transplantation

To date, most allogeneic transplants have used HSCs from a matched sibling donor. However, with improvements in immunosuppression and the ability to prevent or treat GVHD, unrelated donors, umbilical cord blood (UBC), and partially MHC-mismatched donors are now increasingly being used as sources of HSCs. There are presently approximately 10 million unrelated donors listed in more than 72 registries worldwide, including registries of banked unrelated donor UCB collections.

Selection of an allogeneic HSC source is dependent on many variables. In malignant disease, the ease and speed with which a stem cell source can be obtained are important factors. For patients with aggressive malignancies, being able to proceed rapidly to transplantation is particularly desirable. Increasing genetic disparity between donor and host—termed *histoincompatibility*—has historically contributed to both an increased rate of graft rejection and severe aGVHD and cGVHD and is a critical factor in the choice of donor. Even in the setting of HLA-identical siblings, selection can be further refined according to gender, history of donor parity, donor infectious disease status, donor age, and other variables, all of which contribute to the success of transplantation.

For the majority of patients who do not have a matched sibling donor, potential sources include a family member who is phenotypically adequately matched at the HLA loci but is genotypically distinct or a volunteer unrelated donor who shares the majority of HLA alleles with the recipient. The likelihood of locating an appropriate unrelated donor is dependent both on the patient's ethnicity (inasmuch as it determines histocompatibility antigen and haplotype frequency) and on the composition of the donor pool. For example, for whites of middle and northern European descent, the likelihood of finding a six-antigen–matched unrelated donor approaches 50% to 70%.[116] In contrast, the extreme genetic heterogeneity of the African American population coupled with underrepresentation of this population in volunteer registries makes the likelihood of finding a similar matched donor approximately 10% to 15%. Molecular typing techniques demonstrate that the allelic disparities in both whites and nonwhites is much higher than previously expected, thus making the ascertainment of a truly "matched" unrelated donor less likely even as the donor pool expands.[117] Although the implications of specific HLA mismatches are incompletely understood, most studies suggest that high-resolution HLA matching is associated with improved outcome in unrelated donor HSCT.[113-115] Thus, additional strategies to broaden the donor base by using alternative HSCs, such as UCB, that allow greater HLA disparity are being explored.

Sources of Hematopoietic Stem Cells. In the past, most HSCT has used bone marrow mononuclear cells as a source of HSCs. Bone marrow is usually obtained by repeated aspiration of the posterior iliac crests while the donor is under general anesthesia. Multiple aspirations are performed, usually through a limited number of skin holes (one to three per side), to a total volume of 10 to 15 mL/kg recipient body weight. The marrow is filtered through a fine wire mesh to rid the product of aggregates and bony spicules. This is a surprisingly well-tolerated procedure, and serious complications are rare. Risks to the donor are minimized by the fact that the donor is generally a healthy individual undergoing an elective procedure. Potential short- and long-term complications include the risks associated with anesthesia,

blood loss and potential transfusion, pain, neurologic deficits, and psychosocial complications. In the most truly altruistic setting, unrelated marrow donor harvest, only 5% to 8% of donors later expressed any ambivalence about their participation. This was most marked if the transplant was subsequently unsuccessful.[118] Once harvested, red cells must be removed from the bone marrow if there is ABO incompatibility before infusion into the recipient.[119] The marrow may be manipulated ex vivo to remove donor T lymphocytes (see later) or tumor cells. It is estimated that only 1% of the donor's pluripotent HSC population is removed in a typical marrow harvest.

HSCs continuously recirculate from the marrow into the peripheral blood; HSCs can therefore be harvested by collection of peripheral blood mononuclear cells, usually by leukapheresis. The frequency of cells that express the surface marker CD34 is widely used as a proxy for actual HSC frequency and allows enumeration of stem cells. HSCs in peripheral blood are rare, and granulocyte colony-stimulating factor (G-CSF) is usually administered to increased the detachment of HSCs from bone marrow niches and promote their egress into the peripheral blood, thereby increasing their frequency.[120-124] Moreover, studies in adults suggest that additional strategies to further mobilize marrow HSCs are possible. AMD3100 is a reversible inhibitor of the CXC chemokine receptor (CXCR4), a receptor on the surface of HSCs that promotes adhesion to the bone marrow milieu. Combining AMD3100 with G-CSF increases HSC yield in adults,[125] but this approach has not been investigated in children. Complications of PBSC harvest have included bone pain as a side effect of G-CSF and inability to collect cells via peripheral access, thus necessitating central line placement.[126,127] Healthy individuals are at risk for splenic rupture from the administration of G-CSF, although this complication is extremely rare.[128] The implications of mobilizing and harvesting PBSCs from pediatric donors have not been fully explored,[129,130] but cytopenia and hemostatic changes of unknown short- and long-term significance have been observed in healthy donors.[131,132]

Since the first description of its use in a child with Fanconi's anemia (FA) in 1989,[133] UCB has become an increasingly investigated HSC source. Placental blood is recovered from the umbilical vein by drainage or catheterization, and techniques to optimize UCB HSC collection are being investigated.[27,134] Cord blood is immediately frozen and stored until needed. If indicated, in the related setting, determination of the HLA type of the fetus can be performed before delivery. Otherwise, typing and analysis are performed on intrapartum or postpartum samples.

Selection of an unrelated donor, whether bone marrow or UCB, is facilitated by the availability of epidemiologic information (e.g., age, sex), as well as HLA typing stored in a database accessible via the Internet. By comparing a patient's HLA type with donors listed and categorized in the registries, one can estimate the likelihood of a successful search, devise search strategies for patients with uncommon HLA types, and sort among potential HSC sources. Although stored UCB can be readily supplied after confirmatory typing, completion of a unrelated bone marrow donor search is more involved. Potential donors must be contacted and give consent to proceed, and the donor center must arrange for appropriate confirmatory studies, donor medical clearance, and scheduling of a harvest date. The time from formal search to BMT averages 4 months.

Engraftment. After allogeneic HSCT, donor stem cells must expand to repopulate hematopoietic niches and differentiate to form mature blood cells. HSCT recipients show accelerated telomere shortening in peripheral blood cells, which is presumably due to the increased replicative demand of donor stem cells.[135] Donor hematopoietic engraftment after allogeneic HSCT can be documented both by analysis of chimerism and by the recovery of peripheral blood cell counts. However, sensitive DNA amplification technologies have demonstrated residual host hematopoiesis for variable periods of time, certainly up to 1 year.[136-138] Mixed lymphoid chimerism is also well documented.[136-139] The implications of mixed chimerism with respect to subsequent relapse remain controversial, probably because the current extremely sensitive assays generate data that are difficult to interpret uniformly and because outcome may well differ by disease type.[140] For example, chimerism after BMT for CML is quite reliably related to subsequent relapse, but this may not be true for other diseases.[139-141]

The rate and probability of engraftment after allogeneic BMT vary with the source of HSCs, the number of HSCs given, the extent of preinfusion cell manipulation, and the GVHD prophylactic regimen used. In general, neutrophil recovery is achieved within 2 to 3 weeks and platelet recovery 1 to 2 weeks thereafter. Peripheral blood stem cell transplantation (PBSCT) is associated with a more rapid rate of engraftment than BMT is, most likely as a result of the higher CD34$^+$ cell count obtained.[142] Neutrophil engraftment occurs between 1 and 6 days earlier with PBSCT than with BMT and platelet engraftment between 4 and 7 days earlier.[143] Neutrophil and platelet engraftment after UCB transplantation is significantly delayed in comparison to that seen with other stem cell sources[144-148] because of the lower nucleated cell and CD34$^+$ cell dose in cord blood products. This has limited the application of this modality in adults, and currently, use of two unrelated UCB units for a given patient is being studied.[149]

The use of methotrexate as GVHD prophylaxis is associated with delay in count recovery; conversely, recovery after T-cell–depleted BMT is more rapid. Use of colony-stimulating factors after BMT is associated with more rapid neutrophil recovery after related donor BMT, a finding confirmed in small pediatric series.[139-141,150-155] No change in platelet recovery has been noted. Interestingly, preliminary data do not show any colony-

stimulating factor–mediated acceleration of engraftment in patients undergoing unrelated donor BMT.[155]

The number and quality of T cells that are present in grafts from peripheral blood, bone marrow, and UCB confer different rates of GVHD. GVHD, particularly cGVHD, is more frequent in PBSCT than in bone marrow–derived HSCT, although this risk may be offset by an increased graft-versus-leukemia (GVL) effect.[156] In adults, this increased rate of GVHD has not diminished the efficacy of PBCST. However, in children, PBCST has been associated with a worse outcome than when bone marrow is used as a cell source.[157] The precise indications for PBSCs versus bone marrow as a source in pediatric HSCT therefore remain to be defined. Conversely, the lower rate of GVHD with UCB than with either PBSC or bone marrow sources allows less stringent HLA-typing requirements.[158]

Autologous Stem Cell Transplantation

Over the past decade, increasing numbers of cancer patients with either hematologic malignancies or solid tumors have elected to undergo autologous HSCT. In fact, the number now ranges in the tens of thousands worldwide. The fundamental hypothesis supporting this therapeutic approach is the belief that very high doses of cytotoxic agents (dose intensification) increase tumor cell death and that a high-dose treatment regimen can be devised in which the major dose-limiting toxicity is myelosuppression. This toxicity can be ameliorated by infusion of previously collected and cryopreserved autologous stem cells obtained either by bone marrow harvest or by apheresis of peripheral blood. Use of autologous cells to support and reconstitute the host after aggressive ablative or near-ablative therapy has been most thoroughly explored in both Hodgkin's and non-Hodgkin's lymphomas, less well developed in acute and chronic leukemias, and still considered experimental, albeit relatively widely applied, for a growing number of pediatric and adult solid tumors. In addition, the relative merits and disadvantages of autologous cells collected peripherally or from bone marrow are still not firmly established.

Contamination by Tumor Cells. A major limitation of autologous HSCT remains contamination of the stem cell product with residual malignant cells. Although the relative contributions of either residual tumor within the host or tumor reinfused with stem cells to subsequent relapse remain unknown, increasing evidence from gene-marking studies suggests that reinfused cells contribute to relapse.[159] In addition, in vitro assays of tumor cell colony formation and minimal residual disease detection by polymerase chain reaction (PCR) suggest that contamination of the stem cell source by tumor cells is associated with an increased relapse rate after HSCT.[160] No large randomized clinical trial of PBSCs versus bone marrow with respect to DFS has

been reported. However, paired samples of PBSCs and bone marrow have been examined in a variety of settings (e.g., breast cancer, non-Hodgkin's lymphoma), and PBSCs have been found to have lower levels of tumor cell contamination in the steady-state setting.[161] More recent data suggest that the advantage of PBSCs may be abrogated after mobilization,[162-166] although impact on DFS remains unclear.

A variety of methodologies have been developed to eliminate, or purge, tumor cells from stem cell collections. These methods are based on either positive or negative selection. The major clinically applied positive selection strategy is that of stem cell enrichment, most often selection of CD34+ cells. Negative selection is based on technologies that deplete tumor cells to a greater degree than normal stem cells. Strategies include the use of pharmacologic agents (e.g., mafosfamide), immunologic reagents targeting tissue-specific antigens (e.g., neural crest antigens in neuroblastoma), and manipulation of physical or culture properties of cells. Combinations of both negative and positive selection strategies may improve both the yield and purity of stem cell collections.[167,168] Increasing evidence in multiple clinical settings demonstrates an association between minimal residual tumor contamination and relapse[160] and, conversely, suggests that more effective purging strategies may be associated with improved DFS. However, randomized studies comparing purged and unpurged stem cells have yet to be reported.

Engraftment. Trilineage hematologic reconstitution has been achieved after the infusion of autologous bone marrow, bone marrow and PBSCs, and PBSCs alone. The most mature studies consist of patients reconstituting hematopoiesis via autologous marrow, with engraftment after bone marrow infusion being both reliable and durable; the durability of PBSC-reconstituted hematopoiesis, undertaken more recently, is less fully evaluated. The best predictor of engraftment and the rate of hematologic recovery have not been established. Although colony-forming units, burst-forming units–erythroid (BFU-E), nucleated cell count, and other measures have correlated with time to engraftment in some studies, correlations have not been universal and may additionally depend on the patient population, method of cell procurement, and subsequent cell manipulation. CD34+ cell counts have emerged as the most reliable and practical method for predicting engraftment after PBSC infusion, with retrospective analyses demonstrating that the risk of graft failure is substantially higher in patients who received less than 2×10^6 CD34+ cells per kilogram.[169-171]

Reconstitution of hematopoiesis after autologous bone marrow infusion has shown some tendency to be delayed when compared with the allogeneic setting. This delay is presumed to be due to the extent, nature, and duration of previous therapy. In addition, cell manipulation ex vivo (purging) may also contribute to delayed engraftment. Reconstitution after HSCT with autolo-

gous bone marrow can be hastened somewhat by the addition of hematopoietic growth factors to the post-SCT supportive care regimen, although the extent and nature of previous therapy may limit response to growth factors. Preliminary information in both the preclinical and clinical arenas suggests that previous aggressive chemotherapy may limit the potential for hematologic recovery.[172-174] Previous intensive chemotherapy supported by the use of growth factors may also contribute to poor engraftment after autologous transplantation. In fact, despite recovery of peripheral blood counts, hematologic marrow reserves as assessed by in vitro measures of hematopoiesis may be blunted for many years after autologous HSCT.[175]

The addition of mobilized PBSCs to bone marrow, with or without subsequent growth factor support, has resulted in a dramatic decrease in days of neutropenia and thrombocytopenia in most series. Furthermore, use of mobilized PBSCs as the sole stem cell source has been almost universally associated with more rapid hematologic recovery. It is still debatable whether the use of hematopoietic growth factors in this setting further enhances the rate of engraftment, but available data suggest that it may. Whether the process of PBSCT will result in durable hematopoiesis over decades is not yet evaluable, but reports of late graft failure are rare. Most studies suggest that the increased rate of engraftment observed with PBSCs results in decreased days in the hospital, use of antibiotics, and need for associated supportive services. The overall impact of PBSCs versus bone marrow as a stem cell source on the outcome or cost of transplantation has yet to be determined.

Myelodysplasia as a Late Complication. It has long been appreciated that intensive chemotherapy, particularly with alkylating agents, may result in an increased risk for subsequent myelodysplastic syndrome (MDS). Many patients who come to autologous transplantation have received treatment with such agents. Over the past several years, increasing numbers of patients have been reported in whom MDS has developed after autologous transplantation, usually 4 to 7 years after HSCT.[176] The actuarial incidence ranges from 5% to 10% in most series,[177-179] although it has been reported to be as high as 18% at 5 to 6 years after HSCT in single-center experiences.[180,181] Risk factors identified have included the use of etoposide for stem cell mobilization,[179] conditioning regimens using TBI,[177,182,183] and the amount of chemotherapy received before HSCT or the interval between diagnosis and HSCT (or both).[183,184] Whether the MDS results from previously damaged reinfused hematopoietic cells or from residual hematopoietic cells sustaining further injury during conditioning is unresolved. Cytogenetic analysis of bone marrow before autologous HSCT can reveal preexisting abnormalities and should be a standard component of the pre-SCT evaluation.[185] However, most patients in whom MDS has developed

have been reported to demonstrate normal cytogenetics at the time of transplantation.[178] With more sensitive techniques currently available, such as fluorescence in situ hybridization (FISH), the majority of patients in whom MDS develops after SCT have been shown to harbor the same cytogenetic abnormality in pre-SCT specimens.[186] Similarly, using an X-inactivation–based clonality assay in female patients, clonal hematopoiesis was demonstrated in a small percentage of patients before HSCT; these patients were at significant risk for the development of MDS after HSCT.[176] This suggests that many cases of post-SCT MDS evolve from an abnormal clone already present before HSCT. Appropriate evaluation of hematopoietic status before embarking on autologous stem cell collection and transplantation is an area requiring further study.

Immune Reconstitution

The period after HCST is characterized by profound immunodeficiency, and death as a result of infectious complications remains a major obstacle to the success of transplantation. Myeloablative conditioning leads to wholesale loss of the cells necessary to confer protective immunity, including T and B lymphocytes and natural killer (NK) cells. Whereas neutrophil hematopoiesis can return within weeks of transplantation, recovery of a functional immune system can take much longer, and the risk of opportunistic infection remains high for up to a year, even with uncomplicated transplants.

The degree of immunodeficiency varies with time because of different contributions of donor and recipient immune function at different stages after transplantation. Mature T, B, and NK cells are present in the donor inoculum of bone marrow, peripheral blood, or UCB and contribute to some degree of host immunity in the immediate post-transplant period. The ability of these transferred cells to provide immune protection is dependent on how immunologically "experienced" the donor is. For instance, recipients of grafts from donors who are cytomegalovirus (CMV) immune, that is, who have previously been infected with the virus and have mounted a protective immune response, have a lower rate of CMV disease, presumably because of transferred immunologic memory for that virus.[187] Similarly, recipients whose donors have been vaccinated with a pneumococcal vaccine respond to pneumococcal vaccines more rapidly and with higher antibody titers after transplantation, again suggesting that donor immunity can be transferred to the recipient.[188] However, full immune reconstitution, with the ability to mount a protective immune response to new pathogenic challenges, is dependent on the differentiation of immature immune cells from precursors in the donor graft inoculum.

In most patients, NK cells are the first lymphoid population to recover, and in the first month after transplantation, NK cells can represent the main lymphoid

cell in peripheral blood. T cells recover much more slowly, and normal numbers of CD4[+] and CD8[+] T cells are not achieved for 6 to 12 months after HSCT.[189] This delay in T-cell neogenesis is due to the complexity of T-cell development, a process that takes months to complete. It starts with differentiation of stem cells in marrow into early lymphoid progenitors that are capable of migration to the thymus, where further maturation occurs before naïve T cells are released into peripheral blood. During the early period after transplantation, T cells with a naïve phenotype predominate in peripheral blood, thus suggesting repopulation of the T-cell compartment with recent thymic emigrants.[189-191] The relative numbers of recent thymic emigrants can be quantified in the peripheral blood T-cell pool by the quantitative detection of genomic DNA that is present only in thymocytes (T-cell receptor gene excision circle [TREC] DNA). Using these methods, researchers have shown that increased thymic output contributes to the expanding peripheral T-cell pool for 12 to 24 months after HSCT.[192] This thymic output occurs even in adult patients whose thymuses have presumably involuted. The rate of increase in T cells is usually much more rapid in pediatric HSCT patients, however, consistent with the presence of more robust thymic function.[189] The advantage of a functional thymus in immune reconstitution has been demonstrated by the marked decrease in the fraction of naïve peripheral blood T cells in a 15-year-old HSCT patient who had previously undergone thymectomy relative to thymus-bearing HSCT patients.[193] Using quantitative molecular measures of the T-cell repertoire, several studies have shown that it can take as long as 12 to 24 months after HSCT for a full range of T-cell receptor diversity to be present in the T-cell compartment.[190,191,194] This underscores the critical role of naïve thymic emigrants in restoring the full complement of T-cell receptor specificities.

Several factors influence the length of time required for immunologic recovery to occur. Patient age profoundly affects the rate of immune reconstitution, with an inverse correlation between recipient age and the absolute number of T cells 1 year after HSCT.[195] The use of mobilized PBSCs as a source of stem cells appears to be associated with a faster rate of recovery than does the use of HSCs from bone marrow, at least partially because of the infusion of a larger cell dose.[121,196] The intensity of the conditioning regimen also has an impact on the speed of immune reconstitution, and the increasingly intensive preparative regimens used in autologous recipients have delayed recovery to a degree comparable to that seen in patients undergoing allogeneic HSCT.[195] Although hematopoietic engraftment appears to be delayed in UCB recipients, immune reconstitution in children after UCB HSCT is comparable to that in children undergoing unrelated donor BMT.[197] The presence of GVHD can significantly delay immune reconstitution as a result of both disruption of normal T-cell development and the additional immunosuppressive therapy required for man-

agement of the disease.[198] The consequences of delayed immunologic recovery are significant: slow recovery of immune function is associated with an increase in the cumulative incidence of infectious complications and non–relapse-related mortality.[121,199]

PERITRANSPLANT SUPPORTIVE CARE

Transfusion Support

The intensive myeloablative conditioning regimens used in the majority of pediatric HSCT to achieve tumor eradication and successful engraftment result in an extended period of pancytopenia. Virtually all patients undergoing HSCT require red blood cell and platelet transfusions during transplantation, and some patients remain transfusion dependent for months. All blood products should be gamma-irradiated to prevent transfusion-induced GVHD as a result of competent donor T lymphocytes in the cellular product.[200] Multiple processes, including psoralen photochemical treatment and leukocyte filtering, have been investigated for prevention of transfusion-associated GVHD, but gamma irradiation remains the standard of care.[201-204] Additionally, blood products must either be leukofiltered to achieve white blood cell reduction or be CMV seronegative (obtained from a donor previously unexposed to CMV) to prevent the transmission of virus to nonimmune patients. Previous studies indicated that both methods were equally efficacious.[205,206] However, a recent meta-analysis of the available literature suggests that the risk of transfusion-transmitted CMV is lowest when CMV-seronegative products are used for CMV-naïve patients.[207]

The ideal threshold for platelet and red blood cell transfusions in the peritransplant period remains an area of controversy. No studies in the modern era have evaluated the use of prophylactic platelet transfusions versus therapeutic transfusions administered when symptoms of bleeding develop. More recent studies have addressed different therapeutic triggers for prophylactic transfusions, specifically, 10×10^9/L versus 30 or 20×10^9/L.[208,209] A review of studies of prophylactic platelet transfusion triggers found no statistically significant differences between groups with regard to mortality or severe bleeding events.[210] Although no statistical significance was found, these studies were small and no recommendations can supplant the need for clinical judgment in individual situations.

Infection Prophylaxis and Treatment

Even after successful neutrophil engraftment, patients continue to have depressed T-cell function and decreased antibody production and thus remain at risk for a variety of infections. This risk is greatest in the allogeneic and T-cell–depleted transplant settings, where despite pheno-

typically normal circulating lymphocytes, depressed cellular immunity is present for at least 1 year after HSCT.[211,212] During this time, viral infections continue to present a major risk to patients. Both CMV-seropositive patients and CMV-seronegative patients who have received grafts from seropositive donors are at risk for CMV, with the greatest risk occurring in seropositive recipients of a seronegative donor, in whom reactivation of virus latent in the patient can occur.[213,214] A large multicenter trial found that those undergoing unrelated donor HSCT from CMV-positive donors had an improved overall 5-year survival when compared with patients receiving cells from CMV-negative donors.[215] T-cell depletion abrogated this effect, which suggested that the improved survival was due to transfer of donor immunity. The clinical manifestations of CMV after HSCT include pneumonia/interstitial pneumonitis, colitis, hepatitis, and CMV-related cytopenia. Before the use of ganciclovir for CMV prophylaxis and treatment, CMV infections developed in more than a third of allogeneic SCT patients.[213] Pneumonia developed in almost 20%, with a mortality rate of 85%.[213] With the availability of effective antiviral therapies, almost all patients at risk for CMV disease receive prophylaxis during the first month after transplantation. Randomized studies have found acyclovir, valacyclovir, and ganciclovir prophylaxis initiated at engraftment to be effective in reducing CMV disease before day 100.[216-219] Prophylactic use of acyclovir has been shown to decrease overall mortality for at-risk patients.[220,221] In addition, studies found that prophylactic use of ganciclovir after engraftment was limited by drug-induced cytopenia and other toxicities. There are multiple studies of preemptive CMV treatment based on the results of positive culture, PCR, antigen, or bronchoalveolar lavage (BAL) fluid.[222-225] A review of the published CMV literature since 1995 found no advantage of prophylactic treatment over preemptive treatment in response to screening tests.[225] Moreover, this review found that preemptive therapy based on PCR tests or antigen assay was superior to culture- or BAL-based strategies. Both ganciclovir and foscarnet are considered to be first-line therapy for CMV reactivation or treatment of CMV disease.[226] Ganciclovir and foscarnet are similar in efficacy and primarily differ in terms of side effect profile.[227] CMV-seropositive patients undergoing autologous HSCT have not generally received either screening or prophylaxis,[226] although CMV reactivation and even disease occurs in a small percentage of these patients.

Up to 50% of patients undergoing either autologous or allogeneic HSCT experience reactivation of varicella-zoster virus, usually within the first year after SCT.[228] The vast majority of patients respond to acyclovir treatment. In children, the onset may be earlier, with most disease limited to the skin and few cases of visceral involvement. In general, pediatric patients respond well to antiviral therapy, and fatalities are rare.[229,230] Varicella vaccination is not currently recommended for patients after autologous or allogeneic HSCT. A pilot study of the live attenuated vaccine in autologous patients found the vaccine to be safe, but efficacy data are still pending.[231]

Fungal infection remains a significant problem, especially in those receiving steroids for treatment or prophylaxis of GVHD. A randomized trial demonstrated that prophylactic administration of fluconazole for 75 days after allogeneic HSCT yields ongoing protection against disseminated candidal infections and improved survival.[232] However, prophylactic fluconazole has been associated with the emergence of resistant species such as *Candida krusei*.[233] Low-dose amphotericin B has also been used prophylactically and is as effective as fluconazole, but more toxic.[234] The use of liposomal amphotericin has improved the toxicity profile.[235]

All HSCT patients are at risk for infection with *Pneumocystis carinii* after transplantation. Standard practice is to administer prophylaxis to recipients of autologous HSCT for 6 months after day 0 and for 6 months after discontinuation of immunosuppression for recipients of allogeneic transplants.

Nutrition Support

Provision of nutritional support during HSCT requires an appreciation of the metabolic needs of the individual patient, which are influenced by body composition, underlying nutritional state, and complications of transplantation. Patients who are underweight have been shown to be at higher risk for death than patients of normal weight in the early period after transplantation.[236] The impact of obesity on transplant outcome is debated, with some studies noting no effect and others reporting lower survival in obese patients.[236-238] Both the direct effects of conditioning regimens (mucositis) and complications of HSCT (GVHD, VOD, infection) can induce gastrointestinal damage that compromises the nutritional status of HSCT patients. Enteral feeding has been shown to be effective and safe and to have fewer complications than parenteral nutrition (PN) during HSCT, but it is not always practical for children.[239-241] Several studies have demonstrated the efficacy of PN when enteral nutrition is no longer possible.[242-244] However, in addition to expense, PN has attendant potential complications, including vascular access difficulties, induction of cholestasis, and the potential for hyperglycemia and hyperlipidemia. Thus, the best approach may be to reserve PN for patients unable to tolerate enteral feeding[245]; the occasional patient may be able to maintain nutritional needs orally throughout the transplantation period. Resumption of enteral feeding should be encouraged, and continued monitoring of nutritional intake and weight is necessary not only through engraftment but also after discharge from the hospital. Malnutrition appears to be relatively frequent after HSCT, and even patients with minimal or no GVHD may have significant and pro-

longed nausea, anorexia, feeding intolerance, and other nutritional problems.

EARLY COMPLICATIONS OF STEM CELL TRANSPLANTATION

Veno-occlusive Disease of the Liver (Sinusoidal Obstruction Syndrome)

VOD, also known as sinusoidal obstruction syndrome, is a clinical syndrome characterized by hepatomegaly, right upper quadrant pain, jaundice, and fluid retention.[246-248] VOD can be a complication of both autologous and allogeneic SCT[247,249-251] and is the result of chemotherapy/radiation-mediated endothelial and hepatocyte damage.[247,250,252,253] Injury to the sinusoidal endothelial cells and hepatocytes in zone 3 of the liver acinus appears to be the initial event and is marked by subendothelial edema and endothelial cell damage with microthromboses, fibrin deposition, and the expression of factor VIII/von Willebrand factor within venular walls.[254] Later features include deposition of collagen within venular lumens and eventual obliteration and hepatocyte necrosis.[252,255,256] Identified risk factors for VOD include previous chemotherapy regimens that include gemtuzumab, ozogamicin, or busulfan-based conditioning regimens (especially when combined with cyclophosphamide and methotrexate); underlying diseases associated with intensive chemotherapy, including advanced-stage malignancies; total PN for longer than 30 days; higher concentrations of certain chemotherapeutic agents; and unrelated donor transplantation.[249,250,255,257-266]

Hepatomegaly and right upper quadrant pain with fluid retention are the first clinical manifestations of VOD and typically occur 10 to 20 days after chemotherapy.[250] These findings are followed shortly by other clinical indicators of disease, including hyperbilirubinemia, peripheral edema, ascites, sodium avidity, and pulmonary infiltrates/effusion/edema.[247,250] Patients with VOD are at increased risk for renal insufficiency and failure.[250,267] Frank hepatorenal syndrome occurs in approximately half of patients with severe disease,[250] and there are often associated changes in mental status. It is hypothesized that portal hypertension from sinusoidal injury leads to decreased renal perfusion and tubular injury resulting in renal insufficiency.[250,267,268]

Exclusion of other causes of the signs and symptoms of VOD is essential in establishing the diagnosis. Liver biopsy is the gold standard for diagnosis of VOD and, in conjunction with hepatic venous pressure measurements, can provide valuable diagnostic information but unfortunately is associated with considerable morbidity in this population.[269,270] Hepatic venous pressure gradients greater than 10 mm Hg are specific for a diagnosis of VOD but are not highly sensitive.[269] Computed tomography (CT) can be useful in identifying features suggestive of VOD, such as periportal edema, ascites, and a narrow right hepatic vein.[271] The utility of hepatic Doppler ultrasound for the diagnosis of VOD is variable; at times, findings are nonspecific and not always noted early in the disease.[272,273] The presence of ascites, gallbladder wall thickening, hepatomegaly, decreased or reversed flow in the portal vein, and increased mean hepatic artery resistive index is supportive, but not necessarily diagnostic of VOD.[247,272-276] When clinical concern for VOD is high and a liver biopsy is not practical, serial ultrasound can be diagnostically helpful.

Reported overall survival rates for pediatric patients with established VOD range between 50% and 100%.[249,258,264,265,277-280] Reported predictors of mortality for children with VOD include allogeneic transplantation from donors other than matched siblings, concomitant moderate to severe hepatic or cutaneous GVHD, and more severe VOD (higher peak bilirubin, higher maximal weight gain, presence of pleural effusion, requirement for intensive care unit admission).[249,258]

Treatment and prophylactic options for patients with VOD remain limited. The most straightforward preventive technique is to identify patients at highest risk and to consider alternative conditioning regimens when feasible.[246-248] Ursodeoxycholic acid has been used as a preventive agent with inconclusive results.[281-287] Other preventive strategies such as the use of fresh frozen plasma, prostaglandin E_1, N-acetylcysteine, and antithrombin III are potentially effective but need further study.[288-295] Because 70% to 80% of patients recover spontaneously, supportive care with meticulous fluid and blood product management is the mainstay of therapy.[296] Based on histologic observations of microthrombi and fibrin deposition coupled with laboratory evidence of abnormalities of the coagulation cascade, many therapeutic strategies have been directed at promoting thrombolysis or fibrinolysis.[295,297-301] Multiple small studies have investigated the use of thrombolytic agents and anticoagulants (typically tissue plasminogen activator and heparin) for the prevention or treatment of VOD (or both).[295,297-299,302,303] Although these strategies appear to generally be safe, they have not decreased the incidence or improved the outcome of patients with severe disease and have been associated with serious bleeding in some cases.[288,297-299,304-311] Defibrotide, a single-stranded polydeoxyribonucleotide that has antithrombotic and thrombolytic activity, has been demonstrated to be effective for both prevention and treatment of VOD with minimal toxicity.[312-319] Response rates between 35% and 50% have been reported for patients with severe VOD treated with defibrotide.[315,320,321] Surgical intervention is uncommonly used for the treatment of VOD. Liver transplantation has resulted in clinical improvement in about 30% of the small numbers of patients stable enough to undergo the procedure, although the immediate and long-term issues are formidable.[322] Transjugular intrahepatic portosystemic shunting (TIPS) has been performed safely in patients with severe VOD, but it has not been shown to improve overall survival and should be reserved for

instances in which fluid retention and ascites are relatively isolated issues.[323-328]

Graft Rejection

Primary graft rejection, defined as failure to recover hematopoietic function of the stem cell graft by day 30, is an uncommon, life-threatening event that occurs after approximately 4% of unrelated donor stem cell transplants and is even less common in related donor transplants.[329] It is an immune-mediated process that occurs because of genetic disparity between the donor and recipient.[22,330,331] Although both donor NK and T cells are considered mediators of graft rejection, it is characterized by the presence of recipient T cells and the absence of donor cells.[332-339] The risk of graft rejection is increased in patients who are mismatched at the HLA-A, HLA-B, or HLA-DRB1 loci; receive a low cell dose; have a positive crossmatch for antidonor lymphocytotoxic antibody; receive T-cell depletion as GVHD prophylaxis; have aplastic anemia, especially if previously multiply transfused; or have storage disorders or osteopetrosis.[329] An altered host microenvironment can also contribute to graft rejection.

Adjustments in both the chemotherapy and radiotherapy components of conditioning regimens, the use of monoclonal antibodies targeting selected populations of recipient T cells, and increases in cell dose (including the use of PBSCs in addition to bone marrow) are among the interventions that have shown some promise in preventing graft rejection. Depletion of host T cells with antithymocyte globulin (ATG) and the use of CD52 monoclonal antibodies are commonly used approaches.[340,341] A number of strategies have been exploited to overcome the increased incidence of graft failure associated with T-cell depletion. First, simply increasing the number of stem cells in the graft has been successful, thus implying that residual host hematopoietic elements are involved in mediating graft rejection. However, such intensification is associated with increased GVHD. Additionally, because the risk of graft failure appears to increase with more exhaustive T-cell depletion, less extensive T-cell removal from the graft with and without T-cell add-back has been attempted.[342-345]

Therapeutic options for patients with graft rejection include a second allogeneic transplantation, infusion of frozen autologous stem cells, use of hematopoietic growth factors, particularly granulocyte-macrophage colony-stimulating factor (GM-CSF), modification of the host's immunologic status, and infusion of donor leukocytes.[231,346-351] Infusion of stem cells with or without additional conditioning can be an effective intervention for the treatment of primary graft failure.[352] It has been studied with bone marrow or PBSCs, although recently the use of unrelated cord blood units[352-355] has been explored. The use of allogeneic PBSCs is appealing in the second transplant setting because PBSCs have been associated with a shorter duration of neutropenia and a higher neutrophil recovery rate.[346] Graft rejection is a potentially morbid, uncommon complication of HSCT with limited effective therapies. Patients exhibiting signs of graft rejection should be identified as early as possible to maximize potential therapeutic options.

Acute Graft-versus-Host Disease

Grafts from genetically disparate donors, specifically, any donor other than self or an identical twin, can initiate an immune reaction termed *acute graft-versus-host disease*.[356] In general, the greater the degree of genetic difference between the donor and recipient, the higher the risk and severity of aGVHD. The main genetic loci that determine the compatibility of donor and recipient are HLA I and II located on chromosome 6. Each of these loci encode polymorphic glycoproteins—major histocompatibility antigens—that are expressed on the surface of human tissues in a complex with small peptides from degraded intracellular proteins. T-cell receptors on the surface of T cells are finely tuned to recognize the "foreignness" of MHC molecules. Recipient T cells recognize donor antigens and can cause graft rejection. Conversely, donor T cells can recognize recipient antigens and are responsible for the syndrome of aGVHD. The mechanisms by which T cells cause GVHD include both direct effector mechanisms and release of inflammatory mediators that cause tissue damage. The presence of tissue damage either from immunologic events or from direct effects of conditioning can propagate the inflammatory response and trigger further immune responses in a positive feedback loop that has been termed a "cytokine storm."[357-359]

The syndrome of aGVHD was first reported by Barnes and Loutit in 1954.[6] They observed that skin abnormalities and diarrhea developed in lethally irradiated animals given allogeneic spleen cells and that the animals eventually succumbed to a wasting illness. It became clear that for aGVHD to develop, certain criteria had to be in place, and these were summarized by Billingham in 1966[360]: (1) "the graft must contain immunologically competent cells"; (2) "the host must possess important transplantation alloantigens that are lacking in the donor graft, so that the host appears foreign to the graft and is, therefore, capable of stimulating it antigenically;" and (3) "the host itself must be incapable of mounting an effective immunological reaction against the graft, at least for sufficient time for the latter to manifest its immunological capabilities; that is, it must have the security of tenure."

However, the allogeneic immunologic effect also confers potential benefits. Donor graft inocula contain immunologic cells—T cells, NK cells,[361] and possibly others—that are capable of recognizing malignant cells and mediating a GVL and, perhaps, a graft-versus-tumor effect.[362-364] Indeed, patients with hematologic malignancies in whom mild to moderate GVHD develops have a decreased risk for disease relapse.[365-368] Conversely, T-cell depletion from the marrow inocula reduces the risk for

GVHD but can lead to an increased risk for both graft rejection and disease recurrence.[369] The ability to distinguish the populations of T cells that mediate GVHD from those that mount a GVL response remains a central goal in GVHD research.[370] For instance, a well-characterized population within the CD4+ T-cell compartment that constitutively expresses the interleukin-2 (IL-2) receptor α chain (CD25) and the transcription factor FOXP3 has been observed to have marked immunosuppressive activity in vitro and in vivo.[371-373] This cell population, termed regulatory T cells, is able to minimize GVHD in an animal model while retaining the graft-versus-tumor effect of the allogeneic graft. The ability to select and expand[374] human regulatory T cells offers the possibility of a novel approach to mitigating GVHD.

The clinical syndrome of aGVHD develops within 100 (and usually within 60) days of allogeneic SCT. cGVHD is a distinctive clinical syndrome that occurs after day 100 and is discussed later. aGVHD classically involves the skin, liver, and lower gastrointestinal tract, although the degree of involvement of each organ varies. For that reason, the severity of aGVHD is graded by staging the involvement of individual organs and the

clinical performance of the patient and then determining an overall grade for the disease. Table 9-1 presents the modified Glucksberg criteria, introduced in 1974,[375] and with several revisions and additions,[376-379] this is the system historically used for assessing aGVHD. As newer methods of both preventing and treating aGVHD were developed, there was concern about the ability of the Glucksberg stage to accurately reflect transplant outcomes. The International Bone Marrow Transplant Registry (IBMTR) constructed a severity index based on organ involvement alone with no need for subjective assessment of performance. This has been shown to correlate well with outcome and is the staging system used in most current studies (Table 9-2).[380]

The first manifestation of GVHD is often a rash, usually a maculopapular eruption commonly involving the palms and soles and the back of the neck and ears at first and later the trunk and extremities. Biopsy specimens from involved areas demonstrate epidermal basal cell vacuolization, followed by epidermal basal cell apoptotic death with lymphoid infiltration.[381] Characteristic eosinophilic bodies may be seen. Unfortunately, the specificity of skin biopsy is not high and it is often unable to

---

TABLE 9-1   Glucksberg Criteria for Staging and Grading of Acute Graft-versus-Host Disease

Organ	Stage	Extent of Organ Involvement
Skin	1	<25%
	2	25%-50%
	3	Generalized erythema
	4	Desquamation, bullous
Liver bilirubin	1	2-3 mg/dL*
	2	3.1-6 mg/dL
	3	6.1-15 mg/dL
	4	>15 mg/dL
Gastrointestinal (children)	1	10-15 mL stool/kg/day
	2	16-20 mL stool/kg/day
	3	21-25 mL stool/kg/day
	4	>25 mL stool/kg/day; severe pain with or without ileus
Gastrointestinal (adult)	1	500-1000 mL stool/day; nausea, anorexia
	2	1000-1500 mL stool/day; histologic diagnosis† of upper gastrointestinal graft-versus-host disease
	3	1500-2000 mL stool/day
	4	>2000 mL stool/day; ileus, severe pain

Overall Clinical Grade	Organ System	Clinical Stage
I (mild)	Skin	1-2
	Liver	1
	Gastrointestinal	0
II (moderate)	Skin	1-3
	Liver	1-2
	Gastrointestinal	1
III (severe)	Skin	2-4
	Liver	2-4
	Gastrointestinal	2-4
IV (life threatening)‡	Skin	2-4
	Liver	2-4
	Gastrointestinal	2-4

†Data from Weisdorf DJ, Snover DC, Haake R, et al. Acute upper gastrointestinal graft-versus-host disease: clinical significance and response to immunosuppressive therapy. Blood. 1990;76:624-629.
‡With severe constitutional symptoms.

TABLE 9-2	International Bone Marrow Transplant Registry Severity Index for Acute Graft-versus-Host Disease			
Severity Index	Maximum Organ Stage	RR of Treatment-Related Mortality (95% CI)	RR Treatment Failure (95% CI)	Glucksberg
0	No GVHD	1.00	1.00	0
A	Skin only stage 1	0.84 (0.6, 1.18)	0.85 (0.68, 1.05)	I
B	Any organ stage 2*	1.90 (1.5, 2.42)	1.21 (1.02-1.43)	I, II, III, IV
C	Any organ stage 3	4.34 (3.33, 5.67)	2.19 (1.78, 2.71)	II, III, IV
D	Any organ stage 4	11.9 (9.12, 15.5)	5.68 (4.57, 7.08)	IV

*Any organ stage 1 other than skin alone (e.g., skin 1, gut 1 = severity index B).
CI, confidence interval; RR, relative risk.

differentiate GVHD from drug allergy or reaction to the conditioning regimen.[382] Bulla formation with epidermal separation and necrosis is seen in advanced stages of skin GVHD.[383] Hepatic GVHD is often manifested as cholestatic jaundice, which must be differentiated from VOD, infection, and drug toxicity.[384,385] Though not without attendant risks of bleeding and pain, liver biopsy may be helpful because characteristic pathologic changes can be observed that aid diagnosis.[386,387] Gastrointestinal involvement is classically seen as watery diarrhea with a "seedy" component and may progress to include crampy abdominal pain, bleeding, and even ileus.[384,385] By convention, stool volume is used to quantitate the severity of gut involvement. Rectal or colonic biopsy may reveal crypt cell necrosis with lymphocytic infiltration and, with increasing severity, crypt abscess or loss and mucosal denudation.[388] These three organs are staged individually for the severity of involvement, after which an overall grade of GVHD is assigned according to criteria developed by Glucksberg and co-workers (see Table 9-1) or the IBMTR (see Table 9-2). However, other clinical findings may be indicative of aGVHD. Involvement of the upper gastrointestinal tract is manifested by symptoms of anorexia, inanition, and vomiting.[378] The differential diagnosis of such symptoms also includes viral or fungal infection, dyspepsia, and gastritis, all common conditions in an immunosuppressed SCT recipient. Endoscopy of the upper gastrointestinal tract with biopsy is minimally invasive and can detect the presence of crypt cell apoptosis with dropout, which is diagnostic of GVHD. Finally, pulmonary involvement with effusions and vascular leak may accompany aGVHD.

Several risk factors for the development aGVHD have been identified. Increasing genetic disparity between the donor and host increases the incidence and severity of GVHD[389-392] and is the most important single predictor of aGVHD. More recently, other genetic risk factors have been evaluated. The existence of polymorphisms in genes between the donor and host offers a plausible mechanism to explain variations in the magnitude of the inflammatory response to tissue injury and hence GVHD. Indeed, specific polymorphisms in the recipient IL-10 promoter region and IL-10 receptor β gene have been found to be associated with a lower rate of GVHD.[393]

Many other candidate genes are currently being examined for similar associations. Moreover, the falling cost and growing scale of genomic sequencing technologies suggest that an increasingly complex and accurate genomic prediction of risk for GVHD is likely to evolve over the coming years.

Other factors increasing the risk for GVHD include older age of the recipient,[390,394,395] use of a female donor for a male recipient, use of parous female donors, and history of previous herpesvirus infection in the recipient.[390,391,394,396] The source of allogeneic stem cells may also affect the risk for subsequent GVHD. For example, the number of T cells collected during pheresis is significantly greater than the number collected during bone marrow harvest. Nonetheless, it appears that the rate of severe aGVHD in patients receiving T-cell–rich PBSCs with standard GVHD prophylaxis may not be greater than that seen after BMT.[124,130,397] Results from large series indicate that there may be a decrease in the severity of aGVHD in UCB transplants.[26,145-147] The reason for this has not been completely elucidated but may be related to the putative relative immunologic "naïveté" of the immune cells contained in the cord graft, or more likely, the lower T-cell dose.

Therapeutic strategies aimed at the prevention (prophylaxis) of aGVHD begin with selection of the best available donor. When a matched sibling donor is not available, HLA matching via molecular techniques is the single most important factor in preventing severe GVHD.[392,398] Considerations of donor sex and parity are advisable if there is a choice of donors. If the patient is seronegative for CMV, use of a CMV-negative donor appears to reduce the risk of GVHD, as well as CMV, after transplantation.[396] Whether the source of HSCs (i.e., bone marrow, PBSCs, UCB) modifies the risk for aGVHD is an area of controversy. Supportive care measures such as the use of protective isolation and gut decontamination also protect against the development of GVHD.[399-401]

Conventional prophylactic approaches have attempted to inhibit T-cell responses by relying on in vivo immunosuppression. Essentially all current pharmacologic regimens use combinations of immunosuppressive agents that target different molecular intermediates of T-cell

signaling. Cyclosporine (Sandimmune) and tacrolimus (Prograf) both inhibit calcineurin activity, a serine-threonine phosphatase whose activity is essential for T-cell cytokine transcription.[402] Methotrexate prevents T-cell proliferation,[403] whereas high-dose corticosteroids are lympholytic. Current combinations use cyclosporine or tacrolimus plus methotrexate or prednisone (or both).[404-406] A common prophylactic regimen includes cyclosporine given intravenously at a dose of 1.5 mg/kg every 12 hours until oral administration every 12 hours is tolerated. Doses are adjusted to achieve desired blood levels. Cyclosporine is continued on a tapering schedule through day 180 after transplantation. Methotrexate is given at 15 mg/m^2 on day 1 and at 10 mg/m^2 on days 3, 6, and 11 after marrow infusion. This regimen has been shown to reduce the incidence and severity of aGVHD and improve long-term survival when compared with single-agent therapy in comparable patient cohorts.[407,408] Combinations using newer immunosuppressive agents, such as sirolimus, are also being developed.[409]

As discussed earlier, selective depletion of T lymphocytes from the donor marrow inocula effectively prevents GVHD. T cells can be removed by a variety of techniques, including lectin depletion, anti–T-cell monoclonal antibodies plus complement, coupling with immunotoxin derivatives, or purging with magnetic beads. Each of these techniques may effect up to a 3 log or greater depletion of T cells. Unfortunately, T-cell depletion is associated with an increased risk for graft failure, delayed immune reconstitution, post-SCT lymphoproliferative disease, and in patients with hematologic malignancies, leukemic relapse.[366] Thus, the long-term survival rates of patients who have received T-cell–depleted grafts are similar to those of patients who have received conventional in vivo immunosuppression after transplantation.[410,411] Strategies using "add-back" of donor T cells at various time points after SCT are being explored,[412-415] and the ultimate role of T-cell depletion in SCT has not been completely resolved.

The outcome and long-term survival of patients with aGVHD vary directly with the grade of GVHD and response to treatment. The mainstay of therapy for established aGVHD remains glucocorticoids. Glucocorticoids (generally methylprednisolone) have been used in a variety of schedules and doses.[404,416] The lympholytic effects of very-high-dose corticosteroids must be balanced against the increased risk of infections,[417] and doses higher than 2 mg/kg/day may not increase efficacy.[418] Patients failing to improve or progressing with corticosteroid therapy have been given a variety of other immunosuppressive agents, but secondary treatment of GVHD is often unsuccessful.[419] Generally, cyclosporine is continued at therapeutic levels in patients in whom aGVHD develops, and it may be initiated in patients who have never received the drug. ATG, extracorporeal photochemotherapy,[420] newer immunosuppressive agents such as mycophenolate mofetil,[421] and methods targeting CD5, CD3, IL-2 receptor,[379] and tumor necrosis factor-α

and its receptor have all been attempted with varying, incomplete, or unpredictable responses. Novel and reproducible methods of approaching the treatment of patients with corticosteroid-resistant aGVHD that do not compromise the ability to mount an immune response against infection are needed because the outcome for these patients remains poor.

DELAYED COMPLICATIONS OF TREATMENT

The use of both autologous and allogeneic transplantation for an increasing number of malignant and nonmalignant conditions coupled with marked improvements in supportive care has resulted in a substantial number of long-term survivors. Thus, delayed complications secondary to both the chemoradiotherapy used to prepare patients for SCT and the transplant process itself (e.g., GVHD and propensity for infection) are becoming better defined with regard to incidence, severity, and outcome. It is essential that follow-up occur in conjunction with HSCT specialists so that as consensus statements regarding post-HSCT care are developed, they can be implemented for all patients.

Chronic Graft-versus-Host Disease

GVHD was initially characterized as taking place in two phases: aGVHD generally occurred within the first 100 days after transplantation, whereas cGVHD occurred after day 100 (Table 9-3). It has become evident that certain cases of cGVHD, defined by both clinical and histopathologic criteria, can occur as early as day 50 to 60 after marrow infusion.[422] The pathogenesis of cGVHD is not completely elucidated. It is thought to involve

TABLE 9-3	Comparison of Acute and Chronic Graft-versus-Host Disease	
	Acute GVHD	**Chronic GVHD**
Onset day	7-60 (up to 100)	Day >100 (may be seen from day 60 on)
Manifestations:		
Skin	Erythematous rash	Sclerodermatous changes
Gut	Secretory diarrhea	Dry mouth; sicca syndrome Malabsorption
Liver	Hepatitis/ cholestasis	Cholestasis/ cirrhosis
Other	Fever	Pulmonary dysfunction Alopecia Thrombocytopenia Xerostomia

donor T-cell recognition of minor histocompatibility antigens or loss of peripheral T-cell tolerance leading to symptoms that are very similar to those present in autoimmune disorders. The morbidity and mortality of cGVHD are most severe in patients who have progressive disease after aGVHD and tend to be less severe in those in whom it occurs de novo.[423] Risk factors for the development of cGVHD include HLA disparity between donor and host, previous aGVHD, increasing patient age, and a TBI-based conditioning regimen. A recent review of risk factors in children found that patient age older than 15 years or donor age older than 5 also significantly increases risk.[424] In addition, the use of adult female donors for male recipients increases the likelihood of cGVHD, probably related to donor antibody responses to antigens coded for by genes on the recipient Y chromosome[425]; the impact of pediatric female donors on the incidence of cGVHD has not been evaluated.

cGVHD is a constellation of clinical and pathologic features. The syndrome resembles autoimmune systemic collagen vascular diseases, with protean manifestations potentially involving almost every organ (Table 9-4). Pathologic changes in the skin result from epithelial cell damage characterized by basal cell degeneration and necrosis and, later, epidermal atrophy and dermal fibrosis.[426] Skin involvement may be manifested as lichen planus, areas of local erythema, and areas of hyperpigmentation or hypopigmentation. The skin may be dry, freckled, or ulcerated, and findings are aggravated by exposure to sunlight. Sclerodermatous changes may evolve to flexion contractures that can greatly impair function and may be helped by surgical release procedures. Hair follicles can be involved, with resulting partial or total alopecia. Ocular abnormalities are common and consist of sicca syndrome, including dry eyes and photophobia; decreased tearing is quantitated by the Schirmer test. Dry mouth is a common initial complaint of patients with oral GVHD, and decreased saliva production predisposes to caries. Tongue depapillation or scalloping of the lateral margins of the tongue can be seen. The tongue, buccal mucosa, and gums may have lichen planus–like lesions, which must be differentiated from oral candidiasis. A biopsy specimen typically shows lichenoid changes with epithelial cell necrosis, salivary gland inflammation, lymphocytic infiltrates, and fibrosis. Involvement of the liver with cGVHD is manifested as lymphocytic portal triaditis with resulting obstructive jaundice, which may progress, if untreated, to bridging necrosis and cirrhosis. Gastrointestinal signs include inanition with progressive weight loss, chronic malabsorption, diarrhea, anorexia, nausea, and vomiting. Biopsy demonstrates single-cell apoptosis with crypt destruction and may show fibrosis of the lamina propria. Early cGVHD may be manifested as diffuse myositis and tendonitis. Progressive joint involvement, which may result from the myositis and tendonitis or simply from overlying skin fibrosis, results in decreased range of motion and flexion contractures. Perhaps the most debilitating effect of cGVHD occurs

TABLE 9-4	Clinicopathologic Features of Chronic Graft-versus-Host Disease
System	**Features**
Systemic	Recurrent infections with immunodeficiency Weight loss Sicca syndrome Debility

Skin	Lichen planus, scleroderma, hyperpigmentation or hypopigmentation
	Dry scale, ulceration, erythema, freckling
	Flexion contractures
	  Biopsy:
	    Epithelial cell damage
	    Basal cell degeneration and necrosis
	    Epidermal atrophy and dermal fibrosis

Hair	Alopecia

Mouth	Sicca syndrome, depapillation of the tongue with variegations and scalloping of the lateral margins
	Lichen planus and ulcer, angular tightness
	  Biopsy:
	    Lichenoid changes with mononuclear infiltrates
	    Epithelial cell necrosis
	    Salivary gland inflammation, lymphocytic infiltrate, fibrosis

Joints	Decreased range of motion, diffuse myositis/tendonitis
Eyes	Decreased tearing; injected sclerae, conjunctivae

Liver	Increase in alkaline phosphatase greater than increase in transaminases and bilirubin
	Cholestasis, cirrhosis
	  Biopsy:
	    Focal portal inflammation with bile ductule obliteration
	    Chronic aggressive hepatitis
	    Bridging necrosis
	    Cirrhosis

Gastrointestinal	Failure to thrive (children), weight loss (adults)
	Esophageal strictures, malabsorption, chronic diarrhea
	  Biopsy:
	    Crypt destruction, single-cell dropout
	    Fibrosis of the lamina propria

Lung	Cough, dyspnea, wheezing Bronchiolitis obliterans or restrictive pulmonary change Pneumothorax
Hematology	Refractory thrombocytopenia Eosinophilia Howell-Jolly bodies

Box 9-2	**Staging of Chronic Graft-versus-Host Disease**

LIMITED CHRONIC GVHD

Localized skin involvement and/or
Hepatic dysfunction secondary to chronic GVHD

EXTENSIVE CHRONIC GVHD

Generalized skin involvement or
Localized skin involvement or hepatic dysfunction (or
   both) as a result of chronic GVHD plus
     Liver histology showing chronic aggressive hepatitis,
       bridging necrosis, cirrhosis, or
     Eye involvement: Schirmer test (<5-mm wetting), or
     Involvement of minor salivary glands or oral mucosa
       demonstrated by buccal biopsy, or
     Involvement of any other target organ

with pulmonary involvement, manifested as obstructive lung disease progressing to bronchiolitis obliterans (discussed later). Persistent immunodeficiency with profoundly depressed B- and T-cell responses predisposes to recurrent and severe infections. Patients may have reduced IgG2 and IgG4, decreased mucosal IgA, diminished delayed-type hypersensitivity, and functional asplenia. They remain susceptible to opportunistic infections with encapsulated organisms (primarily pneumococcus), *P. carinii*, varicella-zoster, and herpes simplex and may have a variety of chronic infections, including sinusitis, bronchitis, and conjunctivitis.[427]

Staging of cGVHD is based on the degree of organ involvement (Box 9-2). Limited cGVHD has localized skin involvement with or without hepatic dysfunction. All other manifestations of cGVHD are classified as extensive cGVHD.[426] Limited cGVHD may resolve spontaneously without specific therapy, and these patients have a favorable outcome.[423] Patients with lichenoid skin changes, progressive changes of cGVHD, thrombocytopenia, hyperbilirubinemia, or any combination of these findings have a worse prognosis.[427,428] Recent work has focused on developing a more detailed comprehensive scale to measure symptoms of cGVHD so that response to therapy can be more clearly assessed.[429]

It is essential that patients with cGVHD be managed by a multidisciplinary team with expertise in this complicated and often frustrating condition. Steroids are usually the first approach to therapy, and a regimen of alternating-day cyclosporine and prednisone was shown to be effective in more than half of patients and to have an acceptable toxicity profile.[430] There is no standard approach for patients who are refractory to initial therapy or whose disease flares during taper of immunosuppression.[428] A number of other therapies are being tested, including high-dose pulse steroids,[431] extracorporeal photopheresis,[432] daclizumab (a humanized IL-2 receptor antagonist),[433] mycophenolic acid,[434] rapamycin,[435]

and pentostatin.[436] All of the therapeutic options have a significant impact on immune function, and most fatalities occur from infectious complications as opposed to specific organ toxicity from cGVHD. Meticulous and preemptive management of the complications associated with cGVHD and its therapy is a crucial component of care. Recommendations for patient education, prophylactic interventions, and follow-up are extensively outlined in the Ancillary Therapy and Supportive Care Working Group document of the National Institutes of Health.[437]

Ophthalmologic Problems

A number of different ophthalmologic complications can occur as sequelae of HSCT. Decreased lacrimation secondary to cGVHD may contribute to ocular sicca syndrome and the related complications of photophobia, punctate keratopathy, scar formation, and corneal perforation. Therapy includes artificial tears and lacrimal duct (punctual) plugging, which can be useful even in young children. Patients remain at risk for ocular infections, particularly with herpes simplex viruses. Cyclosporine use is associated with a number of eye complaints, including a well-described syndrome of headache, hypertension, seizures, visual impairment, or any combination of these symptoms, as well as temporary blindness (see "Neurologic Complications" for a detailed description).[438-440] In addition, transplant-related retinopathy can be manifested as optic disc edema, either asymptomatic or accompanied by visual blurring, in patients taking cyclosporine. Ischemic fundal lesions, detected as cotton-wool spots and, in some patients, as optic disc edema, have been reported in patients treated with both TBI and cyclosporine and were not observed in patients who did not have concordance for these risk factors.[441,442] Lesions appeared 3 to 6 months after SCT, with complaints of decreased visual acuity or other visual disturbances. Most patients discontinued cyclosporine, and half were treated with systemic corticosteroids. The majority recovered visual acuity and their ischemic lesions resolved over time, but little further information is available about the course or long-term prognosis of this complication. Occlusive microvascular retinopathy has also been described after autologous SCT in patients receiving high-dose cytarabine and TBI, thus suggesting that particular high-dose chemotherapy regimens may predispose to vascular injury at otherwise safe radiation doses.[443]

Cataracts are a common complication of HSCT. Radiation—TBI, cranial irradiation, or both—is a well-described predisposing factor. Although historically the incidence was as high as 80% in patients receiving single-dose TBI, patients receiving fractionated TBI or chemotherapy-only regimens still have a 20% to 50% incidence of cataracts 5 to 6 years after transplantation.[444,445] The relative risk of cataracts and the need for subsequent cataract surgery may also be related to

previous therapy or to glucocorticoid use for prophylaxis or management of GVHD. Overall, reports of large pediatric populations have shown that some type of ophthalmologic abnormality occurs in up to 50% of patients, although visual function remains excellent in virtually all patients.[446-448] Thus, yearly examination by an ophthalmologist is essential, including a Schirmer test to rule out xerophthalmia and a thorough retinal evaluation.

Dental Problems

Disturbances in dental development have been described in children conditioned with TBI, particularly if HSCT took place before 6 years of age.[449,450] Characteristic findings include short dental roots, absence of root development, and microdontia. A review of 52 pediatric patients younger than 10 years at HSCT found that all patients had disturbances in dental root growth, with the most pronounced changes occurring in those 3 to 5 years old at the time of transplantation.[451] Subsequent decreased alveolar bone growth may lead to further compromise of dental development. In addition, oral sicca syndrome (occurring as a complication of either TBI or cGVHD, or both) may result in chronic oral mucosal injury, poor oral hygiene, and subsequent dental decay.[452] The effects of prophylactic interventions are not well reported, but yearly evaluation by a dentist knowledgeable about potential HSCT-related issues is recommended.

Pulmonary Complications

Pulmonary dysfunction of both a restrictive and obstructive nature occurs in approximately 25% of pediatric HSCT patients.[453] Pulmonary complications can be seen after both autologous and allogeneic transplants; however, serious pulmonary dysfunction is more common in the allogeneic setting. Patients with pulmonary complications are known to have higher overall mortality.[453] Obstructive lung disease has been reported in up to 20% of children after allogeneic HSCT, comparable to the incidence in adult patients. Bronchiolitis obliterans (BrOb) is a noninfectious, potentially life-threatening complication of HSCT that has been reported to occur in approximately 8% of allogeneic pediatric HSCT patients.[454] It is a pathologic process that leads to obstruction and eventual obliteration of the small airways.[455] There is characteristic chronic airflow obstruction unresponsive to bronchodilator therapy.[456] The etiology of BrOb is not fully understood. It is thought that immune dysregulation and inflammation are precipitating factors in its development, a theory supported by the association between the syndrome and cGVHD.[457,458] Although BrOb has been most firmly associated with cGVHD, viral infections before day 100 and gastroesophageal reflux have also been identified as risk factors.[456,458-460] Patients typically exhibit dyspnea on exertion and cough, with pulmonary function tests revealing an obstructive pattern. High-resolution CT has been shown to have findings

that are both sensitive and specific for BrOb in this population.[461,462] Characteristic findings include air trapping, a mosaic pattern of lung attenuation, and bronchiectasis.[461-463] BrOb is traditionally treated with immunosuppressive agents. Azithromycin has been shown to be a useful adjunct, presumably because of its anti-inflammatory and antibiotic mechanisms of action.[464] Published mortality rates for BrOb after HSCT range between 20% and 100%.[456] The prognosis depends in part on disease tempo and response to first-line therapy.[456,465] Rapid onset and lack of response to steroids define a group of patients with a particularly poor outcome.[465]

Restrictive and diffusion abnormalities have been reported in pediatric patients after SCT.[466,467] These findings may improve over time but do not usually normalize.[466] Risk factors for restrictive lung disease include sclerodermatous-type GVHD, single-fraction TBI, abnormal chest wall growth secondary to radiation, and certain chemotherapeutic agents.[467-472] Treatment depends on the underlying etiology of the pulmonary disease. Because restrictive changes can be asymptomatic, defining the true incidence of this complication depends on the intensity of post-SCT follow-up.

Hematologic Complications

Patients who undergo ABO-incompatible allogeneic HSCT are at risk for immune hemolytic anemias. In the setting of major ABO incompatibility (recipient O and donor A or B, for example), preexisting patient isohemagglutinins can cause lysis of donor red cells. This can potentially cause an acute hemolytic reaction during stem cell infusion, and thus anti-A or anti-B isoagglutinins must be removed from the patient before infusion via pheresis or the stem cell product must undergo red cell depletion. Although the acute issues surrounding transplantation in the setting of major ABO incompatibility are easily managed and not associated with any impact on outcome, pure red cell aplasia may develop in up to a quarter of at-risk patients in the months after HSCT.[473] This occurs when long-lived patient lymphocytes continue to produce antibodies capable of destroying red cell precursors in the graft. Patients who are type O and donors who are type A are at greatest risk, presumably related to the level of isohemagglutinin titers.[474] A relationship of red cell aplasia to post-transplant immunosuppression with cyclosporine alone has been suggested because calcineurin inhibitors permit longer persistence of patient B cells than methotrexate does.[475] Some cases of aplasia will resolve spontaneously over time; plasma exchange with donor-type plasma replacement has also been used, and more recently rituximab, a chimeric anti–B-cell antibody, has been used with success.[476] Minor ABO incompatibility (patient A, donor O, for example) is managed by plasma depletion of the graft before infusion. This situation can also lead to low-level hemolysis in the first months after HSCT as newly formed B lym-

phocytes produce isohemagglutinins targeting residual patient red cells. Occasionally, in the months to years after transplantation, autoimmune hemolytic anemia, autoimmune thrombocytopenia, or autoimmune neutropenia develops as a result of immune dysregulation after HSCT. Steroids and intravenous immunoglobulin (IVIG) are usually the first therapeutic intervention, but rituximab has been used in this setting as well.[477]

A variety of microangiopathic syndromes have also been described after SCT. The use of cyclosporine for GVHD prophylaxis or treatment has been associated with both thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS), described in the next section.

Renal Complications

HUS may develop at a median of 5 months after HSCT.[478,479] This disorder is generally manifested as moderate hemolysis and renal dysfunction, although some patients have more aggressive findings consisting of severe hypertension and seizures. Factors implicated in the development of this syndrome include exposure to radiation and use of calcineurin inhibitors.[480,481] The majority of reported cases appear to resolve spontaneously over time, although modest persistent anemia and decrements in renal function have been described. TTP is rare in pediatric patients and may result from more pervasive endothelial damage than seen in HUS. It usually occurs in the first months after HSCT and can have associated fever, bloody diarrhea, and neurologic symptoms. Unlike classic TTP, HSCT-associated TTP is not accompanied by deficient von Willebrand multimer proteolysis, and plasma exchange therapy is generally unsuccessful.[482]

The incidence of chronic nephropathy is probably underestimated. Up to 25% of adults undergoing allogeneic HSCT were affected at 10 years; post-transplant hypertension was the most significant predictor of chronic kidney disease.[483] Assessment of renal function by determination of the glomerular filtration rate revealed renal impairment in 41% of pediatric patients 1 year after HSCT and in 11% at 7 years, with exposure to TBI being the most significant risk factor.[484] The long-term impact of transplantation on renal function in pediatric patients is not known,[485] but given the natural decline in renal function with age, monitoring function over time should be part of routine care for survivors of pediatric HSCT.

Neurologic Complications

Patients undergoing HSCT may experience a variety of neurologic complications either directly related to treatment, as a consequence of immunosuppression, or as a result of medications used in supportive care. Acyclovir is used for both prophylaxis and treatment of infection with herpes simplex viruses. Confusion, tremors, delusion, and psychosis have been associated with this drug.[486] Simi-

larly, mental status changes, paresthesias, and uncommonly, seizures have been reported with the antiviral agents ganciclovir and foscarnet.[487,488] Impaired renal function, often seen in HSCT patients, may potentiate the occurrence of these symptoms. Both prednisone and cyclosporine may have neurologic side effects. Mood swings or even frank psychosis accompanying corticosteroid therapy are well described.[489] Cyclosporine administration commonly produces an essential tremor. Seizures, visual disturbances, and encephalopathy are more significant but rarer neurologic complications.[490] It has been postulated that both seizures and acute visual loss arise from the hydrostatic changes accompanying cyclosporine-associated hypertension; as in preeclampsia, hypomagnesemia can be an aggravating factor. These changes affect white matter, most commonly in the occipital area, and are accompanied by characteristic radiologic findings on magnetic resonance imaging (MRI).[440,491] In general, symptoms abate rapidly on discontinuation or decreases in the dose of cyclosporine.[492]

Cerebrovascular accidents, including cerebral hemorrhage, may also be observed after SCT and are usually associated with refractory thrombocytopenia. Large intracranial hemorrhages are generally fatal[493]; patients with isolated subdural hematomas typically do well.[494]

Central nervous system (CNS) infectious complications related to immunosuppression, cGVHD, or both can arise after HSCT. The manifestations of CNS infection can differ from those in an immunocompetent patient in that localizing signs and symptoms may be less dramatic. Autopsy series demonstrate that up to 15% of necropsy patients harbor CNS infections, often clinically unsuspected.[495-497] *Aspergillus* species and *Toxoplasma gondii* are the most common organisms found.[498] Bacterial meningitis or encephalitis/meningoencephalitis caused by a variety of viruses, including CMV, herpes simplex types 1 and 6, adenovirus, and varicella-zoster, can also occur. Opportunistic CNS infections in HSCT recipients are often fatal,[498] and a high level of suspicion is warranted in patients with even minimal neurologic symptoms.

Leukoencephalopathy is a poorly understood sequela of HSCT that is manifested as progressive neurologic deterioration in the months after transplantation. Clinical findings include lethargy, slurred speech, ataxia, seizures, decreased sensorium, dysphagia, spasticity, or even decerebrate posturing. Consistent white matter changes are found on MRI. In a series of 415 patients from Seattle, leukoencephalopathy was observed in 7% of patients, but only in those who had received CNS radiation, intrathecal therapy, or both before HSCT in conjunction with intrathecal methotrexate after HSCT.[499] More recently, a 4% incidence of irreversible leukoencephalopathy was reported in children receiving cyclosporine; a third of the patients died during the period of neurologic decline.[500] Cyclosporine levels were usually therapeutic in the affected patients, and it remains unclear what the risk factors are for this rare but devastating complication.

The effects of different conditioning regimens on neuropsychological functioning have been incompletely investigated. In particular, analysis of very young patients is limited. Nonetheless, it is clear that a significant proportion of young children, including those younger than 2 years, can undergo HSCT with chemotherapy and TBI and subsequently have normal neurologic development,[501] perform well in areas such as sensorimotor and cognitive functioning,[502] and have no decrement in academic achievement.[503] Age at HSCT appears to be the most consistent risk factor predicting subsequent cognitive decline.[503,504]

Endocrine Disorders

Much of the endocrine dysfunction after HSCT results from irradiation and is attenuated in both incidence and severity when radiation is fractionated or when non–radiation-containing conditioning regimens are used. Thyroid dysfunction is one of the most frequent late complications of HSCT. After fractionated TBI, the incidence of compensated hypothyroidism ranges from 13% to 39% and that of overt hypothyroidism is around 15%, with diagnosis occurring at a median of 4 years after HSCT.[505-507] Patients treated with busulfan-based regimens have a lower, but still significant incidence of thyroid complications: 20% compensated and 9% overt hypothyroidism.[508,509] Given that the incidence of thyroid dysfunction increases over time, clinical suspicion and yearly monitoring of thyroid function tests are an important part of long-term care for these patients.

Linear growth after HSCT is hard to predict and is affected by many factors: previous therapy, particularly corticosteroids or cranial or spinal radiotherapy, age at transplantation, conditioning regimen, and development of cGVHD with associated long-term steroid exposure. Growth is most disrupted in children who underwent cranial irradiation before HSCT, followed by a TBI-based conditioning regimen.[510] This group of children is also at greatest risk for growth hormone (GH) deficiency. If deficient, GH replacement can have a positive impact on final height, particularly in children younger than 10 years at the time of HSCT. Therapy is not associated with an increase in relapse; however, a higher incidence of osteochondromas/exostosis was seen in GH-treated patients.[511] Nonetheless, many children do not demonstrate GH deficiency, and the role of exogenous hormone in these children or in children older than 10 at the time of diagnosis of GH deficiency is not clear.[512,513] Overall, the mean loss of height appears to be approximately 6 cm as predicted by both genetic height and height at transplantation.[507] Still, nearly 80% of those undergoing HSCT in childhood will achieve a height that is within 2 SD of adult norms.[514]

Gonadal failure after HSCT is common; predictors include previous gonadotoxic therapy and the preparative regimen used for transplantation. For example, children with aplastic anemia who receive cyclophosphamide as their only cytotoxic agent almost always progress normally through puberty, whereas those receiving a busulfan- or TBI-based ablative regimen are very likely to have delayed development.[513] Thus, these children must be carefully monitored by a pediatric endocrinologist as they approach adolescence so that hormone replacement can be appropriately administered. Females who are postpubertal at the time of HSCT also need to be evaluated for hormone replacement therapy. In addition, they are at risk for gynecologic complications, including reduced uterine size, decreased vaginal and cervical size, atrophic vulvovaginitis, introital stenosis, and loss of pubic hair.[515] No comparable data regarding these complications exist for those prepubertal at the time of HSCT. In postpubertal males, HSCT with or without radiation-based conditioning often results in azoospermia,[516] and sperm banking should be offered to all patients with sufficient spermatogenesis. Significant Leydig cell damage resulting in decreased testosterone and decreased testicular volume is less common.[517] In both sexes, spontaneous recovery of gonadal function has occurred years after HSCT. Fertility resulting in live-born infants has been reported for both male and female SCT patients,[518] particularly after conditioning with cyclophosphamide alone. Successful pregnancies are much less common after busulfan- and TBI-based regimens, and there is an increased risk of spontaneous abortion, preterm labor, and delivery of low- or very-low-birth-weight infants. There does not, however, appear to be an increased incidence of congenital anomalies in the offspring.[517] Concern regarding fertility is one of the major issues for HSCT survivors up to a decade after transplantation.[519]

Bone Problems

The most prominent bony complications after HSCT are decreased bone mineral density (BMD) and osteonecrosis. Patients undergoing transplantation have many potential risk factors for abnormal bone health: exposure to corticosteroids before HSCT or for prophylaxis or treatment of GVHD, calcineurin exposure, gonadal failure, prolonged bed rest, and periods of suboptimal nutrition. Because many patients are asymptomatic, the incidence of osteopenia/osteoporosis in children and the impact on future bone health are not well understood. Small series of pediatric patients indicate that up to 50% of survivors of childhood allogeneic HSCT will have abnormal BMD and thus have an excess risk of fractures and other skeletal complications as they age.[520,521] Osteonecrosis or avascular necrosis, the death of a segment of bone, is a potentially debilitating manifestation of bone disruption and can result in significant pain or fractures. Corticosteroid use and the presence of cGVHD appear to be the major risk factors,[522] and children older than 10 appear to be at more risk than younger children.[523] Joints of the lower limb, particularly the hip, are most often involved, and up to half of patients ultimately

require joint replacement.[524] Radiation-induced bone abnormalities, including osteochondromas and metaphyseal growth abnormalities, can occur after TBI-containing transplant regimens; younger patients appear to be at greater risk.[525] Childhood survivors of HSCT should be evaluated regularly to ensure that hormonal and nutritional status is optimized. The role of bisphosphonates in the treatment of these conditions is being investigated. Early data indicate that bisphosphonates can improve BMD, but long-term effects of this intervention in the pediatric population are unknown.[526]

TRANSPLANTATION IN PATIENTS WITH ACQUIRED DISEASES

Aplastic Anemia

Severe aplastic anemia (SAA) is a syndrome characterized by peripheral blood pancytopenia and marrow hypoplasia (see Chapter 7). Historically, the mortality associated with SAA in children can be as high as 50% in the first 6 months.[527] Although a number of immunosuppressive and marrow stimulatory therapies have shown reasonable activity, the only curative treatment remains allogeneic HSCT. The potential efficacy of allogeneic transplantation for patients with SAA was established with the initial publication in 1972 of results achieved in four patients.[528] Randomized studies have since established the superiority of matched allogeneic HSCT over supportive care (androgens in the 1970s, immunosuppressive therapy with ATG in the 1980s and 1990s) in both children and, more recently, adults.[529-532] In the setting of a matched sibling donor, the role of pre-HSCT conditioning is mainly to provide immunosuppression. Cyclophosphamide in combination with ATG is the standard regimen, with cyclosporine and short-course methotrexate given for GVHD prophylaxis. This approach cures almost 90% of patients with none of the sequelae associated with radiation-containing regimens.[533] The stem cell source has traditionally been bone marrow, but many centers have switched to peripheral blood progenitor cell grafts for ease of collection and faster engraftment kinetics. In a retrospective study of European and American registries, patients younger than 20 years had an increased risk for cGVHD and higher overall mortality with peripheral blood versus bone marrow grafts, and bone marrow remains the preferred stem cell source.[534] A course of immunosuppressive therapy before proceeding to matched sibling HSCT also led to an inferior outcome, mostly as a result of increased rates of graft rejection.[535] Young patients with SAA receiving a non–radiation-containing regimen should have preserved fertility after HSCT.[536] In addition, long-term survivors were indistinguishable from healthy controls in terms of reported health, educational achievement, and psychosexual functioning.[537] Given these data and the expected excellent outcomes, patients with SAA who have an available matched sibling donor should be referred expeditiously for BMT to minimize the number of pre-HSCT transfusions and the risk of acquiring serious infections.

Children who lack a matched sibling donor receive immunosuppressive therapy that usually consists of ATG, cyclosporine, and steroids in an attempt to restore normal hematopoiesis. Up to 70% of patients will have a response by 6 months, but only 30% to 50% will have durable responses and remain transfusion independent.[538,539] Additionally, a proportion of patients fail to respond, and responders remain at risk for both relapse of SAA and evolution to MDS/AML.[540,541] The first reports of unrelated donor transplants for SAA used preparative regimens similar to those used with sibling donors. The results were very discouraging, with graft rejection, transplant-related toxicity, and GVHD all being significant problems and survival rates under 40%. Incorporation of TBI into the conditioning regimen decreased the incidence of graft rejection and led to better results in some reports, although the results were also influenced by the time from diagnosis to transplantation and the associated differences in patient condition, number of transfusions, and infectious complications.[542] In the era of improved HLA typing and better transfusion strategies, attempts have been focused on decreasing the intensity of the conditioning regimen, and encouraging results have been reported with cyclophosphamide, ATG, and TBI doses as low as 200 cGy.[543] The long-term results of such approaches, including the durability of donor engraftment, remain to be evaluated. As conditioning regimens become less intense and survival improves, the optimal time to refer SAA patients for unrelated donor HSCT becomes less clear.

Myelodysplasia/Juvenile Myelomonocytic Leukemia

MDS is a heterogeneous group of clonal stem cell disorders that share a propensity to progress to acute leukemia. Though much more common in the adult population, these disorders have been estimated to account for approximately 3% of childhood hematologic malignancies. This figure may be an underestimate inasmuch as a subset of children with de novo AML presumably had antecedent MDS.[53] The French-American-British (FAB) classification system is based on the proportion of leukemic blasts in marrow; most pediatric patients have either refractory anemia (RA), refractory anemia with excess blasts,[492] or RAEB in transformation (RAEB-T). Juvenile myelomonocytic leukemia (JMML), a rare disorder of infants and young children, shares similarities with MDS, and a new classification system has been proposed that allocates pediatric patients with clonal myeloproliferative diseases to three groups: MDS, JMML, and myeloid leukemia of Down syndrome.[544] MDS and JMML are disorders arising from mutated pluripotent stem cells,

and thus allogeneic HSCT with a related or unrelated donor remains the only curative approach. Induction chemotherapy before HSCT is not generally recommended for patients with JMML because remission is unlikely to be attained and toxicity is high.[545] A busulfan-versus TBI-based conditioning regimen has been associated with a lower rate of relapse.[546] As transplant-related mortality has decreased, survival has improved, with recent consortium data reporting an approximately 50% 5-year DFS rate; relapse remains the greatest obstacle to cure.[547] *Cis*-retinoic acid appears to decrease the spontaneous proliferation of leukemic progenitor cells in JMML, as well as abrogate their selective hypersensitivity to GM-CSF.[548] It is used after HSCT as therapy for minimal residual disease, although efficacy has not been firmly established.

The role of induction therapy before HSCT for MDS is unclear, but about half the patients can achieve remission after AML-directed therapy,[549] and this approach may improve survival in patients with increased blasts at diagnosis.[545] Conditioning with both TBI- and busulfan-based regimens has been used, with most studies showing no difference in outcome,[550] although some favor busulfan.[551] Overall, the strongest predictor of survival is stage of disease.[552] Children who undergo transplantation for RA/RAEB have event-free survival (EFS) rates of around 70%; patients with RAEB-T were five times more likely to relapse.[553] Currently, approximately half of pediatric patients with MDS can be cured, and thus allogeneic HSCT should be considered early in the disease course.[554]

Acute Lymphoblastic Leukemia

Although more than three quarters of children with newly diagnosed ALL treated with aggressive, multiagent therapy will be cured, management of patients with certain high-risk features or who have relapsed disease remains controversial. There are two situations in which allogeneic SCT is considered to be the standard approach for children in first remission: children with identified high-risk features at diagnosis and children with primary induction failure. The consensus of what constitutes a high-risk patient is greatest for the approximately 2% of children with Philadelphia chromosome–positive (Ph[+]) ALL, who historically have had a dismal prognosis when treated with conventional ALL-directed chemotherapy.[555,556] Matched sibling HSCT in first remission significantly improved survival; a large European cohort over a 10-year period found a relative risk of 0.3 for relapse or any adverse event with transplantation versus conventional chemotherapy[557] and DFS rates of higher than 60%.[558] As in other transplant scenarios, the decrease in morbidity and mortality associated with unrelated donor transplantation over the past decade has broadened the applicability of this approach. Currently, most patients with Ph[+] ALL undergo transplantation in first remission with the best available donor, with a 5-year

EFS rate of 50% after mismatched family or unrelated donor transplantation.[559] The role of transplantation in first remission is less clearly delineated for other high-risk groups, including patients with the 4:11 translocation, T-cell ALL, or hypodiploid ALL. Hypodiploidy is known to be an adverse prognostic factor. Extreme hypodiploidy of less than 44 chromosomes is particularly uncommon and confers an even worse prognosis with an EFS rate of 30%.[560] This has led to the inclusion of such patients in trials of HSCT in first remission for children with a matched family donor and "ultrahigh-risk" features of ALL,[558,561] although the number of hypodiploid cases is too small to make definitive statements about the impact of HSCT on outcome. The historically poor outcome associated with the T-cell phenotype of ALL has been abrogated by the intensive chemotherapy that these children receive on modern protocols.[562] However, there is an ongoing attempt to define high-risk patients within this group, usually those with some combination of a very high white cell count at diagnosis, poor prednisone response, or induction failure, and some reports suggest that outcome for this subgroup may be improved by transplantation in first remisison.[563,564] Initial response to therapy is becoming an increasingly important prognostic factor for children with ALL,[565] and those not in remission by the end of induction therapy have an enormous risk of relapse. These children have been included in series of high-risk patients, and although the numbers are small, it appears that undergoing HSCT if remission can be achieved is associated with improved EFS (rate of 56% versus 26%).[563] The 4:11 translocation almost always implies rearrangement of the MLL gene. It is not certain that this abnormality implies a worse outcome in children older than 1 year,[566] but infants who harbor this translocation have an almost fivefold increase in the risk for an adverse event when compared with infants without an MLL rearrangement.[567] Even within this group further distinctions can be made: very young infants with mixed lineage leukemia (MLL)[+] ALL and a high white cell count at diagnosis have an EFS rate of less than 5%.[568] A recent international study of infant leukemia found that a poor response to prednisone, in addition to the previously mentioned factors, identified those at the highest risk.[569] It is not definitively known whether HSCT in first remission can improve outcome in this group; however, single-center studies have reported EFS rates of less than 60%,[570,571] and the current version of the international consortium trial is recommending HSCT in first remission for these infants. In summary, it appears that ALL patients with very high-risk features—whatever the specifics of the definition but virtually always including patients who are induction failures or who have the Philadelphia chromosome—have a decreased incidence of relapse and improved survival when they undergo HSCT with stem cells from a matched family donor in first remission and that HSCT confers the greatest advantage in the patients at highest risk.[563] Recent data demonstrating equivalent if not better survival of chil-

dren with relapsed ALL after unrelated donor versus sibling HSCT[572] make it difficult to know the optimal approach to therapy for those lacking a matched family donor, and a thoughtful discussion of the risks and benefits of unrelated donor HSCT versus chemotherapy is essential.

Once ALL has recurred, the chance of cure drops dramatically. In the late 1980s, the Seattle investigators reported their own experience, as well as reviewed the existing literature, and concluded that HSCT with stem cells from a matched family member cured approximately 40% of children whereas continued chemotherapy resulted in subsequent relapse more than 90% of the time.[573] Over the intervening years it has been discovered that children with relapsed ALL constitute a very heterogeneous group. The two strongest predictors of outcome in patients with recurrent ALL are the duration of the first remission and the site or sites of relapse, and the potential effective therapeutic modalities depend heavily on these factors. Patients experiencing an isolated bone marrow relapse fare more poorly than do those with either an isolated extramedullary relapse (usually involving the CNS or testicles) or those with a combined extramedullary/bone marrow relapse. Consequently, most children with an isolated extramedullary relapse, particularly if occurring while off therapy, are treated with intensive chemotherapy and radiation therapy delivered to the site of relapse rather than allogeneic SCT. This strategy results in very good outcomes, with a recent consortium trial showing that three quarters of children with a first remission of greater than 18 months who experience an isolated CNS relapse can be cured with an approach using systemic and intrathecal chemotherapy and cranial irradiation.[574] Patients who experience an early relapse (defined variably as one occurring during therapy or within 18 to 36 months from diagnosis) present one of the most difficult challenges in ALL therapy. It is clear that chemotherapy alone cannot cure these patients, and most studies show a survival advantage for sibling HSCT.[575] Unfortunately, recurrent disease is a major obstacle to success, and a recent report of children who suffered a bone marrow relapse within 12 months of completing therapy found a 3-year EFS rate of approximately 25% for these patients whether receiving chemotherapy, sibling HSCT, or unrelated donor HSCT.[576] Tellingly, over half of the patients had an adverse event (death, relapse) within 3 months of attaining second remission, and thus achieving sufficient disease control to undergo HSCT complicates evaluation of its efficacy as a modality. Most of the aforementioned studies have involved matched sibling donors; as outcomes with alternative donors have improved, equivalent results with unrelated donor HSCT are now being reported.[572,575] In summary, it has not been determined which patients with ALL in second remission conclusively benefit from allogeneic HSCT. Patients with late isolated extramedullary relapses should not undergo transplantation in most circumstances. For the remaining groups, there are no

prospective randomized trials to guide therapy. Some children are unable to tolerate the months of intensive therapy given in relapse protocols and thus should be considered for HSCT.[577] Because most studies reveal a lower incidence of relapse with transplantation that often but not always translates into improved DFS,[578,579] the risks and benefits of transplantation must be carefully considered in each situation by balancing type and match of available donors, medical condition of the patient, and patient and family preference.

Acute Myelocytic Leukemia

Successive clinical trials over the last 25 years have firmly established the role of intensive postremission therapy in the treatment of AML. However, during that time there has been much debate about whether allogeneic HSCT or intensive chemotherapy without stem cell support is the optimum postremission therapy. Allogeneic HSCT offers dose intensity and the possibility of a GVL effect. Alternatively, intensive chemotherapy without stem cell support is feasible for all patients, unlike allogeneic HSCT, and confers less risk of acute and long-term toxicity.

The role of allogeneic HSCT in first clinical remission of AML was initially addressed in a series of prospective trials in the mid-1980s. In 111 consecutive patients, the Seattle group undertook matched sibling allogeneic HSCT for patients who had a donor, whereas the remaining patients received conventional intensification. The probability of 5-year DFS was 49% for HSCT versus 20% for chemotherapy alone.[580] However, since that time, more intensive chemotherapy regimens have been associated with improved disease control in children and adults with AML.[581,582] This has again raised the question of whether allogeneic HSCT is more effective than intensive chemotherapy in the postremission setting. To address this issue, the Children's Cancer Study Group (CCG) conducted a large trial of allogeneic HSCT versus chemotherapy or autologous HSCT in 652 children and adolescents with AML who achieved remission. At the end of induction, patients with five or six HLA antigen–matched relatives were allocated to allogeneic HSCT. All others were randomized between autologous HSCT with 4-hydroperoxycyclophosphamide (4-HC) purging of marrow or four courses of chemotherapy. The results of this trial showed that the outcome with allogeneic HSCT was superior to either chemotherapy or autologous HSCT.[581] For patients treated with an intensive induction regimen, the DFS rate with allogeneic HSCT was 66% versus 53% with chemotherapy and 48% with autologous HSCT.[581] These data underscore the benefit of both intensive induction chemotherapy and first-remission matched sibling donor HSCT in the management of newly diagnosed AML for many patients.

Subsequent studies have attempted to identify patients at increased risk for poor outcomes with chemotherapy alone who would thus derive most benefit from HSCT in first remission. In the pediatric population the

consistent prognostic indicators are response to initial induction therapy and cytogenetic markers.[583,584] The Medical Research Council (MRC) AML 10 trial found 5-year survival rates of 67%, 65%, and 23% in patients who respectively achieved complete remission, achieved partial remission (5% to 15% blasts), and had residual disease.[583] Relapse rates in these groups were 34%, 38%, and 87%. This and other studies stratified patients according to favorable, intermediate, and adverse karyotypic abnormalities. Favorable karyotypic abnormalities include t(8;21), inv(16), t(15;17), and in some studies, t(9;11) and t(16;16).[583-586] Adverse abnormalities include −5, −7, del(5q), abn(3q), and complex karyotypes.[586] Patients with neither favorable nor high risk are considered intermediate risk. In the MRC AML 10 trial, patients with favorable and intermediate karyotypic abnormalities had survival rates of 76% and 52%, with relapse rates of 34% and 44%. This was compared with survival and relapse rates of 40% and 61% in patients with adverse karyotypes.[583] The MRC combined cytogenetics and response to initial therapy to delineate good-, standard-, and poor-risk groups in the MRC 10 trial. The good-risk group included patients with favorable karyotypes or FAB type M3, irrespective of response status after one course of chemotherapy or the presence of other karyotypic abnormalities. The standard-risk group included patients in neither the good- nor poor-risk groups. The poor-risk group included patients with adverse karyotypic abnormalities or with resistant disease in the absence of favorable karyotypic abnormalities and not FAB M3.[583] There was no significant difference in the percentage of deaths during first complete remission between any of the groups.[582] There were, however, significant differences between the good-, standard-, and poor-risk groups in regard to relapse-free survival rate (65%, 62%, and 36%), DFS rate (59%, 54%, and 32%), survival from relapse (61%, 17%, and 0%), and 7-year survival rate from complete remission (78%, 60%, and 33%). The 61% salvage rate after relapse in the good-prognosis group suggested that HSCT in the first complete remission may be inappropriate for this group. Though not assessed in the MRC trial, patients with an activating *FLT3* mutation have been shown to have a poor prognosis and benefit from HSCT in first remission.[587] Although specific definitions of risk groups differ between protocols, current AML trials recommend HSCT based on risk group, and ongoing trials from the Children's Oncology Group (COG) and St. Jude Cancer Research Center recommend chemotherapy only for patients in low risk groups and HSCT for intermediate risk only if a family donor is available. HSCT is recommended for high-risk patients even in the absence of a related donor.

Autologous HSCT has been studied for patients who have no allogeneic donor. In many trials, autologous marrow was purged of residual leukemic cells with 4-HC, although no direct benefit of this technique has been proved. Trials in adults and adolescents with AML suggested that autologous HSCT might offer additional therapeutic efficacy over chemotherapy.[549,588] Pediatric trials and a recent meta-analysis did not demonstrate any advantage to this modality in patients in first complete remission, and data are insufficient to assess the influence of AML subclass on outcome.[589-593]

In most studies of patients with relapsed AML, the duration of first remission is strongly predictive of outcome, with 10% to 20% DFS rates in patients relapsing less than 1 year after diagnosis regardless of the treatment modality used.[594,595] Early studies reported DFS rates of up to 30% for those undergoing allogeneic transplantation in untreated first ("early") relapse.[596,597] In contrast, a more recent report of 379 adults with relapsed or refractory AML found the DFS rate of patients who underwent transplantation in untreated first relapse to be no better than 13%.[598] Patients with treatment-refractory disease had an equivalently poor prognosis. However, the DFS rate in patients who were are able to attain a second remission was significantly better at 32%. The outcome of children with relapsed AML was studied by the MRC Childhood Leukemia Working Party.[594] Of the 81 patients in whom curative therapy was attempted, 69% went into a second remission. Approximately two thirds of these patients were consolidated with allogeneic HSCT, with a survival rate of 44% at 3 years. Although this was not a randomized study, patients treated with HSCT had a longer duration of second remission that did those treated with chemotherapy alone.[594] These data support the use of allogeneic HSCT in the treatment of relapsed AML, especially for patients who can achieve a second remission.

Chronic Myelogenous Leukemia

CML is a proliferative stem cell disorder arising from a translocation (9;22) known as the Philadelphia chromosome. The only curative therapy is allogeneic transplantation. However, with the advent of targeted molecular therapies such as imatinib, a tyrosine kinase inhibitor (TKI), daily administration of an oral agent can control the disease for years, if not longer, with minimal side effects. As a result, the role of HSCT with the attendant short- and long-term toxicities is being redefined. The majority of the literature on both HSCT and TKI therapy reflects studies in adults, where current practice is to use TKI as initial therapy in virtually all patients with chronic-phase CML.[599] The risk-benefit profile is different in the pediatric population, and in the largest pediatric series to date, patients receiving either matched sibling ($n = 182$) or unrelated donor ($n = 132$) HSCT had a 63% and 56% DFS rate, respectively. The best outcome was observed in those going to transplantation in the first chronic phase and within 6 months of diagnosis; the DFS rate with a sibling donor for that cohort was 73%.[600] Given these data and newer studies showing outcomes to be virtually identical with sibling or unrelated donors for pediatric leukemia patients, it is still reasonable to offer HSCT as the first therapeutic intervention for pediatric patients

with a sibling or fully matched unrelated donor. Alternatively, imatinib could be started at the time of diagnosis with careful monitoring of disease response. Recent data allow response to imatinib at specific time points to be categorized as "failures," and such patients should be offered alternative therapies.[599,601] In young patients, whether this next intervention is allogeneic HSCT or a trial of second-generation TKIs depends on donor availability and physician, family, and patient assessment of the risks and benefits attendant on both strategies. There is some concern that pretreatment with a TKI could have an adverse impact on HSCT outcome, but this does not seem to be a problem, provided that imatinib is discontinued at least 2 weeks before transplantation.[602] Rarely, patients with CML are initially seen in accelerated phase or in myeloid or lymphoid blast crisis. Chemotherapy is administered to try to regain stable phase. Allogeneic HSCT can then offer curative therapy for up to 40% of patients.[59,603] Whether the addition of imatinib before or after HSCT can improve outcome for this group is unknown.

For patients undergoing HSCT, careful monitoring of disease status remains an essential component of post-transplant care. Relapse detected early at the cytogenetic or molecular level responds extraordinarily well to donor lymphocyte infusion (DLI). Currently, most patients receive escalating doses of $CD3^+$ T cells in an attempt to achieve disease control without inducing GVHD.[604] The role of TKI in post-HSCT recurrence—either alone or in combination with DLI—is still being elucidated.[605,606]

Hodgkin's and Non-Hodgkin's Lymphoma

Autologous HSCT has been used in children with Hodgkin's disease (HD) or aggressive non-Hodgkin's lymphoma (NHL) who either relapse or have refractory disease after initial treatment with conventional therapy. Both TBI-based and chemotherapy-only approaches have been used with equal success. There has been increasing consensus about the use of autologous PBSCs versus bone marrow as the stem cell source based on the favorable engraftment characteristics for neutrophils and platelets.[607] The potential of high-dose therapy with autologous rescue to salvage pediatric patients with Burkitt's lymphoma was established in 1986, when a 5-year French experience demonstrated approximately a 50% DFS rate.[608] Similar results in children with Burkitt's and large cell lymphoma (LCL), as well as HD, have been reported more recently from other European centers and in larger combined pediatric and adult series.[609-612] Paralleling the findings in adult patients with lymphoma, DFS is most consistently predicted by the presence of chemotherapy-sensitive disease; long-term survival is unlikely in those with bulky disease at the time of HSCT.[613] The addition of rituximab before or after HSCT (or both) for B-cell lymphomas may further improve outcome in this group of patients.[614,615] As for T-cell acute lymphoblastic leukemia (T-ALL), allogeneic HSCT is the standard approach for refractory or relapsed T-cell lymphoblastic lymphoma if remission can be attained.[616]

There has also been interest in the role of allogeneic HSCT in the treatment of relapsed/refractory NHL and HD. Retrospective case-controlled studies in adult/pediatric series suggest comparable results. A prospective trial revealed a lower relapse rate in those undergoing allogeneic BMT but no overall survival advantage because of significant transplant-related mortality. As seen in patients undergoing autologous HSCT, chemosensitivity before transplantation was the major prognostic factor for outcome.[617] The advantage conferred by an allogeneic stem cell source may be dependent on the type of lymphoma; a recent study of pediatric patients with anaplastic LCL reported a remarkable 75% DFS rate, with successes even in patients relapsing after autologous HSCT.[618] Whether the decrease in relapse rate seen in these studies reflects a graft-versus-lymphoma effect or merely the infusion of uncontaminated stem cells is not clear.[619] Characterization of patients at particularly high risk for failure should allow better delineation of which patients could benefit from an allogeneic transplant—either alone or as a tandem approach after autologous transplantation[620]—despite the increase in transplant-related mortality and the risk of cGVHD.

Neuroblastoma and Other Solid Tumors

The most extensive HSCT experience with pediatric solid tumors is in patients with advanced-stage neuroblastoma (see Chapter 14 of *Oncology of Infancy and Childhood*). Historically, patients receiving conventional doses of chemotherapy almost always succumbed to disease. In 1999, a landmark trial showed a significant improvement in DFS (34% versus 22%) for patients randomized to consolidation with autologous BMT versus continued intensive nonmyeloablative chemotherapy.[621] Because regimen-related toxicity was acceptable and dose intensification appeared to have an impact on DFS, sequential or "tandem" transplants with the use of two[622] or three[623] cycles of non–cross-resistant agents over a short period of time along with autologous PBSC support have been investigated. It appears that such approaches can further improve outcome, with a reported 3-year DFS rate of 58%[622] and an estimated DFS rate of 45% at 7 years from diagnosis.[624] Relapse remains a significant problem primarily at diffuse osseous sites. Neuroblastoma cells marked in the stem cell product have been identified at sites of relapse,[159] and a variety of positive and negative selection techniques have been used to purge the stem cells before reinfusion, although none have been definitively shown to have an impact on outcome; profound depletion of T cells from the graft

has, however, resulted in an increase in life-threatening viral infections.[625] Currently, the role of targeted radionuclides such as metaiodobenzylguanidine (MIBG) is being investigated. MIBG has shown encouraging results in children refractory to conventional approaches, and hepatotoxicity and myelosuppression have been the main toxicities; frequently, autologous stem cell infusion is required after this therapy.[626] Allogeneic transplantation has been evaluated in several small series but does not appear to have a favorable impact on survival.[627] Therapy for minimal residual disease after HSCT is essential, with *cis*-retinoic acid being the most thoroughly evaluated,[621] although potentially more toxic approaches such as antibody therapy are currently under investigation.[628] Most children undergoing autologous HSCT for neuroblastoma are very young, and there has been concern about the quality of life after this intensive therapy. However, the literature suggests that most survivors of this previously almost uniformly fatal disease are neuropsychologically intact.[629,630] Survivors are at risk for a variety of medical complications, the most common being short stature, gonadal failure, and hearing loss (seen in three fourths of patients)[631] and must be closely monitored by appropriate specialists to optimize outcome.

The role of high-dose therapy with autologous PBSC rescue for brain tumors is still being evaluated. The literature is most extensive for tumors with a clear dose-response curve, such as medulloblastoma/primary neuroectodermal tumor (PNET) and germ cell tumors.[632-634] HSCT is most often used in the setting of recurrent disease but is occasionally used at the time of first remission in patients with adverse prognostic features or in very young children in an attempt to avoid radiation therapy.[635] EFS rates range from 30% to 50%, and as is the case for most conditions treated with autologous HSCT, those in remission at the time of transplantation fare best. Ongoing consortium trials hope to standardize therapy and further understand which patients can benefit from this therapeutic approach.

Small single-institution series have been published on the use of either allogeneic or autologous HSCT for other nonhematologic malignancies. Some promise in terms of response rate has been observed for patients with sarcomas who have both minimal residual and chemosensitive disease, but the generalizability and durability of these responses will need to be established before widespread application can be supported.

TRANSPLANTATION IN PATIENTS WITH GENETIC DISEASES

Allogeneic SCT has increasingly been evaluated as a potentially curative approach for children with inherited diseases. The most common inherited diseases that have been treated with SCT are reviewed.

Box 9-3	**Immunodeficiency Disorders Treated by Stem Cell Transplantation**

Classic severe combined immunodeficiency disease (B⁻)
Common severe combined immunodeficiency disease (B⁺)
Adenosine deaminase deficiency

Immunodeficiency Disorders

Severe Combined Immunodeficiency Syndromes

Since the late 1960s, allogeneic BMT has been successfully used to cure children with a number of lethal immunodeficiency diseases (Box 9-3), including SCID and Wiskott-Aldrich syndrome (WAS). SCID is a clinical syndrome arising from a variety of genetic abnormalities that all result in profound deficiencies in T-cell function. Depending on the specific genetic abnormality, B-lymphocyte and NK-cell number and function will be affected as well.[636] In classic X-linked SCID there is profound T-cell lymphopenia and a variable number of nonfunctioning B cells, whereas patients with adenosine deaminase deficiency lack B cells, T cells, and NK cells. Autosomal recessive SCID phenotypes have different combinations of B- and NK-cell presence. Without question, conventional matched sibling allogeneic HSCT for SCID is one of the major success stories of transplantation. Unlike the situation in most transplant settings, because of the underlying immunologic defect, SCID patients with a matched sibling donor do not necessarily require conditioning. After infusion of genotypically matched donor stem cells without cytoreduction, immune reconstitution will take place within several weeks, and evidence of good lymphocyte function will be apparent by 2 to 3 months.[637] Significant aGVHD or cGVHD is uncommon. Dramatically improved long-term survivorship from the range of approximately 50% in the 1970s to greater than 90% currently appears attributable to more rapid and precise diagnosis, followed by transplantation in patients at a younger age and in better condition, and to improved supportive care for the associated infectious complications.[638,639]

The optimal approach for children lacking a matched sibling donor is less clear, and two different strategies have been used: T-cell–depleted haploidentical transplantation generally using a parent as the donor or, more recently, transplantation from a matched unrelated donor.

Early experience with haploidentical HSCT was hampered by graft rejection, frequent severe GVHD, and opportunistic infection, which resulted in poor long-term survival. The development of T-cell depletion protocols improved the outcomes for haploidentical nonconditioned HSCT. The advantage of this approach is that neither cytoreductive therapy nor GVHD prophylaxis is needed, and thus peritransplant mortality is low. T-cell function usually takes several months to appear, patients generally do not have B-cell function mandating lifelong IVIG replacement, and graft rejection necessitating a second or even third transplant occurs in approximately 20% of patients. Buckley reported her 30-year experience using with approach and achieved a 78% survival rate. T-cell function normalized and was most robust in children who were diagnosed early and underwent transplantation within the first 28 days of life.[640] There is some concern about the longevity of T-cell function inasmuch as markers of ongoing thymic-dependent T-cell production diminished markedly when evaluated years after HSCT.[641,642] This has led, particularly in Europe, to the more frequent adoption of complete cytoreduction and the use of matched unrelated donors as a stem cell source for patients lacking a matched sibling donor. This approach allows the development of a fully functional donor immune and hematopoietic system. These advantages must be weighed against the time taken to identify an unrelated donor and the risk of GVHD, the increased risk of acute infectious morbidity and mortality associated with myeloablative therapy, and long-term sequelae, including the likelihood of infertility. Recent reports indicate that use of an unrelated donor confers a survival advantage over mismatched related donors (80% versus 52%), as well as improved reconstitution of a full T-cell repertoire.[639] The role of nonmyeloablative HSCT and the ability of this approach to decrease acute toxicity and mitigate long-term sequelae is being investigated but may be a particularly attractive option in children with severe organ dysfunction at the time of HSCT.[643-645]

Wiskott-Aldrich Syndrome

WAS is an X-linked disorder in which progressive T-cell immunodeficiency is associated with eczema, small platelets, and absolute thrombocytopenia. The pathogenesis of this disorder is associated with aberrant expression of the WAS protein, which is involved in cytoskeletal organization, as well as T- and NK-cell activation.[646] This disorder is reviewed in detail in Chapter 23. As with SCID, matched sibling allogeneic SCT was first undertaken in children with WAS in the late 1960s, and full correction of the hematologic manifestations was reported in 1978.[647] Both TBI- and busulfan-based regimens have been used successfully in conditioning patients with WAS, and the reported survival rate of almost 90% in patients with matched sibling donors is among the best of any patient cohort undergoing allogeneic SCT.[648-651] This approach was thus extended to patients with mismatched family or unrelated donors. Early reports were

not encouraging, with survival rates of less than 40% and significant problems related to graft rejection and the development of post-transplant B-cell lymphoproliferative disease.[652-654] Recent data have been more encouraging.[655,656] In a review of the National Marrow Donor Program (NMDP)/IBMTR registry cases, Filipovich and associates found that 85% of boys receiving an unrelated donor transplant before the age of 5 survived, an outcome similar to that seen with sibling donors. In addition, cGVHD was limited in severity and ultimately completely resolved in most affected children.[655] Thus, most children afflicted with WAS are now expeditiously referred for transplantation from the best available donor, with a palliative approach consisting of splenectomy and chronic IVIG administration being used only in rare cases.

Inherited Hematopoietic Disorders

Thalassemia

Thalassemia major (or Cooley's anemia) is the most common transfusion-dependent anemia in the world. Chronic transfusion therapy and chelation to prevent the associated iron overload have modified the natural history of thalassemia and transformed a disease that was uniformly fatal in early childhood into a chronic process with progressive end-organ dysfunction.[657,658] Over time, even medically compliant patients are at risk for complications, including endocrine dysfunction, hepatic cirrhosis, cardiac disease, and transfusion-associated viral infections. In the developed world with sophisticated medical management, life expectancy is 25 to 55 years, depending mostly on compliance with chelation therapy, but in the developing world, the majority of patients still die before their third decade of life.[658,659]

Successful application of HSCT as a curative approach for thalassemia major was first reported in 1982.[660] Subsequently, a very large experience reported by Lucarelli and co-workers[49] unquestionably established the feasibility of SCT for thalassemia, and more than 2000 patients worldwide have received transplants,[661] the overwhelming majority from a matched sibling donor using a busulfan-based conditioning regimen.[662] The Pesaro classification system, based on the presence of hepatic fibrosis as assessed by liver biopsy, the degree of hepatomegaly (an uncertain measurement), and a history of inadequate chelation, allows risk stratification of potential transplant patients younger than 17 years. Class I patients have no risk factors, class 2 patients have one or two risk factors, and class 3 patients have all the risk factors. The probabilities of overall survival, EFS, and graft rejection for patients undergoing HSCT from a matched family donor were 94%, 94%, and 0%, respectively, for class I patients and 80%, 77%, and 9% for class 2 patients. Class 3 patients had only a 53% thalassemia-free survival rate because of increased graft rejection and transplant-related mortality.[49,663] Newer approaches with increased immunosuppression using any combination of hydroxyurea, azathioprine, and fludarabine have yielded

improved results for class III patients, with a thalassemia-free survival rate of 80% in patients younger than 17 years.[664] Post-HSCT management of preexisting hepatic and cardiac iron overload and viral infections is essential for optimal outcome and may allow cirrhosis to be reversed.[665,666] Positive effects on bone mineral density in children may also occur.[667] Although matched sibling HSCT is undoubtedly efficacious, the decision to pursue aggressive chelation strategies versus accepting the short- and long-term risks associated with HSCT remains difficult and should occur on an individual basis after consultation with both hematologists and transplant physicians. Historically, HSCT from an unrelated donor had a dismal prognosis in this disease,[661] and HSCT was considered only if a suitable family donor was available. However, improvements in HLA typing and supportive care have had a global impact on transplant outcomes with unrelated donors, and thus HSCT may now be a reasonable option for selected patients with fully matched donors. As with sibling donors, the best results occur in those with less advanced disease, and thalassemia-free survival rates of 80% to 100% for class 1 or 2 patients have been reported in small series.[668,669]

Sickle Cell Disease

Allogeneic HSCT offers a curative approach for patients with sickle cell disease (SCD). Because the clinical course of SCD is highly variable and, particularly with the advent of pneumococcal prophylaxis, childhood morbidity and mortality are low, it is difficult to know which patients should undergo HSCT. Initial studies offered HSCT to the subgroup of patients with the most life-threatening or debilitating symptoms: those with stroke, recurrent acute chest syndrome, or recurrent painful crises. In the seminal report by Walters and colleagues, the DFS rate after busulfan-based myeloablative conditioning was 73%, and the overall survival rate was 91% at 4 years; end-organ damage was stabilized in patients with sustained donor engraftment.[670] Improved management of transplant complications in general and increased attention to SS-specific toxicities (additional immunosuppression to decrease graft rejection, antiseizure prophylaxis, strict management of hypertension) have resulted in consistent gains in cure rates,[671] with EFS rates of greater than 95% in patients who underwent transplantation after January 2000.[672] Newer approaches such as the use of hydroxyurea to decrease the risk of graft rejection by influencing pretransplant bone marrow cellularity[673] or the use of a nonmyeloablative approach to decrease transplant-related morbidity and mortality[674] or even preserve fertility remain to be evaluated.

HSCT has historically been considered only for patients who have an available matched sibling donor. A multi-institutional survey of factors having an impact on the use of HSCT in this population found that less than 15% of affected children had an acceptable sibling donor.[670] The role of unrelated donor HSCT in patients with the most severe manifestations of disease or in those

unable to receive long-term transfusion therapy is unknown, but multi-institutional trials are currently being developed.[675] Unrelated umbilical cord donors are a theoretically attractive option given the decreased incidence of GVHD and the ability to use donors who have greater HLA disparity. Small numbers of transplants have been reported with successful outcomes, although both GVHD and graft rejection remain obstacles to widespread use.[676]

The choice to proceed to matched sibling HSCT remains complicated, particularly if the disease manifestations are moderate or intermittent. No prospective randomized trials are available to inform the decision, and therapy with hydroxyurea, chronic transfusion, and HSCT each have associated risks and benefits. HSCT clearly has the highest upfront risk but also offers the only curative modality. The Belgian experience illustrates that children who undergo transplantation at a young age before significant complications occur do best, with a DFS rate of 93% and overall survival rate of 100%,[677] and serious late complications of SS disease affecting long-term survival, such as pulmonary hypertension, continue to be identified. Unfortunately, even in the reports of HSCT showing the most favorable outcomes, patients are likely to be infertile,[678] and the risk for extensive cGVHD is low but real.[672] Patients (when of an appropriate age) and parents must be aware of the possible therapeutic options so that they can be informed and active participants in the decision-making process.[679]

Fanconi's Anemia

Fanconi's anemia (FA) is an autosomal recessive disorder clinically characterized by a highly variable physical phenotype, progressive marrow failure, and a marked propensity for the development of AML and certain solid tumors (see Chapter 8). HSCT can be curative for the hematologic manifestations of FA, but early experience revealed excessive regimen-associated morbidity and mortality, and in vitro studies confirmed hypersensitivity to alkylating agents and radiation.[680,681] The development of specialized conditioning regimens mostly using low doses of both cyclophosphamide and radiation has spurred the application of HSCT as a treatment option, and results with HLA-identical sibling donors are excellent if performed early in life before the development of MDS or leukemia,[682,683] with 2-year DFS rates as high as 95%.[684] In addition, the first reported transplant using UCB as a stem cell source was successfully undertaken in a child with FA by using cells from an HLA-identical sibling.[133]

In contrast, the outcome with alternative donors has been markedly worse, with survival rates of approximately 30%[685-687]; graft failure and GVHD were the major obstacles. In a recent review of 98 FA patients undergoing unrelated donor HSCT, patients younger than 10 years who had fewer than 20 transfusions and received a fludarabine-containing regimen and T-cell–depleted

marrow allografts had better outcomes, with a 3-year survival rate of 52%.[688] Thus, the prognosis for FA patients undergoing alternative donor SCT has greatly improved over time, and early referral for discussion of HSCT is indicated for patients with marrow failure. Data are limited on the use of HSCT in FA patients in whom frank leukemia has developed. Anecdotal reports suggest that there are occasionally long-term survivors, but death from regimen-related toxicity or leukemic relapse is the norm. Recent reports suggesting that these children can tolerate cytoreductive therapy before HSCT may ultimately lead to better outcomes.[689] Although HSCT can restore normal hematopoiesis, meticulous follow-up of these patients is essential because they retain a significant risk for the development of solid tumors, particularly squamous cell carcinomas of the upper gastrointestinal tract and anogenital region. The peak incidence is in the second and third decades of life, and it is unclear whether the preparatory regimen for HSCT increases the underlying risk inherent in the disease.[690,691]

Diamond-Blackfan Anemia

Diamond-Blackfan anemia (DBA) is a rare heritable condition manifested as pure red cell aplasia as a result of an intrinsic erythroid progenitor defect. Approximately a third of patients have associated physical abnormalities, including short stature, cardiac or urogenital abnormalities, cleft palate, and microcephaly.[692] Haploinsufficiency of ribosomal protein S19 (RPS19) is seen in 20% to 25% of patients. DBA is generally diagnosed in the first months of life and is characterized by anemia, macrocytosis, and reticulocytopenia (see Chapter 8). Although approximately two thirds of children initially respond to corticosteroid therapy, significant numbers either fail to respond or lose response over time.[693] The toxicity of this approach, whether sequelae of chronic transfusions or prolonged corticosteroid and cyclosporine use, is significant, in addition to the potential for leukemia developing in early to mid adulthood.[693] Although responses may wax and wane, 15% to 25% of children may obtain a durable spontaneous remission.[694] Allogeneic HSCT can offer a curative option. The first transplant was performed in 1976,[695] and of the 354 patients registered in the DBA registry of North America, 20 have undergone HSCT from family or unrelated donors.[696] Transplants using matched sibling donors were performed with a non–radiation-based regimen and resulted in an 87% DFS rate. Patients undergoing alternative donor transplantation fared poorly, with a 14% survival rate. Sixty-one patients with DBA who underwent HSCT were reported to the IBMTR between 1984 and 2000. The 3-year survival rate was 64%, and having a matched sibling donor and a performance status of at least 90% before HSCT conferred the best prognosis.[697] More recently, the Japanese Aplastic Anemia Registry reported a 100% 5-year survival rate in 13 patients with DBA who received an allogeneic transplant from either sibling or unrelated bone marrow donors; however, 3 of 3 patients receiving unrelated cord blood transplants experienced graft failure.[698] Thus, transplantation from a suitable bone marrow donor is a reasonable option, particularly patients who fail to have a sustained response to steroids.

Granulocyte Platelet and Macrophage Disorders

Limited numbers of patients with a variety of qualitative and quantitative disorders of myeloid cell function have achieved successful reconstitution of hematopoietic cells with allogeneic SCT, usually with a busulfan-based regimen (Box 9-4; also see specific diseases in Chapter 21). HSCT has been used successfully for both quantitative granulocyte disorders such as severe congenital neutropenia (SCN or Kostmann's syndrome) and qualitative disorders such as leukocyte adhesion deficiency (LAD), Chédiak-Higashi syndrome (CHS), and chronic granulomatous disease (CGD). Patients with SCN have a 21% cumulative incidence of MDS/AML and an 8% cumulative incidence of mortality from sepsis at 10 years.[699] Those who do not respond to G-CSF and those in whom clonal hematopoiesis develops should proceed expeditiously to HSCT. The SCN registry reported 9 of 11 long-term survivors after related or unrelated HSCT, with 1 survivor having significant cGVHD.[700] Patients with LAD or CD11/CD18 deficiency have impaired neutrophil adhesion, migration, and phagocytosis, and severe infections usually develop early in life. HSCT with related or unrelated donors can be curative.[701,702] Patients with stable-phase CHS may have minimal symptoms but usually progress to an accelerated phase in the first or second decade of life. Acceleration is characterized by pancytopenia, hepatosplenomegaly, and serious infections and is uniformly fatal. HSCT offers a curative option even when patients remain chimeric, and as in other transplant settings, patients with less advanced disease have improved outcomes.[703,704] Medical management of CGD has dramatically improved survival, but HSCT may still be appropriate in patients experiencing recurrent severe infections. After myeloablative conditioning, 22 of 27 patients were cured.[705] Active infection at the time of HSCT was associated with severe GVHD and a worse outcome, so thorough pretransplant evaluation and treatment are essential.

Single-patient reports and small series indicate that HSCT can be curative in patients with congenital platelet disorders, including amegakaryocytic thrombocytopenia

Box 9-4	**White Blood Cell Disorders Treated by Stem Cell Transplantation**

CD11/18 deficiency (leukocyte adhesion deficiency)
Neutrophil actin defects
Shwachman-Diamond syndrome

and severe forms of Glanzmann's thrombasthenia. Most patients had matched sibling donors and received a busulfan-based conditioning regimen. The overall results are encouraging, but regimen-related deaths do occur, and thus the risks associated with HSCT should be balanced against the risks of bleeding episodes and chronic transfusion therapy.[706-708]

Primary hemophagocytic lymphohistiocytosis is the most common congenital macrophage disorder. It is inherited in an autosomal recessive manner and is a disease of infancy or early childhood. Patients have fever, hepatosplenomegaly, and pancytopenia as a result of abnormal proliferation of macrophages and accumulation in the liver, spleen, bone marrow, and CNS. Remission may be attained with immunomodulation consisting of steroids, cyclosporine, and epipodophyllins, but allogeneic HSCT is the only curative modality.[709] As with other diseases, once HSCT from matched related donors was shown to be feasible,[52] the treatment was extended to unrelated donors, usually with a busulfan, etoposide, and cyclophosphamide conditioning regimen, and DFS rates of 45% to 65% were achieved.[710-712] Children who were in remission after pretransplant therapy did best, but cures were still seen in the setting of some degree of disease activity at HSCT. Newer approaches include the use of reduced-intensity conditioning, and a small series reported a 75% DFS rate at a median of 30 months after HSCT; interestingly, three of the nine survivors showed mixed chimerism, albeit with high-level T-cell engraftment, thus suggesting that as with other immunodeficiencies, restoration of T-cell function versus complete myeloablation may suffice for cure.[713]

Osteopetrosis

This rare disorder of osteoclast dysfunction leads to an inability to resorb and remodel bone and the resulting formation of excessive mineralized osteoid and cartilage. Infantile or "malignant" osteopetrosis is inherited in an autosomal recessive manner and causes a severe phenotype. In addition to poor growth and bony encroachment on optic and other cranial nerve foramina causing vision and hearing impairment, eradication of the marrow space ensues with progressive pancytopenia.[714] Murine studies revealed that osteoclasts arise from hematopoietic precursors of the monocytic lineage, and disease reversal was accomplished by engraftment of bone marrow from unaffected animals.[715] Successful HSCT in humans was first reported in 1977, and its applicability has subsequently been shown in many reports,[716-718] mostly using a busulfan-based conditioning regimen. Recently, the European Group for Blood and Marrow Transplantation (EBMT) reported the long-term outcome of 122 children undergoing allogeneic HSCT between 1980 and 2001.[719] The 5-year DFS rate was 73% in those receiving transplants from an HLA-identical sibling versus approximately 40% in those receiving transplants from mismatched family donors or matched unrelated donors. The major causes of failure were lack of engraftment,

attributed in part to disruption of the underlying marrow microenvironment, and pulmonary complications, particularly pulmonary hypertension. Conservation of vision was most likely in those who underwent transplantation before 3 months of age. Patients, especially those older than 2 years at transplantation, are at risk for hypercalcemia as engraftment occurs, and therefore meticulous monitoring of calcium levels is essential in the peritransplant period.[718] At present, HSCT is the only curative option, although calcitriol,[720] interferon gamma,[721] and prednisone[722] have been used to slow progression or ameliorate symptoms, or both. Donor identification and subsequent HSCT should occur expeditiously as soon as the diagnosis is confirmed because neurologic impairment can occur rapidly and may be irreversible, even with successful hematopoietic engraftment.

Storage Disorders

Storage disorders are characterized by accumulation of substrate due to an underlying enzymatic deficiency. This disrupts cellular function and leads to organ impairment. Historically, few treatment options other than palliative and supportive modalities have been available. More recently, the availability of alglucerase (Ceredase) enzyme infusion has dramatically altered the course of patients with Gaucher's disease.[723] Although similar inroads have not yet been made in other diseases, the concepts of gene transfer and somatic cell therapy, as well as infusion of enzymes produced by recombinant techniques, are being investigated in animal models of specific diseases. The rationale for SCT as a therapeutic maneuver is based on the assumption that the most severely affected cell population is hematopoietic in origin or that sufficient transfer of enzyme via enzyme-replete cells can prevent subsequent as well as reverse existing damage. However, the capacity for repair or arrest of damage to affected organ systems, especially the CNS, remains unproven for many storage disorders. Age and neurodevelopmental status before HSCT are consistently the strongest predictors of outcome. Although life expectancy may be prolonged, children severely affected at the time of HSCT are unlikely to experience significant improvement in neurocognitive function. In addition, donor selection is a significant issue inasmuch as siblings may be homozygous or heterozygous for the affected gene. Use of a heterozygous donor does not have an impact on outcome in hematologic disorders such as thalassemia, but whether heterozygosity provides adequate enzyme levels to correct an ongoing process has not been elucidated for this group of disorders.

Several excellent reviews of the results of HSCT for specific storage disorders have been published, with the largest body of literature involving the mucopolysaccharidoses and the leukodystrophies.[724-727] Only for mucopolysaccharidosis IH (Hurler's syndrome), X-linked adrenoleukodystrophy, and infantile globoid cell leukodystrophy (Krabbe's disease) are there sufficient data to

suggest that HSCT is indicated in carefully selected cases.[728] Patients with Hurler's disease who undergo HSCT before 2 years of age and achieve donor engraftment can maintain preservation of neurocognitive function and motor development, although the skeletal abnormalities (dysostosis multiplex) do not improve because chondrocytes have difficulty clearing glycosaminoglycan.[729,730] Most transplants for storage disorders have been performed with matched family donors. Graft failure with autologous recovery has also had a negative impact on success; patients receiving unrelated donor[731] T-cell–depleted grafts or reduced-intensity conditioning are at particular risk.[732] Recently, the use of unrelated UCB donors has provided a rapidly available source of stem cells, as well as being a more permissive source in terms of HLA matching and thus increasing the number of acceptable donors. Encouraging outcomes have been reported, although follow-up has been relatively short. After umbilical cord HSCT, 17 of 20 children with Hurler's syndrome are long-term survivors with normal enzyme levels,[733] 11 of 11 asymptomatic newborns with globoid cell leukodystrophy have normal enzyme levels and are making developmental gains,[734] and 3 of 3 young asymptomatic boys with adrenoleukodystrophy have stable MRI findings and normal neurologic examination results.[735] As seen previously with marrow donors, older children with adrenoleukodystrophy and progressive MRI changes had rapid deterioration of neurologic function and poor outcomes. Thus, although a subset of patients with storage disorders can benefit from HSCT, particularly those who are young, have minimal symptoms, or have indolent forms of a disease, patients with aggressive infantile forms or those who have significant neurologic impairment at the time of referral will need alternative therapeutic interventions to improve outcome.

10 Diagnostic Approach to the Anemic Patient

Carlo Brugnara, Frank A. Oski,* and David G. Nathan

*Deceased.

Most of the chapters thus far have been devoted to descriptions of specific disorders that result in anemia. The purpose of this chapter is to provide both a more general classification of the anemias and an initial diagnostic approach to patients with this laboratory finding. Details of the diagnostic procedures used for ultimate diagnosis of the various anemias are omitted because they are presented in their respective chapters.

DEFINITION OF ANEMIA

Anemia is generally defined as a reduction in red cell mass or blood hemoglobin concentration. The limit for differentiating anemic from normal states is generally set at 2 standard deviations (SD) below the mean for the normal population. This definition will result in 2.5% of the normal population being classified as anemic. Conversely, values for hemoglobin-deficient individuals are distributed in such a fashion that some are placed within the normal range. These individuals, who have the potential for a hemoglobin concentration in the upper part of the normal range, may be recognized only after a response to treatment. Definition of the lower limit of normal for both pediatric and adult patients is critically dependent on the population used to establish the normal range of values.[1] Hematocrit, hemoglobin, and mean corpuscular volume (MCV) are significantly lower in African American than in whites. A third of this difference can be accounted for by the α-globin –3.7-kilobase (kb) deletion.[2] In the absence of a race-specific normal range, the fact that African Americans generally have lower hemoglobin levels than whites do (approximately 0.5 g/dL) could result in 10% of normal African American children being consider anemic just because the proper normal range is not used.[3] Figure 10-1 presents pediatric reference ranges for hemoglobin in non-Hispanic whites, African Americans, and Mexican Americans that were obtained from the National Health and Nutrition Examination Survey (NHANES) III database.

Because the primary function of the red cell is to deliver and release adequate quantities of oxygen to tissues to meet their metabolic demands, it is apparent that some measures of both body oxygen metabolism and accompanying cardiovascular compensation are required to complement the current laboratory definition of anemia. The fact that hemoglobin concentration alone is insufficient to judge whether a patient is "functionally anemic" is best illustrated in a patient with cyanotic congenital heart disease or chronic respiratory insufficiency or in one with mutant hemoglobins that alter hemoglobin's affinity for oxygen (see Chapter 18).

With these caveats in mind, a useful statistical definition of anemia that recognizes the effect of age and sex on the designation of anemia is provided in Table 10-1.[4]

CLASSIFICATION OF ANEMIAS

Anemias may be classified on the basis of physiology or morphology. A combination of both approaches is often used in the initial differential diagnosis.

The best approach for providing an understanding of the multiple disorders capable of producing anemia is to separate the causes of anemia into two categories of functional disturbances:

1. Disorders of effective red cell production, in which the net rate of red cell production is depressed. This can be due to disorders of erythrocyte maturation, in which erythropoiesis is largely ineffectual, or to an

TABLE 10-1	**Normal Mean and Lower Limits of Normal for Hemoglobin, Hematocrit, and Mean Corpuscular Volume**					
	HEMOGLOBIN (g/dL)		**HEMATOCRIT (%)**		**MEAN CORPUSCULAR VOLUME (µm³)**	
Age (yr)	**Mean**	**Lower Limit**	**Mean**	**Lower Limit**	**Mean**	**Lower Limit**
0.5-1.9	12.5	11.0	37	33	77	70
2-4	12.5	11.0	38	34	79	73
5-7	13.0	11.5	39	35	81	75
8-11	13.5	12.0	40	36	83	76
12-14

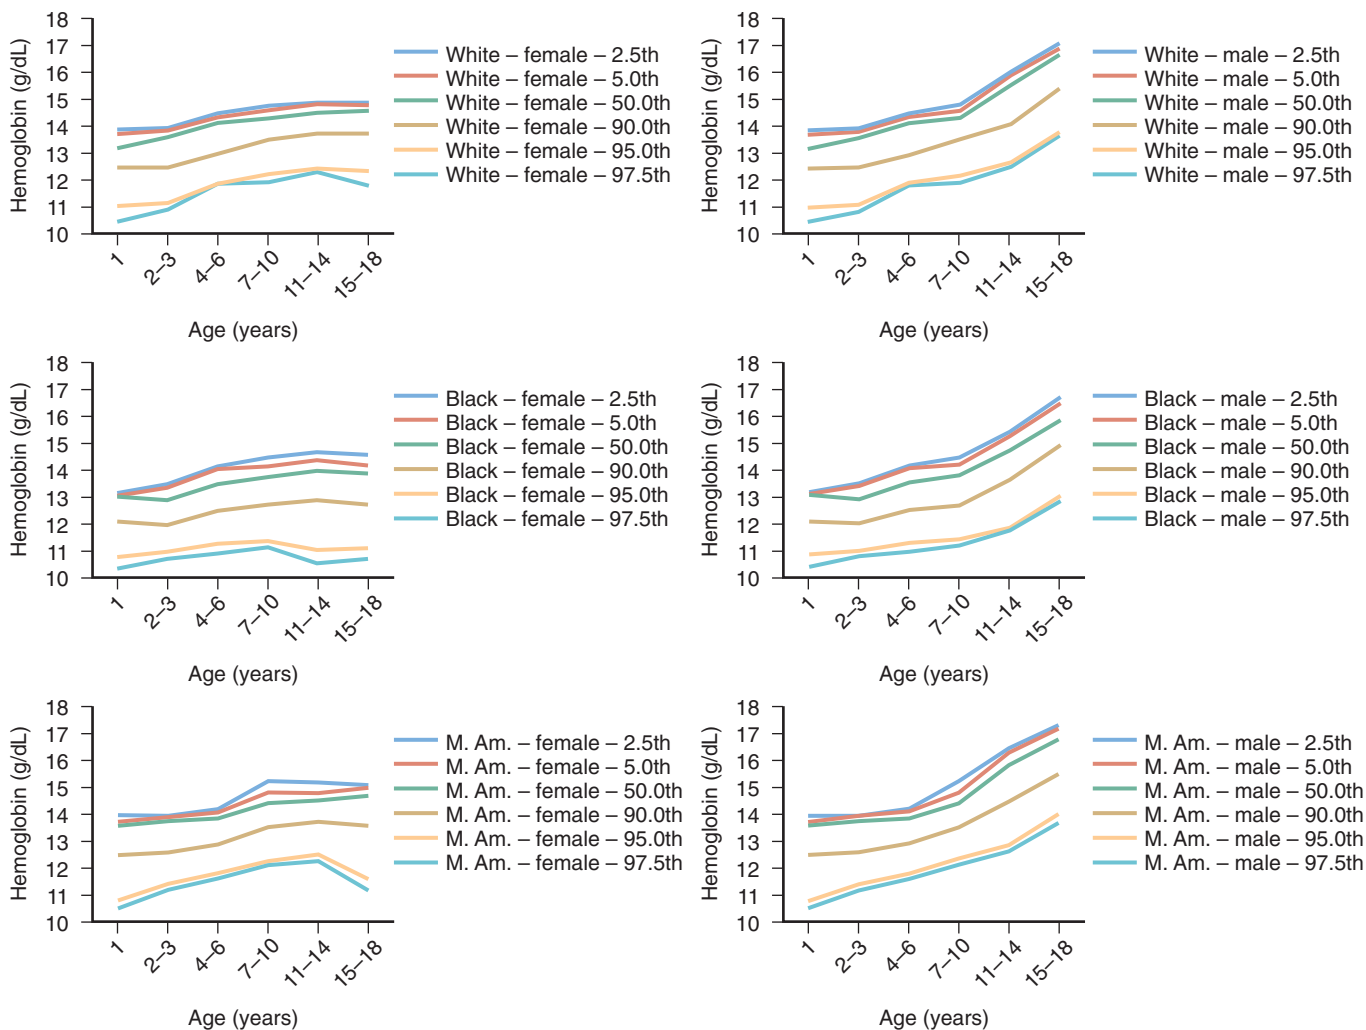
Male	14.0	12.5	43	37	84	77
15-17						
Female	14.0	12.0	41	36	87	79
Male	15.0	13.0	46	38	86	78
18-49						
Female	14.0	12.0	42	37	90	80
Male	16.0	14.0	47	40	90	80


FIGURE 10-1. Pediatric reference ranges for hemoglobin in non-Hispanic whites (*top row*), non-Hispanic blacks (*middle row*), and Mexican Americans (*bottom row*). (Data were kindly provided by Dr. George Cembrowski and obtained from the National Health and Examination Survey (NHANES) III. Presented at the 2004 meeting of the International Society for Laboratory Hematology [Cembrowski GS, Chan J, Cheng C, Bamforth FJ. NHANES 1999-2000 data used to create comprehensive health-associated race-, sex- and age-stratified pediatric reference intervals for the Coulter MAXM. Lab Hematol. 2004;10:245-246]. Data can also be accessed at http://www.mylaboratoryquality.com. See Reference Intervals.)

absolute failure of erythropoiesis. In the former, bone marrow contains many erythroblasts that die in situ before reaching the reticulocyte stage. In the latter, there is absolute erythroblastopenia.
2. Disorders in which rapid erythrocyte destruction or red cell loss is primarily responsible for the anemia.

These two categories are not mutually exclusive. More than one mechanism may be present in some anemias, but one functional disorder is generally the major reason for the patient's anemia. Box 10-1 lists the anemias most commonly encountered in infancy and childhood and classifies them into three categories of functional disturbance.

Anemias may also be classified on the basis of red cell size and then further subdivided according to red cell morphology. In this type of classification, anemias are subdivided into microcytic, normocytic, and macrocytic anemias. This classification is also arbitrary, and categories are not mutually exclusive. For example, macrocytic reticulocytes abound in the hemolytic anemias. Therefore, although mature erythrocytes in the various hemolytic anemias may be normocytic, the MCV of all the cells may be larger than normal because of the contribution of reticulocytes to the volume measurement.[5] Volume distribution curves may reveal the contribution of a subset of large cells to the MCV. Furthermore, during the course of a disease, classification of the patient's anemia may change from one category to another as a result of other clinical or pathologic variables. In Box 10-2 the more common anemias of infancy and childhood are classified on the basis of their characteristic cell size.

Box 10-1	**Physiologic Classification of Anemia**

A. DISORDERS OF RED CELL PRODUCTION IN WHICH THE RATE OF RED CELL PRODUCTION IS LESS THAN EXPECTED FOR THE DEGREE OF ANEMIA
1. Marrow failure
   a. Aplastic anemia
      Congenital
      Acquired
   b. Pure red cell aplasia
      Congenital
      Diamond-Blackfan syndrome
      Aase's syndrome
      Acquired
      Transient erythroblastopenia of childhood
      Other
   c. Marrow replacement
      Malignancies
      Osteopetrosis
      Myelofibrosis
      Chronic renal disease
      Vitamin D deficiency
   d. Pancreatic insufficiency–marrow hypoplasia syndrome
2. Impaired erythropoietin production
   a. Chronic renal disease
   b. Hypothyroidism, hypopituitarism
   c. Chronic inflammation
   d. Protein malnutrition
   e. Hemoglobin mutants with decreased affinity for oxygen

B. DISORDERS OF ERYTHROID MATURATION AND INEFFECTIVE ERYTHROPOIESIS
1. Abnormalities in cytoplasmic maturation
   a. Iron deficiency
   b. Thalassemia syndromes
   c. Sideroblastic anemias
   d. Lead poisoning
2. Abnormalities in nuclear maturation
   a. Vitamin B_{12} deficiency
   b. Folic acid deficiency
   c. Thiamine-responsive megaloblastic anemia
   d. Hereditary abnormalities in folate metabolism
   e. Orotic aciduria
3. Primary dyserythropoietic anemias (types I, II, III, IV)
4. Erythropoietic protoporphyria
5. Refractory sideroblastic anemia with vacuolization of marrow precursors and pancreatic dysfunction/deficiency

C. HEMOLYTIC ANEMIAS
1. Defects in hemoglobin
   a. Structural mutants
   b. Synthetic mutants (thalassemia syndromes)
2. Defects in the red cell membrane
3. Defects in red cell metabolism
4. Antibody mediated
5. Mechanical injury to the erythrocyte
6. Thermal injury to the erythrocyte
7. Oxidant-induced red cell injury
8. Infectious agent–induced red cell injury
9. Paroxysmal nocturnal hemoglobinuria
10. Plasma lipid–induced abnormalities in the red cell membrane

EVALUATION OF THE ANEMIC PATIENT

The initial diagnostic approach to an anemic patient includes a detailed history and physical examination and a minimum of essential laboratory tests. Tables 10-2 and 10-3 list the features of the history and physical examination that are most helpful in providing clues to the cause of the anemia. The initial laboratory tests should include a determination of hemoglobin and hematocrit; measurement of red cell indices, platelet count, white blood cell count and differential, and reticulocyte count; and examination of a peripheral blood smear. After this initial assessment, other useful and simple laboratory procedures may be used, including, when indicated, measurement of erythrocyte porphyrin and serum ferritin concentration, supravital staining of erythrocytes, hemoglobin electrophoresis, a screening test for the presence of unstable hemoglobins, a direct and indirect Coombs test, a screening test for glucose-6-phosphate dehydrogenase deficiency, and examination of bone marrow.

Automated Cell Counting

The most widely used methods for determination of hemoglobin, hematocrit, and red cell indices are now fully automated. When compared with manual techniques, automated methods have the advantages of greater precision and reproducibility and the capacity for completing a large number of measurements quickly.

One of two general principles is used in most of the more popular automated hematology analyzers. They may simply be classified as the electrical impedance principle and the laser light scatter principle.

In automated cell counters using the electrical impedance principle (Abbott, Abbott Park, IL; ABX, Kyoto, Japan; Beckman-Coulter, Miami, FL; Sysmex, Kobe, Japan), cells passing through an aperture cause changes in electrical resistance that are counted as voltage pulses, which are proportional to cell volume. The electrical pulses are amplified and counted during the time that an

Box 10-2	**Classification of Anemias Based on Red Cell Size**

A. MICROCYTIC ANEMIAS
1. Iron deficiency (nutritional, chronic blood loss)
2. Chronic lead poisoning
3. Thalassemia syndromes
4. Sideroblastic anemias
5. Chronic inflammation
6. Some congenital hemolytic anemias with unstable hemoglobin

B. MACROCYTIC ANEMIAS
1. With megaloblastic bone marrow
   a. Vitamin B_{12} deficiency
   b. Folic acid deficiency
   c. Hereditary orotic aciduria
   d. Thiamine-responsive anemia
2. Without megaloblastic bone marrow
   a. Aplastic anemia
   b. Diamond-Blackfan syndrome
   c. Hypothyroidism
   d. Liver disease
   e. Bone marrow infiltration
   f. Dyserythropoietic anemias

C. NORMOCYTIC ANEMIAS
1. Congenital hemolytic anemias
   a. Hemoglobin mutants
   b. Red cell enzyme defects
   c. Disorders of the red cell membrane
2. Acquired hemolytic anemias
   a. Antibody mediated
   b. Microangiopathic hemolytic anemias
   c. Secondary to acute infections
3. Acute blood loss
4. Splenic pooling
5. Chronic renal disease (usually)

accurately metered volume of the suspension is drawn through the aperture. These devices can directly measure MCV and compute the hematocrit from the MCV and red blood cell count.

In automated cell counters using the laser light scatter principle (Abbott, Abbott Park, IL; Siemens Medical Solutions Diagnostics, Tarrytown, NY), single cells passing through a laser beam induce scattering of laser light, which can be detected and translated into measurements of cell size. In the instruments produced by Siemens, red cells first undergo isovolumetric sphering, and then MCV and the mean corpuscular hemoglobin concentration (MCHC) are measured from the low-angle forward light scattering and the high-angle (refractive index) light scattering, respectively.[6-9]

Some of the potential errors that can be generated by automated cell counters for hemoglobin, hematocrit, and red cell indices are listed in Table 10-4.[10] Cold agglutinins in high titer tend to cause spurious macrocytosis with low red cell counts and very high MCHCs. Warming either the blood or the diluent may eliminate this problem.

Electronic cell counting provides a useful means of categorizing anemias based on the MCV and MCHC. The red cell volume distribution width (RDW) is derived from the red blood cell histogram that accompanies each analysis. The RDW is an index of the variation in red cell size and thus can be used to detect anisocytosis. In a normal patient, the histogram is virtually symmetrical. RDW is calculated as a standard statistical value, the coefficient of variation in distribution of red cell volume. The formula can be expressed as

$$RDW = SD/MCV \times 100$$

TABLE 10-2	**Historical Factors of Importance in Evaluating Patients with Anemia**
Age	Nutritional iron deficiency is never responsible for anemia in term infants before 6 months of age; rarely seen in premature infants before the time that they have doubled their birth weight. Anemia occurring in the neonatal period is generally the result of recent blood loss, isoimmunization, or initial manifestation of a congenital hemolytic anemia or congenital infection
	Anemia first detected at 3 to 6 months of age suggests a congenital disorder of hemoglobin synthesis or hemoglobin structure
Gender	Consider X-linked disorders in males (G6PD deficiency, pyruvate kinase deficiency)
Race	Hemoglobins S and C more common in blacks; β-thalassemia more common in whites; α-thalassemia trait most common among black and yellow races
Ethnicity	Thalassemia syndromes most common among patients of Mediterranean origin. G6PD deficiency observed more often among Sephardic Jews, Filipinos, Greeks, Sardinians, and Kurds
Neonatal	A history of hyperbilirubinemia in the newborn period suggests the presence of congenital hemolytic anemia, such as the hereditary spherocytosis of G6PD deficiency. Prematurity predisposes to the early development of iron deficiency
Diet	Document sources of iron, vitamin B_{12}, folic acid, or vitamin E in the diet. A history of pica, geophagia, or pagophagia suggests the presence of iron deficiency
Drugs	Oxidant-induced hemolytic anemia, phenytoin (Dilantin)-induced megaloblastic anemia, drug-induced aplastic anemia
Infection	Hepatitis-induced aplastic anemia, infection-induced red cell aplasia, hemolytic anemia
Inheritance	Family history of anemia, jaundice, gallstones, or splenomegaly
Diarrhea	Suspect small bowel disease with malabsorption of folate or vitamin B_{12}. Suspect inflammatory bowel disease with blood loss. Suspect exudative enteropathy with blood loss

G6PD, glucose-6-phosphate dehydrogenase.

TABLE 10-3	Physical Findings as Clues to the Cause of Anemia	
Skin	**Hyperpigmentation**	**Fanconi's Aplastic Anemia**
	Petechiae, purpura	Autoimmune hemolytic anemia with thrombocytopenia, hemolytic-uremic syndrome, bone marrow aplasia, bone marrow infiltration
	Carotenemia	Suspect iron deficiency in infants
	Jaundice	Hemolytic anemia, hepatitis, aplastic anemia
	Cavernous hemangioma	Microangiopathic hemolytic anemia
	Ulcers on lower extremities	S and C hemoglobinopathies, thalassemia
Facies	Frontal bossing, prominence of the malar and maxillary bones	Congenital hemolytic anemias, thalassemia major, severe iron deficiency
Eyes	Microcornea	Fanconi's aplastic anemia
	Tortuosity of the conjunctival and retinal vessels	S and C hemoglobinopathies
	Microaneurysms of the retinal vessels	S and C hemoglobinopathies
	Cataracts	Glucose-6-phosphate dehydrogenase deficiency, galactosemia with hemolytic anemia in the newborn period
	Vitreous hemorrhages	S hemoglobinopathy
	Retinal hemorrhages	Chronic, severe anemia
	Edema of the eyelids	Infectious mononucleosis, exudative enteropathy with iron deficiency, renal failure
	Blindness	Osteopetrosis
Mouth	Glossitis	Vitamin B_{12} deficiency, iron deficiency
	Angular stomatitis	Iron deficiency
Chest	Unilateral absence of the pectoral muscles	Poland's syndrome (increased incidence of leukemia)
	Shield chest	Diamond-Blackfan syndrome
Hands	Triphalangeal thumbs	Red cell aplasia
	Hypoplasia of the thenar eminence	Fanconi's aplastic anemia
	Spoon nails	Iron deficiency
Spleen	Enlargement	Congenital hemolytic anemia, leukemia, lymphoma, acute infection, portal hypertension

TABLE 10-4	Sources of Spurious Results in Hemoglobin and Red Cell Count Parameters
Erroneous increase in Hb	Lipemia (hypertriglyceridemia, fat emulsion, type I and IV hyperlipoproteinemias)
	Elevated WBC counts (threshold varies from 50 to 250×10^9/L)
	Immunoglobulins (monoclonal IgG, IgM, IgA in Waldenström's or multiple myeloma)
	Hemolysis (when free plasma Hb is markedly elevated because of intravascular hemolysis)
Erroneous increase in RBC counts	High WBC count (especially if greater than 100×10^9/L)
Erroneous increase in MCV	Hyperglycemia (secondary to dilution of a severe hyperglycemic sample)
	Hypernatremia
	Sample storage at room temperature
Erroneous decrease in RBC counts	Cold agglutinin (in association with high MCV and high MCHC)
	Clotting (abnormal mixing, overfilling of sample)

Hb, hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; WBC, white blood cell.

From Zandecki M, Genevieve F, Gerard J, Godon A. Spurious counts and spurious results on haematology analysers: a review. Part II: white blood cells, red blood cells, haemoglobin, red cell indices and reticulocytes. Int J Lab Hematol. 2007;29:21-41.

Because RDW reflects the ratio of SD and MCV, a wide red cell distribution curve in a patient with markedly increased MCV may still generate a normal RDW value. RDW in normal individuals ranges from 11.5% to 14.5%, but it may vary as a function of the model of the electronic cell counter used. Normal values for infants and children appear to range from 1.5% to 15.0%. The hemoglobin distribution width (HDW) is calculated in a similar manner from the histogram for MCHC. Coulter instruments do not directly measure the red cell hemoglobin concentration. The MCHC and HDW values provided by these instruments are sensitive to variations in MCV and should be used with caution in the differential diagnosis of anemias.

Bessman and associates have provided a classification of anemias based on MCV and RDW. An updated version that includes MCHC and HDW appears in Table 10-5.[11]

TABLE 10-5	Relationship of Mean Corpuscular Volume (MCV) and Red Cell Volume Distribution Width (RDW) in a Variety of Disease States		
	MCV		
RDW	**Low**	**Normal**	**High**
Normal	Heterozygous α- and β-thalassemia	Normal Lead poisoning	Aplastic anemia
High	Iron deficiency Hemoglobin H disease S β-thalassemia	Early iron deficiency Liver disease Mixed nutritional deficiencies	Newborns, prematurity Vitamin B_{12} or folate deficiency
		HIGH MCHC/HDW Immune hemolytic anemia SS and SC disease Hereditary spherocytosis/xerocytosis	**HIGH MCHC/HDW** Immune hemolytic anemia

HDW, hemoglobin distribution width; MCHC, mean corpuscular hemoglobin concentration.

Visual analysis of the red cell histograms generated by automated cell counters provides essential clues for the diagnosis of anemias. The presence of either microcytes or macrocytes and increased RDW can readily be appreciated. Histograms for MCHC are particularly useful because they allow prompt identification of dehydrated hyperchromic cells in sickle cell disease, hereditary spherocytosis, hereditary xerocytosis, and immune hemolytic anemias. Moreover, a careful study of volume and hemoglobin concentration histograms allows rapid differentiation of iron deficiency and β-thalassemia trait and differentiation of hemoglobin H and hemoglobin H/CS disease. Figure 10-2 provides the histograms for MCV and MCHC in a normal control and in patients with β-thalassemia trait, iron deficiency, and sickle cell disease.

Automated reticulocyte counting is also available in several hematology analyzers. Automated counting is more precise and accurate than manual counting.[12,13] Absolute reticulocyte counts are easily obtained with these instruments, thereby obviating the limitations of counting reticulocytes only as a percentage or correcting for changes in hematocrit (corrected reticulocyte count). An additional useful feature of automated reticulocyte counters is that stress reticulocytes can easily be identified by their increased volume and RNA content.[13-15] Cellular indices for reticulocytes such as volume, hemoglobin concentration, and hemoglobin content are also available in the Siemens and Sysmex instruments. The reticulocyte hemoglobin content[16] has been shown to be a valuable parameter in identifying iron deficient states in young children and toddlers.[17,18]

The Blood Film

Although automatic blood film machines are now the vogue in clinical laboratories, films made on coverslips are preferable to those made on glass slides because a greater proportion of blood on the coverslip film is technically suitable for microscopic examination. Proper processing of blood films on coverslips is fast becoming a lost art. The details of preparation and examination can be found in a variety of manuals of laboratory hematology, but the lucid and succinct instructions of Wintrobe deserve reproduction here[19]:

1. Use a small drop of blood, only 2 to 3 mm in diameter, taken either from a stylet wound, as described earlier, or from a syringe or needle tip used in venipuncture immediately after the venipuncture has been performed (anticoagulants are not to be used because they will alter the morphologic appearance).
2. Hold the coverslips only by their edges, placing one crosswise over the other, and allow the blood to spread between them for about 2 seconds.
3. Quickly but gently separate the coverslips by pulling them laterally, in opposite directions to one another but in the plane of the spreading film, just before the film reaches the edges (do not squeeze or lift the coverslips from one another).
4. Quickly air-dry the films, either by placing them face up on a clean surface if the humidity is low or by moving them through the air while holding them by their edges with your fingertips.

If the procedure has been carried out successfully, the blood will be spread evenly, and there will be no holes or thick areas in the preparation. A multicolored sheen will be seen on the surface of the dried, unstained film if light glances off it at the proper angle because the thin layer of closely fitting cells acts like a diffraction grating. Later, under the microscope after staining, the red cells will be seen next to each other, but neither overlapping nor in rouleau formation, and central pallor will be visible; lymphocytes will have a readily distinguished cytoplasm rather than a minimal zone bearing closely on the nucleus as occurs with thick films or those that dry too slowly.

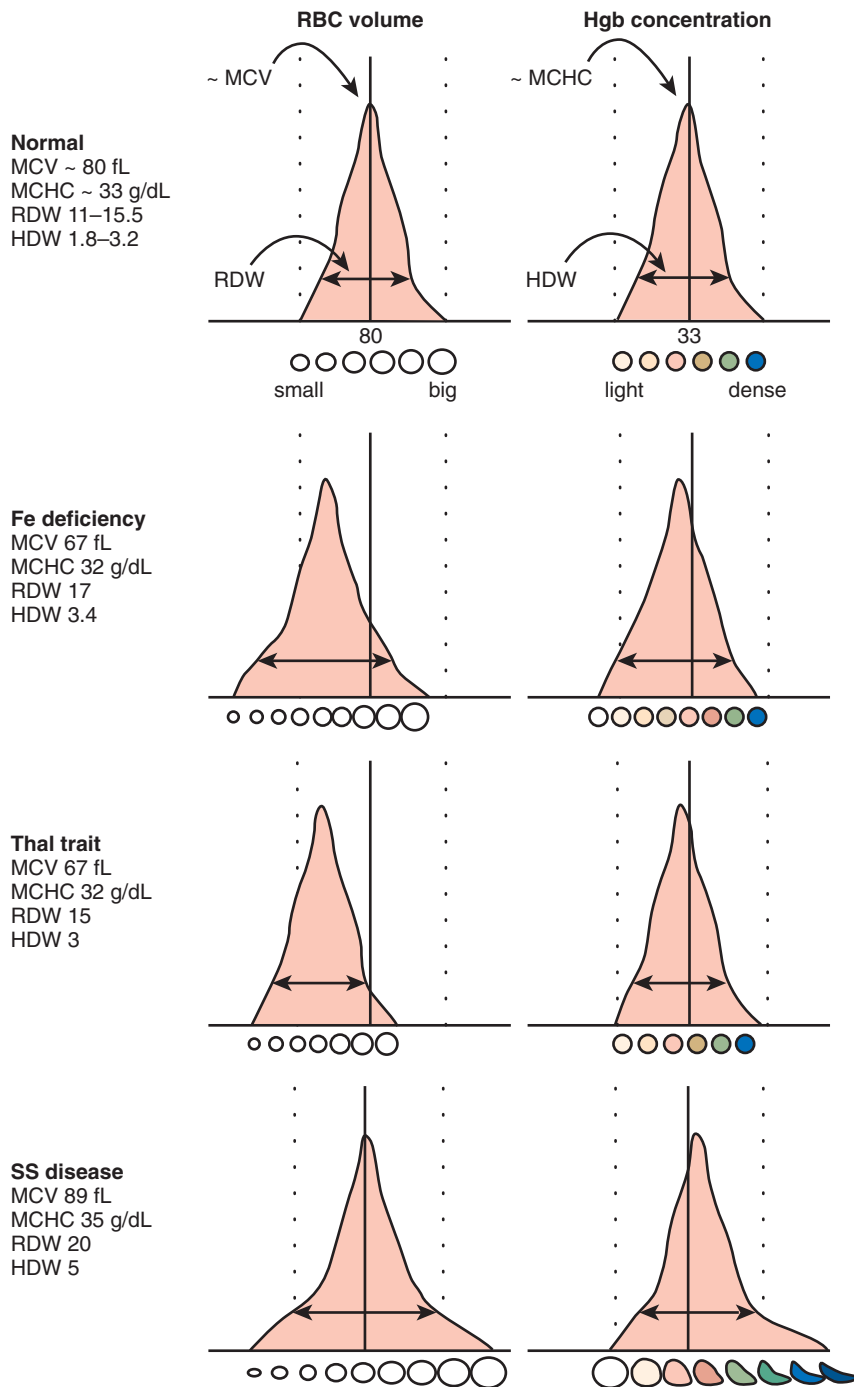
Examination of a peripheral blood film is the single most useful procedure in the initial evaluation of a patient


FIGURE 10-2. Histograms for mean corpuscular volume (MCV, *left column*) and mean corpuscular hemoglobin concentration (MCHC, *right column*) in a normal control subject (*first row*), a patient with iron deficiency (*second row*), a subject with heterozygous β-thalassemia (*third row*), and a patient with homozygous hemoglobin S disease (*bottom row*). Goal posts are placed at 60 and 120 fL for MCV and at 28 and 41 g/dL for MCHC. HDW, hemoglobin distribution width; RBC, red blood cell; RDW, red cell volume distribution width.

with anemia. The blood film should first be examined under low power to determine the adequacy of cell distribution and staining. Signs of poor blood film preparation include loss of central pallor in red blood cells, polygonal shapes, and artifactual spherocytes. Artifactual spherocytes, in contrast to true spherocytes, show no variation in central pallor and are larger than normal red cells. One should never attempt to interpret a poorly prepared blood film.

After the adequacy of the blood film is determined by low-power examination, the blood film should be examined first under 50× magnification and then under 1000× magnification. Cells should be graded for size, staining intensity, variation in color, and abnormalities in shape. Red cell hemolytic disorders can be classified according to their predominant morphology. An approach to such a classification is presented in Box 10-3 and is discussed in detail in Chapters 14 through 17.

The blood film should also be examined for the presence of basophilic stippling and red cell inclusions. The significance of some of these findings is described in Table 10-6.

Box 10-3	Classification of Red Cell Hemolytic Disorders by Predominant Morphology*

SPHEROCYTES

Hereditary spherocytosis
ABO incompatibility in neonates
Immunohemolytic anemias with IgG- or C3-coated red
    cells[†]
Acute oxidant injury (hexose monophosphate shunt
    defects during hemolytic crisis, oxidant drugs, and
    chemicals)
Hemolytic transfusion reactions[†]
Clostridium welchii septicemia
Severe burns, other red cell thermal injury
Spider, bee, and snake venom
Severe hypophosphatemia
Hypersplenism[‡]

BIZARRE POIKILOCYTES

Red cell fragmentation syndromes (microangiopathic and
    macroangiopathic hemolytic anemias)
Acute oxidant injury[‡]
Hereditary elliptocytosis in neonates
Hereditary pyropoikilocytosis

ELLIPTOCYTES

Hereditary elliptocytosis
Thalassemias
(Other hypochromic-microcytic anemias)
(Megaloblastic anemias)

STOMATOCYTES

Hereditary stomatocytosis
Rh$_{null}$ blood group
Stomatocytosis with cold hemolysis
(Liver disease, especially acute alcoholism)
(Mediterranean stomatocytosis)

IRREVERSIBLY SICKLED CELLS

Sickle cell anemia
Symptomatic sickle syndromes

INFRAERYTHROCYTIC PARASITES

Malaria
Babesiasis
Bartonellosis

SPICULATED OR CRENATED RED CELLS

Acute hepatic necrosis (spur cell anemia)
Uremia
Red cell fragmentation syndromes[‡]
Infantile pyknocytosis
Embden-Meyerhof pathway defects[‡]
Vitamin E deficiency[‡]
Abetalipoproteinemia
Heat stroke[‡]
McLeod blood group
(After splenectomy)
(Transiently after massive transfusion of stored blood)
(Anorexia nervosa)[‡]

TARGET CELLS

Hemoglobins S, C, D, and E
Hereditary xerocytosis
Thalassemias
(Other hypochromic-microcytic anemias)
(Obstructive liver disease)
(After splenectomy)
(Lecithin–cholesterol acyltransferase deficiency)

PROMINENT BASOPHILIC STIPPLING

Thalassemias
Unstable hemoglobins
Lead poisoning[‡]
Pyrimidine 5′-nucleotidase deficiency

NONSPECIFIC OR NORMAL MORPHOLOGY

Embden-Meyerhof pathway defects
Hexose monophosphate shunt defects
Unstable hemoglobins
Paroxysmal nocturnal hemoglobinuria
Dyserythropoietic anemias
Copper toxicity (Wilson's disease)
Cation permeability defects
Erythropoietic porphyria
Vitamin E deficiency
Hemolysis with infections[‡]
Rh hemolytic disease in neonates[†]
Paroxysmal cold hemoglobinuria*[‡]
Cold hemagglutinin disease[†]
Hypersplenism
Immunohemolytic anemia[†‡]

*Nonhemolytic disorders of similar morphology are enclosed in parentheses for reference.
[†]Usually associated with a positive Coombs test.
[‡]Disease sometimes associated with this morphology.

DIAGNOSTIC APPROACH

After the laboratory tests have been performed, the results may be used in an initial attempt to diagnostically characterize the patient's anemia, as illustrated by the simple algorithm in Figure 10-3. This algorithm provides two additional diagnostic steps after the initial characterization of anemia based on the complete blood cell count, reticulocyte count, and cellular indices.

If the diagnosis of hemolytic anemia is considered, it is useful to consider the potential pathophysiology before ordering useless and expensive screening tests. The authors have used a simple and reliable approach to

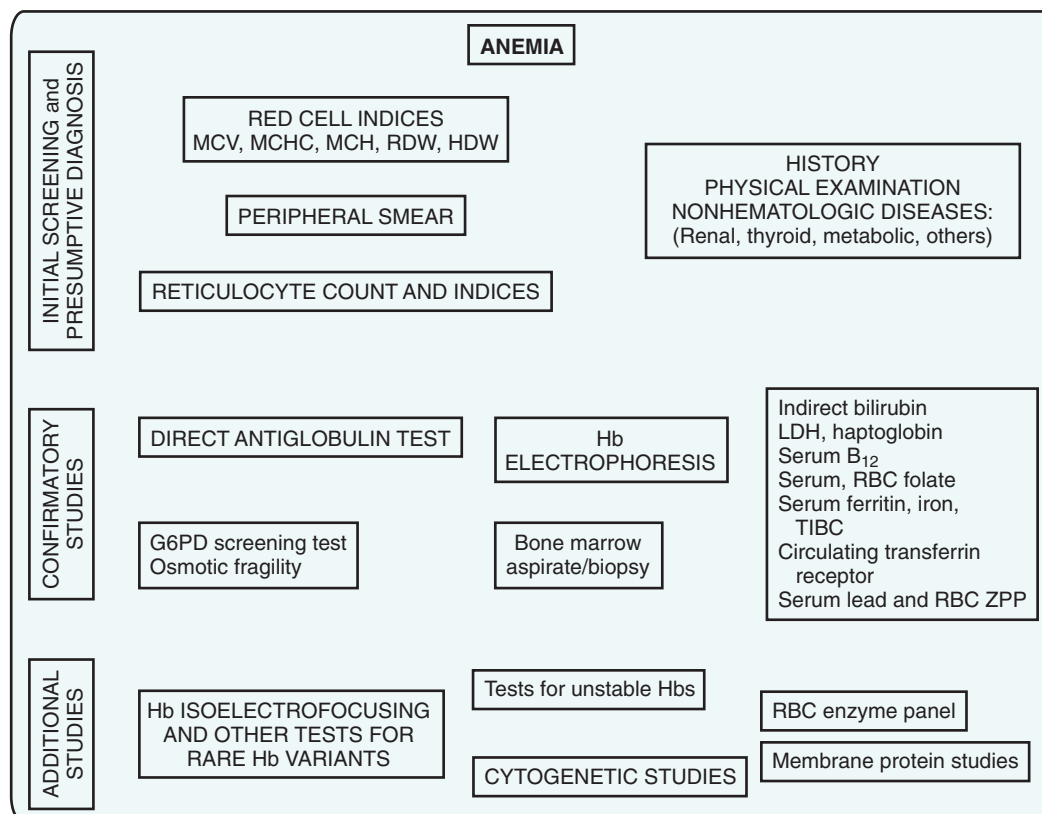
TABLE 10-6	Diagnostic Significance of Red Cell Inclusions	
Inclusion	**Staining Agent**	**Diagnostic Significance**
Basophilic stippling	Wright stain	Represents aggregated ribosomes. May be observed in thalassemia syndromes, iron deficiency, syndromes accompanied by ineffective erythropoiesis and pyrimidine 5′-nucleotidase deficiency; particularly prominent in unstable hemoglobinopathies and lead poisoning
Howell-Jolly bodies	Wright stain	Represent nuclear remnants. Observed in asplenic and hyposplenic states, pernicious anemia, dyserythropoietic anemias, and severe iron deficiency anemia
Cabot's rings	Wright stain	Appear as basophilic rings, circular, or twisted figures-of-eight. Considered to be nuclear remnants or artifacts. Observed in lead poisoning, pernicious anemia, and hemolytic anemias
Heinz' bodies	Brilliant cresyl blue, methyl violet	Represent denatured or aggregated hemoglobin. Observed in patients with thalassemia syndromes or unstable hemoglobins, after oxidant stress in patients with enzyme deficiencies of the pentose phosphate pathway, and in patients with asplenia or chronic liver disease
Siderocytes	Prussian blue counterstained with safranin O	Represent nonhemoglobin iron within erythrocytes. Seen in increased numbers in the peripheral circulation after splenectomy. Observed in increased numbers in patients with chronic infection, aplastic anemias, or hemolytic anemias


FIGURE 10-3. Algorithm for the differential diagnosis of anemia. Initial characterization of the anemia is based on the complete blood cell count, reticulocyte count, cellular indices, erythrocyte morphology, and history. This step is followed by two additional diagnostic steps: either to confirm a relatively common type of anemia or to diagnose one of the uncommon types of anemia. G6PD, glucose-6-phosphate dehydrogenase; Hb, hemoglobin; HDW, hemoglobin distribution width; LDH, lactate dehydrogenase; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; RDW, red cell volume distribution width; TIBC, total iron-binding capacity; ZPP, zinc protoporphyrin.
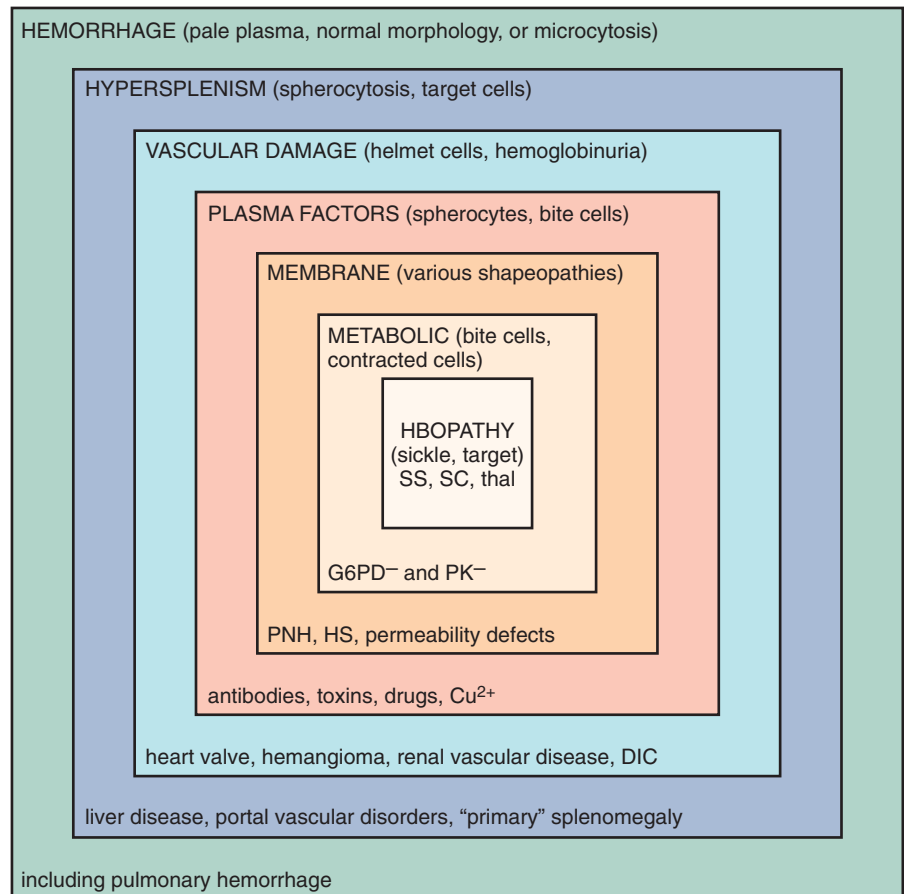

FIGURE 10-4. Assaults on the red cell from the vasculature to the "center" of the cell. The site of damage is in capital letters, the laboratory findings in parentheses, and the common causes in the lower part of the square. Cu^{2+}, copper; DIC, disseminated intravascular coagulation; HBOPATHY, hemoglobinopathy; HS, hereditary spherocytosis; PK, pyruvate kinase; PNH, paroxysmal nocturnal hemoglobinuria; SC, hemoglobin SC; SS, hemoglobin SS; thal, thalassemia.

pathophysiologic analysis that involves consideration of the potential assaults on the red cell from the farthest point to the inner core of the erythrocyte (Fig. 10-4).

The most common cause of rapid red cell loss with reticulocytosis is hemorrhage. In infants and children, unusual causes include hemorrhage beneath the scalp and intraabdominal, urinary tract, and pulmonary hemorrhage. In the latter two situations, hyperbilirubinemia is not present. Indeed, if the hemorrhage is chronic and leads to iron deficiency, the plasma will be pale.

Sequestration in an abnormal spleen will usually cause spherocytosis, but if the hypersplenism is associated with liver disease, target cells will also be present. In this condition, the osmotic fragility test will reveal a sensitive and a resistant population of erythrocytes.

Vascular damage to erythrocytes may be associated with thrombocytopenia and can be caused by hemangiomas (Kasabach-Merritt syndrome); intravascular coagulation, usually secondary to sepsis; damaged artificial heart valves; and renal vascular disease and severe hypertension. Schistocytes, which resemble military helmets of various nationalities, are usually present, and siderinuria and hemoglobinuria are often detected.

Abnormalities in plasma are frequent causes of hemolysis. Antibodies usually induce spherocytosis by causing splenic sequestration, but sometimes they merely fix complement and cause hemoglobinuria without mor-

phologic change. Many drugs and toxins can damage red cells either by oxidant injury with resultant schistocytosis or by direct lysis, as illustrated by bacterial lipases in septic shock. Acute hemolysis may also be caused by excessive release of hepatic copper in Wilson's disease. No morphologic change is noted.

Primary membrane abnormalities that cause hemolysis are usually congenital and are associated with specific morphologic changes. An exception is paroxysmal nocturnal hemoglobinuria, which is an acquired membrane defect associated with no morphologic change. The congenital membrane defects are usually due to abnormalities in structural membrane proteins, such as in hereditary spherocytosis, but they may involve cation channels (hydrocytosis and xerocytosis) and, rarely, membrane lipids (abetalipoproteinemia).

The red cell itself may contribute to its own quietus, as exemplified by glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency, and deficiencies of the other enzymes involved in erythrocyte metabolic pathways. Morphologic alterations are not predictable.

Finally, the red cell may be sabotaged by its own hemoglobin, such as in sickle cell anemia, the thalassemias, and the unstable hemoglobinopathies.

If the clinician considers these options in an inclusive but systematic fashion, direct screening tests can be ordered and expert consultation avoided.

Megaloblastic Anemia

David Watkins, V. Michael Whitehead, and David S. Rosenblatt

Before the mid-1920s, pernicious anemia was a disease dreaded as much as drug-resistant leukemia is today. With its characteristic megaloblastic bone marrow, pernicious anemia was a fatal illness until it was successfully treated with dietary liver in 1926.[1] It is now known that megaloblastic anemia is most often caused by a nutritional deficiency of folates or by a specific malabsorption of cobalamin (vitamin B_{12}) known as pernicious anemia (Box 11-1). Precise means for diagnosing and treating these deficiencies are available. Over the past 80 years, hematologists have gained detailed knowledge of the synthesis, biology, biochemistry, and molecular biology of both cobalamin and folate. It is extraordinary that this knowledge base continues to grow as new discoveries are made.

This chapter reviews aspects of this knowledge as it pertains to pediatric patients in particular. Emphasis is placed on clinical and laboratory diagnosis and on the treatment of overt deficiencies of cobalamin and folate. In addition, attention is focused on subclinical deficiency states as they relate to populations at increased risk, including premature newborns, the elderly, those infected with human immunodeficiency virus (HIV), and those with elevated plasma total homocysteine levels. Consideration is given to the role of these vitamins in the prevention of neural tube defects (NTDs) and cardiovascular disease and in the pathogenesis of cancer. Finally, current knowledge of inborn errors of cobalamin and folate metabolism is presented.

Box 11-1 | Causes of Megaloblastic Anemia

COBALAMIN (VITAMIN B_{12})

Defects in Absorption

Inadequate gastric intrinsic factor as a result of
  Pernicious anemia
  Gastritis
  Total gastrectomy
  Mutations in *GIF* (intrinsic factor gene)
Achlorhydria and pepsin deficiency
Disease of the small intestine
  Surgical resection or bypass of the terminal ileum
  Regional enteritis (Crohn's disease)
  Tropical and nontropical sprue
  Infiltrative disease (Whipple's syndrome, lymphoma)
  Competition by parasites (fish tapeworm, blind loop
    syndrome)
  Imerslund-Gräsbeck syndrome
  Drugs (colchicines, *p*-aminosalicylic acid, neomycin)
  Transcobalamin deficiency

Inadequate Nutrition

Strict vegetarians (vegans)
Maternal deficiency affecting the fetus or infant

Defects in Transport

Transcobalamin deficiency

Defects in Metabolism

Nitrous oxide intoxication
Inherited (cblC, cblD, cblE, cblF, and cblG disease)

FOLATES

Defects in Absorption

Hereditary folate malabsorption
Tropical and nontropical sprue
Infiltrative diseases of the small bowel (Whipple's
  syndrome, lymphoma)

Inadequate Nutrition

Insufficient or poorly selected diet
Maternal deficiency affecting the fetus or infant

Increased Requirement

Alcoholism
Pregnancy
Lactation
Hemolytic anemia
Hyperthyroidism
Anticonvulsant therapy
Lesch-Nyhan syndrome
Prematurity
Homocystinuria
First trimester during neural tube closure

Folate Inhibitors

Antifolates (methotrexate, pyrimethamine, trimethpoprim)
Sulfones

Inherited Defects

Methylenetetrahydrofolate reductase deficiency
Methionine synthase deficiency (cblE and cblG disease)
Others

OTHER CAUSES

Defects in Purine and Pyrimidine Synthesis

Inherited
  Orotic aciduria
Acquired
  Myelodysplasia and leukemia
  Drug induced
  Human immunodeficiency virus infection

Other

3-Phosphoglycerate dehydrogenase deficiency
Thiamine-responsive anemia
Scurvy
Pyridoxine-responsive anemia

DEFINITIONS

Megaloblastic anemia is a macrocytic anemia that is usually accompanied by leukopenia and thrombocytopenia. It is characterized by a specific megaloblastic bone marrow morphology that affects erythroid, myeloid, and platelet precursors. In this chapter the terms *cobalamin* and *vitamin B₁₂* are used interchangeably to refer to corrins that have coenzyme activity or that can be converted to coenzymes in cells (see later). The term *folates* refers to synthetic folic acid and to the various natural folate coenzymes, including reduced dihydrofolates (DHFs) and tetrahydrofolates (THFs) and their single-carbon substituted forms. Natural folate coenzymes are substrates for the enzyme folate polyglutamate synthetase and are converted by it to *folate polyglutamates* containing predominantly six or seven γ-linked glutamate residues. Most folates are present in nature as reduced and substituted folate polyglutamates. These, too, are included under the general term *folates*.

HISTORY

Anemia associated with morphologically abnormal erythrocytes had been observed in patients with pernicious anemia from 1876 to 1877.[2-4] By 1883, macrocytosis had been described. In 1891, Ehrlich stained and described megaloblastic erythroid precursors.[5] Giant myeloid band forms were observed in megaloblastic bone marrow in 1920, and the presence of increased numbers of nuclear segments in circulating neutrophils ("hypersegmentation") was described in 1923. Megaloblastic changes in bone marrow during relapse, with return of normal morphology during remission, were reported in 1921, 5 to 6 years before therapy for the disease was developed. In 1926, Minot and Murphy[1] described conversion of megaloblastic bone marrow to normoblastic bone marrow along with reticulocytosis and correction of the anemia after treatment with dietary liver. The sequence of these events has been summarized in several reviews.[2-4]

Among many subsequent observations, the following are among the most important:

1. Similar clinical syndromes (pernicious anemia of pregnancy and tropical anemia) were described by Wills in 1931 and subsequently demonstrated to be due to deficiency in folates.[6]
2. It was shown that in pernicious anemia, because of atrophy (destruction) of the gastric mucosa,[7] the stomach does not secrete enough of the intrinsic factor needed for absorption of cobalamin from the gut.[8] The disease is caused by failure to absorb adequate quantities of cobalamin.[4,9]
3. Cobalamin injections were found to correct pernicious anemia,[10] and administration of folate to resolve the anemia that was described by Wills. Each vitamin, when given in large doses, could produce some effect on the hematologic abnormalities caused by deficiency of the other.[11,12]
4. The cobalamin-binding protein transcobalamin was shown to play a role in endocytosis-mediated uptake of cobalamin by cells.[13,14]
5. Assays for cobalamin and folates in serum and tissues permitted chemical definition of the deficiencies in patients with megaloblastic anemia.[15-17]
6. It was recognized that subacute combined degeneration of the spinal cord (SCDSC), a neurologic syndrome, often accompanied classic pernicious anemia but not the megaloblastic anemia caused by folate deficiency.[1,18]
7. It was shown that pernicious anemia is an autoimmune disease[19] caused by lymphocyte-mediated destruction of gastric parietal cells, with the possible immunologic target being H⁺,K⁺-adenosine triphosphate (ATPase) on the parietal cell membrane.[20-22]
8. Inherited defects in the metabolism of cobalamin and folates that may cause abnormal development in addition to megaloblastic anemia were identified.[23-26] Identification of the genes affected in these inherited defects has provided insight into cobalamin and folate metabolism in human cells.
9. Purification and subsequent cloning of the genes for intrinsic factor, transcobalamin, and haptocorrin, accumulation of information about their structure, and study of their receptors defined the function of these proteins.[27-32]
10. The pathways for cobalamin biosynthesis by bacteria, including aerobic and anaerobic pathways, were elucidated.[33]
11. Elevated plasma methylmalonic acid and total homocysteine were found to reflect functional deficiency of cobalamin and either folates or cobalamin, respectively, even in patients with vitamin levels within the normal range.[34]
12. It was demonstrated that NTDs, including spina bifida, can be prevented by maternal folate supplementation during the periconceptional interval.[35,36]
13. It was shown that the plasma total homocysteine level, recognized to be a risk factor for arteriosclerotic vascular disease,[37] could be decreased by folate supplementation and that polymorphisms in genes involved in folate metabolism could modulate the total homocysteine level.[38] The total plasma homocysteine level may also influence the incidence of bowel and other cancers.[39]

HEMATOLOGIC DESCRIPTION

Bone Marrow and Blood

The causes of megaloblastic anemia are classified in Box 11-1.

Megaloblastic bone marrow is hyperplastic, with erythropoiesis stimulated by increased levels of erythro-
FIGURE 11-1. Bone marrow with megaloblasts. *(Courtesy of Dr. A.V. Hoffbrand, Royal Free Hospital, London.)*

FIGURE 11-2. Multilobar neutrophil. *(Courtesy of Dr. A.V. Hoffbrand, Royal Free Hospital, London.)*

poietin acting on erythroid progenitor cells. Megaloblastic erythroid cells are prone to undergo programmed cell death, or apoptosis,[40,41] thereby leading to a left shift with young erythroid precursors predominating in the bone marrow. This "ineffective erythropoiesis" results in elevated serum levels of lactate dehydrogenase, bile pigments, and iron derived from dying erythroid precursors. Mature erythrocytes have abnormal shapes and are of various sizes, and their mean cell volume (MCV) is much greater than normal. Macrocytic and misshapen erythrocytes survive for a shorter time in blood than normal erythrocytes do.

Erythroid precursors have a normal DNA content together with an elevated RNA content. They have increased RNA per unit of DNA and are thus larger than normal cells at the same level of maturation.[42] Their nuclear chromatin appears looser than normal on stained smears (Fig. 11-1), which gives the characteristic appearance of the megaloblast. Maturation of the nucleus and cytoplasm is asynchronous, with the nucleus appearing less mature than the cytoplasm. For example, polychromatophilic erythroblasts with considerable accumulation of hemoglobin in the cytoplasm may have vesicular, open, or immature nuclei, and more mature orthochromic erythroblasts may contain nuclei that are not the dense, small, purple-staining pyknotic nuclei of normal orthochromes. Experienced observers usually recognize megaloblastic erythropoiesis by noting the vesicular and open nuclear pattern in the earliest erythroblasts (proerythroblasts and basophilic erythroblasts) (see Fig. 11-1).

Myeloid precursors are larger than normal, with giant metamyelocytes and band neutrophils being the most striking features. These cells may persist in bone marrow for 10 to 14 days after the start of treatment.[43] Giant metamyelocytes and band neutrophils are not seen in the megaloblastoid bone marrow of patients with leukemia or myelodysplasia. Similar abnormalities probably affect megakaryocyte precursors but have not been well described. Neutropenia and thrombocytopenia occur more often with severe megaloblastic anemia, although both may occur in the absence of anemia.
Neutrophil hypersegmentation (Fig. 11-2) is defined as the presence of one or more six-lobed neutrophils or five or more neutrophils with five well-separated lobes among 100 segmented neutrophils. Multilobed neutrophils are a characteristic feature of the peripheral blood of cobalamin- and folate-deficient patients.

Other Tissues

Macrocytosis of buccal cells has been reported in patients with megaloblastic anemia. Similar abnormalities have been described in cells of the tongue, vaginal epithelium, urinary tract, and nasal epithelium. Decreased height of gastric cells and enterocytes has also been described. These changes reverse after treatment of the megaloblastic anemia.[44,45]

COBALAMIN (VITAMIN B$_{12}$)

Chemistry of Cobalamins

Cobalamins, members of the class of molecules called corrins, have the chemical structure shown in Figure 11-3. They consist of a planar corrin ring, similar to but distinct from that of porphyrins such as heme, with a central cobalt atom that coordinates with four nitrogen atoms of the corrin ring. A nucleotide, 5,6-dimethylbenzimidazole, coordinates with the cobalt atom below the plane of the corrin ring and attaches covalently as well to the corrin ring. The central cobalt atom may exist in three different oxidation states: the oxidized trivalent state (cob[III]alamin), the divalent state (cob[II]alamin), and the fully reduced monovalent state (cob[I]alamin). A number of different groups may be attached to the cobalt atom in the upper axial position (position "X" in Fig. 11-3) when it is in the cob(III)alamin state. Corrins that have coenzyme activity or can be converted to coen-
FIGURE 11-3. Cobalamin (vitamin B$_{12}$, Cbl) consists of a planar corrin ring (black) that coordinates with a central cobalt atom (red), with a 5,6-dimethylbenzimidazole base (blue) covalently attached to the corrin ring and coordinating with the cobalt atom. X (green) represents the upper axial ligand, which varies in different biologic and pharmacologic cobalamins. When X is methyl, the compound is methylcobalamin (MeCbl); when it is adenosyl, the compound is 5-deoxyadenosylcobalamin (AdoCbl); when it is CN, the compound is cyanocobalamin (CNCbl); and when it is OH, the compound is hydroxycobalamin (OHCbl).

zyme forms within the cell include cobalamins with CN (cyanocobalamin, CNCbl), OH (hydroxycobalamin, OHCbl), H$_2$O (aquocobalamin, H$_2$OCbl), SH (sulfitocobalamin, SOCbl), glutathionyl (glutathionylcobalamin, GSCbl), methyl (methylcobalamin, MeCbl), or 5'-deoxyadenosyl (adenosylcobalamin, AdoCbl) bound in the upper axial position, as well as cob(II)alamin and cob(I)alamin.[46,47]

Nutritional Sources and Requirements

Although cobalamin is required for metabolism by prokaryotes, animals, and many algae, it is synthesized only by prokaryotes. Two distinct pathways for de novo cobalamin synthesis have been identified, one anaerobic and the other requiring molecular oxygen.[48,49] Eukaryotes lack a biochemical pathway for de novo cobalamin synthesis and are dependent on diet for their cobalamin requirement. Some algae contain large amounts of cobalamin, which they apparently acquire through a symbiotic relationship with cobalamin-synthesizing bacteria.[50] Cobalamin is not required as a vitamin by higher plants, which neither synthesize nor accumulate cobalamin and thus do not contribute it to the diet.

The recommended dietary allowance of cobalamin for adults has been set at 2.4 µg/day, with the aim of ensuring absorption of 1 µg/day, assuming absorption of about 50% from food.[51] The World Health Organization has recommended a daily cobalamin intake of 1 µg for normal adults; 1.3 and 1.4 µg daily for lactating and pregnant women, respectively; and 0.1 µg/day for infants. Studies of chromosomal damage and uracil misincorporation into DNA in different populations suggest that this level may need to be higher, 7 to 10 µg/day, to ensure genomic stability.[52-54]

Because all of the cobalamin needs of humans are met through the diet, inadequate intake causes deficiency. Typical diets in developed countries contain more than adequate amounts of cobalamin, although cobalamin deficiency may occur in vegans, who consume no animal products whatever. Elsewhere, cobalamin deficiency may occur frequently in populations whose diet contains little meat.[51] On the Indian subcontinent, the concentration of vitamin B$_{12}$ in serum and tissues is low in vegans, in lactovegetarians, and in nonvegetarians whose diets nevertheless contain little meat.[55-57] Low cobalamin levels have also been reported in populations in the Middle East, elsewhere in Asia, Africa, Mexico, and Central and South America.

SCDSC secondary to cobalamin deficiency has been described in vegans, but its frequency appears to be very low.[58,59] The reason for this is unknown and merits further study.

Cobalamin-Binding Proteins

Effective transmembrane transport of cobalamins into mammalian cells at the low cobalamin levels found in nature requires mediation of cobalamin-binding proteins interacting with receptors on the cell surface that recognize the cobalamin-protein complex. Three cobalamin-binding proteins play roles in the uptake and transport of cobalamin: intrinsic factor, transcobalamin (previously called transcobalamin II), and haptocorrin (also called transcobalamin I, transcobalamin III, cobalaphilin, and R binder). These proteins have similar primary sequences and intron/exon structure, thus suggesting that they have arisen by duplications of an ancestral gene.[60,61] They show 33% overall homology with each other, and specific regions demonstrate as much as 60% to 80% identity.[62]

Intrinsic Factor

Intrinsic factor, a 45-kd glycoprotein, is synthesized in gastric parietal cells in humans and is required for efficient uptake of dietary cobalamin in the intestine. It is readily digested by pepsin, but not by trypsin.[63] Intrinsic factor binds cobalamins less tightly (K_d = 0.1 to 1.0 nmol/L) than transcobalamin or haptocorrin does.[64] However, its binding affinity for cobalamins is far greater than that for nonfunctional corrin analogues such that the latter are not absorbed from the intestine. Intrinsic factor is encoded by the *GIF* (gastric intrinsic factor) gene on chromosome 11q13.[65]

Transcobalamin

Transcobalamin mediates the entry of cobalamin into a variety of cell types. It is found in plasma, cerebrospinal fluid (CSF), seminal fluid, and transudates and is synthesized in a variety of cells, including fibroblasts, macrophages, enterocytes, renal cells, hepatocytes, spleen, heart, gastric mucosa, and endothelium.[66] Transcobalamin is a nonglycosylated protein with a molecular weight of 43 kd.[67] Plasma turnover is rapid.[68] It binds cobalamin tightly (K_d = 5 to 18 pmol/L) to form holotranscobalamin (holo-TC) but has low affinity for corrins without vitamin B_{12} activity. The *TCN2* gene is localized to chromosome 22q12-13.[61]

Haptocorrin

The *TCN1* gene on chromosome 11q11-q12[69] encodes the haptocorrins, a family of proteins of approximately 46 kd that contain the same protein backbone but differ in their degree of glycosylation. They are synthesized by myeloid and probably other cells. Haptocorrins are present in many secretions, including plasma, bile, saliva, tears, breast milk, amniotic fluid, and seminal fluid, as well as in extracts of granulocytes, salivary gland, platelets, hepatoma cells, and breast tumors.[66,70,71] The fully glycosylated haptocorrin found in plasma has a low isoelectric point and a half-life of 9 days; haptocorrins with higher isoelectric points are cleared more rapidly from plasma into bile. Seventy percent to 90% of the cobalamin in plasma is bound to haptocorrin (holohaptocorrin, holo-HC), with the remainder being associated with transcobalamin; however, only transcobalamin-bound cobalamin is available for uptake by cells other than hepatocytes. Haptocorrins have the greatest affinity for cobalamins of all of the cobalamin-binding proteins (K_d = 3 to 7 pmol/L). In addition, they have considerable binding affinity for other corrins that lack vitamin B_{12} activity. An important function of haptocorrins in vivo may be the binding and excretion of such cobalamin analogues into bile.[72]

Cobalamin Binding

The three-dimensional structure of human transcobalamin has recently been determined. The protein has a two-domain structure with an N-terminal α_6-α_6 barrel and a smaller C-terminal domain. One molecule of cobalamin is bound between the two domains in the base-on conformation.[73] Similar studies with intrinsic factor or haptocorrin are complicated by their carbohydrate content, but studies of isolated domains from intrinsic factor and modeling of the three-dimensional structures of intrinsic factor and haptocorrin are consistent with a similar binding mechanism for cobalamin.[74,75]

Absorption of Dietary Cobalamins

Cobalamin in food is almost entirely protein bound. It is released from protein by the action of acid and pepsin in the stomach, where it binds to the haptocorrin present in saliva and gastric secretions. In the duodenum, the haptocorrin-cobalamin complex is broken down by pancreatic proteases with release of cobalamin, which then binds the intrinsic factor secreted by gastric parietal cells.[76] The intrinsic factor–cobalamin complex binds to receptors in the apical brush border of enterocytes in the distal ileum. Free cobalamin is not recognized by these receptors. The maximum quantity of intrinsic factor–cobalamin that can be bound to receptors in the human intestine is about 1.5 μg.[44]

The ileal receptor is made up of two proteins, cubilin (the product of the *CUBN* gene on chromosome 10p12.1) and amnionless (the product of the *AMN* gene on chromosome 14q32), and has been named "cubam." Cubilin is a 460-kd protein that consists of a 113-residue N-terminal region, followed by 8 epidermal growth factor–like repeats and 27 110–amino acid CUB domains.[77] It binds a variety of ligands in addition to intrinsic factor–cobalamin, including receptor-associated protein, albumin, apolipoprotein A-I/high-density lipoprotein, transferrin, immunoglobulin light chains, and vitamin D–binding protein.[62] It is present in the renal proximal tubule and yolk sac, as well as the ileum.[77] Amnionless is an approximately 48-kd protein that is expressed in the same tissues as cubilin.[78] In a dog model it binds tightly to cubilin and appears to be essential for the production of mature cubilin and its transport to the apical brush border surface.[79] Expression of both cubilin and amnionless is required for uptake of intrinsic factor–cobalamin.[79-81] Another multiligand endocytic receptor, megalin, is coexpressed with cubilin, but it may not play any role in intestinal cobalamin uptake.[77]

Intrinsic factor–cobalamin is rapidly internalized by endocytosis after binding to its receptor.[82] Attachment of cobalamin to transcobalamin appears to occur within enterocytes after its release from intrinsic factor, which is subsequently degraded.[83-85] Holo-TC appears in the portal circulation after about 4 hours. Involvement of the lysosomal compartment in uptake of intrinsic factor–cobalamin is suggested both by impairment of cobalamin uptake by agents that interfere in lysosome function[86] and by the finding of impaired uptake of cobalamin in patients with the cblF disorder, in whom release of free cobalamin from the lysosome into the cytoplasm is impaired.[87]

Cobalamin is excreted in bile, binds to intrinsic factor in the small intestine, and is reabsorbed. This enterohepatic circulation is interrupted in pernicious anemia such that depletion of cobalamin stores occurs more rapidly. Normal body losses have been estimated to be in the range of 2 to 4 μg cobalamin per day.

Cobalamin deficiency may develop in patients with heavy infestations of the fish tapeworm *Diphyllobothrium latum*, which has been shown to be capable of releasing cobalamin from intrinsic factor and accumulating it.[88] Removal of massive quantities of fish tapeworm from patients has corrected megaloblastic anemia. However, it

is likely that cobalamin deficiency caused by the worm is restricted to patients with marginal secretion of intrinsic factor or malabsorption of dietary cobalamin. The recent increase in ingestion of raw fish may provide new cases for study and treatment.

Cobalamin malabsorption has been observed in some patients with intestinal blind loops or stenotic areas of the small bowel.[76] Malabsorption decreased after treatment with antibiotics (e.g., tetracyclines), thus suggesting that bacteria proliferating in stagnant intestinal areas compete with the host for cobalamin in the intestinal lumen, but the exact nature of the process remains unclear. The increased serum folate level observed in many of these patients is attributed to the synthesis of large amounts of folates by intestinal bacteria.

Entry of Cobalamin into Cells

Transcobalamin carries just a fraction of the cobalamin present in blood, but only cobalamin bound to transcobalamin is available for uptake by cells other than hepatocytes. Uptake is mediated by a specific membrane receptor present in many types of cells.[13,64,89] Several groups have purified holo-TC receptors from mammalian cell membranes that have differing properties.[90-93] The primary sequence of the physiologic receptor is not known, and no gene has been identified. There is rapid binding of holo-TC to the receptor at the cell surface, followed by slower internalization with degradation of transcobalamin and release of free cobalamin.[94,95] Internalization involves endocytosis, with holo-TC entering the lysosomal compartment; the process is disrupted by treatment with lysosomotropic agents such as chloroquine or ammonium chloride, which prevent acidification of the lysosome.[14,96] Transfer of free cobalamin from the lysosome to the cytoplasm appears to require a specific transport system, but it has not been characterized. This system is defective in patients with cblF disease and results in accumulation of free cobalamin within the lysosome.[97,98]

Cellular Cobalamin Metabolism

Cobalamin functions as a coenzyme in two reactions in humans (Fig. 11-4). MeCbl is required in the synthesis of methionine from homocysteine and 5-methyltetrahydrofolate (5-methyl-THF). This reaction is mediated by the cytoplasmic enzyme methionine synthase (5-methyl-THF:homocysteine *S*-methyltransferase, International Union of Biochemistry Enzyme Commission [EC] 2.1.1.13)[99,100]:

Reaction 1

Homocysteine + 5-methyl-THF → Methionine + THF
AdoCbl (Ado-B$_{12}$) is required for the conversion of methylmalonyl-coenzyme A (CoA) to succinyl-CoA, which is mediated by the mitochondrial enzyme methylmalonyl-CoA mutase (EC 5.4.99.2)[101]:

Reaction 2

Methylmalonyl-CoA → Succinyl-CoA

In prokaryotes, a variety of other enzymes use cobalamin for reactions that do not appear to occur in mammalian cells.

Once inside the cell, cobalamin is partitioned between the cytoplasm, where it is required for the activity of methionine synthase, and the mitochondria, where it is required by methylmalonyl-CoA mutase. Synthesis of the cobalamin coenzyme derivatives MeCbl and AdoCbl requires reduction of exogenous cobalamin, which is typically in the cob(III)alamin state, to cob(I)alamin before addition of the upper axial ligand. The early steps in this process remain poorly understood. GSCbl may play a role.[102] In bacteria, reduction of cob(III)alamin to cob(I)alamin requires the activity of two separate reductases catalyzing the sequential reduction of cob(III)alamin to cob(II)alamin and cob(II)alamin to cob(I)alamin.[103] A number of enzymes that catalyze these reactions in vitro have been identified in mammalian mitochondrial and microsomal extracts,[104-107] but their physiologic relevance has not been established. Two classes of inborn error of cobalamin metabolism, cblC and cblD, affect early steps in cellular cobalamin metabolism. The cblC disorder results in decreased synthesis of both AdoCbl and MeCbl; the cblD disorder may result in decreased synthesis of AdoCbl, MeCbl, or both. The genes underlying these disorders, *MMACHC* (cblC)[108] and *MMADHC* (cblD),[109] have been identified, but their functions have not been established.

Methionine Synthase

Methionine synthase is the major pathway for remethylation of homocysteine in humans. The reaction catalyzed by methionine synthase involves transfer of a methyl group from 5-methyl-THF to an enzyme-bound cob(I)alamin prosthetic group to generate MeCbl; the methyl group is subsequently transferred from MeCbl to homocysteine to form methionine and regenerate cob(I)alamin.[99,100] Maintenance of the enzyme-bound cobalamin in its active, fully reduced state requires the activity of a second protein, methionine synthase reductase. Once every 100 to 200 turnovers, the enzyme-bound cobalamin spontaneously oxidizes to cob(II)alamin; methionine synthase reductase catalyzes reductive remethylation to regenerate MeCbl by using *S*-adenosylmethionine (AdoMet) as methyl group donor[110,111]:

Reaction 3

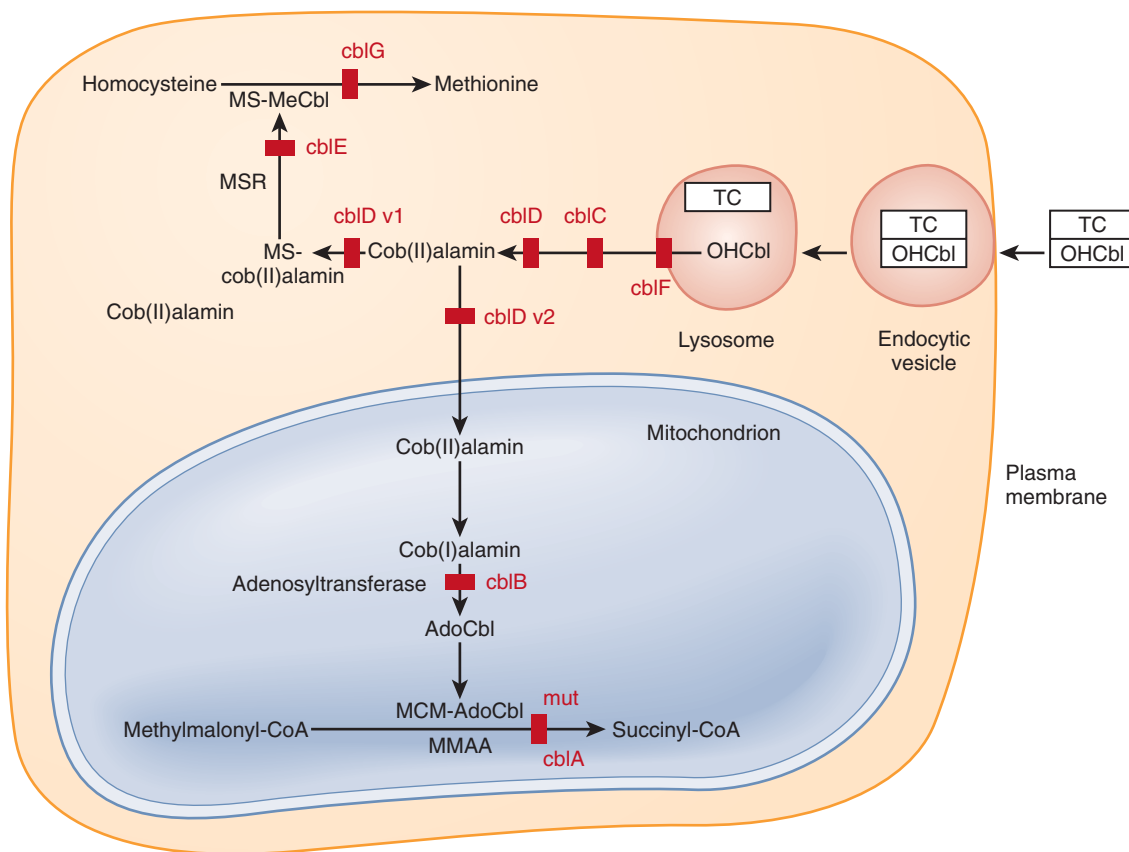
Homocysteine + AdoMet → Methionine + AdoHcy
The gene encoding human methionine synthase, *MTR*, has been localized to chromosome 1q43.[112-114] It consists of 33 exons spanning over 60 kilobases (kb) of genomic DNA[115] and encodes a gene product of 1265 amino acids. The protein is 55% identical with cobalamin-dependent methionine synthase (MetH) from


FIGURE 11-4. Scheme of cobalamin metabolism. The sites affected by methylmalonyl-CoA mutase deficiency (*mut*) and inborn errors of cobalamin metabolism (*cblA* to *cblG*) are shown in red. The cblA disorder is caused by defects in the MMAA protein; cblB is caused by defects in the cob(I)alamin adenosyltransferase (MMAB) protein; cblC is caused by defects in the MMACHC protein; cblD, cblD variant 1 (*cblDv1*), and cblD variant 2 (*cblDv2*) are caused by defects in the MMADHC protein; cblE is caused by defects in the methionine synthase reductase (MSR) protein; cblG is caused by defects in the methionine synthase (MS) protein; and the mut disorder is caused by defects in methylmalonyl-CoA mutase (MCM). The protein affected in the cblF disorder is unknown. MCM-AdoCbl, holomethylmalonyl-CoA mutase (mutase with bound adenosylcobalamin); MS-cob(II)alamin, methionine synthase with bound cob(II)alamin; MS-MeCbl, holo methionine synthase (synthase with bound methylcobalamin); TC, transcobalamin.

Escherichia coli,[113] in which enzyme function has been extensively studied. The *E. coli* enzyme is modular, with an amino-terminal homocysteine-binding domain,[116] a methyl-THF–binding domain,[116] a cobalamin-binding domain,[117] and a C-terminal activation domain that contains the AdoMet binding site required for methionine synthase reductase–catalyzed reductive methylation.[118] X-ray crystallography studies have demonstrated the importance of a triad of amino acids (equivalent to Asp783, His785, and Ser836 of the human synthase) in binding cobalamin to the enzyme. This is a component of an extended cobalamin-binding motif common to several cobalamin-utilizing enzymes, including methylmalonyl-CoA mutase.[119] The human enzyme has a similar arrangement of domains. Crystallography studies have shown structural differences in the activation domain, which interacts with the flavin mononucleotide–binding domain of methionine synthase reductase rather than the flavodoxin/flavodoxin reductase system used by the *E. coli* enzyme.[120]

When MeCbl is bound to methionine synthase, its dimethylbenzimidazole base is displaced from the cobalt and its place is taken by the histidine residue (the "base-off" conformation), which facilitates the methyl transfer reactions of the catalytic cycle.[119] The histidine residue does not appear to be essential for the reductive methylation reaction.[121] Conformational changes in the protein result in apposition of the 5-methyl-THF–binding and the homocysteine-binding domains to the upper surface of the bound cobalamin at appropriate times during the catalytic cycle, as well as apposition of the activation domain to the upper surface of the bound cobalamin during reductive methylation.[122]

Methionine Synthase Reductase

The human methionine synthase reductase gene (*MTRR*) on chromosome 5p15.2-15.3 was identified and cloned on the basis of homology to the flavodoxin/flavodoxin reductase system that plays a similar role in the *E. coli* cobalamin-dependent methionine synthase.[110] *MTRR* encodes a 698–amino acid protein that is a member of the FNR family of electron transferases. Methionine synthase reductase has been shown to support the reduced nicotinamide adenine dinucleotide phosphate (NADPH)-

dependent activation of methionine synthase in vitro.[111] It may also act as an H$_2$OCbl reductase, as well as a stabilizing methionine synthase.[123]

Methionine Metabolism

Methionine is an essential amino acid in humans. The role of methionine synthase is to remethylate the homocysteine generated during cellular metabolism, thereby helping maintain adequate methionine levels, as well as preventing the accumulation of potentially toxic homocysteine. It also represents the only means of converting methyl-THF to THF because the reaction catalyzing the synthesis of methyl-THF from methylene-THF is irreversible under physiologic conditions. A cobalamin-independent enzyme, betaine–homocysteine methyltransferase (EC 2.1.1.5), catalyzes homocysteine remethylation in the liver[124]; however, in situations in which methionine synthase is decreased, as in inborn errors of metabolism or cobalamin deficiency, the betaine-utilizing enzyme is insufficient to prevent accumulation of homocysteine and its sequelae.

Cellular methionine may be used in protein synthesis or adenosylated to form AdoMet by the enzyme adenosine triphosphate (ATP)–L-methionine S-adenosyltransferase (EC 2.5.1.6):

Reaction 4

Methionine + adenosine → AdoMet + 2P$_i$

AdoMet acts as a methyl group donor in at least 39 different AdoMet-dependent transmethylation reactions, including DNA methyltransferase 1, which catalyzes the methylation of cytosine residues at CpG sites of DNA, as well as enzymes catalyzing the methylation of RNA, lipids, proteins (including histones), neurotransmitters, and thiols.[125] These reactions generate S-adenosylhomocysteine (AdoHcy), which in turn can be hydrolyzed to homocysteine and adenosine by the enzyme S-adenosylhomocysteine hydrolase (EC 3.3.1.1):

Reaction 5

AdoMet + R → AdoHcy + CH$_3$-R

Reaction 6

AdoHcy → Homocysteine + adenosine

Intracellular homocysteine is generated from methionine by this cycle. Homocysteine may be remethylated by methionine synthase or betaine–homocysteine methyltransferase, or it may react with serine to form cystathionine in a reaction catalyzed by cystathionine β-synthase (EC 4.2.1.22). Accumulation of intracellular homocysteine results in increased levels of AdoHcy by mass action because the equilibrium of the reaction catalyzed by AdoHcy hydrolase favors synthesis rather than hydrolysis of AdoHcy.[126] AdoHcy in turn inhibits various AdoMet-dependent methyltransferases,[125] with potential adverse effects on numerous systems.

Synthesis of Adenosylcobalamin

The system responsible for transport of cobalamin from the cytoplasm to the mitochondria is not well understood, nor is the reduction state of the cobalamin that traverses the mitochondrial membrane known. Cobalamin uptake by isolated mitochondria was observed only in swollen mitochondria; under these conditions, OHCbl, AdoCbl, and MeCbl were taken up more effectively than CNCbl was.[127] Uptake was apparently achieved by diffusion, followed by binding of cobalamin to a mitochondrial protein, presumably methylmalonyl-CoA mutase, thereby resulting in unidirectional uptake. It is not clear how well cobalamin uptake under these conditions reflects physiologic processes.

Synthesis of AdoCbl occurs before the coenzyme becomes bound to methylmalonyl-CoA mutase. The terminal step in this process, adenosylation of cob(I)alamin by ATP–cob(I)alamin adenosyltransferase (Reaction 7), occurs in mitochondria:

Reaction 7

Cob(I)alamin + ATP → AdoCbl + triphosphate
The gene encoding this enzyme, *MMAB*, has been identified and cloned. It is localized to chromosome 12q24 and encodes a 250–amino acid protein that is a member of the PduO family of ATP–cob(I)alamin adenosyltransferases,[128,129] one of three classes of cob(I)alamin adenosyltransferase that have been identified in bacteria. In addition to catalyzing the adenosylation of cob(I)alamin, adenosyltransferase may also act as a chaperone and deliver cobalamin in an activated (base-off) state to methylmalonyl-CoA mutase.[130-132]

Another protein, the product of the *MMAA* gene on chromosome 4q31.1-2, is also required for the function of methylmalonyl-CoA mutase.[133] *MMAA* encodes a protein of 418 amino acids that is a member of a family of auxiliary P-loop guanosine triphosphatases (GTPases), which includes proteins that function as chaperones in the assembly of metal cofactors. Studies of MeaB, an orthologue of MMAA from *Methylobacterium extorquens*, have shown that it interacts physically with methylmalonyl-CoA mutase.[134,135] MeaB (and by extension MMAA) may act in the GTP-dependent assembly of holomethylmalonyl-CoA mutase from apoenzyme and AdoCbl and in the protection of radical intermediates during enzyme activity.[136]

The majority of intracellular cobalamin exists bound to proteins; it appears that cobalamin is not retained in cells unless it is protein bound. Cytoplasmic cobalamin seems to consist exclusively of MeCbl bound to methionine synthase, whereas most cobalamin in the mitochondria is AdoCbl bound to methylmalonyl-CoA mutase.[138]

Methylmalonyl-CoA Mutase

The mitochondrial enzyme methylmalonyl-CoA mutase catalyzes the final step in the pathway that converts pro-

pionyl-CoA, generated during the catabolism of branched-chain amino acids, odd-chain fatty acids, and cholesterol, to succinyl-CoA. Mutase is encoded by the *MUT* gene on chromosome 6p12-21.2.[139,140] The human enzyme is a homodimer consisting of 77-kd subunits, with two molecules of AdoCbl bound per dimer.[141,142] The protein is synthesized in the cytoplasm as a precursor containing a leader sequence and is processed to a mature protein in mitochondria.[143] The structure and function of bacterial methylmalonyl-CoA mutase (from *Propionibacterium shermanii*) have been studied extensively. This enzyme is a heterodimer composed of an α and a β subunit. The human enzyme shows 60% sequence identity to the α subunit, the only subunit of the bacterial enzyme that binds AdoCbl,[144] and the results of studies of *P. shermanii* methylmalonyl-CoA mutase seem to be relevant to the human enzyme.

Methylmalonyl-CoA mutase contains the same extended cobalamin-binding motif present in methionine synthase. As with methionine synthase, the enzyme-bound cobalamin cofactor is in the base-off conformation, with a histidine residue from the enzyme replacing the dimethylbenzimidazole base at the central cobalt.[145] Binding of substrate to holoenzyme results in change from an "open" enzyme conformation to a "closed" conformation in which the active site is completely buried, coupled with displacement of the adenosyl group from the cobalt. Subsequent exchange of a carbonyl-CoA radical and a hydrogen atom located on vicinal carbons of the substrate results in conversion of methylmalonyl-CoA to succinyl-CoA.[101]

Biochemical Effects of Cobalamin Deficiency

The biochemical consequences of cobalamin deficiency result from decreased activity of the cobalamin-dependent enzymes methionine synthase and methylmalonyl-CoA mutase. Decreased activity of methionine synthase results in elevated levels of its substrate homocysteine in blood and excretion of homocystine in urine. Methionine levels in blood may be decreased or in the low-normal range. Decreased activity of methylmalonyl-CoA mutase results in accumulation of methylmalonic acid in blood and urine.

Diagnosis of Cobalamin Deficiency

Commonly, macrocytic anemia occurs and is accompanied by neutropenia and thrombocytopenia. The MCV is 120 fL or greater unless coexisting iron deficiency or a chronic inflammatory process is present.[146-149] The blood smear contains oval macrocytes and multilobed neutrophils. However, changing technology, including the use of automated cell counters, and the varying competence of technologists reporting blood smears may mean that oval macrocytes and multilobed neutrophils are not always reported. The bone marrow is usually megaloblastic.

Abnormal biochemical findings include increased levels of lactate dehydrogenase, bilirubin, and iron in serum, as well as increased transferrin saturation, which reflects "ineffective erythropoiesis." Serum cholesterol, lipid, and immunoglobulin levels may be decreased. These changes are not specific to cobalamin deficiency but are corrected with cobalamin therapy.[150,151] Increased serum gastrin and pepsinogen levels and antibody to gastric parietal cells, which signals the presence of atrophic gastritis, are equally nonspecific[152,153] because they do not distinguish those who lack intrinsic factor. The presence of antibody to intrinsic factor in serum is highly specific and indicates that the patient has cobalamin deficiency or that it will develop. However, it is present in 70% or less of patients.[19,152,154]

Serum Cobalamin Levels

The most direct evidence of cobalamin deficiency is an abnormally low serum cobalamin level. Although early studies using microbiologic assays showed that the serum cobalamin level was almost always less than 100 pg/mL (78 pmol/L) in patients with megaloblastic anemia secondary to cobalamin deficiency,[155] megaloblastic bone marrow is found in only 20% to 30% of patients with serum cobalamin levels less than 100 pg/mL. Therefore, significant cobalamin deficiency can occur without hematologic manifestations. Neurologic manifestations of cobalamin deficiency may appear before macrocytosis and classic megaloblastic anemia develop.[156]

The serum cobalamin level has been shown to reflect hepatic cobalamin in small numbers of subjects,[44] but the significance of low serum cobalamin levels without clinical evidence of cobalamin deficiency, abnormal metabolism of methylmalonate or homocysteine, or an abnormal deoxyuridine suppression test has not been determined. In many cases these patients are treated with cobalamin, with variable clinical benefit.[157,158]

In contrast, significant cobalamin deficiency may occur in the absence of low serum cobalamin levels in patients who do not have megaloblastic anemia. In one study the serum cobalamin level was greater than 100 pg/mL in 30% to 40% of patients demonstrated to have significant cobalamin deficiency; in 3% to 5%, the serum cobalamin level was in the normal range.[156,159] This failure of the assay to provide a near-perfect clinical correlation[160] is due in part to technical defects, including the specificity of the cobalamin binder used in some commercial ligand-binding assays. It also reflects the limits of the sensitivity and specificity of newer assays[161,162] when used as the sole measure of cobalamin deficiency, particularly when the assay is applied to populations lacking clinical features of cobalamin deficiency. In patients with megaloblastic anemia, the finding of a normal to increased level of serum folate, together with a reduced ratio of erythrocyte to serum folate, provides strong but indirect evidence of cobalamin deficiency.[163]

These studies suggest that evidence of functional cobalamin deficiency in addition to serum cobalamin levels (e.g., macrocytosis, multilobed neutrophils, and elevated levels of plasma methylmalonic acid and total

homocysteine) should be sought when cobalamin sufficiency is evaluated in such populations, as well as in individuals in whom deficiency is suspected. The finding of increased serum levels of methylmalonic acid and total homocysteine provides evidence of functional cobalamin deficiency at the cellular level.

In patients who cannot absorb cobalamin, there is evidence that the amount of cobalamin bound to transcobalamin (holo-TC) decreases before the reduction in total serum cobalamin (mostly holo-HC) occurs.[164] Attempts to improve the clinical accuracy of serum cobalamin determination have focused on measurement of holo-TC, the physiologic component. Recent improvements have been made in the assay,[165,166] but the benefit of this measure over serum cobalamin is the subject of continued study.[158,167-169]

Tests of Cobalamin Absorption

In cases of deficient intestinal cobalamin transport, the diagnosis of cobalamin deficiency used to be confirmed by the demonstration of correction of cobalamin malabsorption by the administration of cobalamin with a source of intrinsic factor (urinary excretion tests, or Schilling tests I and II). Indeed, correction of the cobalamin malabsorption by feeding intrinsic factor and radiolabeled cobalamin together confirmed that a lack of intrinsic factor is the cause of the malabsorption and established that the patient has pernicious anemia.[170] Unfortunately, this "gold standard" for investigating cobalamin absorption is no longer readily available because of the increasing difficulty of obtaining both radiolabeled cobalamin and intrinsic factor. Native human intrinsic factor is no longer available, and hog intrinsic factor is rarely used because of health concerns.[171] Under development is a new test for cobalamin absorption in which changes in serum holo-TC are measured after a physiologic divided dose of cobalamin with plant-derived recombinant human intrinsic factor.[172-174]

Dietary Cobalamin Malabsorption

Malabsorption of dietary cobalamin is a disorder characterized by the inability to release cobalamin from food or its binding proteins.[175-177] It is measured by feeding subjects eggs, meat, or liver from birds or animals fed radiolabeled cobalamin. It is basically restricted to research laboratories and needs to be standardized in each. Patients have reduced serum cobalamin levels with normal free cobalamin absorption (Schilling test). Many have atrophic gastritis and reduced gastric peptic activity. Dietary cobalamin malabsorption affects about 40% of subjects with low serum cobalamin levels and is thus the most common cause of cobalamin deficiency. Proton pump inhibitors, which inhibit gastric acid secretion, can also induce dietary cobalamin malabsorption.[178]

Single-Sample Fecal Excretion Test

The single-sample fecal excretion test of cobalamin absorption avoided the pitfalls of tests that relied on urinary excretion. Labeled cobalamin (free or bound to food) was fed with a nonabsorbable dye (carmine red) together with nonabsorbable [^{51}Cr]chromic chloride. A sample of carmine red–stained stool was counted for ^{51}Cr and ^{57}Co and the ratio of counts compared with that in the sample that was fed. In normal subjects, 36% to 88% of a 1- to 2-μg dose of ^{57}Co-labeled cobalamin was absorbed.[179] This test is not readily available.

Measurement of Plasma Methylmalonic Acid and Total Homocysteine

The presence of methylmalonic acid in the urine of patients with pernicious anemia and its disappearance days or weeks after treatment with cobalamin was described in 1962.[180] Almost all subjects who are cobalamin deficient, both children and adults,[181] accumulate methylmalonic acid in plasma.[34,182-185] Indeed, elevated plasma levels of methylmalonic acid may be found before the appearance of macrocytosis, anemia, or other clinical features of cobalamin deficiency.

Homocysteine accumulates in the plasma of patients deficient in cobalamin, folate, or both.[34,156,159,181,186-188] Plasma homocysteine binds to free SH groups on proteins, and low concentrations may not be detected unless released from proteins by reducing agents, which yields the total plasma homocysteine concentration. Elevated total plasma homocysteine levels are found in more than 80% of patients who are deficient in cobalamin or folates.

An increased neutrophil lobe count and elevated total plasma homocysteine and methylmalonic acid levels indicate functional cobalamin deficiency and add to the interpretation of serum cobalamin and holo-TC measurements.[189] Although elevated plasma methylmalonic acid is more specific than total homocysteine for cobalamin deficiency, this test is more difficult to perform and is less widely available. Methylmalonic acid and total homocysteine levels, as well as holo-TC levels, are increased in patients with renal impairment. The relationship of elevated levels of total plasma homocysteine to NTDs, cerebral and cardiovascular disease, and the incidence of cancer is discussed later in this chapter.

Positive Therapeutic Test

Correction of hematologic, biochemical, and neurologic abnormalities after treatment with cobalamin represents a positive therapeutic test (Fig. 11-5). A single injection of 10 μg CNCbl is given. The test is positive if megaloblastic changes in the erythroid series in bone marrow disappear within 48 hours and at least two of the following occur:

1. Fifty percent decrease in serum iron or lactate dehydrogenase within 48 hours
2. Increase in the reticulocyte count 5 to 10 days after treatment
3. Correction of thrombocytopenia over a 2-week period
FIGURE 11-5. Timeline of clinical response of cobalamin deficiency after the administration of 10 μg of cyanocobalamin.

4. Correction of neutropenia over a 2-week period
5. Decrease in MCV by 5 fL or more after the reticulocytosis has subsided
6. Correction of anemia over a period of 2 to 4 weeks
7. Decrease in the neutrophil lobe count from the elevated to the normal range over a 4-week period
8. Decrease in elevated plasma methylmalonic acid and total homocysteine levels over a 2-week period

A diagnosis of folate deficiency can be established by treating the patient with a low dose of folic acid (in the range of 0.5 mg/day by mouth for 2 to 3 days) and monitoring for metabolic normalization and reticulocytosis in the succeeding 2 weeks. It should be noted that a dose of 2 to 5 mg of folic acid can induce reticulocytosis in most patients with cobalamin deficiency and 100 to 1000 μg of cobalamin can induce reticulocytosis in patients with folate deficiency.

Serum Cobalamin in Folate Deficiency

The serum cobalamin level may be decreased, even into the deficient range, in patients with megaloblastic anemia secondary to folate deficiency. The level increases over a period of 7 days with folate treatment unless the patient is deficient in cobalamin as well.[190] These changes may reflect alterations in the distribution of cobalamin between cells and plasma.

Deoxyuridine Suppression Test

The deoxyuridine suppression test[191,192] is based on the hypothesis that the activity of thymidylate synthase is decreased in cells deficient in cobalamin or folates because of lack of the folate coenzyme 5,10-methylene-THF polyglutamate. Such deficient cells have increased intracellular deoxyuridylate as a result of this decreased activity, and incubation of these cells with deoxyuridine would further expand the deoxyuridylate pool. In the test, bone marrow cells are incubated first with deoxyuridine and then with ^{3}H-labeled thymidine, each for 1 hour, and

the quantity of ^{3}H incorporated into cell DNA is determined.

In normal cells, thymidylate synthase converts deoxyuridine to thymidine during the initial incubation, with the amount of ^{3}H-thymidine subsequently incorporated reduced to less than 10% of that observed when deoxyuridine preincubation is omitted. In bone marrow cells from a patient who is deficient in cobalamin or folates, preincubation with deoxyuridine reduces incorporation of ^{3}H-thymidine into DNA to only 30% to 40%.

This defect in suppression of ^{3}H-thymidine incorporation into DNA in cobalamin-deficient cells can be corrected by the addition of either MeCbl or 5-formyl-THF (folinic acid) during preincubation with deoxyuridine. Addition of 5-methyl-THF to deoxyuridine corrects the defect in folate-deficient but not in cobalamin-deficient cells. There is uncertainty regarding the biochemical processes actually being modulated during this test, but the deoxyuridine suppression test reliably discriminates between cobalamin and folate deficiency, except in patients with concomitant iron deficiency.

Treatment of Cobalamin Deficiency

Severe Deficiency

Patients with severe anemia may have accompanying heart failure because of the anemia itself, sodium retention, and myocardial hypoxia. Initial treatment includes the administration of oxygen and diuretics and slow red blood cell (RBC) transfusion to avoid circulatory overload. Clinical disasters have occurred during initial therapy. Treatment of severely anemic adults with pernicious anemia was associated with immediate death in 14% in one study[193]; however, more recent studies have not confirmed this result.[152] Disasters include life-threatening hypokalemia and cerebral and cardiovascular accidents (usually strokes secondary to thrombosis or embolism). To minimize the risk for severe metabolic disturbances such as hypokalemia in these patients, an

initial dose of 10 µg CNCbl may be given subcutaneously for 2 days. This therapy is sufficient to normalize serum lactate dehydrogenase and iron levels and induce reticulocytosis in 5 to 7 days, but insufficient to normalize plasma methylmalonic acid and total homocysteine levels and replete body stores. For severely affected children, the dose of CNCbl is 0.2 µg/kg/day subcutaneously for 2 days.

The hypokalemia appears to be due to a shift of potassium from the extracellular to the intracellular compartment, accompanied by a delay in renal potassium retention. The clinician should anticipate this complication and provide a potassium supplement if needed. The role of potentially thrombogenic hyperhomocysteinemia in causing thrombosis and stroke during recovery is not known. These complications of initial therapy may affect children with severe cobalamin deficiency as well.

Conventional Therapy

Bone marrow aspiration should be performed before a transfusion is given to establish the presence of megaloblastic anemia and avoid the decrease in erythroid hyperplasia and changes in cell morphology induced by it. The RBC folate blood sample must be obtained before transfusion. Serum cobalamin and folate values are not altered much by transfusion but should be obtained beforehand as well.

Complete correction of megaloblastosis and associated metabolic changes requires anywhere from 15 to 150 µg of CNCbl. Conventional therapy has been 1000 µg of CNCbl or OHCbl by injection daily for 1 week, followed by 100 µg of CNCbl weekly for 1 month and then monthly thereafter. This therapy is believed to replete and sustain body cobalamin stores. Recently, oral and parenteral therapy with CNCbl or OHCbl has been compared and found to yield comparable benefits, particularly in regard to correction of the megaloblastic anemia.[194-196] Indeed, oral therapy with 1 to 2 mg cobalamin daily is cheaper and better tolerated and has become standard treatment in many countries. Whether oral therapy arrests the neurologic toxicity as quickly as parenteral dosing does is not yet known.[197] The answer would depend on the rapidity of delivery of the initial oral dose to the central nervous system (CNS) and on patient-to-patient variability. Another potential problem relates to "timed-release" cobalamin tablets with dissolution times of 3 to 6 hours, which are available in some countries and have been provided to patients by pharmacists.[198] "Timed-release" tablets have not been the subject of study. For these reasons it would be prudent to give an initial injection of cobalamin to patients with neurologic involvement.

Dementia and depression often respond rapidly to therapy, whereas other neurologic abnormalities improve gradually over a period of 6 months and may not return to normal. However, complete recovery from SCDSC in a bedridden patient with positive Babinski reflexes has been observed within 1 to 2 weeks after the start of cobalamin treatment (B. A. Cooper, personal communication).

Patients with pernicious anemia require indefinite replacement therapy. A prudent monthly dose is 100 µg CNCbl subcutaneously, although some patients require higher doses. Similar repletion plus maintenance of stores is achieved with injections of 1000 µg of OHCbl every 3 months[199] or 1000 µg OHCbl for 14 days every 6 to 12 months. The strong tissue binding of OHCbl permits such infrequent injections. Oral therapy consisting of 1 to 2 mg of cobalamin at intervals, with lower dosing in children and monitoring of plasma cobalamin levels periodically, is also an option. In some patients with pernicious anemia, cobalamin levels in serum or plasma can be maintained in the normal range with the daily ingestion of 50 to 200 µg CNCbl taken remote from meals.

In a few patients antibodies develop against the transcobalamin-cobalamin complex.[200,201] These antibodies do not appear to affect health but can result in very high levels of cobalamin in plasma. It is unclear whether this rare cobalamin allergy is more common after OHCbl, MeCbl, or CNCbl injections.

Cobalamin resistance is defined as correction of abnormal metabolite levels and clinical features in subjects with normal serum cobalamin values by treatment with pharmacologic doses of cobalamin. The cobalamin resistance encountered in subjects with diabetes, renal insufficiency, and advanced age may be attributable to kidney failure.[202-206]

In patients with apparent dietary cobalamin malabsorption, normal serum cobalamin levels and tissue stores can be maintained by feeding 10 to 25 µg CNCbl daily. Such treatment should be monitored periodically by measuring serum cobalamin, methylmalonic acid, total homocysteine levels, or any combination of the three. In children with inherited defects of cobalamin metabolism, injection of 1000 µg OHCbl two to three times per week is recommended. The effectiveness of therapy in such cases is monitored by measuring total serum homocysteine, methylmalonic acid, and methionine levels.

Development of Cobalamin Deficiency

Cobalamin deficiency may take years to develop because of the long half-life of cobalamin within the body (about 0.05% to 0.2% is lost per day)[207] and the large hepatic stores of the vitamin. The earliest manifestation in pernicious anemia results from loss of gastric intrinsic factor with reduced absorption of cobalamin from the diet, accompanied by a decrease in holo-TC.[164] Thereafter, levels of cobalamin in the liver and plasma decrease progressively. In most but not all subjects, the plasma cobalamin level falls below the normal range before clinical manifestations of deficiency are detected.[156,159]

The appearance of hypersegmented neutrophils and increased methylmalonic acid and total homocysteine levels in plasma may precede the development of classic

megaloblastic anemia. However, bone marrow morphology may show abnormalities, and oval macrocytes may be observed on blood smear. Neurologic and mental disease may develop at this stage and not be recognized as being related to cobalamin deficiency in the absence of anemia, elevated MCV, or decreased concentration of cobalamin in plasma.[156,159] More prolonged deficiency results in anemia with a megaloblastic bone marrow accompanied by neutropenia and thrombocytopenia. These conditions are most commonly (but not exclusively) seen in patients with the most severe anemia.[155]

Patients with deficiency of cobalamin but without symptoms may be identified by laboratory testing, may have unexplained neurologic signs or dementia, or may demonstrate the full picture of megaloblastic anemia. Progression is more rapid in patients with low cobalamin stores and in those with an additional metabolic insult (exposure to nitrous oxide, simultaneous deficiency of folate, or exposure to antifolates).

Pernicious Anemia

Pernicious anemia is the most common cause of severe cobalamin deficiency in adults in developed countries. It results from the lymphocyte-mediated immune destruction of intrinsic factor–producing gastric parietal cells. This acquired lack of intrinsic factor results in malabsorption of cobalamin. Patients who lack intrinsic factor after gastric resection and those few with a genetic mutation yielding defective or undetectable intrinsic factor are not considered to have pernicious anemia.

Pernicious anemia is characterized by autoantibodies directed against the gastric parietal cells (specifically against parietal cell H^+,K^+-ATPase) and against intrinsic factor. Antibodies against gastrin and pepsinogen may be present as well. Progression of this type A chronic atrophic gastritis to gastric atrophy and clinical anemia takes decades. Thus, the frequency of pernicious anemia increases with age, with most new cases being detected in the fifth to seventh decades of life. In the seventh decade and later, the incidence of pernicious anemia reaches 250 to 500 cases per 100,000. However, rare cases have been described in children. Men and women are equally affected. Studies in Sweden, Denmark, and the United Kingdom between 1942 and 1968 reported an incidence of 100 to 130 cases per 100,000. As the population ages, the frequency of pernicious anemia will increase as well.

Pernicious anemia occurs predominantly in whites. It is less common in blacks, in whom it may appear at a younger age,[208] and it has been reported in Asians.[209] Pernicious anemia is more common in northern Europeans than in those of Mediterranean origin. This north-south gradient of case incidence was also detected within the United Kingdom and Holland.[44]

The existence of families with multiple affected individuals[210] and concordance for pernicious anemia in monozygotic twins[211] suggest a genetic component, although the mode of inheritance is not simple. Attempts to link pernicious anemia with HLA phenotypes have been inconclusive. Pernicious anemia may be associated with other autoimmune disorders, including chronic autoimmune thyroiditis, insulin-dependent diabetes mellitus,[212] Addison's disease, Graves' disease, vitiligo, myasthenia gravis,[213] and possibly Sjögren's syndrome.[214] Hypothyroidism is common and should be evaluated clinically and by measurement of hormone levels.[215]

Patients with pernicious anemia are at increased risk for carcinoma of the stomach,[216,217] which may be found before, coincident with, or years after the diagnosis is made. Annual gastroscopy with biopsy of suspicious areas is recommended. Patients showing mucosal dysplasia or chromosomal changes suggesting a premalignant state require more frequent assessment. The current lack of tests to demonstrate cobalamin malabsorption adds extreme complexity to deciding which cobalamin-deficient patients require such monitoring.

Classic Clinical Findings

Cobalamin deficiency, caused by either dietary deficiency or intestinal malabsorption, is manifested clinically through its effects on rapidly proliferating tissues, principally bone marrow and the lining of the intestinal tract, as well as the nervous system. The result is illness in which megaloblastic anemia, gastrointestinal symptoms, or neurologic degeneration (or any combination) may predominate.

Megaloblastic Anemia

Pernicious anemia is often manifested as severe macrocytic anemia accompanied by neutropenia and thrombocytopenia. The gradual onset of the anemia, to which the patient adjusts by gradually curtailing activity, means that the patient may be largely asymptomatic except for some weakness. Impending or actual congestive heart failure may be present, as may postural or activity-induced shortness of breath. Usually, some neurologic or mental symptoms and signs are also present, as are soreness of the tongue (glossitis) and other intestinal symptoms.

Gastrointestinal Features

In some patients the anemia and neurologic deficits are relatively mild and the predominant symptoms are gastrointestinal, including loss of appetite with minor (5% to 10%) weight loss, nausea, constipation, occasional diarrhea, and glossitis aggravated by spicy or "acidic" foods. Failure to notice mild macrocytic anemia or elicit neurologic abnormalities may result in unwarranted intestinal imaging and visualization. Although the gastrointestinal symptoms may be secondary to the "megaloblastic" changes in gut cells, the relationship of morphologic changes in buccal, esophageal, and enteric cells to glossitis, anorexia, constipation, and diarrhea is uncertain.[45]

Neurologic Disease

The neurologic syndrome of cobalamin deficiency is known as *subacute combined degeneration of the spinal cord*.

SCDSC consists of demyelination and degeneration of the posterior and lateral columns of the spinal cord, along with a peripheral neuropathy that is more severe in the lower than the upper extremities.[218,219] Decreased vibration and position sense is usually the first objective manifestations of SCDSC, with pyramidal tract signs being observed later. The latter may be masked by a decrease in tendon reflexes secondary to the peripheral nerve lesions.[220-222] Cerebral symptoms and optic nerve degeneration also occur. Magnetic resonance imaging (MRI) may reveal white matter changes.[203] SCDSC can occur with little evidence of anemia and includes some or all of the following features:

- Degeneration of the posterior spinal columns, which results in decreased vibration sense below the iliac crests in 48%, loss of position sense in the feet in 42%, and ataxia in 64% of patients.
- Degeneration of the pyramidal tracts, which causes spasticity and dorsiflexion of the toes (Babinski reflex) in 56% of patients.
- Peripheral neuropathy with distal paresthesia, anesthesia, and muscular weakness in 90% of patients.
- Dementia mimicking Alzheimer's disease.
- Depression, with or without dementia, in 90% of patients and affecting virtually all symptomatic patients.
- Optic atrophy, which is very rare in pernicious anemia.

Decreased vibration sense, recently described as the "mobile phone sign,"[223] and paresthesias in the legs probably affect most patients with symptomatic pernicious anemia, but SCDSC affects no more than 30%. In one series, paresthesias were noted in 30% of patients, whereas SCDSC was present in only 6% to 9%.

In many patients with SCDSC, MCV is elevated and the serum cobalamin level is in the deficient range. However, patients with neurologic disease but without anemia may have serum cobalamin levels above the range of deficiency. Therefore, the diagnosis of cobalamin deficiency in patients with neurologic problems should not be excluded on the basis of a normal serum cobalamin level.[157] Similarly, in patients with senile dementia or Alzheimer's disease, elevated levels of plasma methylmalonic acid and total homocysteine should be sought.[224]

The pathogenesis of the neurologic lesions in SCDSC is unclear. Similar neurologic lesions can be induced in primates (including humans) and pigs by chronic exposure to nitrous oxide,[225] which also produces megaloblastic anemia in humans. Nitrous oxide reacts with the cob(I)alamin generated during the catalytic cycle of methionine synthase and causes oxidation of the cobalamin prosthetic group and generation of a reactive oxidant, possibly a hydroxyl radical, that can attack and deactivate the enzyme.[226,227] The nitrous oxide–induced neurologic lesion can be prevented in monkeys and pigs with methi-

onine supplements.[225,228] Similarly, SCDSC is observed in patients with inborn errors that affect the function of methionine synthase in the presence of normal methylmalonyl-CoA mutase activity (the cblE and cblG disorders). These data suggest that SCDSC is the result of decreased remethylation of homocysteine, perhaps as a result of changes in the activity of AdoMet-dependent transmethylases.

The frequency of SCDSC as the initial feature of pernicious anemia appears to have increased over the past 40 years. In a study published in 1961,[229] 10% to 15% reported neurologic symptoms. Hall found neurologic signs in 35% of patients with this disease.[230] In 1988, a study in California reported neurologic or mental disorders in 50% of patients with cobalamin deficiency.[231] It is unclear whether the spectrum of the disease has changed or whether more patients without anemia are being recognized through the availability of RBC volume determination (MCV), as well as assays for serum cobalamin.

Subclinical or Preclinical Pernicious Anemia

Erythrocyte macrocytosis, detected by electronic blood cell analysis, identifies patients with pernicious anemia and others with cobalamin deficiency. Still others are identified through screening programs in at-risk populations, such as the institutionalized, the elderly, and those with neurologic or psychiatric impairments. The diagnosis is usually established by finding a low serum cobalamin or plasma holo-TC level together with an elevated plasma methylmalonic acid or total homocysteine level.[188,189,232-237] Current strategies to evaluate suspected cobalamin-deficient patients have been addressed and controversies highlighted.[162,171,238,239] Most disturbing are clinic-based studies in which patients with macrocytic anemia or neurologic deficits, or both, are tested and then treated with cobalamin irrespective of the test results. Some of those with normal metabolite levels clearly respond clinically.[157] Regardless of whether clinical manifestations of cobalamin deficiency are present, many patients showing biochemical evidence of deficiency volunteer that they "feel better" after treatment with pharmacologic doses of cobalamin.

Maternal and Pediatric Cobalamin Deficiency

Maternal Cobalamin Deficiency

Cobalamin deficiency in newborns is most often the result of deficiency in the mother.[240] Mothers following vegan, vegetarian, macrobiotic, and other special diets are at particular risk. Not surprisingly, poverty and malnutrition lead to cobalamin deficiency in mothers and children in many parts of the world.[241-244]

Severely deficient mothers may be sterile,[245] but those with depleted cobalamin stores because of a cobalamin-deficient diet or early pernicious anemia may bear cobalamin-deficient infants. These mothers have low

serum and milk cobalamin levels, and their infants are born with low cobalamin stores that are not repleted during breast-feeding. If the mother has circulating anti–intrinsic factor antibodies, they may cross the placenta and impair intestinal cobalamin absorption during the initial weeks of life, particularly if the antibody titer is high.[246] Rare, asymptomatic, nonanemic cases of maternal pernicious anemia have been described.[57,247-249]

Maternal dietary cobalamin deficiency is usually associated with a strict vegetarian (vegan) diet entirely free of animal-derived nutrients,[250] but low serum cobalamin levels are also found in lactovegetarians and lacto-ovovegetarians. This is particularly so in immigrants to the West, where hygienic standards minimize the bacterial content of foods believed to be an important source of dietary cobalamin in Asian countries.[251]

Eating the macrobiotic diet described by Kushi and Jack,[252] which contains little animal protein, can deplete maternal cobalamin stores in as little as 3 years. Elevated urinary methylmalonic acid was found in 15 of 16 breast-fed infants of vegetarian mothers who ate a macrobiotic diet. Methylmalonic acid levels correlated inversely with maternal serum cobalamin levels, half of which were low. Maternal milk cobalamin levels were also low, and levels below 362 pmol/L correlated inversely with infant urinary methylmalonic acid. Functional cobalamin deficiency such as this appears to be much more widespread than hitherto thought.[250,253] Twenty-five of 58 pregnant Canadian adolescents 14.5 to 19 years of age had plasma cobalamin values in the suboptimal range (<148 pmol/L) at 36 weeks' gestation, and 71% of them had hypersegmented neutrophils.[254]

Up to 20% of normal pregnancies are associated with lower than normal serum cobalamin levels in mothers. These levels return to normal after delivery.[255] In a recent study, low maternal cobalamin levels were accompanied by elevated total homocysteine and methylmalonic acid levels and were the principal predictors of low cobalamin and raised total homocysteine and methylmalonic acid levels in the newborn. These abnormalities persisted for 6 weeks in the newborns. The authors concluded that cobalamin status in the neonatal period was strongly associated with maternal cobalamin status and parity.[256] The fact that parity increased the risk of low cobalamin status in mothers suggests that diet alone may be insufficient to replenish maternal cobalamin stores and that cobalamin supplements may be needed during pregnancy and after.

Healthy pregnant Korean women were less likely to have folate deficiency and more likely to have cobalamin deficiency than nonpregnant women were.[257] At the first antenatal visit, 61% of Nepali women had elevated serum methylmalonic acid, and 49% had low serum cobalamin values.[258] These authors recommended cobalamin supplements for this population. Worldwide cobalamin deficiency has been the subject of a detailed review.[51]

Less common causes of maternal cobalamin deficiency are gastric resection with loss of intrinsic factor–producing mucosa, fish tapeworm infestation, intestinal bacterial overgrowth, and sprue affecting the terminal ileum (see Box 11-1). Crohn's disease, ulcerative colitis, and surgical resection involving the terminal ileum may cause cobalamin malabsorption as well. Inhalation of the anesthetic gas nitrous oxide inactivates methionine synthase. Sufficient exposure to nitrous oxide can cause severe functional cobalamin deficiency with megaloblastic anemia and SCDSC in mothers or infants.[259,260] The effect of nitrous oxide exposure on the fetus during maternal nitrous oxide inhalation is unknown.

Cobalamin Deficiency in Newborns and Infants

Detection of cobalamin deficiency in newborns and infants can be challenging for clinicians, but the stakes are high because early treatment can prevent irreversible neurologic damage. The diagnosis is based on a high index of suspicion leading to demonstration of a low serum cobalamin level, an increased plasma total homocysteine level, and an increased plasma methylmalonic acid level, confirmed by response to parenteral cobalamin therapy. Assessment of the mother's diet and cobalamin status is important because maternal cobalamin deficiency is the most common cause of cobalamin deficiency in newborns and infants.

In adults, incipient folate or cobalamin deficiency is often suggested by a raised MCV, indicative of macrocytosis. Unfortunately, this is far less useful in detecting such deficiencies in children. In a study of 146 children 6 months to 12 years of age with an MCV of 90 fL or greater, macrocytosis was related to drug ingestion (anticonvulsants, zidovudine, immunosuppressive agents) in 51 of the cases. Other conditions associated with macrocytosis were congenital heart disease (20 cases), Down syndrome (12 cases), reticulocytosis (11 cases), marrow failure/myelodysplasia (6 cases), and miscellaneous causes (21 cases). No cause was found in 24 cases. No cases of cobalamin or folate deficiency were observed.[261]

In infants born to cobalamin-deficient mothers, severe cobalamin deficiency can develop in the early weeks of life. Indeed, cobalamin deficiency has become equated with severe megaloblastic anemia in children. This restrictive association is based on studies published in the 1960s and 1970s and supported by more recent individual case reports.[262-265] For example, frank megaloblastic anemia developed in a 10-month-old, exclusively breast-fed white boy. His mother had undergone a gastric bypass procedure for morbid obesity 2 years before her pregnancy and was not anemic despite a low serum cobalamin level and an abnormal Schilling test that corrected with intrinsic factor.[266] Cobalamin deficiency has been reported after surgery for necrotizing enterocolitis, particularly when resection has included part of the terminal ileum.[267]

A functional lack of cobalamin can be recognized by an elevated plasma or urinary methylmalonic acid level, an elevated total plasma homocysteine level, or a low

plasma cobalamin level in infants born to cobalamin-deficient mothers or mothers consuming vegetarian, macrobiotic, and other diets low in animal protein. Many such infants may not be anemic or may have received transfusions. They can show variable neurologic deficits. Even such subclinical cobalamin deficiency, untreated, can result in long-term neurologic or psychomotor impairment.

Plasma methylmalonic acid and total homocysteine levels were elevated eightfold and twofold above controls in 41 infants receiving a macrobiotic diet. Levels were inversely related to serum cobalamin levels, which were remarkably low. The mothers had been on a macrobiotic diet for 3 or more years, had breast-fed their infants, and had later fed them according to macrobiotic principles. Despite the absence of hematologic or neurologic deficits, these children showed growth retardation and impaired psychomotor development when compared with omnivorous control children.[181,268] In some malnourished or diet-following child populations at risk, even those with the least evidence of deficiency may develop below their full potential. Cobalamin status should be determined in all children suspected of failure to thrive.

In children, perhaps more than adults, functional or quantitative cobalamin deficiency is often clinically obscure. Deficiency of cobalamin is rarely recognized in newborns seen after several months of life with failure to thrive, apathy, anorexia, refusal of solid foods, developmental regression, or any combination of these problems.[265,269,270] Megaloblastic anemia may be present or not. Neurologic deficits may need to be sought with care. The extent to which dietary folates or folate supplements may mask the clinical picture is unknown. Among more recent case reports, several have emphasized the persistence of neurologic deficits despite cobalamin therapy.[248,256,271-277] Cranial MRI studies have shown severe cerebral atrophy and retarded myelination,[263] but the neurologic deficits persisted even after complete resolution of all MRI abnormalities.[278]

Dietary lack of cobalamin in newborns and infants appears to be more common than previously thought, is not restricted to those following specific defined diets, and is not well enough known. For example, a study to assess the efficacy and safety of lowering dietary intake of total fat, saturated fat, and cholesterol to decrease low-density lipoprotein cholesterol in children failed to adequately assess cobalamin nutriture. Self-reported cobalamin intake was significantly reduced, but levels of cobalamin and methylmalonic acid were not measured.[279,280] Cobalamin deficiency should have been of concern with a diet favoring vegetable over animal protein.

The ability of the placenta to accumulate cobalamin results in higher newborn than maternal plasma cobalamin and holo-TC levels[281,282]; as a result, cobalamin deficiency is rarely present at birth, although stores of cobalamin may be reduced. Thus, the increase in methylmalonic acid level may occur after screening for hereditary organic acidurias, including methylmalonic aciduria, has been performed. However, in premature infants, cobalamin supplements proved more effective than those containing folate in reducing the severity of the anemia of prematurity.[283] Additional therapeutic trials could provide more precision in our knowledge of the cobalamin status of newborns.

The consistency of reports documenting the permanence of neurologic damage induced by cobalamin deficiency in newborns, often despite therapy,[256,272,273,276,278] suggests the need to add cobalamin to folate supplements before and during pregnancy. Added cobalamin would reduce the occurrence of both NTDs[284] and nutritional cobalamin deficiency in newborns, along with its risk of permanent neurologic damage.

The other major causes of inadequate cobalamin availability in newborns, detected within the first year of life or sometimes years later, are inborn errors of cobalamin metabolism (described in a later section).

Treatment of cobalamin deficiency in newborns and infants needs to be aggressive to arrest and reverse the neurologic and psychomotor damage. An initial cobalamin injection is recommended. Parenteral cobalamin at daily and then weekly doses of 100 to 1000 µg CNCbl, OHCbl, or MeCbl provides the best hope of success and replenishes cobalamin stores. However, oral therapy may be effective as well (see earlier). After the initial month, cobalamin injections (or oral dosing) can be spread out further. Once neurologic recovery has occurred, oral cobalamin daily doses of 5 to 10 µg CNCbl or another form can be continued. There are reports of a self-limited "infantile tremor syndrome" arising during cobalamin therapy.[248,271,285]

Cobalamin Deficiency in Older Children and Adolescents

Cobalamin deficiency in older children and adolescents shares many causes seen in adults. It may result from diets lacking cobalamin, prepared by parents or selected by teenagers.[286] Gastric and intestinal diseases may result in malabsorption of cobalamin. Pernicious anemia is extremely rare in children younger than 10 years and rare in teenagers. Obese children, particularly teenagers, are at increased risk of having low cobalamin levels.[287] Low serum cobalamin levels and decreased cobalamin absorption as determined by the Schilling test have been reported in patients infected with HIV but without acquired immunodeficiency syndrome.[243,288-290] Treatment with current highly active antiviral therapy improves cobalamin status. Moreover, treatment with cobalamin and folate reduces total homocysteine levels in such patients.[291]

In a survey on the effects of marginal malnutrition on human function carried out in rural Mexico, a deficient plasma cobalamin level was found in 19% to 41% of individuals. In preschool children, 8% and 33% had deficient and low plasma cobalamin levels, respectively,

that persisted for more than a year. Plasma holo-TC was also low. Breast milk cobalamin was low in 31 of 50 lactating women. Deficiency was attributed to dietary lack of cobalamin combined with intestinal malabsorption.[292] In a study of 113 Guatemalan women and their infants, plasma cobalamin was low in 47% of mothers. Most had low holo-TC levels as well. Dietary lack combined with *Giardia lamblia* infection appeared to account for the cobalamin deficiency. Urinary methylmalonic acid was elevated in 12% of infants.[241]

Megaloblastic anemia developed in an 18-year-old woman undergoing diet therapy for phenylketonuria and led to assessment of cobalamin status in 37 adolescent and young adult phenylketonuria patients. Six had low (<150 pmol/L) and six had borderline low (150 to 200 pmol/L) plasma cobalamin levels.[293]

Cobalamin deficiency was identified in a series of infants of families eating a macrobiotic diet, and parents were persuaded to liberalize the family diet. A decade later, adolescents from these families were found to have persisting cobalamin deficiency with low cobalamin and raised methylmalonic acid and total homocysteine levels. These adolescents had impaired cognitive function in comparison to controls.[294,295]

Inborn Errors of Cobalamin Uptake and Transport

Deficiency of Intrinsic Factor

Fewer than 100 children have been identified with megaloblastic anemia and developmental delay as a result of an absence of effective intrinsic factor (intrinsic factor deficiency or congenital pernicious anemia, Mendelian Inheritance in Man [MIM] 261000). Evidence of cobalamin deficiency usually appears after the first year but before the fifth year of life, although clinical deficiency has appeared as late as 12 years of age in patients with partially defective intrinsic factor.[296] Patients have an abnormal Schilling test result that is corrected by exogenous intrinsic factor, but unlike classic pernicious anemia, they have normal gastric acid secretion and normal findings on gastric cytologic examination. In some cases no detectable intrinsic factor is produced[297,298]; in others, there is immunologically reactive but nonfunctional intrinsic factor, including intrinsic factor that has reduced affinity for cubam,[299] reduced affinity for cobalamin,[300] or increased susceptibility to proteolysis.[301] Several mutations have recently been described in the *GIF* gene in patients with intrinsic factor deficiency,[302,303] including some patients in whom Imerslund-Gräsbeck syndrome was clinically diagnosed (see the next section).

Imerslund-Gräsbeck Syndrome

Imerslund-Gräsbeck syndrome, or megaloblastic anemia 1 (MIM 261100), is usually accompanied by clinical manifestations of cobalamin deficiency in children between the ages of 1 and 5 years, although they may appear later.[304-307] At least 300 cases have been described.

Patients typically have failure to thrive, recurrent gastrointestinal or respiratory infections, pallor, and fatigue. Megaloblastic anemia is usually present. Neurologic signs may be relatively mild.[307] In many cases there is proteinuria that is neither of the classic glomerular or tubular type.[308] The disorder was initially recognized among Finns and Norwegians, but it is now more frequently diagnosed in patients from eastern Mediterranean countries. Patients have normal intrinsic factor, no evidence of antibodies to intrinsic factor or H^+,K^+-ATPase, and normal intestinal morphology. There is a selective defect in cobalamin absorption that is not corrected by exogenous intrinsic factor. It is now recognized that Imerslund-Gräsbeck syndrome is a result of deficiency of the intrinsic factor–cobalamin receptor complex, cubam. The proteinuria is a result of disruption of cubam function in the proximal tubule of the kidney.

A number of mutations in the *CUBN* and *AMN* genes have been identified in patients with Imerslund-Gräsbeck syndrome.[80,81,309] All the cases in Finland were due to *CUBN* mutations (three different mutations), whereas all Norwegian cases were due to *AMN* mutations (two mutations). Mutations of both *CUBN* and *AMN* were identified in patients of Middle Eastern origin.[309,310] In some Imerslund-Gräsbeck families, no mutations were identified and linkage to either *CUBN* or *AMN* was excluded, thus suggesting that mutations in at least one additional gene may cause this disorder. Several patients originally thought to have Imerslund-Gräsbeck syndrome on the basis of clinical studies have subsequently been shown to have mutations in the *GIF* gene,[303] thereby leading to the suggestion that sequencing of the *GIF*, *CUB*, and *AMN* genes represents a possible first-line strategy in diagnosing these diseases.

Treatment involves intramuscular injection of cobalamin, initially at 1 mg OHCbl daily for 10 days, followed by monthly injection afterward.[305] Successful treatment has also been reported with oral CNCbl.[172]

Transcobalamin Deficiency

Fewer than 50 patients with transcobalamin deficiency (MIM 275350) are known.[311,312] In these patients severe anemia develops at a much earlier age than in patients with other causes of cobalamin malabsorption, usually in the first months of life. Other symptoms include failure to thrive, weakness, and diarrhea in addition to pallor. The anemia is clearly megaloblastic, but some patients have pancytopenia or even isolated erythroid hypoplasia.[313] The presence of immature white cell precursors in a marrow that is otherwise hypocellular can lead to the misdiagnosis of leukemia. Neurologic disease has appeared from 6 to 30 months after the onset of symptoms.[314-317] Severe immunologic deficiency with defective cellular and humoral immunity has been reported, as has defective granulocyte function. In many patients serum cobalamin levels are normal[315] because most of the serum cobalamin is bound to haptocorrin. Many patients have

no detectable transcobalamin, whereas others have immunologically reactive transcobalamin and one patient had transcobalamin capable of binding cobalamin, although the complex did not mediate vitamin uptake into cells.[318,319] Some patients have abnormal intestinal uptake of cobalamin that is not corrected by exogenous intrinsic factor on the Schilling test, thus indicating a role for transcobalamin in cobalamin transport across the enterocyte.

Although all the transcobalamin in fetal and cord blood is of fetal origin, infants with no detectable transcobalamin in their plasma do not demonstrate manifestations of cobalamin deficiency until several days after birth. Homocystinuria was present in two patients and methylmalonic aciduria in three of five patients before they received cobalamin therapy.[311] After discontinuation of therapy, methylmalonic aciduria may return.

Mutations in the *TCN2* gene on chromosome 22q12-13 have now been identified in several patients with transcobalamin deficiency,[312,320,321] including deletions, nonsense mutations, and a mutation resulting in activation of a cryptic intronic splice site. Transcob alamin is synthesized by cultured cells, including fibroblasts and amniocytes, and prenatal diagnosis is possible even when the specific mutation in a family is not known.[322]

Serum cobalamin levels must be kept very high if transcobalamin-deficient patients are to be treated successfully. Levels ranging from 1000 to 10,000 pg/mL have been required and are achieved with doses of oral OHCbl or CNCbl twice weekly (500 to 1000 μg) or with systemic administration of CNCbl or OHCbl (1000 μg) weekly or more often. Folate in the form of folic or folinic acid has been successful in reversing the hematologic findings in most patients, but it should not be given as the sole therapy because of the danger of hematologic relapse and neurologic damage, which was induced in one patient by folate supplementation without cobalamin.[311]

Haptocorrin (R Binder, Transcobalamin I or III) Deficiency

Deficiency or complete absence of haptocorrin in plasma, saliva, and leukocytes has been described in several individuals.[323-327] It is unclear, however, whether haptocorrin deficiency is a cause of disease in any of these patients. Although serum cobalamin levels are low, holo-TC levels are normal and the patients are not clinically deficient in cobalamin. The original report described two brothers, one of whom had optic atrophy, ataxia, long tract signs, and dementia.[323] A later patient had findings resembling SCDSC.[327] Haptocorrin may play a role in the scavenging of cobalamin analogues that may be toxic to the brain.[72]

Inborn Errors of Cobalamin Metabolism

A number of inborn errors of cobalamin metabolism, designated cblA to cblG, have been identified (Table 11-1). These disorders result in homocystinuria, methylmalonic aciduria, or both, depending on whether synthesis of MeCbl, AdoCbl, or both cobalamin cofactors is affected. Only disorders in which synthesis of MeCbl is impaired, either alone (cblE, cblG, cblD variant 1) or in combination with AdoCbl synthesis (cblC, cblD, cblF), are characterized by megaloblastic anemia.

The diagnosis of inborn errors of cobalamin metabolism is usually carried out with the use of cultured fibroblasts from patients because the pathways for cobalamin metabolism are expressed in these cells. Measurement in intact fibroblasts of function of the cobalamin-dependent enzymes methionine synthase and methylmalonyl-CoA mutase and measurement of conversion of labeled CNCbl to its coenzyme derivatives MeCbl and AdoCbl define the biochemical phenotype. Cell complementation analysis is used to accurately identify which complementation class a patient's mutation falls into.[328,329] This is particularly important for groups such as cblE and cblG,

TABLE 11-1 **Diagnostic Studies of Inborn Errors of Cobalamin: Correlation of Genetic Complementation Group with Biochemical Phenotype and Major Clinical Manifestations**

Clinical Manifestations	COMPLEMENTATION GROUP								
	cblA	cblB	cblC	cblD	cblDv1	cblDv2	cblE	CblF	cblG
MAJOR CLINICAL FINDINGS									
Megaloblastic anemia	−	−	+	+	+	−	+	+	+
Methylmalonic aciduria	+	+	+	+	−	+	−	+	−
Homocystinuria	−	−	+	+	+	−	+	+	+
LABORATORY FINDINGS: INTACT CELLS									
[57Co]CNCbl uptake	N	N	D	D	N	N	N	I	N
AdoCbl (%)	D	D	D	D	N	D	N	D	N
MeCbl (%)	N	N	D	D	D	N	D	D	D
Propionate incorporation	D	D	D	D	N	D	N	D	N
Methyl-THF incorporation	N	N	D	D	D	N	D	D	D

AdoCbl (%), adenosylcobalamin as a percentage of total cellular cobalamin; cblDv1, cblD variant 1; cblDv2, cblD variant 2; D, decreased; I, increased; MeCbl (%), methylcobalamin as a percentage of total cellular cobalamin; N, normal; −, finding is absent; +, finding is present.

which are otherwise identical at the clinical and cellular levels.

Inborn errors of cobalamin metabolism are autosomal recessive disorders, with each class being the result of mutations at a different gene. Most of the genes responsible have been identified, and molecular diagnosis is often possible. Common mutations have been identified, as well as mutations that occur frequently in specific ethnic groups, but most mutations are restricted to a single family. Molecular diagnosis of a new patient with no family history therefore requires sequencing of the entire gene. Thus, analysis of patient fibroblasts in culture remains critical for establishing the diagnosis, especially in families in which the responsible mutations are not known.

Prenatal diagnosis by biochemical analysis of cultured amniocytes or chorionic villus cells has been sought for most of the classes of inborn errors of cobalamin metabolism.[330-333] Analysis of amniocytes appears to be more reliable than that of chorionic villus cells. In addition, gas chromatography–mass spectroscopy or liquid chromatography–tandem mass spectroscopy has been used to detect the presence of methylmalonic acid or homocysteine in amniotic fluid. It is now possible to carry out prenatal diagnosis by molecular genetic analysis when the causative mutations segregating in the family have previously been identified. Two independent methods should be used for prenatal diagnosis to minimize the risk of false-negative or false-positive results.[333]

Functional Methionine Synthase Deficiency

Functional methionine synthase deficiency is characterized by elevated plasma homocysteine, homocystinuria, and hypomethioninemia without methylmalonic aciduria. On the basis of complementation analysis, two distinct groups of patients have been identified: cblE and cblG. The clinical and biochemical findings in the two disorders are virtually identical. Patients are usually seen initially in the first 2 years of life, but some have not been symptomatic until adulthood. The most common findings in both cblE and cblG disease include megaloblastic anemia and various neurologic problems, including developmental delay and cerebral atrophy.[334] Other findings include electroencephalographic abnormalities, nystagmus, hypotonia, hypertonia, seizures, blindness, and ataxia. Findings in patients with adult onset of symptoms have typically involved neurologic or psychiatric symptoms. In one patient with onset at 21 years of age, multiple sclerosis was diagnosed.[335] Methylmalonic aciduria is usually absent, thus indicating normal function of the second cobalamin-dependent reaction catalyzed by methylmalonyl-CoA mutase, although one cblE patient had transient methylmalonic aciduria.[336] The significance of this observation is not known.

Fibroblasts from both cblE and cblG patients show decreased synthesis of MeCbl and decreased activity of methionine synthase in the presence of normal AdoCbl

synthesis and methylmalonyl-CoA mutase activity.[334] In fibroblasts from a minority of cblG patients, there is no binding of labeled cobalamin to methionine synthase.[337] The specific activity of methionine synthase is decreased in cblG cell extracts under all assay conditions, whereas in cblE fibroblasts, decreased specific activity is observed only when the assay is conducted under suboptimal reducing conditions, a finding reflecting decreased activity of methionine synthase reductase.[334,338]

The cblG disorder is the result of mutations in the *MTR* gene, which codes for methionine synthase.[112,339,340] Twenty different mutations in the *MTR* gene, including missense and nonsense mutations, deletions, and splice site mutations, have been identified. One mutation, c.3158C→T (p.P1173L), is especially frequent and represented a third of all disease-causing alleles in a panel of cblG patients.[115] This mutation was present only in the heterozygous state, thus suggesting that homozygotes may not be viable. The cblE disorder is the result of mutations at the *MTRR* gene, which encodes methionine synthase reductase. Eighteen different *MTRR* mutations have been identified in cblE patients.[110,341-344] The most frequent are the intronic mutation c.903+469T→C, which leads to the insertion of 140 bp of intronic sequence into mRNA, and c.1361C→T (p.S454L), which is observed in patients of Iberian origin and may be associated with a milder phenotype.

Generally, systemic therapy with OHCbl, at first daily and then once or twice weekly, has been used to treat these disorders. This corrects the anemia and metabolic abnormalities. The neurologic findings have been difficult to reverse, particularly in cblG disease, thus emphasizing the importance of early diagnosis and therapy. A mother carrying a fetus identified by prenatal diagnosis as having the cblE disorder was treated from the second trimester with systemic OHCbl.[330] The baby was treated from birth and has done very well. It is uncertain how much prenatal therapy contributed to this favorable outcome.

Combined Deficiency of Adenosylcobalamin and Methylcobalamin

The cblC, cblD, and cblF disorders are characterized by decreased synthesis of both MeCbl and AdoCbl, with resultant deficient activity of both methionine synthase and methylmalonyl-CoA mutase. Affected individuals have combined homocystinuria and methylmalonic aciduria. The disorders apparently affect early steps in cobalamin metabolism subsequent to hydrolysis of holo-TC in lysosomes. In the cblF disorder, the defect appears to affect the transfer of free cobalamin from lysosomes to the cytoplasm (see Fig. 11-4). The processes affected in the cblC and cblD disorders remain unknown.

The cblC Disorder

The cblC disorder (MIM 277400) is the most common of the inborn errors of cobalamin metabolism, with more

than 300 patients identified. Patients have homocystinuria and methylmalonic aciduria; in addition, hypomethioninemia and cystathioninuria are present. The infant is usually seen in the first year of life because of lethargy, poor feeding, failure to thrive, and developmental delay.[345] Most patients have megaloblastic anemia, and some have hypersegmented neutrophils and thrombocytopenia. In others, onset of the disorder occurs later in childhood[346,347] or in adulthood,[348-350] with findings of spasticity, myelopathy, delirium, dementia, or psychosis. A characteristic pigmentary retinopathy with perimacular degeneration has been observed in several patients[347,351-353]; other ocular manifestations have also been reported.[354,355] Some patients have had features of hemolytic-uremic syndrome.[356] Other reported findings in cblC disease include erosive dermatitis, hydrocephalus, and hepatic failure.[357,358]

Fibroblasts from cblC patients show decreased synthesis of both MeCbl and AdoCbl and decreased function of both methionine synthase and methylmalonyl-CoA mutase. Endocytosis of the transcobalamin-cobalamin complex and release of cobalamin from lysosomes into the cytoplasm occur normally,[95] but total intracellular cobalamin levels are markedly decreased in most cases as a result of the inability of cells to retain cobalamin that is not bound to intracellular proteins.

The gene mutated in the cblC disorder, *MMACHC* on chromosome 1p34.1, has recently been identified.[108] The function of its gene product is not yet understood. Mutations have been identified in more than 200 cblC patients. One mutation, c.271dupA, accounted for 40% of the identified mutations and is present primarily in patients of European or western Asian descent. Several additional recurrent mutations showed clustering on the basis of ethnicity. There is some evidence of genotype-phenotype correlation. The common c.271dupA mutation, as well as a c.331C→T (p.R111X) mutation, was associated with early-onset cblC disease, whereas a c.394C→T (p.R132X) mutation was associated with late-onset disease.[108,359]

Therapy for cblC disease can be difficult, particularly in patients with early onset. About a third of patients with onset in the first month of life die.[345] Some patients have improved with OHCbl therapy, 1 mg/day by injection, as assessed by a reduction in methylmalonic acid and homocystine excretion. Studies suggest that OHCbl rather than CNCbl should be used.[360] Therapy with MeCbl or AdoCbl has been used, but it is unclear whether these agents offer a therapeutic advantage. Systemic OHCbl treatment was much more effective than oral therapy, and betaine (250 mg/kg/day) appeared to be helpful when used in combination with OHCbl. Neither folinic acid nor carnitine had any effect.[360] Therapy with daily oral betaine and biweekly injections of OHCbl resulted in a reduction in methylmalonic acid levels, normalization of serum methionine and homocysteine concentrations, and resolution of lethargy, irritability, and failure to thrive. However, complete reversal of the neurologic and retinal findings did not occur, which emphasizes the need for early diagnosis and treatment. Even with good metabolic control, surviving patients generally have moderate to severe developmental delay.[345] The prognosis appears to be better in patients with a later age at onset.

The cblD Disorder

The cblD disorder (MIM 277410) was initially described in a single sibship in 1970. One patient was initially seen at 14 years of age with a history of mild mental retardation, severe behavioral pathology, and a poorly defined neuromuscular problem. There were no hematologic findings in this patient. His younger brother, clinically asymptomatic, was shown to have the same disorder. Cerebrovascular disease secondary to thromboembolism was detected at the age of 18 years in one of the brothers.[361] Both had methylmalonic aciduria and homocystinuria.[362] Fibroblasts from both brothers showed a biochemical phenotype indistinguishable from that of cblC fibroblasts, with decreased synthesis of both AdoCbl and MeCbl and decreased function of both methionine synthase and methylmalonyl-CoA mutase. Differentiation of cblD from cblC was achieved by complementation analysis.[363]

Recently, the cblD disorder has been diagnosed in additional patients with rather different clinical and biochemical findings.[364] Two patients had isolated homocystinuria in the absence of methylmalonic aciduria (cblD variant 1). A third patient had methylmalonic aciduria in the absence of homocystinuria (cblD variant 2). Clinical findings and the results of fibroblast studies for the patients with cblD variant 1 were identical to those of patients with cblE or cblG. Findings in the patient with cblD variant 2 were similar to those of patients with cblA disease. The gene on chromosome 2q23.2 affected in the cblD disorder (*MMADHC*) has recently been identified.[109] The function of the *MMADHC* gene product is not known. Mutations affecting its C-terminal region were associated with isolated homocystinuria, mutations affecting the N-terminal region were associated with isolated methylmalonic aciduria, and truncating mutations were associated with combined homocystinuria and methylmalonic aciduria. It has been suggested that MMADHC is involved in channeling cobalamin to its cytosolic and mitochondrial targets.

The cblF Disorder

At least nine patients with the cblF disorder (MIM 277380) are now known. Clinical findings have been variable, with none shared by all the patients who have been studied. Frequent findings include small size for gestational age, poor feeding, failure to thrive, growth retardation, and persistent stomatitis. Macrocytic anemia, neutropenia, thrombocytopenia, and pancytopenia have been observed. Two patients had minor facial abnormalities, and one had dextrocardia.[97,365-368] Typically, hyperhomocysteinemia and methylmalonic aciduria are present, although elevated homocysteine could not be

detected in the blood of the first patient described. Cobalamin absorption and serum cobalamin levels have been decreased in some patients.[87,366,367] One patient died suddenly despite apparent clinical response to therapy with cobalamin.[365]

Fibroblasts from cblF patients show both decreased function of cobalamin-dependent enzymes and decreased synthesis of MeCbl and AdoCbl. Unlike cblC and cblD fibroblasts, large amounts of intracellular cobalamin accumulate, almost all of it unmetabolized free CNCbl present within lysosomes.[97,98,369] The defect in cblF appears to impair transport of the cobalamin that has been released from transcobalamin across the lysosomal membrane into the cytoplasm. The gene affected in this disorder has not been identified. Abnormal intestinal absorption of cobalamin has been observed in two cblF patients, thus suggesting that the same lysosomal transport system plays a role in the transport of cobalamin across ileal cells.[87,366]

The patients with cblF disease appear to respond to systemic therapy with OHCbl, although the first patient responded to oral cobalamin.[97,365-368] A concern in cblF disease is that patients may accumulate cobalamin in lysosomes to such an extent that it impairs other lysosomal functions.

The Methylmalonic Acidurias

Inborn errors affecting activity of the second cobalamin-dependent enzyme, methylmalonyl-CoA mutase, result in accumulation of large amounts of methylmalonic acid in blood, urine, and CSF in the absence of hyperhomocysteinemia. Methylmalonic acid levels are much higher than those seen in adults with cobalamin deficiency, and these patients are prone to life-threatening acidotic crises. Patients with isolated methylmalonic aciduria have been classified on the basis of biochemical studies and somatic cell complementation into three classes: *mut* (mutations in the gene encoding methylmalonyl-CoA mutase) and *cblA* and *cblB* (affecting synthesis of the AdoCbl coenzyme required for methylmalonyl-CoA mutase activity). Methylmalonic aciduria has also been observed in patients with mutations affecting the genes encoding methylmalonyl-CoA epimerase (*MCEE*)[370,371] and succinyl-CoA synthase (*SUCLA2*).[372,373] The incidence of all forms of methylmalonic aciduria in Massachusetts is about 1 in 29,000.

Methylmalonyl-CoA Mutase Deficiency (mut)

Disorders of the mutase apoenzyme result in methylmalonic aciduria that is not responsive to cobalamin therapy. Mutase deficiency has been subdivided into two classes: *mut⁰* cell lines have no residual mutase activity, whereas *mut⁻* cell lines show some residual mutase activity in the presence of added OHCbl, possibly reflecting enzyme with decreased affinity for AdoCbl. Several mut⁰ cell lines synthesize no detectable protein, whereas others synthesize unstable proteins, and at least one has a mutation

that interferes with translocation of mutase to the mitochondria.[374] Similarly, variable levels of mRNA have been demonstrated in different mut⁰ lines. There is no complementation between mut⁰ and mut⁻ cell lines, but intragenic (interallelic) complementation has been seen among some mut lines.[375,376]

Clinically well at birth, patients with mutase deficiency rapidly become symptomatic with protein feeding. They usually come to medical attention because of lethargy, failure to thrive, muscular hypotonia, respiratory distress, and recurrent vomiting and dehydration. In normal children, the methylmalonic acid level is generally less than 15 to 20 μg/g of creatinine; in contrast, in methylmalonic aciduria, excretion is usually greater than 100 mg and may be as high as several grams per day. In addition to methylmalonic aciduria, these patients may have ketones and glycine in blood and urine and metabolic acidosis with elevated levels of ammonia. Many also have hypoglycemia, leukopenia, and thrombocytopenia. One study[377] demonstrated that methylmalonic acid inhibits the growth of bone marrow stem cells in a concentration-dependent manner. Follow-up of children identified by newborn screening[378] has revealed a number who excrete methylmalonic acid and have mutase deficiency, as demonstrated by complementation analysis, and yet are clinically well and have never been acidotic. It is unclear whether these children are at risk for catastrophic acidosis later in life.

The *MUT* gene on chromosome 6p12-21.2 spans 40 kb and consists of 13 exons.[140,379] Nearly 200 mutations have been identified in the *MUT* gene.[380,381] Many of these mutations are private, but several are common within specific ethnic groups, including c.2150G→T (p.G717V) in mutase-deficient patients of African origin,[382] c.349G→T (p.E117X) in Japanese patients,[383] and c.323C→T (p.R108C) in American Hispanic patients.[381]

Therapy consists of protein restriction, with the goal of limiting the amino acids that are the major source of propionate in humans. Formula deficient in valine, isoleucine, methionine, and threonine is used. Mutase-deficient patients are not responsive to vitamin B$_{12}$. Therapy with carnitine has been advocated in patients who are deficient.[384,385] Lincomycin and metronidazole have been used to reduce enteric propionate production by anaerobic bacteria.[386-388] Even with therapy the prognosis is guarded, and brain infarcts and renal dysfunction have been reported as late complications.[389]

Adenosylcobalamin Deficiency (cblA and cblB Disease)

The cblA and cblB disorders result in cobalamin-responsive methylmalonic aciduria and an intracellular deficiency of AdoCbl. They are distinguished by complementation analysis and by the fact that cblA cell extracts, but not cblB cell extracts, support the synthesis of AdoCbl from exogenous CNCbl. Intact fibroblasts from patients with both disorders do not synthesize AdoCbl from

CNCbl. A similar phenotype is seen in patients with the cblD variant 2 disorder,[364] including the patient previously placed in the cblH complementation class.[390] The cblB disorder results from mutations in the *MMAB* gene, which encodes ATP:cob(I)alamin adenosyltransferase.[128] The cblA disorder results from mutations in the *MMAA* gene, which encodes a protein of as yet unknown function.[133]

Most children with cblA or cblB disease become ill within the first year of life. Symptoms are similar to those seen in mutase deficiency but are less severe. Most cblA patients (90%) respond to cobalamin, with almost 70% being well at the age of 14 years. Less than half of cblB patients (40%) respond to therapy, and only 30% survive long-term.[391] Therapy involves the systemic use of either OHCbl or CNCbl. It is not clear whether AdoCbl offers any therapeutic advantage. Prenatal treatment of a fetus with deficient AdoCbl synthesis, ascertained via amniocentesis, by giving oral vitamin B_{12} to the mother[392] yielded a good therapeutic result. It is uncertain whether therapy starting at birth would have been equally effective.

The cblA and cblB disorders are inherited as autosomal recessive traits. Thirty mutations in the *MMAA* gene have been identified in cblA patients.[133,393-395] One mutation, c.433C→T (p.R145X), accounted for 43% of mutant alleles in a study of primarily North American patients.[393] This mutation was observed much less frequently in Japanese cblA patients; in this population, a c.503delC mutation, not detected in other patient populations, was frequent (8 of 14 mutant alleles).[394] Twenty-three mutations in the *MMAB* gene have been identified in cblB patients.[128,395,396] Many are predicted to affect the active site of the enzyme, identified from the crystal structure of its bacterial orthologue.[397,398] A c.556C→T (p.R186W) mutation represented 33% of affected alleles in the largest of these studies.[396]

FOLATE

Chemistry of Folates

Folates are heterocyclic compounds consisting of a pteroyl group conjugated with one or more glutamic acid units (Fig. 11-6). Folic acid, or pteroylglutamic acid, is an oxidized folate consisting of pteroic acid conjugated with a single glutamate residue. Biologically active folates are derived from folic acid by reduction of its pterin ring to form DHF and THF, by the addition of single carbon units at different redox states to nitrogens 5 or 10 of the pterin, and by conjugation of up to seven total glutamate residues by γ-carboxyl bonding. Intracellular folates exist primarily as one carbon group–substituted tetrahydrofolate polyglutamates. Folate derivatives that play an important role in cellular metabolism include 5-methyl-THF; 5,10-methylene-THF; 5,10-methenyl-THF; 10-formyl-THF; 5-formyl-THF; and 5-formimino-THF. Folic acid
FIGURE 11-6. Structure of folic acid (**A**) and 5-methyltetrahydrofolic acid (**B**). Folic acid consists of pteroic acid (black) conjugated to glutamic acid (blue). Cellular folates are derived from this molecule by reduction to 7,8-dihydrofolate (DHF) and further reduction to 5,6,7,8-tetrahydrofolate (THF); by the addition of one carbon group to THF at nitrogens 5 or 10 (shown in red); and by the addition of up to six additional glutamic acid residues via γ-carboxyl bonding. Forms active in cellular metabolism include 5-methyl-THF (shown); 5-formimino-THF; 5-formyl-THF (folinic acid); 5,10-methylene-THF; 5,10-methenyl-THF; and 10-formyl-THF.

itself is available commercially as a stable yellow powder. It has low solubility in aqueous solutions and at acidic pH. 5-Formyl-THF (folinic acid, leucovorin) is a stable reduced folate that is available commercially. Other reduced folates are photolabile and susceptible to destruction by oxidation; they readily break at the carbon 9–nitrogen 10 bond to produce inactive catabolites.[399]

Nutritional Sources and Requirements

Folate is widely available in vegetables, fruit, and meat.[44,400,401] Foods with very high folate content include liver, kidney, orange juice, and spinach[402-404]; however, the reduced folates in food are labile to light and oxidation and are partly destroyed during processing and cooking. Inadequate folate intake is the most common etiology of folate deficiency causing megaloblastic anemia. The dietary folate requirement is a matter of dispute. The daily intake recommended by the World Health Organization is listed in Table 11-2. It should be noted that techniques for measurement of folate in diets can vary widely and give different results. The mean dietary folate intake in populations in which folate deficiency is unusual is about 3 μg of total folates per kilogram of body weight per day. This is about 150 μg/day for women and 200 μg/day for men. Folate levels measured in 500 liver specimens from such a population, most obtained from victims of trauma, appeared to be adequate.[405] In volunteers ingesting diets of known folate content, plasma and erythrocyte folate levels remained within the normal range when intake was 150 to 200 μg/day.[406,407] Intake of this magnitude was calculated for normal subjects by measurement of a catabolite of folate (*p*-acetamidobenzoyl glutamate) that is excreted in urine.[408,409] The recognition that the elevated total plasma homocysteine levels

TABLE 11-2	Recommended Intake of Folate and Cobalamin (Food and Agriculture Organization of the United Nations, 1988)	
Age	Folate (μg/kg/day)	Cobalamin (μg/day)
Infants	3.6	0.1
Ages 1-6	3.3	
Adults	3.1*	1.0

*For pregnant or lactating women, supplement with 300 to 1000 μg/day of folate and 0.3 to 0.4 μg/day of cobalamin.

in many patients with cerebral and cardiovascular disease are reduced with folate supplements, plus the reduction in NTDs as a result of giving mothers a folate supplement in the periconceptional period (even those with normal folate levels), suggests that effective folate deficiency can exist in individuals with apparently normal folate concentrations and no megaloblastic anemia.

Efforts to promote folate sufficiency through consumption of a healthy balanced diet have not been successful, and since January 1998, folic acid fortification of all enriched cereal grain products has been mandated in the United States,[410] Canada, and parts of South America. Current levels of folate fortification are 140, 150, and 220 μg/100 g of flour in the United States, Canada, and Chile, respectively.[411] As a result, the incidence of NTD-affected pregnancies has decreased by 26% in the United States and by 48% in Canada.[412,413] Serum and RBC folate levels are higher as well. However, less than 10% of women of childbearing age have reached the recommended RBC folate level of greater than 906 nmol/L,[414,415] which has been shown to reduce the risk for NTDs substantially.[416] There have been repeated pleas to increase the level of folic acid fortification.[417] To date, adding folate to food seems to have not "masked" the anemia of pernicious anemia.[411] Concerns about folate fortification delaying the diagnosis of cobalamin deficiency and promoting cancer growth and issues of choice have delayed mandating the addition of folate to the diet in Europe and elsewhere.[418]

Because 50% of pregnancies are unplanned, it is recommended that a 0.4-mg folic acid daily supplement be taken by women during the childbearing years to ensure adequate folate during the initial 30 days after conception.[414]

Human milk provides enough folate for the infant, but heat-sterilized bovine milk may not. Goat's milk contains little folate, and severe folate deficiency develops in children maintained on it alone.[419]

Subjects with Increased Folate Requirements

Maternal folate intake beyond that recommended to maintain normal RBC and serum folate levels may be necessary for maximum gain in birth weight and prevention of NTDs. Although folate deficiency can be recognized through its hematologic effects, with the lack of

such defects combined with normal total plasma homocysteine levels being interpreted as folate sufficiency, studies linking folate status with NTDs and with arteriosclerotic vascular disease (see later) suggest the need to re-examine what is meant by "folate sufficiency." Increased folate intake may be required for reduction of the risk of cardiovascular and cerebrovascular disease in at least some adults. Whether this reflects a greater need for folate in the general population or in one or more subpopulations with altered folate metabolism remains to be determined.

Folate requirements appear to be greatest in newborn infants and young children[420]; in pregnant women, in whom folate is shunted to the developing fetus and urinary folate loss is increased; and in lactating women, who secrete 50 μg of folate or more per liter of milk. Folate in milk is concentrated above and does not correlate with the level of plasma folate.[421] Other groups with greater than normal folate requirements include patients with tropical and nontropical sprue and other malabsorptive states; those taking antiepileptic medications[422]; women taking high-dose oral contraceptives[423]; and patients with hemolytic anemia, especially those with sickle cell anemia and thalassemia.

Physiology of Folates

Absorption of Folates from the Gut

Dietary folates are principally folate polyglutamates. They are hydrolyzed within the gut lumen or brush border or in the lysosomes of enterocytes to folate monoglutamates by γ-glutamylhydrolase. Transport of monoglutamates occurs primarily in the proximal small intestine and is promoted by a specific carrier-mediated system that is most active at acidic pH and shows similar affinity for reduced and oxidized folates.[424-428] Folate appears in portal venous blood within 15 minutes of entering the stomach and reaches a maximum level in portal venous plasma about 1 hour later. Reduced folates, such as 5-formyl-THF, are rapidly converted to 5-methyl-THF during absorption.[429] A second potential source of folate is that synthesized by bacteria in the colon, some of which exists as monoglutamates. There is evidence for a folate transport system in the colon with the same properties as in the small intestine system.[430-432] It may contribute to whole body folate homeostasis or at least support the folate requirements of colon cells.

Intestinal folate uptake has been attributed to the reduced folate carrier (RFC), which is expressed in human enterocytes, primarily at the brush border membrane but also to some extent at the basolateral membrane.[433-435] However, RFC-mediated folate uptake in vitro is optimal at neutral pH and shows a preference for reduced folates over folic acid, and no mutations have been detected in the *SLC19A1* gene, which encodes the RFC, in patients with hereditary folate malabsorption. This suggested that folate uptake under physiologic conditions is mediated by another carrier system.[436,437]

Recently, a proton-coupled folate transport protein with an acidic optimal pH and similar affinity for reduced folates and folic acid has been identified in the intestine and choroid plexus[438]; identification of mutations in the gene encoding this protein in patients with hereditary folate malabsorption has demonstrated that this is the physiologic intestinal folate transporter.

Some folates presented to the liver and some hepatic folates are excreted into bile and reabsorbed.[439,440] This enterohepatic circulation mediates slower and more even absorption than would occur in its absence. There is evidence that the enterohepatic circulation of folates is impaired with alcohol ingestion,[440,441] thereby contributing to folate deficiency.[442,443] The efficiency of absorption of folic acid, folate polyglutamates, and dietary folate varies in different subjects. In general, absorption of synthetic folic acid is about twice as efficient as that of folate in food, whereas folate from folate-fortified cereal grain food is absorbed about 1.7 times as efficiently as dietary folate.[444]

Transport of Folates in Plasma

Plasma folate consists almost entirely of 5-methyl-THF.[445] Most of it is unbound; some may be bound to albumin, and a small proportion is bound to a folate-binding protein[446-448] derived from the cell surface protein folate receptor α by cleavage of its membrane-anchoring domain.[449,450] Plasma folate-binding protein levels are increased in pregnancy, in folate deficiency, in renal failure, with breast and ovarian cancers, and with some types of inflammation. Its function in plasma is unclear.[451-453] It is present in milk, where it may function to improve absorption of folate by the newborn.[454,455]

Entry of Folates into Cells

Three distinct systems for cellular uptake of folates have been identified in mammals. The RFC supports a low-affinity, high-capacity system for uptake of reduced folates and methotrexate (an antifolate cancer drug) at high concentrations (in the micromolar range); it is less effective in the uptake of folic acid. The RFC appears to be an important folate transporter in many types of cells, including hemopoietic cells, and has been extensively studied in tumor cells. It is encoded by the *SLC19A1* gene on chromosome 21q22.3.[456-460] There is considerable heterogeneity among transcripts produced from this gene.[461-463] Although silencing of *SLC19A1* results in decreased folate uptake in rat intestinal cells in vitro,[464] the RFC does not appear to be the major specific intestinal folate transporter in humans under physiologic conditions. Inactivation of *SLC19A1* in mice results in neonatal lethality because of failure of erythropoiesis.[465]

A second high-affinity, low-capacity system for folate uptake, active at nanomolar folate concentrations, is mediated by members of the folate receptor family, which bind 5-methyl-THF (the predominant circulating form of folate) and folic acid. Three isoforms of the folate receptor are known. Two of these, designated folate receptor α and folate receptor β, are encoded by separate genes, designated *FOLR1* and *FOLR2*, on chromosome 11q13.3-11q13.5.[466] The genes are similar structurally but differ in their 5′ untranslated regions and in their transcriptional regulatory elements. The folate receptors are attached to the cell surface by a glycosylphosphatidylinositol anchor.[450] The circulating folate-binding protein referred to in the previous section is derived from folate receptor α by cleavage from this anchor. It has been suggested that folate receptors, as well as other glycosylphosphatidylinositol-anchored proteins, are sequestered in cell surface structures called caveolae, where folate is taken up by a process called potocytosis.[467] However, it is also possible that folate uptake occurs by endocytosis.[468] Uptake of folate bound to circulating folate-binding protein may be mediated by the large multiligand receptor megalin, which is expressed in intestinal, renal, and other epithelia.[469]

The contribution of these folate receptors to total folate uptake by cells is not known. The level of cell surface folate receptors increases greatly in cultured mouse cells grown in very low folate concentrations, thus suggesting that they play an important role in cellular folate uptake under these conditions.[470] In addition, homozygosity for an inactivated *FOLR1* gene in transgenic mice results in embryonic lethality in the absence of high-dose folate supplementation.[471] Treatment of pregnant rats with antibodies to folate receptors results in embryonic defects that are preventable with folate supplementation.[472] The presence of autoantibodies to folate receptors in mothers has been associated with the occurrence of NTDs in humans.[473]

A third folate transport protein, the proton-coupled folate transporter (PCFT), has recently been described. It is expressed in enterocytes and choroid plexus cells, has an acidic optimal pH, and transports reduced and oxidized folates with similar efficiency.[438] Identification of mutations in its gene in individuals with hereditary folate malabsorption suggests that this carrier is responsible for both intestinal folate uptake and transport of folates across the blood-brain barrier at the choroid plexus.[438]

Biochemistry of Folates

Intracellular folate metabolism involves the transfer of one-carbon groups at various oxidation states from glycine, serine, histidine, and formate to THF; interconversion of different THF derivatives; and transfer of one-carbon units to other molecules in the synthesis of purines, thymidine, and methionine. A scheme of folate metabolism is illustrated in Figure 11-7.

Reduction of folic acid to DHF and reduction of DHF to THF are catalyzed by the enzyme DHF reductase (EC 1.5.1.3.):

Reaction 8

Folic acid + NADPH + H$^+$ → DHF + NADP
FIGURE 11-7. Cellular folate metabolism. Sources of one-carbon units are shown in the upper part of the figure and reactions that consume one-carbon units are shown in the bottom. Steps blocked in the three confirmed disorders of cobalamin metabolism are shown in orange; note that glutamate formiminotransferase deficiency affects both glutamate formiminotransferase (Reaction 13) and formiminotetrahydrofolate cyclodeaminase (Reaction 14) activities, which are carried on a single protein. Reactions are numbered as in the text. 1, methionine synthase; 8, 9, dihydrofolate reductase; 11, serine hydroxymethyltransferase; 12, glycine cleavage system; 13, glutamate formiminotransferase; 14, formimino-THF cyclodeaminase; 15, methylene-THF reductase; 16, methylene-THF dehydrogenase; 17, methenyl-THF cyclohydrolase; 18, formyl-THF synthetase; 19, methenyl-THF synthetase; 20, thymidylate synthase; 21, glycinamide ribonucleotide (GAR) transformylase; 22, amino-4-imidazolecarboxamide ribonucleotide (AICAR) transformylase.

Reaction 9

$$DHF + NADPH + H^+ \rightarrow THF + NADP$$

This enzyme shows higher affinity and a higher reaction rate for DHF than for folic acid. DHF reductase is required for reduction of any exogenous folic acid or DHF present in the diet, as well as for reduction of DHF generated from methylene-THF in the reaction catalyzed by thymidylate synthase.

A majority of intracellular folates exist as polyglutamylated derivatives, which usually contain a total of six or seven glutamate residues.[474] Synthesis of these folate polyglutamates depends on activity of the enzyme folylpoly-γ-glutamate synthetase (EC 6.3.2.17), which adds glutamate residues one at a time to reduced folates by using ATP as an energy source.

Reaction 10

$$Folate\ Glu_n + glutamate + ATP \rightarrow Folate\ Glu_{n+1} + ADP + P_i$$
DHF and THF are the preferred substrates for human folylpoly-γ-glutamate synthetase, whereas 5-substituted derivatives (5-methyl-THF and 5-formyl-THF) are poor substrates.[475] The affinity of folate polyglutamates for most folate-dependent enzymes is much greater than that of the corresponding monoglutamates. This is critical for cellular folate metabolism because intracellular folate concentrations are far lower than the affinity constants determined in vitro for most folate-dependent enzymes when folate monoglutamate substrates are used. Moreover, folate polyglutamates are channeled between active sites in multifunctional enzymes such as C_1-THF synthase and glutamate formiminotransferase-cyclodeaminase (FTCD), whereas monoglutamates must diffuse between the active sites.[476] Folate polyglutamates do not readily cross the cell or mitochondrial membranes. Polyglutamylation of folates within cells thus contributes to the ability of cells to retain reduced folates in the presence of low extracellular concentrations.

Folate polyglutamates are converted to monoglutamates by the enzyme γ-glutamylhydrolase (EC 3.4.22.12), located in lysosomes and in the intestinal brush border.[477,478] Folate monoglutamates cross cell membranes much better than polyglutamates do, and adequate cellular nutrition is impossible without this hydrolysis.

Sources of One-Carbon Units

Intracellular folates exist predominantly as polyglutamate derivatives, and these are the forms that the various cobalamin-dependent enzymes interact with. In the biochemical schemes described in the following sections, the length of the polyglutamate chains of the folate coenzymes is not indicated.

The majority of one-carbon units for folate metabolism in mammalian cells are derived from catabolism of the amino acids serine and glycine. Interconversion of serine and glycine is catalyzed by the enzyme serine hydroxymethyltransferase (EC 2.1.2.1):

Reaction 11

THF + serine → 5,10-Methylene-THF + glycine

Breakdown of glycine is catalyzed by the glycine cleavage system (EC 2.1.1.10), a four-protein complex composed of P protein, H protein, L protein, and T protein:

Reaction 12

Glycine + THF + NAD$^+$ →
$$5,10\text{-Methylene-THF} + CO_2 + NH_4^+$$
T protein catalyzes the transfer of a one-carbon group from H protein to THF to form methylene-THF.[479,480]

Both these reactions are reversible, although there is no evidence that the glycine cleavage system catalyzes the fixation of NH_3 and CO_2 to form glycine in vivo. Serine hydroxymethyltransferase can catalyze the conversion of glycine to serine when cells are exposed to high levels of glycine.[481] The enzyme is present in both cytoplasm and mitochondria; the two forms are products of separate genes.[482] The glycine cleavage system is present only in mitochondria.

Another source of one-carbon units for folate metabolism is through the degradation of histidine, which generates formiminoglutamate. This compound reacts with THF to form 5-formimino-THF in a reaction catalyzed by glutamate formiminotransferase (EC 2.1.2.5). Formimino-THF is subsequently deaminated to form 5,10-methenyl-THF in a reaction catalyzed by formimino-THF cyclodeaminase (EC 4.3.1.4):

Reaction 13

Formiminoglutamate + THF →
$$5\text{-Formimino-THF} + \text{glutamate}$$

Reaction 14

5-Formimino-THF + H$^+$ →
$$5,10\text{-Methenyl-THF} + NH_3$$
Both these reactions are catalyzed by a single bifunctional enzyme, FTCD, which is an octomeric protein arranged as a tetramer of dimers in a planar ring[483,484] and present only in the liver and kidney. Although increased urinary excretion of formiminoglutamic acid (FIGlu) is a biochemical feature of folate deficiency, it is not measured frequently because of technical difficulties and lack of specificity.

Interconversion of Folate Coenzyme Derivatives

Methylene-THF is converted to 5-methyl-THF by the enzyme methylene-THF reductase (MTHFR, EC 1.5.1.20).

Reaction 15

5,10-Methylene-THF + NADH →
$$5\text{-Methyl-THF} + NAD^+$$

Methyl-THF is the predominant form of folate in plasma and intracellular fluids. It is required for activity of the cobalamin-dependent enzyme methionine synthase, as discussed in the section on cobalamin metabolism (Reaction 1). The reaction catalyzed by methionine synthase is the only means of regenerating THF from 5-methyl-THF in humans. Because the reaction catalyzed by MTHFR is irreversible under physiologic conditions and is inhibited by AdoMet, when activity of methionine synthase is impaired as a result of cobalamin deficiency or mutations affecting its activity, folate becomes trapped as methyl-THF and is unavailable for other folate-dependent reactions (the methyl trap hypothesis).[485] Methyl trapping is the reason that both folate and cobalamin deficiencies result in megaloblastic anemia.

5,10-Methylene-THF can also be oxidized by methylene-THF dehydrogenase (EC 1.5.1.5, Reaction 16) to form 5,10-methenyl-THF, which is then converted to 10-formyl-THF by the enzyme methenyl-THF cyclohydrolase (EC 3.5.4.9, Reaction 17). These two activities, together with formyl-THF synthetase (EC6.3.4.4, Reaction 18), are carried out in the cytoplasm of vertebrates by a trifunctional enzyme [486,487] that has been designated C$_1$-tetrahydrofolate synthase.

Reaction 16

5,10-Methylene-THF + NADP$^+$ →
$$5,10\text{-Methenyl-THF} + NADPH + H^+$$

Reaction 17

5,10-Methenyl-THF + H$_2$O → 10-Formyl-THF + H$^+$

Reaction 18

THF + ATP + formate → 10-Formyl-THF + ADP + P$_i$
A second mitochondrial 5,10-methylene-THF dehydrogenase that preferentially uses NAD rather than NADP has been identified.[488] It is part of a bifunctional enzyme that also includes cyclohydrolase activity and appears to have arisen by duplication of the gene encoding C$_1$-THF synthase, followed by loss of its formyl-THF synthetase domain and change in its cofactor dependence.[489] The mitochondrial bifunctional enzyme is

expressed in embryonic and transformed cells, but not in normal adult tissues.[488] Mitochondrial formyl-THF synthetase activity has also been identified. This activity is catalyzed by an enzyme that was originally described as a mitochondrial C_1-THF synthase[490] but was subsequently shown to lack dehydrogenase and cyclohydrolase activity.[491] This enzyme also appears to have originated by duplication of the C_1-THF synthase gene with subsequent loss of 5,10-methylene-THF dehydrogenase and methenyl-THF cyclohydrolase activity because of mutations.

Conversion of 5,10-methenyl-THF to 5-formyl-THF is catalyzed by the enzyme methenyl-THF synthetase (EC 6.3.3.2).

Reaction 19

5-Formyl-THF + ATP →
$$\text{5,10-Methenyl-THF} + \text{ADP} + P_i$$
5-Formyl-THF does not serve as a cofactor for any reaction in cellular metabolism. Methenyl-THF synthetase is inhibited by 10-formyl-THF, which exists in equilibrium with 5,10-methenyl-THF.[492] This supports the suggestion that 5-formyl-THF acts as a storage form of folate[493,494] that can be converted to metabolically active forms when intracellular levels of 10-formyl-THF fall.

Utilization of Folate One-Carbon Units

Reactions that involve the use of one-carbon units attached to reduced folates include synthesis of methionine, with 5-methyl-THF used as methyl donor (see Reaction 1). Synthesis of thymidylate from deoxyuridylate, the final step in de novo thymidine synthesis, is catalyzed by thymidylate synthase (dTMP synthase, EC 2.1.1.45). In the course of this reaction, folate serves as both a one-carbon donor and a reductant, with the 6-hydrogen of 5,10-methylene-THF being transferred to the methyl group of dTMP. The DHF generated in this reaction is reduced to THF by DHF reductase (see Reaction 9).

Reaction 20

$$\text{5,10-Methylene-THF} + \text{dUMP} \rightarrow \text{DHF} + \text{dTMP}$$

Two steps during de novo purine biosynthesis use 10-formyl-THF as a one-carbon donor to generate carbons 2 and 8 of the purine ring. Conversion of glycinamide ribonucleotide (GAR) to formylglycinamide ribonucleotide (FGAR) is catalyzed by GAR transformylase (EC 2.1.2.2).

Reaction 21

$$\text{GAR} + \text{10-formyl-THF} \rightarrow \text{FGAR} + \text{THF}$$

Conversion of amino-4-imidazolecarboxamide ribonucleotide (AICAR) to formamido-4-imidazolecarboxamide ribonucleotide (FAICAR) is catalyzed by AICAR transformylase (EC 2.1.2.3). AICAR transformylase exists as a bifunctional enzyme with the enzyme that catalyzes the final reaction in purine biosynthesis, inosine 5′-monophosphate (IMP) cyclohydrolase.[495]

Reaction 22

$$\text{AICAR} + \text{10-formyl-THF} \rightarrow \text{FAICAR} + \text{THF}$$

Compartmentalization of Cellular Folate Metabolism

Because folate polyglutamates are unable to cross the mitochondrial membrane, cytosolic and mitochondrial folates form separate compartments. Folate-metabolizing enzymes in mitochondria differ from those present in the cytosol and represent products of alternative splicing (as folylpoly-γ-glutamate synthetase) or separate genes. It has been suggested that the mitochondrial NAD-dependent methylene-THF dehydrogenase favors the synthesis of formyl-THF whereas the cytosolic NADPH-dependent enzyme favors methylene-THF synthesis. Expression of the mitochondrial enzyme, which occurs only in rapidly proliferating tissues, would result in the synthesis of formate, which after crossing the mitochondrial membrane could be used for synthesis of the 10-formyl-THF needed for purine biosynthesis in the cytoplasm.[496]

Folate Deficiency

Next to iron deficiency, folate deficiency is the most common micronutrient deficiency. It is prevalent worldwide and coexists with poverty, malnutrition, and chronic parasitic, bacterial, and viral infections. Women are more frequently affected than men. Inadequate diet, overcooking of vegetables with loss of folates, and malabsorption secondary to tropical sprue are important contributors. Interestingly, vegetarian diets low in animal protein can provide more folate than omnivorous diets such as those eaten in the West.[181] Also at increased risk are the elderly, the very young, and pregnant and lactating mothers. In addition, many Europeans and North Americans fail to consume 200 μg of folates daily. Megaloblastic anemia secondary to folate deficiency is common worldwide, as is anemia with megaloblastosis in patients with multifactorial malnutrition and ill health. The finding of elevated total plasma homocysteine levels in patients with cerebrovascular and cardiovascular disease and their reduction with folate supplements, plus the reduction in NTDs as a result of giving mothers a folate supplement in the periconceptional period (even those with normal folate levels), raise questions about the definition of dietary folate sufficiency (see later).

Diagnosis of Folate Deficiency

The hematologic diagnosis of folate deficiency is similar to that for cobalamin deficiency. The bone marrow is indistinguishable from that in deficiency of cobalamin, and the same abnormalities may be noted in clinical chemistry data. In most patients who are deficient in folate,

serum and erythrocyte folate levels are low. The level of serum folate (normal range, 4 to 20 ng/mL [8.8 to 44.0 nmol/L]) decreases rapidly during folate deprivation and falls into the range of deficiency (<3 ng/mL or 6.6 nmol/L) within 2 weeks of cessation of folate intake.[497] The erythrocyte folate level decreases slowly (normal, 200 to 800 ng/mL [440 to 1800 nmol/L]) because deficient erythrocytes replace sufficient ones during the 3- to 4-month turnover of RBCs. Most deficient subjects have erythrocyte folate values that are less than 150 ng/mL (330 nmol/L). With chronic low folate intake or malabsorption, both values fall into the deficient range, whereas patients in whom deficiency develops rapidly from alcohol abuse, from receiving unsupplemented intravenous amino acids, or from some antibiotics may have low serum folate levels only. The level of FIGlu in a 24-hour urine sample with or without a histidine load is often elevated in patients with folate deficiency but is infrequently measured.

Total plasma homocysteine, but not methylmalonic acid, is increased in the majority of patients with folate deficiency.[498] The result of the deoxyuridine suppression test with bone marrow cells is abnormal and is corrected by the addition of 5-formyl-THF, 5-methyl-THF, or other folates during preincubation with deoxyuridine (see earlier).

Erythrocyte Folate Levels in Cobalamin Deficiency

Erythroid precursors in the bone marrow accumulate 5-methyl-THF from plasma and convert it to THF by means of the cobalamin-dependent enzyme methionine synthase. THF is converted to THF polyglutamates and retained in mature RBCs as 5-methyl-THF polyglutamates. The reaction catalyzed by methionine synthase is impaired in cobalamin-deficient cells, and 5-methyl-THF is a poor substrate for polyglutamylation, such that patients deficient in cobalamin have lower erythrocyte folate levels together with normal or raised serum folate levels.[163,499] This interpretation of the cause of erythrocyte folate changes in cobalamin deficiency is known as the "methylfolate trap hypothesis."

Treatment of Folate Deficiency

Five mg of folic acid daily by mouth (100 μg/kg body weight for children) is sufficient to correct folate deficiency, whether dietary or secondary to malabsorption. The megaloblastic anemia responds to very small doses of folic acid (200 to 500 μg/day), and the response provides verification of the diagnosis because that caused by cobalamin deficiency does not respond to such low doses of folate. Daily treatment with 1 mg is more than adequate. Larger doses are usually given because folic acid is available in 5-mg tablets. There is concern that folate can exacerbate the neurologic damage in patients with cobalamin deficiency by delaying diagnosis and treatment. In patients with inborn errors of cobalamin metabolism mistreated with folate, neurologic degeneration has occurred.[361]

Above oral doses of 200 μg of folic acid, unmetabolized folic acid appears in the circulation.[500] However, such unmetabolized folic acid has never been associated with toxicity in patients such as those with sickle cell disease or other hemolytic anemias who are receiving long-term folic acid supplements. Likewise, the unnatural isomer *dl*-5-formyl-THF has never been associated with toxicity.

Reduction in plasma zinc in newborns was attributed to a dose of 1 mg oral folic acid daily, but not to doses of 0.05 to 0.2 mg/day.[501] Although such lower doses are both effective and prudent, there are no firm data attributing toxicity to folic acid.

Nutritional folate deficiency requires an improved diet or a folate supplement, or both. For patients with folate malabsorption, 5 to 15 mg/day of folate should yield normal or high serum and erythrocyte folate levels.

Clinical responses have been reported in a small number of patients with dementia, restless leg syndrome, and other neurologic ailments treated with large doses of folic or folinic acid.[502-504]

Maternal and Pediatric Folate Deficiency

Maternal Folate Deficiency

The major problem with folate insufficiency in children occurs before rather than after birth. It has been well established that maternal folate deficiency in the periconceptional period is the cause of more than 50% of cases of NTDs, including spina bifida, meningomyelocele, and anencephaly.[35,36,505] Intrauterine growth retardation has also been linked to reduced maternal folate levels and increased total homocysteine levels.[506]

Folate deficiency is common in mothers, particularly where poverty and malnutrition are common, intestinal malabsorption is prevalent, and dietary supplements are not provided.[507] It is usually accompanied by iron deficiency. The growing fetus imposes an increased demand for folate, which is further increased in mothers with thalassemia minor or sickle cell disease.

Several researchers have reported lower serum or RBC folate levels in users of oral contraceptive agents (OCAs) in the past. However, these results preceded the development of lower-dose OCA preparations. This question was re-evaluated in adolescent Canadian females aged 14 to 19 years. Twenty-one percent were using current OCAs, most frequently Triphasil (Wyeth-Ayerst Canada), Marvelon (Organon Canada), Ortho 7/7/7 (Ortho Pharmaceutical), and Cyclen (Ortho Pharmaceutical). Smoking and OCA or alcohol use were not linked to low serum or RBC folate levels.[508] However, OCA use was associated with an unexplained 33% lower serum cobalamin level. Thus, current OCA use seems to not predispose women to future maternal folate insufficiency.

Levels of plasma folate are higher in cord than maternal blood. Perfusion of the human placental cotyledon revealed a two-step maternal-to-fetal transfer of methyl-THF consisting first of a concentrative component. Folate

is bound to placental folate-binding proteins/folate receptors on the maternally facing chorionic surface. Gradual release of methyl-THF from this bound pool added to incoming folates generated an intervillous blood folate level three times that in the maternal circulation. In the second step, folates were passively transferred to the fetal circulation along a downhill concentration gradient.[509]

Except in extreme cases, this mechanism was believed to protect the fetus in utero from maternal folate deficiency. Nevertheless, three early abortions and two stillbirths were associated with hyperhomocysteinemia and the homozygous thermolabile 677C→T allele of MTHFR in a woman with low plasma folate. Because treatment with folate and pyridoxine normalized the homocysteine level and favored a subsequent successful pregnancy, it may be that some recurrent miscarriages are associated with hyperhomocysteinemia.[510] Maternal folate deficiency is also related to fetal hypotrophy. In a small well-nourished population, there was a significant correlation between birth weight and both folate status of the mother at 32 weeks of pregnancy and the decrease in her RBC folate levels before delivery.[511] Maternal serum folate concentrations at 18 and 30 weeks correlated negatively with the extent of fetal growth retardation in a study of 289 pregnant women.[512] In 832 women, a low mean daily folate intake was linked to a doubling of the risk for preterm delivery and low infant birth weight.[513] These findings suggest that maternal folate status may affect other birth outcomes beyond causing NTDs. Thus, preferential transfer of folate to the fetus from the placenta may provide limited protection against the deleterious effects of maternal folate insufficiency.

A survey conducted in the United States after food fortification has found modest, yet statistically significant reductions in transposition of the great arteries (12%), cleft palate only (12%), pyloric stenosis (5%), upper limb reduction defects (11%), and omphalocele (21%). More substantial subgroup decreases were observed for renal agenesis in programs that conduct prenatal surveillance (28%), for common truncus among Hispanics (45%), and for upper limb reduction defects among Hispanics (44%).[514]

Deficiency in Newborns and Infants

Levels of plasma and RBC folate fell and total plasma homocysteine levels increased during pregnancy in 404 healthy Danish mothers.[515] Despite this finding, folate deficiency in the infant as a result of folate deficiency in the mother is unusual. Clinical folate deficiency is seldom present at birth. However, the rapid growth in the first few weeks of life demands increased folate. There is a need for folate supplements at this time, particularly for premature infants.[283] Maternal milk folate levels remain elevated during the development of maternal folate deficiency but decrease once deficiency is present.

Folate must be added to hyperalimentation solutions given to newborns in intensive care units. Infections or other illnesses may increase folate needs. Hemolysis secondary to vitamin E deficiency, glucose-6-phosphate dehydrogenase deficiency, or rarer RBC enzyme deficiencies increases demand for folates. Folate absorption is reduced with chronic diarrhea. As mentioned earlier, folate deficiency develops in infants fed goat's milk.[419]

Folate deficiency in infants may not be manifested as classic megaloblastic anemia. After transfusion, neutropenia and thrombocytopenia may be the only hematologic features. Where general malnutrition exists, features of folate deficiency may be overshadowed by the clinical picture of marasmus or protein-calorie malnutrition. The increased requirement for growth and the lack of long-term folate stores make folate deficiency a regular component of starvation. Because folate is stored mainly in the liver, hepatitis and other diseases of the liver may disturb stores and precipitate folate deficiency. Inborn errors of folate metabolism are rare but of considerable interest (discussed later).

Deficiency in Older Children and Adolescents

Malnutrition is the most common cause of folate deficiency in older children. Subgroups at particular risk include those with sickle cell disease, thalassemia major, hepatitis, HIV infection, and malabsorption. Certain drugs and medications predispose to folate deficiency. Folate deficiency has been reported in patients taking chronic antiepileptic medications and older, high-dose oral contraceptives.[422,423] Antifolate drugs such as triamterene and sulfisoxazole-trimethoprim inhibit human DHF reductase to some degree and may induce folate deficiency. Alcohol abuse is associated with folate deficiency and affects a proportion of children and adolescents.

Folates and Neural Tube Defects

Folate insufficiency in the first trimester of pregnancy has been implicated in the occurrence of NTDs in infants.[516,517] Studies have demonstrated that folate supplementation during the periconceptional period (from initiation of pregnancy to closure of the neural tube at about 1 month of gestation) reduces the occurrence[36] and recurrence[35] of NTDs by 50% to 70%. Pregnancies at particular risk may be identified by the maternal total plasma homocysteine level or by MTHFR polymorphism status.[518-520] The most effective way to ensure that pregnant women receive sufficient folate during this period is to fortify foods with folate.[521] Fortification of flour and other enriched grain products with synthetic folic acid has been compulsory in the United States and other countries since 1998.[522] This fortification has been associated with a decrease in the prevalence of NTDs.[514,523,524]

Periconceptional folate supplementation may also be associated with a decreased risk of having a child with nonsyndromic cleft lip with or without cleft palate,[525-527] although not all studies support such an association.[528,529] No consistent effect of the c.677C→T MTHFR polymorphism on orofacial clefting has been observed.[530]

Folates and Down Syndrome

Folate insufficiency or gene polymorphisms (or both) have been linked with other birth defects, in particular Down syndrome.[531,532] A raised total plasma homocysteine concentration is a risk factor for Down syndrome.[533-536] In some studies, the *MTRR* 66A→G, *MTR* 2756A→G, *MTHFR* 677C→T, *MTHFR* 1298A→C, and *RFC1* 80A→G polymorphisms in association with elevated total homocysteine or decreased folate or cobalamin increased the maternal risk of having a child with Down syndrome,[533,537-540] although other studies do not support this finding.[539,541,542] There is a significant increase in the frequency of Down syndrome in mothers who have had a child with spina bifida and vice versa.[543] Fortification of food with folate has not decreased the incidence of Down syndrome as yet, perhaps because a much higher level of folate is needed to prevent the genomic instability associated with marginal folate deficiency.[531]

Folates and Arteriosclerotic Vascular Disease

The premature occurrence of arteriosclerosis in patients with severe homocystinuria first implicated homocysteine as an atherogenic factor.[544] It was subsequently demonstrated that a thermolabile variant of MTHFR was associated with moderate elevation of the total plasma homocysteine concentration and the development of atherosclerotic disease.[545] Thermolability was shown to be due to homozygosity for the T allele of a 677C→T polymorphism in MTHFR that causes conversion of alanine to valine at position 222 of the protein; such conversion results in an approximately 50% decrease in enzyme activity when present in the homozygous state.[38] Epidemiologic studies have shown a significant association between elevated total plasma homocysteine levels and cardiovascular disease and a modest, but statistically significant increased risk of cardiovascular disease in patients with the 677T allele of MTHFR.[546] Heterozygosity for cystathionine β-synthase deficiency may account for a small number of cases of elevated plasma homocysteine as well.[37] Patients participating in the Framingham Heart Study showed a strong correlation between homocysteine levels, carotid stenosis, and low folate levels.[547]

Treatment of subjects who have elevated total plasma homocysteine levels with vitamin B_6, folic acid, or betaine normalizes the homocysteine level[548]; such therapy may prevent recurrent or occurrent arteriosclerotic disease.[549] However, three large studies of cobalamin, pyridoxine, and folate treatment to lower total plasma homocysteine failed to reduce the risk for major cardiovascular events in patients with vascular disease.[550-553] Nevertheless, the power of these individual studies may be insufficient to detect the current assessment of an 11% and 19% expected reduction in the incidence of heart attacks and strokes, respectively, for a 25% reduction in the total homocysteine level, and conclusions may need to await a meta-analysis of data from up to a dozen of such studies.[554]

Folates and Cancer

Epidemiologic studies have found an association between folate deficiency and premalignant changes in several epithelial tissues, including the cervix,[555] bronchus,[556] and colon.[39] Some studies demonstrated an apparent reversal of the pathologic lesions with folate supplementation. Difficulty differentiating between megaloblastic and dysplastic changes may have confounded these results. The relationship between folate levels and carcinogenesis has been studied in colorectal cancer. Dietary folate correlates inversely with risk for colorectal adenoma and cancer, and serum homocysteine levels are higher in subjects with colorectal neoplasia.[557] Results from studies of other types of cancer are less clear. A quandary exists that although folate may assist in stabilizing the genome and thus reducing the rate of mutations and the incidence of certain cancers, it may also promote the growth of some malignancies already present.

Folate Antimetabolites

Antifolates are analogues of folic acid that block folate metabolism, thereby interrupting DNA synthesis and causing cell death. They inhibit the enzyme DHF reductase as the primary target.

Methotrexate is an anticancer agent effective in combination chemotherapy for carcinoma of the breast, lung, bone, ovary, head, neck, and elsewhere. It contributes to cure of choriocarcinoma and childhood acute lymphoblastic leukemia. Methotrexate is also used for its immunosuppressive and antiproliferative properties in the treatment of psoriasis, rheumatoid arthritis, and graft-versus-host disease after bone marrow transplantation. Cancer and leukemia cells develop resistance to methotrexate in a variety of ways, including diminished transport of methotrexate (and reduced folates) into the cell; amplification of the *DHFR* gene, with overproduction of DHF reductase; mutations in the *DHFR* gene resulting in a DHF reductase with decreased binding affinity for methotrexate; decreased folate polyglutamate synthetase activity, with resultant diminished polyglutamylation of methotrexate; or increased γ-glutamylhydrolase activity, with decreased retention of methotrexate polyglutamates.[558]

Newer antifolates have been synthesized and tested over the past 40 years.

Pyrimethamine is an antimalarial drug with greater affinity for parasitic than human DHF reductase. Trimethoprim is an antifolate with antibacterial activity and higher affinity for bacterial than human DHF reductase. In combination with sulfisoxazole, which interferes with bacterial synthesis of folic acid, there is a double synergistic antifolate attack on bacteria. Bactrim and Septra

are such combinations widely used to treat urinary tract and other infections. They are effective in preventing *Pneumocystis carinii* pneumonia in immunocompromised patients undergoing chemotherapy or in persons infected with HIV.

Inborn Errors of Folate Transport and Metabolism

Hereditary Folate Malabsorption

Hereditary folate malabsorption (MIM 229050) has been reported in fewer than 20 patients.[559-564] It is characterized by megaloblastic anemia, diarrhea, mouth ulcers, failure to thrive, and usually, progressive neurologic deterioration. A majority of the patients documented have been girls. Megaloblastic anemia and low serum folate levels appear in the first few months of life, with excretion of FIGlu and orotic acid in urine. Patients with hereditary folate malabsorption fail to absorb folic acid or reduced folates across the intestinal membrane and the choroid plexus, thereby resulting in decreased folate levels in both blood and CSF. Uptake of folate into cultured and uncultured cells is normal.

Mutations in the *SLC46A1* gene on chromosome 17q11.2, which encodes the PCFT, have now been identified in six patients with hereditary folate malabsorption.[438,565] Identification of mutations in patients with hereditary folate malabsorption and segregation studies in one family make it clear that this is an autosomal recessive disorder.[438,565] The reason for the preponderance of females among patients remains unknown.

Hematologic changes respond to relatively low levels of folate, but levels in CSF may remain low.[566] The clinical response to therapy with folates has varied. Both oral and parenteral administration of folate in pharmacologic doses has corrected the hematologic abnormalities in some patients, with less effect in correcting the low folate levels in CSF. Folinic acid and methyltetrahydrofolic acid may be more effective in entering CSF. In some cases, seizures were reduced in number, and in others, seizures worsened with folate therapy.[361] It is essential to maintain levels of folate in both blood and CSF in the range associated with folate sufficiency. Oral doses of folates in excess of 100 mg daily or systemic therapy may be needed. Intrathecal folate may be needed if CSF levels remain low.

Cellular Folate Uptake Defects

A series of patients with well-characterized abnormalities in folate uptake into cells have been described. It remains unclear whether any of these abnormalities represent primary defects.

In one large family, the prevalence of severe hematologic disease was very high, with anemia, pancytopenia, and leukemia in 34 individuals resulting in the death of 18.[567,568] The proband had severe aplastic anemia that responded to folate therapy. Uptake of methyl-THF was markedly reduced in stimulated lymphocytes from the proband and four family members despite normal uptake of folic acid. The proband and his son also had a lesser reduction in methyl-THF uptake in bone marrow cells. In one son the transport defect developed only after he became neutropenic, thus suggesting that the abnormality may not be the primary defect. In another family, the proband and three daughters had dyserythropoiesis without anemia.[569] An abnormality in methyl-THF uptake was detected in RBCs and bone marrow cells but not in lymphocytes. There was little correlation in the family between clinical findings and cellular folate uptake.

Methylenetetrahydrofolate Reductase Deficiency

MTHFR deficiency is the most common inborn error of folate metabolism (Table 11-3), and at least 85 cases are known.[25,26,570] The clinical manifestations are variable, with many patients initially seen during infancy with severe neurologic disease leading to death, others initially seen as adults, and some remaining clinically asymptomatic.[571] Most come to medical attention as infants because of developmental delay, breathing disorders, gait abnormalities, seizures, and macrocephaly. Patients have been described with schizophrenia and severe MTHFR deficiency, which has focused attention on the role of MTHFR deficiency in psychiatric disease.[572-574]

Homocystinuria is always present in patients with MTHFR deficiency, with the homocystine level ranging from 15 to 667 μmol/24 hr (mean, 130),[25] lower than levels in patients with homocystinuria secondary to cystathionine β-synthase deficiency. More than one determination of homocystine excretion may be needed because false-negative values occur. Serum methionine is in the low-normal range or decreased, whereas in cystathionine β-synthase deficiency, methionine is elevated. Values range from 0 to 18 μmol/L (mean, 12 μmol/L; normal range, 23 to 35 μmol/L).[25] Neurotransmitter levels in the CSF of a few patients have been low. Megaloblastic anemia is rarely present, in contrast to other disorders in which synthesis of methionine from homocysteine is impaired (cobalamin deficiency, cblC, cblD, cblE, cblF, and cblG). This reflects the lack of trapping of folate as methyl-THF in MTHFR deficiency and its availability for purine and pyrimidine biosynthesis.

Findings at autopsy in patients with MTHFR deficiency[575-580] include dilation of cerebral vessels, internal hydrocephalus, and microgyria. Perivascular changes, demyelination, macrophage infiltration, gliosis, and astrocytosis have been reported. A major cause of death was arterial and cerebral venous thrombosis.[575] The neurovascular findings in severe MTHFR deficiency resemble those seen in classic homocystinuria secondary to cystathionine β-synthase deficiency. Patients with the classic findings of SCDSC, similar to that seen in cobalamin deficiency, have been reported.[579,580] Because methyl-THF is the only form of folate that can cross the blood-brain barrier, MTHFR deficiency may result in

TABLE 11-3	Inherited Defects of Folate Metabolism

functionally low levels of folate in the brain. Neurologic findings in MTHFR deficiency may be the result of low methionine levels and decreased function of AdoMet-dependent methyltransferase reactions. Alternatively, decreased CNS folate levels may result in impaired purine and pyrimidine synthesis. Because MTHFR has dihydropteridine reductase activity,[581] it may also have a direct role in neurotransmitter synthesis.

The diagnosis of severe MTHFR deficiency is established by measurement of enzyme activity in the liver, leukocytes, or cultured fibroblasts or lymphocytes. The specific activity of MTHFR in cultured fibroblasts is dependent on the stage of the culture cycle, with activity being severalfold greater at confluence than during logarithmic growth[582]; it is thus important to compare activities of patient samples and control cell lines at confluence. MTHFR activity, the proportion of total intracellular folate that is methyl-THF, and the extent of labeled formate incorporation into methionine are inversely correlated with clinical severity.[583,584] When compared with normal enzyme, enzyme from many individuals, including several patients with severe MTHFR deficiency, is unstable when incubated at 55° C, especially in the presence of the cofactor flavin adenine dinucleotide.[545,585]

The human *MTHFR* gene on chromosome 1p36.3 is 2.2 kb in length and consists of 11 exons; it encodes an active protein of about 70 kd.[586,587] MTHFR deficiency shows autosomal recessive inheritance. To date, 41 mutations of the *MTHFR* gene have been identified.[588-595] None occurs frequently in patients from different families. Prenatal diagnosis has been reported with amniocytes and chorionic villus cells.[26,594,596-598] In most cases, MTHFR activity in cell extracts was measured. Because the known *MTHFR* mutations are private, mutation analysis has been limited to families in which the mutations have been sequenced. The existence of common intragenic polymorphisms has allowed the use of linkage analysis to establish the diagnosis.[599]

In addition to mutations that result in severe MTHFR deficiency, several common polymorphisms have been identified. One of them, a 677C→T (cDNA)/A222V (protein) sequence change, results in reduction of MTHFR activity by approximately 50% of control values when the T allele is present in the homozygous state.[38] The T allele represents 30% to 50% of MTHFR alleles in many European, North American, and Japanese populations[600]; its frequency is much lower in Africans and African Americans. This polymorphism is the cause of MTHFR thermolability in both patients with severe MTHFR deficiency and normal individuals. A second polymorphism, 1298A→C (cDNA)/E429A (protein), reduces MTHFR activity to 68% of the wild-type value.[601] Several additional polymorphisms have been identified whose effects on enzyme activity are not known.[602,603]

MTHFR deficiency is difficult to treat, with a poor prognosis once neurologic involvement is evident.

Therefore, it is important to diagnose MTHFR deficiency as early as possible. The following agents have been used for therapy:

1. Folates, to maximize any residual enzyme activity
2. Methyl-THF, to specifically replace the missing product of MTHFR
3. Methionine, to correct deficiency of this amino acid, which requires methyl-THF for synthesis
4. Pyridoxine, because it is a cofactor for cystathionine synthase and thus may lower homocysteine levels
5. Cobalamin, because MeCbl is a cofactor for methionine synthase
6. Carnitine, because of its requirement for adenosylmethionine
7. Betaine, because with homocysteine, it is a substrate for betaine methyltransferase, an enzyme that also converts homocysteine to methionine and is primarily active in the liver.

Betaine has the double advantage of raising methionine and decreasing homocysteine levels. However, because betaine methyltransferase is a liver enzyme, the effects of betaine on the brain are thought to be mediated through changes in circulating levels of metabolites. A summary of the treatment protocols for individual patients with MTHFR deficiency has been published.[25] Such protocols have been highly variable and, for the most part, unsuccessful until the introduction of betaine. Therapy with methionine alone or combined with methyl-THF has not been effective. A regimen consisting of oral betaine, folinic acid, cobalamin, and vitamin B_6 has been suggested.[604] Therapy with betaine after prenatal diagnosis has resulted in the best outcome reported to date.[605]

Glutamate Formiminotransferase Deficiency

Glutamate formiminotransferase deficiency results from mutations in the bifunctional (glutamate formiminotransferase plus cyclodeaminase) enzyme encoded by the *FTCD* gene. It is not clear whether this disorder is associated with any consistent clinical findings. Fewer than 20 patients have been described. FIGlu excretion, either constitutively or in response to a histidine load, is the one constant feature of formiminotransferase deficiency. Patients have ranged in age from 3 months to 42 years at diagnosis. Two distinct phenotypes have been described. The severe form is characterized by mental and physical retardation, abnormal electroencephalographic activity, and dilation of the cerebral ventricles with cortical atrophy. No mental retardation occurs in the mild form, but excretion of FIGlu is greater. Analysis of mutations in the *FTCD* gene has not supported the hypothesis[606] that the mild form is due to a defect in formiminotransferase activity whereas the severe form results from a block in cyclodeaminase.[607]

Several patients had macrocytosis and hypersegmentation of neutrophils, three had delayed speech, two had

seizures, and two had mental retardation as their initial signs. Two were identified because they were siblings of known patients. Mental retardation was described in the majority of the original patients from Japan,[608-610] but in only three of the remaining eight patients.[25,611-613] Elevated FIGlu excretion and increased FIGlu levels in blood after a histidine load, as well as high to normal serum folate levels, have been reported. Plasma amino acid levels, including histidine, are usually normal; however, hyperhistidinemia and hyperhistidinuria have been found on occasion, as have low plasma methionine levels. Excretion of hydantoin-5-propionate, the stable oxidation product of the FIGlu precursor 4-imidazolone-5-propionate, and excretion of 4-amino-5-imidazolecarboxamide, an intermediate in purine synthesis, have also been reported.

Hepatic enzyme activity was measured in five patients and was higher (14% to 54% of control values) than would be expected if its deficiency caused the disease. Because FTCD enzyme activity is expressed in the liver and kidney only, cultured cells cannot be used to confirm the diagnosis of formiminotransferase deficiency. There have been reports of measurement of formiminotransferase activity in erythrocytes, but these have not been confirmed.[25]

The human *FTCD* gene on chromosome 21q22.3 consists of 15 exons and generates multiple transcripts.[614] Three *FTCD* mutations have been identified in patients; one patient also had a deletion that eliminated one copy of the *FTCD* gene.[607] Expression of the mutations in vitro demonstrated that they reduced enzyme activity to 30% to 50% of control values, in line with the results of liver assays of affected individuals.[606] These studies confirmed that mutations in the *FTCD* gene underlie cases of formiminotransferase deficiency and demonstrated autosomal recessive inheritance of the disorder.

Two patients in one family[611] responded to folate therapy with decreased FIGlu excretion, whereas six other patients did not.[25] One of two patients responded to methionine supplementation.[612,613] Because the relationship between clinical expression and FIGlu excretion is uncertain, the value of reducing FIGlu excretion is unknown.

Amino-4-Imidazolecarboxamide Ribonucleotide Transformylase Deficiency

A single patient has been reported with deficiency of AICAR transformylase (MIM 60868), one of the 10-formyl-THF–dependent reactions in de novo purine biosynthesis. The patient had profound mental retardation, epilepsy, dysmorphic features, and congenital blindness. Megaloblastic anemia was not observed. Very high levels of AICAR, as well as its diphosphate and triphosphate derivatives, were observed in patient erythrocytes. Two mutations were identified in the *ATIC* gene on chromosome 2q35, which encodes the bifunctional AICAR transformylase–IMP cyclohydrolase enzyme. Enzyme assay demonstrated a profound deficiency in AICAR

transformylase activity, with IMP cyclohydrolase activity being 40% of control values.[615]

Other Possible Inborn Errors of Folate Metabolism

Three patients have been reported to have DHF reductase deficiency,[616] but alternative genetic lesions affecting other enzymes involved in folate or cobalamin metabolism have subsequently been identified in two of the patients.[361,617] Three patients were reported to have methenyl-THF cyclohydrolase deficiency, but the diagnosis was retracted in a later publication from the same group.[610]

3-PHOSPHOGLYCERATE DEHYDROGENASE DEFICIENCY

Megaloblastic anemia has been reported in two brothers with 3-phosphoglycerate dehydrogenase (EC 1.1.1.95) deficiency (MIM 601815),[618] a rare disorder (six patients in four families have been reported) that results in impaired ability to synthesize serine from 3-phosphoglycerate. Although serine is a nonessential amino acid, impairment of this pathway results in severely decreased levels of serine in serum and CSF,[619] thus demonstrating that diet alone does not provide sufficient serine to support normal metabolism. Patients with this disorder are characterized by macrocephaly beginning before birth, with severe psychomotor delay and intractable seizures developing during the first year of life. Cataracts, hypogonadism, adduction of the thumbs, and thrombocytopenia were present in some patients.

The disorder is characterized biochemically by markedly decreased levels of serine in CSF and by decreased plasma serine after an overnight fast. The low levels of serine in CSF may reflect relatively low affinity of the neutral amino acid transporter for serine, which leaves the CNS particularly dependent on de novo serine synthesis to meet its metabolic needs.[619] The level of methyl-THF in CSF is also reduced.[618] Under normal conditions, serine is the major source of one-carbon units for cellular folate metabolism, and serine deficiency may therefore result in decreased levels of folate coenzyme forms. Patients have been treated with high doses of serine and in some cases with glycine as well. Treatment has resulted in correction of the biochemical deficits and decreased frequency of seizures, but no progress in psychomotor development has been observed in patients when treatment was started after 1 year of age.[620] One affected individual who was identified by prenatal diagnosis and was treated with serine beginning in the prenatal period has shown normal development.[621]

Two mutations in the *PHGDH* gene on chromosome 1q12 have been identified in patients with 3-phosphoglycerate dehydrogenase deficiency. Five patients, including the brothers with megaloblastic anemia, were homozygous for a c.1468G→A (p.V490M) mutation; the

sixth patient was homozygous for a c.1273G→A (p.V425M) mutation. Both mutations resulted in decreased dehydrogenase activity in vitro.[622]

THIAMINE-RESPONSIVE MEGALOBLASTIC ANEMIA

Thiamine-responsive megaloblastic anemia (TRMA; MIM 249270) is a rare autosomal recessive disorder characterized by megaloblastic anemia, diabetes mellitus, and sensorineural deafness that responds to pharmacologic doses of thiamine.[623-625] Additional clinical findings have included optic atrophy, cardiomyopathy, and stroke-like episodes. The bone marrow is characterized by megaloblastic changes and ringed sideroblasts. The disorder has been reported in fewer than 30 families.

Dietary thiamine is taken up by cells and converted to its active coenzyme derivative thiamine pyrophosphate by the enzyme thiamine pyrophosphokinase (EC 2.7.6.2). Thiamine pyrophosphate is required for the activity of four known mammalian enzymes: transketolase, pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, and branched-chain ketoacid dehydrogenase.

TRMA has been shown to be caused by mutations affecting the *SLC19A2* gene on chromosome 1q23.3.[626-629] This gene encodes a thiamine transporter protein that has homology to the RFC (which is encoded by the gene *SLC19A1*). TRMA fibroblasts have decreased thiamine uptake relative to control fibroblasts and, unlike control cells, undergo apoptosis when incubated in medium lacking thiamine.[630] At least 14 mutations in the *SLC19A2* gene have been reported in patients with TRMA.[626]

12 Disorders of Iron Metabolism and Sideroblastic Anemia

Nancy C. Andrews, Christina K. Ullrich, and Mark D. Fleming

HEME PROTEINS

Hemoglobin
Myoglobin
Cytochrome *a*, *b*, *c*
Cytochrome P-450
Tryptophan-1,2-dioxygenase
Catalase
Myeloperoxidase

IRON-DEPENDENT ENZYMES

Aldehyde oxidase
Reduced nicotinamide adenine dinucleotide
    dehydrogenase
Tyrosine hydroxylase
Succinate dehydrogenase
Prolyl hydroxylase
Tryptophan hydrolase
Xanthine oxidase
Ribonucleotide reductase
Aconitase
Phosphoenolpyruvate carboxykinase

Iron lacks the glitter of gold and the sparkle of silver but outshines both in biologic importance. This plebeian metal is vital to the function of a wide variety of critical enzymes, including catalases, aconitases, ribonucleotide reductase, peroxidases, and cytochromes, that exploit the flexible redox chemistry of iron to execute a number of chemical reactions essential for our survival (Box 12-1). In addition, we depend on hemoglobin, another iron-containing protein, to transport inhaled oxygen from the lungs to peripheral tissues. Human existence is inextricably linked to iron, and disturbances in its metabolism may have dire consequences.

PHYSIOLOGIC CHEMISTRY OF IRON

Iron and Oxidation

The key to the biologic utility of iron is its ability to exist in either of two stable oxidation states: Fe^{2+} (ferrous) or Fe^{3+} (ferric). This property permits iron to act as a redox catalyst by reversibly donating or accepting electrons. An excellent example is the electron transport chain of oxidative phosphorylation, in which adenosine triphosphate (ATP) is generated from glucose by the orderly transfer of electrons through a network of iron-containing mitochondrial cytochromes.

When dissolved in aqueous solution, ferrous iron rapidly oxidizes to its ferric form, which is insoluble at physiologic pH. The resulting ferric hydroxide salts (rust) are of no metabolic utility. To achieve stable solubility under physiologic conditions, iron must be complexed to iron-binding agents termed chelators. Chelators are synthesized by all organisms ranging from microbes (e.g., deferoxamine produced by *Streptomyces pilosis*) to humans (e.g., transferrin in human plasma). These molecules are crucial to the acquisition of iron from the environment and to its transport and storage within the body.

Iron-Protein Complexes

Iron-protein complexes capitalize on the properties of the metal to perform metabolic functions. Stable coordination complexes form between iron and electron-donating amino acids in proteins. Iron acts as the chemical workhorse, and protein structure dictates biologic specificity.

Individual iron atoms can interact directly with amino acid side groups in proteins, as in ribonucleotide reductase. Alternatively, iron may form coordination complexes with other small molecules. Protoporphyrin IX donates four of the six electrons needed to form a stable coordination complex with iron. Heme, the iron–protoporphyrin IX complex, is so stable that removal of the iron moiety requires the enzyme heme oxygenase. The functional properties of heme are determined by the nature of the associated protein or small molecule ligands supplying the remaining two electrons. The best-characterized heme protein is hemoglobin, in which a globin histidine residue donates the fifth electron and the sixth comes from molecular oxygen.[1] This configuration enables hemoglobin to transport oxygen safely throughout the body.

Iron and sulfur atoms can form stable complexes ("clusters") that catalyze enzymatic reactions. The Krebs cycle enzyme aconitase, for example, contains an iron-sulfur (Fe/S) cluster. As discussed later in this chapter, the iron content of the Fe/S cluster of a related aconitase-like molecule allows it to "sense" iron concentrations within the cell and to act as an iron regulatory protein (IRP) to modulate the translation of genes of iron metabolism.

Iron Toxicity

The ability of iron to catalyze redox reactions also accounts for its toxicity. As an enzymatic cofactor, the metal is involved in the restructuring of cellular components, including proteins, carbohydrates, and nucleic acids. Unbound iron has unbridled redox activity, however, and may wreak havoc. We live in an oxygen-rich atmosphere and our bodies require oxygen for many metabolic processes. However, oxygen is highly reactive and thus is toxic. The reactive oxygen intermediates superoxide (O_2^-) and hydrogen peroxide (H_2O_2) are generated by normal cellular reactions. Oxidative stress develops when production of reactive oxygen species exceeds the body's processing capacity. Under these circumstances, reactive oxygen intermediates may be

converted to injurious free radicals by the iron-catalyzed Fenton reaction[2]:

$$O_2^- + Fe^{3+} \rightarrow O_2 + Fe^{2+}$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO\bullet + OH^-$$

$$O_2^- + H_2O_2 \rightarrow O_2 + HO\bullet + OH^-$$
Hydroxyl radicals (HO•) attack many biologic macromolecules, including proteins and DNA. They also promote peroxidation of membrane lipids, a problem exacerbated by iron overload and pathologic membrane binding of iron. Intracellular structures are particularly susceptible to iron-dependent peroxidation. In iron-overloaded cells, injured lysosomes become fragile and leaky.[3] Release of lysosomal proteases causes further cell injury and may ultimately lead to cell death. This process contributes to the severe tissue damage seen in the liver, heart, joints, and pancreas of patients with iron overload disorders (see later).

Iron is not normally present in cell membranes. However, in both sickle cell disease and thalassemia, iron, heme, ferritin, and denatured hemoglobin adhere to the inner surface of the red cell plasma membrane and thereby contribute to the pathogenesis of these congenital anemias.[4,5] The membrane complex containing denatured hemoglobin has been termed *hemichrome*.[6] The red cell anion transport protein band 3 appears to nucleate the formation of these iron aggregates.[7,8] Injured cells decorated with membrane iron deposits are removed by a functioning spleen in patients with thalassemia and hemoglobin SC disease, but they circulate in functionally asplenic patients with homozygous hemoglobin SS disease. Membrane-associated iron promotes free radical formation and further membrane damage, marked by generation of the lipid peroxidation product malonyldialdehyde and by cross-linking of membrane proteins.[4,5] Membranes become rigid and thus contribute to the formation of irreversibly sickled cells that occlude the microcirculation.

Sometimes reactive oxygen intermediates can be beneficial. Neutrophils contain a membrane-associated reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase that produces superoxide to kill ingested microorganisms (reviewed by Clark[9]). Superoxide and secondary reactive oxygen intermediates are potent antimicrobial agents. Congenital defects in this NADPH oxidase, collectively termed *chronic granulomatous disease* (see Chapter 21), are characterized by a serious defect in defense against bacterial pathogens.

Neutrophils and iron also injure tissues in inflammatory diseases such as rheumatoid arthritis.[10] Synovial macrophages ingest red cell hemoglobin introduced by intermittent joint hemorrhage. Iron is deposited in the synovial membrane, proximate to superoxide and hydrogen peroxide generated by neutrophils and macrophages participating in the inflammatory reaction. Iron catalyzes the conversion of these compounds to free radical species, which promote lipid peroxidation. Iron therapy exacer-

bates this process. In contrast, antioxidants and iron chelators retard free radical generation, thereby affording some theoretical protection against injury in rheumatoid arthritis.[11,12]

These deleterious properties of iron are threatening only when the element is in a "free" state or in an abnormal compartment within the cell. Protection of cell structures from iron-dependent free radical damage is crucial to survival. When iron is bound to protein either directly or in the form of heme, the generation of free radicals is largely abrogated. Thus, tight chelation of iron is a means of controlling its reactivity. As discussed later, cytoplasmic ferritin allows iron to be stored safely within cells by sequestering it in an innocuous form. Expression of ferritin is induced by oxidative stress.[13] Both prokaryotic and eukaryotic cells contain ferritins, and mice lacking one of the two ferritin genes do not develop past the early embryonic stages.[14] Thus, ferritin appears to be necessary for most, if not all living cells.

ACQUISITION AND DISTRIBUTION OF IRON

Although the average adult has 4 to 5 g of iron, a meticulous balance exists between dietary uptake and loss. About 0.5 to 1 mg of iron is lost each day through sloughing of cells from skin and mucosal surfaces (Fig. 12-1).[15] Because menstruating females lose an average of an additional 1 mg of iron daily, their dietary iron requirement is increased.[16] Neither the liver nor the kidney has a significant capability to excrete iron in humans. Consequently, absorption appears to be the primary means of regulating body iron stores.[17] During neonatal and childhood growth spurts, iron requirements increase in response to augmentation of body mass.

Iron Absorption

Iron absorption occurs predominantly in the proximal duodenum.[18,19] The physical state of iron entering the duodenum greatly influences its absorption. At physiologic pH, ferrous iron is rapidly converted to the insoluble ferric form. Acid produced by the stomach serves to lower the pH in the duodenum and thereby enhance the solubility and uptake of iron (see later). Heme is absorbed separately from and more efficiently than inorganic iron,[18] independent of duodenal pH. Consequently, meat is an excellent nutritive source of iron. Heme iron absorption is poorly understood, but a heme oxygenase inhibitor has been shown to block heme catabolism in the intestine and result in an iron-deficient state.[20]

A number of dietary factors influence iron absorption.[21] Ascorbate and citrate increase iron uptake, in part by acting as weak chelators to help solubilize the metal in the duodenum. Iron is readily transferred from these compounds to the absorptive epithelium. Conversely, plant phytates, bran, and tannins inhibit iron absorp-
FIGURE 12-1. The body's iron economy. Although the average adult has 4 to 5 g of body iron, only 1 mg of dietary iron enters and leaves the iron economy on an average day. Dietary iron enters through the duodenum and becomes bound to plasma transferrin for delivery to tissues. The erythron is the largest site of iron utilization, but all cells require the metal. Storage iron is found primarily in the liver. Reticuloendothelial macrophages carry out iron recycling. Iron is lost from the body with bleeding and with exfoliation of skin and mucosal cells. $Fe_2 - TF$, diferric transferrin. *(Adapted with permission from Andrews NC. Iron homeostasis: insights from genetics and animal models. Nat Rev Genet. 2000;1:208-217.)*

tion.[21-23] These compounds also chelate iron but prevent its uptake by the absorption machinery (see later).

Through a combination of genetic and biochemical approaches, much has been learned about the absorption of nonheme iron over the past decade. Nonheme iron arrives at the apical surface of the absorptive duodenal enterocyte in its ferric (Fe^{3+}) form. It is reduced through the action of a brush border ferric reductase. This enzyme may be duodenal cytochrome b, a heme protein that is homologous to b_{561} cytochromes.[24] Expression of duodenal cytochrome b is significantly greater in the proximal duodenum than elsewhere and increases in iron deficiency.

Ferrous (Fe^{2+}) iron is then taken up by the enterocyte through the action of divalent metal transporter 1 (DMT1, formerly known as Nramp2, DCT1).[25-27] Transport requires movement of protons along with metal ions in the same direction (symport) to generate an electrical

gradient. DMT1 functions only at low pH; it has little or no activity at neutral pH. DMT1 is widely expressed, but duodenal levels increase dramatically in iron-deficient animals.[27,28]

DMT1 can also transport other divalent metal ions, including Cd^{2+}, Co^{2+}, Cu^{2+}, Mn^{2+}, Pb^{2+}, and Zn^{2+}.[27] Competition studies have shown that lead, manganese, cobalt, and zinc can share the intestinal absorption pathway used by iron. Increased iron absorption induced by iron deficiency also enhances the uptake of these elements. Because iron deficiency often coexists with lead intoxication, this interaction has vast public health significance and can produce particularly serious medical complications in children.[29] Interestingly, as discussed later, copper absorption and metabolism appear to be handled by an entirely different mechanism.

After iron enters the absorptive enterocyte through the action of DMT1, it has at least two possible fates. It can be retained by the cell and subsequently be lost when the enterocyte dies and is sloughed into the intestinal lumen, or it can be transported across the basolateral membrane to enter the body. Iron retained by the enterocyte is used for cellular metabolism or incorporated into ferritin. Exported iron leaves the cell through the action of a unique basolateral transmembrane iron transporter, ferroportin (FPN1, also known as SLC40A1, MTP1, IREG1).[30-33]

Basolateral iron transfer also requires a change in the oxidation state of the metal, probably mediated by the multicopper ferroxidase hephaestin,[34,35] which bears strong homology to the plasma protein ceruloplasmin. A comprehensive model of intestinal iron absorption, primarily derived from studies in mice, is shown in Figure 12-2. This model pertains only to nonheme iron transport; details of heme iron uptake have not yet been worked out. A candidate intestinal heme transporter was reported but subsequently proven to be a folate transporter instead.[36] Although this is a good representation of what takes place in mice, it is possible that human iron absorption is significantly different.

Normally, only about 10% of dietary nonheme iron entering the duodenum is absorbed. However, this value increases significantly with iron deficiency.[37] In contrast, iron overload reduces, but does not completely eliminate absorption, thus reaffirming the fact that body iron stores regulate absorption. Finch[37] and subsequent investigators have designated this modulation the "stores regulator." In addition, both iron deficiency anemia and the anemia associated with ineffective erythropoiesis induce a marked increase in iron absorption. This effect is greater than that seen with variations in iron stores, and it has been designated the "erythroid regulator."[37] Additionally, hypoxia increases iron absorption, independent of anemia.

The peptide hormone hepcidin links the actions of all these regulators through a unifying molecular mechanism. Hepcidin is a 25–amino acid peptide produced in the liver from a larger precursor (reviewed by Nemeth and Ganz[38]). It circulates in serum and binds to the iron
FIGURE 12-2. Duodenal iron transfer. The microstructure of the iron absorption apparatus is depicted in this cartoon. Iron is taken up by enterocytes lining the duodenal villi. These absorptive cells start out as undifferentiated precursors in the intestinal crypts. Crypt cells appear to be programmed for an iron absorption "set-point" that is determined in response to iron needs. As the cells differentiate, they migrate up the villi and begin to express iron transporter proteins. According to current models, nonheme iron uptake occurs in mature enterocytes through the enzymatic reduction of iron, transmembrane import into the cell by DMT1, transmembrane export from the cell by ferroportin, and enzymatic oxidation by hephaestin before loading onto apotransferrin to produce diferric transferrin (HOLO-TF). *(Adapted with permission from Andrews NC. Iron homeostasis: insights from genetics and animal models. Nat Rev Genet. 2000;1:208-217.)*

exporter ferroportin on the basolateral surface of absorptive enterocytes, which causes ferroportin to be internalized and degraded.[39] In this way, hepcidin controls cellular iron egress. Hepcidin thus regulates iron absorption at the level of the intestinal epithelium in that any iron unable to leave the enterocytes is lost when these cells senesce and are sloughed into the gut lumen.

Expression of hepcidin is induced in response to iron overload[40,41] and inflammation[42,43] and repressed in response to increased erythropoietic activity[43,44] and hypoxia.[43] Regulation appears to be at the level of hepcidin gene transcription. However, the signals that govern hepcidin transcription in response to these stimuli are incompletely understood. Only the inflammatory cytokine interleukin-6 has been definitely shown to be involved in regulation of hepcidin expression by physiologic changes outside the liver.[45-47]

Most of the total body iron is ultimately incorporated into hemoglobin in erythroid precursors. An average adult produces 200 billion red cells daily to achieve a red cell renewal rate of 0.8% per day. Each red cell contains more than 1 billion atoms of iron, and each milliliter of packed red blood cells contains 1 mg of iron. To meet this daily need for 2×10^{20} atoms (or 20 mg) of elemental iron, iron is recycled from senescent red cells and returned to the circulation. Plasma iron turnover (PIT) represents the mass turnover of transferrin-bound iron in the circulation (expressed as milligrams per kilogram per day).[48] Accelerated erythropoiesis increases PIT and enhances iron uptake from the gastrointestinal tract.[49] Although hepcidin appears to be the effector molecule that alters intestinal absorption, an upstream, circulating factor that communicates the iron needs of the erythron must exist.[37,50] Several candidate factors have been considered unlikely, including transferrin[51] and erythropoietin.[52]

This erythroid control of hepcidin expression is particularly apparent in patients with thalassemia intermedia, in whom marked iron overload develops even without transfusions. The accelerated (but ineffective) erythropoiesis taking place in thalassemia substantially boosts iron absorption. Hepcidin expression is markedly decreased.[53-56] Increased PIT also leads to increased gastrointestinal iron absorption in pregnancy, in which PIT is accelerated by placental removal of iron. This increases the availability of the element to meet the needs of the growing and developing fetus. Decreased expression of hepcidin is probably involved in this situation as well, but definitive studies have not yet been reported.

Intercellular Iron Transport

As illustrated in Figure 12-1, only a small proportion of total body iron enters and leaves the body each day. Consequently, intercellular iron transport is quantitatively more important than intestinal absorption. The greatest mass of iron is found in erythroid cells, which make up about 60% to 80% of the total body endowment in normal individuals. The reticuloendothelial system recycles a substantial amount of iron from effete red cells that approximates the amount used by the erythron for production of new hemoglobin.

Approximately 0.1% (4 mg) of total body iron circulates in plasma as an exchangeable pool. In normal individuals, nearly all circulating plasma iron is bound to transferrin. Transferrin serves three purposes: (1) it renders iron soluble under physiologic conditions, (2) it prevents iron-mediated free radical toxicity, and (3) it facilitates transport into cells. Transferrin is by far the most important physiologic supplier of iron to red cells.[57] In fact, plasma transferrin serves to deliver iron to most tissues of the body. It is an 80-kd glycoprotein that has homologous N-terminal and C-terminal iron binding domains.[58] The molecule is related to several other proteins, including ovotransferrin in bird and reptile eggs,[59] lactoferrin in extracellular secretions and neutrophil granules,[60,61] and melanotransferrin (p97), a protein pro-

duced by melanoma cells.[62] The functions of these related proteins are incompletely understood.

The liver is the major site of synthesis and secretion of transferrin.[63] Other tissues, including Sertoli cells of the testis, oligodendrocytes of the central nervous system (CNS), lymphocytes, muscle cells, and mammary cells, can, however, also produce the protein.[64-69] Local synthesis within the brain and testis apparently provides transferrin for these tissues because serum transferrin does not penetrate their unique capillary barriers. The blood-testis barrier prevents free flow of proteins from the circulation into the lumen of the seminiferous tubules. The Sertoli cells of the testis synthesize a significant quantity of transferrin that bathes developing germ cells.[68,69] These rapidly dividing cells require substantial amounts of iron for normal growth and differentiation. The transferrin supplied by Sertoli cells is believed to be vital to spermatocyte development. However, forced overexpression of transferrin in the testes appears to be deleterious for spermatogenesis.[70]

Transferrin mRNA and protein have also been detected in oligodendrocytes.[65] Like the testis, the CNS has limited access to serum molecules because of the blood-brain barrier. Unlike the testis, however, the CNS has no cohort of rapidly proliferating cells. Iron may be needed instead to support a vast array of redox reactions that produce specialized neurotransmitter compounds such as γ-aminobutyric acid. The question of whether synthesis of transferrin by oligodendrocytes is absolutely required for distribution of iron to neural tissues remains unanswered. Interestingly, however, mice with an inactivating mutation in the transferrin gene[71] have been reported to have subtle abnormalities in CNS architecture.[72]

Activated T lymphocytes also synthesize and secrete transferrin.[67] At rest, mature T cells do not generate transferrin and do not express surface transferrin receptors. After mitogenic stimulation, however, both proteins are produced.[67,73] Synthesis of transferrin is restricted to CD4$^+$ helper lymphocytes. Transferrin mRNA production and transferrin receptor synthesis by these cells precede cell division and have been postulated to be part of an autocrine regulatory loop.[67]

Transferrin genes have been cloned from many different species. A basic similarity exists both in the protein structure of the transferrin molecule and in its genomic organization. Human transferrin mRNA is 2.3 kilobases (kb) in length and encodes 679 amino acids, including a 19–amino acid leader sequence.[74] It is located on chromosome 3q, near genes for the transferrin receptor and melanotransferrin (p97).

Transferrin production is regulated at multiple levels. Several *cis*-acting control regions exist upstream of the gene. The transferrin promoter contains binding sites for tissue-specific nuclear factors that activate transcription differentially in the liver and other tissues (e.g., Sertoli cells).[75] Transferrin gene expression is also modulated by iron, hormones, and inflammatory stimuli.[76-80] In the setting of iron deficiency, serum transferrin levels rise substantially as a result of enhanced synthesis of transferrin mRNA by the liver.[78] In contrast, inflammation depresses levels of both serum transferrin and serum iron, the latter through the action of the iron regulatory hormone hepcidin. The total amount of diferric transferrin has been proposed to modulate expression of the iron regulatory hormone hepcidin.[81]

Control of transferrin gene expression contrasts with that of the transferrin receptor. Transferrin is abundant and serves as a buffer to prevent the toxicity of free iron. Consequently, its expression does not have to be altered acutely to respond to external events. Primary control of transferrin expression at the level of message transcription allows modulation of systemic iron metabolism in response to a variety of factors such as inflammation or the hormonal changes of pregnancy. Liver-derived serum transferrin levels fall in patients with genetic or acquired iron overload, although mRNA levels have been reported to be unchanged.[82] This suggests that hepatic transferrin is also controlled at the level of translation or secretion. Interestingly, the quantity of transferrin mRNA in nonhepatic tissues (including the testis, kidney, and spleen) is not affected by iron deficiency. The liver-derived transferrin, therefore, appears to have the unique responsibility of responding to iron status.

X-ray crystal structures have been determined for transferrin and related proteins (reviewed elsewhere[83-85]). All members of the transferrin protein superfamily exhibit similar polypeptide folding. The N-terminal and C-terminal domains are globular moieties of about 330 amino acids; each of these domains is divided into two subdomains, with the iron and anion binding sites located in the intersubdomain cleft on either side of a central plane of symmetry, thus suggesting an origin by gene duplication from a primordial protein containing a single iron binding site. The binding cleft opens with iron release and closes with iron binding.[86] The N-terminal and C-terminal binding sites are very similar. No cooperativity exists in binding of iron by the two sites, and the protein can be proteolytically cleaved into two halves, each of which retains iron-binding capability.[87,88] Transferrin binds ferric iron much more avidly than ferrous iron.[89]

The precise mechanism by which iron is loaded onto transferrin as it leaves intestinal epithelial cells or reticuloendothelial cells is unknown. Ferroportin has been postulated to mediate iron export from these cells. The copper-dependent ferroxidase ceruloplasmin and its homologue hephaestin probably also play a role. Compelling evidence indicates that ceruloplasmin is involved in mobilizing tissue iron stores to produce diferric transferrin.[90-92] Transferrin binds iron avidly with a dissociation constant of approximately 10^{-22} mol/L.[89] Ferric iron binds only in the company of an anion (usually carbonate), which serves as a bridging ligand between the metal and protein and excludes water from two coordination sites.[89,93,94] Without the anion cofactor, iron binding is negligible; with it, ferric transferrin is resistant to all but

the most potent chelators. The remaining four coordination sites provided by the transferrin protein are a histidine nitrogen, an aspartic acid carboxylate oxygen, and two tyrosine phenolate oxygens.[83,95,96] The available evidence suggests that anion binding takes place before iron binding. Release of iron from transferrin involves protonation of the carbonate anion to loosen the metal-protein bond.

The sum of all iron binding sites on transferrin constitutes the total iron-binding capacity (TIBC) of plasma. Thus, on a molar basis, TIBC is twice the concentration of transferrin protein because each transferrin molecule can bind two iron atoms. Under normal circumstances, about a third of transferrin's iron binding pockets are filled. Consequently, except for the situation of iron overload, in which all transferrin binding sites are occupied, non–transferrin-bound iron in the circulation is present at very low concentrations.[97] The distribution of plasma and tissue iron can be traced with the use of ^{59}Fe as a radioactive tag by reinfusing a subject with autologous transferrin loaded with radiolabeled iron. Blood samples can be analyzed at timed intervals to determine the rate of loss of the radioactive label. Such ferrokinetic studies indicate that the normal half-life of iron in the circulation is about 75 minutes.[48] The absolute amount of iron released from transferrin per unit time is the PIT (see earlier).

Such radioactive tracer studies indicate that at least 80% of the iron bound to circulating transferrin is delivered to the bone marrow and incorporated into newly formed reticulocytes.[98,99] Other major sites of iron delivery include the liver, which is a primary depot for stored iron, and the spleen. Hepatic iron is found in both reticuloendothelial cells and hepatocytes. Reticuloendothelial cells acquire iron primarily by phagocytosis and breakdown of aging red cells; they extract the iron from heme and return it to the circulation bound to transferrin. Hepatocytes take up iron by at least two different pathways. The relative amounts of iron in each of these cell types depend on clinical circumstances, as discussed in detail later.

Given the preeminent role of bone marrow in the clearance of labeled iron from the circulation, ferrokinetic studies provide a window on erythropoietic activity. Conditions that augment erythrocyte production increase PIT. For example, hemolytic anemias such as hereditary spherocytosis and sickle cell disease induce rapid delivery of transferrin-bound iron to the marrow. In contrast, disorders that reduce red cell production, such as Diamond-Blackfan anemia and aplastic anemia, prolong PIT.

When erythrocytes are produced and released into the circulation in a normal fashion, the process of erythropoiesis is termed *effective*. In patients with certain anemias, however, the abnormal, nascent red cells are destroyed before they leave the marrow cavity. In this situation, erythropoiesis is *ineffective*, which means simply that the erythropoietic precursors have failed to accomplish their primary task: delivery of intact erythrocytes to the circulation. The ferrokinetic profile in this case shows rapid removal of iron from transferrin with delayed entry of label into the pool of circulating red cell hemoglobin. β^+-Thalassemia is an important example of this pattern. In β^+-thalassemia, ineffective erythropoiesis is coupled with markedly enhanced PIT.

Intracellular Iron Metabolism

Transferrin and the Transferrin Cycle

Although transferrin was first characterized more than 60 years ago,[100] its receptor eluded investigators until the early 1980s, when monoclonal antibodies prepared against tumor cells were found to recognize the transferrin receptor glycoprotein.[101] Subsequently, receptor-mediated endocytosis of iron bound to transferrin has been characterized in detail. A diagram showing key features of the transferrin receptor is presented in Figure 12-3. Each subunit of the disulfide-linked homodimer contains 760 amino acids.[102-104] Oligosaccharides account for about 5% of the 90-kd subunit's molecular mass.[105] Four glycosylation sites (three *N* linked and one *O* linked)
FIGURE 12-3. Structure of the dimeric transferrin receptor. The N-terminals of both subunits are inside the cell, and the C-terminals are outside. The 61–amino acid (aa) intracellular domain has three structural features that appear to play a role in endocytosis: a tyrosine-threonine-arginine-phenylalanine (YTRF) amino acid motif, a phosphorylated serine residue (*encircled* "P"), and a covalently linked molecule of palmitic acid (*solid circle*). The transmembrane domain is 28 amino acids long. The extracellular domain has 671 amino acids, including disulfide linkages (C-S-S-C), as well as four glycosylation sites (*branched lines*). A potential protease cleavage site is located between amino acids 100 and 101.

are found in the protein.[106,107] Glycosylation-defective mutants have fewer disulfide bridges, less transferrin binding, and less cell surface expression. The transmembrane domain, located between amino acids 62 and 89, functions as an internal signal peptide because there is none at the N-terminal end.[108] A molecule of fatty acid (usually palmitate) is also covalently linked to each subunit at the internal edge of the transmembrane domain and may play a role in membrane localization. Interestingly, nonacylated mutants mediate faster iron uptake.[109,110] The transferrin binding regions of the protein have not been definitively identified. However, the crystal structure of the ectodomain of the transferrin receptor has been reported.[111] Although no one has yet succeeded in cocrystallizing the receptor with transferrin, binding studies of mutant transferrin receptor proteins have yielded important insights.[112]

Iron is taken into cells by receptor-mediated endocytosis of diferric transferrin (Fig. 12-4).[113-116] Receptors on the outer face of the plasma membrane bind iron-loaded transferrin with very high affinity. The C-terminal domain of transferrin appears to mediate receptor

FIGURE 12-4. The endocytotic transferrin cycle. Apotransferrin (APO-TF) binds two atoms of iron per molecule to form diferric transferrin (HOLO-TF). Diferric transferrin binds to the transferrin receptor (TFR) on the cell surface. The complex is internalized by invagination of clathrin-coated pits to form specific endosomes. The endosomes import protons, thus lowering the pH within the organelle and decreasing the affinity of transferrin for iron. Liberated iron is translocated through the endosome membrane to the cytoplasm by DMT1. The iron released is shuttled to mitochondria for synthesis of heme and to ferritin for storage. The apotransferrin-transferrin receptor complex recycles to the cell surface, where neutral pH promotes release of apotransferrin into serum for reuse. Details are given in the text. *(Adapted with permission from Andrews NC. Iron homeostasis: insights from genetics and animal models. Nat Rev Genet. 2000;1:208-217.)*

binding.[117] Diferric transferrin binds with much higher affinity than monoferric transferrin or apotransferrin does.[118-120] The dissociation constant (K_d) for bound diferric transferrin ranges from 10^{-7} to 10^{-9} mol/L at physiologic pH, depending on the species and tissue. The K_d of monoferric transferrin is approximately 10^{-6} mol/L. The concentration of circulating transferrin is about 25 μmol/L. Therefore, cellular transferrin receptors are ordinarily fully saturated.

After binding to its receptor on the cell surface, transferrin is internalized through a constitutive mechanism that begins with invagination of clathrin-coated pits and the formation of endocytic vesicles. This process requires the short, 61–amino acid intracellular tail of the transferrin receptor molecule.[121-124] Receptors with truncated N-terminal cytoplasmic domains do not recycle properly. This portion of the molecule contains a conserved tyrosine-threonine-arginine-phenylalanine (YTRF) sequence that functions as a signal for endocytosis. Genetically engineered addition of a second YTRF sequence enhances receptor endocytosis.[125]

An ATP-dependent proton pump lowers the pH of the internalized endosome to about 5.5.[126-128] Acidification of the endosome weakens the association between iron and transferrin and promotes a conformational change in the transferrin receptor to enhance binding of apotransferrin and facilitate release of iron.[129] An endosomal ferrireductase must reduce iron from the Fe^{3+} state to Fe^{2+}, either at the same time that it is released from transferrin or soon afterward. This reductase was recently shown to be STEAP3, a membrane protein localized to transferrin cycle endosomes in erythroid precursors.[130] Related proteins may serve similar functions at other sites.[131]

The iron released from transferrin must leave the endosome and enter the cytoplasm and mitochondria for use in heme biosynthesis, Fe/S cluster formation, storage, and other purposes. This transmembrane transport step is also mediated by DMT1.[132,133] DMT1 is unusual in that it is expressed on two very different types of membranes—the apical membrane of intestinal enterocytes and the endosomal membrane of transferrin uptake vesicles in nonpolarized cells. Once transported out of the endosome or across the plasma membrane, iron must be delivered to sites of use or stored in the form of ferritin. Unlike copper (see later), however, there are no known cytosolic protein chaperones for iron, and how iron traverses the cell is unknown. In erythroid cells, iron is delivered across the mitochondrial inner membrane by mitoferrin 1 (SLC25A37),[134] where it is incorporated into heme by the enzyme ferrochelatase.

The fate of transferrin and the transferrin receptor is distinct from that of iron. Rather than entering lysosomes for degradation, as do ligands in other receptor-mediated endocytosis pathways, intact receptor-bound apotransferrin recycles to the cell surface, where neutral pH promotes detachment into the circulation. Thus, preservation and reuse of transferrin are accomplished

by pH-dependent changes in the affinity of transferrin for its receptor.[126,128,135] Exported apotransferrin binds additional iron atoms and undergoes further rounds of iron delivery to cells. The average transferrin molecule, with a half-life of 8 days, may be used hundreds of times for delivery of iron.

Topologically, the cell exterior and the endosome interior are equivalent compartments. The primary role of the transferrin–transferrin receptor interaction is to sequester iron near the cell membrane, thereby increasing the likelihood of iron uptake. DMT1 may reside on the plasma membrane of the cell before endocytosis. If so, it should be oriented to transport iron directly into the cell, without the assistance of transferrin (as diagrammed in Fig. 12-4). Such non–transferrin-bound iron uptake activities have been characterized in tissue culture cells (see later). This uptake system could function constitutively but inefficiently in tissues in which pH is low enough to provide protons for DMT1 function.

It was once a widely accepted belief that the transferrin cycle was important, if not necessary for uptake of iron by all mammalian cells. However, two lines of evidence indicate that such is not the case. First, mice and human patients with severe deficiencies of plasma transferrin have iron deficiency anemia but excess iron in nonhematopoietic tissues.[57,71,136-141] This finding indicates that uptake of iron bound to transferrin is important for red blood cell hemoglobinization and maturation but transferrin is not essential for delivery of iron to most other tissues. Second, mouse embryos lacking transferrin receptor die midway through gestation as a result of severe anemia, but nonhematopoietic tissues appear to generally be intact.[142] Aside from the erythron, only the developing CNS shows an apparent requirement for transferrin receptor. In its absence, primitive neuroepithelial cells undergo apoptosis at a greatly increased rate. Taken together, these observations indicate that the transferrin cycle is of primary importance in erythropoiesis and neurogenesis but of lesser importance in other mammalian tissues, at least early in embryonic development.

Non–Transferrin-Bound Iron Uptake

Both hypotransferrinemia and iron overload lead to complete saturation of available plasma transferrin, and non–transferrin-bound iron circulates in a chelatable, low-molecular-weight form (reviewed by Cabantchik and colleagues[143]). This iron is weakly complexed to albumin, citrate, amino acids, sugars, and other small molecules, and it behaves differently from iron associated with transferrin. Nonhematopoietic tissues (particularly the liver, endocrine organs, kidneys, and heart) preferentially take up non–transferrin-bound iron. Radiolabeled iron administered to mice with and without available transferrin-binding capacity is distributed in markedly different patterns.[57] In normal animals with excess plasma iron-binding capacity, hematopoietic tissues are the primary sites of uptake. When free transferrin iron binding sites

are absent, however, most iron is deposited in the liver and pancreas, thus indicating that these organs serve as the initial iron reservoirs in the situation of iron overload. Notably, this pattern of distribution is similar to that seen in idiopathic hemochromatosis.

Kaplan and co-workers have studied cellular assimilation of iron from $FeNH_4$ citrate in HeLa cells.[144,145] Intriguingly, they found that its transferrin-independent uptake increases in direct proportion to the concentration of this compound, similar to hepatic uptake of non–transferrin-bound iron in patients with saturated transferrin. They speculated that this is a protective alternative pathway that removes the toxic metal from the circulation. Other investigators have described similar uptake in a hepatic cell line and have shown that it is interrupted by the addition of chelating compounds.[146]

A nontransferrin iron uptake mechanism with different properties has been described in K562 erythroleukemia cells.[147,148] In the absence of ferric transferrin, uptake of iron into K562 cells is sensitive to treatment with trypsin, thus suggesting that it requires a protein carrier. Higher ambient iron concentrations do not increase cellular iron uptake. As discussed earlier, this transport may be accomplished by the same machinery responsible for passage of iron out of transferrin cycle endosomes into the cytoplasm. These two processes accomplish essentially the same task. However, the fact that DMT1 functions only at acidic pH suggests that it probably does not, by itself, account for all non–transferrin-bound iron transport.

Non–transferrin-bound iron is highly toxic to cells.[149] Plasma non–transferrin-bound iron can potentiate the formation of free radicals through the Fenton reaction (see earlier) and thereby induce cell membrane damage. Cardiac cells are particularly susceptible to this damage. Hence, therapeutic chelation must effectively remove plasma non–transferrin-bound iron.

Role of Iron in Cell Proliferation and Differentiation

Iron is indispensable for DNA synthesis and a host of metabolic processes. Iron starvation arrests cell proliferation, presumably because ribonucleotide reductase and other enzymes require the metal.[150] Although transferrin receptors are expressed on all dividing cells in numbers that roughly reflect their growth rate,[151] the erythron is the tissue that relies most heavily on delivery of iron by transferrin, as discussed in detail earlier. However, the transferrin cycle also appears to play a significant, if expendable role in other cell types.

Studies of mature T lymphocytes exemplify the general relationship between expression of transferrin receptor and cell proliferation. Transferrin receptors, absent from resting T cells, have long been recognized as a marker of T-cell activation. Initiation of cell division by a mitogen such as phytohemagglutinin dramatically

increases both surface expression of transferrin receptor and iron uptake.[152] Along the same lines, tumor cells upregulate transferrin receptor expression to optimize acquisition of iron for proliferation.

Blockade of transferrin receptor function can halt cell division. For instance, certain monoclonal antibodies against the transferrin receptor curb proliferation of tumor cells in vitro and in vivo.[153-158] Some 159 of these antibodies actually prevent binding of transferrin to its receptor, whereas others suppress receptor recycling but do not abrogate ligand binding.[154] Interestingly, some reports have suggested that the transferrin receptor may have an additional role in activated T cells, apart from its iron uptake function. Anti–transferrin receptor monoclonal antibodies have been described that can trigger T-cell activation and secretion of interleukin-2. These antibodies presumably activate a signal transduction pathway beginning with the transferrin receptor but independent of iron trafficking. The transferrin receptor also appears to have a role in early lymphocyte development. Embryonic stem cells in which both transferrin receptor genes have been inactivated fail to differentiate into circulating lymphocytes in vivo in chimeric mice.[159] It is not yet clear whether this is due to defective iron delivery or perturbation of some other, as yet unknown function of the transferrin receptor.

Chelators that deplete intracellular iron and limit its bioavailability in extracellular fluids further demonstrate the central role of iron in cell proliferation. Agents such as deferoxamine, desferrithiocin, and pyridoxal isonicotinoyl hydrazone inhibit the growth of a variety of tumor cells in culture[160,161] and greatly reduce T-cell proliferation.[162-165] A likely inhibitory mechanism is iron deprivation, with reduced ribonucleotide reductase activity and lower levels of deoxyribonucleotides. This, in turn, leads to mitotic arrest in the S phase of the cell cycle.[166] The addition of iron to the medium reverses the growth inhibition. Chelators may also induce apoptosis, or programmed cell death, through other mechanisms that are not yet understood.

Erythroid precursors need an extraordinary amount of iron to support hemoglobin synthesis and differentiation into mature red cells. The density of transferrin receptors on the cell surface is modulated during erythroid development. Transferrin receptors first appear in measurable numbers on colony-forming unit–erythroid (CFU-E) cells and increase to 300,000 per cell on proerythroblasts and as many as 800,000 per cell on basophilic erythroblasts at the time of maximal iron uptake. Numbers then fall to 100,000 per cell on circulating reticulocytes and to negligible levels on mature red cells.[167] A precise correlation exists between iron requirement and transferrin receptor number, thus indicating that the abundance of transferrin receptors on the cell surface is a major determinant of erythroid iron uptake. In culture, a monoclonal antibody to the transferrin receptor that permits ligand binding but subsequently slows receptor recycling partially blocks erythroid iron uptake. The level of iron uptake is sufficient for cell division but not hemoglobin synthesis.[168]

Beug's group[169] demonstrated that an anti–transferrin receptor monoclonal antibody blocks differentiation of chick erythroid cells at the erythroblast or early reticulocyte stage and promotes premature, pyknotic cell death. The antibody apparently prevents normal cycling of transferrin receptors and inhibits efficient iron uptake. Its effects were specific for erythroid differentiation because it did not inhibit proliferation of a variety of other cell lines. Ferric salicylaldehyde-isonicotinyl-hydrazone (Fe-SIH) was added to antibody-treated cells to determine whether direct delivery of iron by this compound could rescue the normal erythroid program. Interestingly, Fe-SIH only partially restored maturation of antibody-treated avian cells. The investigators postulated that insufficient levels of heme or hemoglobin might shut off production of the proteins required for differentiation. These data are in accord with those of Ponka and Schulman,[170] who have shown that the rate of heme synthesis is influenced by the efficiency of iron uptake. A wealth of literature demonstrates that oxidized heme (hemin) promotes differentiation of erythroleukemia cell lines in tissue culture.[171-174] Conversely, deficient heme biosynthesis abrogates chemical induction of differentiation in an erythroleukemia cell line subclone.[175]

Other reports indicate that heme biosynthesis indirectly regulates the transcription of globin, transferrin receptor, and ferritin genes.[176-178] Heme also regulates globin mRNA translation by an elegant mechanism involving a kinase that binds heme to modulate translation factor activity (reviewed by Chen[179]). Although some of the precise mechanisms remain to be elucidated, it is clear that iron uptake, heme biosynthesis, and globin protein production are coordinately regulated. Interrelated regulatory networks apparently allow red cell precursors to maximize hemoglobin formation without accumulating excess globin proteins, unbound iron, or toxic protoporphyrin intermediates.

REGULATION OF PROTEINS OF IRON METABOLISM

Ferritin

Once inside the cytoplasm, iron is probably bound by unidentified carrier molecules that may assist in delivery to various intracellular locations, including mitochondria (for heme biosynthesis) and ferritin (for storage). The identities of the intracellular iron carrier molecules remain unknown. The amount of iron in transit within the cell at any given time is small and difficult to measure. This minute pool of transit iron, which is believed to be in the Fe^{2+} oxidation state, is the biologically active and potentially toxic form of the element. Metabolically inactive iron, stored in ferritin and hemosiderin, is nontoxic and in equilibrium with this exchangeable transit iron.

Both prokaryotes and eukaryotes produce ferritin molecules for iron storage. Mammalian ferritin molecules are complex 24-subunit heteropolymers of H (for heavy or heart) and L (for light or liver) protein subunits. L subunits are 19.7 kd in mass, with isoelectric points of 4.5 to 5.0; H subunits are 21 kd in mass, with isoelectric points of 5.0 to 5.7. The subunits of the ferritin molecule probably arose by gene duplication, although the degree of nucleotide sequence homology between the two is only about 50%. They assemble to form a sphere with a central cavity in which up to several thousand atoms of crystalline iron can be stored in the form of poly-iron-phosphate oxide.[180] Eight channels through the sphere are lined by hydrophilic amino acid residues (along the threefold axes of symmetry), and six more are lined by hydrophobic residues (along the fourfold axes).[181] Strong interspecies amino acid conservation is seen in the residues that line the hydrophilic channels, whereas marked variation is seen in those along the hydrophobic passages. The hydrophilic channels terminate with aspartic acid and glutamic acid residues and are lined by serine, histidine, and cysteine residues (all of which potentially bind metal ligands).

Although the two ferritin chains are homologous, only H ferritin has ferroxidase activity. A mechanism involving dioxygen converts ferrous to ferric iron, thereby promoting incorporation into ferritin.[182,183] The composition of ferritin shells varies from H-subunit homopolymers to L-subunit homopolymers and includes all possible combinations between the two. Isoelectric focusing of ferritin from a particular tissue reveals multiple bands representing shells with different subunit compositions. These isoferritins, as they are called, show tissue-specific variation. Ferritin from liver, for instance, is rich in L subunits, as is that from the spleen. In contrast, the heart has ferritin rich in H subunits. Increased H-subunit content correlates with increased iron utilization, whereas increased L-subunit content correlates with increased iron storage.[184] The H-to-L ratio increases with increased cell proliferation.[185] Thus, ferritin provides a flexible reserve of iron.

Despite the fact that it does not, itself, have enzymatic activity, a mutation in L ferritin has been shown to cause a distinctive iron deposition disease in humans. In patients carrying a nucleotide insertion altering the carboxy-terminus of L ferritin, iron overload develops in the basal ganglia and leads to a neurodegenerative disease with variable extrapyramidal features.[186]

Ferritin molecules aggregate into clusters that are engulfed by lysosomes and degraded. The end product of this process, hemosiderin, is an amorphous agglomerate of denatured protein and lipid interspersed with iron oxide molecules.[187] In cells overloaded with iron, lysosomes accumulate large amounts of hemosiderin, which can be visualized by Prussian blue (Perls) staining. Although the iron enmeshed in this insoluble compound constitutes an end-stage product of cellular iron storage, it remains in equilibrium with soluble ferritin. Ferritin iron, in turn, is in equilibrium with iron complexed to low-molecular-weight carrier molecules. Therefore, introduction of an effective chelator into the cell captures iron from the low-molecular-weight "toxic" iron pool, draws iron out of ferritin, and eventually depletes iron from hemosiderin as well, though only very slowly. As might be expected, the bioavailability of hemosiderin iron is much lower than that of iron stored in ferritin.

The large number of processed pseudogenes that exist for each subunit initially confounded pinpointing the chromosomal location of ferritin genes. Functional ferritin genes for the H and L subunits are located on human chromosomes 11 and 19, respectively.[188] In addition, there is an intronless gene encoding a mitochondrion-specific, H-like ferritin molecule located on human chromosome 5q.[189] The function of mitochondrial ferritin remains uncertain, although the fact that its expression is increased in erythroid precursors from patients with sideroblastic anemia suggests that it is involved in mitochondrial iron management.[189,190]

Ferritin formation is controlled at multiple levels—transcription, message stabilization, translation, and subunit assembly. In the liver and in HeLa cells, iron rapidly induces the synthesis of L-subunit mRNA, with no effect on H-subunit transcription.[191,192] In contrast, induced differentiation of HL-60 promyelocytic leukemia cells and mouse erythroleukemia cells increases production of H-subunit mRNA.[193,194] Tumor necrosis factor induces H-chain transcription in human myoblasts.[195] Iron, heme, reactive oxygen species, and oxidative stress all enhance transcription and translation of the ferritin heavy chain (reviewed by Rouault[196]).

Cytoplasmic ferritin mRNA forms a stable complex with several proteins. Both iron and interleukin-1β enhance translation of ferritin messenger ribonucleoprotein.[197] Influx of iron into cells shifts the message onto the ribosomes, thereby enhancing the synthesis of ferritin subunits.[198] This translational control mechanism involves an RNA-protein interaction that links the expression of genes encoding ferritin, the transferrin receptor, enzymes of heme biosynthesis, DMT1, ferroportin, and other proteins. Munro and colleagues[198] initially showed that ferritin synthesis was regulated at the level of message translation. Comparison of the 5′ untranslated regions of ferritin mRNA encoding both heavy and light chains showed striking conservation of a 28-bp sequence motif that was predicted to form a stable RNA stem-loop structure and was necessary for translational control of ferritin (Fig. 12-5, inset).[199,200]

Subsequently designated the iron response element (IRE), this RNA stem-loop is recognized by at least two specific RNA-binding proteins called IRP1 and IRP2 for iron regulatory proteins 1 and 2. IRP1 is a 98-kd soluble polypeptide with striking homology to the mitochondrial tricarboxylic acid cycle enzyme aconitase.[201] The crystal structure of IRP1 bound to an IRE was recently reported.[202]
FIGURE 12-5. IRE/IRP regulation. Two mechanisms of action of iron regulatory proteins (IRPs) are shown. An IRP molecule binds to an iron response element (IRE) stem-loop structure located in noncoding mRNA sequences. A consensus IRE structure is shown in the *inset*. Under low-iron conditions, IRP binds avidly to RNA. With abundant iron, no binding occurs. Binding of IRP to IRE elements in the 5′ untranslated region (UTR) (e.g., in ferritin mRNA) blocks translation. In contrast, binding of IRP to 3′ UTR IRE elements (e.g., in transferrin receptor mRNA) prevents site-specific nucleolytic cleavage, thereby stabilizing the message. In this way, a single regulatory element plays two different roles in the translational regulation of proteins involved in cellular iron metabolism.

IRP1 and mitochondrial aconitase have identical amino acid residues in the region corresponding to the aconitase active site, and IRP1 probably serves as the major cytosolic aconitase. The enzymatic active site of IRP1 contains a 4Fe/4S cluster. When the iron concentration in the cytosol is high, the cluster is complete, and this form of IRP1 has aconitase activity but cannot bind mRNA. Under these circumstances, the ferritin message is translated efficiently. Conversely, when the iron concentration is low, aconitase activity is absent, RNA binding is avid, and ferritin message translation is blocked because translation initiation complexes cannot form properly.[203-208] Thus, IRP1 is a dual-function protein, with ambient iron controlling the switch by its participation in the 4Fe/4S cluster. Other molecules that modulate the switch include ascorbic acid, nitric oxide, and heme.[209-211] This mechanism allows ferritin protein expression to be rapidly downregulated without degradation of mRNA. The importance of IRP-mediated translational control is underscored by the fact that hyperferritinemia and ferritin-containing cataracts develop in patients with mutations in the L-ferritin IRE but these patients do not have abnormalities in iron homeostasis.[212,213] Furthermore, it appears that an iron overload disorder resembling hereditary hemochromatosis develops in rare patients with mutations in the H-ferritin IRE, presumably because increased H-ferritin expression leads to increased cellular iron assimilation, retention, or both.[214]

A second IRE-binding protein, IRP2, also modulates post-transcriptional expression of mRNA by binding to IREs in much the same way. Initially isolated in the liver, IRP2 has been found in all tissues examined and is more abundant than IRP1 in some.[215,216] Although the two proteins differ in molecular mass (90 kd for IRP1 and 118 kd for IRP2), the key difference is that IRP2 lacks aconitase activity[217] and does not contain an Fe/S cluster to function as a "ferrostat." Rather, IRP2 protein levels are modulated directly by iron or by heme and the molecule is actively degraded when iron or heme (or both) are abundant.[215,218-220] IRP1 and IRP2 function differently when oxygen tension changes, and IRP2 appears to be more important in vivo, in settings in which tissue oxygen tension is relatively low.[221]

The Transferrin Receptor

IRPs also modulate expression of the transferrin receptor gene. The gene encoding the transferrin receptor is located on human chromosome 3q26.2-qter, near the gene encoding transferrin at 3q21.[222] It consists of 19 exons spread over 31 kb.[223] The transferrin receptor

mRNA is approximately twice the length needed to encode the receptor protein. Its lengthy 3′ untranslated region contains five potential RNA stem-loop structures that are structurally similar to those of the ferritin IREs.[224-226] These conserved regions of the mRNA bind the same proteins as the IREs of the ferritin mRNA do.[226] The attached protein increases the stability of the transferrin receptor message by obscuring an endonucleolytic cleavage site.[227] The result is a larger amount of transferrin receptor mRNA in the cell. A deficit of cellular iron, then, raises transferrin receptor mRNA levels at least in part through enhanced message stability. However, IRE regulation is probably not responsible for the primary increases in transferrin receptor number in erythroid cells because this occurs at the transcriptional level and is unaffected by iron status. Relatively little is understood about the tissue-specific transcriptional regulation of the transferrin receptor.[228]

The versatile regulatory functions of IREs may also confer iron-dependent regulation on other proteins. IREs are present in the 5′ untranslated regions of the mRNA encoding the erythroid form of the heme biosynthetic enzyme δ-aminolevulinic acid synthase, mitochondrial aconitase, and ferroportin.[30,31,33,229-231] A single 3′ IRE is found in one splicing isoform of DMT1 mRNA.[232] As the rate-limiting enzyme in heme biosynthesis, the IRE in the erythroid form of δ-aminolevulinic acid synthase produces a conceptually satisfying link between iron and heme production. However, the functions of the IREs in the other mRNAs are not yet understood. It is postulated that all IREs serve the common purpose of coupling changes in the iron status of the cell with its ability to utilize and store the element (see Fig. 12-5). When the intracellular iron concentration is low, the IRE of ferritin mRNA binds IRP and reduces ferritin synthesis because additional iron storage capacity is not needed in this circumstance. Simultaneously, the level of transferrin receptor mRNA increases as the IRP stabilizes the message, thereby increasing expression of the transferrin receptor. Together, these events increase the flow of iron into cells while protecting against iron toxicity. When iron levels in the cell are high, the opposite scenario is operative. Although the IRPs accomplish these regulatory feats under extremes of iron status, the importance of IREs and IRPs in modulating gene expression in normal humans and animals is not fully understood. Recently, novel IRE-containing genes have been identified, with roles less directly related to iron homeostasis.[233-235]

In an attempt to sort out the unique functions of IRP1 and IRP2 and to evaluate their roles in vivo, targeted mutagenesis was used to generate mutant mice lacking each of the proteins.[236-241] Surprisingly, IRP1 knockout mice had no identifiable defects, but IRP2 knockout mice had abnormalities in several tissues. Initially, the most striking aspect of the IRP2 knockout phenotype was a late-onset neurologic disorder associated with abnormal deposition of iron in white matter tracts and nuclei throughout the brain.[239] The mice dem-

onstrated ataxia, bradykinesia, and tremors. However, these findings could not readily be explained by known activities of IRP2, and a second group reported that an independently targeted line of mice did not have obvious neurodegeneration.[238] It is possible that the discrepancy may be explained by differential severity of a neurologic phenotype on different genetic backgrounds. More recently, both groups have reported that IRP2-deficient mice have mild microcytosis because of functional erythroid iron deficiency, as well as other subtle perturbations in systemic iron homeostasis.[236,242]

Serum Ferritin and Transferrin Receptors

Although most ferritin is located within cells, a measurable amount of the protein exists in serum. Intracellular concentrations, particularly in the liver, are several orders of magnitude higher than serum concentrations. Therefore, a small amount of cellular lysis could liberate a relatively large amount of ferritin. However, the vast majority of serum ferritin appears to be secreted. There are probably several cell types that are sources of secreted extracellular ferritin, including iron-recycling macrophages and hepatocytes. Circulating ferritin consists almost exclusively of L-chain subunits.[243] In contrast, intracellular ferritin contains a mixture of H and L subunits. In addition, unlike intracellular ferritin, circulating ferritin is glycosylated, thus suggesting that it passes through the endoplasmic reticulum and Golgi apparatus as do other secreted proteins.

Serum ferritin levels decline with iron deficiency and rise with iron loading.[244] In the absence of liver disease, infection, or chronic inflammation, serum ferritin is roughly proportional to total body iron stores. The correlation between serum ferritin levels and body iron stores is useful in the evaluation of patients with possible iron deficiency or iron overload. A low serum ferritin level (less than 12 μg/L) invariably represents iron deficiency, and high serum ferritin levels are found in patients with iron overload. Extreme serum ferritin levels should be interpreted cautiously, however, because the correlation between ferritin levels and body iron stores is approximately linear only for storage reserves of iron ranging between 1 and 3 g. In addition, normal circulating ferritin values vary with sex and age. These considerations must be factored into any evaluation of iron stores based on ferritin values, particularly in children.

Various conditions modify serum ferritin levels. Inflammation increases the serum ferritin concentration severalfold.[245] Infections, particularly chronic conditions such as tuberculosis or osteomyelitis, may also increase levels substantially, presumably because of the associated inflammatory response. Chronic renal disease and chronic liver disease are likewise associated with elevated levels. A number of tumors are variably associated with an increased level of circulating ferritin. For example, ferritin is an important prognostic factor in childhood neu-

roblastoma, in which serum ferritin levels correlate with disease severity.[246]

The mechanisms by which inflammation and tumors increase the quantity of plasma ferritin are not fully understood. Treatment with interleukin-1β, a prime mediator of the inflammatory response, increases synthesis of ferritin in human hepatoma cells,[197] whereas tumor necrosis factor has been shown to increase ferritin mRNA levels in murine cells in culture.[195] These cytokines may also increase ferritin synthesis in cells secreting the protein. In addition, the inflammatory cytokine interleukin-6 induces hepcidin expression,[45] which results in increased macrophage iron storage and probably contributes to increased serum ferritin. Furthermore, serum ferritin elevated out of proportion to iron stores is a hallmark feature of ferroportin disease (see later).[247]

Soluble transferrin receptors are also found in serum. Small vesicles containing transferrin receptors are shed from reticulocytes during their maturation to erythrocytes.[248] In addition to these vesicle-associated receptors, the extracellular portion of the transferrin receptor lacking its transmembrane anchor can be found in the circulation.[249-251] One mechanism by which soluble transferrin receptors are generated is a membrane-associated protease activity that clips the molecule between amino acids 100 and 101, at the base of its extracellular stem.[252,253] This cleavage is potentiated by mutation of an *O*-linked glycosylation site at amino acid 104, thus suggesting that differential glycosylation may play a regulatory role.[254] The transferrin binding domain is intact in these soluble receptors, and they are likely to be complexed with transferrin in serum.

Because maturing red cells shed their transferrin receptors, the amount of soluble transferrin receptor in plasma reasonably reflects the degree of erythropoiesis. Measurement of serum levels of soluble transferrin receptor provides a means of estimating erythropoietic activity that is simpler than the relatively cumbersome PIT determination.[255] Serum transferrin receptor (sTfR) is present in substantially lower amounts in patients with aplastic anemia relative to normal individuals. In contrast, values in patients with anemia caused by ineffective erythropoiesis are markedly increased. Patients with iron deficiency also have increased levels of circulating soluble transferrin receptors. This may result in part from the increase in cellular transferrin receptor expression produced by iron starvation and in part from the increased erythroid turnover associated with the ineffective erythropoiesis of iron deficiency. sTfR and serum ferritin values can be considered together as the ratio of sTfR to the log of ferritin (sTfR-F index). Values greater than 1.5 suggest iron deficiency alone or in combination with an inflammatory condition; values less than 1.5 are characteristic of the anemia of chronic inflammation.[256] The sTfR-F index also appears to be sensitive enough to detect iron deficiency before iron-restricted erythropoiesis is clinically apparent.[257] sTfR and the sTfR-F index are both decreased in patients with iron overload.[258,259]

EXTREMES OF IRON BALANCE

Iron disorders are invariably abnormalities in iron balance, distribution, or both. Iron deficiency is primarily due to acquired causes. In contrast, primary iron overload usually results from genetic abnormalities that perturb the regulation of intestinal iron absorption. Disorders affecting other steps in transport may be manifested as inappropriate iron accumulation in some tissues and iron deficiency in other tissues.

Iron Deficiency

Epidemiology of Iron Deficiency

Iron deficiency is the most frequent and widespread nutritional deficiency in the world[260] because it is common in developing and developed countries alike. In fact, iron deficiency is the only micronutrient deficiency that is also prevalent in virtually all developed countries.[260] To this end, one of the U.S. national health objectives for 2010 is to reduce iron deficiency in vulnerable populations such as toddlers and women of childbearing age by 3% to 4%.[261]

Increasing rates of breast-feeding and the availability of iron-fortified formula (see later), in conjunction with initiatives such as the U.S. Special Supplemental Food Program for Women, Infants and Children and the American Academy of Pediatrics' promotion of formula in place of cow's milk, have greatly reduced the prevalence of iron deficiency *anemia* in infants in developed countries. Nonetheless, iron deficiency, both with and without anemia, remains relatively common. According to the Fourth National Health and Nutrition Examination Survey (NHANES IV), iron deficiency without anemia exists in 7% of toddlers aged 1 to 2 years, 9% of adolescent girls, and 16% of women of childbearing age.[262] Adolescents participating in strenuous training are another pediatric subpopulation at risk for iron deficiency. For example, young military recruits and elite adolescent athletes have an increased risk of nonanemic iron deficiency.[263-265]

Socioeconomic factors are associated with iron deficiency anemia in children. For example, infants and children of low-income and minority backgrounds have higher documented rates of iron deficiency anemia.[266-268] Although food insecurity is known to be associated with iron deficiency anemia,[269] other factors such as bottle-feeding patterns may also play a role in the prevalence of iron deficiency.[270] The iron status of young children correlates closely with the iron status of their mothers, thus indicating that a constellation of factors in the child's environment influence iron intake and therefore iron status.[271]

Phases of Development of Iron Deficiency

Because most of the body's iron is directed toward synthesis of hemoglobin, erythrocyte production is among

the first casualties of iron deficiency to become clinically apparent in usual laboratory evaluations. However, it actually represents a late stage of iron depletion. Iron deficiency progresses through three discernible phases:

1. *Prelatent iron deficiency* occurs when tissue stores are depleted, without a change in hematocrit or serum iron levels. This stage of iron deficiency may be detected by low serum ferritin measurements.

2. *Latent iron deficiency* occurs when reticuloendothelial macrophage iron stores are depleted. The serum iron level drops and TIBC increases without a change in hematocrit. This stage may be detected by a routine check of fasting, early morning transferrin saturation. Erythropoiesis begins to be limited by a lack of available iron, and sTfR levels increase. The reticulocyte hemoglobin content (CHr) decreases because newly produced erythrocytes are iron deficient.[272] The bulk of the erythrocyte population appears normal. For this reason, sole reliance on indicators derived from the entire erythrocyte population frequently fails to detect this stage of iron deficiency.[272,273]

3. *Frank iron deficiency* anemia is associated with erythrocyte microcytosis and hypochromia. It is detected when iron deficiency has persisted long enough that a large proportion of the circulating erythrocytes were produced after iron became limiting.

Etiology of Iron Deficiency

The development of iron deficiency is a result of the interaction between iron intake, physiologic iron requirements, and the potential for blood loss.

Inadequate Iron Intake

Dietary Sources. Heme, derived from animal tissues, is the most readily absorbed form of iron. Uptake occurs independently of gastric pH and, like the uptake of nonheme iron, is increased in patients with high marrow erythroid activity. Much of the world's population eats little or no meat, with their nutrition derived from cultivated grasses such as rice. These plants are relatively poor sources of iron,[22] which contributes to the fact that iron deficiency anemia is the most common nutritional anemia worldwide.

In developing countries, nutritional iron deficiency is often compounded by chronic blood loss from parasitic infections and malaria (see later). In industrialized countries, however, iron deficiency is usually due to insufficient dietary intake to meet physiologic needs. Because of their rapid growth and increased need for iron, infants, toddlers, female adolescents, and childbearing women are especially vulnerable.

Consumption of cow's milk may contribute to iron deficiency through several mechanisms. Cow's milk and human milk both have low iron content, but the bioavailability of iron in human milk is greater.[274] Therefore, the transition from human milk to cow's milk may place toddlers at risk for iron deficiency. Indeed, the prevalence of iron deficiency increases with the duration of bottle-feeding of cow's milk.[270] Cow's milk also compounds iron deficiency by replacing iron-rich foods in the diet. In addition, components of cow's milk, such as calcium and caseinophosphopeptide, can directly interfere with iron absorption.[275,276] Furthermore, whole cow's milk contains proteins that may irritate the lining of the gastrointestinal tract in infants, and even low-grade but chronic hemorrhage may produce significant iron deficiency.[277] The neonatal growth spurt requires a tremendous quantity of iron, thus compounding the disadvantages of cow's milk. For these reasons, current recommendations exclude cow's milk from the infant's diet in the first year of life, limit subsequent consumption of cow's milk to 24 ounces per day, suggest that non–breast-fed infants should receive iron-fortified formulas, and advise an additional source of iron for infants who are breast-fed after 4 to 6 months of age, when they have depleted the excess iron that was present in newborn stores and erythrocytes.[278,279]

Poor Bioavailability. Although iron is abundant in the environment, it is nearly insoluble in aqueous solution, which makes acquisition of the common element a major challenge. Most environmental iron exists as insoluble salts. Gastric acidity assists in conversion to absorbable forms, but the efficiency of this process is limited.[280] Many plant products contain iron, but absorption frequently is limited both by low solubility and by powerful natural chelators that bind ambient iron. Phytates (organic polyphosphates) found in wheat products, for example, bind iron with tremendous avidity. The challenge of acquiring sufficient iron from the environment may have been an important factor in the spread of genes for hemochromatosis disorders.

High gastric pH reduces the solubility of inorganic iron and thereby impedes absorption. Surgical interventions, such as vagotomy or hemigastrectomy for peptic ulcer disease, formerly were the major causes of impaired gastric acidification with secondary iron deficiency, particularly in adults. The histamine H_2 blockers and the more recently introduced acid pump blockers, used to treat peptic ulcer disease and acid reflux, may cause defective iron absorption.[281,282] There is, however, little evidence that they substantially alter iron status in those without preexisting iron deficiency.[283-285]

The impaired function of gastric parietal cells associated with pernicious anemia not only reduces the production of intrinsic factor but also lessens gastric acidity and hence compromises absorption of iron. In addition, megaloblastic enterocytes absorb iron poorly. Frank iron deficiency can accompany the anemia produced by cobalamin deficiency.[286-288] However, the rarity of pernicious anemia in children makes this complication uncommon in pediatric populations.

A number of environmental factors can produce dietary iron deficiency by interfering with iron absorption, including metals such as cobalt, which share the iron absorption machinery. Lead may fall into this cate-

gory, although it remains to be definitively established whether DMT1 is the primary intestinal lead transporter in vivo.[27] Regardless of the mechanism, it is clear that iron deficiency increases the rate of uptake of both iron and lead from the gastrointestinal tract. Iron deficiency and lead intoxication frequently coexist.

Malabsorption. Some disorders disrupt the integrity or surface area of the enteric mucosa and thereby hamper iron absorption (Box 12-2). Inflammatory bowel disease,

---

Box 12-2	**Causes of Iron Deficiency Anemia**

INADEQUATE ABSORPTION

Poor bioavailability (absorption of heme Fe > Fe^{2+} > Fe^{3+})
Antacid therapy/high gastric pH
Bran, tannins, phytates, starch
Other metals (Co, Pb)
Loss/dysfunction of absorptive enterocytes

INSUFFICIENT/INACCESSIBLE IRON STORES

Gastrointestinal Blood Loss

Epistaxis
Gastritis
Ulcer
Meckel's diverticulum
Milk-induced enteropathy
Parasitosis
Varices
Tumor or polyps
Inflammatory bowel disease
Arteriovenous malformation
Colonic diverticula
Hemorrhoids

Vaginal Blood Loss

Increased menstrual flow

Urinary Blood Loss

Chronic infection
Tumor

Pulmonary Blood Loss

Pulmonary hemosiderosis
Tuberculosis
Bronchiectasis

Inflammation/infection

Defects in intestinal iron uptake (e.g., TMPRSS6 mutations)

INADEQUATE PRESENTATION TO ERYTHROID PRECURSORS

Atransferrinemia
Anti–transferrin receptor antibodies

ABNORMAL INTRACELLULAR TRANSPORT/UTILIZATION

Erythroid iron trafficking defects (e.g., DMT1 mutations)
Defects in heme biosynthesis

---

particularly Crohn's disease, may injure extensive segments of the small intestine, including the jejunum and duodenum. Invasion of the submucosa by inflammatory cells and disruption of the tissue architecture impair iron absorption and uptake of dietary nutrients.[289] Occult gastrointestinal bleeding exacerbates the problem. The result is iron deficiency anemia complicated by the anemia of chronic inflammation. Furthermore, Crohn's disease frequently involves the terminal ileum, with the concurrent development of cobalamin deficiency. These disorders are not diagnostic enigmas. Patients with extensive bowel involvement are very ill. Diminishing the underlying inflammatory process best treats the iron deficiency.

Tropical sprue and celiac disease can also interfere with iron absorption.[289] Degeneration of the intestinal lining cells along with chronic inflammation causes profound malabsorption, although some patients with deranged iron absorption lack gross or even histologic changes in the structure of the bowel mucosa. The anemia in these patients is often complicated by a superimposed, generalized nutritional deficiency.[290] Celiac disease frequently improves with ingestion of a gluten-free diet, with secondary correction of the anemia.

Iron absorption may be disrupted when substantial segments of bowel, particularly the proximal duodenum, are removed surgically. Intractable inflammatory bowel disease, traumatic abdominal injury, and structural complications such as intestinal volvulus or intussusception all may necessitate intestinal resection. Iron deficiency develops slowly afterward and may not become evident for several years after the surgical procedure.

Malabsorption of iron is rare in the absence of gross or microscopic structural defects of the intestine or the anemia of chronic inflammation (see later). However, several families with an autosomal recessively inherited predisposition to iron deficiency and systemic iron malutilization have been described.[291-294] These individuals exhibit iron deficiency anemia at early age that is characterized by a nearly complete lack of response to oral iron supplementation and a slow, incomplete response to parenteral iron therapy—so-called iron-refractory, iron deficiency anemia (IRIDA). Recently, it has been shown that individuals with IRIDA have biallelic inactivating mutations in the TMPRSS6 protein, a transmembrane serine protease expressed in the liver, that leads to inappropriate hepcidin overexpression and eventuates in impaired iron absorption and iron recycling.[294,295] Although mutations in DMT1 might also be expected to lead to a somewhat similar congenital iron deficiency anemia phenotype, in fact, reported patients with DMT1 mutations have iron-restricted erythropoiesis in the setting of systemic iron overload.[296-300]

Systemic Iron Loss

Gastrointestinal Blood Loss. Blood loss is the leading cause of iron deficiency worldwide. The gastrointestinal tract is both the site of iron uptake and the most common

site of blood loss, particularly when bleeding is not readily apparent. However, bleeding from other sites should also be considered if iron deficiency has not otherwise been explained.

Anatomic defects of the gastrointestinal tract commonly cause blood loss and consequent iron deficiency. The most frequent congenital defect is Meckel's diverticulum, which results from a persistent omphalomesenteric duct. This abnormality can produce abdominal pain and, occasionally, intestinal obstruction in young children. Adolescents with Meckel's diverticulum may have occult blood loss and secondary iron deficiency.[301] Peptic ulcer disease is extremely uncommon in children but should be considered as a cause of gastrointestinal blood loss when the clinical setting suggests it.

Other structural defects of the gastrointestinal tract may cause bleeding as well. Arteriovenous malformations involving the superficial blood vessels occur in patients with hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome). These defective vessels frequently bleed to a degree that engenders iron deficiency. Although the disorder is transmitted as an autosomal dominant trait, the characteristic vascular lesions rarely attain clinical significance before young adulthood. The condition is easily recognized because the mucosal lining of the oropharynx and nasal cavity exhibits characteristic telangiectases.

The leading cause of gastrointestinal blood loss worldwide is parasitic infestation. Hookworm infection, caused primarily by *Necator americanus* or *Ancylostoma duodenale*, is endemic to much of the world and is often asymptomatic. Microscopic blood loss leads to significant iron deficiency, particularly in children.[302] More than 1 billion people, most in tropical or subtropical areas, are infested with parasites. Combined, their total daily blood loss exceeds 11 million L. The larvae spawn in moist soil and penetrate the skin of unprotected feet. Hookworm infection, once prevalent in the southeastern United States, declined precipitously with better sanitation and routine use of footwear when outside.

Trichuris trichiura, the culprit in trichuriasis or whipworm infection, is believed to infest the colon of 600 to 700 million people. Only 10% to 15% of these individuals have worm burdens sufficiently great to produce clinical disease. However, most are children between the ages of 2 and 10 years. Growth retardation, in addition to iron deficiency, occurs with heavy infestation.[303] Trichuriasis is the most common helminthic infection encountered in Americans returning from visits to tropical or subtropical regions of the world.

Urinary Blood Loss. Occasionally, blood loss into the urinary tract outstrips iron absorption. However, urinary blood loss is usually apparent and sufficiently alarming that patients seek medical attention before substantial iron deficiency develops. Iron deficiency resulting from hematuria secondary to renal disease is relatively uncommon.

The best characterized cause of significant renal blood loss is Berger's disease, which produces relapsing episodes of gross or microscopic hematuria. The disorder occurs most commonly in older children and young adults. It is characterized by diffuse mesangial proliferation or focal and segmental glomerulonephritis. Diffuse mesangial deposits of IgA are the hallmark of the disorder. Although the disease spontaneously remits in some children, progression to end-stage renal disease may occur. Occasionally, Goodpasture's syndrome produces substantial urinary blood loss. Immunofluorescent staining of biopsy specimens reveals the characteristic antibodies to basement membrane lining the glomeruli. Blood loss into the urinary bladder can occur in association with infectious cystitis. Hematuria to the point of iron deficiency is extremely uncommon, however.

Pulmonary Blood Loss. Although pulmonary blood loss may be sufficiently severe to produce iron deficiency, it is distinctly rare. Idiopathic pulmonary hemosiderosis primarily affects children and young adolescents (reviewed by Specks[304]). This potentially deadly disorder is characterized by slow but intractable hemorrhage into the bronchioles and alveoli. Iron deficiency anemia is a major part of the clinical picture of pulmonary hemosiderosis inasmuch as pulmonary macrophages are distinct from the normal iron-recycling circuit and iron trapped within these cells is effectively lost from the functional systemic pool. Consequently, a paradoxical situation evolves in which iron deficiency anemia develops in the presence of a surfeit of total body iron. Bronchoalveolar lavage reveals hemosiderin-laden macrophages that are characteristic of the disorder. Chronic pulmonary infection with bronchiectasis, once considered to be a frequent cause of pulmonary hemorrhage, is now rare. Formation of toxic products is induced by the iron that accumulates in these cells, which leads to the activation of macrophages. These cells begin to damage the delicate lining of the bronchoalveolar tree and produce severe fibrosis. Oxygen exchanges poorly across the damaged alveolar surfaces, thereby lowering the efficiency of oxygen/carbon dioxide exchange. Late in the course of pulmonary hemosiderosis, the radiographic picture of the lungs is striking and frequently shows marked retraction and scarring.[305] The restrictive lung disease and substantial pulmonary arterial shunting across the lung may eventually be fatal.

Most often the cause of pulmonary hemosiderosis evades elucidation. In a number of patients, it occurs in conjunction with disorders of immune dysfunction, including celiac disease[306] and Goodpasture's syndrome.[307,308] Treatment of the associated disorder can lead to remission of the pulmonary process, consistent with an immunologic mechanism of the lung injury.[309] Chloroquine treatment has been used with modest success in some patients.[310] Cyclophosphamide has produced responses in a number of patients.[311] A combination of prednisone and azathioprine has also been used.[312] Other immunosuppressive agents may prove to be even

more effective as immunologic suppressers in the treatment of this condition, but the infrequency of the disorder means that a large, multicenter trial is needed to collect definitive treatment information. Although the prognosis was once believed to be very poor for all patients with idiopathic pulmonary hemosiderosis, more recent data suggest that such may not be the case.[309]

Menstrual Blood Loss. Blood loss associated with menstruation predisposes women to iron deficiency. In a sample of healthy, menstruating, nonpregnant Danish women 18 to 30 years of age not receiving iron supplementation, serum ferritin levels correlated inversely with the duration and intensity of menstrual bleeding.[313] Menorrhagia or dysfunctional uterine bleeding may lead to frank iron deficiency anemia. In many cases, dysfunctional uterine bleeding is due to anovulation, a common phenomenon in pubertal females. Progestational agents or oral contraceptives may ameliorate the dysfunctional uterine bleeding or menorrhagia. If this approach does not resolve the abnormal bleeding, other causes such as pelvic abnormalities or disorders of hemostasis, particularly von Willebrand's disease, should be considered. Women with menorrhagia, especially menorrhagia present since menarche, have a high incidence of von Willebrand's disease (13%), which in the general population is 1% to 2%.[314,315]

Consequences of Iron Deficiency

Although anemia is the most prominent manifestation of iron deficiency, there may be other clinically significant sequelae of iron deficiency, even in the absence of anemia. Organ and tissue dysfunction, including impaired immunity, decreased muscle performance and neurocognitive function, and poor weight gain, may occur with iron deficiency. Significant inroads in understanding some of these effects, particularly cognitive dysfunction in young children, have been made in the past few years.

Neurocognitive Effects

The association between iron deficiency anemia and impaired neurocognitive function is well established, and this association holds even when potential confounders such as psychosocial and environmental factors are taken into account. Infants and toddlers, who are undergoing critical neurocognitive development, may be at particular risk for such effects.[316]

Iron deficiency that has not yet progressed to anemia is also associated with impaired mental and motor functioning.[317,318] For example, when tested with the Bayley Scale of Infant Development, nonanemic, iron-deficient infants had lower developmental scores than iron-sufficient infants did, and these abnormalities were detected in children as young as 9 to 12 months.[317] In addition, the degree of developmental deficits in infants may correlate with the level of iron deficiency.[319] Older populations of children, such as nonanemic iron-deficient preschoolers, have lower mental development

scores,[320] and school-age children and adolescents have lower math and verbal scores than their iron-sufficient peers do.[320-323]

In some investigations, dietary iron supplementation has reversed the cognitive dysfunction.[317,318,323] For example, in the study of 9- to 12-month-old infants cited earlier, iron replacement increased Mental Development Index scores substantially in only 7 days.[317] Numerous other studies, however, failed to show improvement in depressed performance.[319,324-326] Lozoff and colleagues have also demonstrated that these effects remain evident as long as 19 years later and that children of low socioeconomic status may be disproportionately affected.[327]

Iron deficiency may increase the risk for lead exposure through either pica or increased absorption. Concomitant lead toxicity can further hamper the psychological development of these children.[328] Information on the long-term effects of iron deficiency during infancy highlights the importance of early detection and intervention. Health care providers must therefore work actively to prevent and detect iron deficiency during infancy.

The mechanism by which iron deficiency impairs neurologic function is unknown. Iron deficiency could impair neurotransmitter mechanisms. It has been shown to decrease expression of dopamine receptors in the rat brain.[329] Iron deficiency may also interfere with myelination and alters myelin proteins and lipids in oligodendrocytes.[330] In addition, several enzymes in neural tissue require iron for normal function.[331] The cytochromes involved in energy production, for example, are predominantly heme proteins.

Pica. Pica, the compulsive consumption of nonnutritive substances, is a recurrent symptom in patients with iron deficiency. The precise pathophysiology of pica is unknown, but it is probably attributable to CNS iron deficiency. Patients often consume laundry starch, ice, soil, or clay. Both clay and starch can bind iron in the gastrointestinal tract and exacerbate the deficiency.[332,333] A dramatic example of the problems produced with clay consumption occurred in the 1950s in iron-deficient children along the border between Iran and Turkey.[334,335] These youngsters had other peculiar abnormalities, including massive hepatosplenomegaly, poor wound healing, and a bleeding diathesis. Presumably, the children initially had simple iron deficiency associated with pica, including geophagia. The soil contained compounds that bound both iron and zinc.[335] Secondary zinc deficiency was thought to cause the hepatomegaly and other unusual features.[334]

Epithelial Changes

Iron deficiency produces significant gastrointestinal tract abnormalities, reflecting the enormous proliferative capacity of this tissue. Angular stomatitis and glossitis with painful swelling of the tongue may develop. The flattened, atrophic, lingual papillae make the tongue

smooth and shiny. A rare complication of iron deficiency is the Plummer-Vinson syndrome with the formation of a postcricoid esophageal web. Long-standing, severe iron deficiency affects the cells that generate the fingernails and produces koilonychia, or spooning. The nail substance is soft, so ordinary pressure on the fingertips, as occurs with writing, for instance, produces a concave deformity. Most of these abnormalities are now uncommon in industrialized nations.

Iron Deficiency Anemia

On physical examination, pallor, tachycardia, splenomegaly and a systolic murmur may be appreciated. The microcytic, hypochromic anemia of iron deficiency impairs tissue oxygenation and produces the symptoms of pallor, weakness, fatigue, and lightheadedness. Thalassemia trait (see Chapter 20) also produces microcytic cells and is sometimes confused with iron deficiency. Iron deficiency alters red cell size unevenly. Electronic blood analyzers determine the mean red cell volume (MCV), as well as the range of variation in red cell size (expressed as the red cell distribution width [RDW]). RDW and the cell hemoglobin distribution width (both determined as part of electronically processed complete blood cell counts) are normal in patients with thalassemia trait but high in those with iron deficiency.[336] Other common features of thalassemia trait are basophilic stippling and target cells. These characteristics are not sufficiently distinctive to be diagnostically useful, however. A simple, reliable approach is to examine the color of plasma. It is watery in iron deficiency and straw colored in thalassemia trait.

The plasma membranes of iron-deficient red cells are abnormally stiff, and such cells are more prone to hemolysis.[337] This rigidity could contribute to poikilocytic changes, seen particularly with severe iron deficiency. Small, stiff, misshapen cells are cleared by the reticuloendothelial system, thereby further contributing to low-grade hemolysis. The cause of this alteration in membrane fluidity is unknown.

Thrombocytosis with platelet counts in the range of 500,000 to 700,000 cells/fL occurs frequently in iron-deficient patients. Megakaryocytes and normoblasts are derived from a common committed progenitor cell, the colony-forming unit–granulocyte, erythrocyte, macrophage, megakaryocyte (CFU-GEMM). Thrombopoietin, the molecule that stimulates the growth of megakaryocytes and the production of platelets, is homologous to erythropoietin (see Chapter 6). The high levels of erythropoietin produced by iron deficiency anemia conceivably could cross-react with megakaryocyte thrombopoietin receptors and modestly raise the platelet count. However, this hypothesis has not been proved experimentally.

Diagnosis of Iron Deficiency

Because they are inexpensive and widely available, hematologic markers are frequently used to assess iron status. A hemoglobin content less than the 5th percentile in a reference population is often used to define anemia.

Changes in erythrocyte parameters accompanying iron deficiency anemia include a decrease in MCV, reflecting microcytosis, and an increase in RDW, reflecting anisocytosis, as described earlier. Because these parameters represent averages of the entire red blood cell population, iron deficiency must be present for some time before it deviates from these measures.

The American Academy of Pediatrics and the U.S. Centers for Disease Control and Prevention recommend the use of hemoglobin to screen children at risk for iron deficiency. Because only the later stages of iron deficiency result in anemia, relying on hemoglobin (or hematocrit) to screen for iron deficiency misses many children who are, in fact, iron deficient and in whom adverse consequences, such as potentially irreversible neurocognitive impairment, may have already begun to occur. For example, based on NHANES data, a hemoglobin concentration of less than 11 g/dL has a sensitivity of 30% for detecting iron deficiency, as defined by ferritin, erythrocyte protoporphyrin, and transferrin saturation.[338] That adverse consequences of iron deficiency may occur in the absence of anemia highlights the importance of diagnostic approaches that detect iron deficiency early, without relying on hematologic indicators that are altered only after iron deficiency has progressed.

Biochemical parameters based on iron metabolism are often used to diagnose and in fact define iron deficiency. A low serum ferritin level is a very specific and early indicator of iron deficiency. Plasma iron concentrations fall as iron is depleted, but they are also affected by diurnal variation and dietary intake. The availability of plasma iron binding sites, or TIBC, increases as iron stores fall. Serum iron concentration divided by TIBC may be calculated to yield transferrin saturation, a measure of occupied binding sites on transferrin. These biochemical tests may be altered by physiologic states unrelated to iron stores. For example, ferritin, serum iron, and TIBC are acute phase reactants. In the setting of inflammation, ferritin, a positive acute phase reactant, may overestimate iron stores. Ferritin has in fact been shown to be a poor indicator of iron deficiency in the pediatric population.[272]

Because of the limitations of both hematologic and biochemical tests, novel methods of diagnosing iron deficiency have been sought. sTfR is a truncated form of the receptor that is cleaved from reticulocytes and erythroid cells and circulates in plasma largely attached to transferrin. sTfR is upregulated in iron deficiency. Though not uniformly available in all clinical laboratories, it may be an important adjunct in diagnosing iron deficiency,[339,340] particularly insofar as it may help distinguish iron deficiency anemia from the anemia of inflammation.[341]

CHr is another test available only in selected laboratories because it is unique to instruments manufactured by Bayer (Tarrytown, NY). CHr was recently evaluated prospectively as a means of routinely screening infants and toddlers.[273] In this setting a CHr cutoff of 27.5 pg had 83% sensitivity and 72% specificity, whereas a hemo-

globin concentration of less than 11 g/dL was a poor predictor of iron deficiency, with only 26% sensitivity. CHr has also been used to accurately assess the iron status of potential adult blood donors.[342]

Treatment of Iron Deficiency

The most important steps in the evaluation and treatment of iron deficiency are determining the cause and correcting the abnormality. Malignancy of the gastrointestinal tract, the most worrisome etiology in adults with iron deficiency, is vanishingly rare in children. Growth spurts, poor dietary patterns, menstrual losses, and benign gastrointestinal bleeding are much more common. After initial diagnostic investigations, oral iron supplementation usually replaces stores most efficiently.

Oral Supplementation

Iron salts offer inexpensive, effective therapy for iron deficiency. Although ferrous sulfate is most often recommended, patients frequently complain of gastrointestinal discomfort, constipation, and bloating, as well as stool discoloration, thus making its use unacceptable to many. Interestingly, in a randomized, controlled trial comparing 3 mg/kg/day of ferrous sulfate drops with placebo in 278, 12-month-old infants, there was no difference in the frequency of vomiting, diarrhea, or fussiness, and infants in the placebo group had a higher incidence of constipation (95% versus 1%).[343] Iron is frequently provided to children at a dose of 3 mg/kg/day divided into three-times-a-day dosing. Single-dose daily regimens, however, are tolerated as well as three-times-a-day regimens.[344] Administration of iron on an empty stomach at night will lessen the gastrointestinal difficulties. The decreased gastrointestinal motility of sleep will also enhance absorption.

The absorptive capacity of the normal duodenum for iron is essentially saturated with about 25 mg of elemental iron in ionic form. Ferrous gluconate, which is roughly equivalent in cost, contains about 50 mg of elemental iron per tablet. This form of replacement may produce fewer problems than ferrous sulfate and is excellent as the initial treatment of iron deficiency. Ascorbic acid supplementation enhances iron absorption, although it has a relatively minor effect in individuals ingesting normal, balanced diets.[345] Combination tablets containing iron salts and ascorbic acid are significantly more expensive than separate tablets for each. Even with faithful use of oral iron, adequate replacement of body stores in patients with moderate iron deficiency anemia requires several months. With ongoing blood loss, replacement of stores with oral iron becomes very difficult.

Polysaccharide/iron complexes differ from iron salts. Polar oxygen groups in the sugars form coordination complexes with iron atoms. The well-hydrated microspheres of polysaccharide iron remain in solution over a wide range of pH values. Most patients tolerate this form of iron better than the iron salts, even though the 150 mg of elemental iron per tablet is substantially greater than that provided by iron salts.

Iron supplements must be stored in a childproof manner. Unintentional iron poisoning from iron supplements is a leading cause of poisoning-related injury in young children and frequently occurs when children obtain improperly stored iron.[346]

Box 12-3 lists potential causes of a poor response to oral iron supplementation. A variety of barriers, including treatment-associated factors and system-wide barriers, contribute to the shortcomings in iron deficiency screening and correction that have been documented.[347]

Parenteral Iron Replacement

Parenteral iron is now available in the United States in three intravenous forms: iron dextran, iron gluconate, and iron sucrose.[348-351] This medication is indicated when (1) oral iron is poorly tolerated; (2) rapid replacement of iron stores is needed; (3) gastrointestinal iron absorption is compromised; or (4) erythropoietin therapy is necessary, particularly in renal dialysis patients. Iron dextran can also be administered by intramuscular injection, but this route is discouraged because it can be painful and leakage into subcutaneous tissue produces long-standing skin discoloration. A "Z-track" injection into the muscle minimizes the chance of subcutaneous leakage. The suboptimal muscle mass frequently associated with nutritional deficiency further complicates this mode of replacement. Intravenous infusion circumvents these problems altogether. With either route of administration, a small test dose should be given and the patient observed by a physician for 30 minutes to rule out an anaphylactic reaction to the medication. Such reactions do occur but are infrequent. The newer iron sucrose and iron gluconate preparations are believed to be less likely to cause complications, but there is less accumulated experience with these preparations, and many practitioners still use iron dextran routinely.

Box 12-3	Reasons for Poor Response to Oral Iron

Noncompliance
Ongoing blood loss
Insufficient duration of therapy
High gastric pH
   Antacids
   Histamine H_2 blockers
   Gastric proton pump inhibitors
Inhibitors of iron absorption/utilization
   Lead
   Aluminum intoxication (hemodialysis patients)
   Chronic inflammation
   Neoplasia
Incorrect diagnosis
   Thalassemia disorder
   Sideroblastic anemia
   Anemia of chronic inflammation

Ten percent to 15% of patients experience transient mild to moderate arthralgias the day after intramuscular or intravenous administration of iron dextran. Acetaminophen usually relieves the discomfort effectively. Iron dextran is generally avoided in patients with rheumatoid arthritis because it may provoke painful flares of their disease.[12] The symptoms may result from release of inflammatory cytokines such as interleukin-1 and tumor necrosis factor. Iron dextran is cleared from the circulation by macrophages, which are probably activated to release proinflammatory peptides.

In uncomplicated cases of iron deficiency, intravenous replacement may produce subjective improvement in symptoms within a few days. Peak reticulocytosis occurs after about 10 days, and complete correction of the anemia takes 4 to 6 weeks, although the hematocrit rises sufficiently in 1 or 2 weeks to provide symptomatic relief for most patients.[345] CHr is a very sensitive measure of response.[352] Brugnara and colleagues have demonstrated that a rise in CHr is appreciated within 2 to 4 days of the administration of intravenous iron.[352]

Refractory bleeding that cannot be prevented, as occurs, for example, with hereditary hemorrhagic telangiectasia, presents a management problem. Oral iron supplementation often fails to keep pace with losses. Blood transfusions replace red cells in the short term and iron in the long term, but infection and alloimmunization make such therapy unacceptable for many patients. Intermittent iron replacement with infusions of intravenous iron is the most reasonable alternative. Replacements should occur over short intervals two or three times a year, with the aim of repleting body stores. A simple formula can be used to determine the replacement dose of iron dextran:

$$\text{Dose (mL)} = 0.0442 \times (\text{Desired Hb} - \text{Observed Hb}) \times \text{Lean body weight} + (0.26 \times \text{Lean body weight})$$

Alternatively, there is a calculator provided on the Internet at http://www.infed.com/calcltor.htm. The maximum adult dose of iron dextran is 14 mL.

Over many years this treatment can produce massive deposition of hemosiderin (from iron dextran) in macrophages, the liver, and the pancreas despite the fact that plasma transferrin is iron deficient because of increased iron delivery to erythroid precursors. This supports the concept that tissue iron content is unimportant for erythropoiesis and that erythropoiesis relies exclusively on iron from transferrin.[99,142]

Iron Replacement in Infants

Because the fetus accumulates iron at the mother's expense in the third trimester of pregnancy, full-term infants are born with adequate iron stores to last approximately 6 months. Preterm infants are at greater risk for iron deficiency, with their stores depleted by 3 to 4 months of age.

Human breast milk initially contains relatively high amounts of iron, but the level decreases, independent of maternal iron status, to approximately 0.3 mg/L after 5 months of lactation (reviewed by Griffin and Abrams[353]). The iron is present in several forms: in casein, in whey, in fat, and to a small extent, in the abundant protein lactoferrin. The rate of absorption of iron from human milk has been estimated to be 20% to 50%, which is adequate early in life when iron stores are still high but inadequate to meet an older infant's needs. Based on all available information, the Committee on Nutrition of the American Academy of Pediatrics has recommended the following[278]:

1. Breast milk should be provided for at least 5 to 6 months when feasible. During that period, young infants can mobilize iron from their large stores. Iron supplementation of 1 mg/kg/day should be provided to infants who are exclusively fed breast milk beyond 6 months of age.
2. Infants who are not breast-fed should be nourished with an iron-supplemented formula (at least 12 mg/L) until the end of the first year of life.
3. Iron-enriched cereals should be among the first foods introduced with a solid diet.
4. Cow's milk should be avoided during the first year because it contains substances that chelate iron and it sometimes induces occult gastrointestinal hemorrhage in young infants.

Maternal Iron Stores and Effects on the Fetus

When the mother is iron deficient, the placenta is concerned only with the welfare of the fetus and will continue to remove iron from the mother to support fetal development, even at the cost of negative maternal iron balance. For years, investigators debated the effect of maternal iron deficiency on the fetus. Early findings by Cook and colleagues indicated that the iron storage status of the mother does not affect the infant's iron status as measured by ferritin.[354] The controversy was fueled by the indirect and imprecise assays of neonatal iron status, such as the cord blood ferritin level or transferrin saturation. These parameters in cord blood are subject to all the vicissitudes that affect their values in later life. Accurate determination of neonatal iron status was difficult, if not impossible. The one point on which nearly universal agreement existed was that neonatal anemia secondary to maternal iron deficiency is rare.

It is likely that in fact maternal iron status over a wide range of values does affect the iron stores of the neonate. The most compelling data have come from a study of women who underwent elective abortions.[355,356] The iron status of the mothers was determined from transferrin saturation, plasma ferritin levels, and hemoglobin values. This information was correlated with the iron status of the fetuses, which was determined by atomic absorption spectroscopy of the complete abortus. This procedure determined the absolute fetal iron content. Fetal iron stores varied linearly with maternal hemoglobin, which

ranged between 6 g/dL (severe iron deficiency) and 13 g/dL (adequate, though possibly low iron stores).

Fetal iron stores, in turn, may influence neonatal outcomes. Maternal iron deficiency before midpregnancy is associated with an increased risk for preterm delivery. Maternal anemia detected during the last trimester of pregnancy is not associated with an increase risk for preterm birth. This anemia probably reflects the expansion of maternal plasma volume rather than actual maternal iron stores.

Neonatal iron stores are also influenced by other maternal factors apart from iron stores. Maternal diabetes is associated with decreased fetal stores, as evidenced by lower cord blood ferritin and an increased demand for iron reflected by higher soluble transferrin receptor levels.[357] This may be due to neonatal polycythemia and increased erythropoietic drive associated with maternal diabetes. Similarly, maternal smoking is also associated with increased cord hemoglobin and decreased iron stores.[358]

The infant's gestational age is related to the development of adequate iron stores, as described earlier. The timing of umbilical cord clamping at birth may also affect neonatal iron stores. A randomized, controlled trial of delayed clamping (2 minutes after delivery) versus usual clamping found that infants in the delayed umbilical cord clamping group had higher ferritin and total body iron stores at 6 months of age.[359] The effect of delayed clamping was particularly pronounced in infants otherwise at risk for iron deficiency, such as those not receiving iron-fortified milk or formula, mothers with low ferritin levels at birth, and lower-birth-weight infants.

Iron supplementation of gravidas during the first 28 weeks is associated with higher mean birth weight and a lower incidence of low-birth-weight infants, but not maternal anemia or higher preterm delivery rates.[360] Consequently, at this time there is insufficient evidence to support or reject the routine practice of prophylactic iron supplementation during pregnancy as opposed to supplementing iron-deficient gravidas or pregnant women at risk for iron deficiency.

Iron Overload

The Evolutionary Advantage of Iron Overload

The fact that multiple mutations in diverse populations all lead to iron overload (see later) raises the possibility that these conditions once conferred a selective advantage. As previously noted, iron deficiency is the most common nutritional cause of anemia in the world. Anemia was probably a selective disadvantage earlier in human history. A genetic change that increased the efficiency of iron absorption may therefore have been an advantage. A person who survived into the third decade would have reproduced and passed genes to the next generation, including those that increase iron absorption. Survival into the fifth decade, when severe iron overload begins

to produce problems, was uncommon until recently. However, a problem develops with this tidy theory when the inhabitants of Asia are considered. The incidence of iron overload is reportedly quite low in this region of the world, the home of most of the Earth's population.

Hereditary Hemochromatosis

Hereditary hemochromatosis is a condition that originates from a genetic predisposition to iron overload as a result of mutations in one of several genes involved in iron metabolism (see later). It is caused by an alteration in the iron absorption mechanism that fractionally increases the uptake of dietary iron.[361,362] Although the rate and extent of iron loading vary widely among patients, dangerous levels of tissue iron develop in many people by middle age. Iron deposits in cells of the liver, heart, endocrine tissues, and skin. It promotes oxidative cell damage, which leads to fibrosis and, when unrecognized, to the classic manifestations of "bronze diabetes," including liver dysfunction, increased melanization of the epidermis, and pancreatic insufficiency.[363] Because erythropoiesis is normal, iron can be removed through phlebotomies performed regularly. If untreated, hemochromatosis may be a lethal disease and result in death from cirrhotic liver failure or, less often, from cardiomyopathy.

Pediatricians are often asked to evaluate children who have close relatives with hemochromatosis. This is a complicated task because iron loading occurs gradually over a period of many years and may not be apparent before adulthood. Although the genes responsible for most forms of hemochromatosis have been identified, at this time commercial laboratories test for only one form of the disease. However, this situation is likely to change over the next few years and simplify presymptomatic diagnosis. Until then, assessment should take into account the family history, serum transferrin saturation, serum ferritin levels, and if indicated, quantitative liver iron determined by analysis of a biopsy sample (Fig. 12-6).

In the United States, Canada, Australia, and the northwestern part of Europe, most patients with hemochromatosis are homozygous for a unique missense mutation designated C282Y (for cysteine 282 to tyrosine) in the gene encoding HFE, a protein that resembles class I major histocompatibility (MHC) molecules.[364] The HFE gene lies on chromosome 6p, near the HLA-A locus. It was discovered through a positional cloning approach that took advantage of the fact that patients with the C282Y mutation are descended from a common ancestor who probably lived in a Celtic population in the British Isles 60 to 70 generations ago.[365]

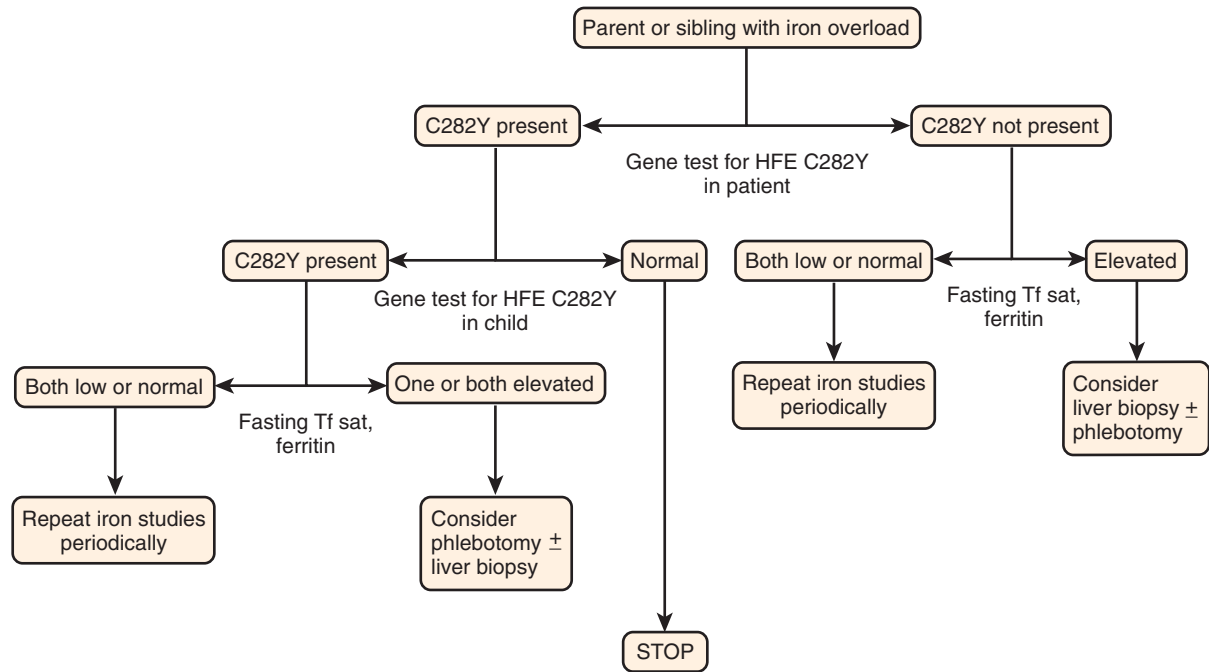
Like class I MHC proteins, HFE forms a heterodimer with β_2-microglobulin and is expressed on the cell surface. However, unlike other family members, HFE cannot bind a small peptide. Its structure, as determined by x-ray crystallography, does not allow enough space within the groove that is involved in peptide binding by MHC class I molecules.[366] Some insight into the function of HFE was gained from observations that it forms a


FIGURE 12-6. Algorithm for the workup of children at risk for iron overload. *(Adapted with permission from Andrews NC. Inherited iron overload disorders. Curr Opin Pediatr. 2000;12:596-602.)*

high-affinity complex with the transferrin receptor.[366] HFE binds to a site that overlaps the binding site for ferric transferrin, which results in competition between HFE and transferrin for occupancy of the transferrin receptor.[367] Studies in transfected cells overexpressing HFE indicate that the HFE-transferrin receptor association alters cellular iron uptake. However, the effect of HFE on iron homeostasis is not directly attributable to its effect on cellular iron uptake. As discussed later, we now know that HFE and several other forms of hemochromatosis result from aberrant expression of the iron regulatory hormone hepcidin.

In patients with HFE hemochromatosis, serum transferrin becomes saturated with iron before clinical signs appear. The increased serum iron is deposited in parenchymal cells of the liver, heart, pancreas, and other tissues. In knockout mice lacking murine Hfe, an iron overload disorder develops that closely resembles human hemochromatosis.[368,369] The mutant allele for HLA-linked hemochromatosis is prevalent in the United States. Studying a cross section of the American population, Steinberg and colleagues found that 9.5% of non-Hispanic whites, 2% of non-Hispanic blacks, and approximately 5% of the population overall were C282Y carriers.[370] Testing for the HFE C282Y mutation allows identification of patients in whom clinical hemochromatosis may develop. Heterozygotes rarely have clinically significant iron overload, but homozygotes are at risk. Published data give conflicting estimates of the proportion of patients homozygous for C282Y in whom complications of the disease will develop; such estimates range from less than 1% to greater than 20%. It is clear, however, that some individuals have severe iron loading as young adults whereas others may never manifest signs

or symptoms of hemochromatosis. There must be both environmental and genetic modifiers that affect the extent of iron loading. Current efforts are aimed at defining these modifiers to aid in predicting in which genetically at-risk individuals clinically significant iron overload will develop.

Other polymorphisms and potential mutations have been described in the HFE coding sequence. One of these polymorphisms, H63D (histidine 63 to aspartic acid) is prevalent throughout the world and found in as many as a quarter of asymptomatic patients. Although clinical laboratories currently test for and report the H63D polymorphism, most patients with one or two copies of the H63D allele are probably not at risk for iron loading. Other polymorphisms associated with altered amino acids or altered mRNA splicing have also been reported (reviewed by Camaschella and co-workers[371]). Some of these polymorphisms do appear to be associated with iron overload, but most clinical laboratories do not look exhaustively for them.

Since the identification of HFE, it has become clear that there are at least four other types of hemochromatosis. A disorder that may be clinically indistinguishable from HFE-associated hemochromatosis results from homozygosity for mutations in the gene encoding transferrin receptor 2 (TFR2).[372] TFR2 is highly homologous to the transferrin receptor, particularly in its extracellular domain, but it binds transferrin with much lower affinity.[373,374] It is primarily expressed in the liver and in erythroid cells. Its function remains incompletely understood, as does the reason why loss of the protein results in iron overload. Similar to the transferrin receptor, TFR2 forms a protein complex with HFE, which is believed to be involved in regulation of hepcidin expression.[375]

Two other types of hemochromatosis are easier to distinguish from HFE-associated hemochromatosis. Juvenile hemochromatosis, also called type 2 hemochromatosis, is a more severe disorder with accelerated iron loading that typically leads to death by the third decade.[376] Patients have iron deposition in the same pattern as that seen in those with HFE-associated hemochromatosis, but the rapid accumulation of metal leads to a different clinical picture dominated by cardiac disease and endocrine dysfunction. Patients are often identified when they fail to enter puberty. If these patients are recognized before end-stage organ disease develops, they can be treated by aggressive phlebotomy. Juvenile hemochromatosis is inherited in an autosomal recessive pattern and is caused by mutations in *HAMP*, the gene encoding hepcidin,[377] or in an unrelated gene encoding hemojuvelin (*HJV*, also called *HFE2*, *RGMC*).[378] Hemojuvelin is a cell surface protein that acts as a bone morphogenetic protein (BMP) coreceptor to stimulate hepcidin expression, presumably in response to as yet unidentified BMP signals.[379] Targeted disruption of the murine hemojuvelin gene results in a phenotype very similar to human juvenile hemochromatosis, with a near absence of hepcidin mRNA expression.[380,381]

Although all of the forms of hemochromatosis discussed thus far (caused by mutations in *HFE*, *TFR2*, *HAMP*, and *HJV*) are associated with inappropriately low hepcidin production, there is one hemochromatosis disorder that is not. A subset of patients carrying mutations in *SLC40A1*, the gene encoding ferroportin, have autosomal dominant hemochromatosis that is similar to other forms of the disease.[382-384] Apparently, these mutations render ferroportin resistant to hepcidin regulation. A second class of ferroportin mutations cause a distinct autosomal recessive disorder characterized by macrophage iron loading, an early rise in serum ferritin levels, comparatively less saturation of transferrin with iron, and no major increase in total body iron stores.[247,385,386] Both forms of "ferroportin disease" are autosomal dominant because functional ferroportin exists in cells as a multimer and mutation of one subunit is deleterious for transport function.[387]

African Iron Overload Syndrome

During the 1960s, several groups of investigators reported that iron overload occurred at a very high rate among sub-Saharan Africans.[388-391] Many patients had massive iron stores approaching or exceeding those seen in individuals with hemochromatosis. Some indigenous inhabitants of the region prepared alcoholic beverages in nongalvanized steel drums, thus raising the possibility that iron overload resulted from the high iron content of these beverages. Iron loading was thought to be exacerbated by an increase in gastrointestinal iron absorption induced by alcohol. The term *Bantu siderosis* was coined to describe the condition.[391]

Later reports suggested that African iron overload was not simply the result of increased intake.[392-394] In only a fraction of the group who drank the beverage did iron overload develop. In fact, a more extensive study showed that similar degrees of iron overload occurred in people who consumed little, if any of this brew. Although the pattern of inheritance has not been definitively worked out, the disorder may be autosomal codominant, with obligate heterozygotes expressing an intermediate level of iron loading. African iron overload is not associated with HFE mutations.[395]

Intriguingly, African iron overload syndrome most closely resembles nonhemochromatosis ferroportin disease in the cellular distribution of iron. In contrast to other forms of hereditary hemochromatosis, in which the iron is almost entirely confined to parenchymal cells, reticuloendothelial macrophages display massive iron deposition in the African variety of iron overload.[388] A common missense mutation in ferroportin, Q248H, has been implicated as a possible genetic factor.[396,397] However, the ultimate clinical consequences of iron overload are similar to those seen in all other forms of hemochromatosis, irrespective of the cause of the accumulation. African iron overload syndrome is not confined to any ethnic group, although it appears to be restricted to the inhabitants of sub-Saharan Africa. In some areas, the incidence may be as high as 10%, which makes it one of the most common, clinically significant iron disorders in any population.

An important, unanswered question is whether mutated genes causing this syndrome are found in people of African descent elsewhere in the world. No comprehensive study of iron overload has been performed in African Americans, but preliminary data suggest that a substantial portion of this population may be at risk.[398,399] There has not yet been an exhaustive examination of hemochromatosis disease genes in this group.

Neonatal Hemochromatosis

Neonatal hemochromatosis (NH) is a rare condition characterized by neonatal liver failure associated with systemic iron overload, parenchymal iron deposition, thrombocytopenia, and coagulopathy in the absence of evidence of any known causative agent or condition, including Down syndrome, metabolic liver disease (e.g., tyrosinemia, galactosemia), congenital infection (e.g., herpesviruses), or congenital anemia (e.g., α-thalassemia, hydrops fetalis secondary to ABO/Rh incompatibility) (reviewed elsewhere[400-403]). In addition to fetal diseases, NH has been associated with maternal autoimmune disorders, including lupus erythematosus and Sjögren's syndrome. Although iron chelation and antioxidant cocktails have been studied and occasionally have led to some clinical improvement, the outcome in NH is nearly always fatal in the absence of prompt hepatic transplantation.[404-406] The rare individuals who have survived without transplantation have recovered full organ function,[407,408] and the disease usually does not recur in those who have undergone transplantation successfully, thus suggesting

that the hepatic insult is developmental or transient in nature.

Mutations in several of the "adult" hemochromatosis genes have not been identified in NH patients, and there is substantial evidence of a nonmendelian or otherwise unconventional hereditary predisposition to NH.[401,402,409] Specifically, the possibility of mitochondrial inheritance or inheritance of a maternally imprinted gene has been raised by the discovery of several kindreds in which women have borne affected children fathered by different men. However, neither of these types of inheritance can account for the tendency for a mother's first pregnancy to be spared of or mildly affected by the disorder whereas subsequent pregnancies have a greater than 50% risk for the development of clinically overt NH. These latter observations, in particular, have spawned the current leading hypothesis that NH is the consequence of prenatal alloimmune liver injury.[410,411] In this model, which parallels the paradigm of neonatal alloimmune thrombocytopenia (see Chapter 33), the mother is sensitized to a fetal antigen during a first pregnancy and subsequent pregnancies provoke an amnestic immune response that results in a severe clinical phenotype. What the antigen might be or how it perturbs iron metabolism is unknown. Nonetheless, a recent clinical trial demonstrated that clinically significant liver disease can be avoided in the vast majority of at-risk fetuses by treating the expectant mother with intravenous immunoglobulin beginning in the early second trimester of gestation, thus further substantiating the alloimmune hypothesis.[412]

Iron Overload Caused by Erythroid Hyperplasia and Ineffective Erythropoiesis

The connection between hematopoiesis and iron absorption is most strikingly apparent in patients with ineffective erythropoiesis. With disorders such as β^+-thalassemia (thalassemia intermedia) and X-linked sideroblastic anemia, the fractional absorption of ingested iron is increased. Patients with these disorders can manifest iron overload without transfusion.[413]

The mechanism by which bone marrow activity modulates gastrointestinal iron absorption is only partially understood. A soluble factor appears to be released that depresses hepcidin production.[414] Recently, it was reported that GDF15, a member of the transforming growth factor β superfamily, is induced in patients with thalassemia and that GDF15 suppresses expression of hepcidin by human hepatocytes.[415] It is not yet clear, however, whether this is the major or the only factor contributing to the "erythroid regulator."

In humans, depressed hepcidin levels and, consequently, robust absorption of iron from the gastrointestinal tract are associated most often with ineffective erythropoiesis.[56] Some patients with pyruvate kinase deficiency, a condition frequently associated with reticulocyte counts as high as 70%, manifest iron overload without transfusion. Hemolytic anemias with effective erythropoiesis rarely lead to iron loading. Without some

compounding variable, such as hereditary hemochromatosis trait, iron loading without transfusion is not generally seen with conditions such as sickle cell anemia or hereditary spherocytosis, in which the erythroid cells mature and leave the bone marrow before they are destroyed.

Consequences of Iron Overload

The effects of iron overload on some organs, such as the skin, are trivial, whereas hemosiderotic harm to other organs, such as the liver, can be fatal. Few notable symptoms precede advanced injury. Abdominal discomfort, lethargy, depression, arthralgias, erectile dysfunction, and fatigue are common but nonspecific complaints. Dyspnea with exertion and peripheral edema indicate significant cardiac compromise and reflect advanced iron loading.

As the major site of iron storage, the liver is a conspicuous target for excessive iron deposition. Mild to moderate hepatomegaly develops early, followed by shrinkage produced by fibrosis and micronodular cirrhosis. Hepatic tenderness may be present, but hemosiderotic liver damage produces little inflammation. Consequently, significant hepatic iron deposition and even fibrosis can occur with very little increase in serum transaminase levels. Disturbances in liver synthetic function indicate advanced disease. Liver biopsy is still the "gold standard" for determining the extent of hepatic iron deposition, although noninvasive imaging techniques do have a role. Hematoxylin-eosin staining reveals a brownish pigment in the hepatocytes that staining with Perls Prussian blue unmasks as iron. Large amounts of iron are also deposited in Kupffer cells in patients with ferroportin disease, African iron overload syndrome, or transfusional iron overload. Electron microscopy reveals substantial hemosiderin aggregates in addition to large quantities of ferritin.

Congestive cardiomyopathy is the most common heart problem that occurs with iron overload, but other abnormalities have been described, including pericarditis, restrictive cardiomyopathy, and angina without coronary artery disease.[416-419] There is strong correlation between the cumulative number of blood transfusions and functional cardiac derangements in children with thalassemia.[420] Findings on physical examination are surprisingly benign, even in patients with heavy cardiac iron deposition. Once evidence of cardiac failure appears, however, heart function deteriorates rapidly, and medical intervention is frequently ineffective. Biventricular failure produces pulmonary congestion, peripheral edema, and hepatic engorgement. These potentially lethal cardiac complications have, in some cases, been reversed by vigorous iron extrication.[421]

Iron deposition in the bundle of His and the Purkinje system can lead to conduction defects.[422,423] Sudden death is common in these patients, presumably as a result of arrhythmias. At one time, patients treated with the chelator deferoxamine for transfusional iron overload

received supplements of ascorbic acid in the range of 15 to 30 mg/kg/day to promote iron mobilization. Reports of sudden death prompted cessation of this practice.[424] Given carefully at lower doses (2 to 4 mg/kg) by an experienced practitioner, ascorbic acid is a safe adjunct to chelation therapy in patients with transfusional iron overload.

Cardiac dysfunction can also occur with very little tissue iron deposition. The total quantity of iron is less important than the unbound, or "toxic," iron fraction in the circulation. The concentration of unbound iron in tissues is extremely low and virtually impossible to measure. This toxic iron is precisely the component that is bound and neutralized by iron chelators. Therefore, cardiac damage is best prevented in patients with transfusional iron overload by maintaining a constant, low level of chelator in the circulation (and consequently in the tissues where the protection is rendered).

Dysfunction of the endocrine pancreas is common in patients with iron overload.[425,426] Overt diabetes mellitus requiring insulin therapy develops in some patients. The disturbances in carbohydrate metabolism may be more subtle, however. An oral glucose tolerance test often unmasks abnormal insulin production. Vigorous removal of excess iron may reverse the islet cell dysfunction.[427] Exocrine pancreatic function, in contrast, is usually well preserved.

Pituitary dysfunction may produce several endocrine disturbances.[428] Reduced gonadotropin levels are common. When coupled with primary reductions in gonadal synthesis of sex steroids, sexual maturation is delayed in children with transfusional iron overload.[429] Secondary infertility is common. Although Addison's syndrome is uncommon with iron overload, production of adrenocorticotropic hormone is occasionally deficient. A metapyrone stimulation test shows delayed or diminished pituitary secretion of this hormone.[430] Thyroid function is usually well preserved in patients with iron overload. In contrast, parathyroid activity is frequently compromised. Functional hypoparathyroidism can be demonstrated in many patients by inducing hypocalcemia with an intravenous bolus of ethylenediaminetetraacetic acid (EDTA) while monitoring the production of parathyroid hormone.[431]

Hyperpigmentation is a nonspecific skin response to a variety of insults, including excessive exposure to ultraviolet light, thermal injury, and drug eruptions. Cutaneous iron deposition damages the skin and enhances melanin production by melanocytes. Ultraviolet light exposure and iron are often synergistic in the induction of skin pigmentation, and consequently, many patients with siderosis tan very readily. Fair-skinned people who tan poorly may never exhibit hyperpigmentation despite very large body iron burdens. In contrast, a striking, almond-colored hue frequently develops in patients with moderate baseline pigmentation. With a particularly heavy iron overload, visible iron deposits sometimes appear in the skin as a grayish discoloration.

Arthropathy is a common problem in patients with hereditary hemochromatosis but rare in patients with secondary iron overload.[432,433] Patients with hemochromatosis typically exhibit involvement of small joints, particularly in the hands, but large joints, such as the hip, may also be involved. Chondrocalcinosis is a late but characteristic feature of the arthropathy seen in hereditary hemochromatosis. Other troubling musculoskeletal problems include severe, recurrent cramps and disabling myalgias. Muscle biopsy shows iron deposits in myocytes, but the pathophysiologic connection to the pain and cramps is unclear.

Iron Overload and Opportunistic Infections

Withholding iron from potential pathogens is believed to be a natural part of the host defense repertoire.[434] Because transferrin binds iron with extremely high affinity and two thirds of the iron binding sites of the protein are normally unoccupied, there is very little free iron available in plasma and extracellular fluids. Not surprisingly, both transferrin and its homologue lactoferrin are bacteriostatic in vitro for many bacteria.[435-437] However, the very high transferrin saturations attained in patients with iron overload compromise the bacteriostatic properties of the proteins, and transferrin can serve as a source of iron for some microorganisms.[438] Various infections with unusual organisms have been reported in patients with iron overload (Box 12-4).[439-442] Host defense is compromised even further in patients with sideroblastic anemia and secondary iron overload because of abnormal neutrophil function. Although aggressive antimicrobial therapy is often successful, some infections, such as the mucormycosis produced by *Rhizopus oryzae*, are usually fatal.

Acute Iron Poisoning

Acute iron poisoning from the accidental ingestion of large doses of medicinal iron is a medical emergency. Significant gastrointestinal symptoms occur with doses as low as 20 mg/kg of elemental iron, and systemic toxicity becomes evident with ingestions of 60 mg/kg (reviewed by McGuigan[443]). Treatment consists of removing as

much residual iron as possible from the gastrointestinal tract and administering intravenous deferoxamine, which chelates the toxic non–transferrin-bound iron.[443,444] It is appropriate to consult a toxicologist or poison center for assistance.

DISORDERS OF IRON UTILIZATION

Anemia of Chronic Inflammation

The anemia of chronic inflammation, also called the anemia of chronic disease, is a well-recognized condition associated with a broad spectrum of maladies. It was elegantly described in a classic review by Cartwright almost half a century ago.[445] Typically a mild to moderate, normochromic and normocytic anemia, the RDW is slightly elevated as a result of a mild anisocytosis. This is often the only hint on the blood smear that the anemia is due to insufficient iron available for erythropoiesis. Serum iron and serum transferrin levels are usually low. Serum ferritin levels are generally increased but may not be when coexistent with iron deficiency. Similarly, sTfR levels are normal unless iron deficiency accompanies the disorder. Not surprisingly, the diagnosis of anemia of chronic inflammation may be challenging to make. Inflammation is the key to the condition.

Bone marrow examination with Perls Prussian blue stain usually reveals deposits of iron in the reticuloendothelial cells. This characteristic feature of the anemia of chronic inflammation reflects ineffective iron recycling. Normoblasts that fail to mature properly and effete erythrocytes are engulfed by reticuloendothelial macrophages in the marrow, liver, and spleen. The phagocytes degrade the protein and lipid and recycle the iron from hemoglobin onto transferrin for reuse. The anemia of chronic inflammation disturbs this cycle, with iron left trapped in the reticuloendothelial cells.

Much has been learned about the pathogenesis of the anemia of chronic inflammation over the past few years. Initially, studies of patients with an unusual metabolic disorder complicated by anemia and hepatic adenomas provided a clue that increased hepcidin expression might account for both the reticuloendothelial block and the decreased intestinal iron absorption characteristic of the anemia of inflammation.[44] Subsequent investigations confirmed that hepcidin expression was elevated in patients with inflammation associated with a variety of infectious and noninfectious conditions.[42,446] Hepcidin production is induced by the inflammatory cytokine interleukin-6 through a direct effect on the hepcidin promoter.[45-47,447]

Patients with the anemia of chronic inflammation may have unusually low plasma erythropoietin levels for their degree of anemia.[448] This finding was previously attributed to proinflammatory cytokines, which were shown to suppress production of erythropoietin by cells in culture.[449] However, erythropoietin responsiveness is also suppressed in an animal model of anemia of inflammation developed by transgenic expression of hepcidin in noninflamed animals.[450] In addition, hepcidin has been reported to have a direct effect on erythroid colony formation in vitro.[451] Taken together, these findings suggest that induction of hepcidin in response to inflammation results in most, if not all of the characteristic features of the anemia of inflammation.

Control of the inflammation (e.g., by colectomy in patients with ulcerative colitis) usually eliminates the anemia and corrects the disturbances in iron metabolism. In general, the anemia is recalcitrant when the inflammation is uncontrolled. However, it is likely that new treatment strategies will be developed that take advantage of our current understanding of the pathogenesis of the anemia of inflammation and regulation of hepcidin production.

SIDEROBLASTIC ANEMIAS

The sideroblastic anemias are a heterogeneous group of congenital and acquired bone marrow disorders defined by the presence of pathologic iron deposits within the mitochondria of erythroid precursors. On Prussian blue or Perls iron-stained bone marrow aspirate smears or biopsies, these iron-encrusted mitochondria appear as coarse granules that typically form a halo or "ring" around the nucleus, thus giving rise to the term "ringed sideroblast," which is, by definition, an abnormal cell[452] (Fig. 12-7). Mitochondrial localization of the iron deposits can be confirmed by electron microscopy, but it is not used routinely for diagnostic purposes. A recent report suggests that the iron deposits may contain a mitochondrial ferritin molecule encoded by a nuclear gene that is distinct from those encoding H- and L-ferritin polypeptides.[189,190]

Up to 30% to 40% of the erythroid precursors in normal, iron-replete bone marrow contain several fine, more peripherally placed iron deposits that represent iron
FIGURE 12-7. Prussian blue stain of a bone marrow aspirate from a patient with sideroblastic anemia. The granules that circle the nucleus of the normoblasts are iron-laden mitochondria.

in cytosolic ferritin. Such cells are termed "sideroblasts" and are absent or decreased in iron deficiency or the anemia of inflammation. "Siderocytes" are mature, enucleated peripheral blood erythrocytes that contain stainable iron, which may be the consequence of residual mitochondria from ringed sideroblasts or cellular ferritin, organelle, and nucleic acid concretions left over from terminal erythroid maturation.[452] Both are recognized as "Pappenheimer bodies" on conventional Wright-Giemsa–stained peripheral blood smears and are abundant in patients with sideroblastic anemia and a number of other anemias, including thalassemia syndromes and hemoglobinopathies.

In addition to the obligatory ringed sideroblasts, the bone marrow in patients with sideroblastic anemia is typically hypercellular with erythroid hyperplasia. Ineffective erythropoiesis frequently eventuates in elevated body iron stores and may be so severe that it results in clinically significant iron overload with secondary organ dysfunction. All patients are anemic, and thrombocytopenia and neutropenia develop in some, particularly acquired, neoplastic forms. The anemia may be normocytic, microcytic, or macrocytic and is typically characterized by a relative reticulocytopenia (Table 12-1 and Box 12-5; reviewed by Fleming[453] and Bottomley[454]).

Congenital Sideroblastic Anemias

Genetically defined, congenital sideroblastic anemias may be inherited in an autosomal recessive, an X-linked recessive, or infrequently, a maternal fashion (reviewed elsewhere[453,454]). Most cases of congenital sideroblastic anemia are considered to be inherited conditions but defy genetic characterization at the present time. In classifying the known causes of congenital sideroblastic anemia, it is helpful to consider the MCV of the anemia, whether other hematopoietic cell lineages are affected, and whether syndromic associations or other distinctive clinical findings are present (see Table 12-1).

X-Linked Sideroblastic Anemia

X-linked sideroblastic anemia (XLSA) is the prototype of all congenital sideroblastic anemias. As the name implies, the disorder is linked to the X chromosome and disproportionately affects men and boys, although females may be affected because of skewed X-chromosome inactivation or Turner's syndrome.[455-457] The cardinal features of XLSA include (1) a congenital microcytic, hypochromic anemia with a large RDW and erythrocyte dimorphism (particularly in carrier females) and Pappenheimer bodies apparent on the peripheral blood smear; (2) an abundance of ringed sideroblasts, especially in late erythroid precursors; and (3) a variable clinical response to pharmacologic doses of pyridoxine (vitamin B_6).[454] Sys-

temic iron overload may also develop as a result of chronic, severe, ineffective erythropoiesis.[458,459] Nearly all patients with XLSA have missense mutations in the protein-coding regions of the erythroid-specific isoform of the heme biosynthesis enzyme δ-aminolevulinic acid synthase (ALAS2) (reviewed elsewhere[453,454]); rare patients have promoter mutations,[460] and unusual affected females carriers harbor nonsense or frameshift mutations.[461] The missense mutations tend to cluster in amino acids surrounding the catalytic site or the subunit interface of the homodimer, thereby leading to enzymes with decreased stability or decreased affinity for the cofactor pyridoxal phosphate, which can account for the clinical response to large doses of pyridoxine.[462] Because ALAS2 is the rate-limiting step in heme biosynthesis in the erythron, mutations inevitably impair the production of heme in developing erythroblasts. How heme deficiency leads to the hallmark ringed sideroblast is uncertain; however, the characteristic hypochromia and microcytosis are almost certainly the result of the protean effects of heme on erythroid transcription, mRNA stability, and translation.

The age at clinical onset of XLSA varies greatly. Anemia develops in some individuals within a few months of birth, whereas in others it occurs later in childhood and often even in adulthood. Generally, the anemia is progressive, with transfusions often required to maintain an adequate hemoglobin level. Frequent transfusions can hasten the development of iron overload. Oral pyridoxine therapy is useful in many patients with XLSA. Often, however, correction of the anemia is incomplete. Some patients become more pyridoxine responsive after their excess body iron stores are depleted.[463] A few children who failed pyridoxine therapy have responded to the parenteral administration of pyridoxal-5-phosphate.[464] Unfortunately, many children with XLSA improve little, if at all with either of these interventions. Because pyridoxine is inexpensive and lacks deleterious side effects, all children with sideroblastic anemia should receive a trial of vitamin therapy. Splenectomy is ill advised because of thrombotic risks.[454] There is one case report of successful allogeneic peripheral stem cell transplantation for refractory sideroblastic anemia.[465]

X-Linked Sideroblastic Anemia with Ataxia

X-linked sideroblastic anemia with ataxia (XLSA/A) is a very rare, distinct X-linked form of sideroblastic anemia caused by missense mutations in the mitochondrial ATP-binding cassette transporter ABCB7.[466-468] Patients with XLSA/A typically have static or slowly progressive cerebellar ataxia and only later are found to have a mild sideroblastic anemia with morphologic features similar to those of classic XLSA.[469,470] However, they do not require transfusion therapy, systemic iron overload does not develop, and they do not respond to pyridoxine therapy. ABCB7 and its yeast orthologue Atm1p are essential genes involved in the biogenesis of cytosolic Fe/S clusters.[471-477] Interestingly, another protein implicated in Fe/S cluster biogenesis in yeast and zebra fish, GRX5, has

been shown to be mutated in a single patient with severe sideroblastic anemia and iron overload.[478-480] In all cases, these Fe/S cluster biogenesis mutants appear to disrupt regulation of IRP1 RNA binding activity,[477,479] thus raising the possibility that this is a common mechanism for the development of sideroblasts.

Thiamine-Responsive Megaloblastic Anemia

Children with thiamine-responsive megaloblastic anemia (TRMA), also known as Rogers' syndrome, exhibit a characteristic triad of megaloblastic anemia with ringed sideroblasts, diabetes mellitus, and deafness.[481,482] The clinical manifestations of TRMA are progressive and may also include optic atrophy and nonthrombotic, nonembolic strokes. The anemia is characteristically macrocytic, and erythroid maturation in bone marrow, as the name implies, is megaloblastic and associated with variable numbers of ringed sideroblasts. Patients may also have leukopenia. The gene responsible for TRMA encodes a transmembrane thiamine transporter designated SLC19A2.[483-486] TRMA patients are not thiamine deficient but rather have a defect in high-affinity thiamine uptake in a number of cell types.[487] The megaloblastic marrow maturation is probably related to defective thiamine-dependent steps in nucleic acid synthesis[488]; however, the pathogenesis of sideroblasts remains obscure. Therapy with pharmacologic doses of thiamine ameliorates the anemia and may abrogate progression of the neurologic and pancreatic phenotypes.[481,489,490]

Pearson's Marrow-Pancreas Syndrome

Pearson's marrow-pancreas syndrome (PMPS) is a fatal, multisystemic disorder of infancy with marked disturbances in bone marrow and pancreatic function.[491] The initial manifestation is often a severe, transfusion-dependent macrocytic anemia associated with a variable degree of neutropenia and thrombocytopenia. Marrow examination characteristically shows vacuolization in the erythroid and myeloid precursors and ringed sideroblasts.[492] Exocrine pancreatic dysfunction as a result of pancreatic fibrosis is characteristic, and hepatic, renal, and neurologic dysfunction develops in some patients as well. The variability and pleiotropy of the disorder can be accounted for by the fact that PMPS is a mitochondrial cytopathy; nearly half of the patients share heteroplasmy for a common, nearly 5-kb deletion of mitochondrial DNA that is associated with other mitochondrial disorders, particularly Kearns-Sayre syndrome, and the distribution of defective mitochondrial genomes will necessarily influence expression of the disorder.[493,494] Defective energy production appears to be the central disturbance, and no treatment other than supportive care currently exists.

Mitochondrial Myopathy with Lactic Acidosis and Sideroblastic Anemia

Mitochondrial myopathy with lactic acidosis and sideroblastic anemia (MLASA) is a recently recognized autosomal recessive disorder of mitochondrial dysfunction caused by mutations in the gene for pseudouridine syn-

thase 1 (PUS1).[495-500] Most cases are associated with a unique founder mutation present in the Persian-Jewish population. Individuals with MLASA have highly variable neurologic abnormalities that most characteristically consist of exercise intolerance and lactic acidosis but may include severe hypotonia, muscle wasting, developmental delay, and mental retardation. The anemia, which is typically slightly macrocytic, is equally variable despite a common genotype, with some patients having asymptomatic anemia and others requiring transfusional support. PUS1, which localizes to mitochondria, the cytosol, and nuclei, is one of several enzymes that modify uridine residues in long-lived RNA (e.g., tRNA) to the alternate base pseudouridine. This modification is thought to enhance the stability of these molecules and enhance protein translation.

Acquired Sideroblastic Anemias

A number of drugs and toxins that impair heme biosynthesis or perturb mitochondrial iron metabolism can produce sideroblastic anemia (Box 12-5) (reviewed by Ammus and Yunis[501]). The most important of these agents is lead. This element inhibits several enzymes in the heme biosynthetic pathway, including δ-aminolevulinic acid dehydratase, coproporphyrinogen oxidase, and ferrochelatase.[502] Lead screening, therefore, is mandatory in any child suspected of having sideroblastic anemia because lead poisoning can be treated. Isoniazid also produces sideroblastic anemia by causing functional depletion of pyridoxine, which inhibits heme biosynthesis.[503,504] Prophylactic treatment with pyridoxine is now part of the standard therapeutic regimen with this drug.

Acquired, clonal neoplastic sideroblastic anemias such as refractory anemia with ringed sideroblasts (RARS) and other myelodysplastic syndromes (MDSs) are exceptionally uncommon in the pediatric age group, except perhaps in children who have previously received chemotherapy for cancer.[505] The extent to which the considerable experience with these disorders in adults might be applicable to children is uncertain; however, when compared with other categories of MDS, RARS has a lesser propensity to evolve to acute leukemia and may often be associated with iron overload in the absence of significant transfusional support.[506] Intriguingly, some patients have been shown to have mutations within the mitochondrial genome that alter the coding sequence for cytochrome *c* oxidase.[507]

COPPER METABOLISM

Copper Physiology and Transport

A total of 100 to 150 mg of copper is present in an adult human. As with iron, the fetus accumulates large amounts of copper near the end of gestation, particularly in the liver, where concentrations are 5 to 10 times greater at birth than in adulthood. These stores do not decrease to adult levels until 5 to 15 years of age. The liver has the highest copper content, which together with muscle and bone, accounts for 50% to 75% of total body copper. The normal net copper intake is 2 to 5 mg in an adult and 0.04 to 0.15 mg/kg in a growing child. After about 6 months of age, normal plasma copper levels range between 70 and 140 mg/dL. Values are lower in early infancy.[508] Depressed plasma copper levels are a good indicator of early copper deficiency; however, functional tests of enzymatic activity (e.g., ceruloplasmin) may be better.

Like iron, copper is essential for normal cell growth and metabolism but toxic in excess. Unlike iron, however, copper balance is regulated by excretion, as well as by absorption.[509,510] The gastrointestinal tract absorbs about 30% of the copper present in an average diet. The liver promptly disposes of much of that copper in bile, whereas a lesser amount is lost through the intestinal mucosa.[511]

Plasma copper, which is held much more constant than plasma iron, exists in two forms. Albumin and amino acids loosely bind 10% to 15% of circulating copper. Ceruloplasmin, a multicopper ferroxidase, tightly binds the remaining copper in plasma. Ceruloplasmin was once thought to be a copper transport protein; however, it is now clear that it functions primarily to change the oxidation state of iron, thereby aiding in release of iron from storage cells, including hepatocytes and macrophages (as discussed earlier). In human patients[512-515] and mice[92] lacking ceruloplasmin, a distinct clinical syndrome characterized by neurodegeneration, hepatic iron overload, diabetes, impaired iron recycling by reticuloendothelial cells, and mild iron deficiency anemia develops.

Copper is an essential component of cytochrome oxidase, the terminal oxidase of the electron transport chain required for combining hydrogen with oxygen to form water. As such, the element is essential for the oxidative generation of ATP. The enzyme tyrosinase is a copper-containing protein required for the synthesis of melanin. Thus, copper-deficient animals have depressed levels of cytochrome oxidase in most tissues, along with loss of hair pigment. Another copper metalloenzyme, lysyl oxidase, plays a role in the cross-linking of collagen and elastin. Lysyl oxidase deficiency may cause the vascular defects, including aortic aneurysm, seen in copper-deficient animals and patients with Menkes' disease (see later).[509]

Copper trafficking is relatively well understood (reviewed by Kim and colleagues[516]). A multitransmembrane domain protein, CTR1, appears to be the major transporter that brings copper into mammalian cells.[517-519] Knockout mice lacking CTR1 die early in gestation with findings that may be attributable to severe copper deficiency. Once copper is inside cells, it moves to its sites of utilization escorted by specific chaperone proteins (reviewed elsewhere[520,521]). These proteins appear to be conserved from yeast to mammals. Targeted disruption of one of these proteins, Atox1, in mice leads a

poorly viable, copper-deficient phenotype, thus indicating that its copper chaperone function is important but not essential.[522]

Two inherited defects of human copper metabolism have given insight into copper transport within cells. Menkes' disease, or Menkes' kinky hair syndrome, is a congenital disorder characterized by a low serum copper concentration, reduced activity of copper metalloenzymes, slow growth, hypopigmented kinky hair, cerebral degeneration, and an X-linked pattern of inheritance.[523] Parenteral copper administration, like all other attempts to treat the disease, is ineffective, and death before 3 years of age is typical. By contrast, in the autosomal recessive disorder Wilson's disease, the predominant clinical phenotypes—liver disease and neurodegeneration—are due to copper cytotoxicity.

Positional cloning led to identification of the genes mutated in Menkes' and Wilson's diseases.[524-529] Each is a P-type adenosine triphosphatase transmembrane copper transporter (Cu-ATPase) containing Gly-Met-Thr-Cys-X-X-Cys copper-binding motifs at their N-termini. The Menkes protein is involved in transport of copper in intestinal enterocytes, as well as a number of other cell types. Deficiency of the Menkes proteins leads to paradoxical systemic copper deficiency as a result of impaired intracellular intestinal copper transport accompanied by intracellular copper accumulation in certain cell types, particularly the kidney. By contrast, deficiency of the Wilson disease Cu-ATPase leads to cellular copper accumulation in the liver, basal ganglia, and kidney, along with impaired production of ceruloplasmin and hepatobiliary copper excretion. Interestingly, although Menkes' disease patients are copper deficient, anemia is not a prominent feature of the syndrome (see later). Wilson's disease may be manifested in children as fulminant hepatic failure associated with severe acute intravascular hemolysis.[530,531]

Hematologic Aspects of Copper Deficiency

Copper deficiency commonly causes hypochromic, microcytic anemia among farm animals in areas of the world where the soil is poor in copper.[532-535] In humans, the predominant clinical feature of copper deficiency is most commonly peripheral neuropathy. Because of milk's low copper content (about 0.12 mg/L), infants who consume a diet consisting largely of milk may be at risk for marginal copper nutrition or deficiency.[536] Nutritional copper deficiency can be due to extraordinary dietary circumstances, such as inadvertent omission of copper from intravenous alimentation formulations for an extended time or treatment of severely malnourished patients with a copper-deficient milk diet.[509,510,537] Impaired copper absorption may be a consequence of a variety of renal and gastrointestinal disturbances, including nephrotic syndrome, inflammatory bowel disease and other forms of malabsorption, or bariatric or other intestinal surgery.[538,539] Excessive zinc supplementation may

also lead to copper deficiency because zinc readily induces intestinal epithelial metallothionein, which preferentially chelates intestinal copper and prevents absorption.[509,540] Coexisting iron deficiency or severe malnutrition can obscure the manifestations of copper deficiency.

In humans, the anemia of copper deficiency is most typically normocytic, but it may be microcytic or macrocytic. Leukopenia with very marked neutropenia is particularly prevalent; thrombocytopenia is unusual. Bone marrow aspirates from copper-deficient individuals are often hypocellular and show a relative erythroid hyperplasia with prominent vacuolization of erythroid precursors and variable degrees of dyserythropoiesis or megaloblastoid changes (or both), with or without the presence of ringed sideroblasts. As many recent reports indicate, resistance to treatment with typical hematemics combined with the morphology may suggest the errant diagnosis of MDS (reviewed by Haddad and associates[541]). The coexistence of peripheral neuropathy, also typical of copper deficiency, may suggest the correct diagnosis. Osteoporosis may occur with severe copper deficiency.

Oral treatment with 0.1 to 0.3 mg/kg of copper per day (two or three times the estimated daily requirement) as 0.5% copper sulfate (containing about 2 mg of copper per milliliter) produces prompt reticulocytosis and correction of the anemia and neutropenia. Intravenous copper may also be given in severe deficiency states. Generally, the dietary imbalance that produced the deficiency can be corrected when the problem is recognized.

LEAD POISONING

Sources of Lead

Lead is a toxic metal without any function in the human body. Because of its useful properties, lead has been mined for several centuries. As a result, progressively larger amounts have been removed from the depths of the earth and introduced into the biosphere. Enough lead has found its way into humans that at least in the industrialized parts of the world, all people have some lead in the body and hence in the blood. It has thus become customary to refer to the blood lead values found in apparently healthy populations as "normal" blood lead levels. This term is an obvious misnomer because it implies some kind of minimum physiologic requirement for lead.

Airborne lead enters the human body through inhalation; about 35% is absorbed and 15% to 18% is retained.[542] Intake of airborne lead is greater in children because they breathe at a lower height, where the lead concentration is greater, and have a greater respiratory rate per unit of body weight.[543] Sources of inhaled lead include combustion engines that burn leaded fuel and primary and secondary (recycling) lead smelters. Lead

can also be ingested through the intake of contaminated food, water, and beverages. Lead absorption is increased by deficiencies of essential minerals, such as iron and calcium.[544] High maternal lead levels can result in fetal lead toxicity.[545]

Children living in older houses are exposed to the additional risk of lead in paint. Although lead in air, food, and beverages can be considered "*low-dose*" sources, lead in paint is by far the most concentrated source. As much as 40% lead by weight is present in dried paint used before World War II. Since then, lead levels in paint have been progressively reduced. For many years it was believed that lead poisoning in children occurs primarily as a result of pica (the urge to ingest nonfood material), with consequent ingestion of paint chips.[546] Although this is not an uncommon occurrence, it is neither the only nor even the prevailing mechanism of ingestion of lead paint. Small children, through their ordinary hand-to-mouth activities (such as thumb sucking) directly ingest dust and thus take in large amounts of lead. Despite legislative efforts and scientific advances in the United States, millions of dwellings still contain leaded paint. These dwellings present an obvious risk, particularly to children of the poor, who tend to live in the oldest houses. The state of repair of the dwelling is almost as important as the lead content of the paint; peeling or flaking paint is obviously more accessible to small children. Because iron deficiency often induces pica, lead poisoning is more common in iron-deficient children.

Less common sources of lead include fumes from old battery casings; illegally distilled whiskey; printed paper, particularly colored magazines; and lead-painted toys. An uncommon source of lead that may result in severe poisoning is improperly glazed earthenware vessels used to store acidic beverages (such as fruit juices or cider).

Biochemical and Hematologic Effects of Lead

Lead has strong affinity for the sulfhydryl groups of cysteine, the amino group of lysine, the carboxyl groups of glutamic and aspartic acids, and the hydroxyl group of tyrosine. Lead binds to proteins, modifies their tertiary structure, and inactivates their enzymatic properties. Enzymes that are rich in sulfhydryl groups appear to be most sensitive. Mitochondria are particularly sensitive to lead. Many prominent effects of lead on heme synthesis are mediated through alterations of the mitochondrial membrane. Heme synthesis starts and ends inside the mitochondria; intermediate steps take place in the cytoplasm. In all cells, heme is an essential component of molecules of the cytochrome system, also located inside the mitochondria. Additionally, in erythropoietic precursors, very large amounts of heme are formed to make hemoglobin. Lead interferes at several points in the heme synthetic pathway in all cells. The two most important steps affected are those catalyzed by δ-aminolevulinic acid dehydratase (a cytoplasmic enzyme) and ferrochelatase (an intramitochondrial enzyme). Both these enzymes depend on critical sulfhydryl groups for their activities. The inhibition by lead of ferrochelatase, which catalyzes the ultimate insertion of iron into protoporphyrin, results in the accumulation of protoporphyrins in maturing erythrocytes. Ultimately, despite the presence of a normal or increased intracellular content of iron, the mitochondria are starved for iron. Metalloporphyrins inhibit several mitochondrial enzymes, and the increased concentration of zinc protoporphyrin resulting from lead toxicity further impairs mitochondrial function.[547] There is a relationship between the concentration of lead that inhibits ferrochelatase in mitochondria and the ambient concentration of iron in the medium. At any concentration of lead, inhibition of ferrochelatase is most marked when the iron concentration is the lowest.[548] This biochemical mechanism explains the greater elevation of erythrocyte protoporphyrin observed, at equal lead exposure, in children with concomitant iron deficiency.[549] A progressive, exponential increase in erythrocyte protoporphyrin concentration is observed at blood lead levels of 5 to 90 μg/dL.[550] The erythrocyte protoporphyrin level is an indicator of adverse metabolic effects. It is very effective as a screening test for severe lead poisoning, but it cannot be used to screen for blood lead levels below 40 to 50 μg/dL.

The bulk of lead in blood (>90%) is contained in erythrocytes, but blood lead content is independent of the hematocrit. Basophilic stippling results from deposition of ribosomal DNA and mitochondrial fragments.[551] Moderate basophilic stippling may be seen in iron deficiency and thalassemia trait, but stippling is particularly prominent in the polychromatophilic erythrocytes in lead poisoning, unstable hemoglobinopathies, including severe β-thalassemia, and pyrimidine-5′-nucleotidase deficiency. Anemia is observed in children with lead poisoning, primarily in severe cases or in those with concomitant iron deficiency.[548] This is not an unexpected finding because the defect in heme synthesis affects only a very small fraction of the total protoporphyrin production and clinically significant anemia usually develops in the late stages. It is not uncommon to observe severe neurologic toxicity in the absence of anemia in children. On the other hand, lead intoxication and iron deficiency anemia tend to occur in the same lower socioeconomic population and are aggravated by each other. Iron-deficient children are more severely affected because iron deficiency increases lead ingestion through pica, increases lead absorption, enhances the defect in heme synthesis, and increases the toxicity of lead.

Other enzymes of heme biosynthesis are also affected by lead, but less severely. Uroporphyrinogen synthetase activity is inhibited only by a rather high (10^{-4} mol/L) lead concentration.[547] Coproporphyrinogen decarboxylase, another mitochondrial enzyme, also is inhibited by lead.[547] There is a marked increase in urinary coproporphyrin levels in lead intoxication. Measurement of urinary coproporphyrin has been widely used for the diagnosis

of childhood lead poisoning, particularly in emergency departments. Although this test has been superseded by the easier measurement of erythrocyte protoporphyrin, it is important to recognize its usefulness in discriminating between recent and past lead exposure. Because of the protracted persistence of protoporphyrin within erythrocytes, significant elevations may be observed as long as 2 to 3 months after exposure to lead.[552] In contrast, increased coproporphyrin production, as a result of its high solubility, is immediately reflected in excess urinary excretion. Hence, when exposure to lead is current, both the erythrocyte protoporphyrin level and the urinary coproporphyrin level are increased; when exposure to lead is no longer present, there is a discrepancy between the elevated erythrocyte protoporphyrin level and normal urinary coproporphyrin excretion.

The process of heme synthesis is not exclusive to the erythron. All cells contain essential heme proteins, particularly in the respiratory cytochrome system, also located in the mitochondria. The most visible effects of lead on heme synthesis are those detectable in peripheral blood because this is the easiest tissue to sample. However, the ubiquitous presence of active heme synthesis in the mitochondria of all body cells and the affinity of lead for mitochondria result in widespread impairment of cellular function. Lead intoxication inhibits the synthesis of cytochrome P-450, the key enzyme in the mixed oxidase system. It appears likely that the toxic effects of lead, particularly in the nervous system, reflect the derangement in heme synthesis.[553]

In adults, peripheral neuropathy, abdominal colic, and anemia are the most common initial signs of lead poisoning. In children, the clinical effects of excessive exposure to lead are apparent primarily in the CNS; alterations in renal function and anemia occur only in the most severe cases. Acute encephalopathy can be the first manifestation of severe childhood lead poisoning. The onset is usually marked by seizures, often intractable, followed by coma and cardiorespiratory arrest. The syndrome may be fatal within 24 to 48 hours. Survivors often suffer permanent neurologic damage.[554] Acute encephalopathy may be accompanied by Fanconi's syndrome with aminoaciduria, glycosuria, and hyperphosphaturia.[555]

Chronic symptoms of lead toxicity are vague and include abdominal pain, vomiting, general malaise, and behavioral changes. These symptoms are nonspecific and of little diagnostic help, particularly in the youngest children, aged 1 to 3 years, who are the most frequently affected. The threshold blood lead level at which encephalopathy occurs in children is difficult to define. *Acute lead poisoning* with clinical signs other than encephalopathy has been observed at blood lead levels ranging between 60 and 450 µg/dL. On the other hand, it is possible to observe blood lead levels as high as 200 µg/dL in children without overt neurologic symptoms. The probability of overt neurologic problems increases with the blood lead level and becomes significant when the blood

lead level rises above 70 µg/dL. For these reasons and because of the impending risk of an unpredictable clinical deterioration, children found to have blood lead levels of 70 µg/dL or greater should be treated as medical emergencies, even in the absence of symptoms.[556]

As a result of the greater awareness of childhood lead poisoning by physicians, extensive screening programs in large cities, and the reduction of lead in the air subsequent to the wider use of lead-free gasoline, severe lead poisoning is extremely rare. Additionally, there is a greater awareness of the subclinical effects of lead and the fact that there is no threshold below which body lead levels can be considered safe. In view of the evidence of adverse effects of exposure to lead, even at low levels, there has been progressive lowering of the "acceptable" blood lead level. Therefore, it is important to not confuse "intervention level" (decided on pragmatic considerations) with "safe" levels.

The insidious nature of lead toxicity mandates the detection of excessive exposure in apparently asymptomatic children before irreparable damage occurs. Screening for lead poisoning is made particularly difficult by the fact that the most commonly affected children are those of preschool age, who are also the least accessible, as a group, to mass testing. Screening in this age group is most often performed by pediatricians at routine office visits. It would be desirable, instead, for screening programs to reach out to the community and focus on the most economically deprived children, who have the least access to medical care, as well as the highest risk.

Nationwide programs for screening children must be directed primarily at identifying those in need of medical attention. The definition of *lead poisoning* now includes the category of children with blood lead levels of 10 to 19 µg/dL. Yet it has been shown that at this level the potential loss of IQ is so low that most people would agree that it is trivial.[557,558] Although medical intervention is not necessary for this group, educational and dietary advice is recommended. Children in need of medical attention are those with blood lead levels of 20 µg/dL or higher. Above this level, cognitive issues become significant.[557,558] Severe lead poisoning is defined as levels above 45 µg/dL.

Treatment of Lead Poisoning

The first and most essential step in treating childhood lead poisoning is identification and removal of the source of lead. Without elimination of the exposure, any treatment is futile. Environmental analysis, including home visits, is recommended to ascertain and remove the source of lead. Although complete removal of lead from the environment remains a formidable task for modern society, it offers the only viable solution to prevent lead toxicity in children. Multiple studies have shown that neurotoxicity is unlikely to be reversible, regardless of treatment, once lead intoxication is discovered. Because lead exposure is additive, removal of automobile-

generated lead from the air has already had a profound impact on the problem of urban lead poisoning. However, residual lead-based paint continues to be a major problem.

Children who are symptomatic require urgent treatment. However, because the symptoms of lead poisoning may be elusive, treatment is indicated even in their absence if there is clear evidence of excessive body burden of lead. The goal of treatment is prevention of subclinical damage without producing complications of the therapy itself; it is necessary to exercise judicious compromise. Two parenteral treatments are used in severe lead poisoning: dimercaprol (formerly called BAL for British antilewisite) and CaNaEDTA. Both these agents chelate lead and induce its excretion. Dimercaprol is an oily, malodorous compound that is unpleasant to patients. It forms an emetic compound with iron, so iron therapy should not be given to a patient receiving dimercaprol.[559] It is dissolved in peanut oil and thus is contraindicated in children allergic to peanuts. Approximately half of patients treated with dimercaprol have side effects, many of which can be ameliorated by the concurrent use of antihistamines.[556]

CaNaEDTA is water soluble and best administered by continuous intravenous infusion. When administered intramuscularly (a less preferable and much more painful option), 2% procaine should be added to avoid severe local pain. CaNaEDTA may itself be toxic, particularly to the kidneys. Overdosage may induce tubular necrosis directly or renal toxicity as a result of hypercalcemia. CaNaEDTA is also able to chelate zinc, thus presenting another risk. Because δ-aminolevulinic acid dehydratase, a zinc-dependent enzyme, is already damaged by lead, the additional removal of zinc leads to its complete paralysis. This results in a burst of neurotoxic δ-aminolevulinic acid into plasma, which may aggravate (and even induce) convulsions. For these reasons, CaNaEDTA should never be given alone to symptomatic children or to asymptomatic children with blood lead levels of 70 μg/dL or greater; instead, it should be given after administration of dimercaprol to prevent these acute effects.[559] An additional note of caution is necessary with regard to the use of EDTA. Besides CaNaEDTA, a commercial preparation of disodium EDTA is also available and occasionally used for hyperparathyroidism. Disodium EDTA should never be used for the treatment of lead poisoning because it may induce acute hypocalcemia, which may be fatal. Only CaNaEDTA should be used for the treatment of lead poisoning. Hospital pharmacies should exercise maximum caution in dispensing disodium EDTA, which could be fatal if erroneously given to a child with lead poisoning but without hypercalcemia.

Because of their different pharmacologic properties, dimercaprol and CaNaEDTA are advantageously used in combination to treat children with symptomatic lead poisoning, with or without concomitant encephalopathy, as well as asymptomatic children with blood lead levels greater than 70 μg/dL.[556] The combined use of dimer-

caprol and CaNaEDTA is both safer and more effective than the use of CaNaEDTA alone. Treatment should always start first with dimercaprol to avoid precipitating encephalopathy.[559] Involvement of an experienced toxicologist is strongly advised for safe, effective management of these patients.

Succimer is a derivative of dimercaprol in which the methyl groups are replaced by carboxylic groups. This results in excellent water solubility, thus allowing it to be used orally. Although the advantages of an oral chelator are obvious, it is crucial to be cautious in the use of succimer because with its great water solubility and affinity for lead, it may result in increased absorption if used in a lead-laden environment. For this reason, succimer should be used only when it is absolutely certain that the child has been removed from the lead-containing environment and is in a safe home. In a recent trial, succimer was shown to be effective in reducing blood lead levels in patients with levels of 20 to 45 μg/dL.[560] Importantly, however, it did not reverse neurologic and cognitive deficits. For this reason, the authors concluded that it is not indicated in children with moderate lead levels (20 to 45 μg/dL). Experience with this drug in treating children with blood lead levels of 70 μg/dL or higher is very limited. In these cases, as well as in symptomatic children, it may still be prudent to treat with a combination of dimercaprol and CaNaEDTA.

Regardless of the treatment, it is important to remember that improvement in blood lead levels does not mean that all lead has been removed. Blood levels are likely to rebound 1 to 2 weeks after therapy as tissue lead (particularly from bone) enters the circulation. Children with a large body burden of lead, such as those with clinical symptomatology or blood lead levels in excess of 70 μg/dL, invariably require several cycles of chelation therapy before a substantial reduction in the body burden of lead is obtained.[559] The need for additional cycles of therapy can be established by measurement of urinary lead excretion during the first days of treatment. The lead excreted should be related to the amount of EDTA given. Children who excrete lead in larger proportions are in greater need of additional cycles of therapy. It is not uncommon for a child to require several months of chelation therapy, initially with both dimercaprol and CaNaEDTA and later with CaNaEDTA alone, before urinary lead excretion declines and the blood lead level stabilizes below 30 μg/dL. Only at that point can chelation therapy be stopped.[559]

13 The Porphyrias

John D. Phillips and James P. Kushner

The porphyrias are disorders caused by reduced activity of enzymes that constitute the heme biosynthetic pathway. Almost all are inherited. The porphyric disorders, with the exception of porphyria cutanea tarda (PCT), are uncommon, and clinical manifestations in children are quite rare. Porphyrins are planar molecules composed of four pyrrole rings connected by four methene groups and are also referred to as tetrapyrroles (Fig. 13-1A). Porphyrins are intensely colored compounds (the word porphyria is derived from the Greek *porphuros*, meaning red-purple). All porphyrins, because of the alternating single- and double-bond structure of the porphyrin macrocycle, avidly absorb light in a region near 400 nm of the spectrum (the Soret band). Porphyrins also have four minor absorption bands at higher wavelengths. Once excited by light, porphyrins emit photons in the red region of the spectrum, a phenomenon responsible for their fluorescent properties. The emitted photons mediate the skin damage, which occurs in sun-exposed skin in some of the porphyric disorders.

The porphyrin precursors δ-aminolevulinic acid (ALA) and porphobilinogen (PBG) (a monopyrrole) are colorless compounds that do not fluoresce. Recent evidence suggests that these compounds are responsible for the neurovisceral manifestations of several of the porphyric disorders. A convenient classification scheme divides the porphyric disorders into three groups according to their clinical manifestations (Box 13-1). Alternative schemes have been proposed by which the porphyrias are classified according to the organ in which the enzymatic defect is most apparent (hepatic porphyrias versus erythropoietic porphyrias), but these schemes are less useful to the clinician. Most heme synthesis takes place in erythroid precursors and is used for the generation of hemoglobin, but approximately 15% of the daily production takes place in the liver,[1] mainly for the formation of cytochrome P-450 enzymes. Heme is also a component of numerous other cellular proteins, including cytochromes, myoglobin, catalase, peroxidase, guanylate cyclase, and others; the heme biosynthetic pathway is present in all cells.

With the exception of ferrochelatase (FECH), the terminal enzyme in the pathway that catalyzes the inser-

tion of iron into protoporphyrin IX, all enzymes in the pathway that use cyclic tetrapyrroles require fully reduced porphyrinogens as substrates. Porphyrinogens are flexible, colorless, reduced compounds with hydrogen atoms added to each of the bridge carbons and to nitrogens of the pyrrole rings (see Fig. 13-1B). Porphyrinogens are very sensitive to oxidation. When the heme biosynthetic intermediates uroporphyrinogen and coproporphyrinogen are oxidized to the corresponding porphyrins, they can no longer serve as substrates (Fig. 13-2) and are excreted in urine and stool. Protoporphyrinogen oxidase (PPO) also requires the reduced compound protoporphyrinogen as substrate. Nonenzymatic oxidation of the substrate to protoporphyrin results in excretion of protoporphyrin in stool.

Hans Fischer[2] originally developed the porphyrin nomenclature currently used. Protoporphyrin IX was the ninth isomer of protoporphyrin synthesized by Fischer and corresponded to the only isomer of protoporphyrin

---

Box 13-1	**Clinical Classification of the Porphyrias**

PHOTOSENSITIVITY SYMPTOMS

Congenital erythropoietic porphyria (4)★
Porphyria cutanea tarda (5)†
Hepatoerythropoietic porphyria (5)★
Erythropoietic protoporphyria (8)★

NEUROVISCERAL SYMPTOMS

Aminolevulinate dehydratase porphyria (2)★
Acute intermittent porphyria (3)‡

PHOTOSENSITIVITY AND NEUROVISCERAL SYMPTOMS

Hereditary coproporphyria (6)‡
Variegate porphyria (7)‡

Numbers in parentheses designate the enzymatic defect responsible for the disorder (see Fig. 13-2).

★Clinical manifestations usually recognized in childhood.
†Clinical manifestations rarely recognized in childhood.
‡Clinical manifestations rarely occur before puberty except in children with homozygous or compound heterozygous genotypes.
FIGURE 13-1. Porphyrin and porphyrinogens. Porphyrins are tetrapyrroles. **A,** Porphyrins are the oxidized form of porphyrinogens. The alternating single- and double-bond sequence at the periphery of the molecule imparts the color and fluorescent properties of porphyrins and produces a rigid planar shape. **B,** Porphyrinogens, the reduced form, are colorless, do not fluoresce, and are highly flexible.

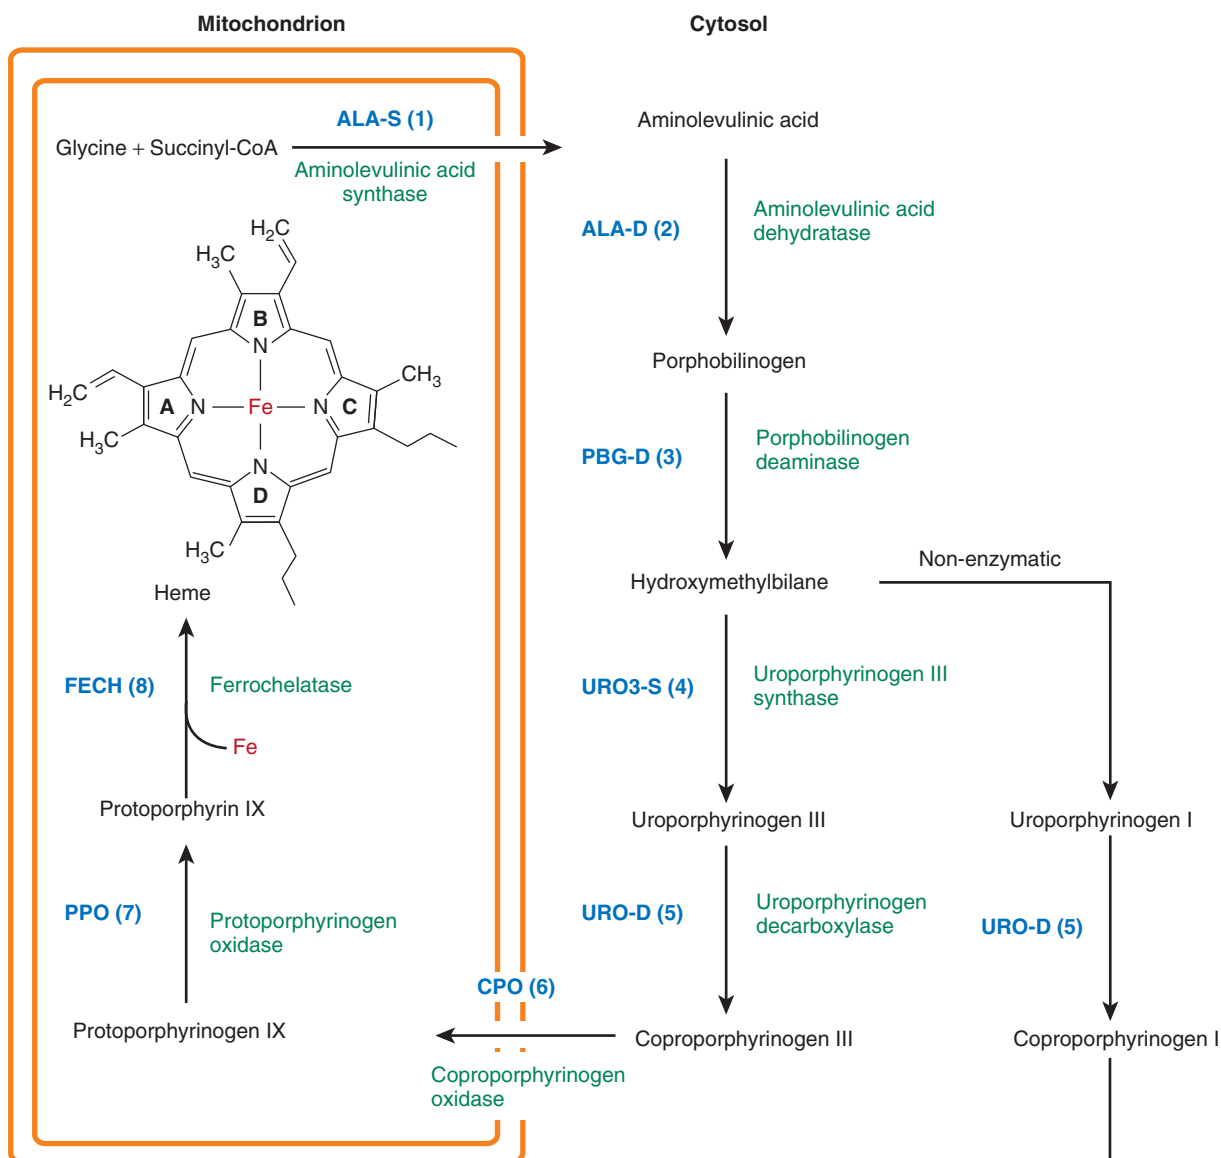

FIGURE 13-2. Heme biosynthetic pathway. The eight enzymes required to synthesize heme are named (*green*). Abbreviations used throughout this chapter are in *blue*. Synthesis starts in mitochondria, depicted by the *double orange line*, continues in the cytosol, and terminates in mitochondria. Enzyme 6, coproporphyrinogen oxidase, is located in the mitochondrial intermembrane space. Enzyme 7, protoporphyrinogen oxidase, is an integral membrane protein located on the outer surface of the inner membrane. Enzyme 8, ferrochelatase, an integral membrane protein, is located on the matrix side of the inner mitochondrial membrane.

found in nature. Uroporphyrinogen and coproporphyrinogen can occur in four isomeric forms, but only the I and III forms occur in nature. The I and III isomers of uroporphyrinogen differ solely in the position of the acetate and propionate side chains on the D ring (see Fig. 13-1), but only the III isomer can ultimately be converted to protoporphyrin IX and heme.

In eukaryotic cells, the heme biosynthetic pathway is divided between three compartments: the mitochondrial matrix, the mitochondrial intermembrane space, and the cytosol (Fig. 13-2). The pathway enzymes have been intensively studied in recent years. All of the genes have been cloned, and mutations responsible for the porphyrias have been identified. The crystal struc-

tures of all the enzymes have been determined, and these structures have provided models for the mechanisms of catalysis and the effects of specific mutations (Table 13-1).

Here, we will dissect the complex heme biosynthetic pathway into four basic processes, and each porphyric disorder will be described in the context of the process that is defective:

1. Formation of the pyrrole
2. Assembly of the tetrapyrrole
3. Modification of the tetrapyrrole side chains
4. Enzymatic oxidation of protoporphyrinogen IX to protoporphyrin IX and insertion of iron

FORMATION OF THE PYRROLE

The δ-Aminolevulinate Synthases

Regulatory mechanisms controlling heme synthesis in erythroid precursors and in the liver differ. In the liver, heme biosynthesis must respond rapidly to changing metabolic requirements. In erythroid cells, the pathway is regulated to permit a high steady-state level of heme synthesis, and regulation is tied to the availability of iron. The first and rate-limiting enzyme in the pathway in all cells condenses glycine and succinyl coenzyme A to yield ALA (Fig. 13-3). This highly exergonic reaction occurs in the mitochondrial matrix and involves cleavage of the thioester bond of succinyl coenzyme A. Two ALA synthase (ALA-S) enzymes have evolved to accommodate the requirements of the liver (and other tissues) and the unique demands of the erythron. The first, ALA-S1, is expressed ubiquitously but at very low levels in erythroid precursors. The dominant form of ALA-S in erythroid cells is ALA-S2. The gene encoding ALA-S1 maps to the short arm of chromosome 3,[3] whereas ALA-S2 is encoded on the X-chromosome.[4] The two forms of ALA-S are 62% identical at the amino acid level.[5] Although these two forms of ALA-S are regulated differently, both forms require pyridoxal 5-phosphate (PLP) as a cofactor, and both are expressed as homodimers. Pyridoxine deficiency is therefore associated with hypochromic anemia.

ALA synthases are highly conserved between species, and the crystal structure of a bacterial ALA-S (from *Rhodobacter capsulatus*) has been determined[6] (Fig. 13-4). The crystal structure supports the enzyme mechanism that had been suggested by biochemical studies.[7]

In eukaryotes, both forms of ALA-S are synthesized in the cytosol and then translocated to the mitochondrial matrix, the site of generation of succinyl coenzyme A by the tricarboxylic acid cycle. Both forms contain an amino-terminal mitochondrial targeting sequence that also contains heme binding domains designated as heme regulatory motifs (HRMs).[8] Binding of heme to the HRM inhibits mitochondrial import of both forms of ALA-S, which represents a post-translational point of
FIGURE 13-3. Synthesis of δ-aminolevulinic acid (ALA). In mitochondria, glycine is decarboxylated after forming a Schiff base with the cofactor pyridoxal phosphate (PLP). The reaction continues by condensation with succinyl coenzyme A (succinyl-CoA), followed by release and recycling of CoA. The origin of the carbon atoms in ALA and CO_2 is indicated with either numbers or letters.

end-product feedback inhibition of the pathway.[9] The effect is greater for ALA-S1 than for ALA-S2. In addition, developing erythroid cells express a heme transporter that prevents the accumulation of unbound heme in the cytosol (FLVCR).[10]

The genes for both ALA-S1 and ALA-S2 are transcriptionally regulated, but by quite different mechanisms. Extensive studies in avian embryonic liver cells indicated that hemin, a chloride salt of heme, represses transcription of ALA-S1,[11] but the precise mechanism responsible for this effect has not been defined. Transcription of ALA-S1 is upregulated by the peroxisomal proliferator–activated receptor γ coactivator 1α (PGC-1α),[12] a coactivator of nuclear receptors and transcription factors.[13] Transcriptional regulation of ALA-S1 by PGC-1α is mediated by the interaction of Nrf-1 (nuclear regulatory factor 1) and FOXO-1 (a forkhead family member) with the ALA-S1 promoter.[14] When cellular glucose levels are low, transcription of PGC-1α is upregulated,[15,16] thereby leading to increased levels of ALA-S1 and creat-
FIGURE 13-4. The active site of aminolevulinate synthase (ALA-S) from *Rhodobacter capsulatus*. Pyridoxal phosphate (PLP, *orange*) forms a covalent linkage with a lysine residue. Glycine is bound through a transient Schiff base with PLP. Condensation with the succinate moiety of succinyl CoA (CoA in *green*) allows the release of CoA, ALA, and PLP. The PLP cofactor is then bound again for subsequent rounds of catalysis. *(Figure based on the coordinates 2BWN, available from the Protein Data Bank.)*

ing conditions capable of precipitating acute attacks of the neurovisceral porphyrias. Upregulation of PGC-1α probably explains the clinical observation that fasting may precipitate attacks whereas glucose infusions are useful therapeutically.[17,18]

There are two alternate splice forms of ALA-S1 in humans. The major form lacks exon 1B (Fig. 13-5) and is destabilized by heme.[19,20] The minor form includes exon 1B and is resistant to heme-mediated destabilization.[21] It is apparent that heme regulates ALA-S1 by multiple mechanisms, including transcription, translation, and translocation of the protein from the cytosol to the mitochondria. The regulatory effects of heme are mediated by the concentration of heme in small "pools" of heme not bound to hemoproteins.[22,23] Factors depleting unbound heme pools result in induction of ALA-S1, an effect that is the prime factor in precipitating acute attacks of the neurovisceral porphyrias. No disease-causing mutations of ALA-S1 have been identified in humans, but downregulation of ALA-S1 by infusion of glucose or hemin (or both) forms the basis of therapy for acute porphyric attacks.[17]

In contrast to ALA-S1, ALA-S2 is transcriptionally regulated by erythroid-specific factors (including GATA1) that interact with promoter sequences found in many genes differentially regulated in red cells.[24] Translational regulation also plays a major role in regulating expression of ALA-S2. The ALA-S2 transcript contains a 5′ iron responsive element (IRE) that interacts with an IRE-binding protein (IRP).[25] The IRE-IRP complex prevents translation of ALA-S2 mRNA. Addition of an iron-sulfur cluster (Fe/S) to IRP1 changes the conformation of the protein and reduces its affinity for IRE. Fe/S clusters are generated and exported by mitochondria, thus linking regulation of heme biosynthesis in the red cell to the availability of iron and mitochondrial function.[26-28] Mutations in ALA-S2 cause X-linked sideroblastic anemia. This disorder and the spectrum of causative ALA-S2 mutations are described in detail in Chapter 12.

δ-Aminolevulinate Dehydratase

Once synthesized, ALA exits mitochondria by an unknown mechanism probably involving a transporter. In the cytosol, two molecules of ALA undergo a condensation reaction catalyzed by aminolevulinate dehydratase (ALA-D, also known porphobilinogen synthase) to form the monopyrrole porphobilinogen (Fig. 13-6). The crystal structure of human ALA-D and ALA-D from many other species indicates that the enzyme functions as a tetramer of homodimers formed from eight identical subunits.[29,30] Each of the homodimers contains one active site.[31] Each of the eight subunits binds a zinc atom, and the enzyme is inactivated by replacement of the zinc with lead, hence the hypochromia of lead poisoning. Four zinc molecules are essential for catalysis. The remaining four zincs serve to stabilize the tertiary structure of the enzyme.[32-34] Each active site binds two molecules of ALA through the formation of Schiff base linkages with active-site lysine residues, one for each of the two substrate molecules. One molecule of ALA contributes the acetate side chain and the aminomethyl groups of PBG. The other contributes the propionate side chain and the pyrrole nitrogen (Fig. 13-6).

In contrast to ALA-S, there is a single ALA-D gene located on chromosome 9q34[34a] (see Table 13-1). The gene consists of two alternatively spliced noncoding exons (1A and 1B) and 11 coding exons[34b] (see Fig. 13-5). The translational start site is located in exon 2. A housekeeping promoter is located upstream of exon 1A, and a second erythroid-specific promoter is located between exons 1A and 1B. The erythroid promoter contains binding sites for erythroid-specific transcription factors, including GATA1.[34b] Although the housekeeping and erythroid transcripts differ, they both encode identical proteins because they share the same translational start site in exon 2.
FIGURE 13-5. Genomic organization of the promoters for early steps in heme synthesis. Chr., chromosomal location for the gene. Two distinct genes encode aminolevulinate synthase (ALA-S), a housekeeping form (ALA-S1) and an erythroid-specific form (ALA-S2). An iron regulatory element (IRE) in exon 1 of ALA-S2 controls post-transcriptional gene expression. The next three genes use specific promoters for erythroid (E) or nonerythroid tissues (H). The ATG start sites are designated: C, common; E, erythroid; H, housekeeping. ALA-D, aminolevulinate dehydratase; PBG-D, porphobilinogen deaminase; URO3-S, uroporphyrinogen III synthase.
FIGURE 13-6. Reaction catalyzed by aminolevulinate dehydratase (ALA-D). In the cytosol, two molecules of δ-aminolevulinic acid (ALA) condense to form porphobilinogen. The carbon atoms of each molecule of ALA are numbered for reference.

A common polymorphism of ALA-D, K59N,[35] has been detected in approximately 10% of white individuals,[36,37] 3% of African Americans,[36] and 6% to 11% of Asians.[37] This polymorphism has been designated the ALA-D2 allele. The ALA-D2 allele retains normal enzyme activity and appears to have higher affinity for both zinc and lead than the ALA-D1 allele does.[38] Lead entering plasma is rapidly taken up by red cells and binds to ALA-D by displacing zinc and inactivating the enzyme.[39] Multiple studies have shown an association between the ALA-D2 allele and high blood lead levels,[36,38] but it remains unclear whether this allele is associated with increased susceptibility or increased resistance to lead toxicity.[39]

Although the quaternary structure of human ALA-D is that of a homo-octamer, recent studies have also detected a homohexamer form of ALA-D composed of three homodimers. The homohexamer has low enzyme activity. The octameric and hexameric forms of ALA-D are described as morpheeins, which indicates that dissociation of the high-activity octamer is followed by a conformational change and then reassembly as the structurally

different low-activity hexamer. Conformational changes in the component dimers may result from substrate binding, but the most dramatic effects result from ALA-D mutations causing ALA-D porphyria.

In all tissues the enzymatic activity of ALA-D greatly exceeds the activity of ALA-S. The abundance of ALA-D in comparison to all of the heme biosynthetic enzymes has been ascribed to the finding that ALA-D plays several roles: it serves as a proteasome inhibitor affecting the adenosine triphosphate (ATP)/ubiquitin-dependent degradation of proteins, plays a role in chaperone-assisted protein folding, and is an enzyme in the heme biosynthetic pathway.[40]

Aminolevulinate Dehydratase Deficiency Porphyria

ALA-D deficiency porphyria (ADP) is caused by homozygosity or compound heterozygosity for mutations of the ALA-D gene.

Frequency. ADP is an autosomal recessive disorder resulting from loss-of-function mutations of ALA-D. The disorder is exceedingly rare, and fewer than 10 cases have been reported, 2 in one family.[41] Most of the cases have represented compound heterozygotes. Eleven disease-causing ALA-D mutations have been described, 10 of which are point mutations leading to amino acid substitutions.[42,43] The sole exception is the deletion of two sequential bases resulting in a frameshift yielding a premature stop codon.[44] Estimates of the frequency of heterozygosity for loss-of-function alleles of ALA-D, based on half-normal or less enzyme activity in the erythrocytes of asymptomatic northern Europeans, range from 1% to 2%.[45,46] The extreme rarity of homozygosity or compound heterozygosity for ALA-D mutations suggests a high incidence of embryonic lethality when two mutant alleles of ALA-D are present.

Clinical Manifestations. The clinical manifestations of ADP resemble those of the neurovisceral porphyrias but vary greatly in severity. The first two cases reported by Doss and colleagues[47,48] in Germany involved unrelated 15-year-old boys. Both suffered recurrent attacks of abdominal pain, nausea, vomiting, constipation, tachycardia, and a motor neuropathy causing paralysis. In a third German patient reported by Doss and associates,[49] symptoms also developed at age 15, including abdominal pain and a severe polyneuropathy. All three German patients were compound heterozygotes for ALA-D mutations.

The youngest reported patient with ADP was a Swedish boy in whom muscle hypotonia was recognized at birth. At the age of 3 years, recurrent attacks of abdominal pain, vomiting, and motor polyneuropathy developed. This child also proved to be a compound heterozygote for ALA-D mutations.[50] A liver transplant was performed at the age of 6 under the assumption that the metabolic defect was most profound in the liver. No

change in excretion of ALA was observed after the transplant, thus strongly suggesting that red cells were the major source of this porphyrin precursor. The child died at the age of 9 of pneumonia and respiratory deficiency.[51]

The oldest reported patient with ADP was a Belgian man in whom a motor neuropathy and markedly increased urinary excretion of ALA developed at the age of 63.[52] ALA-D activity in his erythrocytes was dramatically reduced to 1% of normal controls. The syndrome developed together with a clonal myeloproliferative disorder, namely, polycythemia vera. Molecular studies revealed heterozygosity for a loss-of-function mutation (G133R) present in the polycythemia clone that became clinically manifested with clonal expansion.[53] This represents the only case in which a fully penetrant phenotype occurred in a heterozygote.

In two other cases, partial biochemical evidence of ALA-D deficiency was detected in heterozygotes, but by a completely different mechanism. The first was a healthy Swedish newborn undergoing neonatal screening for hereditary tyrosinemia.[54] Erythrocyte ALA-D activity was 12% of normal, and there were slight elevations in urinary ALA and coproporphyrin, as well as an increase in erythrocyte protoporphyrin. The child proved to be heterozygous for an F12L mutation, a catalytically inactive mutant that also affects the secondary structure of the protein and favors the formation of (with wild-type protein) the low-activity hexameric form of ALA-D.[43,55] Despite the ALA-D defect, the child remained healthy and developed normally.

The second case of partial biochemical expression in a heterozygous ALA-D mutant occurred in a 23-year-old American man and was also due to the F12L mutation.[56] This patient had an acute porphyric attack that was clinically and biochemically compatible with hereditary coproporphyria (HCP). Indeed, a mutation of coproporphyrinogen oxidase (CPO) was identified. Because of a greater than usual increase in urinary ALA excretion and an increase in erythrocyte zinc protoporphyrin, an additional defect in ALA-D was suspected. Subnormal erythrocyte ALA-D activity was detected, and molecular studies revealed heterozygosity for the F12L mutation.

Pathogenesis. The pathogenesis of the symptom complex associated with ADP is poorly understood. It has been suggested that ALA may act as a neurotoxin based on structural similarities between ALA and glutamate and ALA and γ-aminobutyric acid (GABA).[57] High concentrations of ALA may interact with GABA receptors or inhibit uptake of glutamate. ALA has been demonstrated to bind to GABA receptors in vitro, and GABA receptors are highly expressed by oligodendrocytes.[58] In addition, oligodendrocytes are highly sensitive to glutamate-dependent metabolic pathways, which could be impaired by the effect of ALA on glutamate uptake.[59] A possible role for ALA as a neurotoxin is supported in

patients with hereditary tyrosinemia, who exhibit neuro-visceral symptoms associated with marked inhibition of ALA-D by succinylacetone[60] (see later).

Laboratory Diagnosis. Although ADP is rare, it should be suspected when an acute attack of abdominal pain suggests the possibility of a porphyric attack, especially when a prominent distal motor neuropathy is present. The dramatic reduction in ALA-D activity (to levels of 5% or less) results in the urinary excretion of large amounts of ALA and normal or minimally increased levels of PBG, a finding that distinguishes ADP from other neurovisceral porphyrias. Urinary excretion of coproporphyrin is markedly increased. The mechanism responsible for the increase in urinary excretion of coproporphyrin is not known, but similar findings occur when ALA-D is inhibited in lead poisoning and when ALA is administered orally to normal individuals.[61] Zinc protoporphyrin accumulates in erythrocytes in patients with ADP, again by a poorly understood mechanism.

Heterozygous parents and siblings of probands with ADP have approximately half-normal ALA-D activity as measured in red cell lysates. Erythrocyte ALA-D assays are available in reference laboratories in the United States and Europe. Gene sequencing is available for mutation analysis of ALA-D through the Department of Human Genetics at the Mount Sinai School of Medicine in New York.

It is important to emphasize that ALA-D activity can be subnormal in disorders other than ADP. Patients with lead poisoning often exhibit clinical signs and symptoms similar to those found in patients with ADP and other neurovisceral porphyrias. Lead in plasma is taken up by red cells and inhibits ALA-D activity by displacing zinc atoms from the enzyme.[39] The result is excess ALA in blood and urine, excess urinary excretion of coproporphyrin, and accumulation of zinc protoporphyrin in erythrocytes, findings also associated with ADP. The abnormal accumulation and excretion of porphyrins may be due, in part, to inhibitory effects of lead on CPO and FECH[62] but are more likely due to disposition of the excess ALA, as occurs in ADP. Lead poisoning can be distinguished from ADP by measuring the blood lead level.

Patients with hepatorenal tyrosinemia type I, an autosomal recessive disorder caused by deficiency of fumarylacetoacetate hydrolase (FAH), manifest acute episodes of porphyric-like neurologic crises and secrete large amounts of ALA in urine.[63] The FAH defect results in the generation of succinylacetone, a structural analogue of ALA and a potent inhibitor of ALA-D.[64]

A single patient with an acquired reversible, unidentified inhibitor of ALA-D, high urinary ALA levels, and a porphyria-like acute attack has been reported.[65] In addition, both styrene and bromobenzene have been shown to inhibit ALA-D in rats.[66,67] Humans exposed to these compounds have moderately decreased erythrocyte ALA-D activity but do not suffer clinical consequences.

ADP is a rare disorder that must be differentiated from other causes of ALA-D deficiency. Biochemical and molecular evidence is essential to establish the diagnosis of ADP.

Treatment. Clear recommendations for the treatment of ADP are difficult because the number of reported cases is small and the results of therapy have been variable. Suppression of ALA-S1 by the infusion of heme (heme arginate) proved effective in three German patients (all adolescent boys),[48,49] and infusions of glucose, narcotic analgesics, and hemin were effective in a 14-year-old American boy.[42] Hemin infusion proved ineffective in a Swedish infant.[50] The Swedish child underwent liver transplantation at the age of 7,[68] but there were few biochemical or clinical changes. The findings in the Swedish infant suggest that the main source of excess ALA was the erythron.

Avoidance of drugs known to induce acute attacks in other neurovisceral porphyrias, generally by depleting hepatic heme pools and inducing ALA-S1, is suggested but has not been proved to be useful.

ASSEMBLY OF THE TETRAPYRROLE

Porphobilinogen Deaminase

A polymer of four molecules of PBG is generated by porphobilinogen deaminase (PBG-D, a.k.a. hydroxymethylbilane synthase), a cytosolic enzyme. The polymer, an unstable tetrapyrrole, is designated hydroxymethylbilane (HMB) (Fig. 13-7). PBG-D functions as a monomer, and the crystal structure of the enzyme from several sources has been determined.[69] Purification of PBG-D from both mammals and bacteria has yielded an enzyme with a dipyrrole (dipyromethane) in the active site. The dipyrrole serves as a cofactor and is required for enzyme activity. A novel mechanism has been proposed to explain how PBG-D acquires the dipyrrole.[70] PBG-D first binds HMB and then deaminates and polymerizes two additional molecules of PBG to form a hexapyrrole. The distal tetrapyrrole is cleaved and released as HMB. The proximal dipyrrole remains covalently bound through a thioester linkage and serves as the cofactor for subsequent rounds of catalysis[71] (Fig. 13-8). The source of the first HMB molecule to bind to PBG-D remains unexplained. Polymers of PBG can be formed nonenzymatically,[72] but incubation of apo–PBG-D with PBG yields very little holoenzyme with the dipyrrole cofactor bound.[73] It seems likely that the sequence of events involves nonenzymatic condensation of four molecules of PBG to form the aminomethylbilane, which interact with PBG-D. Though a poor substrate, aminomethylbilane is deaminated to form HMB, which is capable of forming a covalent thioester bond with PBG-D leading to assembly of the initial hexapyrrole.[70]

FIGURE 13-7. Reaction catalyzed by porphobilinogen deaminase (PBG-D). A dipyrrole cofactor, dipyromethane (*red*), is covalently linked to the enzyme via a thioester bond. Four molecules of PBG are added, each releasing an amino group. Once a hexapyrrole has been formed, the terminal tetrapyrrole is cleaved and released as hydroxymethyl-bilane (HMB). The acetate (a) and propionate (p) side chains of the mono-pyrroles are labeled.
The human PBG-D gene has been cloned and mapped to chromosome 11q23-11qter.[74,75] The gene spans 10 kilobases (kb) and contains 15 exons.[76] Two separate promoters control transcription and allow tissue-specific regulation of gene expression, a mechanism also used by ALA-D and uroporphyrinogen III synthase (URO3-S) (see Fig. 13-5). The housekeeping promoter lies upstream of exon 1 and is active in all tissues. The erythroid-specific promoter lies upstream of exon 2 and resembles other erythroid-specific promoters.[77] Processing of the transcript initiated by the housekeeping promoter results in splicing of exon 1 to exon 3 and loss of exon 2. Transcription initiated by the erythroid promoter results in a transcript containing exons 2 through 15. Translation of erythroid mRNA is initiated at an AUG located in exon 3 because exon 2 lacks an AUG codon.[76] The AUG translational start codon in exon 1 of the housekeeping transcript is spliced in frame with the AUG in exon 3, thereby resulting in a protein 17 amino acids longer at the amino-terminus than the erythroid protein.[78]

Acute Intermittent Porphyria

Acute intermittent porphyria (AIP) is caused by mutations of the PBG-D gene. More than 300 PBG-D mutations have been described.[79] The spectrum of mutations includes point mutations, deletions, duplications, and insertions, and they have been found in the housekeeping promoter, in exons 1 and 3 through 15, and in each of the 14 introns. Exon 12 appears to be a mutational hot spot with 46 identified mutations.[79]

Frequency. AIP is transmitted as an autosomal dominant trait, although occasional homozygotes or compound heterozygotes have been reported.[57,80-83] AIP is the most common of the acute neurovisceral porphyrias, but estimates of prevalence vary according to the screening method used (clinical manifestations, erythrocyte PBG-D assays, molecular methods). Prevalence estimates based on clinical diagnoses range from 3 to 5 per 100,000 in Finland, Australia, and the United States.[84,85] Estimates of prevalence in Sweden are higher at 1 in 10,000, mainly because of a founder effect in northern Sweden.[86] When subnormal erythrocyte PBG-D activity is used for screening, the incidence of AIP in European populations is as high as 20 to 200 per 100,000.[87,88] Estimates based on erythrocyte PBG-D activity must be interpreted with caution because the normal range is wide, with considerable overlap between low-normal and high-activity carrier values. Additionally, improper sample processing, storage, and shipping lead to decreased enzymatic activity.[17] Molecular screening for PBG-D mutations on a large scale in a general population has not been done. It is likely that the prevalence of undetected gene carriers in the population may be high because most gene carriers remain free of symptoms throughout their lives and only 10% to 20% experience acute attacks.[89] In all series, clinical symptoms occur more commonly in women than men.

Clinical Manifestations. Clinical manifestations of AIP may occur before puberty in homozygotes or compound heterozygotes for PBG-D mutations, but most cases occur after puberty.[80,82,83,90] Pediatricians are likely to encounter adolescent patients with symptomatic AIP, particularly adolescent girls after menarche. Virtually all of the clinical signs and symptoms that characterize attacks of AIP are due to neurovisceral dysfunction (Table 13-2). Diffuse abdominal pain, often accompanied by nausea, vomiting, abdominal distention, and constipation, is the most common symptom of an acute attack.[85,91-95] The abdominal pain is usually unremitting and severe but may occasionally be cramping. Decreased bowel sounds and even signs of ileus are generally present, although some attacks may be associated with enhanced gut motility and diarrhea. Tachycardia is present in up to

TABLE 13-2	Signs and Symptoms of an Acute Porphyric Attack	
Signs and Symptoms	**Frequency***	**Comments**
GASTROINTESTINAL		
Abdominal pain	Common	Generally constant and not localized
Nausea and vomiting	Common	Accompanies abdominal pain
Constipation	Common	Urinary retention may occur also
Diarrhea	Uncommon	
NEUROLOGIC		
Pain in the back, chest, neck, head, extremities	Occasional	Pain may migrate to the abdomen. May be accompanied by a sensory neuropathy
Paresis	Common	More proximal than distal. Arms involved more often than the legs
Respiratory paralysis	Uncommon	Occurs with progressive motor neuropathy and paresis
Mental symptoms	Occasional	Ranges from agitation to psychosis
Convulsions	Uncommon	Mainly occurs with hyponatremia
CARDIOVASCULAR		
Tachycardia	Common	Rate control with β-blockers may be needed
Systemic arterial hypertension	Occasional	May become chronic and affect renal function

*Common, greater than 61%; occasional, 21% to 60%; uncommon, less than 20%.

80% of attacks,[94] but in some series the frequency is as low as 37%.[91] Other symptoms secondary to sympathetic overactivity or autonomic neuropathy include hypertension, tremors, sweating, and restlessness. Anxiety is a particularly common symptom, both during acute attacks and between attacks.[96] A variety of other neuropsychiatric symptoms associated with AIP ranging from hypomania to overt psychotic behavior have been described,[97-99] and psychiatric symptoms may be the only manifestation of biochemically evident AIP.[100,101]

Peripheral neuropathy may occur with or without an acute attack of abdominal pain. The neuropathy, caused by axonal degeneration, is manifested mainly as muscle weakness in the extremities.[102] Nerve conduction abnormalities may be minor, even with symptomatic weakness, but sophisticated studies of slow motor fiber conduction have been abnormal, even in the absence of symptoms.[103,104] Cranial neuropathies are uncommon, although blindness secondary to optic nerve involvement or occipital lobe involvement has been reported.[105,106]

Seizures may occur during an acute attack and are often associated with hyponatremia.[107] When serum sodium levels are normal, it is difficult to determine whether the seizure is due to porphyria or to coexistent idiopathic epilepsy. In a large study including 268 patients, the lifetime prevalence of seizures was 5.1% in those who had suffered at least one acute attack and 2.2% in known carriers.[107] Seizures occurring during latent periods are likely to be related to AIP. It is essential to establish a firm diagnosis of idiopathic epilepsy in patients with AIP who experience seizures because many antiseizure medications may precipitate acute attacks (see later). If seizures are associated with the hyponatremia of an acute attack, prolonged antiseizure therapy is not necessary.

Hyponatremia is a common finding during acute attacks.[91,108] Hyponatremia may be due to inappropriate

secretion of antidiuretic hormone,[109] but renal salt wasting has been implicated in patients with the lowest serum sodium levels.[91] Serum sodium values below 120 nmol/L are generally found only in severe attacks.[110]

The likelihood of full recovery after an acute attack has increased dramatically over the last 25 years, undoubtedly because of the introduction of effective therapy with hemin or heme arginate (see later). The risk of death, however, has not been eliminated. A review of 136 patients hospitalized with acute attacks at the University of Minnesota between 1940 and 1998 (i.e., both before and after the introduction of hemin therapy) found that 29 (21%) had died during an acute attack.[111] In a study from Finland and Russia, 7 of 55 patients (13%) died as the result of an acute attack between 1966 and 2002 (hematin therapy was first used in 1971[112] but was not widely used until 1978[113,114]). In another study of 47 Finnish patients ascertained between 1967 and 1989, six deaths (12.8%) occurred as the result of an acute attack.[89]

Pathogenesis. Heterozygotes for PBG-D mutations have approximately half-normal enzyme activity in all tissues, which is usually sufficient for heme homeostasis. The enzymatic defect becomes manifested when demand for hepatic heme is increased and ALA-S1 is induced. The result is increased production of ALA and PBG, which creates a situation in which the half-normal activity of PBG-D becomes rate limiting and PBG (and ALA) accumulate in hepatocytes, circulate in plasma, and are excreted in urine. Drugs are the most commonly recognized factors that increase the demand for hepatic heme, especially those metabolized by hemoprotein enzymes of the cytochrome P-450 family. Barbiturates, anticonvulsants, and steroid hormones are well-recognized precipitating factors in patients with AIP, but other factors not

directly connected with P-450 metabolism have also been incriminated, including fasting, dieting, and the stress of an acute illness.[115-117] Most drugs taken by patients with AIP and other neurovisceral porphyrias have been classified as unsafe, potentially unsafe, probably safe, or safe. Isolated case reports have resulted in many drugs being classified as unsafe or potentially unsafe, so caution needs to be exercised when drawing conclusions. Some drugs, however, have repeatedly been associated with acute porphyric attacks and must be avoided. A selection of such drugs is presented in Box 13-2.

The current prevailing view is that symptoms of the porphyric attack result from the toxic effects of ALA or PBG (or both) rather than from a deficiency of heme in neurons.[57,118] The most striking evidence in support of this view is a report of a young woman with AIP who suffered repeated, life-threatening attacks. An allogeneic liver transplant normalized urinary excretion of ALA and PBG within a day and eliminated her recurrent neurovisceral attacks.[118] In a second case, liver transplantation corrected the biochemical findings in a patient with variegate porphyria (VP).[119] These impressive case reports support the causative role of hepatic overproduction of ALA and PBG in acute neurovisceral attacks, but it is premature to consider liver transplantation as a broadly applicable treatment, especially with the efficiency of hemin or heme arginate infusions (see later).

Laboratory Diagnosis. The signs and symptoms of an acute porphyric attack are quite nonspecific, and correct diagnosis requires both consideration of a neurovisceral porphyria and performance of a highly specific laboratory test. An acute porphyria is frequently not considered until fruitless, expensive imaging studies (and often unnecessary surgical exploration) are complete.

Increased urinary excretion of PBG is the key diagnostic finding in patients suffering an acute attack of AIP, HCP, or VP. Most methods used to quantify urinary PBG excretion rely on formation of a violet pigment when the sample is reacted with *p*-dimethylaminobenzaldehyde (Ehrlich's aldehyde). Because Ehrlich's aldehyde reacts with other compounds secreted in urine, mainly urobilinogen, PBG must be partially purified. Ion exchange chromatography effectively separates PBG and ALA from interfering substances.[120] PBG can then be reacted with Ehrlich's aldehyde. ALA is condensed with ethyl acetoacetate to form a pyrrole, which will react with Ehrlich's aldehyde. Ion exchange chromatography is a rapid, specific assay when performed in an experienced laboratory and measures both ALA and PBG. Typical reference ranges for excretion of PBG are 0 to 18 µmol/day (0 to 4 mg/day); values for ALA range from 0 to 60 µmol/day (0 to 8 mg/day). In contrast, during an acute attack, urinary PBG excretion generally ranges from 220 to 880 µmol/day and ALA excretion ranges from 100 to 450 µmol/day.[17]

A simplified method for measuring PBG at the bedside or in the emergency department uses a small anion exchange column packed in a kit that includes all the required reagents and a color chart. The trace PBG kit (Thermo Trace/DMA, Arlington, TX) can detect PBG at concentrations greater than 6 mg/L.[121] The kit does not measure ALA.

Urinary porphyrin excretion (mainly uroporphyrin) is increased during acute attacks of AIP, but this finding is much less specific than increased excretion of PBG and ALA. Fecal and plasma porphyrin levels are generally normal. In contrast, increased urinary porphyrin excretion during an acute attack of HCP or VP consists mainly of coproporphyrin, and stool porphyrin excretion is also increased. Markedly increased stool coproporphyrin and protoporphyrin are found in VP. Fluorescence scanning of diluted plasma at neutral pH readily distinguishes VP from the other neurovisceral porphyrias, even during asymptomatic periods.[122,123]

A word of caution is required when interpreting urinary porphyrin values. Minimal elevations of urinary coproporphyrin may be found in patients with liver disease, marrow disorders, and a host of other illnesses. An incorrect diagnosis of porphyria is commonly made by overinterpreting minimal elevations in urinary coproporphyrin, which can lead to a delay in establishing the true cause of the abdominal pain and other neurovisceral symptoms.

Assays of PBG-D activity in erythrocyte lysates have been widely used to confirm the diagnosis of AIP and to detect asymptomatic family members once an index case has been identified. Erythrocyte PBG-D activity is approximately half-normal in most patient with PCT.

Normal PBG-D activity, however, does not exclude a diagnosis of AIP because of differential splicing of the PBG-D transcript in the liver and the red cell. Mutations in exon 1 of the PBG-D gene affect activity of the enzyme in the liver, but the erythrocyte enzyme is encoded only by exons 2 through 15.[76] Furthermore, the normal range for erythrocyte PBG-D activity is wide, and low-normal values overlap with high mutation carrier values. Falsely low values can be obtained when samples are processed, stored, or shipped improperly. It is important to emphasize that a valid half-normal measurement of erythrocyte PBG-D activity does not distinguish between asymptomatic (latent) and clinically manifested cases of AIP. Only urinary PBG levels can make this distinction.

Detection of PBG-D mutations by DNA analysis has proved to be more reliable than PBG-D enzyme assays and is now the preferred method for confirming a diagnosis of AIP and for identifying asymptomatic carriers. DNA studies have demonstrated that enzymatic assays may misclassify up to 15% of individuals tested.[124,125] Detection of mutations for AIP patients and their relatives is now readily available through the Department of Human Genetics at the Mount Sinai School of Medicine in New York.

Treatment. Treatment of an acute attack of AIP (and the other neurovisceral porphyrias) is designed to repress the activity of hepatic ALA-S1 and to offer supportive care and relief of symptoms. Intravenous infusions of heme result in a rapid reduction in levels of ALA and PBG in plasma and urine.[112,114,126] Heme binds to plasma hemopexin and albumin and is then taken up by hepatocytes, where it expands the heme pool and represses ALA-S1. Many small, uncontrolled trials have demonstrated both biochemical and clinical responses to infusion of heme.[112,114,126-130] In one study involving 22 patients suffering 57 acute attacks, all patients responded favorably; however, therapy was most beneficial when administered early in the attack,[128] a finding confirmed by others.[129,131] A single placebo-controlled trial found dramatic biochemical benefits of heme infusion, although clinical benefits were more difficult to confirm.[132]

Heme is not soluble at neutral pH, but solubilized hemin (heme chloride) and heme arginate have been administered to many patients. In the United States, a lyophilized preparation of hemin (Panhematin, Ovation Pharmaceuticals, Deerfield, IL) has been approved by the Food and Drug Administration for the treatment of acute porphyric attacks. Hemin is unstable when reconstituted with sterile water, and degradation may cause an anticoagulant effect and phlebitis at the site of infusion.[133,134] Phlebitis can be avoided by the use of intravenous catheters that extend to larger veins (e.g., the superior vena cava). Instability and the locally irritating effects of lyophilized hemin can be attenuated by solubilizing it in 25% albumin,[127] a method now recommended.[17] The recommended regimen for heme therapy is 3 to 4 mg/kg infused once daily on 4 consecutive days.

Clinical improvement generally occurs within 1 or 2 days, but when neuronal damage is severe because of a delay in initiating therapy, complete recovery may take months. The key to success is initiation of therapy as soon as an attack is recognized and completion of a 4-day course. Rare side effects of therapy include constitutional symptoms such as fever, myalgia, and malaise, but one case of marked hypotension[135] and another of transient renal failure[136] have been reported. The latter case was associated with an excessive dose (1000 mg) of hemin.

Heme arginate (Normosang, Orphan Pharmaceuticals, Paris) is more stable than hemin in solution, is equally effective, and is widely available in Europe and South Africa but remains an experimental drug in the United States. Phlebitis is a rare complication with heme arginate,[137] and the shelf life is considerably longer than that of hemin. Adenoviral-mediated expression of PBG-D corrects the metabolic defect in a mouse model of AIP,[138] but no studies have been performed in humans. Intravenous infusions of recombinant human PBG-D have been administered to normal subjects and asymptomatic PBG-D mutation carriers.[139] Transient decreases in plasma concentrations of PBG were noted, and no serious side effects occurred. No trials of recombinant PBG-D for the treatment of symptomatic AIP have been reported.

Intravenous infusions of glucose (300 to 500 g/day, administered as 10% glucose) may be effective when an attack is mild or until hemin is obtained[17]; however, glucose is far less effective than hemin. The mechanism of the glucose effect relates to the finding that transcription of ALA-S1 is upregulated by PGC-1α[12] and transcription of PGC-1α is controlled by the availability of glucose. Under conditions of low glucose, PGC-1α production is increased, thereby leading to increased levels of ALA-S1 and heme, conditions promoting a porphyric attack. Just the opposite would occur under conditions of high glucose. Regulation of ALA-S1 by PGC-1α ties together the observation that caloric deprivation can precipitate an acute porphyric attack with the benefits of high-dose glucose.[140] Insulin may also downregulate PGC-1α,[12] and it has been suggested that the combination of glucose and insulin may be more effective than glucose alone.[18]

Acute attacks require treatment of symptoms in addition to therapy directed at ALA-S1. Pain is often severe, and full doses of morphine or other opioids are both safe and effective. Phenothiazines in modest doses are safe and useful for control of nausea and anxiety.[17] Hypertension and tachycardia may respond to β-adrenergic blocking agents,[141,142] but these drugs should be used with caution when patients are hypovolemic because increased catecholamine secretion is often an important compensatory mechanism. Seizures during an acute attack can be a particularly vexing problem inasmuch as most antiseizure drugs have the potential to worsen the intensity of the attack. Clonazepam and gabapentin may be safe,[143-145] and benzodiazepines are probably safe.[17]

Hyponatremia and hypomagnesemia should be corrected because these abnormalities are common and may induce seizures.

Long-term management of patients with acute neuroviseral porphyrias is focused on the prevention of future attacks. Avoidance of unsafe drugs is critical, as is maintenance of a balanced, calorically adequate diet. In some women, acute attacks occur only in the luteal phase of the menstrual cycle. In such cases, gonadotropin-releasing hormone (GnRH) analogues can be highly effective.[146,147] Prolonged use of GnRH analogues in young women may cause irreversible bone loss, but low-dose transdermal estradiol may safely prevent this complication.[148,149] Both cyclic and noncyclic attacks may be prevented by frequent infusions of hemin[113]; however, the expense and the potential for iron overload (8 mg of iron per 100 mg of hemin) makes this option unattractive.

Levels of progesterone, an inducer of hepatic heme synthesis, are elevated in pregnancy, but pregnancy is well tolerated by most women with acute porphyrias. In a large series reported from Finland of 176 pregnancies in women with AIP or VP, porphyric symptoms occurred in less than 10%.[89] Worsening symptoms during pregnancy may be due to harmful drugs,[150,151] inadequate nutrition, or both.[17]

An unexplained finding in patients with AIP and VP is a 35- to 70-fold increased risk for the development of hepatocellular carcinoma.[152-156] It has been suggested that DNA damage induced by ALA may be responsible for these observations.[157,158]

Uroporphyrinogen III Synthase

The product of the PBG-D reaction, HMB (see Fig. 13-8), serves as the substrate for URO3-S. URO3-S catalyzes the asymmetric cyclization of HMB to the III isomer of uroporphyrinogen. The reaction involves "flipping" of the D ring to yield the asymmetric product (Fig. 13-9). Rearrangement of the D ring occurs by a complex mechanism involving cleavage and formation of carbon-carbon bonds.[159,160] Spontaneous cyclization of HMB can also occur (Fig. 13-10), but the product, uroporphyrinogen I, cannot ultimately be converted to heme. URO3-S functions as a monomer. Although the primary sequence is highly divergent, the crystal structure of human URO3-S and a bacterial URO3-S is nearly identical.[161,162] The structure of URO3-S from the bacterium *Thermus thermophilus* has been determined with the uroporphyrinogen III product bound.[162] The structure suggests that the enzyme prevents the formation of uroporphyrinogen I by positioning the A and D rings to favor the formation of uroporphyrinogen III (see Fig. 13-10).

The human URO3-S gene is localized to chromosome 10q25.2-26.3[163] (see Table 13-1) and contains 10

FIGURE 13-9. Reaction catalyzed by uroporphyrinogen III synthase. Uroporphyrinogen III synthase (URO3-S) enzymatically closes the tetrapyr-role ring with concomitant "flipping" of the D ring. The acetate (a) and propionate (p) side chains are labeled. In the uroporphyrinogen III product, the acetate and propionate groups of the D ring are reversed.
FIGURE 13-10. Proposed mechanism for formation of uroporphyrinogen III. Hydroxymethylbilane (HMB), structure 1, forms a spiro-lactam intermediate, structure 2. The intermediate is resolved by cleaving the carbon bond between pyrrole rings C and D on the opposite side, structure 3. The final step is closure of the macrocycle, structure 4, to form the III isomer of uroporphyrinogen. HMB can also cycle nonenzymatically to form uro-porphyrinogen I, structure 5.

coding exons.[164] The translational start site is located in exon 2B (see Fig. 13-5). Both housekeeping and ery-throid-specific transcripts are produced. The housekeep-ing promoter lies upstream of exon 1.[165] The housekeeping transcript results from a splicing event that joins exons 1 and 2B. The erythroid-specific promoter lies within intron 1 and contains eight GATA1 binding sites. The ery-throid-specific transcript contains all of exon 2. Although the housekeeping and erythroid transcripts are expressed from different promoters, they produce identical proteins.

Congenital Erythropoietic Porphyria (Günther's Disease)

Congenital erythropoietic porphyria (CEP) is a rare form of porphyria in humans caused by mutations in URO3-S. Fewer than 200 cases have been reported. The disorder is of historical interest in that it was the first porphyria

to be recognized as an inherited trait and the first to be characterized biochemically.[166-168] CEP also occurs in squirrels,[169] cows,[170] and other species.[171] More than 30 URO3-S mutations have been reported, including exonic and promoter point mutations, deletions, insertions, and splice site mutations.[172-176]

Frequency. The rarity of CEP makes estimating its frequency difficult, but the disorder has been described in multiple ethnic groups.[177] The frequency of heterozygosity for URO3-S mutations is not known because heterozygotes have no phenotype and population-based sequencing screens have not been done. Though rare, CEP is recognized more frequently than ALA-D porphyria, perhaps because of the dramatic cutaneous phenotype.

Clinical Manifestations. Cutaneous photosensitivity is the most dramatic feature of CEP and is usually recognized in early infancy. The diagnosis may be suspected because of the dark brown color of urine-soaked diapers that demonstrate a distinctive, intense red-pink fluorescence when illuminated with long-range ultraviolet light (e.g., Wood's light)[178] (Fig. 13-11). The severity of the skin lesions varies widely and is related to the amount of residual URO3-S activity,[179] which in turn determines the magnitude of porphyrin accumulation and excretion. In most cases the photosensitivity is severe and characterized by skin fragility, bullous lesions, ulcerations, and secondary infections.[177] If exposure to sunlight is not rigorously avoided, mutilation of the face and hands is the ultimate outcome (Fig. 13-12). A common finding in

CEP and the other porphyric disorders associated with photosensitivity is the presumably protective response of extensive hypertrichosis.[177] Photo-induced damage to nails and ocular structures may also occur.[177,180,181] A unique finding in children with CEP is red-brown discoloration of the teeth as a result of deposition of por-
FIGURE 13-11. The diaper from a child with congenital erythropoietic porphyria. Urine porphyrins, primarily uroporphyrin I, fluoresce with a brilliant pink color when illuminated with a Wood's light.

FIGURE 13-12. Skin changes in congenital erythropoietic porphyria (CEP). **A,** A 3-year-old boy with early facial photodermatitis. **B,** Severe case of CEP in an adult. Sun exposure has led to blistering, erosions, secondary infections, and subsequent photomutilation.

phyrins in dentine and enamel during tooth development.[182] The teeth fluoresce when illuminated with Wood's light.

Hemolytic anemia of varying severity is found in nearly all cases, but detailed morphologic findings in blood and bone marrow have been reported infrequently. Ineffective erythropoiesis may also be present. Poikilocytosis, nucleated red cells, and basophilic stippling are common, and the marrow demonstrates erythroid hyperplasia and may manifest marked dyserythropoiesis.[183-186] Fluorescence microscopy may demonstrate fluorocytes in peripheral blood, but this is more dramatic in bone marrow.[171,183,186,187] Splenomegaly generally accompanies the hemolytic anemia, and the magnitude of splenic enlargement reflects the severity of hemolysis. Leukopenia and symptomatic thrombocytopenia may occur as a result of splenic sequestration.[188]

A variety of osteolytic skeletal lesions have been described when the disease reaches the stage of mutilation.[177] Vitamin D deficiency secondary to sun avoidance may play a role in the development of osteolysis.[189] The role of porphyrins deposited in bone is uncertain, but at postmortem examination the skeleton is fluorescent under long-range ultraviolet light.[190]

Pathogenesis. Loss-of-function mutations in URO3-S lead to accumulation of the HMB substrate in erythrocyte precursors, which is readily converted nonenzymatically to uroporphyrinogen I (see Fig. 13-10). Residual URO3-S activity is generally less than 10% of normal. Uroporphyrinogen I may be auto-oxidized to uroporphyrin I or may serve as a substrate for uroporphyrinogen decarboxylase (URO-D) (see Fig. 13-2) and ultimately generate coproporphyrinogen I. This results in a metabolic "dead end" inasmuch as the next enzyme in the pathway, CPO, is stereospecific and will accept only coproporphyrinogen III as a substrate. Uroporphyrin I and, to a lesser extent, coproporphyrin I accumulate in erythroid precursors. Erythrocyte fragility and hemolysis result by an undefined mechanism and liberate porphyrins into plasma. Uroporphyrin I mediates the cutaneous photosensitivity[191] and is excreted in urine. Coproporphyrin I is excreted in stool and, to a lesser extent, in urine.

Two phenotypic forms of CEP have been reported. In one, a partial defect in URO-D combined with a congenital dyserythropoietic anemia produced mutilating photosensitivity and massive uroporphyrinuria.[192] The pattern of urinary porphyrin excretion differed from CEP in that large amounts of heptacarboxyl porphyrin were found in addition to even larger amounts of uroporphyrin. In the other, a mutation in the erythroid-specific transcription factor GATA1 resulted in subnormal URO3-S in red cells and a phenotype of CEP, thalassemia intermedia, and thrombocytopenia.[193]

CEP may become evident in adult life, and clinical symptoms are generally less severe than in the more typical early-onset cases. In most of the adult-onset cases, moderate URO3-S defects became evident only when an acquired marrow disorder developed.[194-199]

Laboratory Diagnosis. Urinary porphyrin excretion is massively increased in CEP, in some cases up to 1000 times normal. The pattern of porphyrin excretion, determined by high-performance liquid chromatography (HPLC), is characteristic. The dominant urine porphyrin is uroporphyrin I, with smaller amounts of coproporphyrin I.[200,201] Assays of URO3-S have been performed on erythrocytes and cultured cells, but the assays are available in just a few research laboratories.[202,203] The most practical way to confirm the diagnosis of CEP is through direct sequencing of the gene, a procedure available through the Department of Human Genetics at the Mount Sinai School of Medicine in New York. URO3-S mutations can be detected in chorionic villi or cultured amniotic cells.[204] This may be useful in subsequent pregnancies when parents have had a child with CEP.

Treatment. The only curative therapy for CEP is an allogeneic marrow transplant. Eleven patients with CEP who have undergone allogeneic transplantation have been reported.[193,205-209] The published experience suggests that early transplantation is preferred, but this approach is not universally applicable because of potential donor availability, treatment-related morbidity, and financial constraints. Allogeneic transplants should probably be restricted to the more severe cases of CEP because conservative management can yield longevity of 40 to 60 years.

The morbidity associated with marrow allografts could be avoided by autologous hematopoietic stem cell transplantation if stem cells could be stably transfected with normal URO3-S cDNA. This has been accomplished in a murine model of CEP with a lentivirus vector.[210] Complete correction of the phenotype was achieved. No studies of this type have yet been reported in humans with CEP.

Avoidance of sunlight is at the core of conservative management and can be achieved with protective clothing and effective sunscreens. Conventional sunscreens containing para-aminobenzoic acid are ineffective, and opaque "pancake" makeup is preferred. Splenectomy may reduce the severity of hemolysis and correct the leukopenia and thrombocytopenia, but beneficial effects on photosensitivity are often transient.[211] Erythropoiesis and endogenous porphyrin production can be suppressed with aggressive transfusion regimens,[212] although transfusion-induced iron overload results.[213]

MODIFICATION OF THE TETRAPYRROLE SIDE CHAINS

Uroporphyrinogen Decarboxylase

Uroporphyrinogen III is converted to coproporphyrinogen III by sequential removal of the carboxyl groups of the four acetate side chains to yield four methyl groups. This reaction is catalyzed by cytosolic URO-D

FIGURE 13-13. Reaction catalyzed by uroporphyrinogen decarboxylase (URO-D). Uroporphyrinogen undergoes four successive decarboxylations, starting at the asymmetric D ring. The acetate side chains (a) are decarboxylated to form methyl groups. URO-D will decarboxylate both the I and III isomers of uroporphyrinogen, but coproporphyrinogen I is not a substrate for coproporphyrinogen oxidase.

Uroporphyrinogen III

4 CO$_2$

URO-D

Coproporphyrinogen III
(Fig. 13-13). Decarboxylation of uroporphyrinogen III begins at the asymmetric D ring and proceeds in a clockwise manner.[214] Uroporphyrinogen III is the preferred substrate. The enzyme will accept uroporphyrinogen I as a substrate, but the product, coproporphyrinogen I, cannot be converted to heme.

Human URO-D is encoded by a single gene located on chromosome 1p34[215,216] (see Table 13-1). Unlike ALA-D, PBG-D, and URO3-S, there is no erythroid-specific promoter in the URO-D gene.[217] URO-D mRNA is highly expressed in developing erythrocytes, but the mechanism responsible for erythroid-specific upregulation is not known.[218]

URO-D has been purified from human erythrocytes,[219,220] from bovine liver,[221] and from yeast and bacteria.[222] Unlike most decarboxylases, URO-D does not require cofactors or prosthetic groups for activity. Determination of the crystal structure of human URO-D has revealed that URO-D functions as a homodimer.[223,224] Each monomer contains an active-site cleft. The active site can accommodate only the flexible porphyrinogen macrocycle[225] (Fig. 13-14). Oxidation of the bridge carbons connecting the pyrrole rings renders the molecule rigid and planar and may explain why uroporphyrin is not a substrate for URO-D.

Porphyria Cutanea Tarda

PCT is due to subnormal activity of URO-D in the liver. The disorder is characterized clinically by a photosensitive dermatosis that is usually less severe than in CEP. Expression of the clinical phenotype is associated with one or more risk factors, including homozygosity for the C282Y mutation of the hemochromatosis gene (*HFE*), hepatitis C, alcohol abuse, and the use of medicinal estrogens.[226-233] The frequency of these risk factors is far higher than the observed incidence of PCT, thus suggesting that susceptibility factors, either genetic or environmental and yet to be identified, are important determinants of disease expression.[234]
FIGURE 13-14. Crystal structure of uroporphyrinogen decarboxylase with uroporphyrinogen III bound in the active site. Uroporphyrinogen III (*green*) is shown in the active site. The fully reduced bridge carbons permit uroporphyrinogen to adopt the domed configuration positioning the 4-pyrrole nitrogens for hydrogen bonding with aspartic acid 86 (Asp86). The positive charge of arginine 37 (Arg37) interacts with the negatively charged propionate groups of uroporphyrinogen to correctly position the substrate in the active site. *(Figure based on the coordinates 1R3Y, available from the Protein Data Bank.)*

Two major variants have been identified. The first, designated familial PCT (F-PCT), is associated with heterozygosity for mutations at the URO-D locus.[235-237] F-PCT is transmitted as an autosomal dominant trait. Affected individuals display approximately half-normal URO-D activity and half-normal URO-D protein in all tissues.[236,238] There is considerable variation in URO-D activity inasmuch as different mutations have varied effects on enzyme activity.[239] F-PCT accounts for approximately 25% of clinically observed cases.[234,240,241] Most carriers of a mutant URO-D allele do not express a porphyric phenotype unless one or more of the risk factors mentioned earlier are also present.[234] Clinical expression

of F-PCT in childhood is rare.[242-247] The authors have evaluated three children with F-PCT, two of whom were brothers who were also homozygous for the C282Y *HFE* mutation.

The second major variant—and the most prevalent form of PCT—is designated sporadic PCT (S-PCT) and accounts for approximately 70% of cases.[234] In S-PCT, reduced activity of URO-D is restricted to the liver. No URO-D mutations have been identified in patients with S-PCT, and there is no evidence of a liver-specific URO-D transcript.[248] Nevertheless, S-PCT may cluster in families and thus suggests the presence of predisposing genetic factors.[249] The concentration of URO-D protein is normal in all cells, including hepatocytes, yet when the disease phenotype is expressed, enzyme activity is markedly reduced in the liver. A normal URO-D protein concentration coupled with subnormal URO-D enzymatic activity strongly suggests the presence of an enzyme inhibitor.[250-252] Risk factors identified when S-PCT is clinically evident are identical to those associated with F-PCT.[226,234]

A third rare variant of PCT occurs in children who have inherited two mutant alleles of URO-D.[226,253-256] This variant has been designated hepatoerythropoietic porphyria (HEP) because porphyrins accumulate in both the liver and red cells. Severely reduced levels of URO-D resulting from the genetic defect become rate limiting. Activity in red cell lysates is generally less than 10% of normal[257] but may be as high as 20% in patients with a mild phenotype.[255]

A fourth variant of PCT, designated toxic PCT, has been associated with exposure to halogenated aromatic hydrocarbons. An epidemic of toxic PCT occurred in Turkey between 1956 and 1961 after the ingestion of wheat treated with the fungicide hexachlorobenzene.[187,258] Many of the Turkish cases were children. Later studies in animals established that halogenated aromatic hydrocarbons diminish hepatic URO-D activity.[259-265] PCT in humans has also been reported after exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD)[266,267] and to dichlorophenols and trichlorophenols.[268]

Frequency. PCT is the most common of the porphyric disorders, but the incidence varies in different populations. In white populations of northern European origin, the incidence may be as high as 2 to 5 per 20,000, probably because of the high incidence of hemochromatosis gene mutations in this group.[268] In contrast, PCT is uncommon in African Americans but does occur in the Bantus of South Africa, in whom iron overload develops from drinking beer brewed in iron pots.[269] PCT has occurred commonly in patients undergoing chronic hemodialysis[270-272]; however, substitution of erythropoietin for red cell transfusions has reduced the incidence.

The high frequency of PCT, with a quarter of cases associated with URO-D mutations, would predict that HEP should not be rare. Instead, fewer than 40 cases have been reported.[255] This is best explained by embry-

onic lethality of the extremely low residual activity of mutant URO-D enzymes or the lethal effect of null alleles.

Clinical Manifestations. Skin fragility on the dorsal aspect of the hands is often the initial finding, but blistering lesions (bullae) then appear on all sun-exposed areas. The fluid-filled bullae rupture and the denuded area heals slowly, often forming thick eschars and eventually hyperpigmented patches (Fig. 13-15). Facial hypertrichosis is common, particularly in children and women. Facial hypertrichosis may be localized to periorbital regions (Fig. 13-16A) or can be manifested in a lanugo-like diffuse facial pattern with or without pigmentation (see Fig. 13-16B). In some patients, scleroderma-like skin changes develop, mainly in light-exposed areas.[273,274] When PCT becomes chronic, milia (small, cyst-like collections of keratin) are common on the hands.[275] Similar photocutaneous findings have been seen in patients with pseudoporphyria, a disorder in which plasma and urine porphyrins are normal. The skin findings are probably due to other photosensitizing compounds. Nonsteroidal anti-inflammatory drugs have been implicated in most cases.[276]

The cutaneous manifestations of HEP can be very dramatic and may resemble those seen in CEP.[277] Recurrent blisters and erosions complicated by infection can lead to severe scarring, scleroderma-like changes, and photomutilation.[80,257] In other cases, the skin is less severely damaged and appears more like mild PCT.[278,279] Hemolytic anemia and splenomegaly may be present, findings not associated with PCT.[257]

Evidence of abnormal liver function is nearly always present in patients with PCT, even in those without hepatitis C. In some reports, approximately 80% of males with PCT have been infected with hepatitis C,[230,280] but the association of hepatitis C with PCT is lower in northern

Europe.[280,281] The high concentration of porphyrins in the liver results in brilliant fluorescence of liver biopsy samples illuminated with Wood's light (Fig. 13-17). Microscopic examination reveals needle-shaped, fluorescent porphyrin crystals in hepatocytes.[282] Other histologic findings are not specific,[283] but increased hepatocellular iron stores are a nearly constant finding.[284-286]

Pathogenesis. More than 50 URO-D mutations have been identified in patients with PCT.[287,288] The functional consequences of many of these mutations have been studied,[288] but heterozygosity for mutant URO-D alleles alone cannot explain the phenotype because half-normal URO-D activity is not rate limiting. Immunoreactive URO-D in the liver of patients with clinically evident F-PCT is half-normal, yet enzyme activity is 25% of normal or less.[289] No URO-D mutations are found in patients with S-PCT, and immunoreactive URO-D in all tissues is normal. When S-PCT becomes clinically evident, immunoreactive URO-D in the liver remains normal, but

enzyme activity is reduced to approximately 25% of normal, the same level of activity found in F-PCT.[290,291] These findings indicate that the specific activity of hepatic URO-D is affected. Furthermore, the catalytic activity of URO-D returns to normal after phlebotomy-induced iron depletion,[289] thus suggesting that an iron-dependent process is responsible for the reduction in specific activity of hepatic URO-D. Similar findings, a reduction in URO-D activity without a change in URO-D protein, have been noted in several animal models of PCT.[292-296] Collectively, these data suggest a common mechanism in the pathogenesis of PCT, namely, generation of an inhibitor of URO-D by an iron-dependent mechanism.

The inhibitor of URO-D in humans with PCT and in animal models of PCT has been identified as uroporphomethene. Uroporphomethene differs from uroporphyrinogen by oxidation of a single bridge carbon between adjacent pyrrole rings[297] (Fig. 13-18). Uroporphomethene is sufficiently flexible to adapt to the spatial requirements of the active site of URO-D, but variance from the structure of uroporphyrinogen prevents the inhibitor from serving as a substrate.[297]

Generation of the uroporphomethene inhibitor probably requires liver-specific isozymes of cytochrome P-450[298]; however, the mechanism of the iron effect remains unidentified. Iron clearly plays a central role inasmuch as iron depletion through phlebotomy therapy reverses the clinical and biochemical phenotype. Replacement of iron removed by phlebotomy produces a prompt relapse.[299] Iron depletion prevents or dramatically attenuates the porphyric phenotype in animal models of PCT, and iron

supplementation accelerates development of the phenotype.[231,264] Despite these data, PCT develops in very few patients with hemochromatosis or other disorders associated with iron overload. Hepatic iron loading, therefore, is not sufficient to produce the PCT phenotype. Other factors, both genetic and environmental, appear to be required to create susceptibility to PCT.

The cutaneous findings in PCT, as in other porphyrias associated with photosensitivity, result from the interaction of light at a wavelength of approximately 400 nm (the Soret band) with porphyrins that accumulate in the skin.[300] The photo-excited porphyrin returns to a stable state by emitting energy as a photon that disrupts membranes and intracellular organelles.[301] The photodynamic reaction activates inflammatory mediators, which damage the epidermal basement membrane and cause fragility of the skin and blistering.[302] Another prominent site of photodamage is at the vascular level of the skin, where thickening of superficial dermal vessel walls is a constant finding.[303,304]

Laboratory Diagnosis. Laboratory testing is essential for confirmation of the clinical diagnosis of PCT and HEP. The appearance of the skin and skin biopsy findings resemble those of other photosensitizing porphyrias and pseudoporphyria. A useful initial approach to establishing that a porphyric disorder is present is to measure the total porphyrin content of plasma.[305] A normal value excludes the diagnosis of PCT and HEP. If the plasma porphyrin level is high, additional testing is required to distinguish PCT and HEP from HCP and VP. Chromatographic separation and quantification of urinary and stool porphyrins serve this purpose. In PCT and HEP, greatly increased amounts of uroporphyrin and heptacarboxyl porphyrin are excreted in urine (Fig. 13-19). Urinary excretion of coproporphyrin may be slightly increased.[285,306] Daily urine porphyrin excretion averages 3000 µg (normal, <50 µg) and may be considerably higher. Cutaneous symptoms are usually mild or absent

when uroporphyrin excretion is less than 1000 µg/day. A distinctive tetracarboxylic porphyrin, isocoproporphyrin, is excreted in feces, but total fecal porphyrin excretion is normal or minimally increased.[307] HEP can be distinguished from PCT by the presence of anemia and an increase in erythrocyte zinc protoporphyrin.[308]

Erythrocyte URO-D assays can be useful but are not widely available. Furthermore, distinguishing between F-PCT and S-PCT is not critical for patient management. Very low activity of URO-D in erythrocyte lysates can distinguish HEP from F-PCT and would affect therapeutic choices, but directly determining URO-D mutation status is more precise and facilitates genetic counseling.

In patients with PCT, additional laboratory testing is indicated to determine body iron burden (serum iron, total iron-binding capacity, and serum ferritin), liver function status, hemochromatosis genotype, and the presence or absence of antibodies to hepatitis C and human immunodeficiency virus.

Treatment. Two effective forms of therapy have been widely used in patients with PCT, phlebotomy and low-dose chloroquine. Phlebotomy is preferred in patients with marked increases in hepatic iron stores, as determined by liver biopsy and serum ferritin values. Removal of 500 mL of blood every 2 weeks for 3 to 4 months will usually surface,[285,309] but additional treatment is required for patients with hemochromatosis. The objective is to produce iron depletion, not iron deficiency. A useful target is a serum ferritin value of approximately 50 µg/L. Skin lesions clear when urine porphyrin excretion falls below 1000 µg/day, but it may take a year or more for the urine to become completely normal. Relapses are infrequent, especially if risk factors (alcohol and oral estrogens) are avoided. Transdermal estrogen administration after phlebotomy-induced remission of PCT in women, however, appears to be safe.[227]

Low-dose chloroquine therapy is an effective alternative treatment and at some centers is preferred for patients

FIGURE 13-19. Urine porphyrin profile in porphyria cutanea tarda (PCT). Urine porphyrins were separated by high-performance liquid chromatography and quantified fluorometrically. The tracing from a normal person is shown in *blue* with the scale on the right (0 to 7 absorbance units). The profile of urine porphyrins from a patient with PCT is shown in *red*, with the scale on the left (0 to 70 absorbance units). Uroporphyrin (URO) and 7-carboxyl porphyrin (HEPTA) predominate in the PCT sample, whereas coproporphyrin (COPRO) is the main porphyrin present in normal urine. The intermediate porphyrins with 6- and 5-carboxyl groups (HEXA and PENTA) are also increased in the PCT sample.
with modest iron overload.[310] The time required to produce clinical remission is longer than with phlebotomy, but ultimately, the results are equivalent. Chloroquine at a dose of 125 mg by mouth twice weekly (or hydroxychloroquine at a dose of 100 mg by mouth twice weekly) will gradually reduce plasma and urinary porphyrins.[311-313] Chloroquine concentrates in the liver, where a water-soluble complex with uroporphyrin is formed and promotes urinary excretion.[314] Higher doses of chloroquine should be avoided because marked hepatotoxicity may occur, an effect that is unique to patients with PCT.[315,316] There is some risk of retinopathy with low-dose regimens,[317] and transient, modest elevations in transaminase values may occur.[285] Because of these potential reactions to low-dose chloroquine regimens, many centers prefer phlebotomy unless comorbid conditions render it unsuitable.

In contrast to PCT, phlebotomy is not effective therapy for HEP,[257] and responses to chloroquine are infrequent and suboptimal.[318] Treatment of HEP, as with CEP, is focused on symptomatic relief by avoidance of sunlight, use of protective clothing, and topical application of opaque sun screens.

Coproporphyrinogen Oxidase

Coproporphyrinogen III, the product of the URO-D reaction, is transported across the outer mitochondrial membrane by an ATP-binding cassette transporter des-

ignated ABCB6.[319] CPO, located in the mitochondrial intermembrane space, catalyzes sequential oxidative decarboxylation of the propionate groups of pyrrole rings A and B of coproporphyrinogen III to form protoporphyrinogen IX (Fig. 13-20). CPO uses two molecules of O_2 and releases 2 molecules of CO_2 and H_2O_2.[320] It has been suggested that the mechanism of the oxidative decarboxylation requires molecular oxygen to act as the intermediate electron acceptor,[321] but recent data suggest that oxygen reacts directly with the targeted pyrrole ring to yield a hydroperoxide that acts as the electron acceptor.[322] The nuclear-encoded CPO protein possesses an unusually long leader sequence that is required for mitochondrial localization.[9]

CPO in humans, all eukaryotes, and some prokaryotes is an oxygen-dependent enzyme.[323] The crystal structure of both human and yeast oxygen-dependent CPO has been determined.[321,324] The enzyme functions as a homodimer.[323] The structure of CPO allows the enzyme to maintain the substrate as the reduced porphyrinogen, yet permits access of oxygen to the active site for the oxidative decarboxylation reaction and release of H_2O_2.[321,324] The human CPO gene has been cloned and is located on chromosome 3q12.[325] The CPO promoter region encodes an Sp-1–like element, a GATA site, and a novel regulatory element that interacts in a synergistic manner in erythroid cells.[326] The GATA site is not required for transcription in nonerythroid tissues, but the novel regulatory element is necessary. There is increased
FIGURE 13-20. Reaction catalyzed by coproporphyrinogen oxidase (CPO). The propionate groups on rings A and B of the tetrapyrrole are sequentially oxidatively decarboxylated with the formation of vinyl groups. The reaction consumes 2 molecules of molecular oxygen and produces protoporphyrinogen IX (proto'gen IX), plus 2 molecules of carbon dioxide and hydrogen peroxide. Copro'gen, coproporphyrinogen.

expression of CPO in erythroid cells, a finding consistent with erythroid upregulation mediated by the GATA site.[327]

Hereditary Coproporphyria

Mutations in CPO are the cause of HCP. The disorder is transmitted as an autosomal dominant trait with low penetrance. Affected individuals and nonpenetrant mutation carriers have half-normal CPO activity.[328] Acute neurovisceral attacks are identical to those that occur in patients with AIP, but photo-induced skin lesions are occasionally present. Onset before puberty is extremely rare, although several early-onset cases attributable to homozygosity or compound heterozygosity for CPO mutations have been reported.[329,330] Homozygosity for a specific CPO mutation is responsible for a rare form of homozygous HCP, designated harderoporphyria, with onset in infancy and with a prominent erythroid phenotype.[331] Harderoporphyrin is a tricarboxylic porphyrin in which the propionate on the A ring is oxidized to a vinyl group but the propionate on the B ring is not. Harderoporphyrin was named for an unusual porphyrin found in the rat harderian gland. It was later learned that the porphyrin found in the rat was a glycoconjugate of protoporphyrin and not a tricarboxylic porphyrin, thus rendering the term harderoporphyrin a misnomer.[332]

Frequency. The prevalence of HCP is not known, but it is clearly lower than the prevalence of AIP. Homozygous HCP is very uncommon; however, important clinical manifestations occur in children. Harderoporphyria is even more rare, with only six cases reported.

Clinical Manifestations. Acute neurovisceral attacks in patients with HCP are clinically indistinguishable from the acute attacks in patients with AIP. In a series of 53 German patients,[333] abdominal pain was the most common symptom (89%). Neurologic, psychiatric, and cardiovascular symptoms occurred in 25% to 33% of cases. Cutaneous symptoms occurred in only 14%. Similar findings were reported in an earlier series from the United Kingdom, but the incidence of cutaneous findings was slightly higher.[334] The cutaneous findings are the sole feature of HCP that distinguishes an attack from AIP. Most acute attacks of HCP are precipitated by drugs (see Box 13-2)[335]; however, attacks may also occur in association with menstrual cycles. The cutaneous photosensitivity is manifested mainly as bullous lesions and is generally present only in acute attacks. The bullae resemble those seen in PCT, but chronic scarring reactions are uncommon because the photosensitivity is intermittent. Rarely, intermittent photosensitivity may be the only clinical sign of HCP.[334] In children who are homozygotes or compound heterozygotes for CPO mutations, the disorder is an early-onset phenocopy of clinically affected adults who are simple heterozygotes. Growth retardation, hypertrichosis, and skin pigmentation are additional findings in early-onset cases.[329,330]

The clinical manifestations of harderoporphyria are quite different. Hemolytic anemia, intense jaundice, and hepatosplenomegaly are present at or shortly after birth.[331,336] Bullous skin lesions develop if therapy for neonatal jaundice is undertaken. The urine appears red. Nucleated erythrocytes are present on the peripheral blood smear. Exchange transfusions have been helpful. With time, the hepatomegaly resolves but the splenomegaly remains. The hemolytic anemia becomes partially compensated, and additional transfusions are not necessary. The cutaneous photosensitivity persists, and by the teenage years, the skin resembles that seen in PCT. Acute neurovisceral attacks do not occur.

Five of the six reported cases of harderoporphyria occurred in three families, and in all cases homozygosity for a mutation present in exon 6 (K404E) was detected.[337] The sixth patient, a Japanese newborn with jaundice, hemolytic anemia, hepatomegaly, and photosensitivity, proved not to be homozygous for a CPO mutation. This infant was heterozygous for the K404E mutation, inherited from the father, but enzyme activity was not measured in the child or the parents. A promoter mutation in one maternal allele was suspected as the cause of the harderoporphyria phenotype in the child.[338]

Pathogenesis. Accumulation and excretion of coproporphyrin are best explained by loss-of-function mutations in CPO, but acute neurovisceral attacks, as in AIP, require induction of hepatic ALA-S. More than 30 CPO mutations have been described in patients with HCP and homozygous HCP.[339] The mutation responsible for harderoporphyria, K404E, is of special interest because it affects mainly the second decarboxylation reaction in the conversion of coproporphyrinogen III to protoporphyrinogen IX. One other mutation, R401W, that was found in a patient with HCP was expressed in vitro, and a defect in the second decarboxylation reaction was also found.[339] These findings suggest that a region around residues 401 and 404 is important for retaining the tricarboxylic intermediate (harderoporphyrin) in the active site and permitting the second oxidative decarboxylation. The distinctive erythroid phenotype of harderoporphyria is difficult to explain but must be related to a peculiar toxic effect of harderoporphyrin. The accompanying photosensitivity is probably due to the photodynamic properties of coproporphyrin. The roles of ALA and PBG in the pathogenesis of the acute neurovisceral attacks are as described for AIP.

Laboratory Diagnosis. Increased levels of fecal coproporphyrin III are the most prominent findings and are always present in clinically affected cases.[333] The ratio of coproporphyrin III to coproporphyrin I in feces is markedly increased, even in asymptomatic heterozygotes.[333] Urinary excretion of coproporphyrin is strikingly increased during acute attacks but generally returns to normal during remission. Similarly, urinary excretion of ALA and PBG is increased during attacks but then returns to normal. The laboratory findings in homozygous HCP are the same; however, the abnormalities are more dramatic.

Laboratory findings in harderoporphyria are characterized by the presence of harderoporphyrin in feces along with increased amounts of coproporphyrin III. Urinary excretion of coproporphyrin is also increased, and trace amounts harderoporphyrin may be found. There is no increase in the urinary excretion of ALA or PBG. Modest increases in erythrocyte protoporphyrin are detected, but harderoporphyrin is not present in red cells.[336,337] Iron overload as a consequence of chronic hemolysis and ineffective erythropoiesis has also been reported.[337]

Assays for CPO activity have been used but are difficult to perform and are not widely available. Red cells are not a ready source of the enzyme because CPO is localized in mitochondria. Lymphocytes or cultured cells are required.[72] DNA sequencing is the most direct approach, but the biochemical phenotype is so distinctive that a secure diagnosis can be made by simply analyzing fecal and urine porphyrins. Misdiagnosis of HCP is a common problem because urinary coproporphyrin excretion may be minimally increased in many nonporphyric conditions.

Treatment. Acute neurovisceral attacks are treated as in AIP. Hemin therapy is useful.[340] Although the skin lesions resemble those of PCT, phlebotomy and chloroquine are not effective. The chronic photosensitivity associated with homozygous HCP and harderoporphyria is best managed by avoidance of sunlight, protective clothing, and opaque sunscreens. The extreme jaundice and hemolytic anemia in newborns with harderoporphyria responds to exchange transfusions. Phototherapy should be avoided. The chronic compensated hemolytic anemia requires supplementation with folic acid and may require orally administered iron chelators.

ENZYMATIC OXIDATION OF PROTOPORPHYRINOGEN IX TO PROTOPORPHYRIN IX AND INSERTION OF IRON

Protoporphyrinogen Oxidase

Protoporphyrinogen IX is oxidized to protoporphyrin IX by PPO (Fig. 13-21). PPO is functionally conserved in eukaryotes despite low sequence identity. PPO is an intrinsic protein of the inner mitochondrial membrane and requires molecular oxygen and the cofactor flavin adenine dinucleotide (FAD). Three molecules of oxygen serve as terminal acceptors in the six-electron oxidation reaction, and hydrogen peroxide is generated rather than water.[341-343] The reaction proceeds via three two-electron oxidations rather than one six-electron oxidation.[344]

The crystal structure of tobacco PPO revealed that the enzyme functions as a homodimer.[345] Each monomer contains one noncovalently bound FAD molecule. PPO is synthesized in the cytosol and locates to the outer surface of the inner mitochondrial membrane. The human PPO protein does not contain a cleavable leader sequence but contains a mitochondrial targeting sequence within the first 175 residues. The 28 N-terminal residues have some features of a presequence that functions as an independent mitochondrial targeting sequence.[346] Deletion of these residues, however, does not prevent translocation to mitochondria, thus indicating that more distal regions are required for efficient import and insertion into the inner mitochondrial membrane.[347] There is a single 1.8-kb transcript of PPO in all tissues.[343] The human PPO gene is located on chromosome 1q22-q23.[348,349] The 5′ flanking region of human PPO contains a GATA1 binding site, which suggests the potential for erythroid-specific regulation. Induction of erythroid differentiation in mouse erythroleukemia cells with dimethyl sulfoxide leads to increased expression of PPO.[349]

Variegate Porphyria

VP is transmitted as an autosomal dominant trait resulting from subnormal activity of PPO.[350] The clinical and biochemical features of the disease were first described
FIGURE 13-21. Reaction catalyzed by protoporphyrinogen oxidase (PPO). Protoporphyrinogen IX (Proto'gen IX) is oxidized to protoporphyrin IX (Proto IX) with the loss of six protons. Three molecules of molecular oxygen are consumed, and three molecules of hydrogen peroxide are formed in the reaction.

in 1937,[351] but VP was not recognized as a distinct porphyric disorder until the description by Dean and Barnes in 1955.[352] The term VP was applied when it was recognized that patients had either cutaneous photosensitivity, a predisposition to acute neurovisceral attacks, or both. Onset before puberty is extremely rare, but early onset with marked photosensitivity has been reported in children homozygous for PPO mutations or with compound heterozygous genotypes.[80]

Frequency. The prevalence of VP in Europe is established at 0.5 per 100,000.[81] The prevalence is higher in Finland at 1.3 per 100,000,[353] but the disease is extraordinarily common in South Africa, where its prevalence is estimated at 3 per 1000 in the white population.[91] The high prevalence in South Africa is due to a founder mutation introduced from the Netherlands in 1688.[354] The connection with the Netherlands has been confirmed by haplotype association studies in South African and Dutch families with VP.[355] Clinical penetrance in earlier reports was estimated at approximately 90%,[356] but the advent of molecular genotyping and sensitive biochemical markers has reduced the estimate to approximately 40% of PPO mutation carriers.[355,357]

Clinical Manifestations. The acute attacks in patients with VP are identical to those seen in AIP but occur at a lower frequency and a later age.[91] Skin manifestations in VP are similar to those in PCT[358] and are of long duration. In a heterozygous western European population of 103 clinically affected patients with VP, 59% had skin lesions only, 20% had acute neurovisceral attacks only, and 21% had both.[359] This distribution is similar to that observed in a 1980 report from South Africa.[356] In contrast, recent reports from South Africa and Finland indicate a marked reduction in acute attacks and a less dramatic decrease in photosensitivity, changes thought to be due to systematic detection of mutant PPO alleles in families and avoidance of potentially harmful drugs.[91,357]

Homozygous VP in two young siblings was first described by Korda and colleagues in 1984.[360] The clinical phenotype differed dramatically from adult-onset VP. Marked photosensitivity from birth, mental retardation, and seizures were described, although no acute neurovisceral attacks occurred. Since then, more than a dozen additional cases have been described.[361-366] Severe cutaneous manifestations beginning in infancy have been a constant finding. Short stature is common, but mental retardation and seizures are not. A peripheral sensory neuropathy and deformities of the hands were noted in some patients, but in no cases were neurovisceral attacks described.

Pathogenesis. A wide variety of PPO mutations in families with VP have been reported in different ethnic groups.[357,359,367,368] A single mutation, R59N, is found in almost all cases in South Africa.[369,370] There appears to be no correlation between specific mutations and the severity of the clinical syndrome. In all cases, the activity of PPO is approximately half-normal.[371,372] The cutaneous manifestations of VP are due to the photodynamic properties of protoporphyrin and coproporphyrin. The acute neurovisceral attacks are due to episodic overproduction of ALA and PBG. The extreme photosensitivity seen in early-onset VP is mediated by very elevated plasma porphyrins.[373] Most of the early-onset cases have been heteroallelic for PPO mutations (i.e., compound heterozygotes) with markedly reduced PPO activity.[365]

Laboratory Diagnosis. When acute attacks of VP occur, fecal protoporphyrin and coproporphyrin and urinary coproporphyrin are markedly elevated.[357] VP can be distinguished from HCP and AIP by detection in plasma of a characteristic fluorescence emission spectrum with a maximum at 626 nm.[122] This emission spectrum results from a dicarboxyl porphyrin bound to plasma proteins.[374] Detection of the 626-nm peak in plasma is a useful method of identifying asymptomatic gene carriers and is more sensitive than fecal porphyrin analysis.[355,375] Urinary ALA and PBG are increased during acute attacks but may be normal during remissions.

Homozygous VP is characterized by markedly increased erythrocyte zinc protoporphyrin levels and

elevated stool protoporphyrin and coproporphyrin levels. PPO activity can be measured in cells that contain mitochondria,[376] but enzyme assays are not widely available. Direct fluorometric measurement of plasma porphyrins is probably the most rapid method of establishing the diagnosis of VP. Sequencing of the PPO gene is being applied more widely and is available through the Department of Human Genetics at the Mount Sinai School of Medicine in New York.

Treatment. Treatment of acute attacks is as described for AIP and HCP. Protection from sunlight is the only practical way to manage the photosensitivity. Phlebotomy therapy, chloroquine, and hemin are not effective.[350,377,378] A single patient with symptomatic VP has been treated with a liver transplant.[119] The indication for transplantation was advanced alcohol-induced cirrhosis. After transplantation, fecal porphyrin values returned to normal and no further cutaneous or neurovisceral symptoms occurred. Improved treatment, detection of latent family members, and avoidance of potentially harmful drugs have improved the outcome and reduced disease-related morbidity.[91,355]

Ferrochelatase

The final step in the heme biosynthetic pathway, insertion of iron into protoporphyrin IX, occurs on the matrix side of the inner mitochondrial membrane, a reaction catalyzed by FECH (Fig. 13-22). Human FECH has been crystallized and the enzyme functions as a homodimer.[379] Each monomer of FECH contains a nitric oxide–sensitive 2Fe-2S iron-sulfur cluster bound to a cysteine-rich site at the C-terminal.[380] It has been suggested that a direct interaction occurs between PPO on the outer surface of the inner mitochondrial membrane and FECH on the inner surface.[345] This arrangement would permit direct transfer of protoporphyrin IX from PPO to the active site of FECH. This mechanism has been questioned, however, inasmuch as experiments using isolated mitochondria indicate that a complex

between enzymes is not required for synthesis of heme.[381]

The human FECH gene has been cloned and mapped to chromosome 18q21.3.[382] The same transcriptional start site is used in erythroid and nonerythroid tissues and contains binding sites for both housekeeping and erythroid-specific promoter elements.[383] FECH is synthesized in the cytosol and targeted to mitochondria by sequences in the leader peptide,[384] followed by cleavage to produce the active, mature protein. The first 62 amino acids in the leader sequence are sufficient for mitochondrial targeting, but an additional 11 residues are required for efficient proteolytic processing.[385] Expression of FECH is regulated by intracellular iron levels, probably related to the enzyme's requirement for iron-sulfur clusters.[327] Additional regulatory effects occur through interactions with hypoxia-inducible factor.[386]

Erythropoietic Protoporphyria

Erythropoietic protoporphyria (EPP) is an inherited disorder of heme biosynthesis characterized clinically by the onset in childhood or infancy of acute photosensitivity of sun-exposed skin. The disorder was first recognized in 1953 by Kosenow and Treibs[387] but was clinically characterized and named EPP by Magnus and associates in 1961.[388] The inherited nature of the disease was first reported by Haeger-Aronsen in 1963.[389] In most cases, EPP is due to deficient activity of FECH associated with loss-of-function mutations of the FECH gene, but in some cases, EPP results from mutant alleles of the mitochondrial iron importer mitoferrin.[390,391] In a minority of patients with EPP, the excess protoporphyrin IX generated in erythrocytes causes severe cholestatic liver disease requiring liver transplantation.[392]

Frequency. The prevalence of clinically manifested EPP has been difficult to estimate but is probably close to that of AIP. In the European immigrant population of South Africa, clinically evident EPP is estimated to occur in 6.6 individuals per million.[393] The prevalence in the United Kingdom is approximately 7.7 per million.[394]

FIGURE 13-22. Reaction catalyzed by ferrochelatase (FECH). The final step in the synthesis of heme is insertion of ferrous iron into the protoporphyrin IX (Proto IX) macrocycle with the release of two protons.

PROTO IX

HEME
Prevalence estimates for Northern Ireland and the Netherlands have approached 13 per million,[395,396] a finding attributed to a founder effect.[397] A report from Slovenia estimated an even higher prevalence at 17.5 per million.[398] EPP is pan-ethnic but is extremely rare in individuals of African descent.[393]

Clinical Manifestations. The dominant clinical feature of EPP is cutaneous photosensitivity in response to sun exposure with onset in infancy or childhood.[399,400] The clinical picture is very different from that of the other photosensitizing porphyrias. A characteristic burning pain, erythema, and edema develop as an acute response to sun exposure.[394] Early in the course of EPP, the burning discomfort may occur in the absence of objective cutaneous findings.[401,402] Bullous lesions, pigment changes, and scarring are very uncommon. Instead, the skin develops a leathery characteristic that mimics premature aging. The symptoms and objective skin findings change little over time, but increased sun tolerance has been reported during pregnancy.[403,404]

A mild, microcytic anemia is common,[400,405-407] presumably caused by impaired heme synthesis. Iron may accumulate in the cytosol and mitochondria of erythroblasts, but such findings are uncommon.[408] A similar microcytic anemia develops in a mouse model of EPP because of homozygosity for mutant FECH alleles.[409] Serum ferritin values in humans with EPP are reduced, but erythropoiesis does not appear to be limited by iron.[406]

Gallstones develop in approximately 10% of patients with EPP and tend to occur early in life.[400,410] The gallstones contain protoporphyrin IX, which becomes insoluble in bile and alters the solubility of other components of bile.[411,412] When gallstones develop in children, a diagnosis of EPP should be considered.[413] Minor abnormalities in liver function tests, mainly elevations in transaminases, are common,[399] and liver biopsy may demonstrate deposition of protoporphyrin and periportal fibrosis.[400,414-417]

Severe cholestatic liver disease progressing to portal hypertension and fatal decompensated cirrhosis will develop in between 1% and 5% of patients with EPP.[392,418,419] Rarely, acute liver failure may be the initial feature of EPP.[420,421] Approximately 50 fatal cases of EPP-related liver disease have been reported,[392,395,422-424] including two teenagers and an 11-year-old child.[395]

Pathogenesis. More than 85 mutations in the FECH gene have been detected.[393,425,426] The mode of mendelian transmission had been described as autosomal dominant with incomplete penetrance, but heterozygotes expressing the clinical phenotype have consistently shown FECH activity between 15% and 20% of normal.[427] This was explained by a proposed dominant negative effect in which both mutant-mutant homodimers and mutant–wild type homodimers are catalytically inactive, with only wild type–wild type homodimers being responsible for

the measured enzyme activity. This theory was discarded with the discovery of a hypomorphic FECH allele that is common in the population.[428-430] An intragenic polymorphism (IVS 3-48C) in intron 3 is responsible for low expression of the hypomorphic allele. This polymorphism favors the use of a cryptic acceptor splice site 63 bases upstream of the normal splice site. The aberrantly spliced mRNA contains a premature stop codon and is degraded by a nonsense-mediated decay mechanism.[430] The result is a lower steady-state level of wild-type FECH mRNA. Virtually all clinically evident cases of EPP are due to coinheritance of the hypomorphic allele in *trans* to a loss-of-function mutant allele. This genetic combination was found in 98% of French patients with EPP[431] and at a similar frequency in South African patients.[393] The frequency of the IVS 3-48C hypomorphic allele varies widely in different populations and is related to the observed differences in the prevalence of EPP.[431,432]

The rare exception to the compound heterozygous mutant/hypomorph genotype is inheritance of two loss-of-function FECH alleles. The autosomal recessive form of EPP was found in 3% of patients with EPP in the United Kingdom[426] and in occasional cases from other countries.[393,427,433-435] The autosomal recessive form of EPP may carry a higher risk for severe liver disease.

The genetics of EPP is complicated further by the discovery of a phenocopy caused by a mutation in the gene encoding mitoferrin, the principal mitochondrial iron importer.[390,391] Eight patients from six families referred to a liver center because of advanced liver disease were found to be heterozygous for a 477-base insertion in intron 2 of the mitoferrin gene that generates a stop codon at codon 156 in exon 3. None of the patients had FECH-coding mutations or the IVS 3-48C polymorphism.[390] One South African family with a highly penetrant EPP phenotype, yet no mutant FECH alleles, has also been described.[393] Affected members of this family had high levels of erythrocyte zinc protoporphyrin rather than the usual free erythrocyte protoporphyrin, thus suggesting that impaired iron delivery to mitochondria was the underlying defect.

Laboratory Diagnosis. The free erythrocyte protoporphyrin concentration is markedly increased in symptomatic EPP.[400,436] Values ranging from 6- to 100-fold greater than normal have been reported. Elevated erythrocyte protoporphyrin levels are also found in patients with iron deficiency and lead poisoning, but in these conditions the elevation is less dramatic and it is zinc protoporphyrin that is present.[437] Zinc protoporphyrin can easily be distinguished spectrally from the free protoporphyrin found in EPP.[438] Zinc protoporphyrin can also be distinguished from free protoporphyrin by chromatographic techniques.[72] An elevated plasma porphyrin level confirms the presence of a porphyric disorder, but false-negative results may be obtained in patients with EPP because protoporphyrin is particularly susceptible to photodegra-

dation.[439] Care must be taken to shield the plasma sample from sunlight or fluorescent lighting.

Fecal protoporphyrin excretion may be increased up to 15-fold, although values vary widely from patient to patient.[440] Urinary excretion of ALA and PBG is normal. Protoporphyrin, a highly hydrophobic compound, is not excreted in urine.

Assays for FECH activity are not widely available. Detection of FECH mutations is the most direct approach to confirm the diagnosis of EPP. Molecular studies are also the only reliable method for identifying asymptomatic cases in families with an affected proband.

Treatment. Treatment of EPP has two objectives. First, an attempt should be made to minimize the harmful effects of exposure to sunlight. Protective clothing and opaque sunscreens can be helpful, as with other photosensitizing porphyrias. Tolerance to sunlight can be improved in most patients with EPP by inducing carotenemia. This can best be accomplished by administering β-carotene beadlets (Lumitene, Tishcon Corp., Westbery, NY) in doses ranging from 120 to 300 mg/day.[441,442] The only side effect is a dose-related, yellow-orange discoloration of the skin.[443,444] The mechanism of action of β-carotene probably involves quenching of singlet oxygen species or free radicals.[445]

The second objective of therapy is to minimize the hepatotoxic effects of protoporphyrin. Cholestyramine can interrupt the enterohepatic circulation of protoporphyrin excreted in bile and promote fecal excretion. This has been moderately effective in some patients.[411] Oral administration of bile salts (ursodeoxycholic acid or chenodeoxycholic acid) can increase excretion of protoporphyrin into bile.[446,447] A variety of other measures have been used when liver function deteriorates, including plasmapheresis, hemodialysis, exchange transfusions, and suppression of erythropoiesis.[392] In the small proportion of patients with EPP in whom liver failure develops, liver transplantation is the only effective therapy.[392,448,449] Liver transplantation, however, does not address the underlying overproduction of protoporphyrin in the native marrow, and recurrent disease can develop in the transplanted liver.[449-451] This complication was successfully managed in a 15-year-old boy with a bone marrow allograft from an HLA-matched sibling who did not have EPP.[452]

14 Autoimmune Hemolytic Anemia

Russell E. Ware

The vast majority of erythrocyte disorders that occur in the pediatric age group result from abnormalities within the red blood cell (RBC); that is, they are intracorpuscular defects. These intrinsic RBC defects include a wide variety of inherited genetic mutations, as well as acquired nutritional deficiencies, and lead to defects in globin chain and heme synthesis, abnormal membrane structural proteins, or defective intracellular enzymes. Particularly in the congenital conditions, intracorpuscular defects often result in a shortened erythrocyte life span, premature destruction of the erythrocytes (hemolysis), and anemia.

A less common category of erythrocyte disorders includes conditions characterized by abnormalities external to the red cells, known as extracorpuscular defects. Examples include environmental stress (oxidation, toxins, heat, or mechanical injury), microangiopathic erythrocyte damage (hemolytic-uremic syndrome [HUS] or thrombotic thrombocytopenic purpura [TTP]), or immune-mediated RBC destruction. Like many of the intrinsic conditions, extrinsic erythrocyte disorders are typically associated with hemolysis and anemia.

Disorders that result from abnormal interactions between erythrocytes and the immune system are collectively referred to as immune-mediated hemolytic anemia. The most common type is autoimmune hemolytic anemia (AIHA), characterized by the presence of autoantibodies that bind to the erythrocyte surface membrane and lead to premature red cell destruction. Specific characteristics of the autoantibodies, particularly the isotype, thermal reactivity, and ability to fix complement, help shape the resulting clinical picture. In all patients with AIHA, however, the autoantibody leads to shortened RBC survival, hemolysis, and anemia. Additional types of immune-mediate hemolytic anemia reflect abnormal interactions between erythrocytes and varied components of the complement and hemostasis systems, as well as the vessel wall. The reticuloendothelial system, primarily the spleen, plays a critical role in premature destruction of erythrocytes in all forms of immune-mediated hemolytic anemia.

This chapter begins with a description of the spleen, whose anatomy and physiology provide a unique environment for the clearance of normal and abnormal erythrocytes. Three important clinical forms of primary AIHA are then described: (1) warm-reactive AIHA, characterized by an autoantibody (usually immunoglobulin G [IgG]) that binds preferentially to erythrocyte antigens at 37° C, fixes complement in some cases, and leads primarily to extravascular hemolysis; (2) paroxysmal cold hemoglobinuria (PCH), in which an IgG erythrocyte autoantibody binds optimally at 4° C, fixes complement efficiently, and causes mainly intravascular hemolysis; and (3) cold agglutinin disease, characterized by an autoantibody (typically IgM) that binds optimally to erythrocytes below 37° C, fixes complement efficiently, and also leads primarily to intravascular hemolysis. These three disorders are discussed together because of their many similarities, although differences in pathophysiology and therapy are emphasized. Secondary forms of AIHA are then described, including Evans syndrome and autoimmune lymphoproliferative syndrome (ALPS). The next section describes paroxysmal nocturnal hemoglobinuria (PNH), a rare and fascinating acquired hematologic disorder that features hemolysis caused by abnormal interactions between erythrocytes and the complement system. Unlike true AIHA, the defect in PNH is intracorpuscular, but the clinical findings may be similar. Advances in the understanding of PNH are described, including its recognition as an acquired clonal stem cell disorder and identification of specific acquired mutations in the phosphatidylinositol glycan class A (*PIGA*) gene in affected patients. Finally, miscellaneous extracorpuscular disorders that lead to schistocytic hemolytic anemia are described, including congenital and acquired microangiopathy, preeclampsia, and environmental stressors such as heat, toxins, or mechanical injury.

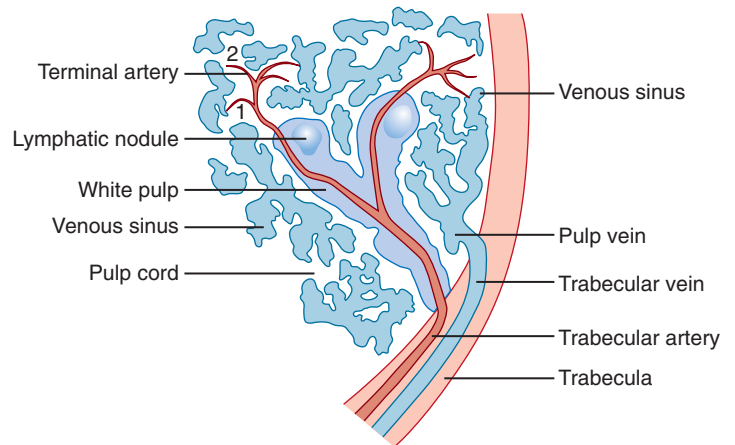
THE SPLEEN

Historical Perspective

Since ancient times the spleen has occupied a mysterious niche among organs within the human body. Its proposed functions and necessity for good health were subjects of debate and discussion for centuries, as recently reviewed.[1] Only in the last few decades has this enigmatic organ begun to yield its secrets and reveal its prominent and vital role in providing important hematologic and immunologic functions.

Hippocrates believed that the spleen helped balance the body's "humors," a process necessary to promote harmony and stability. Plato and Aristotle agreed with this notion of the spleen absorbing unhealthy body fluids but further suggested, based on its location, that it assisted or balanced the liver. Galen noted the anatomic connections among the spleen, liver, and stomach and concluded that the spleen had true digestive functions that included the filtering of humoral impurities. Subsequently, the spleen gained a reputation for controlling feelings and emotions, including laughter, ill temper, melancholy, and others. Shakespeare often referred to the spleen as an organ of anger, merriment, or other strong emotion.

During the Renaissance, when the study of anatomy and physiology became popularized, the spleen's microscopic patterns supported a role for filtration; however, only circulatory connections between the spleen and the stomach, liver, and other digestive organs could be identified. Moreover, survival of both animals and humans after surgical splenectomy demonstrated that the spleen was not absolutely required for life. Only in the modern era, with the discovery of individual blood cells, have investigators begun to elucidate the true functions of the

FIGURE 14-1. Blood circulation in the spleen. As blood enters the spleen, the arterial vessels are surrounded by lymphatic sheaths and nodules that constitute the white pulp. The majority of arterial blood terminates in the venous sinuses (red pulp), where filtration and quality control of erythrocytes take place. Erythrocytes return to the venous circulation via the venous sinuses. *(From Fawcett D. A Textbook of Histology, 11th ed. Philadelphia, WB Saunders, 1985, p 474.)*


spleen. We now recognize that the spleen has vital roles in blood filtration and immunologic competence.

Anatomy and Physiology

The spleen can be identified in human embryogenesis during week 5 of gestation, although the development of characteristic splenic architecture with influx of red and white blood cells occurs much later in gestation. At birth the spleen weighs about 10 g and then grows steadily to 30 g at 1 year of age, to 60 g by 5 years, and finally to the adult size of approximately 200 g.[2] The spleen is located under the confines of the left anterior aspect of the rib cage and can have a triangular, crescent, or rhomboidal shape. Though not accurate as a measure of total splenic volume, spleen size is usually estimated clinically by length alone, specifically, how far below the left costal margin the tip of the spleen can be palpated. Frequently, an enlarged spleen is most easily palpated at the midclavicular line, but it can extend prominently toward the midline or even to the midaxillary line in some patients.

The spleen receives 3-5% of the total cardiac output, thus making it a highly perfused organ.[3] Blood enters and leaves the spleen primarily through the splenic artery and vein, respectively, both located at the hilum on the concave (medial) side of the organ. Within the splenic parenchyma, the splenic arterial branches have little overlap, thereby allowing classification of the spleen into lobes and segments separated by relatively avascular planes.

Histologically, the spleen can be separated into two distinct regions, the red pulp and the white pulp, so named because of the blood cells most commonly found in each area. The red pulp represents a large open circulation within the spleen through which erythrocytes pass slowly for filtration and culling functions. In contrast, the white pulp consists primarily of collections of lymphocytes and macrophages that form small white nodules (1 to 2 mm in diameter) distributed throughout the splenic parenchyma. These two regions provide the vital functions of blood filtration and immunologic response, respectively, which are made possible through a unique
FIGURE 14-2. Lymphoid follicles in the white pulp appearing as bud-like outgrowths from the periarteriolar lymphoid sheath. *(From Neiman RS, Orazi A [eds]. Disorders of the Spleen, 2nd ed. Philadelphia, WB Saunders, 1999, p 10.)*

circulation pattern found within the spleen. Figure 14-1 illustrates the arterial and venous circulations of the spleen and the close proximity of the red and white pulp.

As the largest arteries within the spleen branch progressively into the smallest arterioles, the white pulp can be recognized as a circumferential ring of leukocytes that surround the vessel, also known as the periarterial (or periarteriolar) lymphoid sheath (PALS). The PALS consists primarily of T lymphocytes, and this cylindrical cuff of cells becomes thinner as the artery becomes smaller. Spheroidal lymphoid follicles arise at intervals from the PALS, usually where arterial branch points occur, and these follicles contain primarily B lymphocytes (Fig. 14-2). When immunologically stimulated,

these primary lymphoid follicles develop into secondary follicles with germinal centers, similar to the processes and architecture observed within lymph nodes. Lymphocytes within the white pulp are the beneficiaries of plasma "skimmed" from the central arterial blood supply. Whereas blood cells tend to continue within the vessel, plasma elements enter the PALS via tiny vessels that arise perpendicular to the flow of blood. Soluble antigens are thus herded into the white pulp, where they encounter dendritic cells and macrophages that function as professional antigen-presenting cells and allow proper immune stimulation of T and B lymphocytes.

After plasma is redirected toward the white pulp, the blood cells that continue through the splenic circulation are mostly erythrocytes, and they form the red pulp as they exit the arteries. Occasionally, erythrocytes pass directly from the arterial to the venous circulation via traditional endothelialized capillaries, a process known as the closed (rapid) splenic circulation, which is primarily nutritive. Much more commonly, however, erythrocytes leave the arterial circulation and empty into large pools called the splenic cords, where they encounter macrophages and other immune effector cells. Erythrocytes must survive these intimate encounters in this hypoxic and acidic environment and then pass from the cords through an endothelialized barrier into the splenic sinuses and finally back to the venous circulation. This open (slow) circulation allows careful filtration of individual erythrocytes, with repair or phagocytosis of cells that cannot successfully negotiate the return trip.

Important Functions of the Spleen

All RBCs pass through the spleen many times each day.[4,5] The spleen serves as an efficient filter for erythrocytes and is able to perform grooming (removal of antibodies or other surface molecules), culling (destruction of cells), and pitting functions (removal of intracellular material). While moving slowly through the hostile environment of the splenic cords, erythrocytes are carefully examined for abnormalities, a process constituting a biologic form of quality control. Macrophages in the red pulp identify abnormal erythrocytes, such as those that have IgG or complement on their surface, and either remove a portion of their membrane or fully engulf them. Newly made reticulocytes spend their first day or two in the spleen,[6] during which the cells appear to be groomed with removal of cytoplasmic organelles and surface adhesion molecules. Normal mature erythrocytes, in contrast, typically endure macrophage scrutiny without difficulty. To leave the red pulp, erythrocytes must then pass back from the splenic cords through potential spaces in the endothelial lining of the splenic sinuses. To negotiate these tiny apertures, known as the cords of Billroth, the erythrocytes must deform themselves substantially (Fig. 14-3). Cordal macrophages phagocytose erythrocytes that cannot deform themselves sufficiently, such as senescent cells; as erythrocytes age, they lose volume, gain density, and
FIGURE 14-3. Deformation of erythrocytes returning from the splenic cords (red pulp) back into the venous sinus. The erythrocytes must pass through very small potential spaces in the sinus wall known as the cords of Billroth. *(From Neiman RS, Orazi A [eds]. Disorders of the Spleen, 2nd ed. Philadelphia, WB Saunders, 1999, p 18.)*

eventually lose the deformability that allows reentry into the splenic sinus. In certain pathologic conditions, such as immune-mediated hemolytic anemia, as well as a variety of erythrocyte membrane, hemoglobin, and enzyme disorders, younger erythrocytes will also be trapped in the splenic cords. Erythrocytes with intracellular inclusions, such as nuclear remnants known as micronuclei (Howell-Jolly bodies), denatured hemoglobin (Heinz bodies), siderotic granules (Pappenheimer bodies), or malarial parasites, have their inclusions "pitted" out before they pass through the endothelial slits and return to the circulation.

The spleen also provides several important immunologic functions. Skimming of plasma into the PALS allows particulate antigens to interact with dendritic cells and other antigen-presenting cells, which initiates the immune response for T- and B-lymphocyte response and proliferation. Polysaccharide antigens in particular require this unique immunologic environment for optimal antibody response.[7,8] Intravenous antigens, such as those found during infection or after immunization, are primarily processed by the spleen.[9] Not surprisingly, normal splenic function is required for optimal early (IgM) response to most intravenous antigens, as well as the secondary (IgG) response.[10] In contrast, antigens administered by the intramuscular or subcutaneous routes do not require normal splenic function for a robust immune response.[11,12] Finally, blood-borne bacteria, particularly encapsulated organisms, are removed by splenic macrophages located in the PALS and in the cords. Without a functioning spleen, patients are susceptible to overwhelming bacterial sepsis and to exaggerated parasitemia from *Plasmodium*, *Babesia*, or other organisms.[13,14]

To a much lesser extent, the human spleen can also serve as a reservoir for circulating blood cells. About 50 mL of blood is usually contained in a normal spleen, as well as 30% of the platelet mass. In the abnormal state (see later), the spleen can enlarge and trap a larger portion

of the circulating blood cells, a condition known as hypersplenism. The spleen may also serve a small role in iron metabolism and homeostasis. Unlike the spleen in other species, however, it has no appreciable role in human hematopoiesis.

Abnormalities of the Spleen

Congenital asplenia is found in children with the rare Ivemark syndrome, in which the body has bilateral "right-sidedness" with trilobed lungs and a centralized liver.[15] Cardiac defects are common, as well as a risk of infection.[16] Even rarer patients have congenital asplenia with no other abnormalities.[16a] This resembles mice with a targeted deletion of Hox 11.[16b] Uptake of radionuclide by functioning splenic tissue can be difficult to document because the anatomic features are distorted and liver tissue can obscure any splenic uptake. Circulating erythrocytes with Howell-Jolly bodies or intracellular vesicles that appear as "pits" or "pocks" allow the diagnosis of asplenia to be established noninvasively.[17] Figure 14-4 illustrates the Howell-Jolly bodies that are found in the peripheral blood smear of an asplenic person. The converse arrangement of bilateral "left-sidedness" leads to congenital polysplenia with several spleens of varying size. In most patients the splenic tissue in polysplenia has normal function. Cardiac defects are common, as well as hepatobiliary abnormalities.[18,19]

Accessory spleens can be identified in 15% of normal persons.[20] In most of these individuals, a single accessory spleen measuring only 1 to 2 cm in diameter is present either in the splenic hilum or in the tail of the pancreas. Multiple accessory spleens can exist, however, as well as ectopic spleens in locations ranging from the abdomen to the pelvis and scrotum. The function of accessory spleens depends on the quality and quantity of blood flow; in most instances their filtration capabilities are minimal, but antibody responses may be present.

Splenoptosis, or wandering spleen, occurs when the spleen is not fixed within the retroperitoneum.[21] The resulting mass can be palpated anywhere in the abdomen and may require reattachment (splenopexy) or even splenectomy if symptoms of sequestration or torsion develop.[22] Splenosis refers to the autotransplantation of splenic tissue into the omentum or peritoneal surfaces of the abdominal cavity. Splenosis typically occurs after fracture or rupture of the spleen as a result of spillage and subsequent implantation of splenocytes. Although some protection against infection may be afforded by splenosis,[23] filtering functions and immunologic responses are limited by the relatively small total amount of splenic tissue and reduced blood supply.

Sequestration refers to enlargement of the spleen that occurs when blood enters the organ but is unable to exit properly. This condition is most often observed in children with sickle cell anemia when venous return of blood is hindered by intrasplenic sickling of erythrocytes within the red pulp. Splenic sequestration also occurs in other settings with abnormal erythrocytes, however, including congenital spherocytosis. Splenic sequestration can develop acutely with sudden pooling of blood within the spleen and result in rapid and painful expansion of the splenic parenchyma and capsule. Children exhibit pallor, fatigue, severe anemia, and occasionally hypovolemic shock.[24] Occasionally, splenic sequestration develops over a period of days or weeks and is then termed subacute or chronic because it is accompanied by relatively asymptomatic splenomegaly.

Hypersplenism refers to the condition of splenomegaly with non–immune-mediated trapping of peripheral blood cells and results in mild to moderate cytopenia.[25] Hypersplenism can develop in patients with abnormal erythrocytes, metabolic storage disorders, or other causes of chronic congestive splenomegaly. In these clinical settings, the spleen first enlarges because of progressive trapping of erythrocytes or storage material and then subsequently becomes a reservoir for all circulating blood cells. Typically, the peripheral platelet count is lower than normal, but the leukocyte count can also be low. If surgery is required, peripheral blood counts normalize after splenectomy.

FIGURE 14-4. Howell-Jolly bodies in peripheral blood erythrocytes. These nuclear remnants are identified as small inclusions within circulating erythrocytes and have several characteristic and required features by light microscopy: (1) they are spherical inclusions 0.5 to 2.0 μm in diameter, about the size of a small platelet; (2) they have a smooth contour and no surrounding halo, which distinguishes them from platelets juxtaposed to an erythrocyte; (3) they are always in the same focal plane as the erythrocyte because they are intracellular; (4) they are never refractile, unlike talc or dust particles; and (5) they are homogeneous in appearance, unlike other intracellular inclusions such as Pappenheimer bodies or malarial parasites. Howell-Jolly bodies are normally removed when erythrocytes pass through the cords of Billroth into the venous sinus. Their presence in peripheral blood indicates lack of splenic filtrative function.

Surgery Involving the Spleen

Although the spleen has important hematologic and immunologic functions, in some instances surgical removal is beneficial. A variety of congenital anomalies of the spleen, as well as numerous pathophysiologic processes, are indications for splenectomy.

Benign tumors of the spleen are relatively rare in childhood but primarily include congenital cysts (epidermoid or lymphangiomatous) or pseudocysts that result from liquefaction of splenic parenchyma after infarction or hemorrhage. These tumors may require splenectomy, depending on their size. Malignant splenic tumors are almost always lymphomatous or leukemic in origin, with cancerous cells found diffusely or in a nodular pattern throughout the splenic parenchyma. Perhaps somewhat surprisingly, very few solid tumors metastasize to the spleen. As a general guideline, splenectomy is not usually indicated in the setting of malignancy.

Splenomegaly requiring splenectomy can develop in a variety of clinical settings, including metabolic storage disorders such as Gaucher's disease, transfusion-acquired iron overload from chronic erythrocyte transfusions, or splenic congestion resulting from portal hypertension, among others. Commonly, splenectomy is the recommended therapeutic option for splenic enlargement in patients with primary erythrocyte abnormalities. Congenital hemoglobin, enzyme, and membrane disorders lead to trapping of the abnormal erythrocytes within the splenic cords and gradual expansion of the red pulp. In these settings, splenectomy can relieve the signs and symptoms of splenomegaly, including abdominal discomfort, anemia, hypersplenism, and dependence on transfusions.

Total surgical splenectomy is generally performed by open laparotomy via a left subcostal incision. Laparoscopic splenectomy has become a popular and safe alternative in children[26,27] but requires careful attention and may be technically difficult with very large spleens. With the laparoscopic approach, small amounts of residual splenic tissue may be left or accessory spleens may be missed,[28] which can be a problem for patients with immune-mediated hematologic disorders. When splenectomy is recommended for AIHA or immune thrombocytopenic purpura (ITP), all splenic tissue must be removed to prevent recurrent autoantibody production. Over the past decade, subtotal (partial) splenectomy has become a viable therapeutic alternative to total splenectomy. The partial splenectomy approach is possible because the spleen can be divided into distinct lobes and segments.[29] Removal of 80% to 90% of the enlarged spleen usually provides relief from splenomegaly while retaining sufficient splenic tissue for immune competence. Partial splenectomy has been used successfully in children with nonparasitic splenic cysts,[30] hereditary spherocytosis,[31] homozygous β-thalassemia,[32] and sickle cell disease,[33] although splenic regrowth may limit its long-term efficacy.[34] Even children with massive splenomegaly can successfully undergo partial splenectomy.[35] Based on animal studies, a third of the normal spleen mass is required for normal plasma filtration and antibody formation.[36] When compared to splenic tissue reimplanted either by surgical autotransplantation or splenosis,[37,38] partial splenectomy provides superior retained immune function. Laparoscopic partial splenectomy combines these two new approaches and may represent an ideal option for selected patients who require surgical splenectomy; it is becoming more commonly available for children.[39,40]

The primary danger after total splenectomy is fatal bacterial sepsis, sometimes referred to as overwhelming postsplenectomy infection (OPSI). First recognized more than 50 years ago,[41] bacteremia evolving rapidly into fatal sepsis with or without meningitis can abruptly develop in a patient without splenic function. Pathogens associated with OPSI are primarily encapsulated bacterial organisms and include *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Neisseria meningitidis*. The presumed pathophysiologic origin of OPSI is loss of plasma filtration by the spleen, which allows bacteria to multiply within the bloodstream and evolve from low-grade bacteremia to fulminant sepsis. Risk factors for OPSI include younger age at initial clinical evaluation, younger age at splenectomy, and failure to comply with prophylactic antibiotics or vaccinations. The true risk for the development of OPSI has been estimated in two large studies, although many of the patients were from the prevaccination era. First, in a literature review covering 35 years from 1952 to 1987 (5902 patients), the incidence of infection after splenectomy in children younger than 16 years was 4.4% with a mortality rate of 2.2%; for adults the corresponding values were 0.9% and 0.8%, respectively. Children younger than 5 years and especially infants had a much higher risk for sepsis.[42] In a later survey of 226 splenectomized patients with hereditary spherocytosis that included 5461 years of postoperative follow-up, the estimated mortality rate was 0.73/1000 years for the entire group, but somewhat higher for children.[43] The introduction of polysaccharide and now protein-conjugated vaccines has greatly helped decrease the incidence of pneumococcal bacteremia and sepsis and will help offset the lack of splenic filtration function for children undergoing splenectomy. However, even with the use of presplenectomy immunization, prophylactic antibiotics, and prompt medical attention for fever, a splenectomized child still has a finite risk of OPSI developing with substantial morbidity and mortality.

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

Historical Perspective

Erythrocyte hemolysis characterized by anemia, shortened RBC survival, jaundice, and occasionally hemoglobinuria has been recognized as a clinical entity for more than a century.[44,45] In the early 1900s it was noted that the serum from some patients with hemolytic anemia had the ability to agglutinate or hemolyze erythrocytes in vitro; such sera contained "agglutinins" or "hemolysins," respectively, which suggested an immunologic basis for the hemolysis.[46] The majority of patients with hemolytic anemia did not have these laboratory findings, however, and the mechanism by which their erythrocytes were

destroyed was then unknown. In fact, for many years it was quite difficult to distinguish acquired immune hemolytic anemia (an extracorpuscular defect) from the intracorpuscular defect known as congenital hemolytic jaundice (now called hereditary spherocytosis).

A major advance occurred in 1945, when Coombs and co-workers reported the use of rabbit antihuman globulin serum to detect Rh agglutinins.[47] This substance, soon referred to as the Coombs reagent, amplified weak agglutinins present on sensitized red cells and allowed serologic identification of previously undetectable auto-antibodies on the erythrocyte surface. The authors presciently noted that their reagent "promises to be of practical use" but probably did not foresee that it would completely revolutionize the field of immunohematology. Their subsequent demonstration that the sensitizing agent on erythrocytes was γ-globulin strengthened the idea of an autoimmune process,[48] and it was later documented that IgG warm-reactive antibodies were the most common form of AIHA.[49] By the late 1950s, it was finally possible to distinguish accurately between intrinsic erythrocyte defects and immune-mediated extrinsic erythrocyte destruction.[50]

Over the next 2 decades, several additional important advances were reported. Complement components, as well as γ-globulin, were found on the red cell surface of patients with immune-mediated hemolytic anemia, and by the late 1960s, the role of complement in immune-mediated destruction of erythrocytes was firmly established.[51-55] Interactions between IgG-sensitized red cells and monocytes were investigated,[56-58] including differences related to IgG subtypes[59,60] or erythrocyte antigens.[61] These studies started to elucidate the complex immune mechanisms of erythrocyte clearance by the human reticuloendothelial system.

The development of an animal model, specifically, guinea pigs deficient in complement components C3 or C4, represented an experimental breakthrough that led to greater understanding of both the pathophysiology[62-64] and treatment[65,66] of immune-mediated hemolytic anemia. With this model, the important contributions of antibody, complement, and the reticuloendothelial system to the pathophysiology of erythrocyte hemolysis could be studied. Taken together, these laboratory investigations led to models of immune-mediated clearance of erythrocytes by the reticuloendothelial system that are still accepted today.

Over the next 15 years there were relatively fewer advances in the field, chiefly ones involving increased precision of serologic diagnosis,[67,68] occasional new therapeutic options,[69-71] or large clinical reviews of patient outcome.[72,73] Over the past 20 years, however, there has been an increase in our knowledge of the immunologic abnormalities and mechanistic pathways that may be important in the generation and expansion of erythrocyte autoantibodies in AIHA. In addition, novel therapies directed at specific targets in the immune system have emerged and expanded the treatment armamentarium

for AIHA. The stage is set for research on individual T and B lymphocytes in patients with AIHA, with the goal of understanding the pathogenesis of AIHA at the molecular level. Specific questions remain unanswered regarding the formation of autoreactive antibodies, loss of self-tolerance, and lack of regulation and suppression of these autoantibodies by the immune system.

Classification

AIHA can be classified in a variety of ways, such as by the thermal sensitivity or isotype of the autoantibodies, but a simple and convenient classification scheme separates the disorders into a primary versus a secondary process (Box 14-1). In primary AIHA, hemolytic anemia is the only clinical finding, and there is no identifiable underlying systemic illness to explain the presence of erythrocyte autoantibodies. Some children with this form of AIHA will, however, have had a recent infectious illness. Warm-reactive AIHA is the most common form of primary AIHA in children and usually involves IgG autoantibodies that sensitize erythrocytes and lead to extravascular immune clearance and hemolysis. A second category of primary AIHA is PCH, which is especially common in children after a viral-like illness. PCH is a particularly interesting form of AIHA characterized by an IgG autoantibody that binds at cold temperatures, fixes complement efficiently, and causes intravascular hemolysis. The third major form of primary AIHA, cold agglutinin disease, is more commonly observed in adults, but in children it typically follows *Mycoplasma* infections. In this disorder, an IgM autoantibody binds to erythrocytes optimally below 37° C and fixes complement; erythrocytes undergo either intravascular hemolysis or immune-mediated extravascular clearance from surface-bound complement components.

Box 14-1	**Classification of Autoimmune Hemolytic Anemia (AIHA) in Children**

PRIMARY AIHA*

Warm-reactive autoantibodies, usually IgG
Paroxysmal cold hemoglobinuria, usually IgG
Cold-agglutinin disease, usually IgM

SECONDARY AIHA†

Systemic autoimmune disease (e.g., lupus, malignancy)
Immunodeficiency
Evans syndrome
Autoimmune lymphoproliferative syndrome
Infection (*Mycoplasma*, viruses)
Drug induced

---

*Occurs in the majority of affected children and often follows a viral-like syndrome, but in the absence of another systemic illness.
†Occurs in association with another systemic process.

Secondary AIHA occurs in the context of another clinical diagnosis, with hemolytic anemia being only one manifestation of a systemic illness. Secondary AIHA can occur in patients with generalized autoimmune disease, such as systemic lupus erythematosus (SLE) or other autoimmune inflammatory disorders. AIHA also occurs in patients with malignancy, immunodeficiency states, exposure to drugs, or specific infections. Because AIHA may be the initial manifestation, however, it is imperative that each patient with AIHA be evaluated for the presence of an underlying illness. Evans' syndrome is a unique entity that features autoimmune pancytopenia, although erythrocytes and platelets are most frequently involved. Evans' syndrome often has a severe and relapsing clinical course, and most patients require aggressive systemic therapy. Finally, ALPS is now increasingly being recognized as an important underlying condition in some children with AIHA.

PRIMARY AUTOIMMUNE HEMOLYTIC ANEMIA

Incidence

Primary AIHA is not a rare disorder. The disease has been estimated to affect 1 in 80,000 persons in the general population per year,[74] thus making it more common than acquired aplastic anemia[75,76] but less common than ITP.[77] In the pediatric age group, AIHA may even occur in infants and toddlers, especially after an infection[72,78,79]; teenagers with AIHA are more likely to have an associated underlying systemic illness and therefore have secondary disease.[80-82] Cold agglutinin disease can occur in the pediatric age group but is particularly common in older persons.[83-86] In summary, AIHA can affect persons of any age, race, ethnicity, or nationality. The issue of gender preference is somewhat more controversial; in children, boys may be affected slightly more often, whereas affected teenagers are more commonly female.[72,79,87]

Natural History

The prognosis for the majority of children with primary AIHA is good.[73,87-90] Overall, young patients with cold-reactive erythrocyte autoantibodies appear to have a better clinical outcome than those with warm-reactive antibodies. The former patients tend to have an acute self-limited illness but may require aggressive short-term supportive care. In contrast, the clinical course in children with warm-reactive AIHA is often chronic and characterized by intermittent remissions and relapses, and these patients generally require long-term therapy.

Older series reported a high mortality rate for patients with AIHA, but these studies included many adults with AIHA secondary to malignancy.[49,91] Later series, including several that focused exclusively on children, have demonstrated a much better prognosis. Buchanan and colleagues[88] reported that 77% of children with AIHA had an acute self-limited disease and that the majority of children responded well to short-term therapy; these results have been confirmed in later reviews. Mortality in children with primary AIHA appears to be no greater than 10%, with death occurring primarily in older children with chronic refractory disease, some of whom possibly had unrecognized Evans syndrome or ALPS.

Heisel and Ortega[80] attempted to define prognostic factors for AIHA in childhood. They concluded that children between 2 and 12 years of age had the best prognosis; these patients tended to have an abrupt onset of symptoms with low numbers of reticulocytes but otherwise normal blood counts. The children who fared worse were either infants younger than 2 years or teenagers; these patients had a more prolonged onset of symptoms, had higher reticulocyte counts with nucleated erythrocyte precursors in their peripheral blood, and often had decreased platelet counts.[80] Other studies have confirmed the observation that younger children with an abrupt onset of symptoms have a better prognosis than older patients do.[72,79]

Clinical Manifestations

Proper evaluation of a pediatric patient with AIHA begins with a careful history and physical examination. Many children with AIHA first come to medical attention because of signs and symptoms referable to anemia, such as pallor and weakness, and less commonly dizziness or exercise intolerance. The anemia is usually well compensated from a cardiovascular standpoint, so symptoms of congestive heart failure or circulatory collapse are rare. Occasionally, a patient has jaundice, typically noted in the sclerae, as a result of accelerated erythrocyte destruction and increased bilirubin turnover. The symptom of dark urine generally reflects intravascular hemolysis rather than bilirubin and has been described by patients in a variety of colorful and flavorful terms, including cola, iced tea, mahogany, or even motor oil. Less commonly, the patient will report abdominal pain or fever.

Children with AIHA often have a benign previous medical history, although questions should be asked regarding previous similar episodes. The review of systems should include a query about recent or concurrent medications and careful questioning regarding the possibility of an underlying illness such as a systemic autoimmune disease, inflammatory disorder, or malignancy. The family history is usually negative in AIHA; rare instances of apparent familial AIHA[72,92,93] probably reflect a tendency toward a generalized autoimmune disorder such as SLE.

On physical examination a child with AIHA is often pale and jaundiced with pallor and icterus, especially

apparent in the conjunctivae and palms. The patient should have no physical stigmata of congenital disorders such as Blackfan-Diamond anemia, Fanconi anemia, or constitutional aplastic anemia. Jaundice may be apparent, particularly if the hemolysis is brisk, and is caused by the breakdown and recycling of unconjugated bilirubin from the destroyed erythrocytes. Depending on the skill of the examiner, scleral icterus can be detected at a bilirubin concentration of 2 to 3 mg/dL. Examination of the heart typically reveals tachycardia and an early systolic flow murmur as a result of the high-output anemic state. The liver and spleen may be palpable, in the latter case secondary to an increase in red pulp.[94] However, the presence of massive splenomegaly, hepatomegaly, or enlarged lymph nodes should suggest an underlying infection or malignant process.

Routine Laboratory Evaluation

Similar to that seen with other forms of anemia in young patients, such as aplastic anemia or transient erythroblastopenia of childhood, the degree of anemia in AIHA may be surprisingly marked at initial evaluation. A child with AIHA often has a hemoglobin concentration of 4 to 7 g/dL with no apparent cardiovascular compromise. RBC indices are not generally helpful in establishing the diagnosis because a normal mean corpuscular volume will reflect the weighted average of small microspherocytes and large reticulocytes. Erythrocyte agglutination within the sample tube may give an artificially large mean corpuscular volume on an automated counter.[95] An elevated mean corpuscular hemoglobin concentration (>36 g/dL) is more suggestive of hereditary spherocytosis because a spherocyte has a smaller volume than a normal erythrocyte but contains the normal amount of hemoglobin (see Chapter 15). The leukocyte count and platelet count should be within the normal range. Concurrent thrombocytopenia may indicate a bone marrow failure syndrome (e.g., aplastic anemia) or microangiopathic hemolytic anemia (e.g., HUS or TTP). The combination of AIHA and immune-mediated thrombocytopenia (Evans syndrome) is characterized by broader immune dysregulation.[96] Granulocytopenia may also be present in Evans syndrome as a reflection of the immune-mediated pancytopenia.

Evaluation of the peripheral blood smear is very useful in establishing the diagnosis of AIHA. Numerous small spherocytes are usually present in warm-reactive AIHA; splenic ingestion of a portion of the erythrocyte allows the cell to "sphere," or re-form into a more entropically favored spherical shape.[56] Surface complement may also induce erythrocyte sphering.[97] Occasionally, teardrop shapes or even schistocytes may be observed[98]; the presence of target cells is more consistent with a hemoglobinopathy or primary hepatic disease. Polychromasia is a common finding in AIHA because the bone marrow releases large numbers of reticulocytes and even nucleated RBCs to compensate for the accelerated

erythrocyte destruction. Erythrophagocytosis, first described in 1891,[99] is an unusual finding on the peripheral blood smear but visually illustrates the process of immune-mediated clearance of erythrocytes by monocytes and macrophages of the reticuloendothelial system. Figure 14-5A shows the peripheral blood smear from a patient with warm-reactive AIHA and illustrates numerous small microspherocytes and large reticulocytes. Numerous Howell-Jolly bodies are present because this patient had previously undergone splenectomy. In contrast, Figure 14-5B shows the blood smear of a patient with hereditary spherocytosis and illustrates the morphologic similarities between these two conditions. Spherocytes are seen less commonly in cold-reactive AIHA, but erythrocyte agglutination can be observed on the blood film if the binding affinity of the antibody reaches room temperature. Figure 14-5C illustrates agglutinated red cells in a patient with cold-reactive (IgM-mediated) AIHA; at higher power, nucleated immature erythroid cells released prematurely from the bone marrow can be seen. Figure 14-5D illustrates the phenomenon of erythrophagocytosis by a monocyte on the peripheral blood smear of a child with PCH.

Reticulocytosis is usually present in AIHA because of the bone marrow's compensation for the shortened red cell survival in peripheral blood.[100] Absolute reticulocyte counts are typically 200 to 600×10^9/L, which represents 10% to 30% of the circulating erythrocytes. However, reticulocytopenia is well described in AIHA and probably occurs in 10% of pediatric patients.[101-103] Several explanations have been offered for a low reticulocyte count in the presence of accelerated erythrocyte clearance. The autoantibody may react with antigens on erythroid precursors and lead to immune-mediated clearance within the marrow by resident macrophages. Alternatively, erythrocyte autoantibodies may induce apoptosis of bone marrow erythroblasts.[104] Finally, AIHA may be characterized by a well-compensated anemia that remains subclinical until infection with parvovirus B19 temporarily shuts off erythropoiesis and leads to worse and symptomatic anemia.[105,106] Regardless of its mechanism, however, the presence of reticulocytopenia should not influence therapy or prognosis in AIHA.

Aspiration of bone marrow is not generally necessary for children with AIHA but may be helpful to exclude a malignant process, myelodysplasia, or a bone marrow failure syndrome. In AIHA, the marrow aspirate usually reveals marked erythroid hyperplasia with a myeloid-erythroid ratio below unity. Mild dyserythropoiesis may be observed but should not be a common finding; substantial dyserythropoiesis should suggest an alternative diagnosis such as myelodysplasia.

Results of urine examination may be unremarkable. In patients with AIHA and intravascular hemolysis, however, free plasma hemoglobin is cleared through the renal filtration system, which leads to darkened urine. When hemoglobinuria is present, urine dipstick analysis will indicate the presence of blood, but microscopic
FIGURE 14-5. Examination of peripheral blood in autoimmune hemolytic anemia (AIHA). **A,** Blood from a patient with IgG (warm-reactive) AIHA illustrates many small microspherocytes and larger reticulocytes (×1000). **B,** Blood from a patient with hereditary spherocytosis illustrates the morphologic similarities between these two conditions. **C,** Agglutinated erythrocytes from a patient with IgM (cold-reactive) AIHA are clearly visible at low power (×400). **D,** Erythrophagocytosis by a peripheral blood monocyte (×1000).

examination will reveal few if any RBCs. Chronic hemoglobinuria will lead to accumulation of hemosiderin in uroepithelial cells, which can be detected in the urinary sediment.

The results of a variety of serum chemistry analyses may be abnormal because of erythrocyte hemolysis, but routine measurement should not be essential to establish the diagnosis of AIHA. Elevations in levels of lactate dehydrogenase and aspartate aminotransferase reflect the release of intraerythrocyte enzymes; in contrast, the level of serum alanine aminotransferase or other hepatic enzymes should not be elevated in AIHA. The serum haptoglobin level is almost always low because this protein acts as a scavenger for free plasma hemoglobin. However, haptoglobin is not synthesized well in young infants and is an acute phase reactant[107]; for these reasons, quantitation of serum haptoglobin may not be helpful in the evaluation of a patient with AIHA (or for that matter in any patient). The total serum bilirubin concentration is elevated in most patients with AIHA, although levels greater than 5 mg/dL are unusual and suggest hepatic impairment or the presence of Gilbert syndrome. Because the elevated bilirubin concentration in AIHA reflects accelerated erythrocyte destruction rather than

intrinsic hepatic disease, virtually all of the bilirubin is unconjugated. The direct (conjugated) fraction should not exceed 10% to 20% of the total bilirubin concentration.

Specialized Laboratory Evaluation

The most important and useful laboratory test to establish the diagnosis of AIHA is the direct antiglobulin test (DAT, formerly known as the Coombs test), which identifies antibodies and complement components on the surface of circulating erythrocytes. Therefore, a thorough understanding of the individual laboratory steps that constitute the DAT is essential for accurate interpretation of the test results.

Anticoagulated erythrocytes from the patient are first washed several times to remove all plasma proteins and are then incubated at 37° C with polyclonal rabbit antiserum that binds to human γ-globulin and human complement (usually C3). First described more than 60 years ago,[47] this "Coombs reagent" is clearly the most important diagnostic laboratory tool for a patient with AIHA. IgM autoantibodies are pentameric and can act as a bridge between adjacent erythrocytes (Fig. 14-6A). In
FIGURE 14-6. Interactions between immunoglobulin molecules and the erythrocyte during agglutination tests and the direct antiglobulin test (DAT). **A**, An IgM autoantibody can simultaneously bind two erythrocytes because of its multiple antigen-binding sites. The large size of the IgM molecule allows it to bridge the zeta potential between erythrocytes and cause agglutination. **B**, An IgG autoantibody is too small to bridge the zeta potential. **C**, Hence there is no agglutination of erythrocytes unless the zeta potential is reduced. **D**, On addition of the Coombs reagent, a rabbit antiglobulin that recognizes human IgG, the zeta potential is successfully bridged and red cells agglutinate.

contrast, IgG autoantibodies are smaller and unable to bridge the surface repulsion between adjacent erythrocytes known as the zeta potential (Fig. 14-6B) unless the distance imposed by the zeta potential is reduced (Fig. 14-6C). The broad-spectrum Coombs reagent binds to erythrocyte autoantibodies, bridges the zeta potential, and causes agglutination (Fig. 14-6D).

A positive DAT result with the polyspecific Coombs reagent leads to testing with more specific antisera to discriminate between IgG and complement on the RBC surface. The presence of IgG on the erythrocyte is sufficient evidence for an IgG autoantibody; simultaneous detection of complement indicates that the antibody can fix complement as well. In contrast, the presence of complement alone (with no IgG detected) suggests a cold-reactive autoantibody that fixes complement at lower temperatures but binds poorly to the erythrocyte at 37° C; in this setting, the serum should be analyzed for either the presence of an IgM autoantibody or the unique IgG Donath-Landsteiner autoantibody (described in a later section).

The DAT report for a patient with AIHA should describe the agglutination results of the polyspecific Coombs reagent and, if positive, the results of subsequent testing with the specific IgG and C3 reagents. DAT can be performed at temperatures lower than 37° C, such as 4° C, 10° C, or room temperature (23° C), to assist in the detection of cold-reactive autoantibodies and characterization of their thermal reactivity and amplitude. DAT results are scored on the basis of the amount of agglutination, usually on a scale of 1 to 4.

On occasion, results of the DAT are negative despite good clinical evidence of autoimmune hemolysis.[108] One explanation for this apparent paradox is that the amount of IgG present on the erythrocyte may be below the threshold for detection by standard Coombs reagent testing. In this setting a more sensitive assay for surface-bound IgG, such as enzyme-linked immunosorbent assay,[109] gel card analysis,[110] or flow cytometry[111] may be helpful in identifying IgG on the cell surface. Alternatively, the lack of surface IgG may indicate the presence of a surface antibody other than an IgG molecule, such as an IgA autoantibody[68,112-114] or even a warm-reactive IgM autoantibody.[115-117]

Also of interest is the observation that DAT results may be positive in an otherwise normal person.[108] This is apparently a biologically false-positive result because no evidence of AIHA develops in these individuals, even with extended follow-up.[118,119] Analysis of the immune system of such persons revealed normal T-cell subsets, although the number of B cells was significantly increased.[120]

Differential Diagnosis

The typical patient with AIHA has clear evidence of hemolytic anemia, including jaundice and splenomegaly on physical examination and spherocytes with reticulocytosis on the peripheral blood smear. In this setting the differential diagnosis includes certain forms of nonimmune hemolytic anemia, including intrinsic RBC membrane or enzyme defects, as well as other rare extrinsic causes of hemolysis. Hereditary spherocytosis, described more fully in Chapter 15, can be confused with AIHA. A positive result in the osmotic fragility test, often erroneously considered to be pathognomonic for the diagnosis of hereditary spherocytosis, is also observed in patients with AIHA or congestive splenomegaly. Patients with other rare disorders such as clostridial sepsis[121] or early stages of Wilson's disease[122] can likewise have numerous spherocytes and hemolytic anemia. Patients with microangiopathic hemolytic anemia, such as HUS or TTP, typically have more schistocytes than spherocytes and usually have severe thrombocytopenia as well. In all clinical settings, the diagnosis of AIHA is most easily and accurately made on the basis of positive DAT results.

If the patient has anemia and reticulocytopenia, the differential diagnosis should include other acquired forms of hypoplastic anemia, such as transient erythroblastopenia of childhood or acquired aplastic anemia. In addition, patients with nonimmune hemolytic anemia in whom transient hypoplastic anemia develops as a result of parvovirus B19 infection may display this clinical picture.[123] In these patients the underlying hemolytic anemia may not be clinically recognizable until the parvovirus infection worsens the anemia and leads to clinical symptoms.

TABLE 14-1	Common Characteristics of Erythrocyte Autoantibodies in Autoimmune Hemolytic Anemia		
Characteristic	**Warm-Reactive**	**Paroxysmal Cold Hemoglobinuria**	**Cold Agglutinin**
Immunoglobulin isotype	IgG	IgG	IgM
Thermal reactivity	37° C	4° C	4° C
Fixes complement	Variable	Yes	Yes
Direct antiglobulin test

Characteristics of Erythrocyte Autoantibodies

The sine qua non of both primary and secondary AIHA is the presence of antibodies that bind to erythrocytes. As a direct consequence of the binding of these erythrocyte autoantibodies, circulating erythrocytes have a shortened life span with hemolysis and accelerated clearance by the reticuloendothelial system. The clinical complexity and variability of AIHA depend in large part on the immunologic characteristics of the autoantibody, including its isotype, thermal reactivity, ability to fix complement, binding affinity, and antigenic specificity. Elucidation of each of these characteristics is important in understanding the pathophysiology and clinical course of AIHA in a given patient.[86,124-129] Table 14-1 summarizes the important characteristics of erythrocyte autoantibodies in AIHA, with an emphasis on differences among the three major clinical conditions: warm-reactive AIHA, PCH, and cold agglutinin disease.

Antibody Isotype

One of the most important tasks for the immunohematology laboratory in the evaluation of a new patient with AIHA is to determine the isotype of the erythrocyte autoantibody. In most cases the pathogenic antibody is identified as an IgG molecule.[74,89,130,131] In general, IgG autoantibodies bind to RBC antigens optimally at 37° C, hence the descriptive term warm-reactive autoantibodies. All IgG molecules are heterodimers, with two heavy chains linked noncovalently to two light chains. The heavy and light chains together form two variable antigen-binding sites known as the Fab portions, and the heavy chains also contain a constant structural domain (the Fc portion) that includes the binding site for complement and the binding site for the Fc receptor.

There are four subtypes of IgG antibodies designated IgG1, IgG2, IgG3, and IgG4. These different subtypes have important implications for the fixation of complement, hemolysis, and clearance by the reticuloendothelial

TABLE 14-2	Frequency of IgG Subclasses Identified in Warm-Reactive (IgG Autoantibody) Autoimmune Hemolytic Anemia
IgG Subclass	**% Total Cases**
IgG1	74.0
IgG2	0.7
IgG3	2.1
IgG4	0.9
Multiple, including IgG1	20.1
Multiple, not including IgG1	0.3
None detectable	1.9

system. IgG1 and IgG3 antibodies fix complement better than IgG2 and IgG4 antibodies do.[132,133] A patient who had only IgG4 autoantibody on his erythrocytes was reported to have little hemolysis, presumably because of weak interactions with the Fc receptor on macrophages.[134] Adapted from a review of several thousand patients with AIHA by Engelfriet and colleagues,[131] Table 14-2 lists the relative occurrence of each IgG subclass identified in patients with AIHA and warm IgG autoantibody. IgG1 autoantibodies were by far the predominant subclass identified, followed by multiple subclasses that typically included IgG1.

Less commonly, IgG antibodies are cold reactive; these autoantibodies are characteristic of childhood PCH but have also been reported rarely in cold hemagglutinin disease.[135] In the unusual setting of a pregnant woman with AIHA, certain IgG autoantibodies can cross the placenta and cause acquired neonatal AIHA.[136-138]

In other patients with AIHA, IgM autoantibodies are identified, particularly after infection with an organism such as *Mycoplasma pneumoniae*.[139] In one series, IgM autoantibodies characterized a significant proportion of

instances of AIHA in early childhood.[140] The IgM molecule is a pentameric structure that contains five covalently linked domains, each of which is structurally similar to a single IgG molecule. Because of their large size, IgM autoantibodies can span the zeta potential between adjacent erythrocytes. Erythrocytes that are connected by a bridging IgM molecule become too dense to remain in suspension and thus agglutinate.

IgG and IgM autoantibodies characterize the vast majority of instances of AIHA, but rarely an IgA autoantibody is identified.[68,113,114,141] IgA antibodies do not react with the standard Coombs reagent, and therefore special research reagents must be used for their identification.[108] Testing for IgA autoantibodies should be considered and specifically requested whenever the DAT fails to detect surface-bound IgG or C3 in a patient who otherwise appears to have AIHA. Finally, a combination of different isotypes, especially simultaneous IgG and IgM autoantibodies, has been reported on several occasions.[142-145]

Thermal Reactivity

The thermal reactivity (sometimes called the thermal amplitude) of an erythrocyte autoantibody is another important parameter to determine. Although the core temperature of humans is 37° C, temperatures in superficial vessels (particularly in the face and digits) may fall below 30° C. Binding of antibody to erythrocytes can be considered a process of dynamic equilibrium, depending on the location of a given erythrocyte within the circulation. The thermal reactivity of most IgG autoantibodies is 37° C, so binding to erythrocytes occurs best at normal body temperature. These antibodies are therefore referred to as warm-reactive autoantibodies. Occasionally, warm-reactive IgM autoantibodies are identified, although they are rare.[115-117,140]

Cold-reactive (Donath-Landsteiner) IgG autoantibodies bind optimally at 4° C and are clinically important as the cause of PCH. Because of their unusual characteristics, results of the DAT are often negative or demonstrate only the presence of complement because cold-reacting antibodies are removed during the washing of erythrocytes. A special procedure must therefore be followed to detect the Donath-Landsteiner antibody characteristic of PCH. Specific testing for this antibody should be performed early in the clinical course, ideally before therapy is initiated.

The Donath-Landsteiner autoantibody is a biphasic hemolysin, which means that it binds to erythrocytes and fixes complement at 4° C, but on warming to 37° C, the complement cascade is amplified and leads to hemolysis. Two samples of blood should be drawn simultaneously from the patient and kept at 37° C to prevent in vitro autoantibody binding and hemolysis. The serum samples are separated from the erythrocytes by centrifugation (preferably at a warm temperature) and then incubated with normal erythrocytes and a source of complement, either in a melting ice bath or at 37° C. Both reactions are then warmed to 37° C and analyzed for the presence
FIGURE 14-7. Thermal reactivity curve of a cold-reactive IgM autoantibody. The antibody is optimally reactive at 0° C to 4° C, whereas complement is fixed most efficiently at 37° C. The overlap area is the so-called zone of hemolysis and determines the amount of hemolysis observed. *(Adapted from Issitt PD, Anstee DJ. Applied Blood Group Serology, 3rd ed. Miami, Montgomery Scientific Publications, 1985, p 545.)*

of hemolysis. In the first sample, cold incubation allows the IgG autoantibody to bind and fix complement, after which the subsequent warming step allows complement amplification to occur with resultant RBC lysis. In contrast, the sample maintained at 37° C shows no lysis because no significant IgG autoantibody binding occurred at the warmer temperature to allow complement fixation.

In contrast to many IgG autoantibodies, IgM autoantibodies typically bind optimally to erythrocytes at 0° C to 4° C and hence are called cold-reactive antibodies. The thermal range over which the autoantibody is active is crucial and determines the amount of hemolysis observed (Fig. 14-7). An IgM autoantibody binds optimally in the cold, but complement activation proceeds optimally at warmer temperatures. The overlap between the range of antibody activity and complement activation is the so-called zone of hemolysis.[146]

Complement Fixation

The ability of an erythrocyte autoantibody to fix complement plays a critical role in the pathophysiology of immune clearance and the clinical manifestations of hemolysis because complement augments the destructive effects of the autoantibody. The process of complement deposition, amplification, and pore formation involves a complex series of intravascular enzymatic events.

In the classical complement activation pathway, the Fc portion of the bound immunoglobulin molecule interacts with C1q, the first component of the complement cascade. Two IgG molecules in close proximity are required to bind C1q to the erythrocyte (Fig. 14-8A), whereas a single IgM molecule is sufficient to bind C1q (Fig. 14-8B). Components C1r and C1s then bind to
FIGURE 14-8. Binding of C1, the first component of complement, to antibodies. **A,** Binding of C1 to IgG molecules occurs through the Fc portion of the immunoglobulin molecule. Binding is inhibited by interference from the Fab arms, which is minimized when the hinge region is elongated, as in an IgG3 molecule; hence IgG3 fixes complement more efficiently than IgG4 does. **B,** Complement binding sites of IgM molecules are not available when the antibody is in its fluid-phase planar form. When two of the monomers are affixed, however, the IgM molecule assumes an arched form and C1 binding sites become available for reaction.

C1q to form a multiunit protein complex on the red cell surface. This active complex binds and enzymatically cleaves C4, followed by additional enzymatic events that lead to the deposition of component C3b on the surface of the erythrocyte. At this point the erythrocyte may be cleared by the spleen, liver, or other parts of the reticuloendothelial system that recognize C3b via specific surface receptors. Alternatively, amplification of the complement cascade may continue and lead to formation of the C5b-7 membrane attack complex, followed by fixation of C8 and C9 and finally by polymerization of C9 to form pores within the cell membrane (Fig. 14-9). These pores breach the erythrocyte membrane integrity and cause hemolysis of the cell.

IgM autoantibodies fix complement very efficiently because distinct binding sites within the IgM pentamer are close enough to bind C1q (see Fig. 14-8B). In fact, the "hemolysins" that were identified at the turn of the century were actually IgM autoantibodies that fixed complement efficiently and completely, thereby resulting in membrane pore formation and erythrocyte lysis. Rarely, IgM antibodies that do not fix complement have been reported.[140,147] In contrast, IgG autoantibodies do not fix complement as efficiently as their IgM counterparts, in part because of the necessity of two distinct IgG molecules being in close proximity to allow the initial binding of C1q.[51] If the target autoantigens on the erythrocyte membrane are not mobile or are spaced too far apart, complement cannot be fixed. Moreover, all IgG molecules do not have equivalent complement-fixing ability; the IgG1 and IgG3 subclasses are able to fix complement far better than the IgG2 and IgG4 subtypes can.[132,133] Donath-Landsteiner antibodies, even though they are IgG autoantibodies, fix complement very efficiently and thus lead to brisk intravascular lysis.
FIGURE 14-9. Electron micrograph of lesions that appear in the cell membrane after completion of the membrane attack complex. The dark lesions are hydrophilic complexes of protein about 10 nm in diameter.

Antibody Binding Affinity

The binding affinity of an erythrocyte autoantibody for its antigen has implications both for the likelihood of in vitro detection and for the pathophysiologic process of erythrocyte clearance.[125,129] An IgG autoantibody typically has high affinity for its antigen on the erythrocyte surface and can therefore be identified readily by the DAT. For this same reason, the indirect antiglobulin

test may fail to detect an IgG autoantibody because there is very little unbound antibody circulating in plasma. In contrast, most IgM autoantibodies have little binding affinity at 37° C and are therefore more easily detected as high-titer unbound antibody within plasma.

Antigenic Specificity

When serologic specificity in most patients with warm-reactive AIHA is tested, reactivity with all cells tested is commonly identified. This "panreactive," "nonspecific," or "no specificity defined" pattern of reactivity suggests that the autoantibody is binding to a surface antigenic structure that is common to all human erythrocytes. Interestingly, the autoantibody may not react with cells that lack the entire Rh protein complex; experiments with these rare Rh$_{null}$ erythrocytes provide evidence that the Rh protein cluster is the main antigenic determinant for many warm-reactive autoantibodies.[53,146] Other studies have confirmed that autoantibodies bind to Rh in about 50% of patients with warm-reactive AIHA,[127,128,148] although other candidate autoantigens have been identified.[149]

Occasionally, autoantibody reactivity against a particular Rh antigen such as c or e is identified,[85,150] but this is not common. Warm autoantibodies with defined specificity against unusual protein antigens, including protein 4.1,[151] band 3,[152] Wrb,[67] Kpb,[153] N,[154] and many others, have been described. Reactivity with the ABO blood group antigens[155,156] or with other major systems such as Lewis or Kell is extremely rare in warm-reactive AIHA.[131,146,157] In contrast, IgM autoantibodies often have reactivity against polysaccharides on the red cell rather than surface proteins. The I/i surface structure is a prototypical polysaccharide autoantigen on the red cell surface and is the target of many IgM antibodies that develop in response to infection.[139] In addition to the important I/i surface antigens, other autoantigens have also been reported in cold-reactive AIHA,[85,86,158-160] including the polysaccharide P autoantigen in PCH.[161]

Elucidation of the antigenic specificity of autoreactive erythrocyte antibodies provides information that is useful for several reasons. One is the likelihood of finding compatible blood for transfusion. If an autoantibody is a panreactive antibody that binds to all cells with no apparent specificity, fully compatible blood will probably not be found. Identification of antigenic specificity may also help predict intravascular lysis resulting from activation of complement. If the antigen is within the Rh complex, the antigenic density on erythrocytes makes complement activation remote and complement-mediated intravascular hemolysis less likely. The P antigen system, in contrast, is densely populated on the erythrocyte surface and capable of binding sufficient Donath-Landsteiner IgG antibodies to fix complement efficiently and lead to substantial intravascular lysis.[54]

Immune Clearance of Sensitized Erythrocytes

Much of our understanding about the pathophysiology of immune-mediated erythrocyte clearance derives from experiments performed more than 30 years ago. An elegant series of in vitro and in vivo studies by Jandl and associates[50,56,57,59] and by Rosse[54,55,61] clarified the roles of antibody, complement, and the reticuloendothelial system in the pathophysiology of autoimmune erythrocyte clearance. In the early 1970s, Frank and colleagues developed a guinea pig model for AIHA that permitted dissection of the steps involved in the clearance of erythrocytes coated with antibody or complement. Using ^{51}Cr-labeled RBCs that were sensitized in vitro with rabbit IgG or IgM anti–guinea pig erythrocyte antibodies, these investigators analyzed the rates and patterns of clearance, as well as the sites of sequestration. IgG-coated erythrocytes were removed predominantly by the spleen, regardless of concurrent complement activation, and the amount of surface IgG correlated with the rate of splenic clearance. The liver was the predominant clearance site when very large amounts of IgG were present. Fc receptors on macrophages were responsible for the binding and phagocytosis of IgG-coated erythrocytes.[62,63] In contrast to these findings for IgG-mediated hemolysis, IgM-coated erythrocytes were cleared rapidly within the liver, and the amount of bound IgM correlated with the rate of erythrocyte clearance. However, there was an absolute dependence on complement for the clearance of IgM-coated cells, and macrophage receptors for the C3b molecule were responsible for binding and phagocytosis of erythrocytes.[62,64] Several investigators have attempted to mimic erythrocyte-monocyte interactions and correlate in vitro results with in vivo hemolysis,[162-165] but with limited success.

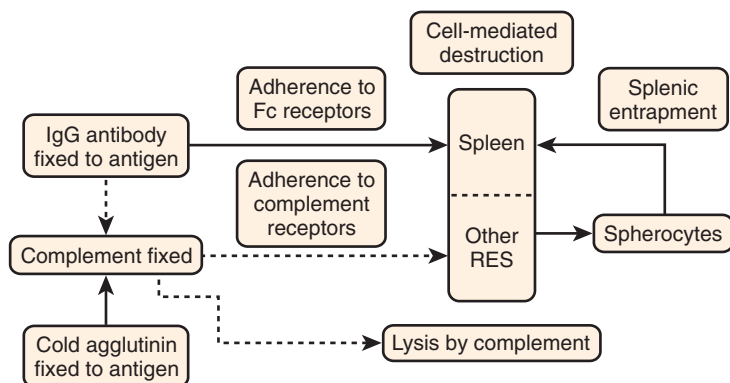
These and other laboratory experiments, coupled with careful clinical observations, have led to the development of a general understanding about immune-mediated clearance of erythrocytes in AIHA (Fig. 14-10). In warm-reactive AIHA, the IgG autoantibodies coat autologous erythrocytes and may fix complement. The sensitized cells pass through the spleen and other parts of the reticuloendothelial system, where they interact with complement and Fc receptors on macrophages. The human macrophage has three distinct classes of receptor for the Fc portion of the IgG molecule, designated FcγRI, FcγRII, and FcγRIII. Although each form of Fc receptor binds IgG with similar specificity, binding affinity varies for individual subclasses of IgG autoantibodies.[166] The sensitized erythrocytes may be fully ingested by macrophages; however, if only a portion of the surface membrane is removed, the erythrocyte re-forms into a spherocyte that is identifiable on the peripheral blood smear. For IgG-coated erythrocytes, the majority of immune clearance occurs within the cords of the spleen[167]; hence the hemolysis is extravascular. If the IgG antibody fixes complement, the erythrocyte can also be cleared by


FIGURE 14-10. Immune-mediated clearance of erythrocytes in autoimmune hemolytic anemia. In warm-reactive disease, IgG autoantibodies are bound to erythrocytes but typically do not fix complement efficiently. The coated cells enter the spleen and other parts of the reticuloendothelial system (RES), where they interact with Fc receptors on macrophages. Erythrocytes may be completely engulfed and destroyed by this interaction or may have only a portion of their membrane removed. In this case the red cells will reshape into spherocytes, which are then doomed on their next passage through the spleen. In cold-reactive disease, complement is typically fixed very efficiently, and intravascular lysis by the complement cascade can occur. Alternatively, the presence of surface-bound complement (C3) can lead to extravascular red cell destruction by the spleen and RES.

macrophages bearing receptors for complement receptors.[59,63,168]

In cold agglutinin disease or PCH, the autoreactive antibody binds preferentially at 4° C and fixes complement efficiently. At normal body temperature there is virtually no antibody identifiable on the cell surface, but complement components, particularly C3b, can be identified with the Coombs reagent. If complement is activated to completion on the cell surface in vivo, the erythrocytes will hemolyze intravascularly and cause hemoglobinemia, followed by hemoglobinuria. When C3b is present on the red cell surface without further activation of complement, however, macrophages within the reticuloendothelial system can bind the erythrocytes via specific complement receptors and engulf them in a manner similar to that in warm-reactive AIHA.[169,170] Complement-coated erythrocytes are cleared extravascularly by macrophages located primarily within the liver rather than the spleen.

Therapy

The need to treat a patient with AIHA depends on the severity and rapidity with which the anemia develops. A child with relatively mild anemia (hemoglobin concentration of 9 to 12 g/dL), especially one who has recently had a viral-like illness, may benefit from observation alone. If the patient has a more severe degree of anemia (hemoglobin concentration of 6 to 9 g/dL) or if the hemoglobin concentration is observed to fall precipitously, therapy should be instituted. Optimal therapy depends on the clinical picture, as well as the form of AIHA. If the autoantibodies are cold reactive, for example, the patient should be kept warm with avoidance of all cold stimuli. Strict adherence to this recommendation is difficult, but it is often the best therapy for a patient with cold-reactive autoantibodies. If severe intravascular hemolysis is present, it is imperative that good renal blood flow and urine output be maintained.[90]

Therapy for acute warm-reactive AIHA in children should begin with close observation, judicious use of erythrocyte transfusions, and administration of corticosteroids. Additional therapy includes the administration of intravenous immunoglobulin (IVIG), plasma

(exchange) transfusion in selected settings, and more recently, targeted therapy with rituximab. Other therapeutic modalities such as cyclosporine, vinblastine, danazol, azathioprine, cyclophosphamide, and other agents have not been widely used in the pediatric age group and therefore have a limited therapeutic role for childhood AIHA. Table 14-3 lists these various treatment modalities; clinical responses and mechanisms of action are described in later sections.

When the anemia is severe enough to cause cardiovascular compromise, usually at a hemoglobin level lower than 5 g/dL, the use of erythrocyte transfusions to provide additional oxygen-carrying capacity should be strongly considered. Although the transfusion process is complicated and can be somewhat intimidating, erythrocyte transfusion may be lifesaving for a patient with AIHA, who may die as a result of complications related to anemia.[171] If clinically warranted, erythrocyte transfusions should never be withheld because of fear of a hemolytic transfusion reaction. The fate of transfused cells will probably not be worse than that of the patient's own erythrocytes, and they may provide temporary support until additional therapy slows the rate of hemolysis. In short, no child with AIHA should die of anemia.

The first problem related to the transfusion of a patient with AIHA is identification of compatible erythrocytes. It is important to provide a relatively large amount of serum and cells for testing well in advance of an anticipated erythrocyte transfusion. Particularly if the antigenic specificity is panreactive, the crossmatch will probably identify no units of blood that are fully compatible. In this instance, certain units that are "least incompatible" with the patient's serum will be identified. For patients who have previously received transfusions, it is critical to identify alloantibodies that may be masked by the stronger autoantibody.[172-174] Adsorption techniques are designed to remove autoantibodies and allow the identification of clinically important alloantibodies.[175,176]

The second difficulty associated with transfusion of a patient with AIHA is the actual transfusion itself. Fortunately, acute symptomatic transfusion reactions are not seen frequently, even with transfusion of units of blood that may have strong in vitro reactivity with the patient's serum.[172,177] The transfused cells have an in vivo survival

TABLE 14-3	Treatment Modalities for Autoimmune Hemolytic Anemia	
Treatment*	**Dose**	**Comments**
Red blood cell transfusions	Sufficient to reach 6-8 g/dL	Incompatibility may cause hemolysis Alloantibodies may be present
Corticosteroids	1-2 mg/kg IV q6h acutely 5-30 mg PO qod chronically	Effective for IgG more than IgM High doses for short-term use only
Intravenous immunoglobulin	1 g/kg/day for 1-5 days	Expensive, inconvenient to administer Effective in only a third of patients

Exchange transfusion or
    plasmapheresis
		Daily until stable; effective for IgM more than IgG
		    Requires large-caliber intravenous access

Splenectomy		Curative in 60-80% of patients Risk of postsplenectomy sepsis
Rituximab	375 mg/m^2 IV weekly × 4	B cell ablative, immunosuppressive
Danazol	50-800 mg/day PO	Hepatic dysfunction Androgenic side effects
Vincristine	1 mg/m^2 IV every week	Neurotoxicity
Cyclophosphamide	50-100 mg/day PO	Carcinogenic
Azathioprine	25-200 mg/day PO	Immunosuppressive
Cyclosporine	2-10 mg/kg/day PO	Nephrotoxicity, hypertension Immunosuppression

*See text for further description and discussion of each therapeutic agent.

that is approximately equivalent to that of endogenous erythrocytes, so they often have a beneficial effect even if they circulate only for a short time. On occasion, however, the transfusion results in severe hemolysis with hemoglobinemia, hemoglobinuria, and renal failure. For this reason, it is prudent to begin the transfusion at a slow rate and check both plasma and urine samples periodically for free hemoglobin. For patients with cold-reactive antibodies, it is useful to warm the patient and the entire room; a blood warmer should be used to raise the temperature of the transfused blood.

A recent report described the successful use of polymerized bovine hemoglobin to provide lifesaving oxygen-carrying capacity in a woman dying of AIHA.[178] Though intriguing as an alternative to erythrocyte transfusion, the use of erythrocyte substitutes such as perfluorochemicals or cell-free hemoglobin-based oxygen carriers must be considered highly experimental at this time.[179] Additional research in this area may identify safe alternatives to transfusions that may eventually benefit children with AIHA.

The use of corticosteroids is widely accepted therapy for AIHA, particularly for patients with IgG antibodies. From the initial report more than 50 years ago,[180] glucocorticoids have been used to interfere with the basic pathophysiologic process and immune destruction observed in AIHA. The guinea pig model of AIHA demonstrated that steroids increase the survival of both IgG- and IgM-sensitized erythrocytes by decreasing sequestration within the spleen and liver, respectively.[63,64] Corticosteroids are believed to inhibit Fc receptor–mediated clearance of sensitized erythrocytes,[66,181] which probably accounts for their effect within 24 to 48 hours

of administration. Corticosteroids may also inhibit autoantibody synthesis, although this effect requires several weeks to occur.

In a patient with warm-reactive AIHA or PCH, a typical dosing regimen of corticosteroids is 1 to 2 mg/kg of methylprednisolone given intravenously every 6 to 8 hours for the first 24 to 72 hours, usually while the patient is the sickest. Oral prednisone at 2 mg/kg/day may then be used when the patient's clinical condition is more stable. Typically, these high doses are required for only 2 to 4 weeks, followed by slow tapering of the dose, which may take 3 months or longer. Tapering of the corticosteroid dose should be aimed toward the use of a single morning dose, preferably every other day, but must be based on the patient's hemoglobin concentration, reticulocyte count, and DAT result. In general, tapering should be slower when active disease is evident. An overall response rate of approximately 80% has been reported.[182] On occasion, corticosteroid therapy may be beneficial in cold agglutinin disease.[183]

IVIG became a popular therapy for ITP in the 1980s.[184] Able to induce a potent blockade of the reticuloendothelial system,[185] IVIG was therefore an attractive option for the treatment of AIHA as well. Unfortunately, AIHA in many patients in early trials appeared to be refractory to IVIG therapy.[186,187] Bussel and colleagues[71] then reported that very high doses of IVIG (5 g/kg given over a 5-day period) were necessary to produce a therapeutic benefit, perhaps because the reticuloendothelial system was enlarged in AIHA patients. Even at this high dose, however, only approximately a third of patients with warm-reactive AIHA had a response to IVIG therapy.[71,188] Prognostic factors that predicted response

to IVIG included a lower pretreatment hemoglobin concentration and the presence of hepatomegaly.[189] Based on these results, as well as on a variety of safety and cost issues,[190] IVIG should not be considered standard treatment for AIHA in children. However, continued investigation of its potential role in modulation of the immune response may shed light on important mechanisms of autoantibody production and immune-mediated erythrocyte clearance.[191]

Exchange transfusion is a reasonable therapeutic option for AIHA in the acute setting because circulating erythrocyte autoantibodies, soluble activated complement components, and sensitized erythrocytes can all be removed from the patient simultaneously.[192] Alternatively, however, plasmapheresis or plasma exchange has been used to remove pathogenic autoantibodies and paraproteins,[193-196] even in very small children.[197] It is generally accepted that patients with IgM autoantibodies respond better to plasmapheresis than those with IgG autoantibodies do,[198] presumably because of differences in the size and binding characteristics of the two molecules, although plasmapheresis can be effective in IgG-mediated hemolysis as well.[199] The larger size of IgM molecules keeps them within the intravascular space and amenable to removal by plasmapheresis. In contrast, IgG autoantibodies diffuse into the extravascular space; thus, plasmapheresis removes only a fraction of the total IgG autoantibodies. In addition, IgM autoantibodies are less tightly affixed than IgG autoantibodies to erythrocytes at warm temperatures and are more likely to be removed by plasmapheresis. For this reason the extracorporeal circuit should be warmed during exchange transfusion of a patient with cold-reactive autoantibodies.[200] Recently, however, the benefits of plasma exchange to improve survival of transfused blood cells has been questioned.[201]

For a child with chronic or refractory AIHA, more aggressive therapy is often required to alleviate the symptoms of anemia and help the child achieve a more normal lifestyle. Long-term use of corticosteroids or immunoglobulin is generally unacceptable because of side effects, cost, and inconvenience. A variety of additional therapeutic agents are available, however, as well as surgical intervention. No simple treatment algorithm can be proposed that is correct for all children with AIHA. The clinician should individualize therapy for each patient based on the hematologic response and side effects.

Targeted therapy against the source of autoantibody production (antibody-secreting B lymphocytes) has recently become a reality. Rituximab (Rituxan) is a humanized murine monoclonal antibody directed against the human CD20 antigen, which is present only on B lymphocytes. Rituximab induces B-cell apoptosis[202] and is highly effective therapy against B-cell lymphoma.[203] Recently reviewed as a therapeutic option for children with a variety of autoimmune hematologic disorders,[204] rituximab offers a relatively safe and effective treatment of chronic or refractory AIHA. The earliest reports involved adult patients with AIHA, but excellent response rates have now been reported in case reports and small series of children with AIHA.[205-207] Rituximab quickly eliminates circulating B cells, and their recovery make take several months, yet serum immunoglobulin levels rarely decline and replacement IVIG is not clinically indicated. Reactivated viral infections have been reported rarely in immunosuppressed patients.[204] Rituximab offers an opportunity to eliminate autoreactive B lymphocytes and "reboot" part of the humoral immune system, and in practice it can obviate the need for nonspecific chemotherapy and surgical splenectomy. Prospective trials with rituximab are warranted to determine its efficacy versus more conventional therapy for childhood AIHA.

Splenectomy is the time-honored therapy for a patient with chronic AIHA.[182,208] The rationale for splenectomy is based in part on the animal model of AIHA, which demonstrated that IgG-sensitized erythrocytes were cleared almost exclusively within the spleen, regardless of whether complement was activated.[65] In keeping with this model, patients with IgG autoantibodies respond better to splenectomy than do patients with IgM autoantibodies.[209] However, preoperative prediction of the clinical response to splenectomy, based on splenic uptake of radiolabeled red cells,[210] is variable at best.[72,91] In 12 patients with AIHA, Parker and colleagues[211] found poor correlation between ^{51}Cr-labeled red cell survival and eventual response to splenectomy. Only three of five patients with a highly elevated spleen-to-liver uptake ratio had a clinical remission after splenectomy, whereas three of five with a very low ratio also underwent remission after splenectomy. The authors concluded that radiolabeled red cell survival studies were not reliable indicators of the clinical response to splenectomy in AIHA.[211] Splenectomy may also benefit patients with AIHA by removing a major site of autoantibody production, similar to the pathophysiologic effect of antiplatelet autoantibody production in ITP.[78]

Coon[212] reported 52 patients with AIHA who underwent splenectomy. There was no surgical mortality and low morbidity, and an excellent response was seen in 64% and improved status in another 21% of patients. However, splenectomy should be avoided in young children if possible because of the risk of postsplenectomy sepsis secondary to encapsulated bacterial organisms. Before splenectomy, children should be immunized with polyvalent polysaccharide vaccines against *S. pneumoniae* and *N. meningitidis* to enhance the humoral immune response against these potentially lethal pathogens. The addition of protein-conjugated vaccines against *S. pneumoniae* and *H. influenzae* type b into the routine infant immunization series has helped provide additional effective immunity against these organisms. Children who undergo splenectomy should receive penicillin twice daily for at least 2 years after surgery; some clinicians prefer lifelong penicillin prophylaxis because fatal sepsis occurring years after splenectomy has been described.[213,214]

Erythromycin should be used if the patient is allergic to penicillin. After splenectomy, prompt medical attention should be sought for children with fever (temperature >38.5° C [101.5° F]) because of the possibility of bacterial sepsis.

Additional therapeutic agents have been used less often in children with AIHA. High-dose pulse dexamethasone, which caused initial but fleeting excitement for patients with chronic ITP, had a beneficial effect for some adults with warm-reactive AIHA.[215] Danazol, a semisynthetic androgen, also has efficacy in some patients with AIHA,[70,216,217] although no young children were included in these reports. One report suggested that danazol was more effective when used as first-line therapy in conjunction with corticosteroids,[217] whereas another demonstrated excellent responses even in patients with refractory AIHA who had previously received therapy, including splenectomy.[70] The mechanisms of action of danazol are not known, but decreased titers of cell-bound IgG and complement have been noted in most patients who had a response.[70] Danazol has been shown to decrease IgG production,[218] thus suggesting that this therapy may have multiple mechanisms of action that could be beneficial for a patient with AIHA. The primary side effects of danazol, however, are elevations in hepatic transaminases and mild masculinizing effects, which essentially preclude its routine use in young or female patients.

Cytotoxic agents have been used in the treatment of AIHA, with the presumed intent of reducing autoantibody formation. Vincristine and vinblastine have limited use in the pediatric age group but should be considered for a patient with refractory AIHA.[69,219,220] In vitro incubation of platelets with vinca alkaloids, followed by transfusion of these "loaded" platelets, has been used to poison the reticuloendothelial macrophages directly.[219] Other cytotoxic agents, including cyclophosphamide, 6-mercaptopurine, and 6-thioguanine, have been successful in adults, but no trials involving children with AIHA have been reported to date. A typical daily dose of cyclophosphamide for an adult with AIHA is 50 to 100 mg orally. Because these agents are generally myelosuppressive and potentially mutagenic,[221] they should be used with great caution in children. The use of high-dose cyclophosphamide, designed to provide immunoablation without complete myeloablation, has been reported anecdotally for severe refractory AIHA.[222-224] Of nine patients with chronic refractory AIHA who received high-dose cyclophosphamide, six achieved complete remission and three had a partial remission. An important side effect of this immunoablative therapy is profound myelosuppression, although it was short-lived and not associated with serious infection.[224] The long-term efficacy of this aggressive approach remains unproven at the current time, but the regimen deserves prospective testing in selected children with life-threatening disease.

Azathioprine is an immunosuppressive agent that affects both the humoral and cellular arms of the immune response, but its greatest effects are on T lymphocytes.[182] By affecting helper T-cell function, azathioprine can interfere with autoantibody synthesis. Azathioprine is unlikely to induce clinical remission as a single drug but could be used as a corticosteroid-sparing agent. A treatment dose of azathioprine ranges from 25 to 200 mg/day orally, and side effects include leukopenia, thrombocytopenia, and hepatic injury. Because the goal of azathioprine therapy is a reduction in autoantibody synthesis, responses may not be noted until after 3 months of therapy.[182]

Cyclosporine, another immunosuppressive agent that focuses primarily on T lymphocytes, has been reported to have been successful in a few patients with steroid-resistant AIHA.[225] Because of the significant side effects associated with long-term use of cyclosporine, however, including nephrotoxicity, hypertension, and even a risk of malignancy, it should not be used routinely in children with AIHA. Targeted therapy against T lymphocytes with Campath 1H monoclonal antibodies has shown promising but short-lived responses in refractory disease.[226]

Several additional miscellaneous agents have been reported anecdotally to have beneficial effects in the treatment of AIHA. The response of a patient with cold agglutinin disease to interferon alfa therapy merits additional investigation.[227] The effects of soluble growth factors on erythrocyte phagocytosis by macrophages in AIHA suggests a potential role for cytokine therapy.[228]

Finally, complete lymphoid ablation and myeloablation, followed by reconstitution with compatible healthy hematopoietic stem cells, could theoretically cure systemic autoimmune diseases. The use of stem cell transplantation for autoimmune disorders such as AIHA has been proposed, and suggested guidelines have been published.[229] For children with refractory AIHA, transplantation of autologous stem cells has been attempted, but with limited success.[230,231] Human leukocyte antigen (HLA)-matched allogeneic stem cells may provide an additional graft-versus-autoimmunity effect,[230] although the current morbidity and mortality associated with allogeneic bone marrow transplantation must be carefully weighed against the adverse effects of conventional therapy. Moreover, AIHA can actually develop after bone marrow transplantation for other indications,[232,233] presumably in the setting of a weakened immune system with lymphocyte dysregulation. At this time, stem cell transplantation should not be considered a reasonable therapeutic option for children with primary AIHA unless they have refractory and life-threatening disease.

Pathogenesis of Autoantibody Formation

The erythrocyte autoantibodies produced in AIHA are clearly pathogenic, and the amount of antibody bound to the cell surface is proportional to the rate of erythrocyte removal by the reticuloendothelial system. Less is

known about the origin of autoantibody formation, however, and why certain individuals have in vivo expansion of autoreactive lymphocytes that should normally be suppressed or eliminated by the immune system. The pathogenesis of autoantibody formation in AIHA has recently been reviewed,[234,235] with several mechanisms proposed for the loss of self-tolerance, including cytokine imbalance, excessive lymphocyte activation, and molecular mimicry between self and foreign antigens, among others.

Older case reports suggest a genetic predisposition for the development of AIHA, with an association noted between AIHA and certain immune response genes, especially the HLA-B locus.[236] Patients with HLA-B8[237] or HLA-B27[238] may have an increased risk for AIHA,[237] whereas HLA-DQ6 may confer protection against AIHA.[239] Genetic loci in mice associated with the development of AIHA have been reported,[240] and a single nucleotide polymorphism in the human CTLA-4 gene locus may confer increased risk for AIHA.[241] Chromosomal abnormalities have been associated with the development of autoimmune cytopenia.[242,243]

Normal polyclonal antibodies develop after in vivo stimulation of B lymphocytes, especially after vaccination or infection. The erythrocyte autoantibodies that develop in most patients with AIHA also represent a polyclonal B-lymphocyte response; even classic warm-reactive AIHA will usually have multiple IgG isotypes and often detectable IgA autoantibodies.[244] For AIHA to develop, these polyclonal autoreactive B lymphocytes must avoid the normal immune tolerance mechanisms of apoptosis and suppression and then proliferate without proper immune surveillance.[245]

Sequence analysis of the immunoglobulin gene rearrangements used by AIHA autoantibodies has revealed a restricted repertoire of variable gene usage and evidence of somatic mutations,[246-248] which suggests that autoreactive B lymphocytes in AIHA undergo traditional in vivo polyclonal antigen-driven selection and mutation. Self-antigens that lead to the breakdown of normal immunologic tolerance mechanisms could actually be neoantigens that develop during inflammatory processes.[249] Although the autoreactive cells generated during immune responses are typically eliminated by apoptosis or suppressed to prevent their deleterious effects, naturally occurring autoantibodies are easily detectable in most healthy individuals, often without apparent immunization against target antigens.[250] Some of these autoantibodies have specificity against immunoglobulins[251] and presumably play a role in the suppression of other antibodies, thus illustrating a complex immunoregulatory process that can go awry and lead to the formation of pathogenic anti-RBC autoantibodies.[252] Long-lived plasma cells can produce these pathogenic autoantibodies for extended periods.[253] In the case of patients with chronic lymphocytic leukemia and AIHA, typically the leukemic cells have intraclonal diversity[254] and may not directly produce pathogenic antibodies.[255]

Although B lymphocytes have the most critical role in autoantibody formation, the traditional concepts of self/nonself discrimination and antigen-driven somatic mutation that characterize adaptive immunity have recently been modified with the elucidation of a more primitive innate immune system. Cell surface pattern recognition receptors, especially the Toll-like receptor family, allow binding of ligand to specific autoantigens and activation of B lymphocytes and dendritic cells, which can lead to autoantibody production.[256] This "Toll hypothesis" is important for certain B-lymphocyte subsets with a low activation threshold, which leads to their expansion in autoimmune models and autoantibody secretion.[257] Dysregulation of intracellular activation and signaling molecules, especially Lyn kinase, may also lead to enhanced autoantibody formation.[258,259]

In addition to B lymphocytes, it is also possible that other elements of the cellular immune system are involved in the pathophysiology that leads to AIHA. T lymphocytes orchestrate the immune response by interacting with antigen-presenting mononuclear cells and helping B cells produce specific antibody. Experimental results from a murine model of AIHA have implicated T lymphocytes in the pathogenesis of the disorder,[260] and T-lymphocyte reactivity with epitopes on the Rh and band 3 molecules has been described.[261-263] AIHA with substantial morbidity and mortality has been reported in patients after bone marrow transplantation[264,265]; the success of stem cell "add back" as treatment of this complication[266] suggests that T lymphocytes could be part of the pathogenesis of AIHA. AIHA also is a well-recognized clinical manifestation of infection with human immunodeficiency virus (HIV),[267,268] which is known to have profound effects on the T-lymphocyte compartment.

The role of cytokines in the pathophysiology of AIHA is also under investigation. Increased levels of regulatory cytokines, including interleukin-4 (IL-4), IL-6, IL-10, and IL-13, have been reported in AIHA.[269,270] An imbalance of the IL-10/IL-12 ratio, reflecting a prevalence of T_H2 over T_H1 cytokines, has also been observed.[271] Successful treatment of refractory AIHA with an anti-human IL-6 receptor monoclonal antibody indicates the importance of cytokine signaling pathways in the pathophysiology of this disorder.[272] Finally, altered expression of FcγRIII on macrophages appears to influence the clearance of antibody-sensitized erythrocytes,[273] thus illustrating the importance of macrophages in the pathophysiology of AIHA and the potential for targeted therapy. Taken together, these data support the hypothesis that polyclonal autoreactive B lymphocytes are present in the immune repertoire of normal individuals but expand and proliferate only after specific immune stimulation in certain clinical settings, such as genetically susceptible individuals or those with T-lymphocyte dysregulation or cytokine-mediated monocyte/macrophage abnormalities, with subsequent loss of normal tolerance mechanisms.

SECONDARY AUTOIMMUNE HEMOLYTIC ANEMIA

The classification scheme presented in Box 14-1 indicates that AIHA can be a primary disorder or can occur in association with other underlying conditions. The latter cases are known as secondary AIHA because they occur in the setting of much broader immune dysregulation. In one large series composed of mostly adults, patients with secondary AIHA represented more than half of the total patients with warm-reactive AIHA.[131] All patients with AIHA should be evaluated for the presence of another underlying illness.

Systemic Disorders

A common form of secondary AIHA occurs in patients with SLE, another recognized autoimmune disease.[274] Other generalized autoimmune and inflammatory disorders, including Sjögren's syndrome,[275] scleroderma,[276] dermatomyositis,[277] ulcerative colitis,[278] Crohn's disease,[279] and autoimmune thyroiditis,[280] have been associated with AIHA. The belief is that these persons have a genetic susceptibility for immune dysregulation, which leads to the expansion and proliferation of autoreactive B lymphocytes and causes the systemic disorder, including AIHA.

AIHA can occur in the setting of malignancy and is sometimes identified clinically before the diagnosis of cancer. In adults, the erythrocyte autoantibodies may reflect an abnormal B-lymphocyte clone found in chronic lymphocytic leukemia,[281] lymphoma,[282] or multiple myeloma.[283] AIHA may also occur in young patients with lymphoma,[284,285] leukemia,[286] or myelodysplasia.[287] Survival of lymphoma patients in whom AIHA develops is poor.[282] Although the cause of AIHA in patients with cancer is not known, an underlying immune deficiency may be the origin of both the autoimmune phenomenon and the malignancy.

Immunodeficiency

Immune cytopenia, including AIHA, can develop in children with congenital immunodeficiency, probably because of the lack of proper immune regulation.[288] In some cases the underlying immunodeficiency may not yet be clinically recognized, as illustrated by four children with autoimmune cytopenia (two with AIHA, two with ITP) who had unsuspected common variable immunodeficiency (CVID).[289] Autoimmune cytopenia will develop in about 11% of patients with CVID, often during childhood.[290] Treatment of AIHA in patients with CVID is similar to that of primary AIHA; corticosteroids, IVIG, splenectomy, and even rituximab have been used successfully.[289-292] Wiskott-Aldrich syndrome (WAS) is another congenital immunodeficiency that can lead to immune-mediated cytopenia. In one large single-center cohort of 55 patients, AIHA developed in 36% of the patients with WAS before the age of 5 years.[293] Similarly, AIHA can also develop in patients with acquired immunodeficiency. Patients infected with HIV are particularly susceptible to the development of erythrocyte autoantibodies,[267,268] probably because of both the polyclonal B-lymphocyte activation and lack of immune regulation by T lymphocytes. Children with marked immunosuppression, such as after solid organ transplantation, are susceptible to the development of AIHA.[294] A recent report documented the efficacy of rituximab for AIHA that developed in children after cardiac transplantation.[295]

Evans' Syndrome

A special association exists between AIHA and other autoimmune cytopenias, especially thrombocytopenia. First described by Evans and colleagues more than 50 years ago,[96] the combination of autoimmune anemia and thrombocytopenia (and occasionally granulocytopenia) is known as Evans' syndrome. In an older review of childhood Evans' syndrome, the typical clinical course was noted to be chronic and relapsing, and the therapy was generally unsatisfactory.[296] A recent review confirmed this challenging and highly variable clinical course but noted that the advent of potent immunosuppressive drugs, rituximab, and stem cell transplantation now offers improved therapeutic options.[297] A variety of immunoregulatory abnormalities have been suggested in this disorder,[298] although no single underlying specific immune defect has been identified. The autoantibodies are apparently directed against specific antigens on each of the various blood cell types; that is, the antibodies against erythrocytes, platelets, and occasionally granulocytes are not cross-reactive.[299] Because many children with Evans' syndrome have refractory life-threatening disease, aggressive therapy is often warranted. Multiagent therapy including vincristine and cyclosporine has been advocated,[300] and recently, stable remissions have been achieved with rituximab therapy alone.[301] Historically, bone marrow transplantation for children with Evans' syndrome has been associated with a poor clinical outcome, although some successful allogeneic transplants have been reported.[297,302] The diagnosis of Evans' syndrome is essentially one of exclusion because other conditions (described in subsequent sections) such as ALPS, microangiopathic hemolytic anemia, schistocytic anemia, and even PNH can mimic its clinical findings.

Autoimmune Lymphoproliferative Syndrome

In 1967, Canale and Smith[303] described a new condition of significant generalized lymphadenopathy with manifestations of autoimmune disease and a chronic clinical course that occurs before the age of 2 years; the authors presciently postulated a primary immunologic disorder. Decades later, two murine models of autoimmunity (lpr and gld mice) were noted to have similar features.

After these mice were found to have mutations in Fas and Fas ligand, respectively,[304,305] similar mutations were identified in the human condition,[306-308] then named *autoimmune lymphoproliferative syndrome*. Children with ALPS have defective lymphocyte apoptosis as a result of failure of developing lymphocytes to undergo Fas-mediated cell death[309]; an excess number of TCRαβ[+]CD3[+]CD4[−]CD8[−] (double-negative) T lymphocytes are characteristically found in the lymph nodes and peripheral blood.[310,311]

National Institutes of Health criteria for establishing the diagnosis of ALPS have been published and include the following three required findings: (1) chronic non-malignant lymphoproliferation, (2) defective in vitro Fas-mediated lymphocyte apoptosis, and (3) 1% or more double-negative T lymphocytes in the peripheral blood or lymphoid tissues. Supportive diagnostic evidence includes autoimmune antibodies and genetic mutations in the Fas-mediated apoptosis pathway.[312] Most patients with ALPS will have lymphadenopathy, organomegaly, and various autoimmune disorders, including AIHA or ITP. In one series of 34 consecutive patients, 21 (62%) had a positive DAT result, in most cases to IgG alone, although only 10 had a history of hemolytic anemia.[313] An elevated risk of malignancy, especially Hodgkin's and non-Hodgkin's lymphoma, has also been documented.[314]

The majority of ALPS patients have specific genetic mutations in either Fas or Fas ligand, although mutations in other genes within the Fas-mediated signaling pathway, such as caspase-8 or caspase-10, have also been identified.[315] Approximately 25% of patients with ALPS have no genetic mutation that can yet be identified. Perforin mutations in a clinical variant of ALPS has recently been reported,[316] thus suggesting that a variety of genetic mutations leading to immunologic dysfunction may result in lymphoproliferation and autoimmunity. Clinical overlap between Evans syndrome and ALPS is also recognized; 12 children with the diagnosis of Evans syndrome were found to have elevated numbers of circulating double-negative T lymphocytes and defective Fas-mediated apoptosis.[317] Taken together, these data indicate that all children with AIHA, especially those with the diagnosis of Evans syndrome, should be evaluated carefully for an underlying immunologic disorder such as ALPS.

Infections

The majority of young children with PCH have recently had a viral-like illness,[79,87,90] although an infectious pathogen is rarely identified. Historically, PCH developed in patients with syphilis, but this is rarely observed today. On occasion, however, a well-defined infection can trigger AIHA with either warm-reactive or cold-reactive erythrocyte autoantibodies. Numerous infectious agents have been reported, including *M. pneumoniae*,[318] Epstein-Barr virus,[319] varicella,[320] hepatitis C,[321] rubella,[322] parvovirus,[323] mumps, and cytomegalovirus, among others. Most of these autoantibodies are IgM with a specificity for the I/i polysaccharide antigen system on the red cells[139]; reactivity of anti-I antibodies with mycoplasmal antigens suggests that the autoantibodies may result from immunologic cross-reactivity.[324]

Acute bacterial infections can cause immune-mediated hemolytic anemia from a different mechanism. The T antigen on the erythrocyte surface is known as a "cryptic" antigen because it is not normally available for antibody binding. In the presence of bacteria with neuraminidase activity, such as clostridial or pneumococcal species, removal of sialic acid leads to exposure of the RBC T antigen. Because many people have naturally occurring cold-reactive IgM antibodies with anti-T specificity, immune-mediated hemolysis and even microangiopathic schistocytic anemia can result.[325,326] Although the practice is controversial, erythrocytes should probably be washed in this clinical setting to avoid transfusing additional anti-T antibodies.[327]

Drugs

Though not common in childhood, drug-induced autoantibodies must be included as a cause of secondary AIHA. Classically described after therapy with methyldopa,[328] red cell antibodies have been reported in association with dozens of different pharmaceutical agents.[329] Medications of particular importance in the pediatric age range that can cause AIHA include a variety of antibiotics: penicillins,[330,331] cephalosporins,[332-334] tetracycline,[335] erythromycin,[336] and ribavirin.[337] Common agents such as acetaminophen[338] and ibuprofen[339] have also been implicated in hemolysis. Drug-induced hemolytic anemia typically results from the generation of antidrug antibodies that cross-react with erythrocytes, although the drug may be required to form a hapten or even a ternary complex with the erythrocyte.[329,340,341]

Therapy

Therapy for patients with secondary AIHA must be twofold: the hemolytic anemia must be treated, and for best results the underlying systemic illness must be addressed as well. For example, treatment of a generalized autoimmune or inflammatory disorder or administration of antibiotics for a specific infection can also have a beneficial effect on AIHA. Discontinuation of the offending drug will help ameliorate hemolysis from drug-induced autoantibodies. In most cases of warm-reactive secondary AIHA, administration of corticosteroids is effective in reducing hemolysis. Short bursts or tapering courses of steroids can be used safely in patients with secondary AIHA, even if they are immunodeficient. In contrast, splenectomy is less likely to be successful in adults with secondary AIHA in association with malignancy than in those with primary AIHA.[342] Successful results with rapamycin and arsenic trioxide in murine models of lymphoproliferation and autoimmunity[343,344] suggest that novel therapeutic strategies may soon be available for patients with AIHA secondary to ALPS.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

A rare condition, PNH has fascinated hematologists for more than a century. In its classic manifestation, patients with PNH have ongoing intravascular hemolysis with intermittent episodes of dark urine (hemoglobinuria), most commonly on awakening in the morning. The hemolysis of PNH is due to abnormal interactions between erythrocytes and the complement system. However, unlike AIHA, PNH is actually an intracorpuscular defect because the hemolysis results from increased sensitivity of the patient's erythrocytes to physiologic complement-mediated lysis. In addition, PNH is a complex disease with protean clinical manifestations, only one of which is hemolytic anemia. The secrets of this enigmatic disorder have only recently yielded to the efforts of modern molecular biology, culminating with identification of the *PIGA* gene, which is mutated in patients with PNH. Current challenges relate to elucidation of the pathogenetic events that lead to PNH, as well as issues of early diagnosis and optimal clinical management.

Historical Perspective

Clinicians first described PNH in the latter part of the 19th century,[345,346] although it took many years to recognize several important facts: (1) the dark pigment in urine was actually hemoglobin; (2) the serum of patients with PNH did not induce hemolysis of normal erythrocytes, thus distinguishing PNH from PCH; (3) the hemolysis was due to an intrinsic defect in the patient's own erythrocytes; and (4) the hemolysis was due to the lytic action of serum complement. Many of the initial insights into the pathophysiology of the hemolysis were due to the efforts of Dr. Thomas Ham, who first clearly demonstrated that acidified serum enhanced the hemolysis of PNH erythrocytes[347-349]; the test that bears his name was for many years the definitive laboratory method to establish the diagnosis of PNH. It was later recognized that complement lysis sensitivity was not all or none in that patients often had a population of erythrocytes with 15- to 25-fold increased complement sensitivity (type III cells), another population with 3- to 5-fold increased sensitivity (type II cells), and a population of normal type I erythrocytes.[350-352] Flow cytometry has now replaced the time-honored Ham test, as well as the sucrose lysis and complement lysis sensitivity tests, as the preferred diagnostic laboratory method for the diagnosis of PNH.[353]

Clinical Manifestations and Therapy

Passing of dark urine is the classic symptom for which the disorder is named. Patients with PNH have hemoglobinuria rather than hematuria as a result of chronic intravascular hemolysis from complement. Although the original descriptions accurately indicated that dark urine occurs more often on awakening, the cause of this temporal variation is not clear. Possibly, accelerated hemolysis occurs during sleep because of the presence of relative hypercapnia leading to slight acidosis and complement activation, which becomes evident in the morning urine. Many patients with PNH have dark urine throughout the day, whereas this symptom never develops in some. The typical patient reports an episode every few weeks, although some have chronic unrelenting hemolysis. Patients may describe hemoglobinuria with colorful language ranging from iced tea to cola to mahogany to motor oil, or they may describe the urine as various combinations of red, orange, brown, and black (Fig. 14-11A). Stress or infections tend to trigger hemolysis, although there is often no identifiable reason. Therapy with oral corticosteroids (1 to 2 mg/kg/day of prednisone) can ameliorate the hemolysis and is often recommended for 24 to 72 hours around the time of an acute hemolytic episode. Eculizumab, a humanized monoclonal antibody against terminal complement protein C5, has recently been shown to significantly reduce intravascular hemolysis and improve quality of life in adults with PNH.[354] Eculizumab is not currently licensed in the United States for the treatment of children with PNH.

The clinical manifestations of PNH include much more than simply hemolytic anemia.[355] Box 14-2 lists the more common signs and symptoms observed in patients with PNH. In addition to hemolysis, patients with PNH tend to have an increased number of infections, particularly those that are sinopulmonary and blood-borne. A more severe clinical complication is venous thrombosis, which occurs in a third of patients and often in unusual locations such as the hepatic veins, where it leads to Budd-Chiari syndrome (Fig. 14-11B), in the mesenteric veins, or in the sagittal veins (Fig. 14-11C). The complications of venous thrombosis can be fatal because the

In this T1-weighted coronal image at the level of the posterior internal cerebral veins, the normally expected black flow signal void in the superior sagittal sinus (*white arrow*) is replaced with an intermediate signal as a result of the thrombus. This appearance contrasts with the normal black venous flow void that is preserved in the internal cerebral veins (*black arrowhead*). (*A, Courtesy of Dr. Wendell Rosse; C, courtesy of Drs. Frank Keller and Jeffrey Hogg.*)

hypercoagulability observed in PNH is very difficult to treat, even with thrombolytic agents. The development of venous thrombosis is a risk factor for poor long-term survival, at least for white patients.[356] In patients of Asian ancestry with PNH, however, venous thrombosis rarely develops, thus suggesting a genetic predisposition for the hypercoagulable state in PNH.[357]

Defective hematopoiesis is present in the majority of patients with PNH, either at initial evaluation or during the course of the disease.[357] Although many patients are aplastic, most have peripheral macrocytic anemia with erythroid hyperplasia in the bone marrow; some evolve into severe aplastic anemia with hypoplastic marrow and suffer the clinical consequences of pancytopenia. Treatment with antithymocyte globulin (ATG) seems to help a portion of patients, particularly those with hypoplastic marrow; the presence of a PNH clone may lead to some increased hemolysis[358] but portends a favorable response to immunosuppressive therapy.[359] Finally, PNH can evolve into myelodysplasia or acute nonlymphoblastic leukemia, which typically occurs within the first 5 years

of disease.[360] The incidence of leukemic transformation is only 1% to 3%, but this rate far exceeds that in the general population.

Though primarily a disease of adults, PNH definitely occurs in children and adolescents, and the diagnosis should be considered in any child with unexplained cytopenia or thrombosis. In a cohort of 26 young patients with PNH, several important differences from the clinical descriptions in adults were noted.[361] In many children, PNH was initially misdiagnosed, with an average of almost 2 years from initial symptoms to the correct diagnosis. Very few children had dark urine as an initial symptom, and in only 65% of children did clinically evident hemoglobinuria ever develop. Thrombosis occurred in approximately a third of patients, and some died of this complication. All patients had laboratory evidence of defective or ineffective hematopoiesis, either at diagnosis or over the course of their disease. The survival curve for these patients indicated that the 10-year survival rate was only 60%, although several deaths were due to complications of pancytopenia in an era before

modern antibiotic and transfusion therapy. Because bone marrow transplantation can be curative therapy for PNH,[362] it should be considered in selected patients with this disorder if an HLA-matched sibling donor is available. A recent summary of 11 pediatric patients with PNH from the Netherlands over a 20-year period reported successful transplantation in 4 of 5 patients.[363] Transplants from unrelated stem cell donors are associated with substantial morbidity and mortality, however, and despite anecdotal success[363,364] cannot be recommended routinely for patients with PNH.

Biochemical Basis

Important clues to the etiology of PNH emerged in the 1980s with the identification of two complement regulatory proteins, CD55 (decay accelerating factor [DAF])[365] and CD59 (membrane inhibitor of reactive lysis).[366] The abnormal peripheral blood cells in patients with PNH were noted to be lacking both CD55 and CD59. As a result of these deficiencies, randomly deposited complement factors and C3 convertase complexes cannot be cleared from the erythrocyte membrane, which leads to formation of the membrane attack complex, pores, and cell lysis.[350]

The commonality of these two complement regulatory proteins goes beyond function because both use a novel motif for anchoring into the plasma membrane (Fig. 14-12). Unlike the majority of surface proteins, which contain a highly hydrophobic domain that serves as a transmembrane region between the intracellular domain and the extracellular domain of the polypeptide,

certain proteins use a glycosylphosphatidylinositol (GPI) anchor for membrane attachment.[367,368] GPI-linked proteins are covalently attached at their C-terminal to a variable glycan moiety, which is itself attached to a phosphatidylinositol molecule in the outer leaflet of the cell membrane lipid bilayer. This glycolipid structure is assembled within the endoplasmic reticulum and is coupled to the protein precursor as a preformed unit.[368,369] Initially described for the alkaline phosphatase enzyme,[370] GPI linkage is now known to be used by a diverse set of surface proteins (Box 14-3), including acetylcholinesterase,[371] Thy-1,[372] lymphocyte function–associated antigen,[373] FcγRIII,[374] the complement regulatory proteins CD55 and CD59,[365,366] CD157 involved in neutrophil diapedesis,[375] and others. The functional advantages of GPI linkage for surface proteins remain speculative, but observations suggest increased lateral diffusional mobility,[376,377] second messenger generation,[378] signal transduction,[379,380] and the ability to be cleaved from the cell surface into the extracellular milieu.[381]

The primary defect in PNH resides in the incomplete bioassembly of GPI anchors because all GPI-linked surface proteins have absent or diminished expression on the surface of the abnormal PNH cells.[382-384] Biochemical analysis of GPI-deficient cells has localized the defect in PNH to an early step in GPI anchor biosynthesis.[385] Mammalian mutant cell lines deficient in GPI-linked surface proteins were then established and classified into different complementation classes.[386] Class A, C, and H mutants cannot transfer the initial *N*-acetylglucosamine to the phosphatidylinositol acceptor, which suggests that at least three genes control this step. Fusion experiments

FIGURE 14-12. Glycosylphosphatidylinositol (GPI) anchor for attachment of surface proteins to the cell membrane. The structure of a GPI-linked protein is shown on the *left*. The GPI anchor consists of a phosphatidylinositol molecule in the outer leaflet of the lipid bilayer connected to a glycan core composed of multiple sugars and side chains. The polypeptide is then linked to the anchor at its C-terminal via an amide bond. The result is a surface protein with a fluid and mobile attachment to the cell surface. The entire polypeptide is present in the extracellular milieu. In contrast, a transmembrane protein is shown on the *right* and consists of an extracellular domain, a short transmembrane domain, and an intracellular domain.

of PNH cells with murine GPI-deficient cell lines further identified the defect as a class A mutation in all patients tested.[385,387] Thus, despite the possibility of various enzymatic defects along the biosynthetic pathway of the GPI anchor, all patients with PNH reported to date have a class A defect.

Altered expression of GPI-linked surface proteins on the abnormal cells in PNH has led to a simpler and more accurate diagnostic test than the older methods of complement-mediated lysis. Peripheral blood erythrocytes and granulocytes can be analyzed by flow cytometry for surface expression of GPI-linked proteins such as CD16, CD48, CD55, or CD59.[353,355] Erythrocytes that are completely deficient in GPI-linked surface proteins are present in almost all patients and correspond to the PNH type III cells. Partially deficient cells can be detected in approximately 50% of patients and correspond to type II cells.[353] Cells with normal GPI-linked surface expression (type I cells) are typically present as well. Identification of these cell populations by flow cytometry analysis is illustrated in Figure 14-13. Surface expression of CD59

FIGURE 14-13. Immunophenotype analysis of erythrocytes in paroxysmal nocturnal hemoglobinuria by flow cytometry. on circulating erythrocytes from a patient with type I and type III cells is shown in Figure 14-13A, that for a patient with type I, II, and III cells in Figure 14-13B, and that for a patient with predominantly type III cells but a few type II cells in Figure 14-13C. Flow cytometry for a normal control is shown in Figure 14-13D. More recently, flow cytometric analysis of PNH has been improved by the introduction of a fluorescent aerolysin (FLAER) reagent that binds to all GPI-linked surface proteins.[388] Flow cytometry using the FLAER reagent is highly sensitive for PNH and has even led to a new category of disease known as "laboratory" or "subclinical" PNH because of the detection of extremely low numbers of PNH cells, sometimes below 0.01%.[355]

Molecular Basis

Analyses of glucose-6-phosphate dehydrogenase allozymes[389] and a monoclonal pattern of X-chromosome inactivation[390] have documented that PNH is a clonal hematologic disorder. The abnormal clone is believed to originate at the level of a primitive multipotent bone marrow progenitor cell in that all cells of the myeloerythroid lineage are affected, including erythrocytes, granulocytes, platelets, and monocytes. Lymphocytes and natural killer cells are also deficient in GPI to varying degrees, however, thus suggesting that PNH is actually a clonal stem cell disorder. The abnormal PNH clone may be too minimal to be clinically apparent, can be relatively minor and affect 10% to 25% of circulating erythrocytes and granulocytes, or can become dominant with more than 95% GPI-deficient circulating cells.[355]

The recognition that all patients with PNH have a class A complementation defect suggested that a single gene was responsible for this disorder. By using the strategy of a human cDNA expression library, a gene was identified that repaired the defect in a class A GPI-deficient cell line.[391] Designated *PIGA* because it repaired the phosphatidylinositol glycan defect in a class A mutant, this cDNA encoded a novel polypeptide with homology to other known glycosyltransferases. *PIGA* was subsequently considered to be a candidate gene for PNH, and relatively quickly several groups reported that *PIGA* is the gene defective in PNH.[392-396] Interestingly, the majority of mutations are short insertions or deletions (one to two nucleotides) that occur throughout the coding region of the *PIGA* gene.[397] These nucleotide changes cause frameshift mutations because the triplet nucleotide coding sequence is altered; usually a premature termination codon follows the frameshift mutation. Missense mutations that substitute a single amino acid residue account for the minority of *PIGA* abnormalities reported.[398]

Chromosomal assignment of *PIGA* to the X chromosome[392,399] and assignment of other genes involved in GPI anchor biosynthesis (*PIGF* and *PIGH*) to autosomes[399] helped explain the predominant class A defect in PNH. Whereas a single *PIGA* mutation could result in

abnormal GPI anchor biosynthesis, mutations in both alleles of other genes involved in GPI anchor biosynthesis would be required to produce clinically overt disease. Recently, an autosomal recessive form of GPI deficiency has been reported[400] to be due to an inherited point mutation in the promoter of *PIGM*, a mannosyltransferase-encoding gene critical in GPI anchor synthesis. In two unrelated consanguineous families, this inherited *PIGM* deficiency led to venous thrombosis and neurologic dysfunction, but not to bone marrow failure or hemolysis. This congenital variant of GPI deficiency without evidence of bone marrow dysfunction suggests that the pathogenesis of PNH involves more than just absence of GPI anchor bioassembly.

Do *PIGA* Mutations Cause Paroxysmal Nocturnal Hemoglobinuria?

The pathophysiology of the various clinical manifestations of PNH presumably reflects the absence or diminished expression of specific GPI-linked surface proteins. Hemoglobinuria is readily explained by the absence of surface CD55 and CD59, which allows chronic complement-mediated intravascular hemolysis. In contrast, the cause of the hypercoagulable state in PNH is not well understood. PNH platelets lack the GPI-linked complement regulatory proteins CD55 and CD59 and respond to the deposition of terminal complement components by vesiculation of portions of their plasma membrane. The resultant platelet microparticles have increased procoagulant properties.[401] PNH cells also lack the receptor for the GPI-linked urokinase plasminogen activator, which may result in impaired fibrinolysis.[402] However, patients with PNH have normal plasma levels of natural anticoagulants, including proteins C and S, thrombomodulin, and antithrombin III, and no known inherited thrombophilic mutations.

The defective hematopoiesis that affects so many patients with PNH is also not well understood. Although GPI-linked surface proteins are likely to be important for normal hematopoiesis, no specific molecule has been identified whose absence leads to marrow hypoplasia. An unusual association is well recognized between PNH and aplastic anemia, however, in that one usually evolves clinically into the other.[403,404] For example, in some patients with severe aplastic anemia, PNH will eventually develop, often after successful immunosuppressive therapy such as ATG or cyclosporine.[405] In contrast, in others with nearly normal blood counts and hypercellular bone marrow, hypoplasia will slowly develop, usually as a terminal event.[357]

Several models have been proposed for the pathogenesis and development of PNH. A one-step model originally proposed more than 40 years ago stated that a single genetic defect leads directly to PNH.[403] Although this model was attractive because of its simplicity, laboratory evidence using embryonic stem cells[406] and murine models[407] indicated that an acquired *PIGA* mutation did not lead to aplastic anemia or clonal dominance by the abnormal cells. A subsequent two-step model[408,409] suggested that aplastic anemia would occur first and then a *PIGA* mutation would develop within a remaining stem cell. The resulting PNH progeny would then be able to grow preferentially over their normal hematopoietic counterparts. However, the identification of multiple clones with distinct *PIGA* mutations in individual patients with PNH,[396,410,411] coupled with the identification of rare hematopoietic cells with *PIGA* mutations in normal healthy persons,[412-414] indicates that the two-step model is also too simplistic.

As illustrated in Figure 14-14, a newer multistep model proposed that *PIGA* mutations develop initially as randomly acquired events,[415] thus explaining their presence in the bone marrow and peripheral blood of normal adults. These *PIGA* mutant cells do not proliferate, however, unless marrow damage occurs, perhaps by autoimmune attack against primarily normal hematopoietic progenitor cells. In the setting of marrow damage, additional genetic events, perhaps including those that confer resistance to apoptosis,[416-418] then lead to a growth

Rights were not granted to include this figure in electronic media. Please refer to the printed publication.

FIGURE 14-14. Multistep model for the pathogenesis and evolution of paroxysmal nocturnal hemoglobinuria (PNH). In contrast to previous models that hypothesized either a one-step or two-step model, a multistep process is proposed. *PIGA* mutations are acquired randomly and are present in most normal healthy persons. In the setting of an aplastogenic event with marrow injury, such as an autoimmune attack on hematopoiesis, surviving cells undergo a selection process. Genetic mechanisms, including those conferring resistance to apoptosis, allow continued clonal expansion and sometimes clonal dominance of the abnormal PNH clone. Additional genetic events occasionally lead to myelodysplasia or aplasia. AML, acute myeloid leukemia; MDS, myelodysplastic syndrome. *(From Ware RE, Heeney MM, Pickens CV, et al. A multistep model for the pathogenesis and evolution of PNH. In Omine M, Kinoshita T [eds]. Paroxysmal Nocturnal Hemoglobinuria and Related Disorders: Molecular Aspects of Pathogenesis. Heidelberg, Germany, Springer-Verlag, 2003.)*

advantage of the *PIGA* mutant cells, clonal expansion, and eventual clonal dominance. Later genetic events can lead to evolution to myelodysplasia or even malignant transformation into leukemia. This multistep model is supported by the recent description of two unrelated patients whose *PIGA* mutant cells also had an acquired rearrangement of the *HMGA2* gene.[419] The recognition that *HMGA2* is a transcriptional factor gene deregulated in many benign lipomas and other mesenchymal tumors led the authors to suggest that PNH might also be considered a "benign tumor of the bone marrow."[419] This intriguing notion is supported by the observations that PNH cell populations are not typically malignant, expand but respect normal tissue boundaries, respond appropriately to physiologic signals, and have no autonomous growth. Mutations in the *HMGA2* gene, which is located on chromosome 12, have also been associated with clonal expansion in polycythemia vera.[420]

SCHISTOCYTIC HEMOLYTIC ANEMIA

Overview

The term *schistocyte* is derived from the Greek word σξιζω (schizo), which translates "to tear" and describes erythrocytes that are broken, torn, or sheared. These bizarre poikilocytes are sometimes referred to as schizocytes, but because this term might be confused with the schizont phase of malarial erythrocyte infection, the term schistocyte is generally preferred. Schistocytic hemolytic anemia is characterized by the development of red cell fragments after exposure of erythrocytes to excessive environmental stress or shearing force within the vasculature. This unusual form of hemolytic anemia arises in various pathophysiologic settings, but each clinical condition features increased external force on the erythrocytes.

RBCs encounter tremendous force as they travel normally through the circulation, including collisions, turbulence, pressure fluctuations, shearing stress, and interactions with a variety of solid surfaces. Erythrocytes are exposed to some of the highest force in the left ventricle as they pass through the aortic valve and flow into the aorta. Among these various forces, experiments have shown that shearing force is the most difficult for erythrocytes to withstand and hemolysis occurs after a threshold is reached. Erythrocytes can withstand shear force of up to 15,000 dynes/cm^2 without hemolysis if this force arises at a fluid-fluid interface,[421] but hemolysis occurs at much lower shear force at a fluid-solid interface. In vitro, hemolysis occurs between 1500 and 3000 dynes/cm^2, especially if the solid surface has irregularities.[422,423] Moreover, the mechanical fragility of erythrocytes is affected by temperature, lipids, viscosity, and plasma proteins.[421]

The clinical features of schistocytic hemolytic anemia reflect primarily intravascular hemolysis because the erythrocytes are damaged and broken within the blood vessels. Anemia with pallor and fatigue is more common than jaundice, and dark urine is often present as the primary manifestation of intravascular hemolysis. Erythrocyte fragmentation leads to hemoglobinemia and hemoglobinuria, as well as elevation of serum lactate dehydrogenase. The serum bilirubin level is usually modestly elevated as a result of extravascular clearance of the damaged erythrocytes. Examination of the peripheral blood smear (Fig. 14-15) reveals schistocytes with characteristic triangular or crescent shapes, which represent erythrocytes that have recently undergone fragmentation. Spherocytes (sometimes called spheroschistocytes) can also be present and represent broken cells that have resealed their membranes and formed into a sphere, analogous to the process that occurs in immune-mediated hemolytic anemia. Teardrop shapes may be seen in response to the anemia, along with polychromasia (reticulocytosis). Depending on the pathophysiologic
FIGURE 14-15. Schistocytic hemolytic anemia. **A**, Congenital schistocytic anemia. **B**, Acquired schistocytic anemia. The peripheral blood smear (×1000) contains several erythrocytes with characteristic sheared, triangular, or crescent shapes reflecting cells that have recently undergone fragmentation. Spherocytes are also identified and represent broken cells that have resealed their membranes and adopted a spherical shape.

changes, there may also be laboratory evidence of intravascular coagulation and thrombocytopenia from platelet trapping or consumption. Schistocytic hemolytic anemia with renal failure and thrombocytopenia is called HUS; the additional presence of fever and neurologic dysfunction is called TTP.

Microangiopathic Hemolytic Anemia

The term microangiopathic hemolytic anemia was used almost 50 years ago by Brain and co-workers[424] to describe schistocytic hemolysis in conjunction with "disease of small blood vessels." Studying a large cohort of patients with schistocytic hemolytic anemia and acute or chronic renal failure, these authors demonstrated that the amount of erythrocyte fragmentation correlated with the degree of microangiopathic disease, and they postulated that schistocytes develop as a direct consequence of vascular injury. Histologically, microangiopathy was most prominent in the kidney, where arteriolar damage and intraluminal thrombi were noted.[424] An instructive case report of a patient with fatal microangiopathic hemolytic anemia appeared several years later; large numbers of microclots composed of fine fibrin strands were identified within the renal and pulmonary arterioles.[425] With scanning electron microscopy, individual erythrocytes were found to be tangled in the fibrin strands, which caused cellular deformation, breakage, and sphering. Figure 14-16 illustrates a "hanged" red blood cell in this destructive intraluminal milieu.[425] Identification of these fine fibrin strands within the small arteriolar circulation provides a pathophysiologic mechanism for schistocyte formation: the small clots do not fully occlude the vessel; hence blood flows at arterial speed and pressure, and erythrocytes are sheared at this irregular fluid-solid interface. Microangio-

FIGURE 14-16. Hanged red blood cell. A dense fibrin band is seen with several finer strands, over which erythrocytes can be found hanging. With the shearing force available within the arterial circulation, such erythrocytes will be broken across these thin fibrin strands and thereby result in schistocytes. *(From Bull BS, Kuhn IN. The production of schistocytes by fibrin strands [a scanning electron microscope study]. Blood. 1970;35:104.)*

pathic schistocytic hemolytic anemia can therefore occur in any disorder of the small blood vessels that features the intravascular formation of fibrin (or large von Willebrand factor [VWF] multimers, see later).

Genetic Basis

In the vast majority of patients, microangiopathic schistocytic hemolytic anemia appears sporadically, although sometimes a trigger or associated medical condition can be identified. However, the rare occurrence of congenital or familial microangiopathic hemolytic anemia in conjunction with thrombocytopenia and renal dysfunction (HUS/TTP), with a clinical course that tends to be chronic and relapsing,[426-428] suggested a genetic basis in some cases. Mutations in two distinct pathways have now been identified in patients with familial disease, thereby providing insight into the pathophysiologic mechanisms of microangiopathic schistocytic hemolysis.

Abnormally large circulating multimers of VWF have been recognized for many years in patients with HUS/TTP.[428,429] Endothelial cells normally release VWF as very large multimers (sometimes reaching 5 to 20 million daltons) that undergo continuous limited proteolytic degradation by a VWF-cleaving protease. The *ADAMTS13* gene encoding this protease is located on chromosome 9q34 and is a member of the *ADAMTS* (a disintegrin-like and metalloproteinase with thrombospondin motifs) family of zinc metalloproteinase genes. Mutations in *ADAMTS13* that lead to a deficiency of VWF-cleaving protease activity have been identified in families with relapsing TTP,[430-432] thus demonstrating that physiologic degradation of VWF is essential for normal in vivo hemostasis. Acquired deficiency of the ADAMTS13 enzyme also occurs in association with autoantibody formation against the VWF-cleaving protease; ADAMTS13 inhibitors can be detected in most patients with an initial acute episode of TTP, but not in cases of HUS.[433,434] Very large undegraded VWF multimers presumably initiate or participate in intravascular coagulation, which leads to arteriolar fibrin and VWF deposition, platelet trapping, and microangiopathic schistocytic hemolytic anemia.

A seemingly different pathophysiologic process for the development of schistocytic hemolytic anemia involves abnormal complement regulation. Factor H is a 150-kd plasma protein that normally regulates the alternative pathway of complement activation. Without proper binding and inhibition of factor H, the C3b produced by C3 convertase is allowed to activate the alternative pathway unchecked. In a porcine model, factor H deficiency is associated with dysregulated complement activation and the development of fatal glomerulonephritis.[435] In humans, missense mutations in the factor H gene (*HF1*) have been identified in both dominant and recessive familial cases of microangiopathic hemolytic anemia.[436,437] Similarly, mutations in the complement inhibitor factor I[438] and membrane cofactor protein (MCP)[439] have been associated with atypical HUS,

defined as disease not associated with exposure to Shiga toxin. Whether all these mutations in complement regulatory proteins lead directly to complement deposition within the kidney, which then leads to microangiopathy, has not been proved, but damage to the endothelium appears to be important.[440] Perhaps complement activation and deposition onto the renal endothelium leads to exaggerated local release of VWF, which then promotes local microangiopathy in a mechanism analogous to that observed in patients with deficiency of VWF-cleaving protease activity. Damage to the renal endothelium could create an irregular fluid-solid interface against which the erythrocytes must pass, thus making schistocyte formation more likely.

Clinical Settings

As noted earlier, when microangiopathic schistocytic hemolytic anemia occurs with acute renal failure and severe thrombocytopenia, the triad is referred to as HUS; the concomitant presence of fever and neurologic deterioration forms a pentad known as TTP. Both these related clinical syndromes typically occur sporadically and are associated with substantial morbidity and mortality. These disorders are discussed more fully elsewhere in the book.

Schistocytic microangiopathy has also been reported in the setting of immune vasculitis. Schistocytic hemolytic anemia can develop in patients with a variety of connective tissue disorders, including SLE,[441] systemic sclerosis,[442] diabetes mellitus,[443] Kawasaki's disease,[444] Wegener's granulomatosis,[445] and antiphospholipid antibody syndrome.[446] The common pathophysiologic process is believed to involve renal involvement by the systemic process, especially small vessel (renal arteriolar) damage. Correlation of autoantibody titers with the degree of microangiopathy,[446] coupled with a case report of neonatal lupus erythematosus with severe microangiopathic hemolytic anemia,[447] suggests that autoantibodies can mediate this process. In the case of microangiopathic hemolytic anemia in association with SLE, the prognosis and outcome appear to be distinct, as opposed to the situation with relapsing TTP.[448]

On some occasions, microangiopathic schistocytic hemolytic anemia occurs in clinical settings that are associated with widespread microangiopathy. Disseminated malignancy, especially adenocarcinoma of the breast or stomach, can lead to schistocytic hemolysis and thrombocytopenia.[449,450] In patients with cancer, laboratory evidence of ongoing intravascular coagulation consistent with a widespread microangiopathic process is observed. Similarly, in patients with systemic infections, schistocytic microangiopathic hemolysis can occasionally develop.[326,451,452] Disseminated intravascular coagulation can lead to schistocytic hemolysis as erythrocytes encounter systemic intravascular fibrin deposition. Schistocytic hemolytic anemia has also been described after allogeneic or autologous stem cell transplantation, usually in conjunction with thrombocytopenia and renal dysfunction. Microangiopathic hemolytic anemia that occurs as a late complication after transplantation is associated with substantial morbidity and mortality; the use of calcineurin inhibitors such as tacrolimus as post-transplant immunosuppressive therapy is an added risk factor.[453]

Microangiopathic disorders associated with pregnancy include preeclampsia, characterized by hypertension and proteinuria, and the more dangerous eclampsia, which can lead to severe hypertension, seizures, and even death. In pregnant women, the development of schistocytic hemolytic anemia, elevated liver enzymes, and a low platelet count is known as the HELLP syndrome. Long recognized but poorly understood, new evidence suggests that HELLP is often a severe manifestation of antiphospholipid syndrome.[454] This triad of abnormalities necessitates aggressive management, including transfusions, plasmapheresis, and especially glucocorticoids.[455] HELLP during a pregnancy may be the first manifestation of antiphospholipid syndrome, but it often recurs and can lead to fetal demise even with aggressive heparin and aspirin therapy.[456] Perhaps the best "therapy" is elective delivery of the infant, which usually leads to complete resolution of the syndrome.[457] Although the etiology and pathophysiologic changes during HELLP have not been fully elucidated, clinical and laboratory observations indicate that schistocytic hemolytic anemia during pregnancy is an ominous development that warrants aggressive intervention during gestation but usually resolves completely after delivery.

Microangiopathic hemolytic anemia can also occur after exposure to a variety of drugs and toxins. Cocaine abuse[458] and the therapeutic use of quinine,[459] immunosuppressants such as cyclosporine[460] and FK506 (tacrolimus),[461] and antineoplastic and other agents[462-465] have all been associated with the development of microangiopathic schistocytic hemolytic anemia. The pathophysiologic process of drug-induced microangiopathy is not known, but it probably follows nephrotoxicity with drug-induced renal endothelial and microvascular damage. Loxoscelism, which refers to the systemic effects after *Loxosceles reclusa* (brown recluse) spider bites, can be associated with a brisk spheroschistocytic immune-mediated hemolytic anemia that includes both intravascular and extravascular hemolysis.[466,467]

Finally, schistocytic hemolysis can occur with hypertension. In patients with pulmonary hypertension, either as a primary disorder[468] or secondary to congenital heart disease,[469] microangiopathic hemolytic anemia can develop from changes within the pulmonary vasculature. Fibrin deposition in the pulmonary arterial and arteriolar circulation can shear erythrocytes efficiently and lead to schistocyte formation. Severe systemic hypertension, sometimes referred to as "malignant" hypertension, can also lead to schistocytic hemolysis; the proposed pathophysiologic process in this setting involves not only intrinsic renal arteriolar changes but also elevated arterial pressure, which increases the shearing force.[470]

Hypertension as a manifestation of antiphospholipid syndrome can be accompanied by thrombotic microangiopathy.[471] Pharmacologic treatment of malignant hypertension can typically reverse the schistocytic hemolytic process, although in rare case reports bilateral nephrectomy was required to control the hypertension and ameliorate the hemolytic anemia.[470]

Therapy

Treatment for patients with microangiopathic schistocytic hemolytic anemia should be individualized according to the degree of anemia and the presence of an associated medical condition. Whenever possible, specific therapy for the underlying process leading to the microangiopathic anemia should be instituted. Transfusion support is warranted if the schistocytic hemolysis is massive or if the anemia is severe enough to be symptomatic. The fate of transfused erythrocytes will probably be the same as that of endogenous RBCs; thus, transfusions should be administered carefully and judiciously. However, erythrocyte transfusions can be lifesaving for patients with schistocytic hemolytic anemia and cardiovascular compromise.

Although a low platelet count can accompany microangiopathic hemolytic anemia, hemorrhagic bleeding is not the norm, even with severe thrombocytopenia. Platelet transfusions are usually unnecessary and can actually lead to worsening of the patient's condition because of in vivo aggregation and consumption.

In patients with congenital schistocytic hemolytic anemia, regular infusions of fresh frozen plasma can help ameliorate the laboratory abnormalities and prevent clinical complications.[472,473] Particularly in patients with documented deficiency of VWF-cleaving protease, prophylactic treatment with fresh frozen plasma can be effective, even with long-term use.[474]

Exchange plasmapheresis has emerged as the most effective acute intervention for patients with severe microangiopathic schistocytic hemolytic anemia due to TTP. The beneficial effects of plasmapheresis derive from both the infusion of fresh frozen plasma and the removal of free hemoglobin, fragments of broken erythrocyte membranes, and any plasma substances promoting intravascular coagulation and platelet aggregation. For patients in whom life-threatening disease develops, plasmapheresis is the therapy of choice[475,476] and is more effective than corticosteroids, aspirin, dipyridamole, or splenectomy.[477] Exchange plasmapheresis is now recommended early in the clinical course, soon after the diagnosis of TTP. However, the patient should be weaned from this therapeutic intervention slowly over a period of several weeks because relapses and periodic exacerbations are often observed when daily plasmapheresis is discontinued. A patient with relapsing refractory microangiopathic hemolytic anemia secondary to autoantibodies to the VWF-cleaving protease may respond to rituximab therapy.[478]

Large Vessel Schistocytic Hemolytic Anemia

In addition to the microangiopathic processes that can lead to schistocyte formation, there are several large vessel or "macrovascular" disorders that also can cause mechanical shearing of erythrocytes. The most common of these large vessel schistocytic disorders occurs in association with hemangiomas, which can lead to hemolytic anemia with intravascular coagulation and severe thrombocytopenia (Kasabach-Merritt syndrome). Most of the cutaneous lesions that lead to Kasabach-Merritt syndrome are not actually hemangiomas at all; they have a kaposiform (spindle cell) hemangioendothelioma pattern on histologic examination, consistent with their aggressive vascular proliferation.[479,480] True capillary hemangiomas, though common in infancy, do not cause erythrocyte fragmentation. In contrast, large cavernous hemangiomas can develop in the liver, spleen, or other organs and cause schistocytic hemolytic anemia at any age.[481-483] However, no single effective therapy has been identified for hemangiomas causing schistocytic hemolysis. Improvement has been reported anecdotally and in small series with the use of steroids and antifibrinolytic agents,[484] embolization,[485] laser therapy,[486] local radiation therapy,[487] and chemotherapy.[488] Initial success with interferon alfa therapy has been dampened by reports of spastic diplegia in association with its use.[489] Newer approaches directed against the angiogenesis process itself, such as the use of angiostatin or related molecules,[490] may eventually prove to be a successful targeted therapy for hemangiomas.

Schistocytic hemolytic anemia is also a well-described complication of valvular heart disease that results from excessive shearing force on the erythrocytes at the interface with the abnormal heart valve. Although mild hemolysis can occur with both congenital and acquired abnormalities of the heart valves, "cardiac" schistocytic hemolysis is most severe after the insertion or failure of a prosthetic heart valve.[491,492] In the immediate postoperative period, erythrocytes can be sheared on valvular surfaces that lack smooth endothelium, thereby leading to schistocyte formation, hemoglobinuria, and anemia. Flow disturbances identified on echocardiography include rapid acceleration, fragmentation, and collision jets that lead to high shear stress and hemolysis.[493] Occasionally, intravascular hemolysis is severe enough to cause massive hemolysis with profound anemia. Transfusions may be required in the short term while the patient awaits endothelialization of the prosthetic valve, although erythropoietin therapy may reduce the transfusion requirement.[494] Surgical correction is often required for patients with chronic or life-threatening transfusion-dependent intravascular hemolysis. The successful use of pentoxifylline for this condition warrants further investigation.[495]

Finally, an infant with fetal schistocytic hemolytic anemia in association with an umbilical vein varix was reported.[496] Turbulent flow through this large vessel was

noted by ultrasonographic examination, and severe schistocytic hemolytic anemia was identified at birth. The infant received aggressive supportive care, including erythrocyte transfusions, and survived.

Miscellaneous Forms of Schistocytic Hemolytic Anemia

The term "march hemoglobinuria" refers to the transient intravascular hemolysis that can occur after strenuous exercise.[497] This relatively rare form of schistocytic hemolytic anemia was originally noted in soldiers after prolonged marching drills and has been attributed to physical trauma to erythrocytes within the soles of the feet. The phenomenon seems to occur only in selected individuals, but it can be associated with severe hemoglobinuria and even renal failure.[498] A better name for this form of hemolysis might be "exertional hemoglobinuria" because it can occur after a variety of exercises, including running, swimming, karate, and even playing of conga drums.[499-501] One study reported that transfused erythrocytes also had shortened survival after exercise, thus documenting the extracorpuscular nature of the defect.[502] Avoidance of the offending physical trauma is usually sufficient to resolve the hemolysis. For persons in whom hemoglobinuria develops after running, insertion of protective insoles may protect against the physical pounding of erythrocytes.[503]

Thermal burns are the most common form of burn injury that causes anemia, although chemical burns can also induce hemolysis.[504] Erythrocytes that are directly exposed to the burn become injured, and this damage either leads to their immediate lysis or results in shape changes that shorten their survival in vivo. If the damage is severe, the erythrocytes circulating through the skin at the time of the injury undergo intravascular hemolysis within hours, thereby giving rise to hemoglobinemia, hemoglobinuria, and anemia. Less damaged erythrocytes continue to circulate but undergo sphering and are prematurely removed by the spleen.[505] This extravascular hemolysis may occur several days or weeks after the burn injury and may lead to marked late-onset hemolytic anemia. Despite earlier reports suggesting a high incidence of positive DAT results after burn injury, there is little evidence for immune-mediated hemolytic anemia in this setting.[506]

Although an initial burn injury may be sufficient to cause anemia, concomitant therapies can also contribute to hemolytic anemia.[507] For example, the liberal use of silver sulfadiazine provides an oxidative stress that can induce hemolysis, especially in patients with glucose-6-phosphate dehydrogenase deficiency.[508] Many burn patients require transfusions of fresh frozen plasma, which can induce hemolysis via passively acquired isohemagglutinins. Finally, infections and the antibiotics used to treat these infections can induce hemolysis. Thus, hemolytic anemia associated with burns is often multifactorial. Immediate and delayed hemolytic anemia occurs as a direct consequence of the burn injury, whereas additional therapies can lead to further hemolysis.

15 Disorders of the Red Cell Membrane

Rachael F. Grace and Samuel E. Lux

The erythrocyte membrane is the most thoroughly studied biologic membrane. It is a small structure, less than 0.1% of the cell's thickness and only about 1% of its weight, but its easy accessibility has enabled researchers to characterize both its primary structure and a number of its important functions. During erythropoiesis it responds to erythropoietin and imports the billion or so iron atoms that each red cell needs to complete the synthesis of hemoglobin. It sequesters the reductants required to protect hemoglobin and other cell proteins from corrosion by oxygen and selectively retains other vital components, such as organic phosphates, manufactured with precious adenosine triphosphate (ATP) energy, but lets metabolic detritus escape. Some evidence hints that it may even help regulate metabolism by reversibly binding and inactivating many glycolytic enzymes.[1] In the circulation it carefully balances cation and water con-

centrations so that red cells do not shrivel or explode. Simultaneously, it exchanges tremendous numbers of bicarbonate and chloride anions ($\approx$10 to 30 billion per second per red cell), which aids transfer of carbon dioxide from tissues to the lungs.[2] It also maintains a slippery exterior so that red cells do not adhere to endothelial cells or aggregate and clog capillaries. Finally, buttressed by the "membrane skeleton," a protein scaffold that lines the inner membrane surface, the membrane achieves the critical combination of strength and flexibility needed to survive 4 months in the circulation. Failure of any of these or numerous other functions shortens red cell survival, a process termed hemolysis. In fact, all hemolysis is ultimately due to membrane failure.

The red cell membrane was originally characterized as an example of the fluid mosaic model proposed by Singer and Nicolson more than 35 years ago.[3] In this

model the erythrocyte membrane is composed of mobile, asymmetrically distributed proteins and lipids that interact in a variety of ways. The model has been revised in the intervening $3\frac{1}{2}$ decades because many membrane proteins are not freely mobile but instead diffuse in complicated patterns or are confined to discrete domains.[4-6] In this chapter we first discuss normal membrane structure with an emphasis on aspects that are most involved in the genesis of membrane disease. We then focus on abnormalities of red blood cell membranes, particularly hereditary spherocytosis (HS) and hereditary elliptocytosis (HE), the two most common and best-understood disorders.

MEMBRANE LIPIDS

Lipid Composition

Lipids account for about 50% of the weight of the red cell membrane (Table 15-1) or about 1.6% of the weight of the hemoglobin. Phospholipids and unesterified (free) cholesterol predominate and are present in nearly equal proportions (cholesterol-phospholipid molar ratio of 0.80).[7,16,17] Small amounts of glycolipids, principally globoside (73% of the glycosphingolipids) (Fig. 15-1), are

also present.[14] The average red cell contains about 250 million phospholipid molecules, 195 million cholesterol molecules, 10 million glycolipid molecules, and 6 million protein molecules in a membrane whose total surface area is about 140 μm^2.[18] Phosphatidylcholine (PC), phosphatidylethanolamine (PE), sphingomyelin (SM), and phosphatidylserine (PS) are the predominant phospholipids (see Table 15-1). Their structures are shown in Figure 15-1. Small amounts of phosphatidic acid (PA), phosphatidylinositol (PI), and lysophosphatidylcholine (Lyso-PC) are also present.

At physiologic pH, PS, PA, and PI have a net negative charge, whereas the other phospholipids are electrically neutral. The polar head groups of PC and SM tend to lie parallel to the membrane surface (Fig. 15-2). The head groups of PE and PS are smaller and more cone shaped, which may help them fit in the inner bilayer.

With the exception of SM and Lyso-PC, the phospholipids have two fatty acids attached to a glycerol backbone. They are usually of similar length and attached through an ester linkage, although sometimes, particularly in PE, one of the fatty acids is a vinyl ether (plasmalogen).[13] Typically, the fatty acid attached to glycerol farthest from the polar head group (*sn*-1 position) is saturated and the nearer (*sn*-2) one is unsaturated.[19] PE and

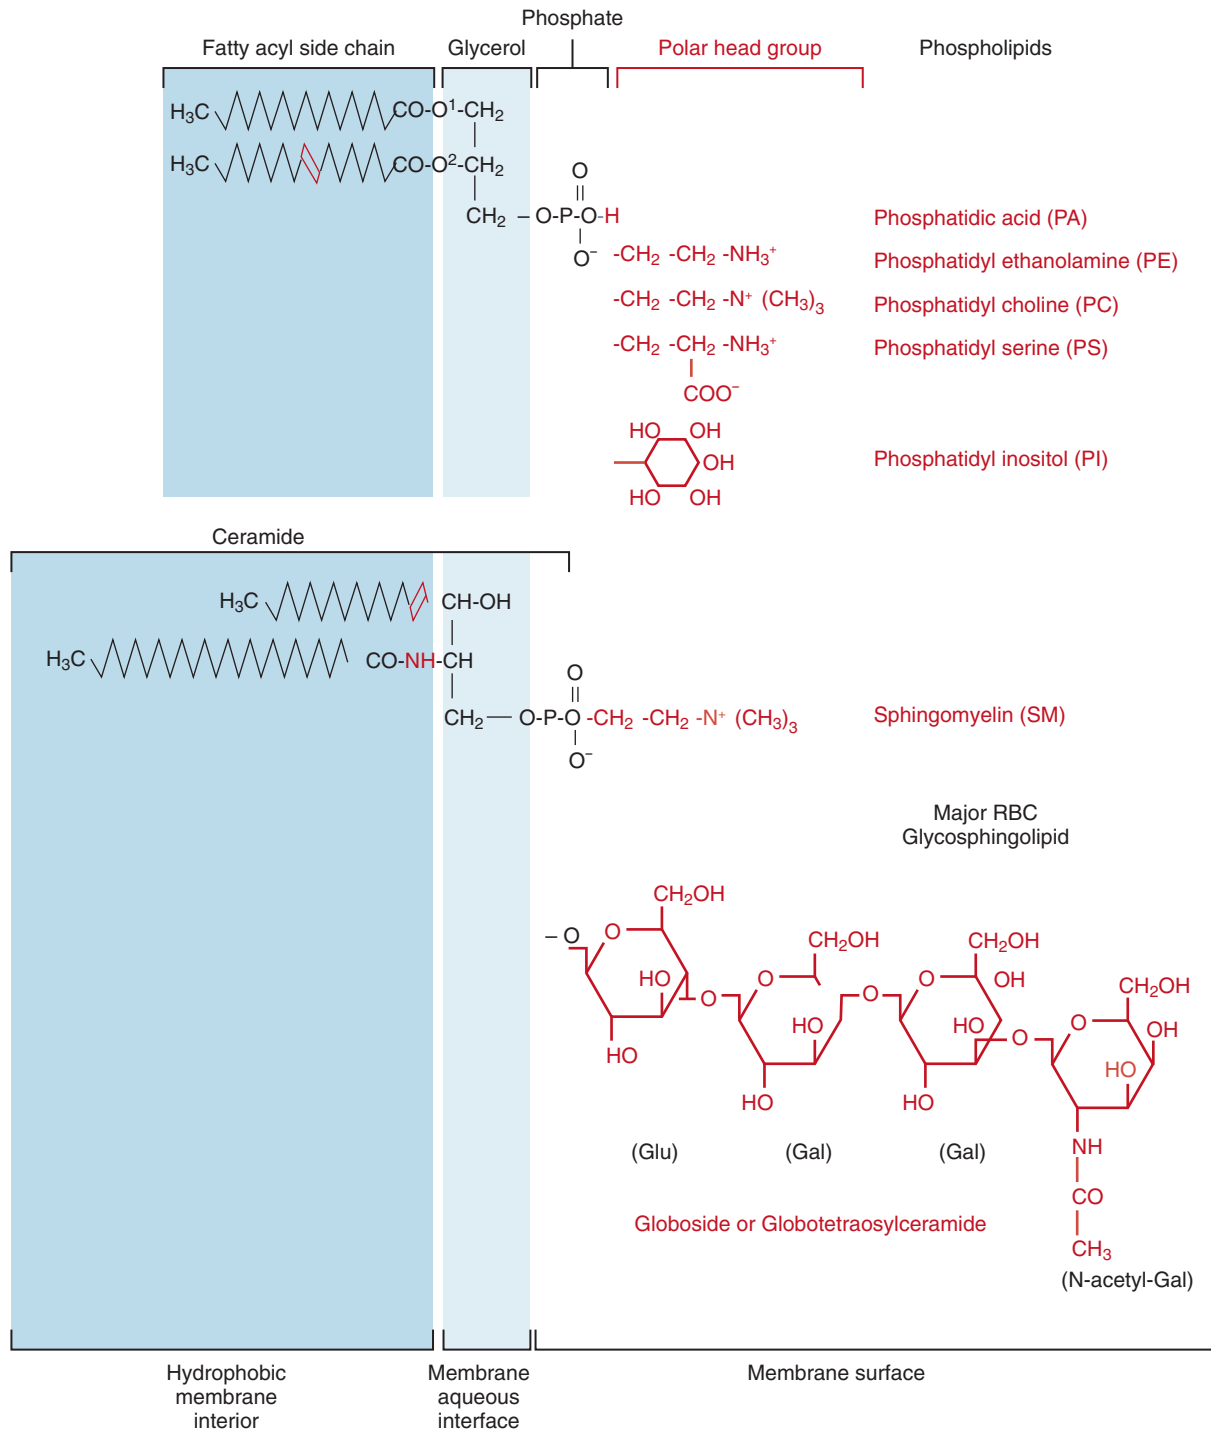

FIGURE 15-1. Chemical structures of the major phospholipids and the major glycosphingolipid (globoside or GL-4) of the red blood cell (RBC) membrane. Note that phosphatidylcholine (PC) and sphingomyelin (SM) share the same polar moiety (choline) and that SM and globoside share the same nonpolar moiety (ceramide).

PS are more unsaturated than PC. In contrast, both acyl side chains are usually saturated in SM, and the amide-linked chain (see Fig. 15-1) is often very long and interdigitates with the hydrocarbon chains of the opposite side of the bilayer. The SM amide linkage also makes its interface region more polar. The *lyso*phospholipids have only one fatty acid and are named for the hemolysis induced because of their detergent-like properties.

Asymmetric Organization of Lipids in the Bilayer

The majority of phospholipids in the red cell membrane are in a planar bilayer with their polar head groups exposed at each surface and their hydrophobic fatty acyl side chains buried in the bilayer core. The phospholipid head groups tend to adopt regular, superlattice-like lateral distributions.[20]

FIGURE 15-2. Approximate orientation of cholesterol and phospholipid (here phosphatidylcholine [PC]) molecules to each other in the membrane bilayer. On average, the cholesterol rings are believed to associate with the first 8 to 10 carbons of the phospholipid acyl chains. Note that the fatty acyl chain attached to the sn-1 position of the glycerol on PC is saturated and straight whereas the sn-2 side chain is unsaturated and kinked (tan, carbon; light blue, hydrogen; yellow, oxygen; orange, phosphorus; green, nitrogen).
Glycolipids and Cholesterol

Glycolipids and cholesterol are intercalated between the phospholipids in the bilayer, with their long axes perpendicular to the bilayer plane (see Fig. 15-2). Red cell glycolipids are located entirely in the external half of the bilayer, and their carbohydrate moieties extend into the aqueous phase. They carry many important red cell antigens, including A, B, H, Le[a], Le[b], and P, and serve other important functions. The P glycolipid, for example, serves as the receptor for parvovirus B19,[21] the agent responsible for most erythroid aplastic crises.

Cholesterol is present on both sides of the bilayer[7,22] and is nearly saturated in the red cell membrane—that is, its concentration is just below the concentration at which major changes in its organization and accessibility to enzymatic modification occur.[23] Its distribution is not known but it is probably slightly more prevalent in the outer half[24,25] because of its high affinity for SM, which is concentrated in the outer bilayer. However, because all of the membrane cholesterol is available for exchange within seconds ($T_{1/2} \approx 1$ second)[26] and has first-order kinetics, inner and outer membrane cholesterol must be exchangeable at an even greater rate. This facilitates membrane bending because movement of cholesterol can offset the difference in surface pressure caused by bending and compression of one of the bilayers relative to the other. Depletion of cholesterol promotes inward curvature of the membrane, whereas enrichment of cholesterol favors outward deflection.[23]

Cholesterol molecules are relatively buried because the 3-OH group, the part of the molecule that is at the aqueous interface, lies approximately at the level of the carbonyl group of the phospholipid fatty acids (see Fig. 15-2).[19,27] Cholesterol has important functions in buffering the fluidity of phospholipid side chains and in forming "lipid rafts," as will be described. In addition, some cholesterol binds directly to some membrane proteins and activates or inactivates them,[28-30] probably through a

sterol-sensing domain.[31] Whether this is important in the function of mature red cells is unknown.

Trans Asymmetry

Red cell membrane lipids, like membrane proteins (to be discussed), are asymmetrically distributed across the bilayer plane.[32-34] Choline phospholipids (PC and SM) are concentrated in the outer half of the bilayer, whereas aminophospholipids (PE and PS) and PI are largely confined to the inner half (see Table 15-1). The evidence has been critically reviewed.[10,35-37]

The asymmetric distribution of phospholipids reflects a steady state involving a constant exchange (flip/flop) of phospholipids between the two bilayer hemileaflets.[35,36] In the red cell membrane this transmembrane diffusion is slow, lasting several hours to a day.[38,39] In contrast, the enzymatic translocation of phospholipids in biologic membranes, described in the following paragraphs, is much faster (minutes). At least three distinct activities are involved in regulating membrane phospholipid asymmetry. They are discussed in recent reviews.[40-43]

Flippase. The Mg-ATP–dependent aminophospholipid translocase, or "flippase," is responsible for localization of PS in the inner leaflet by rapidly translocating it from the outer to the inner leaflet against an electrochemical gradient. The stoichiometry between PS translocation and ATP hydrolysis is close to one. PE is translocated to a slight degree. The half-times for translocation of PS and PE are about 5 and 60 minutes, respectively, at 37° C.[44] Similar activity exists in all mammalian red cells[45] and probably in all cells and some cell organelles. Flippase is likely to contain a critical cysteine because it is inhibited by sulfhydryl-modifying reagents.[40] It is also inhibited by the pseudosubstrates of P-type adenosine triphosphatases (ATPases), such as vanadate, and by high concentrations of Ca^{2+}.

Unfortunately, despite almost 2 decades of effort, the aminophospholipid translocase is not fully characterized.[40] Erythrocyte Mg^{2+}-ATPase, purified and reconstituted into proteoliposomes, enhances the movement of PS analogues, but the active fraction contains multiple proteins ranging from 35 to 120 kd. Although it is possible that the translocase contains multiple subunits, definitive proof that Mg^{2+}-ATPase is responsible for flippase activity has not yet been achieved.

One candidate for the aminophospholipid translocase is ATP8A1 (ATPase II), a Mg^{2+}-ATPase first described in bovine chromaffin granules.[46] Close homologues of this protein are found in human red cells.[47,48] The cDNA predicts a unique P-type ATPase in which several amino acids that are involved in ion translocation in other P-ATPases are replaced by hydrophobic groups. Yeasts lacking a homologous protein, Drs2, are defective in aminophospholipid transport.[46] However, the story is complicated because Drs2 is located in the Golgi apparatus, not in the plasma membrane, and is one of a four similar and mostly redundant proteins in yeast.[42] Furthermore, the purified murine ATP8A1 enzyme,

despite having almost all the characteristics of the red cell aminophospholipid transporter when assayed in vitro, is not activated by N-methyl-PS,[47] which is transported by the red cell membrane flippase, as well as native PS, so it is still unclear whether this enzyme is the physiologic aminophospholipid translocase. If not, the true translocase is probably closely related. The *ATP8A1* gene has not yet been deleted, which will provide an important test.

Floppase. The Mg-ATP–requiring phospholipid translocase, or "floppase," is responsible for movement of phospholipids from the inner to the outer leaflet of the bilayer,[41] and it is less specific than the flippase.[49,50] The outward lipid movement by the floppase is also much slower than the inward movement of PS by the flippase. Recent evidence suggests that the floppase is one of the family of ATP-binding cassette (ABC) transporters, of which the multidrug resistance transporter (ABCB1, MDR1, or P-glycoprotein) is the best known.

ABCB1 has broad specificity for short-chain lipids and xenobiotics and is unlikely to be the floppase.[41,42,51] Similarly, ABCA1 (ABC1), which exports cholesterol and is deficient in Tangier disease,[52] is an unlikely candidate. This is also true for ABCB4 (MDR1), which is specific for PC[51] and is involved in the secretion of PC into bile[53] but is selectively expressed in the liver, not in red cells. However, there is some evidence in support of ABCC1 (MRP1).[54,55] The efflux of short-chain fluorescent phospholipid analogues of PC, SM, and PS can be measured in erythrocytes and requires ATP and reduced glutathione. This activity is lost in mice lacking the gene equivalent to MRP1,[54] and long-term (48-hour) inhibition of activity leads to loss of PC and SM from the outer bilayer but no change in the distribution of PE or PS.[56] However, it is not yet certain that ABCC1 can transport full-length, native phospholipids, which is a required property of the physiologic floppase.

Scramblase. In conjunction with the two ATP-requiring transporters flippase and floppase, the Mg-ATP–independent, Ca^{2+}-dependent phospholipid "scramblase" facilitates rapid, bidirectional movement of all phospholipids in the bilayer, thereby resulting in the collapse of phospholipid asymmetry,[57] which may occur in less than a minute under some circumstances. Indeed, a high Ca^{2+} concentration can disrupt phospholipid asymmetry by activation of the scramblase and inhibition of the flippase. It is generally accepted that under physiologic conditions (cytosolic Mg-ATP concentration in the millimolar range and Ca^{2+} in the submicromolar range), phospholipid asymmetry is maintained by activation of the flippase and floppase and inactivation of the scramblase. Under these conditions, all phospholipids are slowly but continuously moved to the outer leaflet by the floppase, whereas the aminophospholipids PS and PE are immediately shuttled back to inner leaflet by the flippase.

A single polypeptide of approximately 37 kd with scramblase activity has been purified from red cell mem-

branes. It mediates the Ca^{2+}-dependent redistribution of fluorescently labeled phospholipids between leaflets of reconstituted proteoliposomes,[58] and the cloned protein (PLSCR) has other features suggesting that it binds Ca^{2+} and is attached to membranes.[59,60] However, it does not appear to be the authentic red cell scramblase because blood cells from the knockout mouse are not deficient in activation-induced lipid scrambling![61] Thus, the scramblase, like the flippase and floppase, remains to be conclusively identified.

Loss of Phospholipid Asymmetry

High intracellular Ca^{2+} concentrations in red cells lead to loss of phospholipid asymmetry as a result of activation of the scramblase and inhibition of the flippase. Because normal red cells maintain very low intracellular Ca^{2+} concentrations, their membranes preserve an asymmetric phospholipid distribution through their entire 120-day life span.

Phospholipid Asymmetry Is Lost in Sickle and Thalassemic Red Cells. Changes in the equilibrium distribution of phospholipids could occur under conditions in which flippase is inhibited and either the scramblase is activated or floppase or scramblase activity accelerates to a degree that overwhelms the translocase, or both. A subpopulation of circulating sickle red cells show exposure of PS on their surface.[62] There is large variability in the numbers of sickle red cells that expose PS in sickle cell patients (0.5% to >10%). Phospholipid flip-flop is increased and phospholipid asymmetry is lost in sickle cells,[63-65] in which several forms of skeletal protein damage have been documented,[66-68] including decreased phospholipid translocase activity[63] and uncoupling of the lipid bilayer from the underlying skeleton in the sickle cell spicules.[69] A subpopulation of thalassemic red cells also show exposure of PS on their surface,[70] and phospholipid asymmetry is altered in diabetic red cells,[71] which like sickle cells,[72,73] tend to adhere to endothelial cells.[71]

Externalized Phosphatidylserine Triggers Clotting and Phagocytosis. It is generally believed that red cells, as well as essentially all other cells, sequester aminophospholipids on the cytoplasmic side of the plasma membrane because the exposed lipids trigger the conversion of prothrombin to thrombin and promote intravascular clotting.[74-76] Loss of phospholipid asymmetry may also activate the alternative complement pathway.[77]

In addition, macrophages bind and ingest cells, or even liposomes, that have PS exposed on their outer surfaces.[78-81] Exposure of PS is one of the earliest events in apoptosis, and the PS receptor seems to have evolved to scavenge dead or dying cells that have activated scramblase during apoptosis.

Several adhesive surface receptors on macrophages, including CD14, CD36, CD68, and the class B scavenger protein SR-BI,[82] may participate in recognition and removal of PS-exposing cells during apoptosis. However, these receptors do not discriminate between PS and other anionic phospholipids. The PS-specific receptor is not yet fully defined. A candidate receptor called PSR has been cloned by using a monoclonal antibody that blocks binding of PS,[83] and the phenotype in knockout mice is consistent with a protein that functions to clear dead cells[84]; however, subsequent work suggests that it is not the desired receptor (reviewed by Williamson and Schlegel[85]).

Finally, there is some speculation that the aminophospholipid translocase might foster endocytosis by "pumping" PS and PE into the inner bilayer.[86] Even a small excess of inner bilayer phospholipids would tend to make the membrane invaginate (see later).

Scott's Syndrome: A Defect in the Phospholipid Scramblase?

Scott's syndrome is a very rare autosomal recessive disorder characterized by decreased scramblase activity.[87,88] As a consequence, activated platelets fail to expose sufficient PS on their surface to assemble prothrombinase, and affected individuals have a bleeding tendency.[89] Erythrocytes and other cells also lack scramblase, but without apparent consequence. Whether this is due to mutations in the scramblase itself or is a secondary consequence of some other defect is unknown. The putative red cell scramblase gene (*PLSCR*) has been sequenced and is normal.[90]

Eryptosis

Red Cells May Undergo a Kind of Apoptosis in Response to Oxidative Damage. It is unclear whether the PS receptor participates in the removal of erythrocytes that bear surface PS, such as sickled cells or thalassemic cells, but it seems likely that it does. After an initial report by Bratosin and colleagues in 2001,[91] multiple recent papers by Lang and associates describe a process resembling apoptosis in damaged erythrocytes that they term "eryptosis" (reviewed by Lang and co-workers in 2006[92]). The process seems to be a *forme fruste* of apoptosis because it is not induced by classic apoptotic agents such as staurosporine and because mature red cells lack mitochondria and nuclei.[91] It is characterized by decreased red cell volume, membrane blebbing, activation of the protease calpain, and exposure of PS at the outer membrane leaflet, which leads to phagocytosis by macrophages. Eryptosis is triggered by oxidative stress, influx of Ca^{2+} ions, red cell dehydration, osmotic shock, prostaglandin E_2, and a variety of other stimuli and is inhibited by erythropoietin.[92]

The process resembles that induced by caspases, and recent investigations show that mature red cells contain Fas, Fas ligand, Fas-associated death domain, and caspases 8 and 3 and that oxidatively stressed cells recapitulate apoptotic events, including translocation of Fas into lipid rafts (see later), formation of a Fas-associated complex, and activation of caspases 8 and 3.[93-95] Activation of Fas is also associated with inhibition of the aminophospholipid translocase (flippase) and activation of the scramblase.[96] Thus, exposure of PS on red cells, as

on nucleated cells, may often be the consequence of apoptotic events.

If these findings can be confirmed by other groups, they raise the possibility that the hemolysis in many conditions may be mediated by eryptosis, especially conditions associated with increased oxidant damage or cell dehydration (or both), such as sickle cell anemia, thalassemia, Heinz body hemolytic anemias, Hb CC disease, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and hereditary xerocytosis. Moreover, if this is true, interference with the process may be therapeutic.

Recent reports show that Foxos (Forkhead O genes) regulate the cellular response to oxidative stress[97,98] and that the absence of Foxo3, in particular, leads to a marked decrease in expression of antioxidant enzymes in erythroid precursors and marked susceptibility of mature red cells to the reactive oxygen species that red cells generate during their daily oxygen-carrying duties or to exogenous oxidants. It will be interesting to see whether these red cells also die of eryptosis, as would be predicted from the aforementioned studies, and whether manipulation of the Foxo pathway can be used to treat anemias characterized by oxidant damage.

Cis Asymmetry

Macroscopic Domains. Red cell lipids also exist in different domains *within* each of the bilayer planes (*cis* asymmetry). Fluorescent phospholipids partition into doughnut-shaped lipid domains up to several microns in diameter within the membrane of red cells or ghosts.[99] These lipid-rich domains are intrinsic structural features of the membrane, not just "gel-phase" or "fluid-phase" domains.[99] They increase in size when membrane proteins aggregate, and they are lacking in large liposomes made solely of membrane lipids, which suggests that proteins play a role in their formation. How and why this occurs is a mystery.

Microscopic Domains: Protein-Bound Lipids. Lipids also partition on a more microscopic scale within the membrane. Early experiments[100] detected a layer of tightly associated "boundary lipids" attached to membrane proteins that intruded into the bilayer core, but subsequent work[101] suggested that such lipids were bound only transiently ($<10^{-7}$ second) and probably were not distinguishable from other lipids in the bilayer on the time scale of enzyme reactions and other cellular events. However, there are probably exceptions to this generalization because specific lipids are required for the enzymatic functions of some transport proteins, such as the sodium and calcium pumps or the cholesterol-binding proteins described earlier, and because some membrane proteins, such as glycophorin A (GPA; to be discussed), bind anionic (PS, PI) but not choline (PC, SM) phospholipids[102-104] and those lipids are relatively tightly bound.[105] Positively charged amino acids are concentrated on the cytoplasmic side of the bilayer-spanning domains of glycophorins and other membrane proteins,

in part because their position determines the orientation of the protein.[106,107] Although it is not well documented, anionic phospholipids probably cluster near these regions of positive charge. Surface-bound membrane proteins such as spectrin and protein 4.1, which bind preferentially to anionic phospholipids,[108,109] may also contribute to the nonrandom topography of inner membrane phospholipids, and conversely, the lipids appear to contribute to stability of the membrane skeleton.[110]

Membrane Lipid Rafts. Membrane lipid rafts reflect lateral heterogeneity in the lipid bilayer of the plasma membrane and have been implicated in a variety of sorting and signaling processes in cells.[111,112] They appear to be present in all cells and can be functionally isolated as detergent-resistant membranes by virtue of their property of being insoluble in cold, nonionic detergents. Cholesterol and SM are the principal lipids,[111,113] although recent evidence suggests that the rafts also contain large amounts of phosphoinositides.[114] The relatively saturated acyl chains in SM makes SM molecules pack tightly together and interact favorably with the cholesterol ring system. As a consequence, the SM-cholesterol complex is more resistant to solubilization with nonionic detergents. Red cell lipid rafts contain a complex mixture of membrane proteins, including stomatin, flotillin-1 and flotillin-2, the Duffy protein receptor, heterotrimeric $G\alpha_s$, and proteins bearing glycosylphosphatidylinositol (GPI) chains, such as CD55, CD58, and CD59.[115-117] Proteins with myristate or palmitate side chains may also tend to partition into the rafts,[118-120] whereas proteins with prenyl side chains are excluded.[119] The large integral membrane proteins that form intramembranous particles (to be discussed) are also excluded.[113] Altogether, raft proteins constitute about 4% of the red cell's membrane proteins. Depletion of cholesterol from the red cell membrane abrogates raft formation and the ability of raft-associated proteins to form membrane microdomains. When red cell cytosolic Ca^{2+} is increased, some of the lipid rafts are shed in large (micro) and small (nano) vesicles. The microvesicles are highly enriched in stomatin, whereas the nanovesicles contain predominantly synexin, a protein involved in vesicle fusion, and sorcin.[117] The flotillins are not found in either vesicle. This means that there are different kinds of lipid rafts in the membrane, with different fates. Although the function of the rafts in normal red cell physiology remains to be determined, it is interesting to note that they appear to play a critical role in the membrane remodeling necessary for invasion of red cells by malarial parasites (reviewed by Murphy and colleagues[121]).

Bilayer Couple Hypothesis

The shape of the lipid bilayer is responsive to very slight variations (<0.4%) in the surface area of its inner and outer halves.[122,123] This is termed the "*bilayer couple effect*."[124] It reflects the tight packing of membrane lipids,

FIGURE 15-3. Bilayer couple hypothesis. Compounds or processes that selectively expand the outer leaflet of the lipid bilayer will produce uniform membrane spiculation (echinocytosis). Selective expansion of the inner leaflet of the bilayer leads to membrane invagination and cup-shaped red cells (stomatocytosis). *(Adapted from Palek J, Jarolim P. Clinical expression and laboratory detection of red cell membrane protein mutations. Semin Hematol. 1993;30:249, with permission.)*
the independent motion of lipids in each half of the bilayer, and the extreme thinness of the membrane (<0.1% of the diameter of the cell). Processes that expand the outer bilayer (or contract the inner) will produce uniform membrane spiculation, called *echinocytosis* (Fig. 15-3). Conversely, relative expansion of the inner bilayer will lead to membrane invagination and cup-shaped red cells (i.e., *stomatocytosis*). Strongly charged amphipathic compounds, such as phospholipids, cause echinocytosis.[123,125] They are trapped in the outer bilayer by their fixed charge. Permeable amphipaths (e.g., weak acids and bases that can cross the membrane in their uncharged form) will cause the membrane to extend toward the side of greater accumulation.[126,127] In general, cationic compounds will accumulate in the negatively charged inner bilayer and anionic compounds will partition to the neutral outer bilayer. Even subtle effects, such as differences in the cross-sectional area of lipid head groups or fatty acyl tails, can lead to changes in membrane curvature.[125]

The bilayer couple hypothesis predicts that shape changes resulting from expansion of one lipid leaflet can be reversed by a commensurate alteration in the other. For example, the intensely spiculated red cells of patients with abetalipoproteinemia can be almost completely converted to biconcave discs by the addition of small amounts (0.1 mM) of chlorpromazine, a cationic amphipath.[128] Unfortunately, this simple test has not been widely applied to pathologic red cells, so it is difficult to estimate how often bilayer couple effects dictate cell shape in vivo.

There is some evidence suggesting that shape is not totally explained by the bilayer couple hypothesis, which has led some researchers to support a protein scaffold theory, in which complex interactions of the spectrin-actin network, the lipid bilayer, and intracellular water interact to shape the erythrocyte.[129] The plasma lipid bilayer contributes bending rigidity; the membrane skeleton contributes stretch and shear elasticity.[130]

Membrane Phosphoinositides

The polar head group of this interesting class of phospholipids contains PI or its phosphorylated forms phosphatidylinositol 4-phosphate (PIP) and phosphatidylinositol 4,5-bisphosphate (PIP_2). In nucleated cells, phosphoinositides are precursors of important intracellular second messengers such as inositol 1,4,5-triphosphate (IP_3) and diacylglycerol. In mature erythrocytes, phosphoinositides represent 2% to 5% of the total phospholipids. They reside at the inner membrane surface and undergo rapid phosphorylation and dephosphorylation.[131] They help regulate Ca^{2+} transport; interact with membrane proteins such as glycophorin C (GPC), spectrin, and protein 4.1 (see later); and may influence discocyte-echinocyte shape transformation.

Lipid Mobility

Acyl Side Chains

Purified Lipids Exist in Gel or Liquid Crystalline States. Purified phospholipids exhibit discrete transitions from the liquid crystalline to the gel phase that are dependent on the length and degree of unsaturation

of their acyl side chains. Above the temperature of this transition, the acyl side chains waggle very rapidly (10^8 to 10^9 times per second) from side to side, with progressively greater excursions as one proceeds from the glycerol ester linkage to the terminal methyl group.[132] The presence of a double bond in the acyl chain increases the disorder and flexibility all along the hydrocarbon chain,[133,134] especially toward the terminal methyl end. Below the temperature needed for transition from the liquid crystalline to the gel phase, acyl chains of purified lipids are extended in stiff, parallel, hexagonally packed arrays that are more nearly solid than liquid.

Cholesterol Creates an Intermediate State between Gel and Liquid Lipids. Cholesterol buffers the extremes of the gel and liquid crystalline states. At temperatures above the gel-liquid phase transition, cholesterol partially immobilizes the acyl chains of phospholipids, particularly the proximal 8 to 10 carbons that are adjacent to the bulky steroid nucleus.[132] Below this transition, cholesterol disrupts ordering of the acyl chains, in effect preserving membrane fluidity.[135,136] The net result is that cholesterol tends to abolish the gel-to–liquid crystalline transition and creates a condition of intermediate fluidity in which the proximal ends of the hydrocarbon chains are extended and relatively rigid and the distal ends are disordered and fluid.

The red cell membrane contains relatively large amounts of cholesterol (cholesterol-phospholipid ratio, 0.8 mol/mol) and is relatively less fluid than other plasma membranes.[137] The inner bilayer is somewhat more fluid than the outer,[138] probably because it contains more unsaturated fatty acids. The significance of this difference is unknown.

The steady-state polarization of fluorescent probes such as 1,6-diphenyl-1,3,5-hexatriene is widely used to measure lipid "fluidity." However, it is difficult to know whether the polarization changes are due to true alterations in lipid fluidity or to changes in lipid organization that alter the location and spectroscopic properties of the probe or its interactions with membrane proteins.[139]

Lateral Diffusion

Phospholipids move about rapidly within each plane of *model* lipid bilayers.[137,140,141] From the measured lateral diffusion constants (2 to 5×10^{-8} cm^2/sec), one can calculate that phospholipids exchange places with each other about 10^7 times per second. This rate is somewhat dampened in the red cell membrane (estimated diffusion constant of 1.4×10^{-8} cm^2/sec),[142] but the difference is about what would be expected in view of the effects of cholesterol on the lateral mobility of phospholipids.[141]

Lipid Renewal Pathways

Mature Erythrocytes Cannot Synthesize Lipids. Mature erythrocytes are unable to synthesize fatty acids, phos-

pholipids, or cholesterol de novo and depend on lipid exchange and fatty acid acylation as mechanisms for phospholipid repair and renewal (Fig. 15-4). Outer bilayer phospholipids (PC, SM) exchange slowly (approximate turnover time of 5 days)[143] with the phospholipids of plasma lipoproteins.[144,145] Inner bilayer phospholipids (PS, PE) are unable to participate in this process and are virtually unexchangeable.[143]

Esterification Depletes Red Cell Cholesterol. Fatty acids and lysophosphatides exchange more rapidly. Red cell membrane cholesterol (unesterified) also exchanges readily with the unesterified cholesterol in plasma lipoproteins ($T_{1/2} = 7$ hours), where it is partially converted to *esterified* cholesterol by the action of *lecithin-cholesterol acyltransferase* (*LCAT*). Because the newly formed cholesteryl ester cannot return to the red cell membrane (there is virtually no esterified cholesterol in the membrane), LCAT catalyzes a unidirectional pathway (see Fig. 15-4) that depletes the membrane of cholesterol and decreases its surface area. Conversely, if LCAT is absent or inhibited, excess membrane cholesterol accumulates and expands the membrane surface area.[146]

Fatty Acid Acylation May Repair Phospholipid Side Chains. The fatty acid acylation pathway is an active metabolic pathway that requires ATP energy. This system combines fatty acids with lysophosphatides (principally Lyso-PC) to remake the native phospholipid (see Fig. 15-4).[147-149] The acylase enzyme and its phospholipid products are located in the inner bilayer.[150] In theory, this enzyme should facilitate the renewal of lost or damaged fatty acid side chains and should prevent the accumulation of deleterious lysophosphatides within the membrane; however, it is not certain that the phospholipases necessary to remove damaged fatty acids operate in the red cell.

These renewal pathways, though limited, permit slow replacement of membrane lipid components. Approximately 30 days is required before erythrocyte lipids reach equilibrium after a change in dietary fatty acids.[151] Theoretically, this could be pathologically significant in persons on unusual diets (e.g., infants receiving a high intake of medium-chain triglycerides); however, no pathologic consequences have been reported to date.

MEMBRANE PROTEIN COMPOSITION

The red cell membrane (or "ghost") contains at least a dozen major proteins[7] and more than 300 minor ones.[152] The major proteins of the red cell membrane (Fig. 15-5; Table 15-2) and their disorders have been intensively studied,[168-170] and in most cases their genes have been cloned. It is important to realize that enumeration and characterization of all the proteins of the red cell membrane may never be achieved because the membrane is not a separate, discontinuous structure but one that
FIGURE 15-4. Pathways for lipid exchange and fatty acid replacement in the red cell membrane. Chol, cholesterol; FA, fatty acid; Lyso-PC, lysophosphatidylcholine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine.
FIGURE 15-5. Major proteins of the red blood cell membrane. The proteins are separated by sodium dodecyl sulfate gel electrophoresis with the Fairbanks-Agre gel system[11,153] and stained with Coomassie blue. The glycophorins and the Rh proteins bind this dye poorly and are not visible. G3PD, glyceraldehyde-3-phosphate dehydrogenase. *(Adapted from Costa FF, Agre P, Watkins PC, et al. Linkage of dominant hereditary spherocytosis to the gene for the erythrocyte membrane-skeleton protein ankyrin. N Engl J Med. 1990;323:1046, with permission.)*

is in equilibrium with both the cytoplasm and the extracellular space. Many of the minor membrane proteins are technically challenging to isolate because of their low concentration, their insolubility, or their sensitivity to even minor variations in isolation conditions.

The protein constituents of the red cell membrane are classically defined by hypotonic hemolysis of red cells,[171] followed by polyacrylamide gel electrophoresis (PAGE) in sodium dodecyl sulfate (SDS).[7] In general, membrane proteins are classified as either *integral* or *peripheral*. Integral membrane proteins penetrate or traverse the lipid bilayer and interact with the hydrophobic lipid core. They include band 3, the anion exchange channel, and the glycophorins, which generate a negative charge at the cell surface, function as receptors, and display surface antigens (Fig. 15-6). Integral membrane proteins form the randomly distributed 8- to 10-nm intramembranous particles seen on freeze-cleave electron microscopy of red cell membranes. Peripheral proteins interact with integral proteins or lipids at the membrane surface but do not penetrate into the bilayer core. In the red cell, the major peripheral membrane proteins are located on the cytoplasmic membrane face and include enzymes such as glyceraldehyde-3-phosphate dehydrogenase (G3PD) and the structural proteins of the membrane skeleton. The red cell membrane skeleton is operationally defined as the insoluble proteinaceous residue that remains after extraction of red cells[172] or their ghosts[173] with the nonionic detergent Triton X-100. The membrane skeleton contains 55% to 60% of the membrane protein mass and includes such proteins as spectrin, actin, protein 4.1, p55, adducin, dematin, tropomyosin (TM), tropomodulin (TMod), ankyrin, and part of band 3 and protein 4.2 (see Fig. 15-6).

TABLE 15-2   Major Erythrocyte Membrane Proteins

[a]Numbering system of Fairbanks et al.[11] Bands 1 to 8 refer to gels stained with Coomassie blue. PAS-1 to PAS-3 refers to gels stained with periodic acid–Schiff.

[b]Calculated from amino acid sequences.

[c]Based on an estimate of 5.7×10^{-13} g protein per ghost[7] and on the approximate proportion of each protein, estimated from densitometry of SDS gels. The data for spectrin and ankyrin were measured directly by radioimmunoassay,[154] as were the data for glycophorins.[155]

[d]Proteins 1 to 8 were estimated from published[11,156,157] and unpublished (Lux SE and John KM) data.

[e]Protein 2.1 is full-length ankyrin and is the major isoform. Other isoforms are evident on SDS gels, including band 2.2 (195 kd), band 2.3 (75 kd), and band 2.6 (145 kd). Band 2.2 is produced by alternative splicing. The origin of the other bands is unknown. The data shown are for ankyrin 2.1 except for the number of copies per cell and approximate proportion (wt%), which includes all isoforms.

[f]The α- and β-adducins lie at the high-molecular-weight end of SDS gel band 3, a region that is sometimes called band 2.9. Band 4.9 contains both dematin and p55. Band 5 contains β-actin and tropomodulin. Band 7 contains stomatin and tropomyosin, and band 8 contains peroxiredoxin-1 and peroxiredoxin-2.

[g]The protein runs as a broad band on SDS gels because of heterogeneous glycosylation.

[h]The calculated molecular weight does not include the contribution of the carbohydrate chains.

[i]Protein 4.1 is a doublet (4.1a and 4.1b) on SDS gels. Protein 4.1a is derived from 4.1b by slow deamidation.[158] Its proportion is a measure of red cell age.

[j]Protein 4.1 homologues are encoded by at least four genes[159] and exist in a very large number of isoforms.[160-163] The major erythroid gene product is listed here.

[k]Deficiency of protein 4.2 is associated with a variety of red cell morphologies, but spherocytes predominate.

[l]The 52-kd isoform of dematin contains a 22–amino acid, N-terminal, adenosine triphosphate binding domain that the 48-kd dematin lacks.[164,165] The two proteins are derived from the same gene. They form a trimer containing two 48-kd subunits and one 52-kd subunit.[164]

[m]The amount of G3PD associated with the membrane varies from person to person (≈3 to 6 wt%).

[n]Red cell tropomyosin is a heterodimer of 27- and 29-kd subunits. There are about 70,000 copies of each chain per red cell. The two major human tropomyosin isoforms found in red cells are hTM5 and hTM5b and derive from the γ- and α-TPM3 genes, respectively.[166] We have not been able to find the exact sequence of these two isoforms.

[o]Peroxiredoxin-2 is also known as calpromotin, thioredoxin peroxidase B, thiol-specific antioxidant protein (TSA), protector protein (PRP), natural killer–enhancing factor B, acidic peroxidoxin, and torin. It translocates between the cytoplasm (dimer) and the membrane (decamer). There are about 14 million protein molecules in the cytoplasm but only about 200,000 on the membrane judging from SDS gels. The gene is located at 13q12 on the cytogenetic map and at 19p13.2 on the human genome sequence map. This dichotomy is currently unexplained.

[p]The glycophorins are visible only on PAS-stained gels.

[q]Molecular weights, including carbohydrate, were estimated from mobility on SDS gels.[156,167]

[r]Glycophorins C and D are synthesized from the same mRNA but with different translational start sites.[167]

[s]Glycophorin E mRNA has been identified, but it is not certain that the mRNA is translated.

G3PD, glyceraldehyde-3-phosphate dehydrogenase; HAc, hereditary acanthocytosis; HC, hereditary cryohydrocytosis; HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; HS, hereditary spherocytosis; HSt, hereditary stomatocytosis; OH, oxidant hemolysis; RTA, renal tubular acidosis; SAO, Southeast Asian ovalocytosis; SDS, sodium dodecyl sulfate.
FIGURE 15-6. Schematic model of the red cell membrane. The proteins are drawn roughly to scale, although it is not clear that spectrin ever folds away from the membrane in the manner shown. The relative positions of some of the proteins, particularly within the band 3 tetramer–Rh/RhAG–protein 4.2–CD47 complex and the band 3 dimer–Kell–Xk–Rh–Duffy–GPC–GPA complex, are not known. Recent evidence suggests that band 3 dimers are located near the spectrin-actin junction, where proteins 4.1 and 4.2 bind, as well in untethered positions within the lipid bilayer. In addition, to show its various interactions, the actin protofilament is drawn perpendicular to the membrane plane, jutting out into the cytoplasm, whereas it actually lies parallel to the membrane. The complexes of proteins associated with band 3 are not stoichiometric—that is, some proteins are present in much smaller numbers than others (e.g., Rh, Kell, Xk, Duffy, LW). As a consequence the band 3 complexes shown must vary in their composition. Ank, ankyrin; GPA, glycophorin A; GPB, glycophorin B; GPC, glycophorin C; RhAG, Rh-associated glycoprotein.

INTEGRAL MEMBRANE PROTEINS

Band 3 (AE1, SLC4A1)

Band 3, the major integral membrane protein of the red blood cell, accounts for 25% to 30% of the cell membrane protein ($\approx$1.2 million copies per cell). It is also called anion exchange protein 1 (AE1), but its official title is solute carrier family 4 (anion exchanger), member 1, or SLC4A1. The human band 3 gene is located on chromosome 17q21-q22 and encodes a 911–amino acid polypeptide of 102 kd.[174,175] Band 3 migrates as a diffuse band on SDS gels (see Fig. 15-5) as a result of heterogeneous *N*-glycosylation with a short complex oligosaccharide or an extended polylactosaminyl chain.[176] Residues 1 to 403 generate the 43-kd N-terminal cytoplasmic domain, which functions (1) as an anchor point for the membrane skeleton through interactions with the peripheral membrane proteins ankyrin, protein 4.1, and

protein 4.2 and (2) as a binding reservoir for hemoglobin, denatured hemoglobin, and glycolytic enzymes. Residues 509 to 911 form a 52-kd channel that exchanges HCO_3^- and Cl^-, thereby facilitating the critical function of red cells in the uptake of CO_2 in tissues and subsequent release of CO_2 in the lungs. The carboxy-terminal of band 3, which resides on the cytoplasmic side of the membrane, also binds carbonic anhydrase II.[177]

Cytoplasmic Domain

The N-Terminal Portion of Band 3 Is the Cytoplasmic Binding Domain. The cytoplasmic domain of band 3 is readily released from the red cell membrane as a 43-kd fragment after treatment with chymotrypsin or trypsin.[178] The first 45 amino acids are highly acidic and stretch into the cytoplasm (Fig. 15-7). The remainder of the cytoplasmic domain is remarkably mobile, with expansion at high pH and contraction at low pH,[181] because of a conformational transition that is not fully understood.
FIGURE 15-7. Organizational model of human erythrocyte band 3 (anion exchange protein, AE1). The protein is divided into two structurally and functionally distinct domains: an approximately 43-kd cytoplasmic domain (amino acids [aa] 1 to 359) that contains binding sites for several cellular proteins and an approximately 52-kd transmembrane domain (aa 360 to 911) that forms the anion exchange channel. The two regions can be separated by cleavage of chymotrypsin at the inner membrane (C_1). A second chymotrypsin site (C_2) is accessible at the external surface. *Cytoplasmic domain*: The highly acidic N-terminal end (aa 1 to 45) binds deoxyhemoglobin, hemichromes, and the glycolytic enzymes phospho-glycerate kinase (PGK), aldolase, and glyceraldehyde-3-phosphate dehydrogenase (G3PD). Enzyme attachment is blocked by phosphorylation of tyrosines 8 and 21. Antibodies to the N-terminal end also interfere with binding of ankyrin, but the main ankyrin site is aa 175 to 185. Protein 4.1 binds to two sites with the (I/L)RRRY motif, near the end of the domain. The binding site for protein 4.2 has not been clearly identified. *Membrane domain*: One current model[179] suggests that band 3 contains 13 α-helical membrane-spanning segments and two additional transmembrane (TM) regions with nonhelical conformations, all of which are connected by hydrophilic loops. Almost nothing is known about how the various TM segments are positioned relative to each other. There is good evidence that Glu681 is required for anion transport and that TM8 and probably TM1+2 and TM13 form part of the channel. Presumably, the unique nonhelical TM segments between TM regions 9-10 and 11-12 are also involved. Pro854 is the site of the Diego[a] blood group antigen[180] and must be extracellular. A complex carbohydrate structure is attached to Asn642. Carbonic anhydrase II (CA-II) binds to the C-terminal of band 3, and CA-IV binds to the extracellular loop between TM7 and TM8. Both are perfectly positioned to shuttle HCO_3^- ions to or from plasma through band 3. *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858, with permission.)*

The Acidic N-Terminal Sequence of Band 3 Binds Hemoglobin. Hemoglobin binds weakly to the acidic N-terminal of band 3 ($K_{d\ [deoxy\ Hb]}$ = 0.31 mM), but because the concentration of hemoglobin is so high in red cells, roughly half of the band 3 molecules are bound to hemoglobin under physiologic conditions.[182,183] X-ray crystal structures show that the first 11 amino acids of band 3 penetrate the 2,3-diphosphoglycerate (2,3-DPG) binding cavity in the center of hemoglobin.[182] Because the cavity closes when hemoglobin is oxygenated, only deoxyhemoglobin binds to band 3. Thus, band 3 lowers O_2 affinity, but when hemoglobin is only partially saturated with band 3, its cooperativity is also reduced.[184] This has led to the idea that band 3–bound hemoglobin could preferentially bind O_2 at low pO_2 values and then release it upon saturation with 2,3-DPG in the cytoplasm.[184]

Denatured Hemoglobin Molecules Copolymerize with the Cytoplasmic Domain of Band 3 and Form Aggregates, Which May Play a Role in Red Cell Senescence. Hemichromes, a partially denatured form of hemoglobin, bind to band 3 more avidly than hemoglobin does, thereby resulting in the formation of hemichrome–band 3 aggregates.[183,185,186] This clustering of band 3 is believed to generate a cell surface epitope identified by autologous IgG antibodies that targets the cell for phagocytosis (see the later section "Red Cell Membrane Alterations of Senescent Red Cells").[187] The formation of such a senescence antigen by band 3 copolymerization with hemichromes may also contribute to the clearance of sickle, β-thalassemic, and hemoglobin Köln red cells, all of which contain unstable hemoglobin that oxidatively degrades into hemichromes. Band 3 clustering can generate multivalent epitopes composed of surface sialylated poly-*N*-acetyllactosaminyl chains, which in turn can be recognized by anti–band 3 IgG autoantibodies and by macrophages directly.[188]

The N-Terminal Sequence Also Binds Glycolytic Enzymes, Which Probably Form a Membrane Metabolon. The first 23 amino acids of band 3 contain two tandem repeats terminating in the sequences DDY[8]ED and EEY[21]ED. Glyceraldehyde-3-phosphate dehydrogenase (G3PD),[189] phosphoglycerate kinase (PGK),[190] and aldolase[191,192] all bind in this region. Aldolase requires both sites to bind, G3PD binds separately to each, and PGK binds to the more distal site.[193] In confirmation, the red cells from a child with a mutant band 3 that lacks the first 11 amino acids (Bd 3 Neapolis) contain no membrane-bound aldolase.[194]

Approximately 65% of G3PD, 50% of PGK, and 40% of aldolase are membrane bound in the intact red cell,[189,195] and they are inhibited when attached to the membrane.[191,192,196] In addition, lactate dehydrogenase (LDH) and pyruvate kinase (PK) also localize to the membrane, even though they do *not* bind to band 3 (Fig. 15-8).[197] All five enzymes are displaced into cytoplasm by an antibody to the N-terminal of band 3, by phosphorylation of tyrosines 8 and 21, which lie in the middle of the two binding sites, or by deoxygenation, which causes hemoglobin to bind to the N-terminal of band 3 (see later).[197]

The data suggest that at least the distal enzymes in the glycolytic pathway form a complex (a "metabolon") that is bound to band 3 and can be regulated by tyrosine phosphorylation, by the state of oxygenation,[197-199] and perhaps by substrates and cofactors of the enzymes.[189-191] Antibodies show that the enzymes are present in discrete clumps along the membrane, which also supports this idea (see Fig. 15-8). It is not clear whether more proximal glycolytic or pentose phosphate pathway enzymes are also part of this putative metabolon, but there is evidence that diphosphoglyceromutase may be.[200] Interestingly, the existence of a membrane-bound complex of glycolytic enzymes was postulated more than 40 years ago[201] and was indirectly observed more than 25 years ago,[202] but the nuclear magnetic resonance (NMR) methods used in the latter studies were considered suspect at the time and the interpretation was not generally accepted.

The obvious reason for a complex of glycolytic enzymes would be to increase the efficiency of the pathway by channeling glycolytic intermediates from one enzyme to the next (see Fig. 15-8). Furthermore, it would make sense if it were attached to band 3, which transports the phosphate needed to make ATP. However, a glycolytic metabolon might also have other functions. There is relatively recent evidence that human red cells can compartmentalize ATP, thereby allowing its direct use by membrane pumps without release into the cytoplasm.[203] This is another discredited old idea[204] that has been revived. Na^+,K^+-ATPase (the Na, K pump) is metabolically linked to ATP produced by PGK[205] and may be physically associated with PGK or neighboring enzymes.[202] There are only about 290 Na^+,K^+-ATPase molecules per red cell,[206] so perhaps other pumps are also involved.

Some mammalian band 3s lack the acidic N-terminal binding sites on band 3 and do not bind G3PD, which suggests that the interaction of band 3 with glycolytic enzymes either is a late evolutionary adaption[207] or is inconsequential or an artifact. However, deoxygenation of intact human red cells increases glycolysis,[208] and mild oxidants, which stimulate tyrosine phosphorylation in human erythrocytes, also elevate glycolytic rates.[1]

The Cytoplasmic Domain of Band 3 Functions as an Attachment Site for Membrane Skeleton Proteins. *Ankyrin* links the major membrane skeletal protein spectrin to the plasma membrane of the red cell by binding to a β-hairpin loop formed by amino acids 175 to 185 in the cytoplasmic domain of band 3[209]; however, this is probably not the only binding site because removal of the β-hairpin does not cause nearly as much hemolysis as loss of ankyrin or band 3 does.[210] Binding blocks access to the N-terminal of band 3, which is nearby (Fig. 15-9; see also Fig. 15-7). Ankyrin's linkage of spectrin to band 3 forms the basis of the skeletal-membrane attachment,

FIGURE 15-8. Postulated glycolytic metabolon. **A,** Fluorescent imaging of band 3 and aldolase on the *left* and phosphofructokinase (PFK), lactate dehydrogenase (LDH), and pyruvate kinase (PK) on the *right*. Note that band 3 is uniformly and exclusively in the membrane whereas the five enzymes are mostly attached to the membrane (some cytoplasmic staining, especially for LDH) and have a punctate appearance as though they are clustered. Glyceraldehyde-3-phosphate dehydrogenase (G3PD) stains similarly but is not shown. Aldolase, PFK, and G3PD bind to band 3; PK and LDH do not. However all are displaced by a fragment of the band 3 binding site, by phosphorylation of the site, or by deoxyhemoglobin, thus suggesting that all are bound in a complex or "metabolon." **B,** Schematic of the postulated glycolytic metabolon. When the enzyme complex is bound to band 3 (*right*), it is inactive. The complex can be displaced and activated (*left*) by phosphorylation of Tyr8 and Tyr21 on band 3 or by binding of deoxyhemoglobin. There is some evidence that part of the adenosine triphosphate (ATP) produced is retained at the membrane and used by the Na$^+$,K$^+$-ATPase or other membrane pumps. Note that the inorganic phosphate needed for ATP production conveniently enters the cell through band 3. Band 3 also transports phospho*enol*pyruvate, pyruvate, and lactate, all substrates or products of the putative complex. *(Photomicrographs from Campanella ME, Chu H, Low PS. Assembly and regulation of a glycolytic enzyme complex on the human erythrocyte membrane. Proc Natl Acad Sci U S A. 2005;102:2402-2407.)*

which is essential to the mechanical and viscoelastic properties of the red cell. Ankyrin$_R$ preferentially binds to band 3 tetramers and may be required for stabilization of the tetramer.[211,212] It is estimated that 70% of band 3 exists as dimers and 30% as tetramers and higher-order oligomers, with the latter species predominantly associated with the membrane skeleton through interactions with ankyrin.[214]

Protein 4.1, which links the spectrin-actin–based skeleton to the plasma membrane in part via interactions with GPC, has also been shown to bind to the cytoplasmic domain of band 3 at specific (I/L) RRRY sequences near the inner membrane surface (see Fig. 15-7).[215,216]

However, there is controversy regarding whether protein 4.1 binds to band 3 in vivo.[213,217] The different experiments are difficult to reconcile, but recent in vivo experiments suggests that 4.1–band 3 interactions are important.[218] Zebra fish with severe hemolytic anemia because of lack of band 3 can be rescued by expressing normal band 3 in their erythrocytes, but only if the band 3 contains both (I/L)IRRRY sites. Deletion of one site halves the number of fish rescued, and deletion of both sites prevents any rescue from occurring.[218] Because band 3 and ankyrin compete for binding to tetrameric band 3,[213] it may be that protein 4.1 binds preferentially to dimeric band 3 (see Fig. 15-6).
FIGURE 15-9. Crystal structure of the band 3 cytoplasmic domain. The deduced structure of the band 3 tetramer is shown. One dimer is blue, the other green. This is the conformation that binds ankyrin. The ankyrin binding loop[209] is colored a darker blue and the N- and C-terminal ends of the domain are marked by "N" and "C," respectively. Note that the tetramer structure brings two ankyrin sites together on the same side of the molecule (*arrowheads*). Because ankyrin has two band 3 binding sites and would bind with much higher affinity if both were engaged, this may explain why essentially only band 3 tetramers bind ankyrin.[211,212] Note also that the C-terminal ends of the cytoplasmic domain, where protein 4.1 binds, lie close to the ankyrin sites. This may explain why binding of ankyrin and 4.1 is mutually exclusive.[213] *(Redrawn from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858, with permission.)*

Protein 4.2, a 77-kd peripheral membrane protein of the red cell, also interacts with the cytoplasmic domain of band 3. The binding site is not well defined. Red cells from patients with the cytoplasmic band 3 mutations Glu40→Lys and Pro327→Arg show some deficiency of protein 4.2, thus suggesting that both proximal and distal cytoplasmic band 3 sequences may be involved. It is not clear whether protein 4.2 binds to the ankyrin-linked band 3 tetramers or the "free" band 3 dimers, but indirect evidence suggests the latter. In red cells from patients with HS who lack protein 4.2, the mobile fraction of band 3 rotates faster and shows greater lateral diffusion, and a greater fraction of band 3 is in the tetramer form, which suggests that band 3 dimers are preferentially lost as the cells become spheroidal.[219,220] Because protein 4.2 binds to the tail end of spectrin,[221] we suspect that it bridges between band 3 dimers and spectrin and that band 3 dimers localize near the spectrin-actin junction (see Fig. 15-6), but additional experiments are needed to test this hypothesis. Whatever the organizational arrangements, it appears that protein 4.2 depends on band 3 to be expressed in the membrane. Membranes from band 3 knockout mice completely lack 4.2,[222] and membranes from 4.2 knockout mice are partially deficient in band 3.[223]

Membrane Domain

The 52-kd Membrane Domain Contains an Anion Exchange Channel. The anatomy of the membrane domain of band 3 has been an active area of interest, with the goal of research efforts focused on understanding how the membrane domain's topology enables the 1.2 million channels in each red cell to exchange 10^{10} to 10^{11} HCO_3^- and Cl^- anions per second.[2] The membrane domain contains 13 α-helical membrane-spanning seg-

ments and two additional transmembrane regions with nonhelical conformations, all of which are connected by hydrophilic loops (see Fig. 15-7).[179] A fatty acid is esterified to Cys843. Its function is unknown.

Chemical modification of band 3 at Glu681 (which is found in transmembrane domain 8) by Woodward's reagent K (WRK) abolishes chloride transport, thus implicating this critical glutamic acid in channel function.[224] The key role of Glu681 in chloride translocation by human band 3 was confirmed by mouse band 3 mutagenesis (where Glu699 is the equivalent residue).[225] The membrane domain of band 3 can also accomplish sulfate transport, which requires cotransport with a proton supplied by glutamic acid.[226] Interestingly, WRK modification of band 3 does not interfere with sulfate transport except that proton cotransport is no longer required, thereby implicating Glu681 in the important proton donor step during sulfate transport.[225] Because sulfate-proton cotransport occurs in both inward and outward directions in the native protein and because Glu681 can be modified from both sides of the membrane, Glu681 must have access to both the intracellular and extracellular faces of the membrane.

Identification of Glu681 as a component of the band 3 permeability barrier has prompted thorough investigation of the confusing topology of the latter half of the membrane domain.[179,227-232] The current model, derived from this and other work, is shown in Figure 15-7. (1) Amino acids Met664-Ser690 form transmembrane domain 8 (TM8), which is longer than typical transmembrane domains. It appears to form part of the anion exchange channel. (2) Glu681 is located near the carboxy-terminal of TM8, probably at the portion of the channel that separates the inside and outside of the cell. (3) Amino acids on a polar face of TM12 and TM13 are

required for anion exchange, thus suggesting that these domains may line the channel and participate in transport. Lys851, which reacts with an important inhibitor of anion exchange (4,4′-diisothiocyanostilbene-2,2′-disulfonate [DIDS]) is part of the polar face on TM12. The neighboring Ser852-Leu857 amino acids appear to function as a substrate charge filter.[232] (4) Eleven independent patients with hereditary cryohydrocytosis or HS have been identified who have five different mutations in band 3 that astonishingly, cause the anion channel to become a *cation* conductance channel![233,234] The mutations are clustered between the end of TM8 and the beginning of TM10, thus strongly suggesting that this region is also involved in the transport function. (5) There are nonhelical segments between TM9-TM10 and TM11-TM12 that are not externally accessible except for a segment in the middle of the latter loop (Pro815-Arg827), which is sometimes accessible from the extracellular space. (6) Arg656-Met663 (external loop from the carbohydrate side chain to TM8) may form a vestibule-like structure that draws anions toward the transport channel. Carbonic anhydrase IV, a GPI-linked protein, binds to band 3 in this region,[235] probably between Arg656 and Ile661, and forms part of a CO_2/HCO_3^- transport metabolon.

The Transport Channel Exchanges Chloride and Bicarbonate Rapidly ($T_{1/2} = 50$ msec), Which Facilitates CO_2 Transport from Tissues to the Lungs. In peripheral tissues, CO_2 is rapidly converted to HCO_3^- at the surface of band 3 by carbonic anhydrase IV and is transported into the red cell, or it diffuses into the cell and is then converted to HCO_3^- by carbonic anhydrase II, which binds to the carboxy-terminal of band 3.[177] The H^+ by-product of the carbonic anhydrase reaction binds to hemoglobin and facilitates release of O_2 to tissues (i.e., the Bohr effect); this process is reversed in the lungs (Fig. 15-10). As the red cell circulates, intracellular HCO_3^- is exchanged for extracellular chloride. As a result, HCO_3^- is transported in plasma, as well as within the red cell, which increases transport of CO_2 from tissues to the lungs by approximately 60%.[2] HCO_3^--Cl^- exchange is believed to occur via a "ping-pong" mechanism whereby an intracellular anion enters the transport channel and is translocated outward and released, with the channel remaining in the outward configuration until an extracellular anion enters and activates the reverse cycle.[236] As discussed earlier, the amino acids of a subset of the transmembrane segments form the transport channel. Although monomeric band 3 has been shown to independently transport anions,[237] image analysis of negatively stained, two-dimensional crystals of band 3 dimers has demonstrated an apparent channel at the contact site between two monomers, thus suggesting that anion transport may occur via the dimer.[238] Further data suggest that band 3 dimerization produces allosteric effects that may modify channel function.[239]

Although HCO_3^- and Cl^- are the predominant physiologically relevant anions exchanged by band 3, the specificity of the channel is actually quite broad, and larger anions such as sulfate, phosphate, pyruvate, and superoxide are also transported, albeit at much slower rates.[240] Several potent and experimentally useful inhibitors of band 3 anion transport are also known, with the most commonly used being stilbene disulfonates such as DIDS.[240]

FIGURE 15-10. Function of band 3 in O_2 and CO_2 transport. **A,** Tissue CO_2 is converted into HCO_3^- and H^+ in the red cell by carbonic anhydrase. Band 3–mediated exchange of HCO_3^- for Cl^- (Hamburger shift) allows HCO_3^- to be carried in plasma, as well as in red cells, and increases CO_2 uptake by about 60%. H^+ binds to hemoglobin and facilitates release of O_2 (Bohr effect) and tissue oxygenation. **B,** These processes are reversed in the lungs, with promotion of hemoglobin oxygenation and release of CO_2. *(After Weith JO, Anderson OS, Brahm J, et al. Chloride-bicarbonate exchange in red blood cells: physiology of transport and chemical modification of binding sites. Philos Trans R Soc Lond [Biol]. 1982;299:383.)*

The Extracellular Surface of the Band 3 Membrane Domain Is the Site of Specific Blood Group Antigens. Asn642, located in the extracellular loop between TM7 and TM8, is derivatized with a complex lactosaminoglycan that is variable in length and contains the I/i blood group antigens (see Fig. 15-7).[241-243] In fetal cells, the carbohydrate chain is unbranched and has i specificity, whereas in adults, there is a branched structure that yields I reactivity. In rare circumstances, the I antigen is absent from adult red cells as a result of a branching enzyme deficiency.[244] The extracellular domains of band 3 also contain antigens of the Diego blood group system[180] and other polymorphisms accounting for many other antigen subtypes.[245-252] The Wr^b blood group antigen is generated by the association of band 3 with GPA in the red cell membrane (see next paraglaph).[252]

The Integral Membrane Protein Glycophorin A and the Membrane Domain of Band 3 Are Functionally Associated. Although explicit protein binding data have yet to confirm a specific interaction between GPA and band 3, there is mounting evidence that the two red cell membrane proteins have a physiologically relevant association. Expression of the Wright (Wr) blood group antigen (a receptor for the malarial agent *Plasmodium falciparum*) requires interaction between GPA and band 3. Specifically, the presence of Glu658 in band 3 is required for normal expression of this blood group antigen,[253] and an Ala65→Pro mutation in GPA has been shown to cause aberrant Wright antigen expression.[254] Furthermore, a monoclonal antibody directed against the Wr^b antigen immunoprecipitates both proteins.[255] Anti-GPA antibodies have been shown to immobilize GPA *and* band 3 in the red cell membrane as determined by in situ fluorescence recovery after photobleaching (FRAP) assays.[256]

Coexpression of GPA and band 3 in *Xenopus* oocytes facilitates the expression of band 3. A loss-of-function mutation in band 3 at Gly701 leads to impaired protein targeting to the cell surface in *Xenopus* oocytes; the aberrant phenotype is rescued by coexpression of the mutant band 3 with GPA, which suggests a chaperone-like role for GPA in band 3 targeting.[257] GPA also enhances band 3 transport.[258] The effect is significant. For example, SO_4^{2-} transport is diminished 60% in the absence of GPA.[259] This appears to be due to an effect of GPA on band 3 flexibility such that band 3 can adopt a rigid, high-transport structure when GPA is present and a more flexible, lower-transport structure in its absence. Finally, red cells from band 3 knockout mice are completely deficient in GPA, thus showing that band 3 is also important for expression and trafficking of GPA.[260]

Band 3 Mutations

More than 20 different mutations in band 3 are known to cause HS as a result of decreased synthesis, membrane insertion, stability, and protein 4.2 binding of the aberrant band 3 protein. These are discussed in detail in the section "Hereditary Spherocytosis" later in the chapter.

Deletion of amino acids 401 to 408 in band 3 causes Southeast Asian ovalocytosis (SAO),[261,262] an autosomal dominant condition characterized by rounded elliptocytic cells, mild or absent hemolysis, and the presence of unusually rigid and heat-tolerant red cells that resist malarial invasion.[263] Multiple mutations in the membrane domain of band 3 and in the C-terminal tail have been independently associated with the autosomal dominant form of distal renal tubular acidosis (dRTA), a condition characterized by impaired distal nephron secretion of hydrogen ions (reviewed by Toye[264]). The phenotype is believed to result from faulty targeting of band 3 to the apical rather than the basolateral membrane of collecting tubule type A intercalated cells, as opposed to a defect in anion transport.[265] Mutation of Gly701 (located in the intracellular loop between TM8 and TM9) is associated with autosomal recessively inherited dRTA, with the phenotype again deriving from faulty band 3 trafficking.[257] Incomplete processing of the band 3 *N*-linked lactosaminoglycan moiety as a result of a deficiency in the relevant glycosyltransferase occurs in congenital dyserythropoietic anemia type II (CDA II or hereditary erythroblastic multinuclearity with a positive acidified serum lysis test [HEMPAS]), although it is probably not the primary molecular defect. A rare Pro868→Leu mutation in TM13 of band 3 causes hereditary acanthocytosis; affected red cells exhibit decreased ankyrin binding and increased anion transport.[266] Moreover, as noted earlier, mutations in band 3 that convert it from an anion to a cation channel are associated with phenotypes of hereditary cryohydrocytosis or HS.[233] Interestingly, band 3 knockout mice can exhibit a fatal hypercoagulable state that is believed to derive from disruption of red cell membrane phospholipid asymmetry, which can produce a cell surface suitable for activating thrombosis.[267] Knockout mice that survive the neonatal period have severe hemolytic anemia, and the band 3–null red cells are spherocytic with increased osmotic fragility (OF) because of membrane surface loss.[222]

Band 3 and Malaria

P. falciparum parasites are believed to invade red cells via two distinct pathways, one that is dependent on the sialic acids on GPA or GPC and a sialic acid–independent pathway that is linked to band 3. Recent work shows that expression of a parasite protein called PfRh4 correlates with switching to the sialic acid–independent pathway.[268] Liposomes containing purified band 3 inhibit invasion,[269] as does a monoclonal antibody against extracellular epitopes of band 3.[270] Peptides corresponding to the two nonhelical regions in Figure 15-7 also partially block invasion,[271] thus suggesting that these regions serve as receptors. MSP1 (*P. falciparum* merozoite surface protein 1) furnishes the ligand.[271]

Nonerythroid Band 3

Band 3 is a member of a highly conserved anion exchanger gene family (also named solute carrier family 4A

[SLC4A]) that is composed of AE1 (SLC4A1),[174,175] AE2 (SLC4A2),[272,273] AE3 (SLC4A3),[274] and their associated spliceoforms. AE1 is expressed in erythrocytes, testes, and kidneys. The kidney isoform of AE1 is found in type A intercalated cells of the collecting tubules and lacks the N-terminal 66 amino acids that interact with glycolytic enzymes and certain membrane skeletal elements in red cells.[275] Another splice variant of AE1 is found in cardiac myocytes.[276] AE2 is widely distributed (e.g., kidney, stomach, lymphocytes, choroid plexus) and probably represents the general tissue anion antiporter. AE3 localizes to excitable tissues such as the heart, brain, and retina. The role of anion exchangers in polarized epithelial cells, such as intercalated cells of the kidney, is to facilitate bicarbonate reabsorption and acid secretion. The CO_2 that diffuses into the cell is converted to H^+ and HCO_3^- by carbonic anhydrase, which is associated with the anion exchanger at the basolateral membrane. Whereas H^+ is ejected from the cell via the apical membrane H^+,K^+-ATPase, HCO_3^- exits at the basolateral membrane in exchange for chloride.

Glycophorins

The glycophorins are a family of integral membrane glycoproteins that account for the majority of the surface charge of the red cell. The extracellular domains of the glycophorins contain an abundance of sialic acid, which generates a layer of negative charge at the cell surface and thereby prevents adherence of red cells to each other and to the vessel walls. Surface epitopes of the glycophorins, including variants generated by protein defects, account for a wide diversity of blood group antigens in the MNSs system. Glycophorins also serve as receptors for infective agents such as *P. falciparum*. Recent data suggest that glycophorins may also function as chaperones by facilitating the targeting of specific integral membrane proteins to the plasma membrane. The glycophorins belong to the broad family of integral membrane proteins that pass through the lipid bilayer as a single α helix. Because other members of the "single-pass" membrane proteins include growth factor receptors and receptor kinases, the glycophorins have been considered potential candidates for mediating transmembrane signaling in red cells.

Glycophorin A

The GPA gene is located on the long arm of chromosome 4 (4q31) and encodes a 36-kd protein that is the major sialoglycoprotein of the red cell (~10^6 copies per cell, see Table 15-2). Of historical note, GPA was the first membrane protein to have its complete amino acid sequence determined. Amino acids 1 to 61 give rise to the extracellular N-terminal domain, which contains a complex oligosaccharide attached to Asn26[277] and 15 serine or threonine *O*-linked tetrasaccharides with sialic acid moieties (Fig. 15-11A).[278,279] The carbohydrate component

Disorders of the red cell membrane skeleton: hereditary spherocytosis and hereditary elliptocytosis. In Scriver CR, Beaudet AL, Sly WS, Valle D [eds]. The Metabolic Bases of Inherited Disease, 7th ed. New York, McGraw-Hill, 1995; and Fukuda M. Molecular genetics of the glycophorin A gene cluster. Semin Hematol. 1993;30:138.)*

of GPA accounts for 60% of its molecular mass. Experimentally, the glycophorins run anomalously on SDS gels because the abundant carbohydrate interferes with detergent binding. In addition, the carbohydrate interferes with Coomassie blue staining such that special stains (e.g., periodic acid–Schiff) are required to visualize the glycophorins. The amino-terminal of GPA contains the site of the MN blood group antigens; specifically, amino acids 1 and 5 along with the sialic acid residues on adjacent *O*-linked tetrasaccharides dictate the antigenicity.[280] Whereas amino acids 1 and 5 are serine and glycine in MM red cells, leucine and glutamic acid in the corresponding positions characterize NN cells (Table 15-3). The transmembrane domain of GPA is composed of amino acids 62 to 95 and traverses the lipid bilayer as a single α helix. The membrane domain interacts with negatively charged lipids such as PS and PI.[102,313] Self-association of the Leu75-Ile76-XX-Gly79-Val80-XX-Gly83-Val84-XX-Thr87 motif within the transmembrane domain results in homodimerization into a right-handed pair of α helices.[314,315] NMR spectroscopy has shown that Ile76, Val80, and Val84 on the α helix of one monomer interface with Leu75, Gly79, Gly83, and Thr87 on the second monomer.[316] The extracellular domain also contributes to this dimeric interaction,[317] which is strong enough to resist dissociation by detergents.

Recent evidence shows that the cytoplasmic domain of GPA (amino acids 96 to 131) is important for enhancing the trafficking of band 3 to the membrane[317] and that the GPA–band 3 association increases band 3 anion transport (see the section "Band 3").[259] Conversely, GPA is also dependent on band 3 for trafficking or for stable incorporation in the red cell membrane inasmuch as mice that lack band 3 also lack GPA.[260]

Interestingly, treatment of red cells with antibodies (or monovalent Fab fragments) to GPA induces cellular rigidity as measured by ektacytometry, and the quantity of GPA that becomes associated with the membrane skeleton in experimental systems increases.[318] Both these changes are dependent on the presence of the cytoplasmic tail of GPA, which suggests that the cytoplasmic domain binds to the membrane skeleton in response to a transmembrane signal initiated by antibody treatment.[319] Hypothetically, the cellular rigidity induced by adherence of pathogens to glycophorins may serve the beneficial role of heightening reticuloendothelial clearance of infected cells[319] or may help impede invasion by parasites.

GPA has been used as a specific marker for the erythroid lineage because of its early detection in proerythroblasts.[320] In addition, assays to gauge radiation exposure and consequent somatic mutation based on measuring the frequencies of variant GPA phenotypes in red cells have been developed.[321]

Glycophorin B

The gene for glycophorin B (GPB) lies just downstream of GPA on chromosome 4 and is believed to have arisen by gene duplication.[322,323] The first 26 amino acids of the extracellular N-terminal domain are almost identical to the N blood group form of GPA except that the latter form lacks the *N*-linked complex oligosaccharide (see Fig. 15-11B).[280] In addition to N blood group reactivity, GPB carries the S, s, and U blood group antigens, with the S and s antigens differing by substitutions at residue 29 (S = Met, s = Thr) (see Table 15-3).[324] Distally, GPB lacks a portion of the extracellular domain corresponding to exon 3 of GPA and almost all of the cytoplasmic domain.

Glycophorins C and D

Glycophorin C (GPC) and glycophorin D (GPD) have a general domain structure similar to that of GPA and GPB (see Figure 15-11C), but they are encoded by a distinct gene located on chromosome 2 (2q14-2q21).[325] GPD is generated from the same mRNA as GPC by means of an alternative initiation codon.[167] GPC is a 32-kd protein bearing one N-linked oligosaccharide and approximately 12 O-linked oligosaccharides in the N-terminal, extracellular domain. The desialylated form of GPC is exposed on the surface of early erythroid progenitors (burst-forming unit–erythrocyte [BFU-E]) and is a useful marker of early normal or leukemic erythroid differentiation.[326] Normally, glycosylated GPC first appears at the colony-forming unit–erythrocyte (CFU-E) stage.[327] Amino acids 41 to 50 of the extracellular domain contain the Gerbich blood group antigens. Like GPA and GPB, the transmembrane domain passes through the lipid bilayer as a single α helix. The cytoplasmic domain of GPC forms a ternary complex with protein 4.1 and p55 and helps attach the spectrin-actin–based skeleton to the plasma membrane. The 30-kd membrane binding domain (MBD) of protein 4.1 interacts with amino acids 82 to 98 of GPC and the corresponding residues 61 to 77 of GPD.[328] p55 is a member of the membrane-associated guanylate kinase (MAGUK) family of proteins and contains a single PDZ domain that binds to GPC at residues 112 to 128 and to GPD at the corresponding amino acids 91 to 107.[328,329] The ternary complex of GPC/GPD, protein 4.1, and p55 (see Fig. 15-6) aids in maintaining and perhaps regulating red cell membrane deformability and mechanical stability. Unlike GPA and GPB, GPC and GPD are expressed in a variety of tissues (although at lower levels than in erythroid cells and with different glycosylation patterns)[330,331] and may have an analogous functions in the membrane mechanics of nonerythroid cells.

Glycophorin E

The gene for glycophorin E (GPE) lies just downstream of GPB on chromosome 4 and encodes a 78–amino acid protein with structural similarities to GPB (see Fig. 15-11B).[332] The extracellular domain of GPE corresponds to exon 2 of GPB, but the amino acid sequence specifies blood group M rather than N.[332] The transmembrane domain is encoded by exon 5 and contains an eight–amino acid insertion. Like GPB, GPE has a markedly truncated cytoplasmic domain. GPE is believed to have arisen by gene duplication of GPB, which in turn derived from ancestral duplication of GPA.[323] Thus, GPA, GPB, and GPE define an erythroid-specific family of integral membrane sialoglycoproteins. The level of expression of GPE and its specific functional role have not been determined, and we cannot exclude the possibility that it is a pseudogene.

Glycophorin Mutations

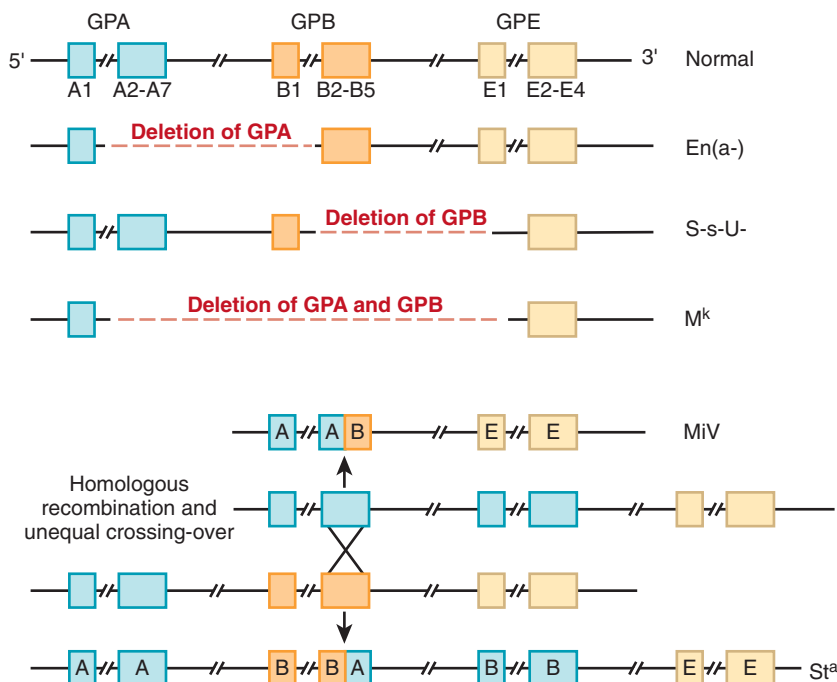
Defects in Glycophorins A, B, and E Give Rise to Nearly 40 Variant Phenotypes of the MNS Blood Group System.[333] Complete loss of GPA, GPB, or both, often by gene deletion from unequal recombination of the neighboring loci, gives rise to En(a–), (S–s–), and M^{k}M^k red cells, respectively (see Table 15-3) (Fig. 15-12). En(a–) red cells, for example, are completely deficient in GPA and have weak MN blood group antigens.[285,286] The affected red cells compensate for a potential 60% loss of surface charge by increasing the glycosylation of band 3


FIGURE 15-12. Organization of the glycophorin A (GPA), B (GPB), and C (GPE) genes on chromosome 4 and probable deletions in the En(a–), S–s–U–, M^k, Miltenburger type V (MiV), and Stones (St^a) variants. The MiV and St^a variants arise from unequal crossing over, analogous to the Lepore hemoglobins. In MiV red cells, the normal GPB gene is replaced by a fusion gene (Lepore-type recombination). In St^a erythrocytes, the product of the reciprocal exchange is inserted between the GPA and GPB loci, but no normal genes are lost (anti-Lepore–type recombination). (Adapted from Vignal A, London J, Rahuel C, Cartron JP. Promoter sequence and chromosomal organization of the genes encoding glycophorins A, B, and E. Gene. 1990;95:289-293.)

such that the overall surface charge is reduced by only approximately 20%.[287] Given the proximity and homology of the GPA, GPB, and GPE genes, hybrid glycophorin molecules may be generated by recombination events during meiosis. In the MiV variant, for example, Lepore-like recombination yields a fusion gene containing the N-terminal of GPA and the C-terminal of GPB.[304] In the St[a] variant, anti-Lepore recombination produces the reverse hybrid (N-terminal GPB with C-terminal GPA), which is inserted between the normal GPA and GPB genes, neither of which is lost.[304] Interestingly, none of the GPA and GPB variants produce detectable changes in erythropoiesis or in the shape, function, or life span of the affected red cells. Rare individuals with complete absence of GPA and GPB apparently exhibit no erythrocyte abnormalities.[276] Similarly, GPA knockout mice have a normal phenotype except that they have 60% less *O*-linked oligosaccharides than normal red cells do.[334] Thus, either GPA, GPB, and GPE do not serve any critical basal functions in red cells or such functions are assumed by other proteins such as GPC or band 3 when GPA/GPB/GPE is deficient. If GPA really has no nonredundant function, it is surprising that deletions and other mutations are not more common because GPA is a major receptor for *P. falciparum* malaria (see later) and must be under intense evolutionary pressure.

Variations in Glycoproteins C and D Affect the Gerbich Antigen System. Mutations in exons 1, 2, and most of 3 modify the N-terminal extracellular domain of GPC and GPD and thus alter the antigenicity of red cells but do not affect cellular mechanical properties.[331,335] Examples include Gerbich-type cells, which lack exon 2; Yus-type cells, which lack exon 3; and Webb-type cells, which have a missense mutation of GPC that converts Asn at position 8 to Ser, thereby precluding *N*-glycosylation at this site.[336,337] By contrast, in the Leach phenotype there is complete loss of GPC and GPD secondary to deletion of exons 3 and 4[338,339] or a frameshift mutation.[339] Affected individuals do not have significant hemolysis, but their red cells are elliptocytic[340,341] and exhibit decreased membrane deformability and mechanical stability.[335,342,343] GPC-deficient cells also demonstrate partial deficiencies of protein 4.1 and p55,[344] and therefore the disturbance in membrane mechanical properties exhibited by Leach cells probably derives from a deficiency of the GPC/protein 4.1/p55 ternary complex. Individuals with homozygous protein 4.1 deficiency likewise exhibit a deficiency of GPC (≈70%) in their elliptocytic red cells,[345,346] thus underscoring that the cellular content of each component of the ternary complex depends on the expression level of the others. Interestingly, absence of the *Drosophila* protein neurexin IV, which contains a cytoplasmic domain homologous to that of GPC, results in mislocalization of Coracle (the *Drosophila* homologue of protein 4.1) at septate junctions, with attendant defects in the formation of septate-junction septa and intercellular barriers (such as the blood-nerve barrier).[347]

Glycophorins as Receptors for Malarial Invasion

Experiments by Perkins published in 1981 identified GPA as the probable red cell surface attachment site for *P. falciparum* upon merozoite invasion.[348] Subsequently, erythrocytes deficient in GPA were shown to resist malarial invasion, presumably by lacking the requisite attachment site for parasitic invasion.[349] It has since been learned that there are alternative pathways for malarial invasion of red cells that depend on the strain of *P. falciparum* and the ability of the parasite to switch its invasion requirements.[350] For example, sialic acid–dependent invasion results from binding of the merozoite protein EBA175 to the Neu5Ac-(α2,3)-Gal moiety on the *O*-linked tetrasaccharides of GPA.[351] Another sialic acid–dependent but EBA175-independent pathway is believed to involve merozoite binding to GPB.[352] The structure of EBA175 bound to the relevant glycan has recently been published.[353] Identification of specific *P. falciparum* strains that invade neuraminidase-treated red cells (i.e., desialylated cells)[350,354] and GPA/GPB-deficient M[k]M[k] cells[355] highlighted the existence of a sialic acid–independent mechanism for malarial invasion. One such mechanism may involve merozoite adhesion to band 3.[269]

Protein 4.1–deficient red cells (which exhibit partial GPC deficiency) and GPC/GPD-deficient Leach-type cells both demonstrate significant resistance to malarial invasion in vitro,[356] thus suggesting that GPC/GPD may also function as an extracellular attachment site for *P. falciparum*. The fact that up to 50% of the Melanesian population in the malarious coastal areas of Papua New Guinea have red blood cells that are Gerbich blood group negative as a result of a deletion in the third exon of the GPC gene also implicates GPC. Recently, GPC has been shown to be the receptor for a second sialic acid–dependent pathway for falciparum malaria.[357-359] The *P. falciparum* erythrocyte binding antigen 140 (EBA140, also called BAEBL) binds with high affinity to the surface of human erythrocytes and facilitates entry of the parasite. EBA140 does not bind to Ge-negative red cells lacking exon 3, nor can the parasite invade such cells via this pathway. It appears that binding depends on the *N*-linked oligosaccharide of GPC, at least for one variant of EBA140.[359] The existence of so many ways for the parasite to invade erythrocytes, as well as the ability to switch between invasion pathways, obviously complicates efforts to create a malarial vaccine.

Stomatin

Stomatin, or band 7.2b, is of particular interest because it is diminished by 95% to 98% in the classic type of hereditary stomatocytosis, a severe hemolytic anemia characterized by red cell membranes that are extremely leaky to Na[+] and K[+] ions. The disease is discussed in a later section ("Inherited Disorders of Red Cell Cation Permeability and Volume"). Recent data make it clear

that hereditary stomatocytosis is not caused by the absence of stomatin, and its role in the pathophysiology of the disease is one of the biggest mysteries in the red cell membrane field.

Stomatin is a Small Integral Membrane Protein That May Regulate an Na⁺ Channel. The 31.5-kd stomatin protein (approximately 28 kd on SDS gels) has been isolated[360,361] and cloned.[361-363] It is a positively charged, homo-oligomeric (*n* = 9 to 12), phosphorylated (cyclic adenosine monophosphate [cAMP]-dependent kinase), palmitoylated integral membrane protein with a single transmembrane helix, a small external segment, and a relatively large cytoplasmic domain.[360,362-365] As noted earlier, it is located, at least in part, in membrane lipid rafts.[115,116] Stomatin is a member of a protein superfamily—the PID superfamily, which stands for *p*roliferation, *i*on, and *d*eath. Red cells contain other members of this family, such as SLP-2[366] and STORP,[367] but nothing is known about their functions or interactions. The stomatin gene (*EPB72*) is located on chromosome 9 at 9q34.1.

Stomatin is expressed in all tissues and in red cells of all tested species, from human to frog,[363] and stomatin-like proteins, of which there are at least 50, are found throughout evolution, even in very primative organisms such as *Rhizobium*.[368] A homologue of stomatin, MEC-2, has been cloned from *Caenorhabditis elegans*.[369-372] It is involved in touch sensation and is linked to an Na⁺ channel called the DEG/ENaC channel. The channel is believed to be mechanically gated by linkage to the extracellular matrix and the membrane skeleton or cytoskeleton. Displacement of the membrane (e.g., by touch) pulls the channel open. MEC-2 greatly increases the activity of the Na⁺ channel. The analogous protein, stomatin-like protein 3 (SLP-3), has recently been found in mice and has a similar function.[373] When expressed in heterologous cells, human stomatin binds to H⁺-gated Na⁺ channels and mutes their transport activity.[374] By analogy, stomatin may localize, structurally support, activate, or regulate an Na⁺ channel in the red cell, perhaps one that is sensitive to shear stress.

Stomatin Interacts with Peroxiredoxin-2 and the Red Cell Glucose Transporter. Stomatin also interacts with peroxiredoxin-2 (see later)[375] and binds and represses Glut1, the erythrocyte glucose transporter.[376,377] The relationship to peroxiredoxin-2 is interesting because this peroxide-reducing protein binds Ca²⁺ and translocates to the membrane,[375,378] where it seems to be involved in activation of a K⁺ egress channel (the Gárdos channel).[379] The interaction with the glucose transporter reinforces the emerging concept that stomatin and its paralogues somehow regulate transporters.

Other Integral Membrane Proteins

Although band 3 and the glycophorins are the major integral membrane constituents of the red cell membrane, a large number of other integral membrane proteins with specific functions have also been identified and characterized.

Aquaporin

Aquaporin-1 (AQP1), a 28-kd channel-forming protein (originally called CHIP28), is the major water channel in red cells.[380] The human *AQP1* gene is located on chromosome 7p14 and encodes a 269–amino acid polypeptide with six membrane-spanning domains. Besides red cells, AQP1 is also expressed in the kidney and in endothelial cells in lung. There are approximately 200,000 copies of AQP1 per cell, and the protein carries antigens of the *Colton blood group*. It exists as a tetramer in the red cell membrane, and the crystal structure of the protein has recently been determined.[381] Human red cells lacking AQP1 exhibit markedly reduced osmotic water permeability. Humans with complete deficiency of AQP1 have defective urinary-concentrating ability, as well as decreased pulmonary vascular permeability.[382,383] AQP1 knockout mice appear normal but become severely dehydrated and lethargic after water deprivation for 36 hours when compared with control mice.[384] Interestingly, implanted tumors grow very poorly in AQP1(–/–) mice because of reduced vascularity and very poor cell migration.[385] These studies show that AQP1 also has an unexpected role in cell migration and hence in angiogenesis and wound healing.

Aquaporin-3 is the glycerol permeability channel in human red cells and carries the high-frequency blood group antigen GIL.[386,387] In mice, aquaporin-9 appears to be the glycerol channel.[388]

Rh Proteins (RhD, RhCE, and RhAG)

The Rh blood group system is composed of at least 40 independent antigens carried by two nonglycosylated, palmitoylated proteins encoded by two homologous genes, *RHD* and *RHCE*, located on chromosome 1.[389-391] *RHCE* encodes the CcEe set of antigens and *RHD* encodes the D antigen. Rh antigen expression at the red cell surface requires the presence of Rh-associated glycoprotein (RhAG), which exhibits 36% sequence identity with Rh proteins and is encoded by a gene located on chromosome 6. All three Rh proteins are predicted to have 12 membrane-spanning domains. There are approximately 10,000 to 30,000 copies of RhD and RhCE proteins and 100,000 to 200,000 copies of RhAG per cell. The interaction between RhAG and Rh proteins in the membrane appears to be stabilized by C-terminal and N-terminal domain interactions. In addition to the interaction between the three Rh subunits, the Rh core complex also contains several other proteins[391]—LW glycoprotein (intercellular adhesion molecule 4 [ICAM-4]), integrin-associated protein (IAP, CD47), GPB, protein 4.2, and ankyrin.[392]

Although the function of the Rh protein complex in the normal red cell has yet to be fully defined, RhAG functions as an ammonium transporter in mouse and

human red cells[393] and can complement defects in ammonium transport in yeast.[394] It may also be partly responsible (along with aquaporin) for the exceptionally high permeability of CO_2 in the erythrocyte.[395] The importance of the Rh complex in regulating red cell membrane structure is revealed by the altered phenotype of Rh_{null} red cells, which exhibit stomatocytic morphology with loss of membrane surface area, cell dehydration, cation permeability abnormalities, and shortened red cell survival leading to a mild compensated hemolytic anemia.[396]

Kidd Glycoprotein

The Kidd glycoprotein is the urea transporter in the red cell membrane.[397] The human Kidd glycoprotein gene is located on chromosome 18q11-q12 and encodes a 391–amino acid polypeptide with 10 membrane-spanning domains. There are 14,000 copies of Kidd glycoprotein per cell, and the protein carries the antigens of the Kidd blood group system.[398] The urea transporter in red cells functions by rapidly transporting urea into and out of red cells as they pass through the high urea concentration in the renal medulla and thereby prevent red cell dehydration.[399] Urea transport across $Kidd_{null}$ red cell membranes is approximately a thousand times slower than across normal membranes.[400] However, no changes in red cell shape or survival have been noted in persons who lack the Kidd glycoprotein.

Xk Protein

Xk protein (also called Kx), a 37-kd protein (444 amino acids) with 10 membrane-spanning domains, is encoded by a gene on the short arm of the X chromosome,[401] Although the Xk protein has structural but not sequence similarity with a family of proteins involved in transport of neurotransmitters, its transport substrate or substrates have not been defined. The Xk protein carries the Kx blood group antigen. In the red cell membrane the Xk protein is covalently linked to the Kell glycoprotein by a disulfide bond.[402] Lack of the Xk protein in McLeod's syndrome results in acanthocytic red cells, compensated hemolytic anemia, and in later life, muscle wasting and choreiform movements.

Kell Glycoprotein

Kell glycoprotein is a 93-kd (732 amino acids) single-pass type II membrane protein encoded by a gene on chromosome 7q33.[403] It has sequence homology with a family of neutral endopeptidases and has been shown to be an endothelin-3 converting enzyme.[404] In addition to cleaving the precursor of endothelin-3, Kell glycoprotein can also cleave the precursors of endothelin-1 and endothelin-2, but much less effectively. Because endothelins are potent vasoactive peptides, it is thought that the Kell glycoprotein may be involved in the regulation of vascular tone. The Kell glycoprotein carries the antigens in the Kell blood group system. In contrast to the red cell pathology seen in Xk-deficient red cells, Kell glycoprotein deficiency does not result in red cell alterations.[405]

Duffy Glycoprotein

The Duffy glycoprotein is a promiscuous chemokine receptor[406] that binds a variety of proinflammatory cytokines of both the C-X-C class (acute inflammation) and the C-C class (chronic inflammation), including interleukin-8 (IL-8), melanoma growth stimulatory activity (MGSA), monocyte chemotactic protein 1 (MCP-1), and RANTES (regulated on activation, normal T cell expressed and secreted). The Duffy glycoprotein gene is located on chromosome 1q22-23 and encodes a 333–amino acid polypeptide with seven membrane-spanning domains.[407] There are 6000 to 13,000 copies of Duffy glycoprotein per cell, and the protein carries the antigens of the Duffy blood group system. The Duffy glycoprotein is the receptor for the malarial parasite *Plasmodium vivax*, and Duffy glycoprotein–deficient red cells are refractory to invasion by *P. vivax*.[408] The function of Duffy glycoprotein in normal red cell physiology remains to be defined.

Lutheran Glycoprotein

The Lutheran blood group glycoprotein (Lu gp) belongs to the immunoglobulin superfamily and is the receptor on erythroid cells for the extracellular matrix protein laminin[409] (reviewed by Eyler and Telen[410]). It is also highly expressed in endothelial cells. The glycoprotein consists of five disulfide-bonded extracellular, immunoglobulin superfamily domains, a single hydrophobic transmembrane domain, and a cytoplasmic tail. Two isoforms of this membrane protein (85- and 78-kd isoforms) are expressed by alternative splicing of a single gene located on human chromosome 19q13.2. Both isoforms bind laminin. The two isoforms are distinguished by differences in their cytoplasmic domains—the 78-kd isoform has a truncated cytoplasmic tail. There are approximately 1500 to 4000 copies of Lu gp on the mature red cell. Although the function of Lu gp in normal red cells remains to be defined, it has been shown to mediate adhesion of sickle red cells to laminin.[411] Interactions between the $\alpha_4\beta_1$ integrin on sickle cells and the Lu gp on endothelial cells may also be important.[412] Because Lu gp is expressed late during erythroid differentiation, it has been suggested that it may play a functional role in mediating erythroblast–extracellular matrix interactions in the bone marrow that regulate egress of reticulocytes from bone marrow into the circulation.

LW Glycoprotein

The LW glycoprotein (LW gp, also termed ICAM-4) present on the red cell membrane also belongs to the immunoglobulin superfamily.[413] It was recently reviewed.[414] The glycoprotein consists of two extracellular immunoglobulin-like domains that show very strong sequence homology with the protein superfamily known as intracellular adhesion molecules (ICAMs). The 40- to 42-kd LW gp is encoded by a gene on chromosome 19. There are approximately 4000 copies of LW gp on the mature red cell. Preliminary evidence suggests that extra-

cellular domains of LW gp can interact with the integrins LFA1 (CD11/CD18),[415] $\alpha_4\beta_1$, and α_v.[416] LW gp is activated by epinephrine and may also play a role in adhesion of sickle cells.[417] In contrast to Lu gp, which is expressed late during erythroid development, LW gp is expressed early during erythropoiesis. Based on this expression pattern, it has been suggested that LW gp may play a role in the erythroblast-macrophage interactions that are critical for erythropoiesis.

Glucose Transporter (Glut-1)

Glut-1 was the first of 14 members of the glucose transporter family identified.[417a] It is an integral membrane protein with 12 transmembrane segments and is the major glucose transporter in many cells. Glut-1 also transports dehydroascorbic acid (DHA), an oxidized intermediate of vitamin C, and recent evidence suggests that this is its primary function in the red cell, and that Glut-4, a related glucose transporter, may transport most of the glucose.[417b] The switch of Glut-1 from glucose to DHA is associated with an increase in stomatin expression and doesn't occur in patients with hereditary stomatocytosis and stomatin deficiency.[417b] The red cell

has roughly 400,000 copies of Glut-1 per cell, which is the highest number of any human cell. High erythroid expression of Glut-1 is limited to mammals that lack the ability to synthesize vitamin C.[417b]

Glut-1 associates with dematin and adducin in a complex that is presumably located near the spectrin-actin molecular junctions[417c] (see Fig. 15-6). The data suggest that dematin and perhaps adducin bind to a 64-amino acid cytoplasmic loop on Glut-1.

MEMBRANE SKELETON PROTEINS

Spectrin

Erythroid spectrin is the major constituent of the red cell skeleton and accounts for 50% to 75% of the membrane skeletal mass.[172,173] The spectrin-based skeleton is anchored to the plasma membrane by an ankyrin-mediated linkage to band 3[418] and protein 4.1–mediated attachment to glycophorin C.[419] Recent evidence that α-spectrin binds protein 4.2[221] suggests that there may be additional connections. As a result of these vertical attach-
FIGURE 15-13. Spectrin structure. The α and β chains are aligned antiparallel with respect to their N- and C-terminal ends. The approximately 106–amino acid "spectrin repeats"[421] are numbered from the N-terminal of each chain. Each repeat is composed of three α helices (A, B, and C).[422] The SH3 domain, which extrudes from between helix B and helix C of repeat 9, is conventionally numbered as repeat 10, although it is not a spectrin repeat. Similarly, by convention the partial spectrin repeat that begins the α-spectrin chain is called α0, whereas the partial spectrin repeat at the end of the β-spectrin chain is called β17. Note that the spectrin self-association site is formed by joining complementary parts of two partial repeats that are left over at the "head" ends of the two chains (*inset*). The α chain contributes helix C and the β-chain, helices A and B. Some repeats are specialized, such as β15, which forms the ankyrin binding site, and parts of the first four repeats at the "tail" of each chain, which nucleate interchain, heterodimer interactions. Repeats α13-α14 and β8-β9 are more flexible and may form a hinge.[423] *Rectangles* denote peptide segments that differ from the repeats and the SH3 domain. They include the actin/protein 4.1/adducin binding sites and a calmodulin-like Ca^{2+} binding region (EF hands) that also binds protein 4.2. The structures of these two domains are shown in more detail in the *insets*. (Adapted from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP (eds). 30° C

Higher oligomers
FIGURE 15-14. Electron micrographs (rotary shadowed) of spectrin heterodimers and heterotetramers. Note that the α and β chains of heterodimers are flexible and twisted about each other and that heterotetramers are made by end-to-end association of dimers. The chains are attached at the ends and sometimes separate in the middle. The scale marker indicates 200 nm (2000 Å). Factors that favor the dimer or tetramer-oligomer state are listed under the photographs. The dimer-tetramer-oligomer equilibrium is kinetically frozen at 0° C. Spectrin extracted and maintained at 0° C retains the distribution of dimers and tetramers that exist on the membrane.

ments, spectrin represents approximately 25% of the membrane-associated mass of the red cell. Spectrin is composed of two large polypeptide chains that associate side by side in an antiparallel arrangement[420]; the 280-kd α chain and the 246-kd β chain are structurally similar but functionally distinct (Fig. 15-13). Electron micrographs of spectrin reveal a slender, twisted, worm-like molecule that is 100 nm in length (Fig. 15-14).[424] Spectrin is a highly flexible protein that assumes a variety of conformational and oligomerization states; in concert with its associated membrane skeletal proteins, spectrin generates a deformable juxtamembranous meshwork that provides the circulating red cell with both stability and flexibility.

The Spectrin Family in Humans Is Encoded by at Least Seven Distinct Genes. Two genes encoding α-spectrin and five genes encoding β-spectrin have been characterized.[425] The αI (or α$_R$) spectrin gene (*SPTA*) is located on chromosome 1q22-q23 adjacent to the Duffy blood group and encodes the erythroid-specific α chain.[426] The αII (or α$_G$) spectrin (also called α-fodrin) gene (*SPTAN1*) has been mapped to chromosome 9q34.1 and encodes an α-spectrin homologue found in nearly all cells except mature red cells.[427] The βI (or β$_R$) spectrin gene (*SPTB*) is located on chromosome 14q23-q24.2 and encodes the β subunit of the erythroid-specific spectrin, designated βIΣ1.[428] The βI gene promoter region contains specific GATA-1 and CACCC-related protein binding sites that account for specific, high-level expression in erythroid cells.[429] Differential 3′ processing of βI-spectrin pre-mRNA generates an alternative βI-spectrin subunit that is found in the brain (predominantly cerebellum) and muscle and designated βIΣ2.[430]

The βII (or β$_G$) spectrin (also called β-fodrin) gene (*SPTBN1*) has been mapped to chromosome 2p21 and encodes the generally expressed β subunit of spectrin, which shares 60% amino acid identity with βI-spectrin.[431]

Thus, erythrocyte spectrin (or spectrin$_R$) is composed of αI and βIΣ1 chains, and the widely expressed spectrin (called fodrin, tissue spectrin, brain spectrin, or spectrin$_G$) contains αII and βII subunits. Muscle spectrin is believed to contain predominantly αII and βIΣ2 subunits. Alternative splicing of the spectrin genes, in addition to interchangeability of the α- and β-chain isoforms in heterodimer formation, gives rise to a rich diversity of spectrin proteins that probably exhibit distinct localizations and functions.

The most recently cloned spectrin subunits, designated βIII, βIV, and βV, have been localized to chromosomes 11q13, 19q13.13, and 15q21, respectively.[432-435] βIII-spectrin is predominantly expressed in the central nervous system, especially the cerebellum. Defects in the protein are associated with spinocerebellar ataxia type V.[436] βIV-spectrin associates with the electrogenic Na$^+$ channel in the axon's initial segments and the nodes of Ranvier in neurons by acting through ankyrin$_G$ (see later).[433] Mice lacking this βIV-spectrin have the quivering (qv) mutation, characterized by progressive ataxia with hind limb paralysis, deafness, and tremor.[437] A truncated isoform of βIV-spectrin is associated with a subnuclear structure (promyelocytic leukemia bodies) and may be part of a nuclear scaffold.[434] βV-spectrin is detected prominently in the outer segments of photoreceptor rods and cones and in the basolateral membrane and cytosol of gastric epithelial cells.[435] Presumably, these homologues of β-spectrin perform specialized functions related to their association with the intracellular and nuclear compartments.

Spectrins Consist Mostly of Tandem 106–Amino Acid Repeats. Each spectrin chain is composed of a series of 106–amino acid repeats, and each repeat is formed by three α helices that are folded into a triple-helical bundle.[422,438,439] The α- and β-spectrins contain 20 and 16 full repeats, respectively.[426,428] An SH3 domain within

the α chain is conventionally called repeat α10, though it is not a true spectrin repeat (see Fig 15-13A). As will be discussed, the α0 and β17 repeats are complementary partial repeats that join to form a full repeat and link spectrins together (see Fig. 15-13A). The primary sequence of each repeat exhibits extensive heptad (seven-residue) symmetry, with conserved hydrophobic residues situated in the first and fourth positions of each heptad motif (designated as positions a and d in Fig. 15-15A).[422,438] Each spectrin repeat forms a triple-helical

structure that is approximately 5 nm long and 2 nm wide (see Fig. 15-15B) and rotated 60 degrees (right-handed) relative to the neighboring repeats.[438]

The prototypical three-dimensional structure of the spectrin repeats was determined by expression studies and x-ray crystallographic analysis of a spectrin repeat from αII-spectrin.[438,439] The first 28 amino acids of the repeat form a straight α helix designated helix A. The polypeptide chain then reverses itself and forms a second 34–amino acid, long straight α helix designated
FIGURE 15-15. Structure of spectrin repeats. **A,** Consensus sequence of a typical 106–amino acid, human erythrocyte spectrin repeat phased according to crystallographic data,[438] which identifies three α helices per repeat. Less conserved amino acids are marked with a *dash*. The amino acids in the repeat are designated "a" through "g." The distance from one "a" to the next corresponds to two turns of the α helix. Residues "a" and "d" are the major contact points between helices. They tend to be hydrophobic and are conserved in most spectrins. **B,** Model of a single repeat based on the crystal structure of *Drosophila* αII spectrin.[438] The positions of the nearly invariant tryptophans at A17 (amino acid 17 of the repeat) and C15 (repeat amino acid 90) are shown. They interact with surrounding residues, including B18 (repeat amino acid 54), at the central junction where the A helix crosses over from B to C. **C,** Cross section of a typical repeat. Note that the A, B, and C helices are in a triangular array and that the "a" and "d" residues lie on one face of each helix. The side chains of these amino acids are usually hydrophobic (Φ) and interact with each other to stabilize the triple helical configuration. Salt bonds between the typically polar amino acids at positions "e" and "g" also help attach the B-C and A-C helices to each other. **D,** Interconnection of two adjacent repeats. The A and C helices are colinear and form one long helix. The distal repeat of each pair is rotated 60 degrees (right-handed). Note that the B helix of the proximal repeat overlaps the A helix of the following repeat. Interactions in the overlap region among conserved hydrophobic residues, such as C29, B4, and B5 (repeat amino acids 104, 40, and 41, respectively), and the mostly hydrophobic residues at A2 (repeat amino acid 2) probably stabilize the connection and limit mobility at the repeat junction. *(Redrawn from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858, with permission.)*

helix B. After another reverse turn, a third α helix is formed and is composed of 31 amino acids with a bend in the middle of the structure. The three helices are arranged in a triangular array held together by hydrophobic interactions between the hydrophobic faces of the helices and by electrostatic interactions, particularly between helices A-C and B-C, where mostly polar amino acids are found in positions e and g of the helices (see Fig. 15-15C).

Interestingly, the three helices are tilted away from each other by 10 to 20 degrees such that the C-terminal end of each repeat is wider than the N-terminal end (see Fig. 15-15B). This tilted structure enables the subsequent repeat to attach without any adjustment in the architecture of the preceding repeats. Thus, the C helix of one triple-helical bundle connects to the A helix of the subsequent triple-helical bundle to form one long α helix (see Fig. 15-15D). The tight connection between repeats causes the B helix of a proximal repeat to overlap the A helix of the distal repeat; the resultant interaction between the two helices restricts movement at the junction between repeats, thereby limiting the overall range of motion of αII chains. Spectrin-type repeats in other proteins show similar features.[421] However, the crystal structures of two connected repeats of chicken brain α-spectrin suggest that flexibility in the spectrin structure may be preserved by conformational rearrangement within the repeat (causing movement in the position of an interhelical loop, for example) and by various degrees of bending at the linker region.[440] The stability of individual spectrin repeats varies widely, and some repeats are unstable at physiologic temperatures, which would also introduce flexibility.[441] Two of the less stably folded repeats, α13-α14 and β8-β9, are adjacent to each other in the spectrin molecule (see Fig. 15-13) and may form a hinge.[423] Measurements of the force required to unfold a spectrin repeat show that the repeats function as elastic springs.[442] When intact red cells deform, certain spectrin repeats partially unfold, which presumably contributes to the elasticity.[443]

Side-to-Side Interactions between α and β Chains Results in Zipper-like Dimerization. Nucleation sites located at repeats 18 to 21 of the α chain and 1 to 4 of the β-chain are implicated in triggering the zipping up of α and β chains (see Fig. 15-13).[444] The key interactions are between the A and B helices of β1 and the C and A helices of α21 and between the C and A helices of β2 and the A and B helices of α20.[445] These helices form complementary electrostatic surfaces that draw the two chains together.[446] After the initial tight association of the complementary nucleation sites, a conformational change is propagated that causes the remainder of the α and β chains to pair together and form a supercoiled rope-like structure.[444] However, the side-to-side interactions beyond the nucleation site are relatively weak,[447] which may be important in allowing the α and β chains to slide past each other when the spectrin molecule flexes in the plane of the heterodimer. A common polymorphism of the α-spectrin allele α^LELY encodes α chains that lack one of the nucleation sites and therefore do not form stable heterodimers.[448,449] This clinically relevant allele is discussed further in the section "Hereditary Elliptocytosis."

Spectrin Tetramerization Occurs in Head-to-Head Fashion by Association of Incomplete Repeats at the Ends of the α and β Chains. The "self-association" sequences required for tetramerization are located at the N-terminal of the α-spectrin chain and the C-terminal of the β-spectrin chain (i.e., at the opposite end of the chain from where the nucleation site is found; see Fig. 15-13).[424,450] For spectrin dimers to associate into tetramers, the dimer bonds located at the opposite end of the chains from the nucleation sites must reversibly open to allow the formation of two new αβ attachments. Thus, opening of the αβ contact, whether present as the internal bond of heterodimers or the αβ attachment site for tetramers, is the rate-limiting step in dimer-tetramer interconversion.[451] The specific structure of the spectrin self-association site has been determined by analysis of mutant spectrins[452] and synthetic spectrin fragments[451,453] and by proteolytic studies.[454] The free C helix at the N-terminal of α-spectrin (α0) associates with the free A and B helices at the C-terminal of β-spectrin (β17) to form a stable triple-helical bundle repeat; in this manner, spectrin heterodimers associate to form tetramers and higher-order oligomers in head-to-head fashion (see Fig. 15-13). The isolated α-chain C helix and the free β-chain A and B helices will associate only if there is at least one adjacent triple-helical repeat present. The formation of spectrin tetramers and higher-order oligomers is critical for maintaining the mechanical strength of the membrane skeleton.[455] Mutations in α- or β-spectrin that interfere with formation of the interchain triple-helical bundle prevent spectrin tetramerization and higher-order oligomerization, thereby weakening the membrane skeleton; such defects in spectrin are the most common causes of hereditary elliptocytosis and hereditary pyropoikilocytosis.

Spectrin Exists Predominantly as Tetramers In Vivo. Whereas physiologic ionic strength and lower temperatures (25° C) favor tetramer formation, low ionic strength and physiologic temperatures favor dissociation to dimers.[456,457] At 0° C, the dimer-tetramer equilibrium is virtually kinetically frozen because of the high activation energy.[450] The oligomerization state of spectrin can be studied directly by extracting spectrin from red cell membranes at various temperatures and by manipulating in vitro conditions to alter the degree of oligomerization.[450,454,455,457] In red cell ghosts, driving the equilibrium toward dimerization produces exceedingly fragile structures, thus underscoring the importance of spectrin tetramerization in membrane skeletal stability.[455] Quantitation of spectrin eluted from normal ghosts at 0° C indicates that approximately 5% of the spectrin is in the dimer form, 50% exists as a tetramer, and the remainder

is divided between higher-order oligomers and very-high-molecular-weight complexes of spectrin, actin, protein 4.1, and dematin.[456]

The Quaternary Structure of Spectrin In Vivo Is Unclear. Although electron micrographs show that spectrin has an end-to-end length of 200 nm, simple calculations show that spectrin tetramers must have a length of just about 65 to 75 nm in vivo if the hexameric spectrin array (see later) is only a single layer thick and has an area equal to the area of the red cell, 140 μm^2. This correlates with the observed length of spectrin filaments in unstretched skeletons.[458] It is not completely clear how spectrin is folded in this physiologic filament. There is some evidence that the molecules condense by twisting the α and β subunits about a common axis. In this model, the degree to which the chains condense is regulated by varying the pitch and diameter of the twisted double strand; native spectrin dimers have approximately 10 turns with a pitch of 7 nm and a diameter of 5.9 nm.[459,460] However, the available pictures do not show this structure very clearly, and it is hard to imagine how spectrin would become so highly wound during its synthesis and assembly into the skeleton in vivo. More studies are needed.

Spectrin Contains Important Functional Domains Involved in Protein-Protein Interactions. In addition to the critical sequences involved in spectrin nucleation and self-association, the α and β chains interface with other proteins via defined structural domains (see Fig. 15-13).

Ankyrin Binding Site. The β subunit of spectrin contains structural domains that interact with multiple membrane skeletal proteins, including ankyrin, protein 4.1, actin, and adducin. The 15th repeat and the first part of the 16th repeat of β-spectrin form the binding site for ankyrin.[461] Spectrin's strongest link to the erythrocyte plasma membrane is achieved by the interaction of β-spectrin with ankyrin, which in turn binds to the integral membrane protein band 3.[209,418,462] In nonerythroid cells, ankyrin homologues mediate the linkage of spectrin to other proteins of the plasma membrane, including Na^+,K^+-ATPase[463] and voltage-dependent sodium channels.[464]

F-Actin, Protein 4.1, and Adducin Binding Sites. The N-terminal 301 amino acids of β-spectrin bind protein 4.1[465] and actin[466,467] and share sequence homology with several actin-binding proteins, including calponin, α-actinin, dystrophin, filamin, ABP120, adducin, and fimbrin. There are two of these "calponin homology domains" (CH1 and CH2) in tandem in β-spectrin. Recent studies show that protein 4.1 and actin bind to each of these domains.[468] Binding to CH2, the more C-terminal CH domain, is normally inhibited by an α helix at its N-terminal end, which may serve a regulatory role. Binding of protein 4.1 to the region is greatly enhanced by PIP_2 (see Fig. 15-13).[468]

The interaction of spectrin with actin is enhanced by protein 4.1 binding.[469-471] The tail ends of spectrin tetramers and oligomers bind to short, double-helical protofilaments of F-actin with the aid of protein 4.1. Approximately six spectrins can be accommodated on each actin protofilament, and this leads to the characteristic hexagonal network that forms the basic framework of the membrane skeleton (Fig. 15-16). The actin–protein 4.1 complexes, which reside at the nodal junctions of the network, are associated with multiple other proteins, including adducin, dematin, TM, TMod, and p55. Assembly of the spectrin-actin skeleton is further enhanced by adducin, a heteromeric calmodulin-binding phosphoprotein that recruits spectrin to the fast-growing ends of actin filaments in addition to binding, bundling, and barbed-end capping of actin.[472-475] The N-terminal domain and first two spectrin repeats participate in forming the spectrin-adducin-actin complex.[476]

EF Hands: Ca^{2+} and Protein 4.2 Binding Sites and Role in Spectrin-Actin Binding. The C-terminal of α-spectrin, like α-actinin, contains two pairs of EF hands (see Fig. 15-13), which are structures that bind and mediate the regulatory effects of calcium.[477,478] The N-terminal EF hands ($EF_{1,2}$) are structurally similar to calmodulin[479] and bind Ca^{2+} with low affinity ($K_d = 0.48$ mM). Binding of Ca^{2+} to EF_1 triggers a conformational change that allows EF_2 to bind Ca^{2+}.[480] The C-terminal EF hands ($EF_{3,4}$) are degenerate.

Recent work has shown that the EF hand domain binds protein 4.2 with high affinity ($K_d = 2.9 \times 10^{-9}$ M).[221] Binding capacity is augmented by micromolar concentrations of Ca^{2+}, and the Ca^{2+} effect is blocked by calmodulin, which itself binds to the EF hand domain in the presence of Ca^{2+}. Because 4.2 binds to band 3, this suggests that a portion of band 3 may also be located near the spectrin-actin junctions. It also suggests that protein 4.2 may form a secondary site for attaching the membrane skeleton to the lipid bilayer.

The relationships of the EF hand domain, the calponin homology domains, and F-actin are not known in spectrin but are likely to resemble those in α-actinin (Fig. 15-17). That is, the EF hand domains are likely to abut the actin/4.1 binding CH domains and may help regulate actin binding. Previously, the EF domains have been considered impotent in erythroid spectrin, although they are known to bind Ca^{2+} and affect the function of $\alpha II \beta II$-spectrin (fodrin).[477] However, the discovery that deletion of just the C-terminal 13 amino acids in the EF domain of the sph[1J] mouse leads to a severe, spherocytic hemolytic anemia and failure of the mutant spectrin to assemble into the membrane skeleton[484] shows that the EF domain must have an important physiologic function. In addition, PfEMP3, a protein from the malarial parasite *P. falciparum* that appears on the red cell membrane late in the parasite's life cycle, binds to α-spectrin in the EF domain region and disrupts the spectrin-actin-4.1 complex, perhaps as a precursor to release of new parasites into the circulation.[482] These observations suggest that the EF

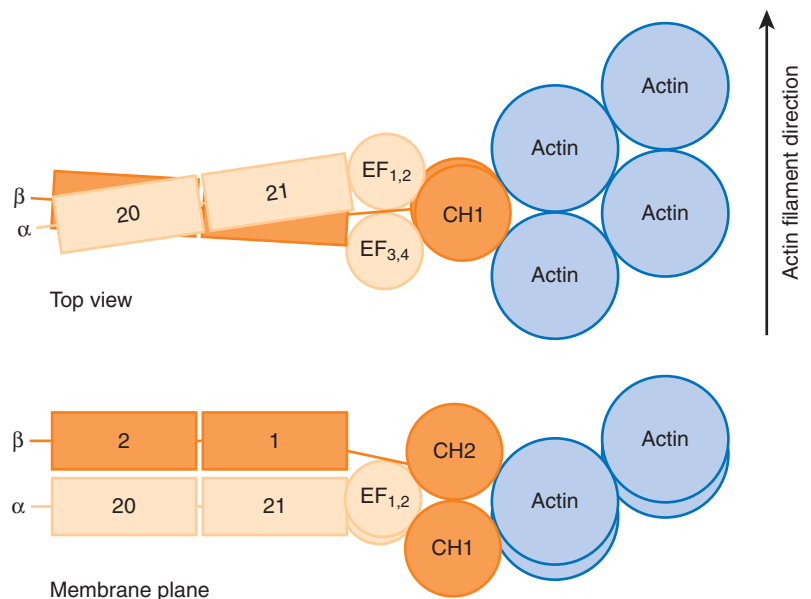
FIGURE 15-16. Electron microscopy of red cell membrane skeletons. The negative-stained skeletons have been stretched during preparation to reveal details of their structure. **A,** Low-power magnification to emphasize the ordered, net-like structure. **B** and **C,** High-power magnification and schematic showing the predominantly hexagonal organization of the skeleton. The location of various skeletal elements is shown in **C**. Sp4, spectrin tetramer; Sp6, spectrin hexamer. *(From Palek J, Sahr KE. Mutations of the red blood cell membrane proteins: from clinical evaluation to detection of the underlying genetic defect. Blood. 1992;80:308.)*

FIGURE 15-17. Structural model, roughly to scale, of the tail end of spectrin deduced from the structure of α-actinin.[481] **Top,** View looking down on the membrane. The *arrow* indicates the direction of the actin filament. **Bottom,** View from within the plane of the membrane skeleton. The top view has been rotated 90 degrees *toward* the viewer (*arrow* pointing up out of the plane). CH1 and CH2 are the actin-4.1 binding sites in the N-terminal, actin binding domain of β-spectrin. $EF_{1,2}$ and $EF_{3,4}$ are the N-terminal and C-terminal pairs of EF hands, respectively, in the EF domain, which lies at the C-terminal end of α-spectrin. The intimate relationship between the EF hands and CH domains suggests that the EF hands may regulate actin binding, and recent evidence supports that hypothesis.[482,483]


domain is important for actin binding, and recent direct evidence supports this speculation. A minispectrin composed of the actin binding and EF domains and the four adjacent spectrin repeats in each chain that form the nucleation site binds to F-actin with the aid of protein 4.1, as expected, but this binding is markedly decreased if the EF hands are missing or even if just the last 13 amino acids of α-spectrin are deleted, as in the sph[1J] mouse.[483]

SH3 Domain. The 10th "repeat" of α-spectrin encodes an Src homology (SH3) domain. SH3 domains generally function as sites of protein-protein attachment at cell membranes. The function of the erythroid α-spectrin SH3 domain and the protein or proteins that bind to it in the red cell are not known. One candidate belongs to a family of tyrosine kinase–binding proteins.[485] Interestingly, plasmepsin II, the aspartic protease of *P. falciparum*,

cleaves spectrin mainly within the SH3 domain of α-spectrin, thus suggesting that specific targeting of the SH3 domain by *P. falciparum* may be part of the strategy to dismantle the membrane skeleton.[486]

PH Domain. All β-spectrins *except* the major erythroid isoform (βIΣ1) have a C-terminal extension that contains a pleckstrin homology (PH) domain.[421,487] The specialized 100-residue PH domain has been identified in proteins involved in signal transduction (e.g., protein kinases and their substrates, phospholipase C isoforms, guanosine triphosphatases [GTPases], GTPase-activating proteins, GTPase exchange factors) and in membrane skeletal organization (e.g. dynamin, β-spectrin) and is believed to mediate membrane targeting of proteins.[487,488] The muscle isoform of erythroid spectrin (βIΣ2) also contains a PH domain,[430] and recent studies have shown that mature red cells contain some of this isoform, which is clumped in submicron-size patches within the membrane skeleton.[489] The erythroid spectrin PH domain binds with equal affinity to PIP$_2$ and phosphatidylinositol 3,4,5-triphosphate.[490,491] The function of the PH domain in red cells is untested, but it seems likely that it contributes to the attachment of spectrin to the membrane.

Phosphorylation Sites. Instead of a PH domain, the C-terminal region of βIΣ1-spectrin contains a 52–amino acid extension just beyond the site of self-association that is phosphorylated by a membrane-associated casein kinase I (see Fig. 15-13).[492,493] There are five Ser and one Thr that are phosphorylated in sequential fashion.[494] In vitro phosphorylation of β-spectrin has no effect on spectrin self-association.[450,495,496] However, increased phosphorylation of β-spectrin in vivo has been shown to decrease membrane mechanical stability, whereas decreased phosphorylation strengthens the mechanical properties of the red cell membrane.[497]

Tryptic Domains. The tryptic domains of spectrin have important historical, structural, and clinical significance. Gentle proteolysis of spectrin generates nine structural domains, each composed of several 106–amino acid repeats.[420,498] Thus, spectrin was initially demonstrated to contain a series of proteolytically resistant domains joined by protease-sensitive regions. Five tryptic fragments represent most of the α chain and include the αI (80 kd), αII (46 kd), αIII (52 kd), αIV (52 kd), and αV (41 kd) domains; the β chain is digested into four domains, including βI (17 kd), βII (65 kd), βIII (33 kd), and βIV (74 kd). Many of the molecular defects in HE have been identified as abnormalities in spectrin domain maps after proteolytic digestion (see "Hereditary Elliptocytosis").

Spectrin Is Synthesized Early in Erythroid Development. Spectrin is abundant in pronormoblasts[499] and is detectable in undifferentiated erythroleukemia cells[500] and possibly in immature committed erythroid stem cells, BFU-E and CFU-E.[501] α-Spectrin is synthesized in at least a threefold excess over that of β-spectrin[502-504] and has a distinctly slower degradative pathway.[505] The limited synthesis and more rapid degradation of β-spectrin suggest that its association with the membrane is the rate-limiting step in spectrin assembly.[504,505] The difference in the rate of α- and β-spectrin production is relevant to the molecular pathophysiology that underlies spectrin-related red cell membrane disorders (see "Hereditary Elliptocytosis" and "Hereditary Spherocytosis").

Mutations in Erythroid Spectrin Affect the Integrity of the Red Cell and Lead to Clinical Disease. Spectrin defects are the major cause of HE and are also important in the pathogenesis of HS (see "Hereditary Elliptocytosis" and "Hereditary Spherocytosis").

Actin

The red cell contains β-actin, which is the actin subtype found in a wide variety of nonmuscle cells.[506] Whereas red cell actin shares structural and functional similarities with the β-actin found in nonerythroid cells,[507] the assembly of *protofilaments*, or short, double-helical F-actin filaments composed of 12 to 14 monomers, is a characteristic feature of red cell actin.[508] Actin protofilaments are stabilized by (1) interactions with spectrin, protein 4.1, and tropomyosin; (2) capping of the pointed or slow-growing end by tropomodulin[509]; and (3) capping of the barbed or fast-growing end by adducin.[510] Thus, another unique feature of the membrane-associated actin filaments in red cells is that actin filaments are capped by adducin instead of CapZ, the ubiquitous barbed-end capping protein of nonerythroid cells.[511] Interestingly, this occurs despite the fact that red cells contain CapZ.[511] However, when β-adducin is deleted in red cells, CapZ expression is upregulated ninefold, presumably as a compensatory mechanism.[512]

Actin protofilaments function within the red cell skeleton meshwork as junctional centers intertriangulated by spectrin (see Fig. 15-16). The protofilaments lie parallel to the lipid bilayer within 20 degrees of the membrane plane.[513] This suggests that the protofilaments may also function as attachments between the membrane skeleton and the lipid bilayer. Spectrin dimers bind to the side of actin filaments at a site near the tail of the spectrin molecule (see Figs. 15-13 and 15-17).[466] Spectrin tetramers are bivalent and therefore cross-link actin filaments, although binding is weak ($K_d \approx 10^{-3}$ M) and ineffectual in the absence of protein 4.1.[470] Spectrin-actin interactions are specifically enhanced by protein 4.1 and adducin (see "Protein 4.1" and "Adducin").

Rac1 and Rac2 GTPases regulate actin structures, and mice that lack both GTPases are prone to the development of a microcytic hemolytic anemia with marked anisocytosis and poikilocytosis.[514] Membrane skeletal junctions are aggregated, and there is pronounced irregularity of the hexagonal spectrin meshwork. These changes

are accompanied by decreased cellular deformability, an increased actin-to-spectrin ratio, and increased phosphorylation (Ser724) of adducin, an F-actin capping protein. Actin and phosphorylated adducin are more easily extracted by Triton X-100 from Rac1(–/–)/Rac2 (–/–) red cells, indicative of weaker association to the cytoskeleton. Osteopontin phosphorylates or activates multiple proteins in human erythroblasts, including Rac-1 GTPase and adducin. Osteopontin knockout mice are anemic and also show defects in F-actin filaments.[515] The results indicate that Rac GTPases regulate organization of the red cell membrane skeleton. It is unclear whether this occurs dynamically in the mature red cell or just during erythropoiesis.

Protein 4.1

Red cell protein 4.1 (technically the 4.1R homologue) is a major component of the erythrocyte membrane skeleton, with approximately 200,000 copies present in each red cell. Protein 4.1 confers both stability and flexibility to circulating red cells by potentiating the interaction of spectrin tetramers with F-actin[470,516] and by linking this membrane skeletal scaffold to the plasma membrane through vertical interactions with glycophorin C (GPC).[419] In the mature red cell, 4.1 exists as a 588–amino acid protein that is 4.7 nm in diameter and has a molecular weight of 66 kd, although it runs as an 80-kd protein on SDS gels. Two forms of the protein are resolved on high-resolution SDS gels, an 80-kd protein designated 4.1a and a 78-kd protein designated 4.1b. Protein 4.1a derives from 4.1b by progressive deamidation of Asn502 during the life span of the red cell; thus, 4.1a is more prominent in senescent red cells.[517] Proteolysis of 4.1 generates four structural domains: an N-terminal 30-kd membrane binding domain (MBD) (also called the FERM domain[518]), a 16-kd linker domain, a 8- to 10-kd spectrin-actin binding domain (SABD), and a 22- to 24-kd C-terminal domain (CTD) (Fig. 15-18).[519] Two posttranslational modifications of the CTD include the previously mentioned deamidation of Asn502 coincident with red cell aging[517] and *O*-linked glycosidation of cytosolic 4.1 with *N*-acetylglucosamine.[520] The functional significance of these modifications is unclear. Protein 4.1 is phosphorylated in vitro and in vivo by protein kinase A (PKA), protein kinase C (PKC), and casein kinase II. In each case, 4.1 phosphorylation leads to a marked decrease in its ability to bind spectrin and promote the spectrin-actin interaction.[521,522] PKC phosphorylation of 4.1 inhibits its binding to membranes by blocking its interaction with band 3[523] and GPC.[522]

Spectrin-Actin Binding Domain (SABD)

Protein 4.1 Significantly Enhances the Interaction of Spectrin with Actin. In physiologic solvent conditions, spectrin tetramers bind weakly to F-actin ($K_d \approx 10^{-3}$ M), whereas the addition of protein 4.1 generates a high-affinity ternary complex ($K_d \approx 10^{-12}$ M).[470] The 10-kd domain of 4.1 specifically facilitates spectrin-actin interactions[516] and is encoded by an alternatively spliced exon 16 and a constitutive exon 17.[524,525] The 21–amino acid peptide encoded by exon 16 and amino acids 37 to 43 encoded by the constitutive exon 17 form the spectrin binding site.[524,525] The F-actin binding site[526] is located within the first 26 amino acids of exon 17, particularly a critical 8–amino acid sequence (LKKNFMES),[527] and thus the actin site is straddled by the bipartite spectrin binding site.[527,528] The stoichiometry of 4.1-actin binding is 1 : 1, and the interaction is highly cooperative such that binding of one 4.1 molecule induces a conformational change in the actin protofilament that promotes further 4.1 binding.[526,528] Thus, the available data suggest that protein 4.1 facilitates spectrin-actin binding by bridging spectrin and actin in a strong ternary complex.

The interactions of spectrin, actin, and 4.1 within the red cell membrane skeleton are dynamic and thus enable red cell membranes to be stable yet deformable as the cells course through the circulation. Phosphorylation of protein 4.1 by PKA, which labels Ser331 in the 16-kd domain and Ser467 in the 10-kd domain, inhibits binding of 4.1 to spectrin-actin.[529] The interaction is also inhibited by tyrosine phosphorylation at Tyr418, which is located in the 10-kd domain.[530] Formation of the ternary complex is further regulated by Ca^{2+} and calmodulin,[531] with attendant consequences on red cell membrane stability.[532] The critical role of protein 4.1 in maintaining red cell membrane stability is underscored by the erythrocyte membrane fragility and resultant hemolysis observed in patients who lack protein 4.1 (see "Hereditary Elliptocytosis"). Interestingly, normal membrane stability is completely restored when patient red cell ghosts are reconstituted with a 64–amino acid fusion protein containing the spectrin-actin binding site (i.e., the 21 amino acids encoded by exon 16 and the first 43 amino acids encoded by exon 17).[528] This finding highlights the critical functional role of the 10-kd domain of 4.1 in red cell function.

The Spectrin-Actin Binding Domain Also Interacts with Myosin. Protein 4.1 binds to heavy meromyosin with 1 : 1 stoichiometry and partially inhibits the actin-activated Mg^{2+}-ATPase activity of myosin.[533] This interaction may be relevant in modulating Mg^{2+}-ATPase–dependent function in erythroid cells.[533]

Membrane Binding Domain (MBD)

The 30-kd Membrane Binding Domain of Protein 4.1 is Conserved among an Entire Family of Proteins Known as ERM Proteins. The ERM family is composed of a diverse and interesting group of proteins, including ezrin, radixin, moesin, merlin (or schwannomin), talin, coracle, and several tyrosine phosphatases (e.g., PTPH1, PTPMEG).[534,535] Merlin, for example, is a tumor suppressor protein that binds to the C-terminal end of αII (or α_G) spectrin[536] and regulates cell growth and organization of the actin-based cytoskeleton.[537] The merlin gene
FIGURE 15-18. Protein 4.1. **A,** Alternative splicing map of protein 4.1 mRNA. Erythrocyte 4.1 is translated from AUG-2 and includes a 63–base pair (21–amino acid) erythroid-specific sequence (*orange*) that is critical for spectrin-actin interactions. The nonerythroid protein that begins at AUG-1 contains an additional headpiece (HP) domain. Many combinations of exons are expressed, particularly in the C-terminal domain, although many are observed only in nonerythroid tissues. *Middle,* Domain map of protein 4.1 indicating binding sites, phosphorylation sites, and the location of a C-terminal asparagine that is deamidinated in old red cells. The deamidation reaction accounts for the variability in the apparent molecular weight of the C-terminal domain. **B,** Structure of the protein 4.1 membrane binding (30K) domain. Various subdomains are marked where specific proteins bind. Critical amino acids in each region are numbered. *(Adapted from Conboy JG. Structure, function, and molecular genetics of erythroid membrane skeletal protein 4.1 in normal and abnormal red blood cells. Semin Hematol. 1993;30:58; and Han BG, Nunomura W, Takakuwa Y, et al. Protein 4.1R core domain structure and insights into regulation of cytoskeletal organization. Nat Struct Biol. 2000;7:871.)*

is defective in neurofibromatosis type 2 and is absent in virtually all schwannomas and many meningiomas and ependymomas. Despite the diverse functions of ERM proteins, they each use the conserved 30-kd MBD, or the FERM domain, to facilitate interactions with cellular membranes.

Protein 4.1 Links the Membrane Skeleton to the Plasma Membrane through Interactions with the Integral Membrane Protein Glycophorin C/D. The majority of membrane-associated 4.1 is bound to the carboxy-terminal of GPC/GPD via the 30-kd MBD (see Fig. 15-18).[419] Although 4.1 also associates with GPA in vitro, there is considerable evidence indicating that the physiologically relevant interaction is the association of 4.1 with GPC/GPD. For example, (1) 4.1-deficient red cells also lack

GPC/GPD but not GPA[419]; (2) any residual GPC/GPD in 4.1-deficient red cells is only loosely bound to the membrane skeleton and becomes tightly bound if the cells are reconstituted with 4.1[419]; (3) stripped, inside-out membrane vesicles from normal red cells bind five times more 4.1 than do vesicles prepared from red cells lacking GPC/GPD[155]; (4) treatment of membrane vesicles with antibodies that block the 4.1 binding sites on GPC/GPD reduces the ability of 4.1 to promote spectrin-actin binding to the vesicles by 85%[217]; and (5) GPC/GPD-deficient red cells, like 4.1-deficient cells, are elliptocytic and mechanically unstable, whereas GPA-deficient cells are morphologically and structurally normal.[327]

Protein 4.1 and GPC/GPD can occur as a ternary complex with p55, a MAGUK protein. The residues Tyr94 to Arg166 of the 30-kd MBD of protein 4.1 inter-

act with a positively charged peptide in the cytoplasmic domain of GPC localized to residues 82 to 98.[155,538,539] The residues Tyr214 to Glu246 of the 4.1 MBD bind to p55 at a positively charged, 39–amino acid segment found between the SH3 domain and the guanylate kinase domain[538]; p55, in turn, binds via its PDZ domain to the C-terminal amino acids 112 to 128 of GPC.[328,540]

The 4.1 Membrane Binding Domain Also Interacts with Other Integral Membrane Proteins of the Red Cell, Including Band 3 and CD44. Binding sites for the 4.1 MBD include two positively charged motifs, LRRRY and IRRRY, located near the beginning of the band 3 transmembrane domain.[541] Approximately 20% or less of the 4.1 in red cells is believed to associate with band 3,[542] and 4.1–band 3 interactions do not link the spectrin-actin–based skeleton to the plasma membrane.[217] Instead, the protein 4.1–band 3 interaction may function to modulate the association of band 3 with ankyrin. In vitro, protein 4.1 competes with ankyrin for binding to band 3. Displacement of 4.1 from band 3 decreases membrane deformability and increases membrane mechanical stability, presumably because of the resultant increase in band 3–ankyrin interactions.[213] Whether 4.1 regulates band 3–ankyrin binding in vivo remains to be demonstrated. One experiment implies that it may. Zebra fish lacking red cell band 3 have a nearly bloodless phenotype, which can be rescued by injecting normal mouse band 3 cRNA into the early band 3(–/–) fish embryos.[543] Rescue is markedly reduced if mouse band 3 containing a mutation in either the LRRRY or IRRRY site is used and is nearly abolished if both sites are mutated.

The MBD also binds to CD44, a transmembrane glycoprotein present in erythroid and nonerythroid cells. The binding sites on CD44 are the positively charged motifs SRRRC and QKKKL, which are homologous to the interacting peptides found in band 3.[544] Analogous to band 3, protein 4.1 competes with ankyrin for CD44 binding and thus may regulate CD44-ankyrin interactions.[544] Ca^{2+}-dependent and Ca^{2+}-independent calmodulin binding sites have been located within the MBD (see Fig. 15-18),[545] and MBD interactions with transmembrane proteins are subject to regulation by Ca^{2+}-calmodulin. For example, Ca^{2+}-calmodulin specifically reduces the affinity of the 4.1-CD44 interaction,[544] as well as 4.1 interactions with band 3, GPC, and p55. Thus, the intracellular concentration of Ca^{2+} is an important influence on the dynamic nature of protein 4.1's MBD–integral membrane protein associations. The crystal structure of the MBD domain of protein 4.1 (see Fig. 15-18B) provides a mechanistic understanding of the binding of 4.1 to various membrane proteins and the regulation of these interactions by Ca^{2+} and calmodulin.[546]

The discovery that both protein 4.1 and protein 4.2 are located near the tail end of spectrin[221] makes it likely that a subset of band 3 is also located there. The probable subset is band 3 dimers because the tetramers are known to bind ankyrin. The number of band 3 dimers ($\approx$400,000) is sufficient to accommodate both proteins (see Table

15-2). The proximity of the calmodulin-like EF hands on α-spectrin to the calponin homology domains on β-spectrin, where 4.1 binds (see Fig. 15-17), also raises the interesting possibility that the EF hands interact with either the Ca^{2+}-sensitive or the Ca^{2+}-insensitive calmodulin binding sites on 4.1.

Protein 4.1 Also Interacts with the Plasma Membrane through Direct Associations with Phosphatidylserine Moieties and Polyphosphoinositides. The interaction with negatively charged phospholipids may account for some of the low-affinity binding of protein 4.1 to membranes, thus suggesting that the membrane may directly serve as a depot for 4.1 that is temporarily unbound from its protein targets. A recent study showed that binding of protein 4.1 to PS is a two-step process in which 4.1 first interacts with serine head groups through the positively charged amino acids YKRS in the MBD domain and subsequently forms a tight hydrophobic interaction with fatty acid moieties.[547] Importantly, it was shown that acyl chain interactions with 4.1 impair its ability to interact with band 3, GPC, and calmodulin.

PIP_2 enhances binding of protein 4.1 to GPC and spectrin, inhibits its binding to band 3, and does not affect binding to p55.[548] Furthermore, GPC is more readily extracted by Triton X-100 from ATP-depleted red cells, which implies that the 4.1-GPC interaction may be regulated by PIP_2 in situ.

C-Terminal Domain (CTD)

Although the functions of the SABD and MBD of 4.1 have been known for years, the functions of the 16-kd domain and CTD in red cells are poorly understood. Several human mutations in the 4.1 CTD have recently been identified.[549] Rather than affect the primary structure and assembly of 4.1 within the membrane skeleton, the CTD mutations depress the accumulation of 4.1 mRNA and reduce the amount of functional protein in the red cell.[549] The 4.1 CTD also contains a consensus sequence for binding to FKBP13, an immunophilin that is enriched in red cell membranes.[550] The purpose of this interaction is unclear.

4.1 Genes

There are five paralogous genes in the 4.1 family: 4.1R, 4.1G, 4.1N, 4.1B, and 4.1O.

4.1R. The human 4.1R gene, designated *EPB4.1*, maps to human chromosome 1p36.1 and is more than 200 kilobases (kb) in length. 4.1R is the erythroid form of protein 4.1, but it is expressed in some nonerythroid cells in the brain, kidney, heart, and stomach[551,552] and has a number of interesting functions that are relevant only to nucleated cells. For example, the SABD binds to nuclear actin,[553] and the CTD binds to NuMA,[554] a nuclear mitotic apparatus protein involved in organizing the spindle apparatus during mitosis and in reassembling the nucleus at the end of mitosis.[555] Overexpression of either domain interferes with nuclear assembly.[556] Spe-

cific spliceoforms of 4.1R contain defined residues that enable importin-mediated nuclear import[557]; these 4.1R spliceoforms are associated with the nuclear matrix and colocalize with several proteins involved in mRNA splicing.[558,559] In resting cells, 4.1R associates with centrosomes,[560] and in dividing cells, 4.1R colocalizes with the mitotic spindle and the midbody at defined time points during the cell cycle.[559] Protein 4.1R is critical for spindle assembly and the formation of centrosome-nucleated and motor-dependent self-organized microtubule asters.[561,562] The 4.1R MBD interacts with pICln, an actin-binding protein thought to play a role in cell volume regulation.[563] It is hypothesized that pICln may join the 4.1R-linked membrane skeleton to a volume-sensitive membrane channel.[563] 4.1R is also located in the tight junctions of epithelial cells, where the CTD specifically interacts with ZO-2, a tight junction MAGUK protein.[564] The exact functions of 4.1R at all these novel sites are unknown, as well as whether the functions are specific to 4.1R rather than the other 4.1 paralogues.

4.1G. 4.1G is the closest homologue to 4.1R and is the general, widely expressed version of protein 4.1.[550,565] The human 4.1G gene (*EPB41L2*) has been mapped to chromosome 6q22-23. Mouse 4.1G is a 988–amino acid protein with a predicted molecular weight of 110 kd that is 53% identical to mouse 4.1R.[550] 4.1G colocalizes with the immunophilin FKBP13, which binds to the 4.1G CTD.[550]

4.1N. 4.1N is a neuronal homologue of 4.1R that is expressed in almost all central and peripheral neurons.[566] The human 4.1N gene (*EPB41L1*) maps to human chromosome 20q11.2-13.1. Like 4.1R (see later), 4.1N has multiple spliceoforms, the predominant 135-kd form being found in the brain and a smaller 100-kd isoform enriched in peripheral tissues.[566] Immunohistochemical studies reveal several patterns of neuronal staining, with localization in the neuronal cell body, dendrites, and axons.[566] A distinct punctate-staining pattern is observed in certain neuronal locations, consistent with a synaptic localization; in neuronal cultures, 4.1N colocalizes with the postsynaptic density protein of 95 kd (PSD95, a postsynaptic marker) and with glutamate receptor type 1 (GluR1, an excitatory postsynaptic marker), thus confirming that 4.1N is a component of the synapse.[566] By analogy to the role of 4.1R in red cells, 4.1N may function to confer stability and plasticity to the neuronal membrane via interactions with multiple binding partners, including the neuronal cytoskeleton, integral membrane channels and receptors, and MAGUK proteins. Like the 4.1R CTD, the 4.1N CTD also interacts with NuMA.[567] PC12 cells stimulated to differentiate with nerve growth factor exhibit translocation of 4.1N into the nucleus concomitant with cell cycle arrest at the G_1 phase.[567] Thus, nuclear 4.1N may mediate the antiproliferative effect of nerve growth factor by antagonizing the role of NuMA in mitosis. Interestingly, 4.1N expression is detected in embryonal neurons at the earliest stage of postmitotic differentiation.[566]

4.1B. 4.1B is another neuronal paralogue of 4.1R that is focally expressed in brain and selected other tissues.[568] Human 4.1B (*EPB41L3*) maps to human chromosome 18p11.32. Alternative splicing produces a brain isoform that lacks the 21–amino acid peptide important in spectrin-actin binding, as well as a skeletal and heart muscle isoform that incorporates this sequence into the SABD.[568] Interestingly, 4.1B is highly expressed in certain neuronal populations of the brain that do not contain 4.1N, namely Purkinje cells of the cerebellum and thalamic nuclei. This finding demonstrates the selective and complementary nature of 4.1 gene expression. 4.1B is enriched at sites of cell-cell contact.[568]

4.10. Protein 4.1O is a smaller (553 amino acids) relative of protein 4.1 that contains a FERM domain and is primarily expressed in the ovary.[569] Its gene is located on human chromosome 9q21-9q22. Nothing is known of its function.

Alternative Splicing of the 4.1R Gene

The 4.1R gene undergoes complex alternative pre-mRNA splicing. It contains at least 24 exons, 13 of which are alternatively spliced (see Fig. 15-18).[160-163] The two major isoforms of 4.1R derive from alternate use of two distinct translation initiation codons. The 17-bp motif at the 5′ end of exon 2 encodes an in-frame ATG start site used by early erythroid cells and most nonerythroid cells to produce a 135-kd 4.1R isoform that contains a 209–amino acid N-terminal extension. The upstream translation initiation sequence is spliced out late in erythroid differentiation and a downstream ATG is used instead to produce the prototypical 80-kd isoform of 4.1R found in mature red cells.[570,571] Selective incorporation of exon 16 late in erythroid differentiation inserts a 21–amino acid sequence into the 10-kd domain of 4.1R to generate the domain essential for spectrin-actin binding. In nucleated cells, incorporation of exon 5 and exon 16 into the 4.1R transcript yields a gene product capable of importin-mediated nuclear import.[557] Selective exclusion of exon 17b from the CTD of 4.1R occurs in cultured mammary epithelial cells induced to divide, whereas nondividing cells in suspension uniformly include this exon; thus, incorporation of a specific exon correlates dramatically with changes in cell morphology induced by altering cell culture conditions.[572] Understanding the functional significance of each of the many 4.1R spliceoforms continues to be an active area of research.

4.1R Mutations

Mutations in the human 4.1R gene cause hereditary elliptocytosis, a disease characterized by red cells with (1) elliptical rather than discoid morphology, (2) decreased membrane stability, and (3) decreased circulatory half-

life, all of which lead to varying degrees of hemolytic anemia (see "Hereditary Elliptocytosis").[573] Targeted deletion of 4.1R in mice produces an analogous phenotype of moderate hemolytic anemia with a decreased hematocrit and increased reticulocyte count.[551] The erythrocytes of 4.1R knockout mice have an abnormal spherocytic morphology, decreased membrane stability, and reduced expression of 4.1R-interacting proteins, including spectrin, p55, Xk, Kell, Duffy, Rh, band 3, and GPC,[551,551a] suggesting that all these proteins may interact directly or indirectly with 4.1R near the spectrin-actin junctions (see Fig. 15-6).[551a] Interestingly, knockout mice exhibit specific neurobehavioral deficits in movement, coordination, balance, and learning that correspond to selective localization of 4.1R in granule cells of the cerebellum and dentate gyrus.[552] Thus, the data generated by 4.1R knockout mice underscore the relevance of 4.1R to the cellular physiology of both erythroid *and* nonerythroid cells.

Protein p55

Protein p55 is a membrane-associated guanylate kinase (MAGUK) homologue found in the red cell membrane as part of a ternary complex with glycophorin C (GPC) and 4.1R.[574] The p55 gene has been localized to Xq28 and is situated just distal to the factor VIII locus.[575] The protein is heavily palmitoylated, which contributes to its tight association with the plasma membrane.[576] The structure of p55 is composed of five domains, including an N-terminal PDZ domain, an SH3 domain, a central 4.1R binding region, a tyrosine phosphorylation zone, and a C-terminal guanylate kinase domain (Fig. 15-19).[577] The single PDZ domain of p55 interacts with C-terminal residues 112 to 128 of GPC.[328,329] The binding site lies in a hydrophobic groove on one side of the PDZ domain.[578] The central 39–amino acid, positively charged motif binds to the 30-kd domain of 4.1R. Interestingly, this 4.1 binding domain is conserved in other MAGUK proteins.[579] It is not known whether p55 shares functional characteristics with other MAGUKs, which participate, for example, in ion channel clustering, signal transduction, and regulation of cell proliferation and tumor suppression. It is clear, however, that p55 forms a tight complex with GPC and 4.1R[580] such that red cells lacking either 4.1R or GPC are also deficient in p55.[344] There are 80,000 copies of p55 per red cell,[576] a number less than the available binding sites for p55 on GPC and 4.1R. Thus, it remains to be determined whether there are functional differences between GPC-4.1R complexes that contain p55 and those that do not.

Adducin

Adducin is a heteromeric membrane skeleton protein that functions in regulated assembly of the spectrin-actin network. Adducin is composed of an 81-kd α subunit associated with either an 80-kd β subunit or a 70-kd γ

FIGURE 15-19. Model of p55 and its interactions. **A,** Domain structure of p55. 4.1, protein 4.1R binding site (HOOK domain; exon 7); GUK, guanylate kinase domain; PDZ, PSD-95/discs large/ZO-1 domain; SH3, Src homology 3 domain; Tyr-P, site of tyrosine phosphorylation. Protein p55 belongs to the membrane-associated guanylate kinase (MAGUK) protein family. **B,** Ternary interactions between glycophorin C (GPC), protein 4.1, and p55. Note that p55 and GPC bind at two distinct sites on the 30K membrane binding domain (MBD) or FERM domain of protein 4.1R (the p55 site resides in exon 10 of protein 4.1R; the GPC site in exon 8). Although p55 is shown as being distant from the lipid bilayer, it is probably adjacent because it is heavily palmitoylated. *(Adapted from Chishti AH. Function of p55 and its nonerythroid homologues. Curr Opin Hematol. 1998;5:116.)*
FIGURE 15-20. Domain organization of adducin. This model of the structure of the αβ-adducin heterodimer shows the three structural domains, the phosphorylation sites, and the identified binding regions. Although the dimer is shown for simplicity, the $\alpha_2\beta_2$ heterotetramer is probably the physiologic form. Binding functions include αβ oligomerization, spectrin-actin binding, and Ca^{2+}-dependent calmodulin (Ca^{2+}/CAM) binding. MARCKS, myristoylated alanine-rich C kinase substrate; PKA, protein kinase A; PKC, protein kinase C; Rho-K, Rho kinase. *(Adapted from Matsuoka Y, Hughes CA, Bennett V. Adducin regulation. Definition of the calmodulin-binding domain and sites of phosphorylation by protein kinases A and C. J Biol Chem. 1996;271:25157.)*

subunit.[472,581,582] The predominant form of adducin in red cells is the $a_2\beta_2$ heterotetramer. The human genes for adducins α (*ADD1*), β (*ADD2*), and γ (*ADD3*) have been mapped to human chromosomes 4p16.3, 2p13-p14, and 10q24.2-q24.3, respectively. Whereas α and γ subunits are widely expressed throughout the body, β-adducin is selectively expressed in brain and hematopoietic tissues.[581-583] The subunits of adducin are approximately 50% identical to each other at the amino acid level[581,582] and are composed of three distinct domains (Fig. 15-20).[581,584] The N-terminal 39-kd domain forms the globular head region, which is protease resistant and generally more basic than the remainder of the protein.[585] A 9-kd neck region links the N-terminal domain to the 30-kd carboxy tail. The carboxy tail is protease sensitive, is composed almost entirely of hydrophilic residues, and contains a highly basic 22-residue C-terminal motif homologous to the myristoylated alanine-rich C kinase substrate (MARCKS) protein (see Fig. 15-20).[581] There are multiple alternative spliceoforms of adducin subunits, many of which generate truncated isoforms that may subserve tissue-specific functions.[586-589]

Adducin Binds, Bundles, and Caps Actin, in Addition to Enhancing the Association of Spectrin with Actin. In solution, adducin exists as a mixture of heterodimers and tetramers, with the 39-kd head domains contacting one another to form a globular core.[584] An important oligomerization site has been localized within the 9-kd neck domain.[474] The adducin tails, which extend from the head and neck domains, interact directly with the fast-growing ends of actin filaments and together recruit spectrin to the membrane skeletal complex.[474] The N-terminal, actin binding domain and the first two repeats of β-spectrin are involved in complex formation.[476] Adducin-actin interactions require both the C-terminal MARCKS domain and the oligomerization site present in the neck domain.[474] In red cells, adducin also functions as the

barbed-end capping protein and stabilizes actin network assemblies by preventing both elongation and depolymerization at the barbed ends of actin filaments.[473] CapZ, the major barbed-end capping protein found in most cells, is also present in red cells but is confined to the cytoplasm and binds to the membrane only if adducin is removed.[511] Of note, the entire adducin protein is required for capping activity, consistent with the presence of stoichiometric amounts of adducin and actin protofilaments in the red cell membrane skeleton.[473]

Adducin Activity Is Regulated by Phosphorylation and Ca^{2+}-Calmodulin. The C-terminal MARCKS domain contains a serine phosphorylation site targeted by both PKA and PKC.[590] There are also three additional PKA sites located in the neck domain of α-adducin (see Fig. 15-20).[590] PKA phosphorylation reduces both the affinity of adducin for spectrin-actin complexes and the ability of adducin to enhance spectrin-actin binding.[590] Phosphorylation of the MARCKS domain by PKC inhibits actin capping activity and prevents adducin-mediated recruitment of spectrin to actin protofilaments.[591] The MARCKS domain also contains a Ca^{2+}-dependent calmodulin binding site.[590] PKA or PKC phosphorylation of the MARCKS domain inhibits calmodulin binding.[590] Calmodulin binding reduces both adducin-actin binding and adducin-mediated enhancement of spectrin-actin binding.[475] Calmodulin also blocks the binding of a second spectrin molecule to an adducin-actin-spectrin complex.[472] Once bound to the MARCKS domain, calmodulin reduces the rate of PKA phosphorylation of β-adducin and the rate of PKC phosphorylation of α- and β-adducin.[590] Despite these in vitro effects, it appears that PKC phosphorylation of adducin has little effect on red cell membrane mechanical stability.[522] α-Adducin is also subject to Rho kinase phosphorylation (see Fig. 15-20), which enhances the interaction of α-adducin with actin filaments and secondarily with spec-

trin. Myosin phosphatase dephosphorylates α-adducin, but this activity is inhibited by Rho kinase–mediated phosphorylation of myosin phosphatase.[592] Thus, adducin activity is tightly regulated in vivo by Ca^{2+}-dependent calmodulin binding and a complexity of differential phosphorylation states. In general, Rho kinase phosphorylation tends to foster interaction of adducin with actin and spectrin, and PKA/PKC phosphorylation or calmodulin binding tends to inhibit such interaction.

Adducin and Dematin Bind to Glut-1. Recently, Chishti and his colleagues have discovered that adducin and dematin both bind to Glut-1,[417c] a glucose and dehydroascorbic acid transporter[417a,417b] (see Fig. 15-6). It is not clear whether adducin and dematin also bind to each other. Since Glut-1 is relatively abundant (~400,000 copies per RBC), this complex forms a third major attachment site between the membrane skeleton and the lipid bilayer.

Red Cells Lacking β-Adducin Are Similar to Erythrocytes from Patients with Mild Hereditary Spherocytosis. Mice with a targeted deletion of β-adducin have osmotically fragile, spherocytic, and dehydrated red cells.[583] Incorporation of α-adducin into the membrane skeleton is decreased by 30%, perhaps because of decreased α-subunit stability in the absence of its heteromeric partner.[583] Interestingly, there is a compensatory fivefold increase in the amount of γ-adducin associated with the red cell membrane skeleton.[583] The defective red cell phenotype and resultant hemolytic anemia produced by β-adducin deficiency underscore a role of β-adducin in stabilizing the red cell membrane skeletal network.

Adducin Is Enriched at Sites of Cell-Cell Contact in Nonerythroid Cells. The predominant adducin subunits found in nonerythroid cells are α- and γ-adducin,[581,582] with β-adducin expression mostly being limited to hematopoietic and neural tissues.[583] In cultured epithelial cells, adducin promptly localizes to sites of intercellular contact in response to the addition of calcium (0.3 mM) to the medium. Treatment with nanomolar concentrations of phorbol esters, which stimulate PKC phosphorylation of adducin, redistributes adducin away from the cell-cell contact sites.[593] Transfection of Madin-Darby canine kidney (MDCK) cells with a mutated, unphosphorylatable form of adducin results in a dramatic change in intracellular localization from the usual intercellular contact sites to a diffuse, punctate cytoplasmic distribution. These data indicate that focal cytoskeletal assembly and stability are regulated by calcium and PKC-induced modulation of adducin function. Interestingly, phosphoadducin-specific antibodies localize the phosphorylated form of adducin in hippocampal neurons to postsynaptic sites, the specialized regions of neuronal membranes that undergo dynamic morphologic changes and membrane skeletal rearrangement in response to extracellular signals.[591]

Polymorphisms in the Adducin Genes Have Been Genetically Linked to Certain Forms of Essential Hypertension. In rat models, a single point mutation in the α-adducin gene accounts for 50% of hypertension cases, with the mechanism of action related to changes in actin polymerization and increased Na^+,K^+-ATPase activity, which results in elevated renal tubular salt reabsorption.[594-596] A Gly460Trp polymorphism in α-adducin is associated with a salt-sensitive form of essential hypertension in certain human populations,[597] but not in others.[598-601] Intracellular erythrocyte sodium content and renal fractional excretion of sodium are significantly decreased, and Na^+,K^+-ATPase, Na^+-K^+-Cl^- cotransport, and Li^+-Na^+ countertransport are increased in subjects with the 460Trp polymorphism.[602,603] Homozygosity for the allele is estimated to be responsible for about 10% of cases of low-renin hypertension.

Dematin (Protein 4.9)

Dematin is an actin-binding protein that bundles actin filaments into cables.[604] Because actin bundles are not seen in electron micrographs of red cell skeletons, it probably has other functions in erythrocytes. One of these may be to help attach the membrane skeleton to Glut-1 and the lipid bilayer.[417c] The dematin gene has been mapped to human chromosome 8p21.1 and is widely expressed throughout the body. Red cells contain both a 48-kd gene product and a 52-kd spliceoform that incorporates a 22–amino acid insertion[164,605]; additional alternative spliceoforms have been identified in the brain.[606] The protein is composed of two domains, a rod-shaped N-terminal tail and a C-terminal actin-binding headpiece that shares homology with villin, an actin-bundling protein localized to the epithelial brush border.[605] The 22–amino acid insertion contains an ATP binding site within a conserved 11–amino acid motif that is also found in protein 4.2.[165] The native protein exists as a trimer composed of two 48-kd subunits and one 52-kd subunit held together by disulfide bonds.[164] Dematin is phosphorylated by PKA and PKC,[607] with cAMP-dependent phosphorylation completely abolishing its actin-bundling capability.[608] Phosphorylation at the cAMP-dependent site Ser74 induces a conformational change in the structure of the headpiece that is presumably responsible for this change in function.[609] Dematin interacts with the Ras–guanine nucleotide exchange factor Ras-GRF2 in extracts from brain, blocks transcriptional activation of Jun by Ras-GRF2, and activates ERK1 via a Ras-GRF2–independent pathway.[610] Because Rho GTPases regulate actin organization, dematin may help organize and stabilize actin within the membrane skeletal network.

Knockout of the dematin headpiece leads to a very mild spherocytic hemolytic anemia,[611] thus suggesting that the actin-binding activity of dematin is either redundant or not critical for membrane stability. When dematin and β-adducin knockouts are combined, the effect on

membrane shape, stability, and life span is much more severe.[612] This suggests that the adducin–dematin–Glut-1 complex is a physiologically important connection between the membrane skeleton and the lipid bilayer.

Tropomyosin

TM is a heterodimeric protein (reviewed by Gunning and colleagues[613]) that functions in red cells to stabilize F-actin protofilaments in uniform segments measuring 37 nm long.[166,614] The α-helical 27- and 29-kd subunits of TM form a rod-like coiled coil in vivo and migrate in the region of band 7 when subjected to SDS gel electrophoresis (see Fig. 15-5).[615] The two major human TM isoforms found in red cells are designated hTM5 and hTM5b and derive from the γ- and α-TM genes, respectively.[166] hTM5 and hTM5b are each composed of 248–amino acid residues, measure 33 to 35 nm in length, and have high affinity for F-actin and TMod. They are shorter than muscle TM. Each actin protofilament binds two TM molecules such that one TM binds to 1 of the 12 to 14 monomeric actin filaments contained in the protofilament double helix.[615] Thus, all of the actin protofilaments within the red cell membrane skeleton are coated with TM, which strengthens the filamentous network. The corresponding sizes of TM and actin protofilaments have led to the hypothesis that TM functions as a molecular ruler, along with actin-capping proteins, in dictating the length of the actin protofilaments. The amino-terminal of TM binds with high affinity to tropomodulin (TMod), the capping protein for the pointed or slow-growing end of actin. Two molecules of TM bind per TMod in a cooperative manner.[616] This interaction limits the cooperativity of actin-TM associations, thereby restricting the length of actin filaments beyond the length of TM itself.[617] Binding of TM to actin is unaffected by spectrin, but spectrin-actin interactions are inhibited by saturating concentrations of TM,[618] and red cell membranes that lack TM are markedly more fragile than normal.[619] The actin binding domain of β-spectrin is more easily exchanged into the membrane skeleton of TM-depleted red cell membranes, thus indicating that TM strengthens spectrin-actin-4.1 binding.[619] Only endogenous TM and not the longer muscles isoforms can restore mechanical stability to the TM-depleted membranes. These findings suggests that actin-TM interactions may dictate the site specificity, strength, or extent of spectrin binding along the actin filament and that endogenous TM is required for these effects.

Caldesmon

Caldesmon is a 71-kd protein identified in red cells in 1:1 stoichiometry with TM. In conjunction with TM, actin-bound caldesmon has been shown to modify actin-activated myosin ATPase activity.[620] It has been speculated that caldesmon may function as the inhibitory component of an incompletely characterized contractile system that may be present within the red cell.

Tropomodulin

TMod is a 41-kd protein that functions as an actin-capping protein at the pointed or slow-growing end of actin filaments. The C-terminal end of TMod has pointed-end actin-capping activity, whereas the N-terminal portion binds with high affinity to two molecules of TM,[616] which results in further strengthening of actin capping.[621] Among TM homologues, TMod binds with highest affinity to the shorter nonmuscle erythrocyte isoforms (hTM5 and hTM5b) and not as well to the longer muscle TM.[166,617,622] An intact coiled coil at the N-terminal of TM is required for TMod binding.[623] The interaction of TMod with TM inhibits the head-to-tail associations of TM molecules along actin filaments, thereby restricting the lengths of TM-stabilized actin filaments.[624] TMod remains attached to the red cell membrane even after removal of spectrin, actin, and TM. The membrane binding site for TMod and the significance of this membrane interaction are unknown.

Myosin

Red cells contain a nonmuscle myosin composed of two light chains (19 and 25 kd) and one heavy chain (200 kd).[625,626] The protein has two globular heads, a rod-like tail that self-associates to form bipolar filaments, and the characteristic actin-activated Mg^{2+}-ATPase activity.[626] There are approximately 80 actin monomers for every myosin molecule in the red cell, an actin-myosin ratio comparable to that in other nonmuscle cells.[627] Interestingly, neonatal red cells have 2.5 times the myosin of adult cells, perhaps accounting for the enhanced motility of neonatal reticulocytes.[628] The spectrin-actin binding domain of 4.1R binds to myosin and partially inhibits its actin-activated Mg^{2+}-ATPase activity.[533] Thus, 4.1R binding may function as a means of regulating myosin activity in erythroid cells.

Ankyrin

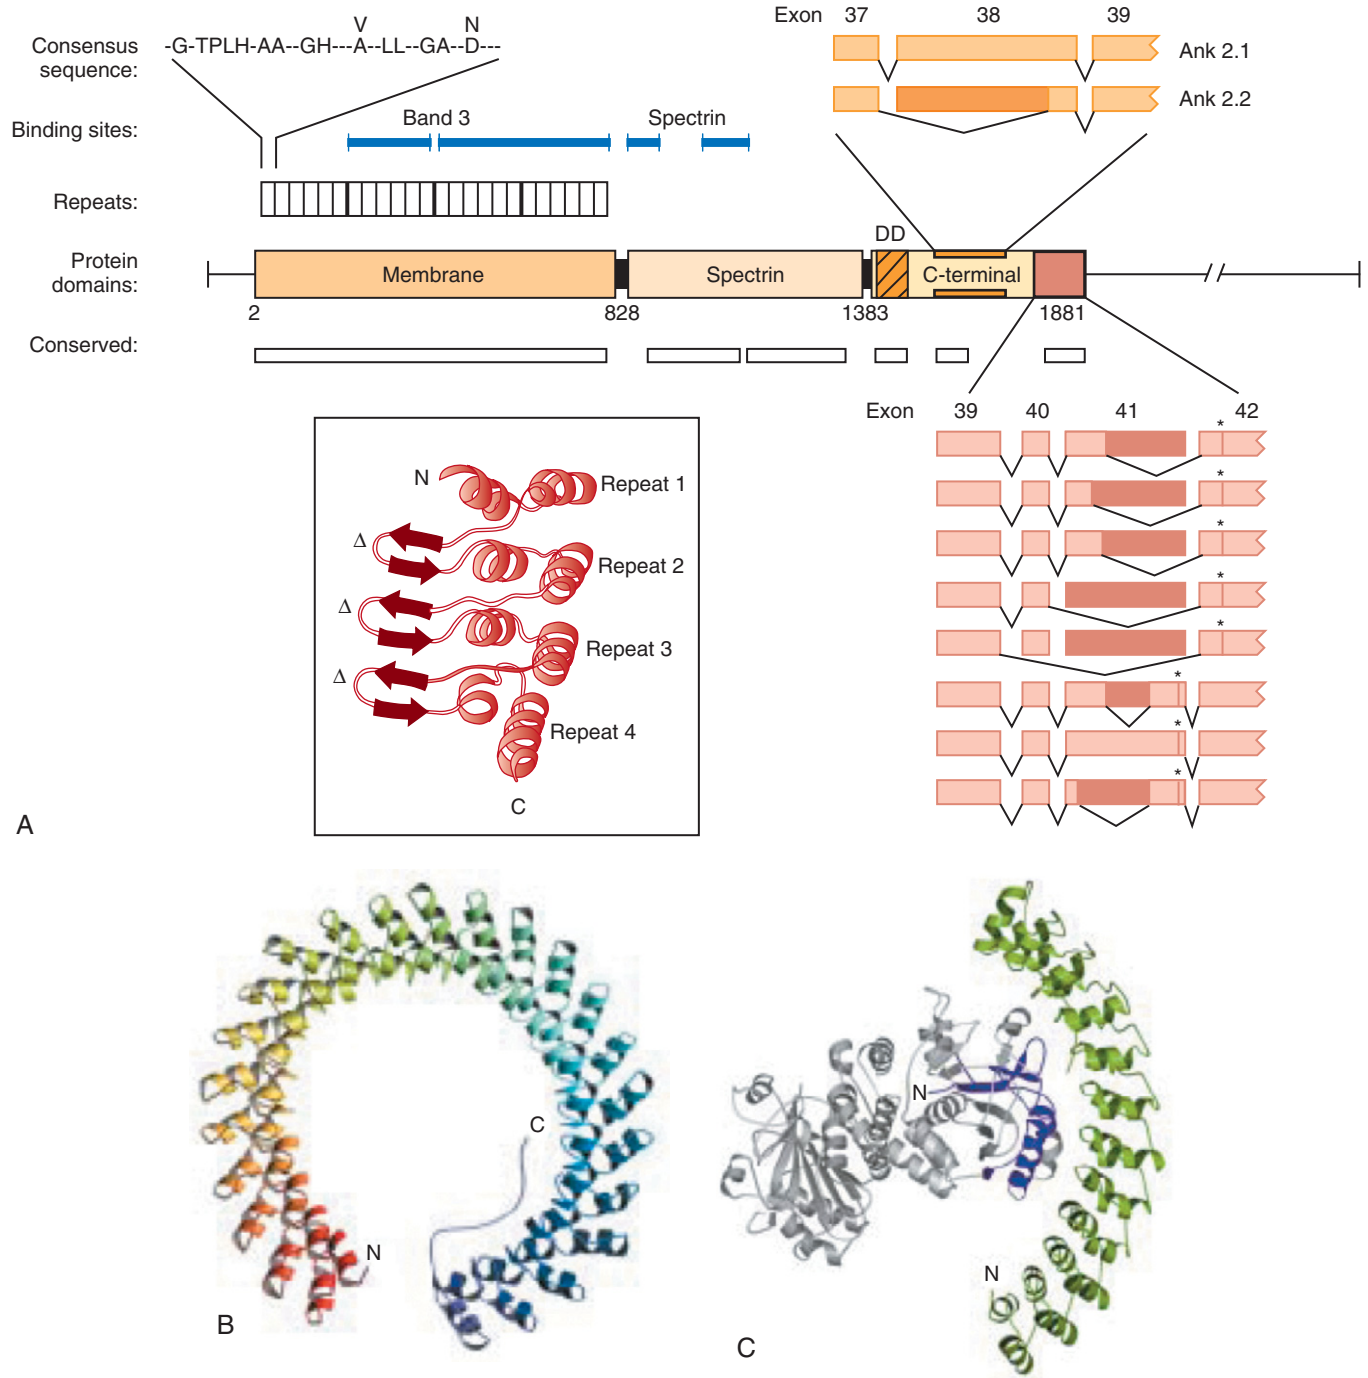
Erythrocyte ankyrin (ankyrin-1 or ankyrin$_R$) is a 206-kd protein[629] that links spectrin to band 3 and thus forms the basis of the skeleton-membrane attachment so critical to the mechanical and viscoelastic properties of the red cell. Ankyrin$_R$ is encoded by the *ANK1* gene, which has been localized to the short arm of chromosome 8 near the centromere (8p11.2).[630] The protein is composed of three domains: an 89-kd membrane domain (amino acids 2 to 827) that interacts with band 3 (and other integral membrane proteins in nonerythroid cells), a 62-kd spectrin binding domain (amino acids 828 to 1382), and a 55-kd C-terminal domain (CTD) (amino acids 1383 to 1881) that modulates ankyrin's interactions with spectrin and band 3 (Fig. 15-21). Alternative


FIGURE 15-21. A, Model of the erythroid ankyrin (Ank1 or AnkR) structure. The *membrane domain* (89 kd) contains 24 "Ank" repeats (33 amino acids each) grouped functionally into subdomains of six repeats. Their consensus sequence is shown at the *top left* in single-letter amino acid code. *Dashes* indicate less conserved residues. There are two binding sites for band 3, one involving repeats 7 to 12 and one involving repeats 13 to 24. The *spectrin domain* (62 kd) contains the binding site or sites for spectrin. These two domains are the most conserved. The *C-terminal (regulatory) domain* (55 kd) is thought to modulate the binding functions of the other two domains. A conserved death domain (DD) resides at the beginning of this domain. It is similar to death domains in proteins involved in apoptosis, but its function in ankyrins is unknown. In the middle of the domain a highly acidic inhibitory region in exon 38 is spliced out of full-length ankyrin (ankyrin 2.1) to make ankyrin 2.2. At least eight isoforms of the last three exons exist. In addition, isoforms lacking exons 38 and 39, 36 through 39, and 36 through 41 have been detected. The *asterisk* and *vertical line* under it indicate the location of the translation terminator codon. The *inset* shows the structure of four consecutive ankyrin repeats.[631] Each repeat forms an L-shaped structure. A β-hairpin loop (*arrows*) makes up the bottom of the L, and two antiparallel α-helical coils form the vertical stem. The hairpin loops of neighboring repeats interact to create an antiparallel β-sheet, and the α helices interact to form helical bundles. The small *triangles* in the *inset* indicate the junction between adjacent repeats. **B,** Model of the membrane domain based on the structure of half the domain[632] and viewed along the spiral axis. **C,** Model of the interaction between a dimer of the cytoplasmic domain of band 3 (*gray* and *purple*) and repeats 13 to 24 of ankyrin (*green*). Residues predicted to bind to ankyrin are shown in *purple*. (*A,* Redrawn from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858, with permission. *B* and *C,* redrawn from Michaely P, Tomchick DR, Machius M, Anderson RG. Crystal structure of a 12 ANK repeat stack from human ankyrin_R. EMBO J. 2002;21:6387.)

splicing, particularly in the CTD, generates several ankyrin species in the red cell and accounts for the presence of ankyrin bands 2.1, 2.2, 2.3, and 2.6 on SDS gel electrophoresis (see Fig. 15-5).[629] Disruption of the ankyrin–band 3 interaction by exposing intact red cells to alkaline pH causes marked membrane instability, thereby emphasizing the importance of the ankyrin linkage to red cell physiology.[633] Indeed, defects in ankyrin are the most common cause of HS (see the section "Hereditary Spherocytosis").[634]

Membrane Domain

The 89-kd N-Terminal Domain of Ankyrin Contains 24 Consecutive 33–Amino Acid Repeats.[629] The ankyrin repeats are organized functionally into four subdomains of six repeats each[635] and contain two distinct and cooperative binding sites for band 3.[636] One band 3 binding site occurs at repeats 7 to 12 (subdomain 2) and the other at repeats 13 to 24 (subdomains 3 and 4) (see Fig. 15-21A and C). Thus, the presence of two binding sites on ankyrin for dimeric band 3 facilitates the tetramerization of band 3 upon ankyrin binding.[214] The high-affinity binding interface for ankyrin on the cytoplasmic domain of band 3 ($K_d \approx 10^{-7}$ to 10^{-8} M) has been localized to an external loop (amino acids 175 to 185) in the middle of the cytoplasmic domain (see Fig. 15-9).[637,638] Removal of this loop abolishes affinity for ankyrin.[209] Surprisingly, however, red cells containing the loop-deleted ankyrin are only mildly spherocytic and unstable, much less so than red cells that lack ankyrin or band 3.[210] This suggests that either there are additional ankyrin–band 3 interactions or that loss of ankyrin or band 3 affects other interactions attaching the lipid bilayer and membrane skeleton. Both may be true. There is some evidence that ankyrin also interacts with the N-terminal of band 3, both proteins interact with protein 4.2 (see later), and ankyrin and 4.2 both interact with spectrin and with elements of the Rh complex (see Fig. 15-6).[392,639,640] The fact that the ankyrin binding site is mutated in Rh proteins and RhAG from some weak D and Rh(null) variants, respectively, suggests that the Rh-RhAG/ankyrin interaction is crucial for biosynthesis or stability of the Rh complex.[640]

Ankyrin Repeats Are Found in Hundreds of Proteins in All Phyla and Are One of the Most Common Protein Sequence Motifs. The ankyrin repeat motif[641] functions as a site of protein-protein interaction in a broad range of proteins involved in development, cell cycle control, oncogenesis, transport, and many other functions.[642,643] Ankyrin repeats form a novel L-shaped structure consisting of a β hairpin (bottom of the L) followed by two α helices that pack side to side in an antiparallel fashion (stem of the L) (see Fig. 15-21A and B).[631,632,644] In ankyrin, the repeats correspond to individual exons.[645] They start at the tip of the β hairpin and line up side to side like overlapping L's, with the hairpins forming a β sheet that is perpendicular to the plane of the α helices. The concave and convex surfaces of the connected repeats provide an ideal interface for protein-protein interac-

tions, thus making the ankyrin repeat a versatile binding partner. A model of the 24 repeats of ankyrin resembles one twist of a spring (see Fig. 15-21B), and recent mechanical studies show that ankyrin repeats have spring-like properties[646]; some speculate that they may serve as mechanoreceptors to link external mechanical forces to signal transduction or changes in ion transport.[646,647] A model of how red cell band 3 might interact with ankyrin is shown in Figure 15-21C.

Spectrin Domain

The central 62-kd domain of ankyrin binds to β-spectrin and attaches the spectrin-actin–based skeleton to the plasma membrane. Ankyrin-spectrin interactions are cooperative such that ankyrin binding promotes spectrin tetramer and oligomer formation.[648] The spectrin binding interface involves regions at the beginning and middle of the domain (see Fig. 15-21A).[649,650] The site in the middle of the spectrin domain is highly conserved among erythroid and nonerythroid ankyrins and probably represents a critical point of spectrin attachment; the amino acid sequence at the beginning of the domain is less well conserved among ankyrins and may account for selective interactions with distinct β-spectrin homologues.[650] The binding site on spectrin is formed by the last third of β-spectrin repeat 14 and repeat 15 (see Fig. 15-13).[461] β-Spectrin repeat 15 is distinguished by the lack of a conserved tryptophan at position 45 of the repeat (amino acid 1811 of β-spectrin I) and by a nonhomologous 43-residue segment in the terminal third of the repeat; the first 30 residues of repeat 15 are highly conserved among erythroid and nonerythroid β-spectrins and are believed to be critical for ankyrin binding.[461]

C-Terminal (Regulatory) Domain

The 55-kd CTD contains sequences that regulate ankyrin interactions[651,652] and has been dubbed the "regulatory domain."[629] Alternative splicing within the CTD yields at least 15 ankyrin isoforms that differ in size and presumably function (see Fig. 15-21A).[645] For example, one isoform of ankyrin, represented by band 2.2, lacks an acidic 162–amino acid peptide present in full-sized ankyrin (band 2.1). Omission of this sequence generates an activated ankyrin that exhibits enhanced binding to band 3 and spectrin[652] and facilitates binding of ankyrin to additional distinct targets in nonerythroid membranes.[653] The identification of a membrane-associated protease that cleaves ankyrin suggests that cleavage of a repressor region within the CTD may activate ankyrin.[653] The CTD also contains a region homologous to the "death domain" of proteins implicated in apoptosis,[654] thus suggesting that ankyrins may additionally play a role in this signaling pathway. The function of the death domain in red cell ankyrin is unknown, but the death domain of Ank3 interacts with Fas in renal epithelial cells and triggers apoptosis.[655] There is a reasonable possibility that the C-terminal region of ankyrin also contains other functional domains because the most C-terminal amino acids are reasonably well conserved.

Phosphorylation

Phosphorylation of ankyrin regulates its interactions with spectrin and band 3. In vitro, up to seven phosphates are added to ankyrin by casein kinase I[656] and three to four phosphates are contributed by casein kinase II.[657] Unphosphorylated ankyrin preferentially binds to spectrin tetramers and oligomers rather than spectrin dimers.[648,656,658] This preference is abolished by phosphorylation, which also reduces the capacity of ankyrin binding to band 3.[659]

Ankyrin Genes

There Are Three Ankyrin Genes: *ANK1*, *ANK2*, and *ANK3*. The corresponding proteins ankyrin$_R$ (ankyrin-1), ankyrin$_B$ (ankyrin-2), and ankyrin$_G$ (ankyrin-3) exhibit distinct patterns of expression in the body and have multiple spliceoforms. Whereas ankyrin$_B$ and ankyrin$_G$ both contain membrane and spectrin domains highly homologous to those of ankyrin$_R$, distinctions arise from heterogeneous CTDs and domain insertions, differential cellular and intracellular localizations, and an eclectic array of binding partners. Nonerythroid ankyrins link the spectrin-actin–based skeleton to a large number of structurally diverse integral membrane proteins other than band 3. Examples include transporters such as AE2, Na$^+$,K$^+$-ATPase, the electrogenic and amiloride-sensitive Na$^+$ channels, the Na$^+$-Ca^{2+} exchanger, H$^+$,K$^+$-ATPase, the Rh/RhAG ammonium transporter, the voltage-regulated K$^+$ KCNQ2/3 channels, and the hepatic system A amino acid transporter; receptors such as the IP$_3$ receptor and the ryanodine receptor; and adhesive proteins such as CD44, E-cadherin, and the neural cell adhesion molecules neurofascin, L1, NrCAM, NgCAM, and neuroglian. Ankyrins are capable of associating with a wide variety of target proteins as a result of their versatile ANK repeats.[643,660,661] There is no specific motif that specifies an ankyrin binding site in these proteins. They seem to have developed by convergent evolution. The diversity of ankyrin homologues and spliceoforms has been implicated in establishing and maintaining the spatial organization of integral membrane proteins within specialized subcellular compartments.

Ankyrin$_R$ Is Also Expressed in Nonerythroid Cells. In addition to its critical role as a component of the red cell membrane skeleton, ankyrin$_R$ is found in muscle cells, macrophages, endothelium, and specific neuronal populations. In muscle cells, for example, the full-sized ankyrin$_R$ localizes to the sarcolemma and nuclei and functions to stabilize the myocyte membrane skeleton.[662] In addition, muscle cells express small ankyrin$_R$ spliceoforms (20 to 26 kd) that contain homologous C-terminal sequences in addition to a unique, hydrophobic N-terminal extension. The hydrophobic peptide is believed to insert directly into the sarcoplasmic reticulum membrane and functions to stabilize the sarcoplasmic reticulum through an ankyrin-based linkage to the contractile apparatus.[662,663] In the brain, ankyrin$_R$ isoforms are first expressed during the postmitotic phase of neuronal development[664] and ultimately localize to the cell bodies and dendrites of selective neuronal populations, with particularly robust expression in the Purkinje and granule cells of the cerebellum.[665]

Ankyrin$_B$ (*ANK2*) and Ankyrin$_G$ (*ANK3*) Are Both Expressed in Most Cells but Have Distinct Functions. Ankyrin$_B$ and Ankyrin$_G$ are located on chromosomes 4q25-q27 and 10q21, respectively. There are many splice variants of both ankyrins that add or delete various functional domains and that are differentially expressed in different tissues.[666,667] Among the variants are very large ankyrins that contain a large, extended, hydrophilic, filamentous tail domain inserted between the spectrin domain and the CTD.[668]

The 440-kd α-ankyrin$_B$ is specifically associated with the plasma membranes of unmyelinated and premyelinated axons and, accordingly, is the predominant ankyrin found in neonatal brain.[668] The inserted domain targets the protein to unmyelinated and premyelinated sites, and expression is subsequently downregulated upon axonal myelination.[669] Ankyrin$_B$ knockout mice exhibit hypoplasia of the corpus callosum and pyramidal tracts, ventriculomegaly, optic nerve degeneration, and death by postnatal day 21.[670] This phenotype shares similarities to mice and humans with deficiencies of L1, a member of the L1 CAM family of cell adhesion molecules. These data suggest that 440-kd α-ankyrin$_B$, in conjunction with L1, plays an essential role in the maintenance of premyelinated axons during development.

Ankyrin$_B$ also exists in a complex with Na$^+$,K$^+$-ATPase, the Na$^+$-Ca^{2+} exchanger, and the IP$_3$ receptor within the T tubules of cardiomyocytes.[671] It is presumed that the complex shuttles Ca^{2+} from the sarcoplasmic reticulum across the plasma membrane. Loss-of-function mutations of ankyrin B are quite common in white populations (2%)[672] and cause a dominantly inherited cardiac arrhythmia with an increased risk for stress-induced cardiac death ("sick sinus syndrome").[673,674]

The 200-kd isoform of ankyrin$_G$, which has a typical three-domain ankyrin structure, is expressed in the plasma membranes of many cells throughout the body, particularly epithelial and muscle cells.[666] The 480- and 270-kd spliceoforms of ankyrin$_G$ localize to axon initial segments and the nodes of Ranvier, an axonal membrane site where ion fluxes propagate neuronal action potentials.[675] Ankyrin$_G$ cooperates with spectrin βIV[437] to localize voltage-gated Na$^+$ channels, KCNQ2/3 channels, neurofascin, and NrCAM to axon initial segments and the nodes of Ranvier.[675-678] Mice that fail to express ankyrin$_G$ in the cerebellum become ataxic because of loss of Purkinje neurons, cannot localize voltage-gated sodium channels to axon initial segments, and have difficulty initiating action potentials.[679] Similarly, mice lacking spectrin βIV have diminished protein under the membrane and membrane blebbing at the nodes of Ranvier and axon initial segments.[680]

Ankyrin$_G$ and βII-spectrin collaborate to stabilize the lateral domain of bronchial (and perhaps other) epithelial

cells and localize Na⁺,K⁺-ATPase and E-cadherin at sites of cell-cell contact.[681-683] The two molecules also seem to be involved in biogenesis of the lateral membrane.[681,682]

Other ankyrin$_G$ isoforms are found in the endoplasmic reticulum, Golgi apparatus, and early endosomes[684]; in late lysosomes[685]; and in coated pits, where the representative isoform binds to clathrin and plays a role in the budding of clathrin-coated pits during endocytosis.[686]

Ankyrin$_R$ Mutations

Mice with Normoblastosis (*nb/nb*) Produce a Defective Ankyrin That Causes Severe Hemolytic Anemia. Red cells from *nb/nb* mice contain a nonsense mutation in ankyrin just between the spectrin binding domain and the CTD that leads to the production of decreased amounts of a shortened (157 kd) ankyrin.[687,688] As a result, *nb/nb* red cells are also moderately spectrin deficient despite normal spectrin synthesis.[503,687] The resultant red cells exhibit severe osmotic fragility and a shortened life span because of a defective membrane skeleton. Interestingly, ataxia also develops in mature *nb/nb* mice secondary to dropout of Purkinje cells in the cerebellum.[689] Ankyrin$_R$ is highly expressed in the cerebellar Purkinje cells of normal mice; the observed reduction of ankyrin$_R$ in the Purkinje cells of *nb/nb* mice may contribute to cell fragility and degeneration.

***ANK1* Mutations Are the Most Common Cause of Hereditary Spherocytosis in Humans.** Ankyrin$_R$ mutations lead to combined deficiencies of ankyrin and spectrin. The defective cells produce a variable clinical manifestation ranging from mild hemolysis to severe transfusion-dependent anemia[634] (see "Hereditary Spherocytosis").

Protein 4.2

Protein 4.2 is an 80-kd peripheral membrane protein that participates in stabilizing the red cell membrane skeleton through interactions with band 3, CD47, spectrin, ankyrin, and the lipid bilayer. Protein 4.2 shares homology with transglutaminases and is part of a transglutaminase gene cluster on chromosome 15q15, but it lacks transglutaminase activity, having an Ala instead of a required Cys at its active site.[690,691] It is first detected in late erythroblasts and is the last of the major erythrocyte membrane proteins to be made.[692] There are eight spliceoforms that arise from alternative splicing of exon 3, exon 5, or 90 bp in exon 1.[692,693] The major form lacks the 90-bp segment. The others are all minor species in the mature red cell. The protein is found mostly in erythroid tissues[694] and the lens.[695] Reports of protein 4.2 detected in other tissues by immunologic methods[696] are not adequately controlled for antibody cross-reactivity with tissue transglutaminases.

Protein 4.2 Structure

Band 3 Binding. Protein 4.2 binds to band 3 with a K_d of 10^{-6} to 10^{-7} M. The band 3 binding site on 4.2 has been mapped to amino acids 187 to 211 (Fig. 15-22).[697] This sequence encompasses a palmitoylation site on Cys203, and palmitoylation enhances band 3 binding.[697] The binding site for protein 4.2 on band 3 has not been clearly identified; however, red cells from patients with the cytoplasmic band 3 mutations Glu40→Lys and Pro327→Arg show some deficiency of protein 4.2, thus suggesting that both proximal and distal cytoplasmic band 3 sequences may be involved (see Fig. 15-7). Red
FIGURE 15-22. **A,** Schematic of protein 4.2 indicating its functional regions and post-translational modifications. aa, amino acid. **B,** Protein 4.2 sequence mapped onto the three-dimensional surface of a related transglutaminase, factor XIII. The dimer of factor XIII is shown, with one molecule in *blue* and one in *magenta*. Note that the spectrin binding site lies near the dimer interface and adjacent to the band 3 binding site on one side of the molecule and that the ATP binding site lies on the opposite side of the molecule.

cells that lack band 3 also lack protein 4.2 despite normal protein 4.2 synthesis.[222] Conversely, band 3 is partially deficient in red cells that lack protein 4.2.[223] As noted earlier, it is not clear whether protein 4.2 binds to the ankyrin-linked band 3 tetramers or the "free" band 3 dimers. Studies of band 3 mobility suggest that 4.2 binds to band 3 dimers, but 4.2 also binds to ankyrin, which attaches to band 3 tetramers.[219,220] Because only a fraction of protein 4.2 remains attached to the membrane skeleton (which retains ankyrin-linked band 3 *tetramers*) after band 3 *dimers* are extracted with Triton X-100,[172] it probably binds to both.

Ankyrin Binding. Protein 4.2 also interacts with ankyrin. The two proteins associate in solution[698] and there is indirect evidence that they interact on the membrane. Red cells containing protein 4.2 Komatsu (Asp175→Tyr) lack 4.2, and the recombinant protein fails to bind ankyrin.[699,700] Mapping studies localize the ankyrin binding site to a neighboring region (amino acids 187 to 200),[701] just next to the band 3 binding site (see Fig. 15-22). It seems likely that ankyrin interacts with 4.2 bound to tetrameric band 3, but this is also unknown.

CD47 Binding. Recent work shows that protein 4.2 interacts with the Rh complex through CD47.[639,702,703] Patients lacking protein 4.2 nearly lack CD47,[639,702] and patients with partial deficiency of 4.2 have less CD47 attached to the membrane skeleton.[138] However, mice lack this association[702] (and, interestingly, protein 4.2 is easier to extract from the membrane in mice). On the other hand, mice and humans with absent CD47 or low expression of the protein do not have reduced protein 4.2.[702] This and other recent work[392] provides convincing evidence for an association of the band 3 complex (band 3, ankyrin, GPA, and 4.2) with the Rh complex (RhAg, Rh polypeptides, GPB, LW, and CD47).

Spectrin Binding. Korsgren and colleagues first showed that protein 4.2 binds spectrin.[219] They identified both high- ($K_d \approx 10^{-9}$ M) and low-affinity ($K_d \approx 10^{-7}$ M) sites. Reconstituting 4.2-stripped membrane vesicles with 4.2 increased spectrin binding capacity from approximately 50% to about 80% of normal.[219] The binding site on 4.2 has been mapped to amino acids 470 to 492 (see Fig. 15-22).[704] This peptide contains a segment homologous to ERM proteins, such as protein 4.1.

Post-translational Modifications. Protein 4.2 has a nucleotide-binding P-loop (residues 342 to 352) and binds ATP with a K_d of around 10^{-6} M.[165] This is well below the concentration of ATP in the red cell (1.5 to 1.9 mM), so 4.2 should be nearly saturated with ATP under physiologic conditions. The consequences of this binding are unknown.

Protein 4.2 is myristoylated on its N-terminal glycine[705] and is palmitoylated on Cys203,[706] which sug-

gests that the protein may interact with lipid bilayers. It is likely that most of the 4.2 molecules are myristylated.[705] The extent of palmitoylation is unknown. The myristoyl group seems to influence cellular localization because nonmyristoylated 4.2 does not go to the plasma membrane.[707] As noted earlier, the palmitoyl group enhances binding of protein 4.2 to band 3 at least threefold.[697]

Topology. When the aforementioned sites are mapped onto the surface of factor XIII, a homologous transglutaminase, the putative spectrin and band 3 sites are predicted to lie quite close to each other on the front face of the molecule (see Fig. 15-22B). The ATP-binding loop, on the other hand, is predicted to lie on the rear face, adjacent to the dimer interface. The predicted spectrin site also lies next to the dimer interface on the front. Such topology suggests that it will be important to investigate the effects of ATP and spectrin binding on 4.2 oligomerization and test whether spectrin and band 3 cooperate or compete for binding to protein 4.2.

Protein 4.2 Deficiency Is a Cause of Hereditary Spherocytosis and Ovalostomatocytosis

Mutations in the human protein 4.2 gene are associated with the production of dysmorphic and osmotically fragile red cells, which results in hemolytic anemia (see "Hereditary Spherocytosis"). Protein 4.2–null mice also exhibit mild HS.[223] The defective red cells demonstrate loss of membrane surface area and defective cation transport, with cell shrinkage being associated with increased Na^+ permeability.[223] Whereas the spectrin and ankyrin content of the 4.2-null red cells is normal, there is decreased band 3 protein and a corresponding decline in anion transport activity.[223]

Peroxiredoxins

There are six known mammalian peroxiredoxins (Prdx1 to Prdx6). Peroxiredoxin-2 is the most common in red blood cells and is the third most abundant protein in the cell. Peroxiredoxin-1 and peroxiredoxin-6 are present in smaller amounts. The peroxiredoxins are widely distributed and conserved in evolution. They protect cells from insult by reactive oxygen species and regulate signal transduction pathways that influence cell growth and apoptosis.[708]

Peroxiredoxin-2

Peroxiredoxin-2, also known as thioredoxin peroxidase B, calpromotin, thiol-specific antioxidant protein, protector protein, natural killer–enhancing factor B, acidic peroxidoxin, torin, and band 8, is 198 resides in length (≈22 kd) and is a soluble cytoplasmic protein that translocates to the membrane in the presence of Ca^{2+}. There are approximately 14 million copies per cell,[379,709] but only about 200,000 molecules appear to be associated with the membrane in normal red cells judging from the intensity

of band 8 on SDS gels. Accumulation of peroxiredoxin-2 is maximal in early erythroid development, before the start of hemoglobin synthesis.[710] In common with the glutathione peroxidases, peroxiredoxins are able to reduce hydrogen peroxide (H_2O_2) and lipid hydroperoxides to water or the corresponding alcohol, respectively. The activity of peroxiredoxin-2 depends on a pair of highly conserved cysteine residues that catalyze the peroxide reduction step. Thioredoxin is the hydrogen donor. Peroxiredoxin-2 is especially abundant in the adrenal glands, brain, and lung, as well as in blood.

In the red cell, peroxiredoxin-2 activates the Gárdos channel, a charybdotoxin-sensitive Ca^{2+}-dependent, K^+ channel, which leads to loss of K^+ and water.[379] Such activation is associated with increased Ca^{2+}-dependent binding of dimeric peroxiredoxin-2 to the red cell membrane as a pentamer of the dimers.[375,378] Peroxiredoxin-2 is especially abundant on the red cell membranes of sickle cells, particularly the dense, dehydrated fraction of sickle cells.[711] Interestingly, peroxiredoxin-2 binds stomatin,[375] a protein that is nearly absent in hereditary stomatocytosis, a severe hemolytic anemia associated with markedly increased Na^+ and K^+ permeability (see later discussion).

Recent experiments show that peroxiredoxin-2 is extremely efficient at scavenging H_2O_2.[712] It can rapidly detect and remove even the small amounts generated endogenously by hemoglobin auto-oxidation. In the process the enzyme is oxidized to a disulfide-linked homodimer. Because there is very little thioredoxin reductase activity in red cells, the oxidized enzyme is recycled slowly. However, the concentration of peroxiredoxin-2 is so high that it is still highly effective at protecting the red cell against low concentrations of H_2O_2. This is shown by the fact that mice lacking peroxiredoxin-2 have a Heinz body hemolytic anemia, with Heinz bodies appearing spontaneously at about 2 weeks of age.[713] Smears show burrs, spherocytes, and dense cells.

Peroxiredoxin-1

Despite its low concentration, peroxiredoxin-1 also seems to play an important oxidant-protective role in the red cell. In peroxiredoxin-1 knockout mice, severe oxidant-type hemolytic anemias begin to develop at about 9 months of age, and several types of cancer develop later.[714] The anemias feature an increase in reactive oxygen species, protein oxidation, hemoglobin instability, and Heinz body formation.

ORGANIZATION OF THE MEMBRANE SKELETON

By analogy, the skeleton is sometimes compared to a sweater, which reveals its nodes and individual filaments when stretched, but not when collapsed. Stretched skeletons reveal complexes of F-actin (the nodes) cross-linked by molecular filaments of spectrin in a geodesic dome-like arrangement when viewed by high-resolution, negative-stain electron microscopy (see Fig. 15-16).[508,715,716]

Dematin, adducin, and protein 4.1 colocalize with these complexes on immunoelectron microscopy (Fig. 15-23).[715] Most of the complexes are connected by spectrin tetramers (85%) and three-armed hexamers (10%) (see Fig. 15-16).[716] Ankyrin- and band 3–containing globular complexes attach to spectrin about 80 nm from its distal end or 20 nm from the site of self-association (see Fig. 15-16). The average thickness of the skeletal protein layer has been estimated to be 3 to 6 nm from x-ray diffraction data[717] and 7 to 10 nm from electron micrographs.[718] These dimensions suggest that the skeleton is only one or two molecules thick on average, which means it must cover about 25% to 50% of the inner membrane surface area—and even more if a hydration shell around the proteins is included. This corresponds reasonably to micrographs of unspread skeletons, where the contracted, collapsed spectrin filaments appear to cover most but not all of the inner membrane surface.[458]

A model of the membrane skeleton based on this and other evidence is shown in Figure 15-6. Similar models have existed, with gradual refinement, since 1979.[719] Spectrin dimers are depicted as a twisted, flexible polymers joined head to head to form tetramers and higher-order oligomers. Self-association occurs between the N-terminal end of the spectrin α chain and the C-terminal end of the β chain (see Fig. 15-13), as described in detail in the earlier section on spectrin. Spectrin mole-
FIGURE 15-23. Immunogold labeling of proteins in red cell membrane skeletons. Expanded membrane skeletons were incubated with affinity-purified antibodies to the membrane skeletal proteins indicated and then washed and stained with 5 nm gold-labeled anti-IgG. Note that protein 4.1, dematin, and adducin are located in junctional complexes (*arrowheads*) whereas band 3 and ankyrin reside in globular structures (*arrows*) on spectrin filaments, midway between junctional complexes. *(From Liu S-C, Derick LH. Molecular anatomy of the red blood cell membrane skeleton: structure-function relationships. Semin Hematol. 1992;29:231.)*

cules are linked into a two-dimensional network by interactions with a complex of actin protofilaments, protein 4.1, dematin, adducin, tropomyosin, and tropomodulin (see Fig. 15-6). These associations occur at the tail ends of the bifunctional spectrin tetramer, where protein 4.2 also binds.[221] The predicted complexes are morphologically similar to isolated spectrin-actin-4.1 complexes and to structures observed in situ in normal ghosts (see Figs. 15-16 and 15-23). They appear to serve as a branch point or "molecular junction" in skeletal construction. On average, six spectrin molecules emanate from each complex, although there is some variation. This is evident in the hexagonal arrangement of spectrin in spread skeletons (see Fig. 15-16). In unperturbed skeletons, most spectrin molecules probably fold up to about a third of their length and do not extensively overlap or intertwine.[458,459]

Individual spectrin tetramers and oligomers are attached to the overlying lipid bilayer through high-affinity interactions with ankyrin and band 3, probably with the assistance of protein 4.2. Current evidence suggests that band 3 is a mixture of dimers and tetramers in the membrane[214] and that the tetramer binds only one molecule of ankyrin.[720,721] If so, about 40% of the band 3 molecules are involved in anchoring the membrane skeleton through ankyrin. Although the spectrin tetramer contains two ankyrin binding sites, there is only enough ankyrin to fill one, and on average, only one is filled in situ. We speculate that the remaining band 3 dimers may be attached to proteins 4.1 and 4.2 near the spectrin-actin junctions and provide another point of attachment in conjunction with interactions between protein 4.1, protein p55, and GPC (see Fig. 15-6). Interactions between ankyrin, protein 4.2, and the Rh/RhAG complex and between dematin, adducin, and Glut-1 also contribute to linkage of the membrane skeleton and lipid bilayer.

Modulation of Membrane Skeletal Structure

Red cell membrane proteins are subject to a large number of post-translational modifications or other regulatory effects: phosphorylation, fatty acid acylation, methylation, glycosylation, deamidation, ubiquitination, calpain cleavage, polyphosphoinositide and calmodulin regulation, oxidation, and modification by polyanions. A detailed discussion of most of these pathways has been published[131] but is beyond the scope of this chapter.

Phosphorylation

Almost all of the membrane skeletal proteins are phosphorylated by one or more protein kinases, including casein kinases (spectrin, ankyrin, band 3, protein 4.1, and dematin), PKA (spectrin, ankyrin, adducin, protein 4.1, and dematin), PKC (adducin, protein 4.1, and dematin), and tyrosine kinases (band 3 and protein 4.1).[131]

In all cases studied so far, phosphorylation inhibits membrane protein interactions: (1) ankyrin phosphorylation (casein kinase) abolishes the preference of ankyrin

for spectrin tetramer[648,656] and (2) decreases binding to band 3.[659] (3) Phosphorylation of protein 4.1 (several kinases) diminishes its binding to spectrin and its ability to promote spectrin-actin binding[522,530,722,723] and decreases its attachment to the membrane.[724] (4) Phosphorylation by PKC also inhibits binding of protein 4.1 to band 3[523] and glycophorin C.[522] (5) Phosphorylation of dematin by PKA prevents actin bundling.[725] (6) Phosphorylation of Tyr8 and Tyr21 at the N-terminal end of band 3 blocks the binding of glycolytic enzymes[198] and presumably hemoglobin and results in increased glycolysis.[1] In contrast, despite extensive study,[450,495,496,726] no functional effect of spectrin phosphorylation on in vitro protein-protein interactions has yet been identified. However, increased phosphorylation of β-spectrin in vivo has been shown to decrease membrane mechanical stability, whereas decreased phosphorylation strengthens the mechanical properties of the red cell membrane.[727]

Polyanions

Physiologic concentrations of organic polyanions such as 2,3-DPG and ATP weaken and dissociate the membrane skeleton[728,729] and increase the lateral mobility of band 3 in ghosts.[730] Although some studies suggest that even supraphysiologic concentrations of 2,3-DPG have little or no effect on intact erythrocytes[731,732] in terms of membrane rigidity, there is convincing evidence that increased 2,3-DPG levels decrease membrane mechanical stability.[729] It has been suggested that the developmental switch from fetal to adult hemoglobin, by diminishing available free 2,3-DPG (which does not bind to fetal hemoglobin), may explain the abatement of cell fragmentation and hemolytic anemia that accompanies maturation of infants with HE and infantile poikilocytosis.[729]

Calcium and Calmodulin

There is good evidence that calmodulin modifies the membrane properties of the red cell.[532] Physiologic concentrations of calmodulin, sealed in red cell ghosts, destabilize membranes in the presence but not the absence of micromolar concentrations of Ca^{2+}. Recent studies suggest that the effect may result from interactions of calmodulin with protein 4.1.[531] Submicromolar concentrations of calmodulin, even lower than those that exist in the red cell ($\approx$3 to 6 μM), block protein 4.1–induced gelation of actin in the presence of spectrin.[531] The effect is Ca^{2+} dependent. It begins at a Ca^{2+} concentration of 10^{-6} to 10^{-7} M, which is relatively low, but still higher than the free Ca^{2+} concentration in the erythrocyte (2 to 4×10^{-8} M). Surprisingly, Ca^{2+}-calmodulin does not block spectrin-actin-4.1 complex formation under these conditions,[531] only the extensive cross-linking needed to cause gelation. The Ca^{2+}-dependent and Ca^{2+}-independent calmodulin binding sites in protein 4.1 are located within the membrane binding domain.[545] Ca^{2+}-calmodulin specifically reduces the affinity of the 4.1-CD44 interaction,[544] as well as 4.1 interactions with band 3, GPC, and p55.

Ca^{2+} augments the binding of protein 4.2 to the EF hand domain at the C-terminal of the spectrin α chain,

and the effect is blocked by calmodulin.[221] Calmodulin also binds to the spectrin β chain in a Ca^{2+}-dependent manner[733]; however, the affinity of spectrin for calmodulin is not great, and it is unclear whether this effect occurs at the concentrations of calmodulin that exist in erythrocytes.

β-Adducin is another calmodulin-binding red cell membrane protein ($K_d = 2.3 \times 10^{-7}$ M).[734] The adducin that is bound to spectrin and actin fosters the attachment of a second, neighboring spectrin. In the presence of Ca^{2+} (>10^{-7} M), calmodulin binding reduces both adducin-actin binding and adducin-mediated enhancement of spectrin-actin binding.[475] Calmodulin also blocks the binding of a second spectrin molecule to an adducin-actin-spectrin complex.[472] The physiologic consequences of these effects are unclear.

Several other Ca^{2+}-dependent events do not require the presence of calmodulin. One of them is the so-called Gárdos phenomenon[735] (described later in this chapter), a unidirectional K^+ and water loss that produces cellular dehydration. The Ca^{2+} concentration required to trigger the Gárdos channel is low (in the micromolar range) and thus physiologically significant. As discussed elsewhere in this textbook, this pathway contributes to the dehydration of sickle red cells.

A second calmodulin-independent Ca^{2+} effect involves calpain, one of a family of Ca^{2+}-stimulated neutral proteases that are present in a variety of tissues, including red cells.[131] Susceptible membrane substrates include adducin, ankyrin, protein 4.1, and to a lesser extent, spectrin and band 3.

Finally, Ca^{2+} also induces phospholipid scrambling, as discussed earlier in the chapter.

Thus, increases in intracellular calcium produce a range of deleterious effects. Although these phenomena are well studied in vitro, their role in erythrocyte pathology, particularly in acquired disorders associated with abnormal red cell shape, is not well understood.

Biogenesis of the Membrane Skeleton

Synthesis of Band 3 Initiates Assembly of a Stable Membrane Skeleton. Spectrin and ankyrin synthesis is detectable at very early stages of erythroid development in avian and mammalian erythroid cells (reviewed elsewhere[736-738]). However, these proteins turn over rapidly and they do not assemble into a permanent network. Synthesis of band 3 (the anion exchange protein) and protein 4.1 begins at the proerythroblast stage and increases throughout terminal erythroid maturation, up to the late erythroblast stage. During the same time, mRNA levels and synthesis of spectrin and ankyrin decline. Even so, the proportion (and actual amounts) of newly assembled spectrin and ankyrin on the membrane progressively increase, and these proteins become more stable, as indicated by their slower turnover. This increased recruitment plus stabilization of spectrin and ankyrin, despite declining synthesis, is thought to be related to the progressive increase in the synthesis of band 3 and protein 4.1 because these proteins are the principal sites for attachment of the skeleton to the membrane.[736]

Skeletal Proteins Are Synthesized in Excess. The synthesis of membrane skeletal proteins is wasteful. Only a fraction of newly synthesized spectrin, ankyrin, and protein 4.1 is assembled into the permanent skeletal network. The excess proteins are rapidly catabolized.[737,739,740] Furthermore, skeletal protein synthesis is highly asymmetric. This is most striking in the case of spectrin, where threefold to fourfold more α-spectrin is produced than β-spectrin. Yet the two chains are assembled into the membrane skeleton in equimolar amounts as mixed heterodimers. Because of this high α-spectrin–to–β-spectrin synthetic ratio, heterozygotes for a deleted or synthetically inactive α-spectrin allele are asymptomatic because sufficient α-spectrin is still made to pair with all the β-spectrin.

Rate-Limiting Steps of Membrane Skeletal Assembly. As discussed earlier, the principal rate-limiting step in membrane skeletal assembly is the synthesis of band 3, which contains a high-affinity ankyrin binding site that recruits and stabilizes spectrin and ankyrin on the membrane.[741,742] This view, however, has to be reconciled with observations that some patients with dominantly inherited HS and partial band 3 deficiency do not have a proportional decrease in the amounts of spectrin and ankyrin in their membranes.[634,743] The probable explanation is that band 3 is synthesized in excess. About fivefold more band 3 is made than spectrin or ankyrin, but only the tetrameric fraction of band 3 binds ankyrin with high affinity.[214,721,743] Excess dimeric band 3 is selectively lost in band 3–deficient spherocytes.[743] More convincing evidence that band 3 is not absolutely required for membrane skeletal assembly is the finding that mouse red cells with complete deficiency of band 3 assemble a functional and nearly structurally normal spectrin-based membrane skeleton.[222] This indicated that other membrane sites must bind spectrin and ankyrin in the absence of band 3. The ankyrin/protein 4.2–Rh/RhAG and protein 4.1–p55/GPC complexes are good candidates.

The second rate-limiting step is the availability of ankyrin, which provides the high-affinity binding sites for β-spectrin. This is best illustrated by studies of membrane skeletal synthesis in *nb/nb* spherocytic mice[503] and in a severe form of human HS associated with combined deficiency of spectrin and ankyrin.[502] In both disorders ankyrin synthesis is markedly reduced, which leads to decreased assembly of spectrin and ankyrin on the membrane despite normal spectrin synthesis.

The third rate-limiting step involves the synthesis of β-spectrin. Because α- and β-spectrin polypeptides are assembled on the membrane in equimolar amounts and because β-spectrin binds to ankyrin with high affinity, the availability of β-spectrin seems to regulate the amount of

membrane-assembled α/β-spectrin heterodimers. This regulatory role of β-spectrin is illustrated by the effects of erythropoietin on membrane protein assembly. Erythropoietin stimulates the synthesis of β-spectrin and increases the assembly of α/β-spectrin heterodimers on the membrane.[744] In contrast, α-spectrin, which is made in excess, does not seem to have a limiting role in skeletal assembly. α-Spectrin becomes rate limiting only when its synthesis is markedly reduced, as it is in some patients with recessive HS or HPP.

Membrane Remodeling during Enucleation and Reticulocyte Maturation. At the orthochromatic erythroblast stage, when membrane biogenesis is nearly complete, the cell membrane undergoes a series of critical remodeling steps. The cell nucleus is surrounded by an actin ring, which probably participates in expulsion of the nucleus from the erythroblast. Recent work shows that this process requires the Rac GTPase mDia2, one of the formin proteins that nucleate linear actin filaments.[745] Rac1 and Rac2 bind to mDia2 in a guanosine triphosphate (GTP)-dependent manner, and mDia2 causes the contractile actin ring to form. At the same time, the spectrin skeleton, proteins that attach to it, and selected other proteins segregate into the incipient reticulocyte, and some surface receptors cluster in the membrane surrounding the soon to be extruded nucleus.[499,746] This sorting process is poorly understood.

Further membrane remodeling takes place by exocytosis as the young multilobular reticulocyte attains the biconcave shape (Fig. 15-24).[747,748] This is best studied for transferrin receptors, which enter reticulocytes by endocytosis and are segregated into vesicles called "exosomes" within large membrane-bounded sacs called multivesicular bodies. These bodies fuse with the plasma membrane and discharge the exosomes and their protein cargo (see Fig. 15-24). The transferrin receptor is lost with heat shock protein 70, which binds to the cytoplasmic domain and seems to act as a chaperone.[749] A variety of membrane proteins are lost by this mechanism, including the nucleoside transporter; LFA3; $\alpha_4\beta_1$ integrin, which binds fibronectin; small GTP-binding proteins such as Rab 4p, Rab 5p, and adenosine diphosphate (ADP) ribosylation factor; and GPI-linked proteins such as acetylcholinesterase, CD55, and CD59. Naturally occurring IgM antibodies to lysophosphatidyl choline bind the released exosomes, lead to the deposition of C3, and are probably involved in exosome clearance.[750]

Autophagocytosis also plays an important role in removal of mitochondria, cytoplasmic organelles, and some membrane receptors. Cholesterol-loaded reticulocytes from mice that lack the high-density lipoprotein (HDL) receptor and apoliploprotein E, and that are fed cholesterol, are anemic and contain targeted, macrocytic red cells with large abnormal autophagolysosomes.[751] The cholesterol-loaded reticulocytes also retain ribosomes and transferrin receptor. Removal of cholesterol, incubation in normolipemic serum, or transfusion into
FIGURE 15-24. Maturation of the reticulocyte membrane. **A,** Note that as reticulocytes mature, transferrin receptors, labeled with gold-bound antibodies, collect in small vesicles (exosomes) within intracellular sacs called multivesicular bodies (MVBs). MVBs approach the plasma membrane and begin to fuse (*arrow*), with eventual release (**B**) of exosomes from the cell. A variety of membrane proteins are released by this mechanism. *(From Johnstone RM. Revisiting the road to the discovery of exosomes. Blood Cells Mol Dis. 2005;34:214-219.)*

normal recipients leads to expulsion of the autophagolysosomes and reinitiation of reticulocyte maturation.[751] How cholesterol accumulation inhibits reticulocyte maturation remains to be determined.

RED CELL MEMBRANE DEFORMABILITY AND STABILITY

Material Properties

The material properties of the membrane reflect the properties of both the lipid bilayer and the skeleton. During deformation of the red cell membrane, bending is restricted by the incompressibility of the lipid bilayer
FIGURE 15-25. Model of the effects of deformation on the membrane skeleton. The red cell membrane cannot expand its area. When force applied to a section of nondeformed membrane (**A**) extends the lipid bilayer and its attached spectrin molecules (**B**), the bilayer and spectrin molecules in the nonstressed dimension must shrink to maintain a constant area. Eventually, spectrins reach the limit of their length (**C**). Further extension will disrupt membrane-skeleton interconnections and lead to membrane fragmentation. *Open circles*, sites of spectrin-spectrin association; *solid diamonds*, spectrin-actin-4.1 junctions. *(Redrawn from Mohandas N, Chasis JA. Red cell deformability, membrane material properties, and shape: regulation by transmembrane, skeletal, and cytosolic proteins and lipids. Semin Hematol. 1993;30:171.)*

and is facilitated by rapid translocation of cholesterol from the inner to the outer half of the bilayer.[752] The lipid bilayer cannot expand its surface area more than 3% to 4%. Consequently, when red cells are suspended in hypotonic solutions, such as during OF testing, they swell to a spherical shape and then rupture and discharge their hemoglobin into the supernatant.[753]

The membrane skeleton determines both the solid and the semisolid properties of the membrane.[754] The solid properties are exemplified by an elastic extension of cells that completely restore their normal shape after the applied force has been removed. An example is a cell that has been deformed when passing through fenestrations of the splenic sinus wall. This elastic recovery of the biconcave shape is facilitated by the unique molecular anatomy of the skeletal lattice. In normal red cells, individual spectrin molecules are arranged in a hexagonal array and are folded in a compact configuration. The junctional complexes are close to each other and are linked by shortened spectrin tetramers, thus allowing large unidirectional extensions without disruption of the lattice (Fig. 15-25). The skeletal connections are unperturbed during such deformations. On the other hand, application of large or prolonged force allows the skeletal elements to reorganize and make new connections. This produces a permanent "plastic" deformation (see later). When the force is excessive, membrane fragmentation ensues. An example is the poikilocytosis produced in microangiopathic blood vessels, where red cells may

adhere to damaged endothelium and be stretched by the vascular torrent or may be clotheslined by fibrin strands.[755] After release, many of the cells are either permanently deformed or fragmented.

Cellular and Molecular Determinants of Red Cell Deformability

The need to undergo large deformations is best exemplified in the wall of the splenic sinus, where red cells have to "squeeze" through narrow slits between the endothelial cells that line the splenic sinus wall (see the later section on splenic structure). Such whole-cell deformability is determined by three factors: (1) cell geometry, specifically, a large cell surface-to-volume ratio, which allows cells to undergo large deformations at a constant volume; (2) viscosity of the cell contents, which is principally determined by the properties and concentration of hemoglobin in the cells; and (3) intrinsic viscoelastic properties of the red cell membrane.[754] Among these factors, the contribution of the surface-to-volume ratio is the most important, as exemplified by the cellular lesion of hereditary spherocytes, discussed later in this chapter. On the other hand, the intrinsic deformability of the red cell membrane has a relatively small effect on red cell survival. This is best illustrated by the red cell membrane properties of Southeast Asian ovalocytes, which carry a mutant band 3 protein. As will be discussed, both the intact Southeast Asian ovalocytosis (SAO) red cells and their membranes are extremely rigid, yet the SAO red cells have normal or nearly normal survival in vivo.

Several molecular alterations increase membrane rigidity. One is accretion of denatured hemoglobin, which may contribute to the membrane rigidity of Heinz body–containing red cells.[756] Another is transamidative or oxidative cross-linking, which rigidifies the membrane in vitro.[757] Oxidative cross-linking may also be important in vivo, as evidenced by aggregates of oxidant–cross-linked proteins in red cells containing unstable hemoglobins.[758] On the other hand, transamidative cross-linking is probably not physiologically significant because the high Ca^{2+} concentrations needed for the reaction are unlikely to be attained in vivo.

Integral proteins may also regulate membrane deformability. For example, treatment of red cells by antibodies against GPA, including their Fab fragments, leads to reduced deformability via transmembrane signaling. Red cells that lack the cytoplasmic domain of GPA (e.g., Miltenberger V red cells) are not influenced by such treatment.[256,759] Another important factor is the aggregation state of band 3. Membrane rigidity is increased when band 3 molecules are cross-linked with antibodies or, as in SAO (see later), when mutant band 3s spontaneously stack into linear aggregates.[760,761] This finding presumably also explains the marked restriction of band 3 mobility in SAO red cells. Because aggregates of SAO band 3 contain ankyrin, which attaches the skeleton to the membrane, the decreased

mobility of SAO band 3 may impede skeletal deformation when red cells deform and thereby result in a rigid erythrocyte.

Membrane Structural Integrity and Fragmentation. The skeleton is also the principal determinant of membrane stability. As noted earlier, it is possible to manipulate the proportion of spectrin dimers and tetramers in situ by exposing ghosts to temperatures and salt concentrations that favor or discourage spectrin self-association. Ghosts enriched in spectrin dimers are strikingly fragile.[455] Similarly, HE and HPP are often due to α- or β-spectrin mutations that weaken spectrin self-association (see later). In such cells the hexagonal skeletal lattice is dis-
FIGURE 15-26. Microvesiculation. Red cell ghosts treated with hypertonic saline form spicules. At the end of the spicules the lipid bilayer often separates from the underlying membrane skeleton. The *arrows* point to the boundary between the skeleton (dark material below) and the unsupported lipids (light material above), which are unstable and tend to be released as vesicles (*arrowheads*). A similar process is thought to occur in a variety of disorders associated with spiculation, such as spur cell anemia and hereditary spherocytosis.

rupted,[762] usually in association with red cell fragmentation and poikilocytosis.

Lipid Bilayer Loss and Microvesiculation. The fluid lipid bilayer is stabilized by both the underlying membrane skeleton and transmembrane proteins. In vitro, the bilayer can be uncoupled from the skeleton at the tips of spiculated red cells by force or by various treatments (Fig. 15-26).[763,764] The lipids are released in the form of microvesicles that contain integral proteins but lack skeletal components.[764] Such loss of membrane material may underlie the surface area deficiency of red cells subjected to prolonged storage[765,766] or ATP-depleted red cells.[767] Aggregation of the band 3–containing intramembrane particles in the membrane also destabilizes the lipid bilayer.[768] The particle-free regions bleb and release lipid microvesicles. As discussed later, all these pathways may contribute to the surface deficiency of hereditary spherocytes.

Plastic Deformation of Red Cells. The role of the membrane skeleton in red cell shape is best illustrated by irreversibly sickled cells or hereditary elliptocytes, in which the abnormal shape is retained in the ghosts and membrane skeletons.[769,770] This process is probably an example of "plastic deformation," the result of prolonged exposure of red cells to deforming forces, with the proteins of the deformed skeleton undergoing active rearrangement that permanently stabilizes the cells in the deformed shape (Fig. 15-27).[754] Existing protein-protein contacts disconnect and new associations form. In HE, shape transformations may be facilitated by the weakened skeletal protein interactions. In vitro, plastic deformation occurs more rapidly in normal red cells with skeletons weakened by exposure to urea.[771]

In addition, both normal and abnormal red cell shapes can be stabilized by intermolecular cross-linking
FIGURE 15-27. Plastic deformation. **A,** Discocytic shape of a red cell at rest in solution. If a nipple of membrane from such a cell is aspirated into a micropipette and released immediately, it snaps back to its original position. However, if the aspirated membrane is deformed for some time, a permanent nipple forms (**B**) as a result of reorganization of the membrane skeleton in the stressed portion of the membrane. This semisolid behavior is called "plastic deformation" and is believed to be responsible for the irregular shape of poikilocytes, especially in diseases such as hereditary pyropoikilocytosis, where skeletal reorganization is fostered by genetically weakened skeletal interconnections. *(From Mohandas N, Chasis JA. Red cell deformability, membrane material properties, and shape: regulation by transmembrane, skeletal, and cytosolic proteins and lipids. Semin Hematol. 1993;30:171-192.)*

of membrane proteins, either as a result of the formation of intermolecular disulfide bridges induced by oxidants or as a result of transamidative protein cross-linking catalyzed by a Ca^{2+}-activated cytosolic transglutaminase.[757] These protein modifications are like endogenous fixatives and permanently stabilize cell shape in vitro.

The Red Cell Surface

The red cell surface is rich in sialic acid residues, which accounts for its negative surface charge. Ninety percent of these residues reside on glycophorin A; the remainder are shared by other glycophorins, the anion exchange protein and other integral proteins, and glycolipids. Alterations in surface charge distribution are deleterious. For example, surface charge clustering may contribute to adhesion of sickle red cells to the surface of endothelial cells.[772] Several proteins are removed from the surface of reticulocytes that participate in cell-cell and cell-matrix interactions during erythroid differentiation.[746,773] One example, $\alpha_4\beta_1$ integrin, interacts with vascular cell adhesion molecule 1 (VCAM-1), an endothelial cell adhesion molecule, and may contribute to attachment of sickle cells to the endothelium.[773]

The structure and genetic origins of red cell surface antigens residing either on glycolipids, on externally exposed portions of transmembrane proteins or their carbohydrate side chains, or on the proteins linked via a GPI anchor are discussed in Chapter 35. Furthermore, as discussed earlier, several surface receptors are involved in attachment of malarial parasites to the cells, including glycophorins, band 3 protein, and the Duffy blood group antigen.

Glycosylphosphatidylinositol-Anchored Surface Proteins. To connect externally exposed hydrophilic proteins with the hydrophobic lipid bilayer, Nature has devised a hydrophobic GPI anchor that is embedded in the outer leaflet of the bilayer. Among the large number of GPI-linked surface proteins, a group of complement regulatory proteins are clinically the most important.[774] Defective biosynthesis of the GPI anchor precludes attachment of these proteins to the membrane and causes increased susceptibility to hemolysis by complement, as clinically manifested by paroxysmal nocturnal hemoglobinuria (see Chapter 14). Because this glycolipid anchor is embedded only in the outer leaflet of the bilayer, GPI-anchored surface proteins, such as CD59, are not restricted by the membrane skeleton, in contrast to most transmembrane proteins, and are much more laterally mobile.[774,775] This high mobility may be important in recruiting complement regulatory proteins to sites of complement activation. These regulatory proteins are preferentially enriched in lipid rafts and in the lipid vesicles that are released from abnormal red cells,[776] such as vesicles derived from spicules of deoxygenated sickle cells. Consequently, GPI-linked proteins are diminished in the densest fraction of sickle cells, thus rendering them more susceptible to complement-mediated injury.[776]

Lateral Mobility of Transmembrane and Surface Proteins. The mobility of membrane surface molecules influences the interaction of red cells with the outside environment. For example, cell agglutination requires rapid lateral movement of surface antigens. Their immobilization (e.g., by glutaraldehyde) inhibits agglutination.[777]

The lateral mobility of proteins that are anchored exclusively in the outer leaflet of the bilayer (e.g., GPI-linked proteins) is very fast. Conversely, transmembrane proteins, such as band 3, are much less mobile. In the case of band 3, the limited mobility occurs because of (1) specific binding to ankyrin and the skeleton; (2) steric hindrance by spectrin strands, which entangle the internal portions of band 3; (3) self-association of band 3 into tetramers and higher oligomers; and (4) interaction of band 3 with other transmembrane proteins, such as the glycophorins and Rh/RhAG complex.[778]

MEMBRANE PERMEABILITY

Normally, the red cell membrane is nearly impermeable to monovalent and divalent cations, thereby maintaining a high potassium, low sodium, and very low calcium content. In contrast, the red cell is highly permeable to water and anions, which are readily exchanged by the water channel and the anion transport protein, respectively. Glucose is taken up by the glucose transporter,[779] whereas larger charged molecules, such as ATP and related compounds, do not cross the normal red cell membrane.

The transport pathways for cations and anions in the human red cell membrane can be divided into five categories (Fig. 15-28):

- Exchangers, such as the Na^+-H^+ exchanger and anion exchanger discussed earlier
- Cotransporters, in which the transmembrane movements of more than one solute are coupled in the same direction (e.g., the K^+-Cl^- cotransporter and the Na^+-K^+-$2Cl^-$ cotransporter)
- The Ca^{2+}-activated K^+ channel (Gárdos channel), discussed later
- The cation "leak" pathways, which allow Na^+ and K^+ to move in the direction of their concentration gradients
- Membrane pumps, such as the ouabain-inhibitable Na^+,K^+ pump and the Ca^{2+} pump

A detailed review of these pathways is beyond the scope of this chapter. Interested readers are referred to several excellent recent reviews that discuss them in the pathophysiology of sickle cell disease.[780,781]

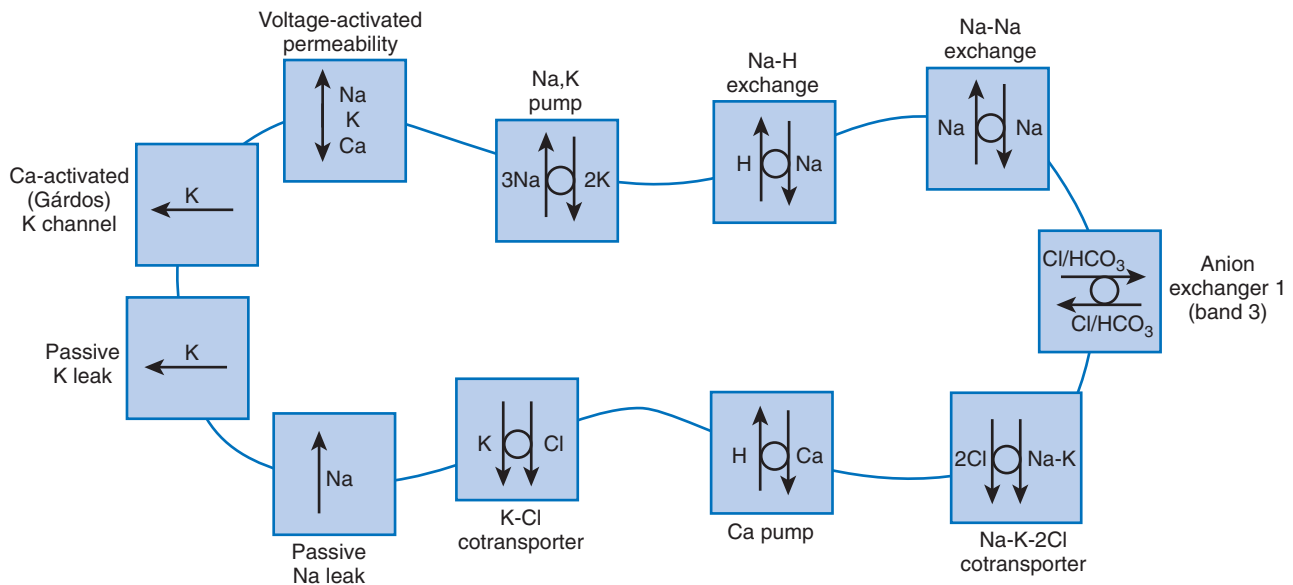
An important feature of a normal red cell is its ability to maintain a constant volume. One of the very intriguing, yet unanswered questions is how cells "sense" changes in cell volume and activate appropriate volume regulatory pathways. One possibility is that they sense mechanical events, such as membrane stretching.[782] Such a mecha-


FIGURE 15-28. Red cell membrane ion transport channels, ion exchange channels, and passive permeability pathways. *(Redrawn from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858, with permission.)*

nism is unlikely to operate in red cells, which by virtue of their large surface area, can undergo a substantial increase in volume without stretching. Another possibility is that cell volume is controlled by the crowding of cytoplasmic macromolecules.[782]

Water Permeability

The water permeability of many cell types is similar to the permeability of pure lipid bilayer membranes, in which water is postulated to enter through small "cavities" in the bilayer.[783] When phospholipids are in the liquid crystalline state, these cavities are thought to be caused by noncooperative rotation and kinking around the C-C bonds.[783] In addition, water permeability may be facilitated by lipids with large polar head groups, such as gangliosides and lysophospholipids, which when dispersed in water, prefer a micellar rather than a bilayer configuration. Additionally, integral proteins are likely to enhance water diffusion by producing localized discontinuities in the lipid bilayer.[783]

The membranes of red cells and some kidney tubules differ from the membranes of most other cells in that they have high water permeability that is endowed by a molecular water channel called AQP1, which has been cloned[380] and had its structure solved[381] (see the earlier section on aquaporin). AQP1 facilitates rehydration of red cells after their shrinkage in the hypertonic environment of the renal medulla.[784]

Transport Pathways Leading to Cellular Dehydration

Two pathways exert a critical volume regulatory effect that can lead to red cell dehydration and destruction

(Fig. 15-29). One is the K^+-Cl^- cotransporter, a typical carrier-mediated cotransport pathway that is particularly active in reticulocytes. It is activated by cell swelling, acidification, depletion of intracellular Mg^{2+}, and thiol oxidation. It is increased in sickle red cells and hemoglobin C erythrocytes, which accounts, in part, for the cellular dehydration of these cells.[785,786]

The second transporter is the Gárdos channel, which causes selective loss of K^+ in response to an increase in intracellular ionized calcium.[735] This channel appears to be regulated by a cytoplasmic protein called calpromotin or peroxiredoxin-2 and by cAMP. The channel is inhibited by insect toxins such as charybdotoxin and by the Ca^{2+} channel blockers nitrendipine and nifedipine. In sickle cells, the combination of the Gárdos pathway and the K^+-Cl^- cotransporter accounts for the net loss of K^+ and water and the subsequent cellular dehydration.[786]

Disruption of the Permeability Barrier in Abnormal Red Cells

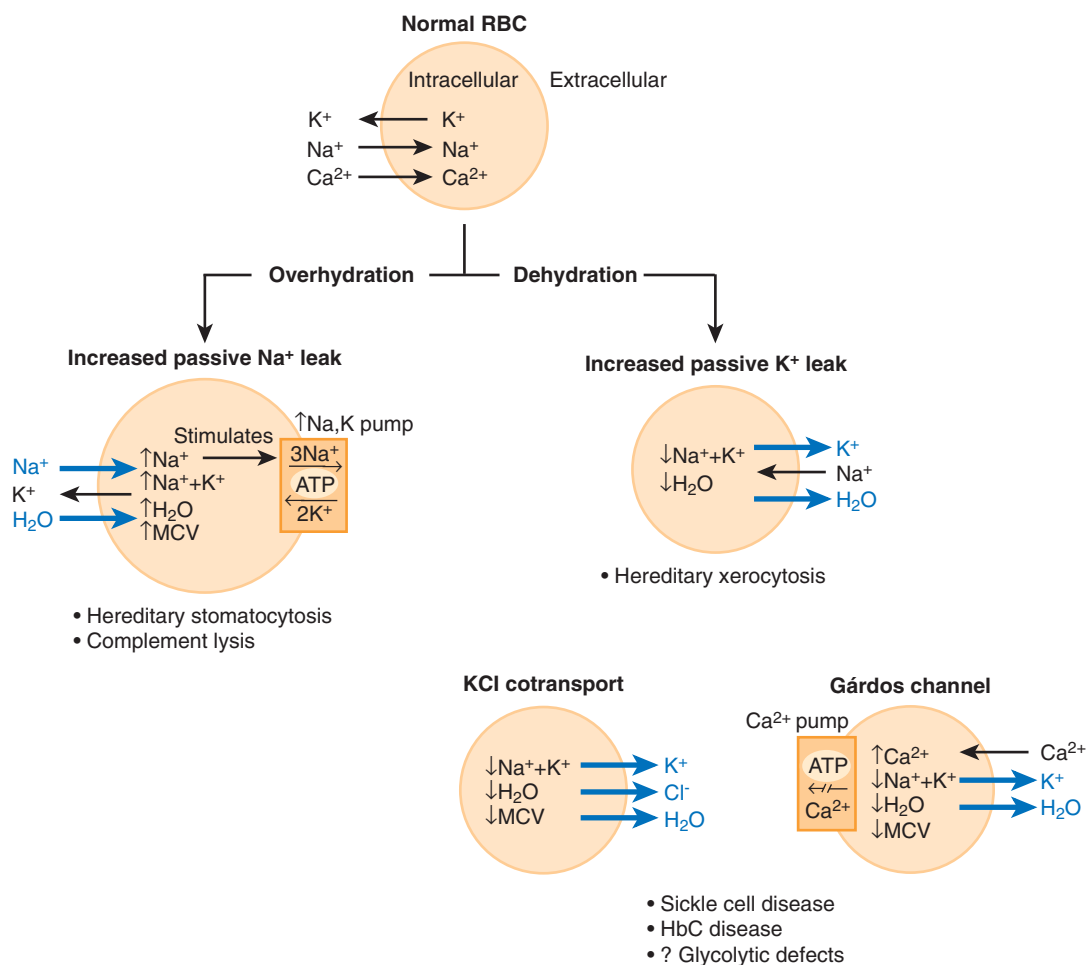
The effects of breaching the red cell permeability barrier are well illustrated by complement hemolysis. Activation of complement on the red cell surface leads to formation of the membrane attack complex, which is composed of the terminal complement components embedded in the lipid bilayer. This multimolecular complex acts as a cation channel and allows passive movement of sodium, potassium, and calcium across the membrane according to their concentration gradients. Attracted by fixed anions such as hemoglobin, ATP, and 2,3-DPG, sodium accumulates in the cells in excess of potassium loss and in excess of the compensatory efforts of the Na^+,K^+ pump (see later). The resulting increase in intracellular monovalent cations and water is followed by cell swelling


FIGURE 15-29. Cation changes leading to dehydration or overhydration of red cells. *Left*, Overhydration is caused by a massive, unbalanced influx of Na^+ that overwhelms the Na^+,K^+ pump and leads to an increase in total monovalent cations ($Na^+ + K^+$) and cell water. *Right*, Dehydration is caused by excess, unbalanced K^+ leakage or by activation of K^+-losing channels such as the K^+-Cl^- cotransport channel or the Ca^{2+}-activated Gárdos pathway. Dehydration is associated with a decline in total monovalent cations ($Na^+ + K^+$) and cell water. *(Redrawn from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858, with permission.)*

(see Fig. 15-29) and ultimately by colloid osmotic hemolysis.

Another leak pathway has been described in sickle cells. It involves an influx of Na^+ and Ca^{2+} and an efflux of K^+ during deoxygenation and sickling.[785,786] Although the molecular basis of this diffusional pathway is unknown, the magnitude of the Na^+ and K^+ leaks correlates with the degree of morphologic sickling and with lipid bilayer–skeleton uncoupling, thus suggesting that it is caused by mechanical events.[786] This conclusion is further supported by the observation that Ca^{2+} permeability is increased by mechanical stress.[787] The mechanism of activation of these channels is unknown, but one of the possibilities involves deformation of the submembrane skeleton.

Membrane Pumps

To maintain low intracellular concentrations of sodium and calcium and a high potassium concentration, the membrane is endowed with two cation pumps, both of which use intracellular ATP as an energy source. The ouabain-inhibitable Na^+,K^+ pump, extrudes sodium and takes up potassium, with a stoichiometry of $3Na^+$ pumped outward for $2K^+$ pumped inward. This exactly balances the normal passive leaks (Na^+ influx = 1.0 to 2.0 mEq/L RBCs/hr; K^+ efflux = 0.8 to 1.5 mEq/L RBCs/hr). The enzyme is activated by intracellular Na^+ (K_m = 25 mM) and extracellular K^+ (K_m = 2.5 mM).[788] Because plasma K^+ is high enough to saturate the extracellular K^+ site, Na^+ and K^+ transport is primarily regulated by increases in red cell Na^+ concentration, and cell K^+ losses are rectified only if there is a concomitant Na^+ gain to stimulate active transport. Even then the ratio between the inward Na^+ leak and the outward K^+ leak must not be less than the physiologic ratio of 3:2. At lower ratios, the Na^+,K^+ pump, driven by the Na^+ leak and internal Na^+ concentration, will not balance the leaks and will actually exacerbate K^+ loss.[789,790] Consequently, conditions in which K^+ loss approaches or exceeds Na^+ gain lead to irreversible depletion of K^+ and cell dehydration.

The calmodulin-activated, Mg^{2+}-dependent Ca^{2+} pump extrudes Ca^{2+} and maintains a very low intracellular free Ca^{2+} concentration (~20 to 40 nM). It protects red cells from the multiple deleterious effects of Ca^{2+} (echinocytosis, membrane vesiculation, calpain activation, membrane proteolysis, and cell dehydration) described earlier in the chapter.

RED CELL MEMBRANE ALTERATIONS OF SENESCENT RED CELLS

Pleiotropic Effects of Red Cell Aging

Removal of senescent red cells from the circulation is a subject of long-standing interest. As discussed in a comprehensive review of the literature published before 1988,[791] the concept of red cell senescence is based on the results of radioactive labeling of a cohort of reticulocytes and bone marrow erythroblasts. In many species, including humans, the fraction of labeled cells remains constant for a defined period, followed by a rapid decline of radioactivity, thus suggesting that the red cells are removed from the circulation in an age-dependent manner. Many techniques have been used to isolate senescent red cells, including methods based on differences in cell density, osmotic fragility, and cell size (reviewed by Clark[791]). Density separation is most widely used, but the results obtained by this technique must be interpreted with caution. Although red cells exhibit a progressive increase in density as they age in vivo, not all dense red cells are senescent.[791-793]

In addition to in vitro separation techniques, various in vivo animal models have been used to study red cell aging.[791] For example, red cells can be labeled with biotin and then removed at defined times with avidin, which complexes tightly to biotin.[794] The senescent cells defined by these techniques exhibit numerous membrane abnormalities.[791,792,794] Of particular note is the loss of potassium and water, which leads to cell dehydration and increased cell density, and the loss of surface area, presumably caused by gradual release of membrane microvesicles.[791,795] The latter phenomenon is probably caused by constant exposure of red cells to the shearing forces of the microcirculation. In addition, membrane proteins and lipids in old red cells are oxidized, as evidenced by high-molecular-weight aggregates containing hemoglobin, spectrin, and band 3[796] and by adducts of proteins and malonylaldehyde, a product of lipid peroxidation.

In addition to red cell membrane abnormalities, red cell aging is associated with a decline in many red cell enzyme activities.[797] However, the red cell ATP concentration is normal.[791] Likewise, no major abnormalities have been detected in Ca^{2+} transport, and there is no compelling evidence that Ca^{2+} accumulates in senescent cells (reviewed by Clark[791]).

An Autologous Autoantibody Targets Senescent Red Cells for Destruction by Macrophages

Although some of the previously discussed alterations may compromise red cell microcirculatory flow, none is likely to destroy old cells. Kay first showed that senescent red cells have small amounts (a few hundred molecules per cell) of autologous IgG on their surface that target the cells for destruction by macrophages.[798] Recent studies suggest that the senescent autoantibody arises from a distinctive subset of B cells, termed B-1, that express CD5.[799] The nature of the "senescent cell antigen" has been a source of some dispute, but it appears to be aggregated and modified band 3 molecules.[794,800-806] There is some evidence that the epitope resides on the band 3 carbohydrate.[807,808] Band 3 clusters have been visualized by immunofluorescence microscopy and detected by biochemical methods in aged red cells.[801,804] Aggregation probably results from cumulative oxidative damage because similar damage, including the binding of autologous IgG, takes place on oxidized red cells or red cells containing Heinz bodies, a product of oxidative denaturation of hemoglobin.[68,801,804,809,810] The senescent cell antigen is also exposed on red cells infected with *P. falciparum*.[811,812]

It should be noted, however, that intramembrane particles, which are mostly band 3, are not reproducibly clustered in cells that bear senescent IgG.[813] This suggests either that the clustered band 3 molecules are rare enough or in small enough clusters that they were missed by electron microscopy or that other band 3 modifications account for increased binding of autologous IgG. For example, band 3 could be structurally modified by proteolysis or oxidation or by other post-translational modification, or band 3 molecules could be vertically displaced, with new antigenic sites exposed or existing sites rendered more accessible to antibodies.

In addition to targeting senescent red cells for macrophage destruction, band 3 antibodies also trigger deposition of complement on senescent cells,[810,814] which would aid cell removal through CR1 receptors on phagocytes. As noted earlier, this process may be facilitated by loss of GPI-linked complement regulatory proteins such as CD55 and CD59 in exosomes and by microvesiculation as red cells age.

Gradual loss of CD47 may also be important. CD47 molecules are recognized by an inhibitory receptor, signal regulation protein-α, on macrophages.[815] This receptor sends a negative signal that can block the phagocytic response. Old red cells have about 30% less CD47 than young red cells do. Depletion of macrophages in mice results in a decrease in the amount of CD47 on red cells and accumulation of senescent red cells.[815]

Although the role of autologous IgG in the destruction of senescent erythrocytes is widely accepted, two observations suggest that other mechanisms must be

considered. First, blockade of the Fc portion of autologous "senescent" IgG with protein G fails to inhibit red cell phagocytosis.[816] Second, red cell survival is the same in agammaglobulinemic mice as in controls.[816] However, the latter data may not be applicable to humans because removal of mouse red cells from the circulation is random.[791]

Red cells uniquely express the LW blood group antigen, renamed ICAM-4 (or CD242), which interacts with various β_2 integrins, including CD11c/CD18, on macrophages. Antibodies to either component inhibit erythrophagocytosis and removal of senescent red cells, which suggests that this interaction contributes to the process.[817,818]

Altered phospholipid asymmetry might also contribute to removal of senescent erythrocytes. This could occur from damage to the aminophospholipid translocase by products of lipid peroxidation.[819] Disordered phospholipid asymmetry leads to removal of cells by macrophages as discussed earlier (see "Loss of Phospholipid Asymmetry"). Although there is no convincing evidence that senescent red cells expose PS on their surface, this hypothesis is favored by some,[820] presumably because it is a proven mechanism for removing other types of damaged cells.

Other alterations of possible pathologic significance include postsynthetic modification of red cell proteins by nonenzymatic glycosylation[821] or carboxymethylation.[822,823] Glycosylation of membrane proteins, such as hemoglobin (to form hemoglobin A_{1c}), occurs gradually over the life of the cell and is proportional to the glucose concentration. Methylation of membrane proteins occurs primarily in older red cells. Ankyrin and protein 4.1 are the principal substrates.

Transamidation of membrane proteins may also play a role in aging. Aged red cells from mice lacking transglutaminase-2 are more osmotically resistant than aged normal red cells,[824] thus suggesting that the knockout red cells lose less membrane surface as they age. Transglutaminase-2 catalyzes the formation of peptide bonds between ε-amino groups on lysine side chains and side-chain carboxyls on aspartic and glutamic acids in the presence of Ca^{2+}.

HEREDITARY SPHEROCYTOSIS

HS (Box 15-1) is a common inherited hemolytic anemia in which defects of spectrin or proteins that participate in the attachment of spectrin to the membrane, ankyrin, protein 4.2, or band 3 lead to spheroidal, osmotically fragile cells that are selectively trapped in the spleen, thereby resulting in a shortened red cell life span.

History

HS was first recognized about 140 years ago by two Belgian physicians, Vanlair and Masius,[825] who gave a remarkably thorough account of the disease. They

described a woman who suffered from the clinical symptoms now known as the hallmarks of HS—anemia, jaundice, splenomegaly, and recurrent abdominal pain. The authors noted that most of the woman's red cells were spherical and hypothesized that a combination of splenic enlargement and liver atrophy led to their rapid destruction and the patient's anemia. They also noted that the patient's sister had suffered from an identical illness. In the 1890s, the British physicians Wilson and Stanley recognized the hereditary nature of the disease and were the first to identify the characteristic pathologic appearance of the spleen engorged with red cells.[826,827] Subsequently, a report by Minkowski in 1900 in the German literature[828] received wide attention, and many additional papers soon appeared, including Chauffard's classic description of osmotic fragility[829] and reticulocytosis[830] as hallmark laboratory features of the disease. The first successful splenectomy for HS was unintentionally performed by Wells in England 20 years before splenectomy became widely accepted[831] and 3 years before Wilson's description of HS. While operating on a jaundiced woman for a supposed uterine fibroid, Wells encountered and removed an enormous spleen. The patient recovered and her jaundice disappeared. Forty years after Wells' splenectomy, Dawson[831] found abnormal erythrocyte osmotic fragility (OF) during an examination of the woman and her son. Thus, the major clinical features of HS were defined by the 1920s, although nothing was known about the pathophysiology of the disease. Readers interested in more details about these and other aspects of the history of HS should consult the chapters by Dacie, Crosby, and Wintrobe in *Blood, Pure and Eloquent*.[832]

Prevalence and Genetics

HS occurs in all racial and ethnic groups. It is particularly common in northern Europeans, in whom approximately 1 in 5000 persons is affected.[833] This is probably an underestimate inasmuch as surveys of red cell OF suggest that mild forms of the disease may be four or five times more common than believed.[834-836] There are no good

estimates of the prevalence in other populations, but clinical experience suggests that it is less common in African Americans and Southeast Asians.

HS exhibits both dominant and nondominant phenotypes. About 75% of patients have typical autosomal dominant disease,[833,837,838] with the remaining 25% exhibiting nondominant inheritance.[839-845] Homozygotes for dominant HS are rare, occurring at an estimated frequency of once in 100 million births, with only two reported cases in the literature.[838,846] In about half of the patients with nondominant disease, HS is due to de novo autosomal dominant mutations, which tend to occur at CpG dinucleotides and are associated with small insertions or deletions.[839,840] In the remaining patients with nondominant inheritance, both parents are clinically normal but may exhibit subtle laboratory abnormalities that suggest a carrier state.[837,840,845] These patients probably have an autosomal recessive form of the disease, although it is not always possible to exclude dominant HS with reduced penetrance or dominant HS caused by a new mutation.[837]

HS is caused by unique familial mutations in different chromosomes at loci involving the membrane skeletal proteins. The mutations that cause HS are consistent within families but vary between almost every family. The first two genetic loci for HS that were described were a deletion of chromosome 8p11.1-p21.2, which eliminated the gene for ankyrin,[847,848] and a deletion of chromosome 14q23-q24.2, which eliminated the gene for β-spectrin.[849] Other loci have since been described in the genes for α-spectrin, band 3, and protein 4.2. Because most mutations are unique within each family, it is rarely clinically useful to determine the specific molecular defect in patients with HS. Readers who are interested in tables listing each mutation reported to cause HS should consult a related chapter by one of the authors (S.E.L.).[850]

Clinical Features

Silent Carrier State

The parents of patients with "nondominant" HS are clinically asymptomatic and do not have anemia, splenomegaly, hyperbilirubinemia, or spherocytosis on peripheral blood smears.[845] However, most do have subtle laboratory signs of HS, including slight reticulocytosis (average, 2.1% ± 0.8%), diminished haptoglobin levels, slightly elevated OF, or slightly shortened times in the acidified glycerol lysis test (AGLT). The incubated OF test is probably the most sensitive measure of this condition, particularly the 100% lysis point, which is significantly elevated in carriers (0.43 ± 0.05 g NaCl/dL) in comparison to normal subjects (0.23 ± 0.07 g NaCl/dL).[837] However, no single test is sufficient. Carriers can be detected reliably only by considering the results of a battery of tests. From the incidence of autosomal recessive HS (1 in 40,000; that is, ≈12.5% of all occurrences of HS, the frequency of which is 1 in 5000 in the United States),[833] one can estimate that roughly 1% of

the population should be silent carriers. Interestingly, screening of normal Norwegian[836] or German[837] blood donors with an OF test or AGLT shows a 0.9% to 1.1% incidence of previously unsuspected "very mild" HS. Presumably, most of these individuals are silent carriers.

Typical Hereditary Spherocytosis

The typical clinical picture of HS combines evidence of hemolysis (anemia, jaundice, reticulocytosis, gallstones,

*Values in untransfused patients.

†By definition, patients with severe spherocytosis are transfusion dependent.

‡Spectrin content is relevant only for patients with spectrin or ankyrin defects. Patients with hereditary spherocytosis who lack band 3 or protein 4.2 have mild to moderate spherocytosis with normal or nearly normal amounts of spectrin and ankyrin. Normal spectrin content is 245 ± 27 (SD) $\times 10^5$ spectrin dimers per erythrocyte.

Adapted from Eber SW, Armbrust R, Schröter W. Variable clinical severity of hereditary spherocytosis: relation to erythrocytic spectrin concentration, osmotic fragility and autohemolysis. J Pediatr. 1990;177:409.

and splenomegaly) with spherocytosis (spherocytes on a peripheral blood smear and positive OF test or AGLT results) and a positive family history (Box 15-2; Fig. 15-30). Mild, moderate, and severe forms of HS have been defined according to differences in hemoglobin and bilirubin concentrations and the reticulocyte count (Table 15-4).[837,851]

HS is typically diagnosed in infancy or childhood, but it may occur at any age.[852] In children, anemia is the most common initial finding (50%), followed by splenomegaly, jaundice, or a positive family history.[853] No comparable data exist for adults. The majority of patients with HS have incompletely compensated hemolysis and mild to moderate anemia. The anemia is often asymptomatic except for fatigue and mild pallor or, in children, non-specific parental complaints such as irritability. Jaundice is seen at some time in about half of the patients, usually in association with viral infections. When jaundice is present, it is acholuric (i.e., unconjugated [indirect] hyperbilirubinemia without detectable direct bilirubinuria). Palpable splenomegaly is detectable in about half of infants and most (75% to 95%) older children and adults.[853-855] Typically, the spleen is modestly enlarged (2 to 6 cm below the costal margin), but it may be massive.[856,857] There is no proven correlation between the size of the spleen and the severity of HS, although given the pathophysiology and response of the disease to splenectomy, such a correlation probably exists.

Typical HS is associated with both dominant and nondominant inheritance. In many patients the nondominant disease is more severe, but there is considerable overlap.[837,839,845] Clinical severity and the response to splenectomy roughly parallel the degree of spectrin (or ankyrin) deficiency in patients with defects in either protein.[837,845,851,858,859] It is not known whether analogous correlations are true for patients with other HS-related mutations.

Mild Hereditary Spherocytosis

Red cell production and destruction are balanced or nearly balanced in 20% to 30% of patients with HS.[854,860] These persons are considered to have "compensated hemolysis" and are usually asymptomatic. In some patients, diagnosis may be difficult because the hemolysis, splenomegaly, and spherocytosis are unusually mild. In this group of patients, reticulocyte counts are generally less than 6%, and only 60% of patients have significant spherocytosis on peripheral blood smears.[837] In addition, red cell spectrin and ankyrin levels are typically greater than 80% of normal.[837]

Hemolysis may become severe with illnesses that cause splenomegaly, such as infectious mononucleosis.[861] Hemolysis may also be exacerbated by pregnancy[862,863] or exercise,[863] to the point where it may impair athletic performance in endurance sports. In many of these patients, HS is diagnosed during family studies or discovered when splenomegaly or gallstones are diagnosed in adult patients. Although mild HS is usually familial, it develops sporadically in families with more severe disease.[864] Presumably, this is due to the coinheritance of modifying genes, such as those affecting spectrin or ankyrin synthesis or splenic function.

It is unclear why patients with HS and compensated hemolysis, with normal hemoglobin levels, continue to have erythroid hyperplasia. It is difficult to reconcile this phenomenon with the generally accepted theory that erythropoiesis is regulated by tissue hypoxia. One possibility is that the erythroid hyperplasia is caused by the concentration of 2,3-DPG, which reportedly is low in hereditary spherocytes before splenectomy (although the

P_{50} of blood from HS patients is normal).[865,866] Another possibility is that the dehydrated HS red cells are rheologically impaired and do not perfuse the juxtaglomerular renal vessels (where erythropoietin is produced) normally, even when the hematocrit is normal. Observations that erythropoietin is inappropriately elevated (up to eight times normal) in HS patients supports this hypothesis.[867,868] However, if this hypothesis is correct, erythropoietin production should correlate inversely with red cell deformability in any disorder (e.g., sickle cell anemia, hereditary xerocytosis) regardless of the hemoglobin level.

Moderate and Severe Hereditary Spherocytosis

A small fraction of patients with HS (5% to 10%) have moderately severe to severe anemia. Patients with "moderately severe" disease typically have a hemoglobin value of 6 to 8 g/dL, a reticulocyte count of about 10%, a bilirubin level of 2 to 3 mg/dL, and 40% to 80% of the normal red cell spectrin content. This category includes patients with both dominant and recessive HS and a variety of molecular defects.

Patients with "severe" disease, by definition, have life-threatening anemia and are transfusion dependent (see Table 15-4). They almost always have recessive HS. Most of these patients probably have isolated, severe spectrin deficiency (<40% of normal), which is thought to be due to a defect in α-spectrin.[869] Some may have ankyrin defects.[870] Patients with severe HS are also distinguished by red cell morphology. They often have some irregularly contoured or budding spherocytes and bizarre poikilocytes, in addition to typical spherocytes.[870,871] Such cells are rare before splenectomy in patients with moderately severe disease, although some may be seen after splenectomy. In addition to the risks associated with recurrent transfusions, patients with "severe" disease frequently experience aplastic crises and may exhibit growth retardation, delayed sexual maturation, or aspects of thalassemic facies.[856,857,871]

Hereditary Spherocytosis in Pregnancy

In general, unsplenectomized patients with HS have no significant complications during pregnancy except for anemia, which worsens as a result of plasma volume expansion[872] and sometimes because of increased hemolysis.[862,863] Hemolytic crises during pregnancy requiring transfusion have been reported.[863] Folic acid deficiency is also a risk.[873,874] One group reported that 20% of patients with HS received transfusions during pregnancy,[863] but in our experience, pregnant patients with HS rarely need transfusions.

Hereditary Spherocytosis in Neonates

HS is often manifested as jaundice in the first few days of life.[875-877] Perhaps as many as half of all patients with HS have a history of neonatal jaundice,[878] and 91% of infants discovered to have HS in the first week of life are jaundiced (bilirubin level > 10 mg/dL).[876] In a French study population of 402 jaundiced neonates requiring phototherapy, 1% were found to have HS.[879] Hyperbilirubinemia usually appears in the first 2 days of life, and bilirubin levels may rise rapidly,[875,877,878] driven by the combination of hemolysis and the reduced capacity of the neonatal liver to conjugate bilirubin. Newborns with both HS and the trait for Gilbert's syndrome, a common polymorphism in the promoter region of the uridine diphosphate–glucuronosyltransferase gene (*UGT1A1*), often have hyperbilirubinemia.[880] Homozygosity for the Gilbert syndrome polymorphism may aggravate neonatal anemia in HS.[881] Kernicterus is a risk[875]; thus, exchange transfusions are sometimes necessary, but in most patients, the jaundice is controlled with phototherapy.

Only 43% of neonates with HS are anemic at birth (hemoglobin level < 15 g/dL), and severe anemia is rare.[876] Most patients have normal hemoglobin levels at birth, which then decrease sharply over the first 3 weeks of life and lead to a transient, severe anemia.[882] In up to three fourths of infants, the anemia is severe enough to warrant transfusion or treatment with erythropoietin (see later). This anemia appears to be aggravated by an inability of the infant's red cells to mount an appropriate erythropoietic response to anemia and to the development of splenic function. Most infants will outgrow the need for transfusion by the end of the first year of life.[882]

Hydrops fetalis has been reported in a few rare patients and is associated with homozygosity or compound heterozygosity for spectrin or band 3 defects.[841,846,883] If hydrops fetalis is detected in utero, these infants may require intrauterine transfusions. No instances of hydrops fetalis have been associated with ankyrin deficiency. It is possible that infants with ankyrin defects, similar to ankyrin-deficient *nb/nb* mice,[884,885] are partially protected in utero by the expression of ankyrin-related proteins in embryonic and fetal erythroblasts.

The diagnosis of HS is sometimes more difficult in the neonatal period than later in life. Splenomegaly is uncommon; at most the spleen tip is palpable, and reticulocytosis is variable and not usually severe.[877,878] Only 35% of affected neonates have a reticulocyte count greater than 10%.[876] In addition, the haptoglobin level is not a reliable indicator of hemolysis during the first few months of life.[886] An even greater problem is that 33% of neonates with HS do not have significant numbers of spherocytes on their peripheral blood smears.[876] Moreover, because fetal red cells are more osmotically resistant than adult cells when fresh, and more osmotically sensitive after incubation at 37° C for 24 hours,[876,887] the OF test occasionally gives false-positive (incubated) or false-negative (unincubated) results unless fetal controls are used. Fortunately, these results have been published,[876] and they appear to reliably differentiate neonates with HS, particularly when the incubated OF test is used.[876-878] However, in our experience it is rarely necessary to use fetal controls. The standard OF test suffices to make the diagnosis in conjunction with the blood

smear, Coombs test, and other data. Studying erythrocytes from the parents is also very useful in the diagnosis of HS, particularly if the infant has received a transfusion.[888]

No evidence exists that patients with HS who show symptoms as neonates have a more severe form of the disease. However, some neonates with HS have trouble "getting their bone marrows started" (i.e., generating an appropriate erythropoietic response to their hemolysis) and become progressively more anemic and require transfusion. The reason for this is unknown. In our experience it is more common after an exchange transfusion, but it also occurs in untransfused infants. Fortunately, the problem is transient, except in rare patients with severe HS, and usually remits after one or two transfusions. If the child is otherwise well, we allow the hemoglobin level to fall to 5.5 to 6.5 g/dL before giving transfusions to try to stimulate the marrow and only raise the hemoglobin level to 9 to 11 g/dL after transfusion to avoid suppressing the desired marrow response. After the bone marrow responds, the course of the disease depends on the equilibrium between rates of red cell production and destruction.

Administration of recombinant human erythropoietin (rHuEPO) to infants with HS and relative erythroid hypoplasia was shown to be beneficial in reducing blood transfusions in an uncontrolled, open label study.[889] In this study, 13 of 16 infants given 1000 IU rHuEPO per kilogram by weekly subcutaneous injection had increases in their absolute reticulocyte count and hemoglobin values. The infants were given the same dose of rHuEPO weekly based on their initial weight (at a range of initial ages from 16 to 119 days), a weekly hemoglobin level of less than 8 g/dL, and an absolute reticulocyte count of 200×10^9/L or less. More recent studies have shown similar effectiveness with different doses and different frequencies.[890] Therefore, erythropoietin therapy in infants with HS has become more standard, although weekly erythropoietin injections can be challenging for parents. Nevertheless, further studies of recombinant erythropoietin therapy for neonatal anemia in HS and a poor retic response are needed to determine the optimal time to initiate treatment, the optimal dose, and the duration of therapy.

Close observation of infants with HS is necessary to avoid complications of severe anemia. All infants with HS should have hemoglobin and reticulocyte measurements every 1 to 2 months during the first 6 months of life. In the second 6 months of life, these intervals may be increased to every 2 to 3 months. In the second year of life, blood cell counts can be measured every 4 months. Infants with more severe disease must be observed carefully to avoid unnecessary side effects of severe anemia.

Etiology: Membrane Protein Defects

The primary molecular defects in HS reside in membrane skeleton proteins, particularly the proteins whose vertical interactions connect the membrane skeleton to the lipid bilayer: spectrin, ankyrin, protein 4.2, and band 3 (see Fig. 15-6). Red cells from the majority of European and American patients with HS, both the dominant and nondominant forms, have deficiencies of spectrin and ankyrin.[845,851,871,891] The degree of spectrin deficiency (and by deduction ankyrin deficiency) correlates well with the spheroidicity of HS red cells, the severity of hemolysis, and the response of patients to splenectomy (Fig. 15-31A).[837,845,892] The mechanical properties of the cells, particularly their ability to withstand shear stress, also correlate with their spectrin content (see Fig. 15-31B).[892,893] Microscopically, HS red

cells show fewer spectrin filaments interconnecting spectrin-actin–protein 4.1 junctional complexes, but overall skeletal architecture is preserved,[894] except in the most severe forms of the disease. A minority of European and American patients with HS have deficiencies of band 3 and protein 4.2 (dominant HS) or protein 4.2 alone (recessive HS).[839,891,895-899] In contrast, these are the most common forms of HS in Japan.[900] In Korean patients, ankyrin and spectrin deficiency is most commonly observed, but protein 4.2 deficiency occurs more commonly than in European or American patients.[901]

α-Spectrin Defects: Recessive Hereditary Spherocytosis

In humans, α-spectrin synthesis exceeds β-spectrin synthesis by 3 or 4 to 1.[902] Heterozygotes for α-spectrin synthetic defects produce enough normal α-spectrin chains to pair with all or nearly all of the β chains that are made. Thus, α-spectrin defects are apparent only in the homozygous or compound heterozygous state and are therefore associated with recessive inheritance. An estimated 5% or less of patients with HS are affected by α-spectrin mutations. In affected patients, the clinical manifestations are often severe, and most patients are transfusion dependent.[845,858,871] The characteristics of HS secondary to α-spectrin deficiency are listed in Box 15-3.

Patients who are homozygotes or compound heterozygotes for α-spectrin defects that produce a 50% to 75% deficiency in spectrin suffer from severe HS. In a report of lethal HS associated with dramatic spectrin deficiency (26% of normal), pulse-labeling studies of BFU-E–derived erythroblasts revealed a marked decrease in α-spectrin synthesis.[841] Although the underlying molecular basis of this defect is unknown, a family history of mild, dominantly inherited HS in the mother and slightly increased OF in the hematologically normal father suggests that the proband inherited at least two genetic defects, which in a simple heterozygote would have minimal adverse consequences. Wichterle and co-authors[903] described a patient with severe HS who was a compound heterozygote for two different α-spectrin gene defects: in one allele there was a splicing defect associated with an upstream intronic mutation, α[LEPRA]; in the other allele there was another mutation, α[PRAGUE] (Fig. 15-32).

The α[LEPRA] allele, a common defect in those with α-spectrin mutations, produces six times less of the correctly spliced α-spectrin transcript than the normal allele does. In many patients with nondominant HS and spectrin deficiency, α[LEPRA] is in linkage dysequilibrium with α[Bug Hill], which contains an amino acid substitution in the αII domain in the same spectrin molecule.[845,858,869,871] It appears that the combination of the α[LEPRA] or α[LEPRA] + α[Bug Hill] alleles with other defects in α-spectrin in *trans* leads to significant spectrin-deficient spherocytic anemia. Interestingly, even in the most severe forms of α-spectrin–linked recessive HS, obligate heterozygotes show little or no spectrin deficiency.[845,858,871]

β-Spectrin Defects: Dominant Hereditary Spherocytosis

Deficiency of the limiting β-spectrin chains restricts the formation of αβ-spectrin heterodimers. Thus, defects in β-spectrin, which affect 15% to 30% of those with HS, are apparent in the heterozygous state and associated with dominant inheritance. The characteristics of HS secondary to β-spectrin deficiency are listed in Box 15-4.

Cloning of the β-spectrin gene, a large gene spanning more than 200 kb, preceded the identification of heterozygous point mutations in a number of unrelated families with dominant HS. Mutations described in β-spectrin have included initiation codon disruptions,[904] frameshift and nonsense mutations, gene deletions, and splicing

defects (Fig. 15-33). The following examples of β-spectrin defects are caused by these unique mutations. Spectrin[Kissimmee] is an unstable β-spectrin that lacks the ability to bind protein 4.1 and, as a consequence, binds poorly to actin.[905-907] This variant is due to a point mutation, Trp202→Arg, in a conserved region near the NH$_2$-terminal of β-spectrin, which forms part of the distal (CH2) protein 4.1 binding site.[905] Truncated β-spectrin

mutations caused by a large genomic deletion that leads to skipping of exons 22 and 23, β-spectrin[Durham], or to splicing mutations, β-spectrin[Winston-Salem] and β-spectrin[Guemene-Penfao], have also been described.[908-910] Moreover, screening of the β-spectrin gene in patients with HS and spectrin deficiency has identified a number of nonsense and frameshift mutations.[911-913] One of these, spectrin[Houston], a frameshift mutation caused by a single nucleotide deletion, was found in patients from several unrelated kindreds[911] and may be a relatively common β-spectrin mutation associated with dominant HS.

Patients with HS caused by β-spectrin mutations have mild to moderate hemolysis and anemia. Interestingly, in HS patients in whom peripheral blood morphology has been described, those with β-spectrin mutations have had a small population (5% to 10%) of acanthocytes or spiculated spherocytes, as well as spherocytes.

Ankyrin Defects

Spectrin heterodimers are stable only when bound to the membrane,[914] and ankyrin, the high-affinity binding site, is normally present in limited amounts. As a result,

Recessive mutations are missense and promoter defects: the −108T→C promoter mutation is common

Both spectrin and ankyrin equally deficient: 15% to 50% deficiency

Mild to moderately severe anemia

Blood smear with spherocytosis and no other abnormal morphology

ankyrin defects are typically expressed as a dominant defect, although recessive mutations have been described. The characteristics of HS caused by ankyrin defects are listed in Box 15-5.

Evidence implicating defects of ankyrin in patients with HS comes from a variety of sources, including biochemical analysis, genetic studies, and study of a murine model of HS. The initial biochemical studies suggested an ankyrin defect in two patients with an atypical, unusually severe form of HS characterized by bizarrely shaped microspherocytes and transfusion-dependent anemia.[870] Both red cell spectrin and ankyrin levels were approximately 50% of normal, apparently because of failure of ankyrin synthesis or synthesis of an unstable molecule.[859] Ankyrin mRNA concentrations were also 50% of normal, and pulse-chase studies showed that newly synthesized ankyrin did not accumulate in the cytoplasm and reached only 50% of normal levels on the membrane. In contrast, spectrin mRNA concentrations were normal. However, only 50% of the synthesized spectrin attached to the membrane, presumably because of the lack of ankyrin sites. These results were the initial indication that ankyrin deficiency or dysfunction leads to spectrin deficiency in HS.

Additional studies have provided evidence that ankyrin deficiency is present in the erythrocytes of many patients with typical dominant HS. Savvides and colleagues[891] measured red cell spectrin and ankyrin levels by radioimmunoassay in the erythrocyte membranes of 39 patients from 20 typical kindreds with dominant HS. Values ranged from 40% to 100% of the normal cellular levels of 242,000 ± 20,500 spectrin heterodimers and 124,500 ± 11,000 ankyrin heterodimers. Both spectrin and ankyrin levels were less than the normal range in 75% to 80% of the kindreds. The degree of spectrin and ankyrin deficiency was very similar in 19 of the 20 kindreds studied. Similar data have been observed in other studies.[851,896-898,901,915,916] The finding of concomitant spectrin and ankyrin deficiency is not unexpected. Decreased ankyrin synthesis could lead to decreased assembly of spectrin on the membrane because ankyrin is the principal spectrin binding site.

Initial genetic studies supported the hypothesis that a defect in the ankyrin gene could be associated with HS. Initially, studies of atypical patients with HS and karyotypic abnormalities, including translocations and interstitial deletions, defined a locus for HS at chromosomal segments 8p11.2-21.1.[847,917-920] After the ankyrin gene was cloned, it was localized to this same region, 8p11.2.[847] Fluorescence-based in situ hybridization of lymphocyte metaphase spreads from a patient with HS, mental retardation, and an interstitial deletion of chromosome 8, band p11.1-p21, with an ankyrin genomic probe provided direct evidence that one copy of the erythrocyte ankyrin gene was deleted.[847] The ankyrin content in the patient's red blood cell membranes was reduced by 50%. A similar phenotype has been reported in another patient with an 8p11.1-p21.3 deletion.[848] These results demonstrated that a deficiency of ankyrin secondary to a gene deletion could be a cause of HS.

Genetic studies have now clearly shown that a defect in the ankyrin gene is the most common cause of dominant HS. The linkage between HS and the ankyrin gene was demonstrated in a large family with typical dominant HS by the use of restriction fragment length polymorphisms.[921] Studies of ankyrin cDNA revealed that a third of patients with dominant HS and spectrin and ankyrin deficiencies expressed only one of their two ankyrin alleles in reticulocyte RNA, thus demonstrating reduced ankyrin expression from one, presumably mutant allele.[922] A series of reports then demonstrated the precise defects in the ankyrin gene that cause HS.[923] Analysis of these mutations revealed the following: (1) ankyrin mutations are common and affect patients with both dominant and nondominant HS, (2) mutations that abolish the normal ankyrin product are common in dominant HS (e.g., frameshift and nonsense mutations), and (3) defects upstream of the coding region in the ankyrin gene erythroid promoter are common in nondominant HS.

The most common ankyrin variant in patients with recessive HS is a T→C nucleotide substitution in the ankyrin gene promoter −108 bp from the translation start site. The allele frequency of this variant was found to be 29% in a German HS population and 2% in normal individuals.[923] It has also been associated with nondominant HS with ankyrin deficiency in Italy.[839] The −108 sequence variant is usually in *cis* with a G→A nucleotide substitution 153 bp from the start site.[924] These defects are silent in obligate heterozygotes; therefore, patients with nondominant HS must have a second mutation.[924] Functional defects associated with these promoter mutations have been demonstrated in a transgenic animal model.[925]

Variations in the clinical severity and red cell ankyrin content of similar mutations indicate that other factors modify the expression of the primary ankyrin defects. For example, ankyrin[Marburg] and ankyrin[Einbeck] are frameshift mutations that occur in the NH$_2$-terminal (membrane) domain and do not produce a detectable product in mature red cells. They would be expected to have a

similar phenotype, but patients with ankyrin[Marburg] have moderate to severe HS and moderate ankyrin deficiency (64% of normal), whereas patients with ankyrin[Einbeck] have very mild disease and normal ankyrin levels. Understanding this and similar phenotypic variations will be one of the critical problems in HS research in the next few years.

Ankyrin mutations are estimated to account for 30% to 60% of cases of HS in northern European populations and 5% to 10% of cases of HS in Japanese populations. Peripheral blood smears demonstrate only prominent spherocytosis. Hemolysis can be mild to severe, and patients with recessive mutations typically have a more severe clinical course. The majority of ankyrin mutations are private; that is, each individual kindred has a unique mutation (Fig. 15-34). One frameshift mutation associated with severe dominant HS, ankyrin[Florianopolis], has been identified in patients with HS from three different kin-

dreds with different genetic backgrounds.[926] Analysis of an ankyrin gene polymorphism in these individuals demonstrated that this mutation is found on different ankyrin alleles, thus suggesting that the ankyrin[Florianopolis] mutation has occurred more than once.

Band 3 Defects: Dominant Hereditary Spherocytosis

A primary defect in band 3 is present in approximately 20% to 30% of patients with dominant HS.[927] Erythrocyte membranes from these patients are deficient in band 3 with a concomitant deficiency of protein 4.2.[928] The characteristics of HS caused by band 3 deficiency are listed in Box 15-6.

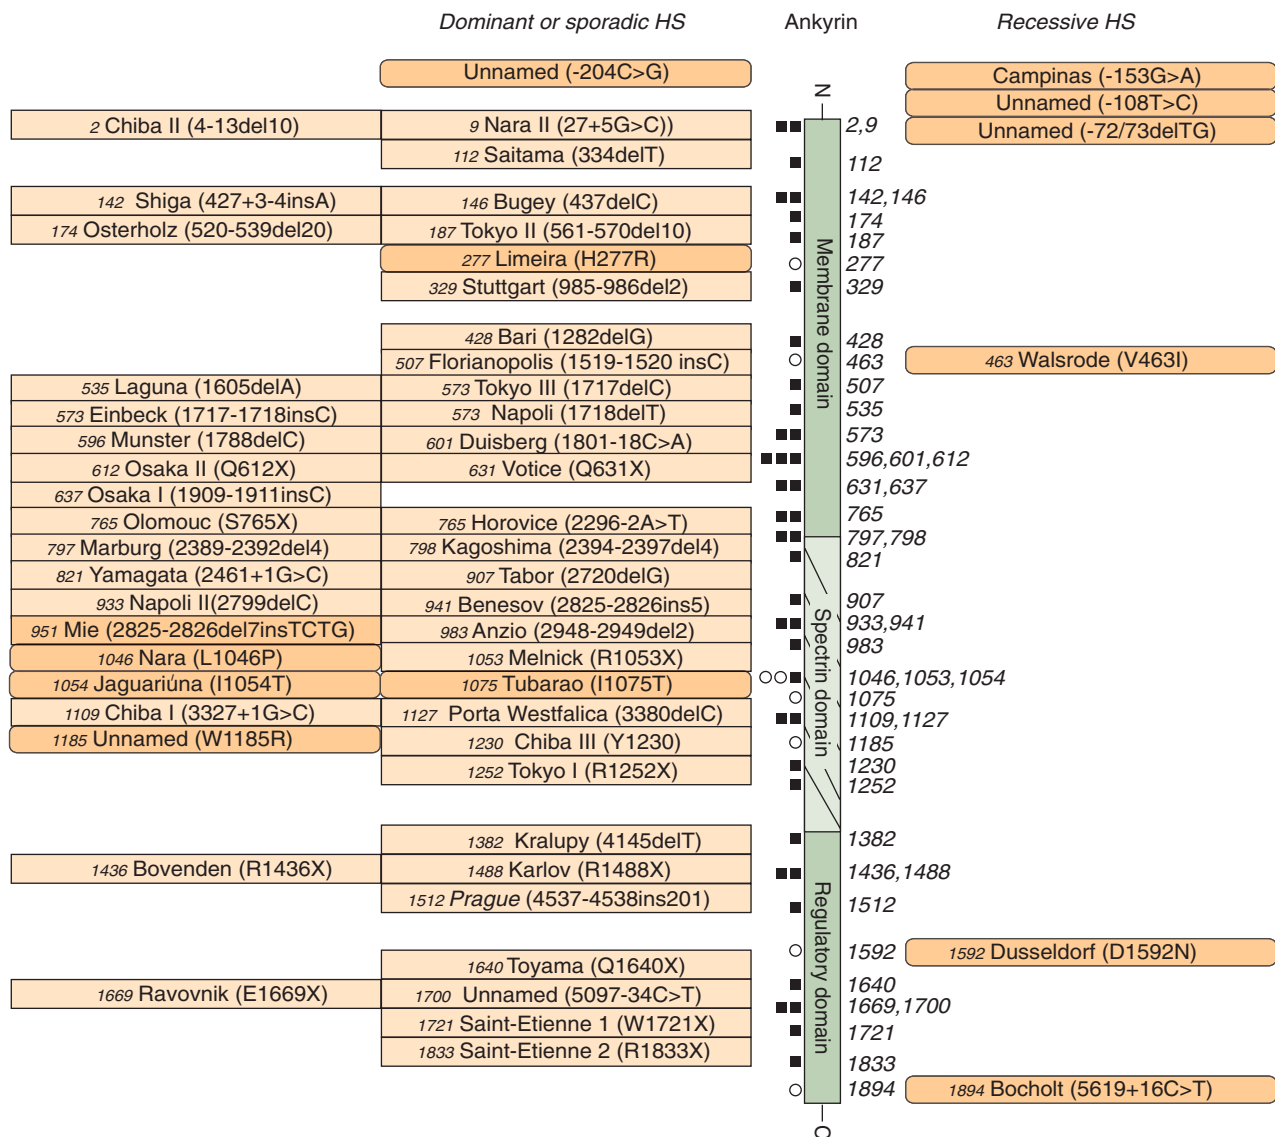
A variety of band 3 mutations have been described, and these mutations are spread out throughout the band 3 gene and occur in both the cytoplasmic and membrane-spanning domains (Fig. 15-35). Band 3 mutations


FIGURE 15-34. Ankyrin mutations associated with hereditary spherocytosis (HS). Null mutations, arising from frameshifts or nonsense mutations, are shown in *light tan rectangles* and *black squares*. Missense and putative promoter mutations are shown in *dark tan rounded rectangles* and *open circles*. (*Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.*)

generally fall into two groups. One group is associated with mild band 3 deficiency and affects protein 4.2 or ankyrin binding. The other group is associated with more severe band 3 deficiency as a result of a mutation that causes mRNA instability or a mutant band 3 protein that

is degraded or not otherwise inserted into the membrane.[928] Similar to the other molecular defects that cause HS, band 3 mutations are unique familial defects with no common mutations among affected groups.

One of the first described band 3 mutants associated with HS was band 3[Prague].[929] This mutant is due to a 10-nucleotide duplication in the band 3 gene that leads to a shift in the reading frame and results in premature chain termination by altering the C-terminal after amino acid 821. The mutation affects the last transmembrane helix and probably alters insertion of band 3 into the membrane because the mutant protein is not detectable in mature red cells.

Conserved arginine residues are frequent sites of mutations in the transmembrane domain of the band 3 gene. Arginine 490 appears to be a particular hot spot for HS-related band 3 mutations.[930,931] The affected argi-

nine residues are located in the same position on the inside edge of most transmembrane proteins and are believed to help orient the membrane-spanning segments. Thus, as predicted, in vitro studies have demonstrated that these arginine substitutions, as well as several other HS-associated band 3 missense mutations, exhibit defective cellular trafficking from the endoplasmic reticulum to the plasma membrane,[932,933] perhaps as a result of misfolding.

Other band 3 mutations causing HS have been described, including nonsense mutations,[923,934] frameshift mutations,[935] partial gene duplications, other missense mutations, and splicing defects.[846,883,936-938] Determination of the crystal structure of the cytoplasmic domain of band 3 is beginning to provide insight into the biologic significance of the missense mutations.[939,940] A few of the HS mutations have been associated with significant protein 4.2 deficiency or with acanthocytosis alone (see later).

Clinically, most patients with band 3 mutations have mild to moderate hemolysis and anemia. The band 3 protein is reduced by 15% to 40% in HS red cells. On average, band 3 defects are somewhat milder than ankyrin or β-spectrin defects, although there is considerable overlap in severity. Patients with HS and band 3 deficiencies have a small number (≤1%) of button, mushroom-shaped, or "pincered" erythrocytes, in addition to spherocytes, on peripheral blood smears. This morphologic characteristic is not observed in the other membrane protein defects.

Because band 3 functions as an anion exchanger and a shortened form of band 3 is expressed in the intercalated cells of the kidney cortical collecting ducts, patients with HS and band 3 deficiency have been examined for a defect in acid-base homeostasis. Patients who are homozygous for band 3 defects, such as band 3[Coimbra],[883] or patients with defects in band 3 mRNA processing, such as band 3[Pribram] or band 3[Campinas],[941,942] have been found to suffer from hemolytic anemia and renal tubular acidosis (RTA). However, the majority of HS patients with mutations in band 3 do not have RTA.[943-946] The lack of RTA in patients with dominant HS and band 3 mutants supports the hypothesis that dominant RTA results from the association of mutant band 3 with wild-type band 3 into hetero-oligomers in the kidney, but not in erythroid cells, thereby leading to intracellular retention or mistargeting of both proteins.[928] It is poorly understood why some residues are critical in the kidney but not in the red cell, with mutations leading to the phenotype of RTA but not HS, or why some residues are critical in the erythrocyte but not the kidney and lead to the phenotype of HS but not RTA. These are important questions to be addressed in future studies.

Protein 4.2 Defects: Recessive Hereditary Spherocytosis

Investigators have described families with recessive HS in which erythrocytes from affected homozygous patients lack protein 4.2. HS caused by protein 4.2 deficiency is most common in Japan, although a few patients have been described in other populations.[895,947,948] The characteristics of this form of HS are summarized in Box 15-7.

The molecular defects causing protein 4.2 deficiency have been described in multiple families (Fig. 15-36). The most common mutation is 4.2[Nippon], in which the red cells contain only a small quantity of a 74/72-kd doublet of protein 4.2 instead of the usual abundant 72-kd species because of an Ala142→Thr mutation that affects processing of protein 4.2 mRNA.[949] Protein 4.2[Nippon]–deficient membranes lose 70% of their ankyrin with low–ionic strength extraction, and the ankyrin loss is blocked by preincubation of the membranes with purified 4.2, which suggests that protein 4.2 stabilizes ankyrin on the membrane.[950,951] This hypothesis is supported by the observation that the amount of protein 4.2 is low in the red cell membranes of ankyrin-deficient *nb/nb* mice and in HS patients who lack one ankyrin gene. In addition, red cells from patients homozygous for 4.2[Nippon] are fragile and have heat-sensitive skeletons, clumped intramembranous particles, and increased lateral mobility of

band 3.[951] However, ankyrin lability is not evident in other patients with protein 4.2 deficiency.[952,953] In addition, erythrocyte protein 4.2 deficiency has also been associated with mutations of band 3.[936,950,954,955] However, it is difficult to assess the significance of these reports because all patients with band 3 deficiency have an equivalent loss of protein 4.2.

Clinically, patients with HS secondary to protein 4.2 deficiency have mild anemia. The peripheral smear sometimes demonstrates typical spherocytosis but more often contains ovalocytes or stomatocytes. The mechanism behind this unique and variable red cell morphology is currently unknown.

Secondary Defects

A large number of secondary abnormalities have been identified over the years. They are catalogued and discussed in detail in previous editions of this chapter.[956]

Tight Binding of Spectrin to the Membrane. Inextractable spectrin was first observed some years ago in 2 of 12 patients with HS, in whom spectrin failed to elute from the membrane after exposure to a low–ionic strength buffer for 72 hours.[957] These are conditions that generally produce greater than 90% spectrin extraction. A third patient was subsequently discovered.[958] The molecular basis of this phenomenon has not been investigated, although the possibility that it might be secondary to a defect in ankyrin or β-spectrin is likely. In addition, some tightly bound spectrin is palmitoylated, and this fraction might be increased.[959]

Increased Membrane Hemoglobin. HS membranes contain increased amounts of hemoglobin and catalase.[960] This relatively nonspecific finding is observed in a number of hemolytic anemias, particularly if red cell dehydration occurs. The molecular basis for finding this is not understood.

Enolase Deficiency. Two reports of apparent HS combined with partial enolase deficiency (~50%) have been published.[961,962] In the first patient, the results of red cell OF and autohemolysis tests were typical for HS, although spherocytes were not apparent on the blood smear. Dominant inheritance was suggested by the history but could not be established. However, dominant inheritance of both HS and partial enolase deficiency was clearly evident in the second family when both diseases could be traced through four generations. In this kindred, the enolase-deficient spherocytes resisted lysis in the acidified glycerol lysis test, another characteristic of typical HS (see later). The similarity of these two patients suggests that they may represent a unique subgroup of HS. In particular, the combination of dominant inheritance and half-normal levels of enolase raises the possibility that the primary defect could lie in an enolase-binding membrane protein, assuming that such a protein exists.

Diminished Membrane Phosphorylation. The discovery that red cell membrane proteins are phosphorylated was followed by numerous reports that phosphorylation was defective in HS. These reports are summarized and analyzed in early editions of this book.[956] Overall, the effects were variable and generally were demonstrable only in ghosts incubated in low–ionic strength buffers for relatively long periods. Initial rates of phosphorylation in HS ghosts were normal,[963-965] as was membrane protein phosphorylation of intact spherocytes from splenectomized individuals.[965] It appears that the phosphorylation defects were probably secondary effects.

Membrane Lipids. The principal lipid abnormality of hereditary spherocytes is symmetrical loss of membrane lipids as part of the overall loss of membrane surface, the hallmark of the pathobiology of HS. The relative proportions of cholesterol and the various phospholipids are normal,[966] and the phospholipids show the usual transmembrane asymmetry, even in severe instances.[867,967] It has been reported that very-long-chain fatty acids are missing from certain classes of phospholipids,[968] but this has not been confirmed.[969] It is unclear whether this difference is due to technical factors or to genetic heterogeneity of the disease. Even if real, it seems likely that the changes in fatty acid composition would be secondary to the underlying membrane protein defects.

Cations and Transport. It has been known for many years that HS red cells are intrinsically more leaky to Na^+ and K^+ ions than normal cells are.[970-972] A similar defect exists in the erythrocytes of *sph/sph* mice with HS.[973] The excessive Na^+ influx activates Na^+,K^+-ATPase and the monovalent cation pump, and the accelerated pumping,[974] in turn, increases ATP turnover and glycolysis. Interestingly, protein 4.2–deficient erythrocytes have increased anion transport, whereas erythrocytes deficient in spectrin, ankyrin, or band 3 have normal or decreased anion transport.[975] At one time it was believed that this modest Na^+ leak was responsible for the hemolysis of hereditary spherocytes,[971] particularly cells trapped in the unfavorable metabolic environment of the spleen, but it is now clear that this is incorrect because the magnitude of the Na^+ flux does not correlate with the extent of hemolysis in HS.[976] In addition, patients with hereditary stomatocytosis (see later) have a much greater defect in Na^+ permeability but microspherocytes do not develop and they sometimes have very little hemolysis. The leakage of Na^+ into red cells in hereditary stomatocytosis is accompanied by the entry of water and cell swelling, a finding that contrasts with the well-established dehydration of hereditary spherocytes.

The dehydration of HS red cells is likely to be inflicted, at least in part, by the adverse environment of the spleen because spherocytes from surgically removed spleens are the most dehydrated.[977] The pathways causing HS red cell dehydration have not been clearly defined. One likely candidate is the Gárdos channel, a Ca^{+2}-

activated K$^+$ channel that is known to mediate erythrocyte dehydration in sickle cell anemia and thalassemia. A recent study examined Gárdos channel activity in mice with erythrocytes devoid of protein 4.1 and showed that the Gárdos channel is functionally upregulated in these erythrocytes and allows more K$^+$ leakage when in a calcium-rich environment.[978] When mouse erythrocytes devoid of protein 4.1 were exposed to clotrimazole, a known Gárdos channel blocker, hemolysis worsened, thus indicating that the Gárdos channel and red cell dehydration protect HS red cells by compensating for the reduced membrane surface area caused by the defective, 4.1-deficient membrane skeleton. Another possible candidate behind the mechanism of cell dehydration is increased K$^+$-Cl$^-$ cotransport, which is activated by acid pH.[979] HS red cells, particularly from unsplenectomized subjects, have a low intracellular pH[865] because of the low pH of the splenic environment (see later). The K$^+$-Cl$^-$ cotransport pathway is also activated by oxidation,[980] which is likely to be inflicted by splenic macrophages. Hyperactivity of the Na$^+$,K$^+$ pump, triggered by increased intracellular Na$^+$, can dehydrate red cells directly because three Na$^+$ ions are extruded in exchange for only two K$^+$ ions.[974] The loss of monovalent cations is accompanied by water. Polymorphisms in the cation channels that decrease K$^+$ loss and red cell dehydration in HS are likely to make the disease worse and are a possible mechanism of clinical variability.

Glycolysis. In general, glycolysis is mildly accelerated in HS red cells,[971,981,982] mostly to support increased cation pumping, and 2,3-DPG concentrations are slightly depressed,[865,866,983] probably because of activation of 2,3-DPG phosphatase by the acidic intracellular pH of the cell. The latter abnormalities are at least partly due to splenic detention because the acidosis and 2,3-DPG deficiency both improve after splenectomy.[865,866]

Phospho*enol*pyruvate Transport. An apparently specific decrease in carrier-mediated transport of phospho*enol*pyruvate has been noted in the red cells of some patients with HS.[984] Unfortunately, only unsplenectomized patients have been studied, so it is possible that the defect is caused by the metabolic derangements that these cells acquire during their detention in the spleen. However, it is more likely caused by diminished anion exchange. Band 3 transports pyruvate and probably phospho*enol*pyruvate. If so, reduced phospho*enol*pyruvate transport would be expected in patients with HS and band 3 deficiency, and indeed, reduced phospho*enol*pyruvate transport has been reported only in the Japanese HS population, in which band 3 deficiency is common.

Pathophysiology

Loss of Membrane Surface by Vesiculation

The primary membrane lesions described earlier, all involving vertical interactions between the skeleton and the bilayer, fit the theory that HS is caused by local disconnection of the skeleton and bilayer, followed by vesiculation of the unsupported surface components. This, in turn, leads to a progressive reduction in membrane surface area and to a shape called a spherocyte, although it usually ranges between a thickened discocyte and a spherostomatocyte.[985] The phospholipid and cholesterol content of isolated spherocytes is decreased by 15% to 20%, consistent with the loss of surface area.[986-989]

Biomechanical measurements show that HS membranes are fragile. The force required to fragment the membrane is diminished and is proportional to the density of spectrin on the membrane.[892,893] Membrane elasticity and bending stiffness are also reduced and are proportional to spectrin density.[990] In addition, HS red cells lose membrane more readily than normal red cells do when metabolically deprived or when their ghosts are subjected to conditions facilitating vesiculation.[989-993] However, this has not been shown to occur in metabolically healthy spherocytes, perhaps because it occurs slowly (1% to 2% per day) under such conditions. Nonetheless, massive vesiculation is evident in mice and zebra fish with severe spherocytic hemolytic anemia (see later).[994-997]

Because budding red cells are rarely observed in typical blood smears from patients with HS, the postulated vesiculation may either involve microscopic vesicles or occur in the reticuloendothelial system. More recent studies suggest that vesiculation may occur in the bone marrow of patients with HS because similar decreases in red cell surface area have been found in reticulocytes in HS as in mature red blood cells.[998] When membrane vesicles are induced in normal red cells, they originate at the tips of spicules, where the lipid bilayer uncouples from the underlying skeleton (see Fig. 15-26).[999] The vesicles are small (about 100 nm) and devoid of hemoglobin and skeletal proteins, so they are invisible during conventional examination of stained blood films. In studies with an atomic force microscope, tiny (50 to 80 nm) bumps have been detected on the surface of red cells obtained from patients with HS whose red cells are actively hemolyzing (Fig. 15-37).[1000] The bumps could be microvesicles, although this needs to be proved with more conventional microscopic techniques. They are less than the length of a spectrin molecule (100 nm) and are not present on red cells from splenectomized patients.

The observation that spectrin or spectrin/ankyrin deficiencies are common in HS has led to the suggestion that they are the primary cause of spherocytosis. According to this hypothesis (Fig. 15-38, hypothesis 1), interactions of spectrin with bilayer lipids or proteins are required to stabilize the membrane. Spectrin-deficient areas would tend to bud off, thereby leading to spherocytosis. However, this conjecture does not explain how spherocytes develop in patients whose red cells are deficient in band 3 or protein 4.2 but have normal amounts of spectrin.[891,950]

An alternative hypothesis argues that the bilayer is stabilized by interactions between lipids and the abun-

Normal

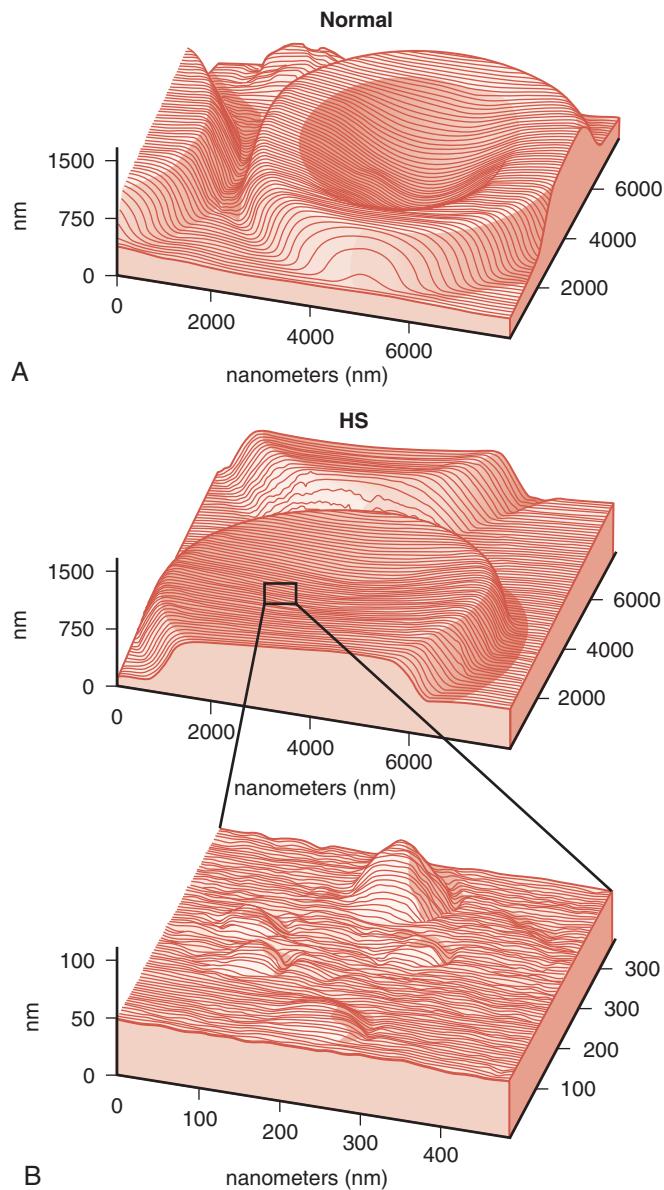
HS


FIGURE 15-37. Comparison of the surface of a normal red cell (**A**) and a hereditary spherocyte (HS) (before splenectomy) (**B**) by atomic force microscopy. Note that at high magnification, 50- to 80-nm pseudopodia are evident on the surface of the spherocyte, which may represent membrane microvesicles (bottom of **B**). These structures were not observed after splenectomy. *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.)*

dant band 3 molecules (see Fig. 15-38, hypothesis 2). Each band 3 molecule contains about 13 hydrophobic transmembrane helices, many of which must interact with lipids. These interactions presumably spread beyond the first layer of lipids and influence the mobility of lipids in successive layers. In deficient red cells, the area between band 3 molecules would increase on average, and the stabilizing effect would diminish. Transient fluctuations in the local density of band 3 could aggravate this situation and allow unsupported lipids to be lost and thus result in spherocytosis. This hypothesis is supported by

targeted disruption of the band 3 gene in mice. Erythrocytes from these mice lose massive amounts of membrane surface despite a normal membrane skeleton.[995] This concept is also consistent with early studies of intramembrane particle aggregation, which leads to particle-free domains, as discussed earlier in the chapter. These domains are unstable and give rise to surface blebs that are subsequently released from the cells as vesicles.[1001]

Spectrin-deficient and ankyrin-deficient red cells could become spherocytic by a similar mechanism. Because spectrin filaments corral band 3 molecules and limit their lateral movement, a decrease in spectrin would allow band 3 molecules to diffuse and cluster transiently, thereby fostering vesiculation. However, it is most likely that both of the aforementioned hypotheses operate to a different degree, depending on the membrane skeletal protein that is deficient—hypothesis 1 dominating in spectrin and ankyrin disorders and hypothesis 2 dominating in band 3 and protein 4.2 defects.

Loss of Cellular Deformability

Hereditary spherocytes hemolyze because of the rheologic consequences of their decreased surface-to-volume ratio. The red cell membrane is very flexible, but it can expand its surface area only about 3% before rupturing.[1002] Thus, erythrocytes become less and less deformable as surface area is lost. For HS red cells, poor deformability is a hindrance only in the spleen because the cells have a nearly normal life span after splenectomy.[1003,1004]

Splenic Sequestration and Conditioning

In the spleen most of the arterial blood empties directly into the splenic cords, a tortuous maze of interconnecting narrow passages formed by reticular cells and lined with phagocytes.[1005-1010] Histologically, this is an "open" circulation, but most of the blood that enters the cords normally travels by fairly direct (i.e., functionally closed) pathways. If passage through these channels is impeded, red cells are diverted deeper into the labyrinthine portions of the cords, where blood flow is slow and the cells may be detained for minutes to hours. Whichever route is taken, to reenter the circulation, red cells must squeeze through spaces between the endothelial cells that form the walls of the venous sinuses (Fig. 15-39). Even when maximally distended, these narrow slits are always much smaller than red cells, which are greatly distorted during their passage.[1007,1008] Experiments have shown that spherocytes are selectively sequestered at this cord-sinus juncture.[1011-1013] As a consequence, spleens from patients with HS have massively congested cords and relatively empty sinuses.[1005,1014-1016] On electron micrographs, few spherocytes are seen in transit through the sinus wall,[1005,1015,1017] which is in contrast to the situation in normal spleens, where cells in transit are readily found.[1009]

During detention in the spleen, HS red cells undergo additional damage marked by further loss of surface area and an increase in cell density. Many of these "condi-

Hypothesis 1:
Hypothesis 2:
FIGURE 15-38. Two hypotheses concerning the mechanism of membrane loss in hereditary spherocytosis. Hypothesis 1 assumes that the "membrane" (i.e., the lipid bilayer and the integral membrane proteins) is directly stabilized by interactions with spectrin or other elements of the membrane skeleton. Because spectrin-deficient areas lack support, they bud off and thereby lead to spherocytosis. Hypothesis 2 assumes that the membrane is stabilized by interactions of band 3 (tan protein) with neighboring lipids. The influence of band 3 extends into the lipid milieu because the first layer of immobilized lipids slows the lipids in the next layer and so on. The partially immobilized lipids are depicted as a darker blue ring around the protein. In band 3–deficient cells, the area between lipid molecules increases, and unsupported lipids are lost. Spectrin-ankyrin deficiency allows band 3 molecules to diffuse and cluster transiently, with the same consequences. *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.)*

tioned" red cells escape the hostile environment of the spleen and reenter the circulation. In unsplenectomized patients with HS, two populations of spherocytes are detectable: a minor population of hyperchromic "microspherocytes" that form the "tail" of very fragile cells in the unincubated OF test and a major population that may be only slightly more spheroidal than normal.

By 1913 it was known that HS red cells obtained from the splenic vein were more osmotically fragile than those in the peripheral circulation.[1018] In addition, this OF was confirmed by other hematologists of the time.[831,1019] However, its significance was not clear until the classic studies in the 1950s by Emerson, Young, and their colleagues, who showed that osmotically fragile microspherocytes are concentrated in and emanate from the splenic pulp (Fig. 15-40).[1013,1020] After splenectomy, spherocytosis persists, but the tail of hyperfragile red cells is no longer evident on OF testing. These and other data led to the conclusion that the spleen detains and "conditions" circulating HS red cells in a way that increases their spheroidicity and hastens their demise.[1013,1021,1022] The kinetics of this process was illustrated in vivo by Griggs and associates, who found that a cohort of ^{59}Fe-

labeled HS red cells gradually shifted from the major, less fragile population to the more fragile, conditioned population 7 to 11 days after their release into the circulation.[1022] Although most conditioned HS red cells that escape the spleen are probably recaptured and destroyed, the damage incurred is sufficient to permit extrasplenic recognition and removal because conditioned spherocytes, isolated from the spleen and reinfused postoperatively, are eliminated rapidly.[1022,1023]

The mechanism of splenic conditioning is less certain. It is difficult to obtain accurate information about the cordal environment, but existing data suggest that it is metabolically inhospitable,[1012,1021,1024,1025] though perhaps less so than originally believed.[1010] Crowded red cells must compete for limited supplies of glucose[1024] in acidic surroundings (pH ≈ 6.6 to 7.2),[1010,1012,1021,1025] where glycolysis is inhibited.[1026,1027] The acidic environment also induces Cl^- and water entry and cell swelling,[1028] but as discussed earlier, it also stimulates the K^+-Cl^- cotransporter, which produces a net loss of K^+ and water from the cells. The adverse effects of the cordal environment are further compounded by the presence of oxidant-producing macrophages. It has also been suggested that
FIGURE 15-39. Scanning electron micrograph of a splenic sinus viewed from within the splenic cords. The narrow transmural slits between the endothelial cells (END) and adventitial cells (ADV) of the sinus are evident. The edges of these slits probably touch each other in a normal spleen, so the openings are potential structures rather than fixed pores. They are revealed here because of a drying artifact. Note that the adjacent erythrocytes (RBC) are considerably larger than the slits and therefore must be flexible to pass into the splenic sinuses and return to the venous circulation. If they are unable to pass into the sinuses, macrophages (MAC) lie in wait. *(From Weiss L. A scanning electron microscopic study of the spleen. Blood. 1974;43:665-691.)*

FIGURE 15-40. Osmotic fragility in hereditary spherocytosis (HS). In the osmotic fragility test, red cells are suspended in salt solutions of varying tonicity between isotonic saline (0.9% NaCl) (*left*) and distilled water (*right*). Normal red cells swell in hypotonic media and eventually reach a limiting spheric shape, beyond which they hemolyze (*bottom*). Spherocytes, which begin with a lower than normal surface-to-volume ratio, can swell less before they reach their limiting volume; hence, their osmotic fragility curve is shifted to the left (higher salt concentrations). They are said to be osmotically fragile. Before splenectomy, a small proportion of the red cells are extra fragile and produce a "tail" on the osmotic fragility curve. The cells have been conditioned by the spleen as shown by their higher concentration in the splenic vein and especially the splenic cords. *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.)*

methylation of erythrocyte membrane proteins could contribute to the splenic conditioning of spectrin-deficient HS red cells.[1029] Hence, the spherocyte, detained in the splenic cords because of its surface deficiency, is stressed by erythrostasis in a metabolically threatening environment.

Erythrostasis

The spherocyte is particularly vulnerable to erythrostasis. This is the basis of the well-known autohemolysis test.[1030] During prolonged sterile incubation in the absence of supplemental glucose, red cells undergo a series of changes that culminate in hemolysis. The sequence of the changes is the same for HS and normal red cells; however, because HS cells are abnormally leaky and bear unstable membranes, their degeneration is accelerated. The importance of the autohemolysis test lies in understanding the pathophysiology and history of HS inasmuch as it is no longer used clinically.

HS red cells are initially jeopardized because their membrane permeability to Na^+ is mildly increased.[970,971] Their propensity to accumulate Na^+ and water is normally balanced by increased Na^+ pumping; however, the increased dependence on glycolysis is detrimental in erythrostasis, where substrate is limited.[971] HS red cells exhaust serum glucose and become ATP depleted more rapidly than normal red cells do. As ATP levels fall, ATP-dependent Na^+,K^+ and Ca^{2+} pumps fail, and the cells gain Na^+ and water and swell. Later, when the Ca^{2+}-dependent K^+ (Gárdos) pathway is activated, K^+ loss predominates

and the cells lose water and shrink. The Na^+ gain is accelerated in HS red cells but is insufficient by itself to induce hemolysis. However, HS red cells are doubly jeopardized. As noted earlier, they are inherently unstable and fragment excessively during metabolic depletion.[989-993] Membrane lipids (and probably integral membrane proteins) are lost at more than twice the normal rate.[991] At first this surface loss is balanced by cell dehydration, but eventually (30 to 48 hours), membrane loss predominates, the cells exceed their critical hemolytic volume, and autohemolysis ensues.

Consequences of Splenic Trapping

Calculations indicate that the average normal red cell passes through the splenic cords about 14,000 times

during its lifetime and has an average transit time of 30 to 40 seconds, surprisingly close to measured transient times in normal human spleens in vivo.[1031] The calculated residence time of the average HS red cell in the splenic cords is much longer, perhaps as long as 15 to 150 minutes, but still far short of the time required for metabolic depletion to occur. This conclusion is supported by direct analysis of splenic red cells. HS red cells obtained from the splenic pulp and containing 80% to 100% conditioned cells are moderately cation depleted and show changes in ADP and 2,3-DPG concentrations consistent with metabolism in an acidic environment, but their ATP levels are normal.[977] Others have reported similar results.[1032,1033]

The data suggest that splenic conditioning is caused by mechanisms other than ATP depletion. For example, K$^+$ loss and membrane instability may be exacerbated by the high concentrations of acids and oxidants that must exist in a spleen filled with activated macrophages lunching on trapped HS red cells. In vitro, oxidants from activated phagocytes can diffuse across the membranes of bystander red cells and damage intracellular proteins within minutes. Red cells moving through the rapid transit pathways in the spleen might escape damage, but those caught in cordal traffic would be vulnerable. Oxidants, even in relatively low concentrations, cause selective K$^+$ loss by a variety of mechanisms[1034-1036] and also damage membrane skeletal proteins.[1037-1043] Finally, there is preliminary evidence that HS red cells may be abnormally sensitive to oxidants.[1044] When exposed to peroxides, they undergo remarkable blebbing and, presumably, vesiculation. If a similar process occurs in the spleen, it could be responsible for the excessive surface loss observed in conditioned cells.

Residence in the spleen may also activate proteolytic enzymes in the red cell membrane. Membrane proteins of red cells from patients with HS and splenomegaly are excessively digested during in vitro incubations, and the degree of proteolysis correlates with splenic size.[1045] Whether this occurs in vivo is uncertain, but if so it could contribute to skeletal weakness and membrane loss.

The possibility that macrophages may directly condition HS red cells should also be considered. It is well known that spherocytosis often results from the interaction of IgG-coated red cells with macrophages, but HS red cells do not have abnormal levels of surface IgG.[1046] Macrophages also bear receptors for oxidized lipids (scavenger receptor) and PS, but there is no evidence at present that HS red cells expose the relevant ligands. The involvement of macrophages is supported by observations that large doses of corticosteroids markedly ameliorate HS in unsplenectomized patients,[1047,1048] similar to the effects produced by splenectomy. Hemoglobin production, reticulocytosis, and the fecal urobilinogen level decline; red cell life span doubles; and hyperspheroidal, conditioned red cells disappear from the circulation. It is well known that similar doses of corticosteroids inhibit splenic processing and destruction of IgG- or C3b-coated red cells in patients with immunohemolytic anemias, probably by suppressing macrophage-induced red cell sphering and phagocytosis.[1049,1050] Electron microscopy shows that splenic erythrophagocytosis is common in HS, particularly in the splenic cords.[1015,1017,1051] In addition, phagocytes expressed from the cords of patients with HS contain bits of ghost-like "debris,"[1052] presumably resulting from membrane fragmentation.

Summary of Pathophysiology

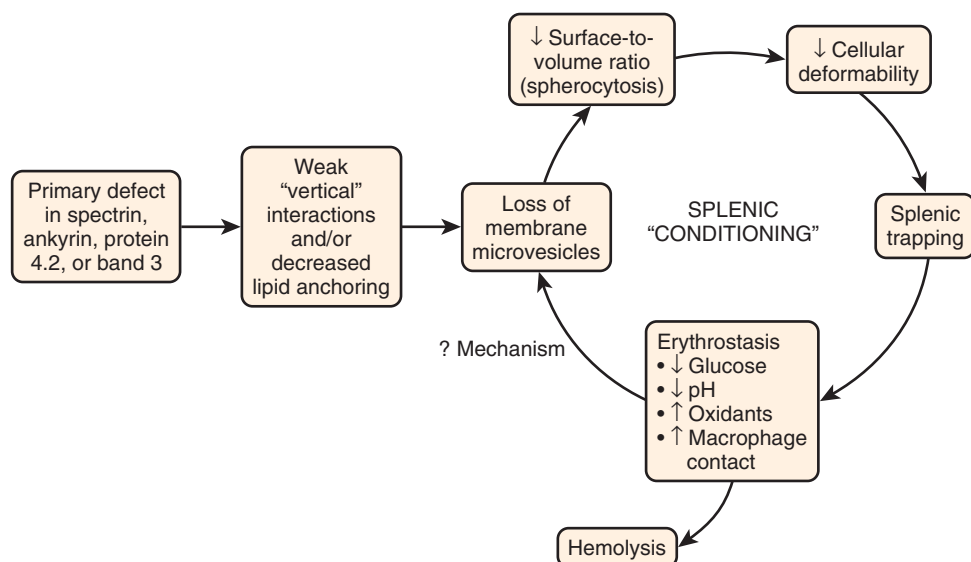
HS red cells are selectively detained by the spleen, which is detrimental and leads to a loss of membrane surface that fosters further splenic trapping and eventual destruction (Fig. 15-41). The primary membrane defects involve deficiencies or defects in spectrin, ankyrin, protein 4.2, or band 3, but much remains to be learned about why these proteins are defective and how this causes surface loss. Obvious membrane budding and fragmentation are


FIGURE 15-41. Pathophysiology of splenic conditioning and destruction of hereditary spherocytosis. (Redrawn from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858, with permission.)

rare in patients with HS. The HS skeleton (including band 3) may not adequately support all regions of the lipid bilayer, thereby leading to the loss of small areas of untethered lipids and integral membrane proteins. It is not clear whether this is due directly to deficiency of spectrin and ankyrin or whether spectrin/ankyrin deficiency operates indirectly by increasing the lateral mobility of band 3 molecules and decreasing their stabilization of the lipid bilayer.

The mechanisms of splenic conditioning and red cell destruction are also uncertain. Kinetic considerations make it unlikely that HS red cells are continuously trapped in the cords for the long periods required to induce passive sphering and autohemolysis by metabolic depletion; however, repetitious accrual of metabolic damage remains a possibility. A unique susceptibility of the HS red cell to the acidic, oxidant-rich environment of the spleen and active intervention of macrophages in the processing of damaged spherocytes must also be considered.

Laboratory Characteristics

Most of the classic laboratory features of HS are those found in other forms of hemolytic anemia, such as reticulocytosis, erythroid hyperplasia of the bone marrow, indirect hyperbilirubinemia, and increased fecal urobilinogens.[853,854,1053] The plasma hemoglobin level is often normal,[1054] and the haptoglobin value is only variably reduced[1055] because most of the hemoglobin that is released when HS red cells are destroyed is catabolized at the site of destruction, so-called extravascular hemolysis. For the same reasons the LDH level is also often normal. The spherocytic morphology distinguishes HS from other forms of hemolytic anemia, along with laboratory tests that measure biophysical properties of the affected red cells, such as the OF test. Biochemical and molecular testing is performed only in research laboratories because these tests are not as clinically useful.

Red Cell Morphology

Spherocytes (see Fig. 15-30) are the hallmark of HS. They are dense, round, and hyperchromic; lack central pallor; and have a decreased mean cell diameter. They are always present in blood smears from patients with moderate or moderately severe HS but are obvious in only 25% to 35% of patients with mild HS.[837,853,854] Hereditary spherocytes are technically misnamed because they range in shape from thickened discocytes to spherostomatocytes when examined under the scanning electron microscope.[985]

In most patients with HS, spherocytes and microspherocytes are the only abnormal cells on the peripheral smear (other than polychromatophils). Rarely, a few stomatospherocytes may be seen. However, specific morphologic abnormalities have been described in association with certain membrane defects in HS (Fig. 15-42). Patients with ankyrin defects and combined ankyrin/
FIGURE 15-42. Red cell morphology in hereditary spherocytosis (HS). **A,** HS caused by an ankyrin defect. Microspherocytes are evident among red cells with some central pallor. **B,** Band 3–deficient HS. Mushroom-shaped ("pincered") red cells (*arrows*) are found in about 80% of patients with this form of HS.[1056] **C,** HS caused by a β-spectrin mutation. Echinocytes and acanthocytes (5% to 15%) are usually observed in addition to typical spherocytes.[906,911] **D,** Severe HS with spherocytes and bizarre poikilocytes. *(From Palek J, Lambert S. Genetics of the red cell membrane. Semin Hematol. 1990;27:290.)*

spectrin deficiency, the most common subgroup, have typical spherocytes and microspherocytes on the peripheral blood smear (see Fig. 15-42A).[923] In addition to spherocytes, acanthocytes or hyperchromic echinocytes are present in many patients with β-spectrin defects (see Fig. 15-42C).[906,911] Other patients with β-spectrin defects, especially truncated β chains, have spherocytic elliptocytosis. In severe HS caused by homozygous α-spectrin mutations, compound heterozygous α-spectrin mutations, or severe ankyrin/spectrin deficiency, misshapen spherocytes, spiculated red cells, and bizarre poikilocytes may be seen and even dominate the blood smear (see Fig. 15-42D). Most patients with band 3–deficient HS have a small number of mushroom-shaped red cells or pincered cells on their peripheral blood smears (see Fig. 15-42B).[1056] Red cell morphology is variable in protein 4.2 deficiency and may even be normal. Acanthopoikilocytes and ovalostomatocytes[1057] have also been observed. Other patients have typical spherocytosis.[950]

In contrast to red cells in autoimmune hemolytic anemia, studies have recently shown that HS red cells lose their surface area in the bone marrow inasmuch as similar decreases in red cell surface area have been found in reticulocytes in HS as in mature red blood cells.[998] HS erythrocytes then gradually lose surface area in the circulation, as is typical with normal erythrocytes. Nucleated red cells are uncommon in blood smears,[853] except in the most severe forms of HS.[871] Howell-Jolly bodies are also uncommon before splenectomy (4% of patients)[853] and suggest reticuloendothelial blockade.

Red Cell Indices

Most patients have mild to moderate HS with mild anemia (hemoglobin level of 9 to 12 g/dL) or no anemia at all (so-called compensated hemolysis). In moderate to severe HS, the hemoglobin concentration ranges from 6 to 9 g/dL. In patients with the most severe disease, the hemoglobin concentration may drop to as low as 4 to 5 g/dL.

The mean corpuscular hemoglobin concentration (MCHC) of HS red cells is increased because of relative cellular dehydration.[854] Spherocyte Na$^+$ concentrations are normal or slightly increased, but the K$^+$ concentration and water content are low, particularly in cells harvested from the splenic pulp.[977,1058-1060] The average MCHC exceeds the upper limit of normal (36%) in about half of the patients with HS, but all patients have some dehydrated cells.[854] An MCHC greater than 35 g/dL has a sensitivity of 70% and a specificity of 86%.[1061] Combining the MCHC with the red cell distribution width (RDW) may lead to a specificity approaching 100%.[1061]

Mean corpuscular volume (MCV) falls within the normal range in HS,[854] except in severe HS, in which the MCV may be slightly low.[871] However, MCV is relatively low for the age of the cells (reticulocytes have a high MCV) in all patients with HS as a result of the dehydrated state of HS red cells. Reticulocyte MCV is also low, which contrasts with the spherocytosis in autoim-

mune hemolytic anemia, in which the reticulocyte indices are normal.

Detection of hyperdense red cells by dual-angle laser scattering is now used as a diagnostic tool.[1062] The Technicon H1 blood counter and its successors (Technicon Corp., Tarrytown, NY), which measure MCV by light scattering, provide a histogram of MCHCs that has been claimed to be accurate enough to identify nearly all patients with HS.[1060,1063,1064] In a sample of HS red cells, there is a right shift of the hemoglobin concentration histogram with a population of hyperdense cells (MCHC > 40 g/dL) because of red cell dehydration and broadening of the volume curve because of the mixture of microspherocytes and large reticulocytes (Fig. 15-43). This simple method may be one of the easiest and most accurate ways to diagnose HS, particularly when one member of a family is already known to have HS and an inexpensive method of screening other family members is desired. Some studies have shown that in HS patients with an intact spleen, the percentage of microcytes reflects the severity of disease and the percentage of hyperdense cells discriminates HS patients from normal individuals.[1065] Similar diagnostic information can be obtained through the use of aperture impedance (Coulter) analyzers.[1061] The elevated MCHC and wide RDW suggests the diagnosis of HS.
FIGURE 15-43. Histogram of the distribution of mean corpuscular volume (MCV) (**A**) and mean corpuscular hemoglobin concentration (MCHC) (**B**) in the red cells of a patient with hereditary spherocytosis before splenectomy. The *vertical lines* mark the normal limits of distribution. For the volume distribution, they separate microcytic (<60 fL) and macrocytic (>120 fL) cells from normocytic red cells (60 to 120 fL). For the hemoglobin concentration distribution, they separate hypochromic (<28 g/dL) and hyperdense (>41 g/dL) cells from normochromic cells (28 to 41 g/dL). The data were collected with a Technicon H1 laser scattering blood counter. Note that the patient with hereditary spherocytosis has subpopulations of microcytes (low MCV) and dehydrated cells (high MCHC). All patients in this study (N = 21) had similar subpopulations. *(Redrawn from Pati AR, Patton WN, Harris RI. The use of the Technicon H1 in the diagnosis of hereditary spherocytosis. Clin Lab Haematol. 1989;11:27-30.)*

Fragility and Autohemolysis Tests

Osmotic Fragility Test. OF testing (see Fig. 15-40) is performed by suspending red cells in increasingly hypotonic buffered NaCl.[1021,1066,1067] In hypotonic solutions, normal erythrocytes are able to increase their volume by swelling until they become spherical and burst, with release of hemoglobin into the supernatant. Cells that begin with a decreased surface-to-volume ratio, such as spherocytes or stomatocytes, reach the spherical limit at a higher NaCl concentration than normal cells do and are termed osmotically fragile. Freshly drawn red cells from approximately a fourth of individuals with HS will have a normal OF, with the OF curve approximating the number of spherocytes seen on the peripheral smear.[855,1068] When the spleen is present, a subpopulation of very fragile erythrocytes that have been conditioned by the spleen form the "tail" of the OF curve. This tail disappears after splenectomy.

The incubated OF test is thought to be more sensitive than the unincubated OF test, although this is not well proven. The incubated OF test is performed the same way as the unincubated test (as earlier) except that the whole blood sample is first incubated for 24 hours at 37° C. During incubation, the HS erythrocytes become metabolically depleted and lose membrane fragments rapidly, which accentuates their spheroidicity and increases the sensitive of the OF test. OF testing, particularly the incubated OF test, is the most sensitive test routinely available for diagnosing HS.[1068] The sensitivity of OF testing is surprising because OF reflects a combination of secondary properties of HS red cells—loss of surface area relative to the loss of K^+ and water—instead of the primary molecular defect in the membrane skeletons. Although HS patients with a negative incubated OF test have been described,[1069] the incubated OF test is the gold standard for the diagnosis of HS.

Acidified Glycerol Lysis Test and Pink Test. The glycerol lysis test, in which glycerol is used to retard the osmotic swelling of red cells, was developed as an alternative to the OF test. In this test, red cells are incubated in glycerol–sodium phosphate–buffered hypotonic saline solution. Glycerol slows the entry of water into cells so that the time for the cells to lyse is prolonged and can be measured accurately. The glycerol lysis time is shortened for HS red cells because of the reduced surface-to-volume ratio.

The original glycerol lysis test lacked sensitivity and specificity.[1070] An acidified version, the AGLT, was more sensitive for some researchers[1069] but was not completely specific.[1071] For unknown reasons, the accuracy of the standard AGLT is greatly improved if the samples are preincubated at room temperature for 24 hours (incubated AGLT).[1072-1074] Under these conditions, the sensitivity and specificity of the test approach 100%, similar to that for the incubated OF test.

Eber and associates[835] found that changing the concentration of the sodium phosphate buffer from 5.3 to 9.3 mmol/L gives 100% sensitivity and specificity without the need for preincubation. The modified test is easy to perform and requires very little blood. Ethylenediaminetetraacetic acid (EDTA)-anticoagulated blood (20 µL) is diluted into a solution of 9.3 mmol/L sodium phosphate and buffered 2 mol/L glycerol-saline (pH 6.90), and the fall in absorbance at 625 nm (largely turbidity) is measured as the red cells hemolyze. The half-time for lysis in the AGLT is longer than 30 minutes for normal samples and less than 5 minutes for HS samples. The simplicity of this test allows it to be used for rapid screening of a large number of blood samples.

Another adaptation of the original glycerol lysis test, called the *Pink test*, is more reproducible and accurate than the original[1075] but requires a 1-day preincubation.[1076] Modifications of the test have made it adaptable to microsize samples (e.g., fingerstick blood samples).[1076,1077] However, direct comparisons suggest that it is less specific than the OF test or incubated AGLT.[1072] Because the modified AGLT has also been adapted to microsamples,[1076,1077] it would appear to be the test of choice if OF testing is not available.

Hypertonic Cryohemolysis Test. This method is based on the fact that HS red cells are particularly sensitive to cooling at 0° C in hypertonic solutions, which causes the cells to lyse and release hemoglobin.[1078,1079] It has been claimed that this test is 94% to 100% sensitive for HS, but its specificity is only 94% for normal individuals and 86% for patients with autoimmune hemolytic anemia. The advantages of this test are its simplicity, high sensitivity, and the ability to use EDTA-preserved blood specimens. The limitations lie in its inadequate specificity, and therefore it is currently rarely used for clinical diagnosis.

Autohemolysis Test. Autohemolysis of erythrocytes after 48 hours at 37° C is normally less than 5% in the absence of glucose or less than 1% in the presence of glucose. Autohemolysis of spherocytes is increased to 15% to 45% in the absence of glucose.[855,1030,1080] In HS, the degree of autohemolysis is reduced by the addition of glucose,[855,1059,1080] whereas in red cell glycolytic disorders and acquired disorders such as immune-mediated anemias, the degree of autohemolysis is not reduced. Although this differentiation may be helpful occasionally, the autohemolysis test is time consuming and cumbersome, gives variable results, and is rarely performed.

Ektacytometry

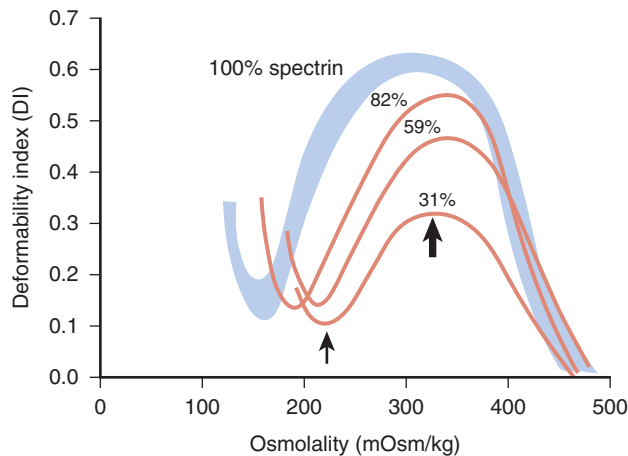
The ektacytometer can be used to assess the surface-to-volume ratio and membrane mechanical strength of red cells in patients with hemolytic disorders.[1081-1083] The ektacytometer is described in detail in the sections on HE and HPP. The best method for demonstrating the low surface-to-volume ratio of hereditary spherocytes is osmotic gradient ektacytometry, a modification of the original technique that is useful in the diagnosis of


FIGURE 15-44. Osmotic gradient ektacytometry of HS erythrocytes with differing degrees of spectrin deficiency. In HS red cells (*brown lines*), the minimum deformability index observed in the hypotonic region (*thin arrow*) is shifted to the right of the control region (*blue shaded area*), thus indicating a decrease in the cell surface area–to-volume ratio. The maximum deformability index (DI_{max}) associated with spectrin-deficient HS red cells (*thick arrow*) is less than that of control cells because of the reduced surface area of HS cells. The more pronounced the spectrin deficiency, the greater the loss of surface area and the lower the DI_{max}. The osmolality in the hyperosmolar region at which the DI reaches half its maximum value is a measure of the hydration state of the red cells. It is decreased in HS patients with the lowest spectrin content, indicative of cellular dehydration. *(Adapted from Tse WT, Lux SE. Hereditary spherocytosis and hereditary elliptocytosis. In Scriver CR, Beaudet AL, Sly WS, Valle D [eds]. The Metabolic and Molecular Bases of Inherited Disease, 8th ed. New York, McGraw-Hill, 2001. p 4665.)*

HS.[1084,1085] In this method, the "deformability index" (a measure of the average elongation of sheared red cells) is measured as a function of the osmolarity of the suspended medium, which is continuously varied (Fig. 15-44). The osmolarity of the suspending medium at which the red cell deformability index reaches a minimum is the same as the osmolarity at which 50% of the red cells hemolyze in an OF test.[1084] This value is an indirect measure of the surface area–to-volume ratio of the red cells.[1085] The maximum deformability index reflects the surface area of the red cells. In HS, the curve is shifted to the right because of the reduced surface area–to-volume ratio of the cells. The height of the curve is also decreased in HS as a result of the decreased absolute surface area of the erythrocytes. One study demonstrated a 100% rate of detection of HS with osmotic gradient ektacytometry and only a 66% rate of detection of HS with the OF test in the same population.[1085] Although this method provides useful diagnostic information, only a few laboratories are equipped with the instrument for this test.

Membrane Protein, RNA, and DNA Measurements

Specialized tests are occasionally used to study patients with complicated disease or those for whom additional information is desired. Useful tests for these purposes include structural and functional studies of erythrocyte membrane proteins, such as protein quantitation, limited tryptic digestion of spectrin, membrane protein synthesis and assembly, or ion transport studies. Membrane fragility may be examined with an ektacytometer.

Membrane protein concentrations are usually assessed with SDS gels. Individual stained bands are quantified by densitometry or by eluting the dye from an excised band and measuring its concentration spectrophotometrically. This technique is satisfactory for detecting spectrin deficiency (expressed as a spectrin-to–band 3 ratio),[851] although it is not as accurate as radioimmunoassay[891] or enzyme-linked immunoassay.[851] With densitometry, spectrin and ankyrin deficiencies may be underestimated because it normalizes them to band 3, which is partially lost along with membrane lipids as spherocytes circulate. As a result, the spectrin-to–band 3 ratio is lower after splenectomy. This is even more true for ankyrin, which is present in smaller amounts and migrates close to β-spectrin on gels. SDS gels do not routinely give reliable results even with a gel system that optimizes spectrin/ankyrin separation.[871] The popular Laemmli gels are unsatisfactory because ankyrin migrates between the spectrin bands in this system. Immunoassays, on the other hand, work well.[851,859] SDS gels are satisfactory for detecting band 3 deficiency (elevated spectrin-to–band 3 ratio) or protein 4.2 deficiency, and they are useful in combination with antibody staining (Western blots) for detecting mutant proteins of altered size. Band 3 can also be quantified by fluorescence, taking advantage of the fact that eosin maleimide reacts exclusively with band 3 on the surface of intact red cells.

However, SDS gels do not always identify the abnormal protein in HS because missense mutations may cause functional defects rather than quantitative defects and because protein deficiencies may be as small as 10%. Therefore, several other approaches have been described in an attempt to define specific molecular defects. In families with multiple affected members, linkage analysis has been performed to include or exclude the candidate genes. In addition, suspected proteins can be sequenced by direct nucleotide sequence analysis of polymerase chain reaction (PCR)-amplified cDNA or genomic DNA. Currently, no commercial laboratories will identify the molecular defects in HS membrane proteins, and therefore these analyses are performed only by a few research laboratories. Nevertheless, the HS membrane protein mutations are mostly defects restricted to specific families and do not predict the severity of the disease, and thus the ability to detect the exact molecular defect is not often clinically important.

Differential Diagnosis

In general, HS is easily diagnosed in patients with the typical laboratory findings of spherocytosis, such as Coombs-negative hemolysis, increased OF, and a positive

family history. However, HS must be differentiated from other causes of spherocytosis, and there are several situations in which diagnosis can be difficult. Other causes of spherocytosis are listed in Box 15-1.

ABO Incompatibility in Neonates. In the neonatal period it may be challenging to differentiate HS from ABO incompatibility.[1086] Anemia, hyperbilirubinemia, circulating microspherocytes, and altered OF are found in both conditions, and results of the direct Coombs test are sometimes negative in ABO incompatibility. However, in most affected infants with ABO incompatibility, anti-A (or anti-B) antibodies can be eluted from the red cells, and free anti-A (or anti-B) IgG antibodies can be detected in the infant's serum.

Immunohemolytic Anemias. Rarely, patients with immunohemolytic anemia and spherocytosis also have so few antibody molecules attached to their red cells that results of the direct Coombs test are negative. In these rare cases, differentiation of the disease from HS is possible only with the use of radioactive antiglobulin reagents, the so-called super-Coombs test.[1087]

Heinz Body Hemolytic Anemias. Spherocytosis is also seen in Heinz body hemolytic anemias during an acute hemolytic crisis and occasionally in the steady state. However, in this situation, bite cells or blister cells (or both) and various dense, irregular cells are always present on the peripheral blood smear, and Heinz bodies can often be detected in red cells supravitally stained with methyl violet.

Aplastic Crises. Diagnostic difficulty may also arise in HS patients who are seen during an aplastic crisis (see later). Early in the crisis, the acute nature of the symptoms may suggest an acquired process, and the absence of reticulocytes may divert the physician from a diagnosis of hemolytic anemia. Later, as marrow function returns, physicians may occasionally be misled by the properties of the emerging young HS red cells, which are less spherocytic and osmotically fragile than usual.

Conditions That Camouflage Hereditary Spherocytosis

HS may be camouflaged by disorders that increase the surface-to-volume ratio of red cells, such as iron deficiency,[1088] vitamin B_{12} or folate deficiency,[1089] obstructive jaundice,[986] β-thalassemia,[1090] or hemoglobin SC disease.[1091] In these types of difficult cases, additional tools, such as immunoassays for red cell membrane proteins and osmotic gradient ektacytometry, may be necessary to confirm the diagnosis of HS.

Iron deficiency corrects the abnormal shape, fragility, and high MCHC of hereditary spherocytes but does not improve their life span.[1088] Megaloblastic anemia can

likewise mask the morphologic characteristics of HS.[1089] OF is also improved. The masking effect is observed in both vitamin B_{12} and folate deficiency and is rapidly reversed after correction of the nutritional deficit.

When obstructive jaundice develops, spherocytosis is transiently improved, and results of the OF test and hemolysis laboratory indices normalize.[986] This improvement is due to the expansion of red cell membrane surface area that follows the increased uptake of cholesterol and phospholipids from the abnormal plasma lipoproteins released by the obstructed liver. In normal cells, this increase in surface area leads to the formation of target cells, but in spherocytes, it leads to the appearance of discocytes. For example, we have seen a 6-year old child in whom jaundice and symptoms of biliary obstruction developed. She had a palpable spleen tip, evidence of mild compensated hemolysis (hemoglobin concentration of 14 g/dL; reticulocyte count of 3.3%), a normal peripheral blood smear, and normal results of an OF test (fresh and incubated cells). Abdominal radiographic studies showed calcified stones in the gallbladder and common bile duct. After cholecystectomy and relief of the partial biliary obstruction, the child's hemolysis worsened (reticulocyte count of 10.8%), and anemia (hemoglobin concentration of 10.2 g/dL), spherocytosis, and abnormal results on an incubated OF test developed. She subsequently underwent splenectomy with clinical improvement.

The coexistence of HS and β-thalassemia trait has been described in a few case reports and has been reported to worsen,[1092,1093] ameliorate,[1090,1094] or have no effect on the clinical status of the patient. In a large French family with independently segregating HS and β-thalassemia trait, patients with both traits had signs of both diseases: small, hemoglobin A_2–rich, osmotically fragile cells and some spherocytes on peripheral blood smears. However, the HS phenotype in these patients was less severe than that of family members with HS but without β-thalassemia trait.[1090]

Coinheritance of HS and hemoglobin SC disease may exacerbate the hemoglobinopathy.[1091] A 15-year-old boy with both diseases was much more anemic than his siblings with SC hemoglobin disease and experienced five splenic sequestration crises. However, the two diseases may also disguise each other morphologically. Only a few spherocytes or target cells were evident on the boy's blood smear, and the surface-to-volume ratio of his red cells (and probably their OF) was normal. This is probably due to the balancing effects of HS (loss of surface area) and hemoglobin SC (loss of cell volume) on red cells.

Sickle trait may also be worsened by HS.[1095,1096] Yang and colleagues[1097] reported two patients with the combination who suffered multiple splenic sequestration crises. On the other hand, spontaneous regression of HS, presumably as a result of the development of a hyposplenic state, has also been observed in two family members who had HS and sickle cell trait.[1098]
FIGURE 15-45. Proportion of normal and hereditary spherocytosis (HS) patients with gallstones as a function of age. The graph is redrawn from data in a study[1100] of gallbladder disease in 152 consecutive patients seen at The Cleveland Clinic before 1952. Only patients whose gallbladders were examined at surgery or by cholecystography are included. Data for the general population are derived from an autopsy series of patients who did not have hemolytic anemia.[1101] Note that the prevalence of gallstones in HS patients rises sharply between the ages of 10 and 30 years and parallels the general population after 30 years of age. *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.)*

Complications

Most patients with HS have well-compensated hemolysis and are rarely symptomatic. These patients seek medical attention only when complications occur. Complications are generally related to chronic hemolysis and anemia.

Gallstones

The formation of bilirubinate gallstones is one of the most common complications of HS and is a major impetus for splenectomy in many patients. Instances of gallstones occurring in infancy[1099] have been reported, but most appear in adolescents and young adults. In a retrospective study of 152 consecutive patients with HS conducted before the development of ultrasonography, gallstones were detected in only 5% of children younger than 10 years who were adequately examined and in approximately 50% of HS patients between 10 and 30 years of age (Fig. 15-45).[1100] The increase in incidence of gallstones after the age of 30 parallels the incidence in the general population,[1101] which suggests that cholelithiasis secondary to HS is primarily manifested in the second and third decades.

The incidence of gallstones in HS patients is related to the ability of the liver to metabolize increased amounts

of bilirubin. A common polymorphism in the promoter of the uridine diphosphate–glucuronyl transferase gene (*UGT1A*) causes decreased enzyme production and, in the homozygous form, Gilbert's syndrome. Recent studies have clearly demonstrated that coinheritance of Gilbert's syndrome and HS increases the risk for cholelithiasis.[1102-1105] One retrospective study of 103 children with HS showed that the rate of gallstone formation was 2.19 times higher in patients with a homozygous mutation in the *UGT1A* gene than in those with a heterozygous mutation and 4.5 times higher than in HS patients lacking the Gilbert polymorphism.[1102] Recent studies also demonstrate that gallstones develop at a younger age in HS patients with a homozygous mutation in the *UGT1A* gene.[1106] Therefore, analysis of this allele is useful in predicting the risk for cholelithiasis in HS.

Because the pigment stones typical of HS are easily detected by ultrasonography, all patients with HS should undergo ultrasound examinations about every 5 years if the spleen is intact and just before splenectomy. Unfortunately, longitudinal studies using modern techniques (i.e., liver and biliary tree ultrasonography) are not available, thus making the true incidence and natural history of gallstones in this population unknown. Indeed, many patients with gallstones are asymptomatic, and it is unclear in how many patients symptomatic gallbladder disease or biliary obstruction will develop. Anecdotal reports in the old HS literature suggested that 40% to 50% of HS patients with cholelithiasis had symptoms and that a high proportion of patients with stone-containing gallbladders had histologic evidence of cholecystitis.[1107] However, studies that include large numbers of patients with mild HS show a much lower incidence of symptomatic gallbladder disease.[1108] Clearly, more accurate data about the long-term complications of pigment stone disease are needed to assess the risk-to-benefit ratio of splenectomy in HS and the need for cholecystectomy in asymptomatic patients with cholelithiasis.

Because of the lack of knowledge about the natural history of cholelithiasis in HS, the treatment of gallbladder disease in HS patients is debatable. Once gallstones are found, an initial observation period is recommended.[1109] Surgery is indicated for recurrent symptoms or signs of biliary obstruction. If a patient is undergoing splenectomy, ultrasound of the gallbladder is indicated before surgery to assess for the necessity of concomitant cholecystectomy.[1110] Prophylactic cholecystectomy or splenectomy solely to prevent the formation of gallstones is not indicated. One analysis[1111] offers the following recommendations for adult patients who have not undergone splenectomy and in whom gallstones develop: for patients younger than 39 years, both splenectomy and cholecystectomy should be performed even if the patient has no symptoms; for patients between 39 and 52 years of age, both operations should only be performed if the patient has biliary colic; if a patient is older than 52 years, cholecystectomy alone should be performed for biliary colic.

TABLE 15-5	Classification of Crises				
Type	**Anemia**	**Reticulocytes**	**Jaundice**	**Cause**	**Comment**
Hemolytic	Increased	Increased	Increased	Viral infections leading to splenomegaly	Frequent, usually mild
Aplastic	Increased	Decreased	Decreased	Parvovirus B19	Occurs once Severe. Risk to pregnant contacts
Megaloblastic	Increased	No change or decreased	No change or increased	Relative folic acid deficiency	Rare, preventable

Crises

Patients with HS, like patients with other hemolytic diseases such as sickle cell disease, face a number of potential crises. Table 15-5 summarizes the types of crises that occur in patients with HS.

Hemolytic Crises. Hemolytic crises are probably the most common form of crisis in HS. They usually occur with viral syndromes, particularly in children younger than 6 years.[1112] They are characterized by a mild transient increase in jaundice, splenomegaly, anemia, and reticulocytosis. No medical intervention is usually required. Some of these patients may actually be in the recovery phase of an aplastic crisis. Severe hemolytic crises occur rarely. Characteristic features include jaundice, anemia, vomiting, abdominal pain, and tender splenomegaly. In such cases, hospitalization, red cell transfusion, and careful monitoring may be required.

Aplastic Crises. Aplastic crises are less common than hemolytic crises but are more serious and may lead to severe anemia and result in congestive heart failure or even death.[856] These crises are usually caused by parvovirus B19, the cause of erythema infectiosum (fifth disease).[1113] Parvovirus B19 infection may be accompanied by fever, chills, lethargy, vomiting, diarrhea, myalgia, and a maculopapular rash on the face (slapped cheek appearance), trunk, and extremities.[1114] In addition, an HS patient having an aplastic crisis may experience anemia, jaundice, pallor, and weakness.[1115,1116] Parvovirus B19 selectively infects erythropoietic precursors and inhibits their growth by inducing apoptosis and cell cycle arrest at G_2.[1117-1120] Parvovirus infections are often associated with mild neutropenia ($\approx$20%) or thrombocytopenia ($\approx$40%), and instances of transient pancytopenia have been reported.[1113,1121-1123] Parvovirus may infect several members of a family simultaneously.[1123-1127]

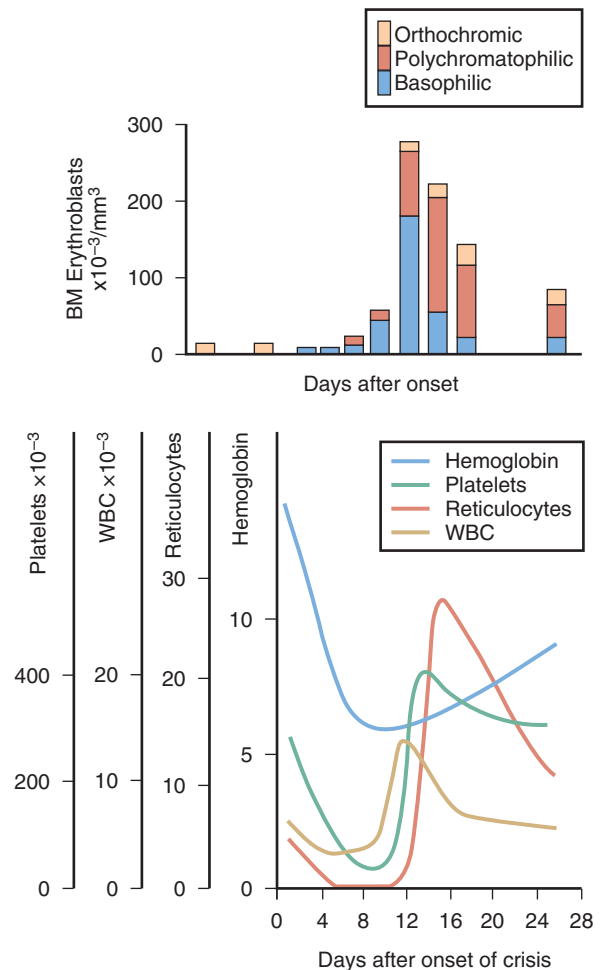
The sequence of events in an aplastic crisis is well described in the classic article of Owren[1115] and is illustrated in Figure 15-46. During the aplastic phase, the hematocrit and reticulocyte count fall, marrow erythroblasts disappear, and unused iron accumulates in serum. As production of new red cells declines, the cells that remain age, and microspherocytosis and OF increase. Bilirubin levels may decrease as the number of abnormal red cells that can be destroyed declines. Return of marrow


FIGURE 15-46. The temporal sequence of a severe aplastic crisis in a patient with hereditary spherocytosis who previously had well-compensated hemolysis. Note the profound reticulocytopenia and mild leukopenia and thrombocytopenia in the early phases of the reaction. Note also that the re-emergence of reticulocytes is heralded by the sequential return of peripheral blood granulocytes and platelets and bone marrow (BM) normoblasts. As in this patient, jaundice frequently declines during an aplastic crisis because of a decrease in the total number of abnormal red cells that have to be destroyed. WBC, white blood cells. *(Data from Owren PA. Congenital hemolytic jaundice. The pathogenesis of the "hemolytic crisis." Blood. 1948;3:231.)*

function is heralded by a fall in the serum iron concentration and the emergence of granulocytes, platelets, and finally, reticulocytes. During this recovery phase, serum phosphorus can drop to dangerously low levels.[1128] Furthermore, the lack of reticulocytes early in the recovery

phase should not eliminate hemolytic anemias from diagnostic consideration.

Infection with parvovirus B19 is a particular danger to susceptible pregnant women because it can infect the fetus and lead to fetal anemia, nonimmune hydrops fetalis, and fetal demise.[1129-1131] The risk of nonimmune hydrops fetalis in the fetus of a woman who becomes infected with B19 during pregnancy is probably low. Nevertheless, because the virus is highly contagious and is easily transmitted to patients and staff[1132,1133] and because only half to two thirds of pregnant women have acquired protective antibodies,[1134] it has been suggested that patients who have or are suspected of having an aplastic crisis be placed on precautions while hospitalized and that IgG-negative contacts who are pregnant be tested for evidence of seroconversion. Nonimmune hydrops fetalis can be detected by ultrasonography and treated with intrauterine transfusions.[1135]

During an aplastic crisis, many asymptomatic patients with HS and compensated hemolysis receive medical attention. As would be expected, aplastic crises develop at the same time in many family members with undiagnosed HS who are infected with parvovirus B19.[1123,1124,1136-1138] Diagnostic confusion may arise during re-emergence of marrow function, when the physician may mistake an aplastic crisis for a hemolytic one. Because aplastic crises generally last 10 to 14 days[1115] (about half the life span of HS red cells),[1031,1139] the hemoglobin value typically falls to about half its usual level before recovery occurs. Thus, aplastic crises are a serious threat to young children with HS, particularly those with more severe forms of the disease. Intensive medical management is required in these cases.

The diagnosis of parvovirus infection can be made with serum PCR or immunologic tests. Pathologic examination of the bone marrow demonstrates giant pronormoblasts, which are a hallmark of the cytopathic effects of parvovirus B19.[1140,1141] Treatment is supportive until the aplastic episode self-resolves. In children with severe anemia, red cell transfusions may be necessary. In immunocompromised patients, intravenous immunoglobulin assists in clearing the virus. Respiratory and contact precautions, from before the onset of symptoms to at least 1 week after symptoms appear, assist in preventing spread of the virus. Immunity after parvovirus infection is lifelong.

Megaloblastic Crises. Rarely, HS patients may have megaloblastic crises as a result of folate deficiency. These crises occur in patients whose dietary intake of folic acid is inadequate for the increased needs of the red cell precursors in the bone marrow. Therefore, megaloblastic crises typically occur in patients with HS who are recovering from an aplastic crisis or who are pregnant.[873,874] In these patients, dietary intake of folic acid is inadequate for the increased needs of the erythroid HS bone marrow. A megaloblastic crisis in pregnancy has been reported as the first manifestation of HS. All patients with hemolytic anemia, including HS before splenectomy, should routinely receive folic acid supplements (≈1 mg/day) to prevent this complication.

Other Complications

Gout and Leg Ulcers. Rarely, gout,[1142,1143] indolent leg ulcers,[1144,1145] or a chronic erythematous dermatitis on the legs develops in adults with HS.[1146,1147] Splenectomy appears to be curative.

Extramedullary Hematopoiesis. Extramedullary masses of hematopoietic tissue, particularly alongside the posterior thoracic or lumbar spine[831,1143,1148-1153] or in the hila of the kidneys, may also develop in adults with HS.[831] These masses may spontaneously bleed and lead to hemothorax.[1151] In one unusual instance, extramedullary hematopoiesis simulated an adrenal mass in a 9-year-old boy with HS.[1154] Surprisingly, these tumors frequently arise in patients with mild HS, perhaps because they often do not undergo splenectomy, and are the first manifestations of HS. The masses gradually enlarge and may be mistaken for neoplasms.[1143] Biopsy may lead to extensive bleeding. If necessary, open biopsy should be performed. These bone marrow tumors can be diagnosed by magnetic resonance imaging (MRI),[1155] which may make biopsies unnecessary. The masses stop growing and undergo fatty metamorphosis after splenectomy, but they do not shrink in size.[1148,1149]

Hematologic Malignancy. Over a dozen occurrences of HS and hematologic malignancy, including myeloproliferative disorders, multiple myeloma, and leukemia, have been reported.[1156-1159] It has been suggested that this association is due to long-standing hematopoietic stress or chronic reticuloendothelial stimulation because splenic clearance of abnormal red cells induces proliferation of lymphocytes and plasma cells, as well as macrophages.[1160] Patients with HS have a mild polyclonal hypergammaglobulinemia,[1156-1158,1160] and there is some evidence favoring the association of myeloma and chronic gallbladder disease.[1156,1161] However, it is not currently clear whether there is a true connection between HS and myeloma or myeloproliferative disease or a chance association.

Hemochromatosis. Untreated HS may exacerbate hemochromatosis in patients who are heterozygous for the hereditary disease.[1162-1165] Several patients with HS subsequently died of liver failure or hepatoma.

Heart Disease. Untreated HS may aggravate underlying heart disease and precipitate heart failure.[1166] Gradually worsening congestive heart failure may rarely be the initial manifestation in an elderly patient with HS in whom progressively worsening anemia has developed as marrow senescence evolves.

Angioid Streaks. These brownish or gray streaks resembling veins in the optic fundus have been described

in adult members of several HS kindreds.[1167,1168] The rate of occurrence of this association is unknown. Angioid streaks are relatively common in some other hematologic disorders, notably sickle cell disease and thalassemia,[1167,1169] and may be complicated by retinal vascular proliferation that requires treatment.[1170]

Pseudohyperkalemia. Because HS red cells leak potassium ions more rapidly than normal red cells do, serum samples from HS patients may demonstrate pseudohyperkalemia if allowed to sit for a long time before electrolytes are analyzed.[1171]

Splenic Rupture. Although splenomegaly is a common symptom in HS patients, cases of splenic rupture are rare.[1172] This contrasts significantly with the splenomegaly that accompanies acute viral infections such as Epstein-Barr virus, in which splenic rupture occurs at higher frequency. It is unclear why this difference exists, although it may reflect the unique pathophysiology of splenic enlargement in the different conditions. Children with HS and splenomegaly should not be restricted from normal activities. However, older children and adults with splenic enlargement that extends below the rib cage should avoid activities that may inflict a powerful, direct blow to the abdomen, such as football or ice hockey.

Nonerythroid Manifestations. Kindreds with HS and neurologic manifestations have been described. In the older literature, multiple case reports describe patients with HS and various neurologic abnormalities such as Freidrich-like disease, cerebellar disturbances, muscle atrophy, and a tabes-like syndrome.[1173-1176] More recently, patients with certain ankyrin gene deletions have been reported who have psychomotor retardation, hypogonadism, and various neurologic manifestations.[847,848,870,917-919] Additional reports describe patients with ankyrin-deficient HS and slowly progressive spinocerebellar disease.[1173] The discoveries that erythroid ankyrin[662-665] and β-spectrin[430] are expressed in the cerebellum and spinal cord and that delayed cerebellar ataxia develops in mice with a lack of ankyrin because of slow loss of Purkinje cells[1177] suggest that unique types of ankyrin and β-spectrin mutations may affect the neurologic system, in addition to red blood cells.

Families with HS and hypertrophic cardiomyopathy have also been reported. For example, a three-generation Russian family with cosegregating HS and hypertrophic cardiomyopathy has been described.[1178] Two brothers with HS, a movement disorder, and myopathy have also been reported.[1179] These cases are interesting because spectrin and ankyrin are known to be expressed in muscle.

Splenectomy

Splenectomy cures all patients with typical mild to moderate HS by eliminating anemia and hyperbilirubinemia and reducing the reticulocyte count to nearly normal levels (1% to 3%). In most patients, red cell survival becomes normal or remains only slightly shortened. Spherocytosis and altered OF persist, but the "tail" of the OF curve, created by conditioning of a subpopulation of spherocytes by the spleen, disappears. After splenectomy, patients with the most severe forms of HS still show shortened erythrocyte survival and hemolysis, but their clinical improvement is striking.[845,871] Splenectomy appears to have a more beneficial effect on spectrin/ankyrin-deficient erythrocytes than on band 3–deficient erythrocytes.[1180]

Currently, the major decisions about treatment are who should undergo splenectomy, what kind of operation should be performed, and how patients should be cared for postoperatively. However, the indications for splenectomy should be weighed carefully inasmuch as a small fraction of patients will die of overwhelming postsplenectomy infections.[1181-1185] Because the risk of postsplenectomy sepsis is very high in infancy and early childhood, splenectomy should be delayed until the age of 5 to 9 if possible and until at least 3 years of age in all children, even if transfusions are required chronically in the interim. There is no evidence that further delay is useful, and it may be harmful because the risk of cholelithiasis increases dramatically in children after 10 years of age.[1100]

Risks of Splenectomy

Immediate Postsplenectomy Complications. Early complications of splenectomy include local infection, such as a subphrenic abscess, and bleeding. Pancreatitis has been reported immediately after splenectomy, presumably as a result of injury to the tail of the pancreas incurred during removal of the spleen.[1186]

Postsplenectomy Sepsis. Overwhelming serious bacterial infection with encapsulated bacterial organisms is one of the most significant risks of splenectomy. The risk is highest with encapsulated organisms, such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*. Postsplenectomy sepsis can be rapidly fatal, and it is unclear how the risk for postsplenectomy infection changes over time. Some studies have suggested that the risk is highest immediately after splenectomy and lessens over time. Other studies conclude that the risk of sepsis is present indefinitely after splenectomy.[1187,1188]

It is difficult to estimate the risk for postsplenectomy infections after infancy.[1189] The surveys of Schwartz and colleagues[1184] and Green and co-workers[1181] are limited to adults and largely predate immunization for *S. pneumoniae* and other bacteria. These surveys show an incidence of fulminant sepsis in adults of 0.2 to 0.5 per 100 person-years of follow-up and a death rate of 0.1 per 100 person-years. In addition, other serious bacterial infections (e.g., pneumonia, meningitis, peritonitis, and bacteremia) in adults were much more common (4.5/100 person-years) than normal, particularly in the first few years after the operation. The incidence of postsplenec-

tomy sepsis appears to be higher in children, particularly younger children.[1189-1192] More recently, in a 30-year follow up of more than 200 splenectomized adult HS patients, Schilling[1185] reported a postsplenectomy mortality rate of 0.073 per 100 person-years, which is substantially lower than the risk reported in the earlier studies.[1181,1184] Three of the four deaths occurred 18 or more years after the operation, and none of the patients who died had received pneumococcal vaccine or prophylactic antibiotics.

The majority of studies of postsplenectomy sepsis in adults and children have serious methodologic problems. Most studies are case reports or retrospective reports subject to recall bias. The patients included in the studies have heterogeneous diseases and are often splenectomized for a variety of indications. Furthermore, in most studies the adults patients are not fully immunized and do not receive antibiotic prophylaxis. Further research is necessary to quantitate the risk over time for postsplenectomy sepsis in HS patients treated according to current practice guidelines.

With development of the *H. influenzae* type b conjugate vaccine, meningococcal conjugate and nonconjugate vaccines, and pneumococcal conjugate and nonconjugate vaccines, the risk of postsplenectomy sepsis should in theory be reduced. However, most members of the older population who were splenectomized before 1990 have not received all of these vaccines (unpublished data). Furthermore, most of these patients do not continue to take their antibiotic prophylaxis in adulthood (unpublished data). Waghorn examined current cases of overwhelming postsplenectomy infection and found that only 31% of 77 patients with overwhelming postsplenectomy infection received the pneumococcal vaccine.[1193] In this study, few patients were found to be adequately educated on antibiotic prophylaxis and fever management. This study indicates the necessity for quality improvement in the care of HS patients after splenectomy.

Babesiosis and Malaria. Splenectomized HS patients are at increased risk for serious parasitic infections, such as babesiosis[1194-1196] and malaria.[1197] Babesiosis is a tick-transmitted zoonotic infection by an intraerythrocytic protozoan that is endemic in Europe and in the northeastern, upper midwestern, and coastal northwestern United States.[1198] In the United States the etiologic agent of babesiosis is *Babesia microti*. The clinical symptoms usually begin with chills, anorexia, and fatigue, followed by intermittent fever and symptoms that include myalgia, arthralgia, headache, and vomiting.[1198] In healthy patients, the infection is often asymptomatic or mild. In patients with asplenia, severe illness with hemolytic anemia can occur, including fulminant illness resulting in death. Diagnosis is made by microscopic identification on Giemsa- or Wright-stained thick or thin blood smears. Serologic tests for *Babesia* antibodies and PCR are also available. Because the primary vector for the parasite is the tick *Ixodes scapularis*, which is shared by the agents

causing Lyme disease and ehrlichiosis, these infections should be considered as well.[1198] Current treatment includes clindamycin and oral quinine for 7 to 10 days.[1198] Exchange blood transfusions should be considered for severely ill patients, especially those with parasitemia of greater than 10%. Splenectomized HS patients, when traveling in endemic areas, should attempt to avoid tick bites by wearing long pants and using tick repellants.

Although animal experiments demonstrate that the spleen is essential in eliminating malaria parasitemia,[1199] only anecdotal reports demonstrate an increased risk for malaria in asplenic individuals.[1197,1200,1201] There are no studies that definitively demonstrate an increased risk for severe malaria in asplenic individuals. Nevertheless, the authors know experienced hematologists practicing in areas endemic for malaria who will not allow their patients to be splenectomized. This "local knowledge" suggests the risk is higher than the limited number of reports suggests. Accordingly, we believe that splenectomized HS patients should strictly adhere to malaria chemoprophylaxis when traveling in endemic areas or avoid such areas altogether.

Thrombosis and Thromboembolic Diseases. Many studies demonstrate an overall increased risk for thrombosis in patients after splenectomy performed for various underlying conditions.[1202-1204] Hirsh and Dacie reviewed 80 patients who were splenectomized because of anemia.[1202] Of these patients, 13% had thromboembolic complications, including two deaths. The time from splenectomy to thrombosis ranged from 4 months to 10 years. A meta-analysis of 12 studies examining the risk for thrombosis after splenectomy found that the risk for postsplenectomy thrombosis was 1.5% to 55%.[1203]

Unlike other pathologic red cell states associated with increased thrombosis, such as thalassemia, erythrocytes from patients with HS and HE do not demonstrate increased exposure of PS on their outer surfaces.[1205] Whether thrombosis after splenectomy for anemia is incited by changes in the membrane surface of pathologic erythrocytes[1206] or in circulating vesicles released from them, or is due to other factors, such as associated diseases, nutritional status, genetic modifiers, infection, environment, or treatment modalities, is unknown.[1207] Furthermore, it is likely that the risk for thrombosis after splenectomy varies according to the underlying disease. Nonetheless, major large vessel and organ thrombosis is a common finding in murine models of HS and may be a risk postsplenectomy in humans with HS.[1207,1208] Further studies specifically examining the risk for thrombosis after splenectomy in HS are needed to test this possibility.

Portal Vein Thrombosis. Many investigators have examined the risk for portal vein thrombosis after splenectomy performed for various underlying conditions. Capellini and co-investigators reviewed the data on coagulation and splenectomy in 2005 and found that the overall

incidence of postsplenectomy portal vein thrombosis in the United States was 6.3% to 10%.[1209] A Dutch study reviewed 563 patients with splenectomies and found that 9 patients had portal vein thrombosis (2%), with a higher frequency in patients with hematologic diseases.[1210] Another study of 101 splenectomized patients found an 8% rate of postoperative thrombosis.[1203] In this study, 74% of the patients with portal vein thrombosis were splenectomized for an underlying hematologic disease. In the aforementioned studies, the majority of patients who experienced a postoperative thrombotic event were taking Lovenox at the time of thrombosis. The variability in the reported incidence of postsplenectomy portal vein thrombosis between studies might be due to the high rate of silent disease, in that most patients found to have portal vein thrombosis via ultrasound for study purposes are asymptomatic. It has also been hypothesized that the risk for postsplenectomy portal vein thrombosis is increased after more invasive intraoperative manipulations because of large spleen size or difficulty during surgery for trauma. There have been no reported studies to date examining the risk for portal vein thrombosis specifically in patients with HS, so the exact risk in this population is not known. However, an increased rate of portal vein thrombosis may contribute to an increased risk for pulmonary hypertension (see later).

Ischemic Heart Disease and Stroke. The risk for ischemic heart disease and stroke may increase after splenectomy for HS. In one study, Robinette and Fraumeni[1204] observed that death from ischemic heart disease occurred 1.86 times more often in splenectomized young men than in matched control subjects during a 28-year period of follow-up. These findings have been corroborated by others.[1211] In a retrospective review of 232 patients with HS, Schilling found that splenectomized patients older than 40 years had a 5.9 times increased rate of arteriosclerotic events (stroke, myocardial infarction, and coronary or carotid artery surgery) in comparison to HS patients with intact spleens.[1212]

Pulmonary Hypertension. The prevalence and significance of pulmonary hypertension after splenectomy are not known. Pulmonary hypertension has been reported in splenectomized patients with HS,[1213-1216] as well as in many splenectomized patients with other types of anemia.[1217-1222] Hoeper and associates found an 11.5% incidence of postoperative asplenia in 61 patients with pulmonary hypertension versus a 0% incidence in patients without pulmonary hypertension.[1215] Histopathologic examination of individuals with pulmonary hypertension after splenectomy demonstrated abundant microthrombotic lesions. Of the seven patients who had pulmonary hypertension and splenectomies, three were splectomized because of anemia from HS. Jais and colleagues also examined the rate of splenectomy in patients with pulmonary hypertension and found it to be 8.6%, which was 20 times that expected for the general population.[1223] In

this study, of the patients with HS, the interval between splenectomy and the diagnosis of pulmonary hypertension was as long as 30 to 35 years. A meta-analysis examining the risks associated with splenectomy found an increased risk for pulmonary hypertension regardless of the indication for splenectomy.[1224] The risk seemed to be enhanced by various triggering risk factors and appeared to be present indefinitely, with the greatest risk many years after surgery.

Postulated Mechanisms of Hypercoagulability after Splenectomy in Anemic Patients. The etiology of the association between splenectomy and thrombosis appears to be complex. Chronic postsplenectomy thrombocytosis with platelet aggregation, microthrombosis, stasis, and possible vasoconstrictive effects leading to pulmonary capillary obstruction has been suggested as a cause of pulmonary hypertension after splenectomy.[1225,1226] Loss of the filter function of the spleen, thus allowing abnormal erythrocytes to remain in the circulation, which triggers platelet activation and subsequent trapping of these activated platelets in the pulmonary bed, has been implicated. Furthermore, dysregulation of vascular tone after splenectomy for anemia may contribute to an increased risk for thrombosis. After splenectomy for anemia, increased free hemoglobin is released into serum, which decreases serum nitric oxide, possibly disturbing normal regulation of vascular tone and causing vasocontriction. An animal model supporting this hypothesis has been described.[1227] The investigators divided New Zealand white rabbits into three groups: one group injected with sonicated (damaged) blood, a second group injected with normal blood after ligation of the splenic artery, and a third group injected with sonicated blood after ligation of the splenic artery. The only group found to have pulmonary thromboembolism was the third group, which received damaged red blood cells and underwent ligation of the splenic artery. This study may indicate that both abnormal red blood cell membranes and splenectomy are necessary for the development of pulmonary hypertension in human patients.

The development of postsplenectomy portal hypertension secondary to portal vein thrombosis (see earlier) may contribute to the development of pulmonary hypertension.[1228-1231] In this scenario, portal hypertension leads to intrapulmonary shunting and hypoxic pulmonary vasoconstriction, which is then implicated in the pathogenesis of pulmonary hypertension.[1231]

Many have postulated that the risk for thrombosis increases after splenectomy performed for anemia because as the anemia improves, patients have an increase in cholesterol level, serum hematocrit,[1212] and platelet count, all known risk factors for thrombosis. In the Framingham study, the incidence of stroke was two times higher in patients with high versus low hemoglobin.[1232] Schilling and colleagues examined the risk for arteriosclerotic events (i.e., arterial thrombotic events) in families with HS.[1233] They found the risk for arteriosclerotic events in

patients with HS and a spleen to be a fifth the risk in unaffected family members, thus implying that HS with a spleen may be protective against arteriosclerotic disease. However, it is not clear whether this protective effect is due to a lower hematocrit and lower cholesterol level rather than the presence of the spleen.

The risk for thrombosis after splenectomy may also increase because of increasing circulating damaged red blood cells. In patients with thalassemia, red cells are recognized as being more procoagulant than healthy red cells. The prothrombinase assay can use thalassemic red blood cells as a source of phospholipids, which requires them to act as activated platelets. Damaged red blood cells are more procoagulant and become more prevalent after splenectomy because they are no longer filtered through the spleen. "Blood dust" shed from fragmenting erythrocytes with PS exposed on the surface may activate the clotting cascade. In support of this concept, frequent red cell transfusions are protective in splenectomized thalassemia major patients, probably by allowing fewer damaged red blood cells in the circulation.[1203] It is unclear whether this same phenomenon would be true in HS patients.

The risk for thrombosis after splenectomy for HS is not well defined, and further studies are needed to confirm this risk. Nevertheless, a conservative approach to splenectomy is supported by this correlation. Furthermore, once a patient with HS has been splenectomized, a thoughtful approach to clotting risk is recommended, in so far as attempting to limit additional hypercoagulable risk factors.

Indications for Splenectomy

In view of the potential risks, splenectomy should be performed only if there are clear indications. All patients with severe spherocytosis who are transfusion dependent or have growth failure or skeletal changes should undergo splenectomy. Splenectomy is usually recommended for patients with moderate HS if they suffer from reduced vitality or physical stamina as a result of anemia, if later in life anemia compromises vascular perfusion of vital organs, or if leg ulcers or extramedullary hematopoietic tumors develop. Whether patients with moderate HS and asymptomatic anemia should undergo splenectomy remains controversial. Partial (subtotal) splenectomy may be indicated in some of these patients (see later). Splenectomy can be deferred, probably indefinitely, in patients with mild HS and compensated hemolysis. In young symptomatic children with HS, splenectomy should be delayed until at least 3 years of age and, if possible, until 6 to 9 years of age because of the risk for infection. In addition, after the early school years, the number of febrile infections is reduced, which decreases the frequency of postsplenectomy fever evaluations.

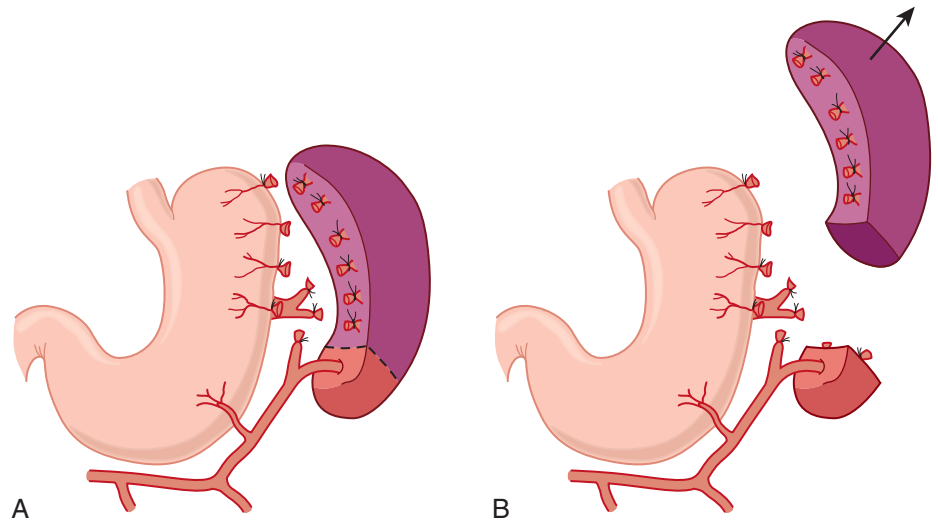
Treatment of patients with mild to moderate HS and gallstones is also debatable, particularly because new treatments for gallstones, such as laparoscopic cholecystectomy, endoscopic sphincterotomy, and extracorporal cholelithotripsy, lower the risk of this complication.[1234,1235] If such patients have symptomatic gallstones, the authors and others favor combined cholecystectomy and splenectomy,[1236,1237] especially if acute cholecystitis or biliary obstruction has occurred. Prophylactic cholecystectomy at the time of splenectomy is not indicated in patients who do not have cholelithiasis.[1238]

Surgical Procedures

Laparoscopic Splenectomy. When splenectomy is warranted, laparoscopic splenectomy has become the method of choice in many centers.[1239-1245] The procedure can be combined with laparoscopic cholecystectomy if desired.[1236,1237,1249,1242] The benefits of laparoscopic splenectomy are less postoperative discomfort, quicker return to preoperative diet and activities, shorter hospitalization, decreased cost, and smaller scars.[1241,1242] The drawbacks of a laparoscopic approach are longer operative time,[1239,1242,1243] risk of conversion to standard splenectomy,[1240,1244,1246] chance of missing an accessory spleen,[1243,1247] potential difficulty in controlling bleeding,[1246] and capsular fracture with subsequent splenosis.[1248] Recent studies have compared the laparoscopic approach with the open surgical approach and have demonstrated longer operating times but shorter hospital stay and decreased pain in the laparoscopic group.[1249-1251] The majority of studies to date support the laparoscopic approach to splenectomy as the method of choice in centers in which the surgical staff is experienced.

Partial (Subtotal) Splenectomy. The emergence of antibiotic-resistant pneumococci and increasing evidence suggesting an increased risk for thrombosis after splenectomy have led to re-examination of the role of alternative treatment modalities. Partial splenectomy has been suggested for selected patients with HS, especially those with only moderate disease. The goal of this operation is to decrease hemolysis while maintaining residual splenic phagocytic function. In practice, at least 80% to 90% of the enlarged organ is removed (Fig. 15-47). Partial splenectomy is mostly performed as an open operation, but a laparoscopic approach has been reported.[1252] The procedure is more time consuming than total splenectomy, and the time needed for recovery is longer (4- to 7-day hospitalization), but studies have shown that partial splenectomy is safe and reduces the rate of hemolysis.[1253-1257]

In an initial study by Tchernia and colleagues,[1253] the frequency of complications after partial splenectomy was low, and regrowth of the splenic remnant was not observed during a 4-year follow-up period. Long-term follow-up of 40 patients, monitored for up to 12 years after partial splenectomy, demonstrated that mean hemoglobin increased from 9.2 to 12.7 g/dL and the absolute reticulocyte count decreased from 523 to 267 × 10⁹ cells/L (Fig. 15-48).[1254] In children with at least 10 years of follow-up, no differences in hemoglobin and reticulocyte levels were noted between the partial and total splenec-

FIGURE 15-47. Surgical technique used for partial (~80%) splenectomy. **A,** All vascular pedicles supplying the spleen are divided except those arising from the left gastroepiploic vessels. **B,** The upper pole of the spleen is removed at the boundary between the well-perfused and poorly perfused tissue. *(Adapted from Tchernia G, Gauthier F, Mielot F, et al. Initial assessment of the beneficial effect of partial splenectomy in hereditary spherocytosis. Blood. 1993;81: 2014.)*


tomy groups.[1254] Significant splenic regrowth was seen in the first year after partial splenectomy, but after the initial growth, the rate of splenic growth in this study was much reduced (see Fig. 15-48). Nevertheless, 8% of patients in this study, particularly those with severe HS, required total splenectomy after partial splenectomy because of splenic regrowth and resumption of hemolysis. Moreover, in 4 of 18 patients in whom the gallbladder was not removed during the initial surgery, subsequent cholecystectomy was necessary.[1254]

Splenic tissue has tremendous regeneration potential, as attested to by reports of previously splenectomized individuals with HS in whom enlarged accessory spleens or ectopic splenic tissue together with recurrent hemolysis developed later in life. Thus, it is not surprising that splenic regrowth has been a problem necessitating reoperation in those with severe HS.[1255-1257] Some authors postulate that the spleen will grow back to its age-equivalent size 2 to 3 years after partial splenectomy. After conventional partial splenectomy, the surgical revision rate for recurrent hemolysis is estimated to be 10% after 5 years and 33% after 10 years.[1256] Moreover, it is important to note that the longest follow-up of partial splenectomy for HS is 10 to 15 years, and therefore the percentage of HS patients with splenic regrowth and recurrent hemolysis many years after partial splenectomy is unknown.

A new procedure called near-total splenectomy, in which a more radical approach to open resection is taken to reduce the risk for continued hemolysis as a result of splenic regrowth, yet maintain splenic function, has recently been performed in Germany. Near-total splenectomy leaves a splenic remnant of 10 cm³ as a residual. One longitudinal cohort study of 42 patients demonstrated that this procedure may be safe and effective, with no patients requiring postprocedure transfusions and no postprocedure hemolysis developing.[1258] More experience and longer follow-up are needed before partial, or near-total, splenectomy can be recom-

mended as a routine procedure for the majority of patients with HS.

Embolization. Several case studies have reported partial splenic arterial embolization as an alternative to splenectomy to treat hemolysis in patients with HS.[1259,1260] The technique has also been used to decrease operative blood loss in patients with very large spleens before laparoscopic splenectomy.[1261] Because experience with this procedure is limited, it cannot be recommended as routine therapy.

Postsplenectomy Changes

After splenectomy, spherocytosis persists but conditioned microspherocytes disappear, and changes typical of the postsplenectomy state, including Howell-Jolly bodies, target cells, siderocytes, and acanthocytes, become evident in the peripheral blood smear. On average, MCV and mean red cell surface area increase and MCHC and OF decrease, but the effects are modest (5% to 10%).[1262] In typical dominant HS, reticulocyte counts fall to normal or nearly normal levels,[845] although red cell life span, if carefully measured, remains slightly shortened (96 ± 13 days).[1004] In all but the most severe occurrences, anemia and jaundice remit and do not recur.

Splenectomy Failure

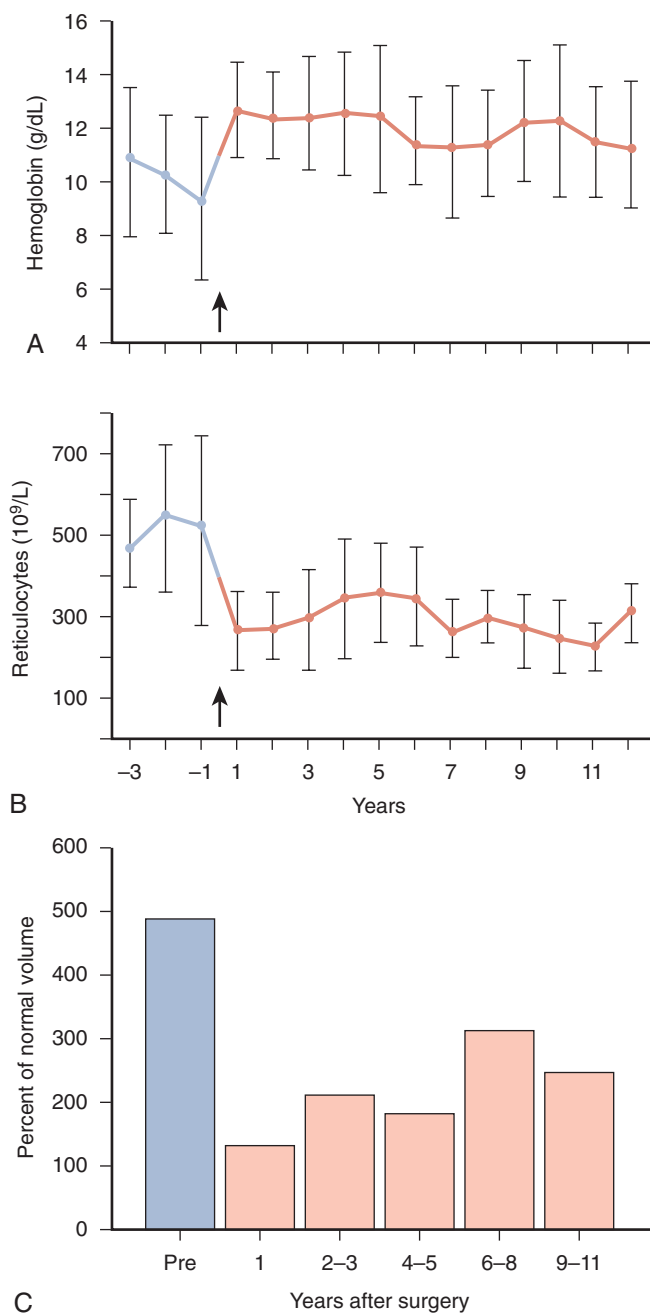
The rare splenectomy failure (i.e., recurrence of hemolysis) is usually caused by an accessory spleen that was missed during surgery[1255,1263] or by another red cell disorder, such as PK deficiency.[1264,1265] Accessory spleens are present in 15% to 40% of patients and must always be sought.[1107,1186,1266] Recurrence of hemolytic anemia years or even decades[1255] after splenectomy should raise suspicion of an accessory spleen, particularly if Howell-Jolly bodies are no longer evident on peripheral blood smears. The absence of "pitted" red cells with crater-like surface indentations, readily seen by interference contrast microscopy, is also a sensitive measure of recrudescent splenic


FIGURE 15-48. Long-term follow-up of partial splenectomy in hereditary spherocytosis. Data are the results of 12 years of experience with the procedure in 40 patients (aged 1 to 25 years). **A** and **B,** Change in hemoglobin and reticulocyte count with time before and after subtotal splenectomy (*arrow*). The mean and standard deviations are shown. Both the rise in hemoglobin and the fall in reticulocytes have been sustained for more than a decade. **C,** Size of the spleen during the same period. There is some regrowth of the splenic remnant, especially in the first few years. It remains to be seen whether the remannt reaches a stable size or, as some studies have indicated, continues to grow. *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.)*

function.[1267,1268] The ectopic splenic tissue can be confirmed by a radiocolloid liver/spleen scan or a scan using ^{51}Cr-labeled, heat-damaged red cells.[1263,1269]

Other Therapies

Vaccination and Antibiotic Prophylaxis

All candidates for splenectomy should receive a complete series of vaccinations against encapsulated organisms, including pneumococcus, meningococcus, and *H. influenzae* (Table 15-6). Yearly influenza immunizations are recommended to reduce the chance of secondary bacterial infections. Recent studies (unpublished results) have shown that the majority of adults who were splenectomized as children are not up to date with their vaccinations. In a study examining current cases of overwhelming postsplenectomy infection, only 31% of 77 patients with such infection received the pneumococcal vaccine.[1193] It is important to emphasize the importance of immunizations to the affected parents of children with HS.

Pneumococcal Vaccines. All patients older than 2 years should receive the 23-valent pneumococcal polysaccharide vaccine (PCV23) at least 2 weeks before splenectomy. In addition, all patients should receive two doses, at least 8 weeks apart, of the 7-valent pneumococcal conjugate vaccine (PCV7) before splenectomy.[1270] After both PCV23 and PCV7 have been given, it is not necessary to give booster vaccines of PCV23. However, some physicians continue with this regimen because of the lack of data on the necessity of giving booster vaccines for PCV23 after PCV7 is administered and because of the lack of studies on the safety of PCV7 in populations older than 5 years.

***Haemophilus Influenzae* Type b Vaccine.** The conjugated *H. influenzae* type b vaccine should be given to all patients at least 2 weeks before splenectomy. No studies have been performed on the need for reimmunization, which is not recommended at this time.

Meningococcal Vaccines. All patients undergoing splenectomy after age 2 should be immunized with the meningococcal conjugate vaccine (MCV4). Similar to the *H. influenzae* vaccine, no studies have been performed on reimmunization, which therefore is not recommended at this time.

Antibiotic Prophylaxis

Prophylactic antibiotics are recommended after splenectomy with an emphasis on protection against pneumococcal sepsis (i.e., penicillin V or equivalent, 125 mg orally twice daily in young children [<5 years of age] and 250 mg twice daily in older children and adults). For patients allergic to penicillin, erythromycin is recommended. Antibiotic prophylaxis is recommended at least

TABLE 15-6	Recommended Immunizations at Least 2 Weeks before and after Splenectomy	
	AGE AT SPLENECTOMY	
Vaccination	**6 to 23 Months**	**Older than 2 Years**
PCV7	As per routine schedule	2 doses, ≥2 mo apart★
PPV23	No	1 dose every 3-5 yr, at least 8 wk after PCV7
MCV4	No	1 dose
MPSV4	No	1 dose if MCV4 is unavailable
Influenza	Yearly	Yearly
Hib	As per routine schedule	1 dose★

★Children or adults who received the primary series as infants do not need to be immunized further.

Hib, *Haemophilus influenzae* type b conjugate vaccine; MCV4, meningococcal conjugate vaccine; MPSV4, meningococcal polysaccharide vaccine; PCV7, pneumococcal conjugate vaccine; PPV23, pneumococcal polysaccharide vaccine.

through childhood and, for teenagers and adults, for at least the first 5 years after surgery.

Some physicians recommend lifelong antibiotic prophylaxis because it is unclear that the risk for overwhelming postsplenectomy infection changes over time. The emergence of penicillin-resistant pneumococci (5% in 1989 to ≥35% in 1997) has led many to reconsider this recommendation, particularly because previous antibiotic use is a risk factor for the development of penicillin resistance in pneumococci.[1271] Patient who do not take prophylactic antibiotics should have a supply of oral antibiotics on hand, which they should take immediately if fever higher than 101.5° C develops. They should then seek medical attention right away.

The risk for infection is decreased in immunized patients because 50% to 70% of postsplenectomy sepsis is due to *S. pneumoniae* and about 80% of pneumococcal disease is due to strains contained in the two vaccines. However, it is likely that strains omitted from the vaccines will rise in frequency as pathogens because of selection. Further risk reduction would be anticipated from the chronic use of prophylactic penicillin. Nevertheless, the risk cannot be reduced to zero. Postsplenectomy infections occur occasionally in successfully immunized patients,[1272-1274] and compliance with prophylactic medication regimens is a problem, particularly in teenagers.[1275]

The occurrence of penicillin-resistant pneumococci is increasing very rapidly all over the world.[1276-1278] In some countries, more than half of all isolates are resistant.[1279] In the United States, the prevalence is approximately 35%, but it is much higher in some localities and is rising.[1276,1278,1280] Although most of the strains show some sensitivity to penicillin, some are highly resistant and others are multiply resistant.[1280-1282] The emergence of these strains will greatly complicate the use of antibiotics for pneumococcal prophylaxis during the next decades.

Folic Acid

Patients with HS should take folic acid (0.5 to 1 mg/day orally) before splenectomy to prevent folate deficiency.

Animal and Fish Models of Hereditary Spherocytosis

Animal models, such as the well characterized mouse and zebra fish models, have assisted in our understanding of the pathophysiology of HS. Four types of spherocytic hemolytic anemia have been identified in the common house mouse *Mus Musculus*[1283]: *ja/ja* (jaundice); *sph/sph* (spherocytosis) and its alleles *sph¹ʲ/sph¹ʲ* (hemolytic anemia), *sph²ʲ/sph²ʲ* (now lost), *sph²ᴮᶜ/sph²ᴮᶜ*, and *sphᴰᴱᴹ/sphᴰᴱᴹ*; *nb/nb* (normoblastosis); and *wan/wan*. The nomenclature indicates that anemia is observed only in the homozygous state and that the mutants represent four loci: *ja*, *sph*, *nb*, and *wan*. All defects are autosomal recessive and cause severe hemolysis with spherocytosis, jaundice, bilirubin gallstones, and hepatosplenomegaly,[1284] except in the *sphᴰᴱᴹ/sphᴰᴱᴹ* mice, which have HE. Another recessive spherocytic hemolytic anemia has been described in the deer mouse *Peromyscus maniculatus*.[1285] This disorder is less severe and closely resembles the autosomal dominant form of human HS. The spectrin content of deer mouse erythrocytes is reduced by about 20% (unpublished data).

Spectrin Mutants

The *ja/ja* mutant has a defect in the spectrin β chain (Arg1160→Stop) and produces no detectable spectrin.[1286] The *sph/sph* variants lack α chains but have small amounts of β-spectrin. These mice do not produce α-spectrin because of either decreased synthesis, function, or stability. The *sph* and *sph²ᴮᶜ* alleles are frameshift mutations and null alleles.[1287,1288] The sph¹ʲ allele lacks the last 13 amino acids of α-spectrin and causes marked spherocytosis.[1289] Thus, the amino acids in the C-terminal of the spectrin tail are functionally important in attaching spectrin to actin. The *sphᴰᴱᴹ/sphᴰᴱᴹ* mouse is missing exon 11 and 46 amino acids near the amino-terminal of repeat 5. These mice have elliptocytes, spherocytes, and poikilocytes and therefore clinically appear to be a cross between HS and HE (see later).[1289]

Cardiac thrombi, fibrotic lesions, and renal hemochromatosis are found in *ja/ja* and *sph/sph* mice who die after the first few days of life.[1290] Transplantation of hematopoietic cells from *sph/sph* mice is sufficient to induce thrombotic events in the transplant recipients.[1291] In mice with α-spectrin mutations, 70% to 100% experience cerebral infarction.[1292,1293] Studies of red cell adhesion in these mice demonstrate 10-fold higher adhesion to thrombospondin than with normal red blood cells and increased adhesion to laminin.[1294] Therefore, it is hypothesized that changes in the red cell adhesive characteristics contribute to the thrombotic events in these mice.

Reisling (*ris*) is an induced mutation in zebra fish that results in a nearly bloodless phenotype that causes severe anemia and congestive heart failure.[997] The *ris* phenotype is caused by a null mutation in β-spectrin. The red blood cells of affected zebra fish are spherocytic rather than elliptocytic, the normal zebra fish red cell shape. Scanning electron micrographs show membrane loss, as is in other forms of severe HS.

Ankyrin Mutants

Mice with the *nb/nb* mutation have a primary defect in ankyrin. This defect is due to a single nucleotide deletion leading to a frameshift and premature chain termination in the regulatory region of ankyrin.[1295,1296] The *nb/nb* red cells have 50% to 70% of normal spectrin levels but only a trace of ankyrin mRNA and protein.[1177,1284] This is in striking contrast to ankyrin defects in human HS, in which ankyrin and spectrin levels are comparably depressed.[891,851] Fetal *nb/nb* mice have no anemia and normal reticulocyte counts at birth,[884] possibly because of expression of ankyrin-related proteins in utero.[885] Humans may also be protected in utero, at least partially, because hydrops fetalis has not been reported in patients with probable ankyrin defects (i.e., combined spectrin/ankyrin deficiency), even in patients who become transfusion dependent after birth.

The *nb/nb* mice also lack ankyrin in their cerebellar Purkinje cells,[886,1177] which leads to an age-related loss of Purkinje cells during the first 5 to 7 months of life and the emergence of cerebellar ataxia.[1177] Spinocerebellar degeneration and related syndromes have also been reported in a few adult humans with HS,[1173-1176] although it is not yet known whether ankyrin is affected.

Band 3 Mutants

Complete deficiency of band 3 was first described in cattle with a recessive form of HS. In cows, homozygosity for a nonsense mutation in the band 3 gene leads to absence of band 3 and protein 4.2.[1297] Red cell membranes are unstable and show loss of surface area, as demonstrated by invagination, vesiculation, and extrusion of microvesicles. Affected cattle have defective anion transport and a mild acidosis but mild hemolysis in comparison to other band 3–deficient species.

In mice, targeted disruption of the band 3 gene causes severe spherocytic hemolytic anemia with exuberant loss of the membrane surface as vesicles, tubules, and myelin form.[995] Red cell membranes also lack protein 4.2 and GPA.[1298] Surprisingly, the content of membrane skeletal proteins and the architecture of negative-stained, spread skeletons is normal or nearly normal.[1299] Therefore, band 3 appears to be required for stabilizing membrane lipids but not for assembly of the membrane skeleton. For unclear reasons, these band 3–deficient mice have a significant propensity for thrombosis and often die in the neonatal period.[1300]

A new mouse model, *wan/wan*, in a C3H/HeJ background with a null defect in the band 3 gene was discovered.[1301] These mice have a severe anemia that is lethal in the neonatal period. However, when *wan/wan* mice are crossed with wild-type mice of a different strain, *Mus castaneous*, the F_2 generation shows variable hematologic severity. The genetic modifier causing this variability in hematologic abnormalities has been localized to a small chromosomal region containing the β-spectrin gene.[1301]

Finally, zebra fish with band 3 mutations associated with the *retsina* (*ret*) phenotype suffer from severe anemia with a complete arrest in erythroid maturation at the late erythroblast stage.[218] The rare *ret/ret* red blood cells are spherocytic rather than elliptical. Many of these arrested erythroblasts have bilobed nuclei reminiscent of those seen in congenital dyserythropoietic anemia, and demonstrate defects in cytokinesis.

Protein 4.2 Mutant

Mice with targeted deletions of the protein 4.2 gene survive normally and have only mildly spherocytic anemia and hemolysis.[1302]

Protein 4.1 Mutants

Mice lacking the protein 4.1 gene because of targeted deletion have moderate hemolysis and decreased red cell membrane stability.[1303] In addition to lacking protein 4.1, these mice are also deficient in protein p55, ankyrin, spectrin, and a complex of integral membrane proteins (band 3, glycophorin C, Xk, Kell, Duffy, and Rh).[551a] Their red cell morphology is remarkable for a spherocytic rather than an elliptocytic shape, probably related to the spectrin deficiency. Two zebra fish models with protein 4.1 deficiency have been established, *merlot* and *chablis*, and these mutants have very severe hemolytic anemia characterized by spherocytosis and increased OF.[994]

β-Adducin Mutant

Mice lacking β-adducin have been produced by gene targeting.[583] They have a mild spherocytic hemolytic anemia[583] and mild defects in learning and memory.[1303a]

HEREDITARY ELLIPTOCYTOSIS AND HEREDITARY PYROPOIKILOCYTOSIS

HE is characterized by the presence of elliptical or oval erythrocytes on peripheral blood smears (Fig. 15-49). Clinically, these disorders range from the asymptomatic

FIGURE 15-49. Peripheral blood smears from subjects with various forms of hereditary elliptocytosis (HE). **A,** Simple heterozygote with mild common HE associated with an elliptogenic spectrin mutation. Note the predominant elliptocytosis with some rod-shaped cells (*arrow*) and virtual absence of poikilocytes. **B,** Hereditary pyropoikilocytosis. Note the prominent microspherocytosis, micropoikilocytosis, and fragmentation. Only a few elliptocytes are present. Some poikilocytes are in the process of budding (*arrow*). **C,** Spherocytic elliptocytosis. Rounded elliptocytes dominate the morphology. In some patients, spherocytes or microelliptocytes are seen. **D,** Southeast Asian ovalocytosis. The majority of cells are oval; some contain either a longitudinal slit or a transverse ridge (*arrow*). The latter are sometimes referred to as theta cells and are characteristic of the disease.
carrier state to severe hemolysis to death in utero as a result of hydrops fetalis. Erythrocyte biochemical defects range from none to severe. In the past, hereditary elliptocytic disorders have been considered to simply be variants of HS and worthy of little further attention. However, the membrane defects and their pathophysiologic consequences in HE differ fundamentally from those of HS and must be regarded separately.

History

HE was first reported in 1904 by Dresbach,[1304] a physiologist at Ohio State University in Columbus, who discovered the condition in one of his histology students during a laboratory exercise in which the students were examining their own blood. This report elicited some controversy because the student died soon thereafter, leading to speculation that the student actually suffered from incipient pernicious anemia.[1305] A number of famous pathologists supported Dresbach's view that the elliptocytosis was a primary disorder,[1306] and this view was substantiated during the next 2 decades by reports of Bishop[1307] and Huck and Bigalow.[1308] Demonstration of the disease in three generations of one family clearly established the hereditary nature of this disorder.[1309,1310]

In the 1930s and 1940s there was some debate about whether HE was a disease or just a morphologic curiosity.[1309-1314] Early on, some confusion also existed in the differentiation of HE from sickle cell anemia, from hypochromic elliptocytosis (probably thalassemia), and later, from HS.[1312] These reports emphasize the morphologically deceptive nature of HE and its hemolytic variants. Additional historical and clinical features of the disease

are found in the reports of Wyandt and associates,[1313] Wolman and Ozge,[1314] and Dacie.[1315]

Prevalence and Genetics

In the United States, HE has been estimated to occur in 1 in 2000 to 4000 of the population.[1313,1316] The true incidence of HE is unknown because its clinical severity is heterogeneous and many patients are asymptomatic. HE is more common in areas of endemic malaria, specifically in people of African and Mediterranean ancestry.[1316-1324] The higher frequency of HE in these populations suggests that this disease may confer some resistance to malaria. In a study of HE in Benin, Western Africa, an incidence of 1.6% was observed.[1317]

HE variants are inherited predominantly in an autosomal dominant manner. Typically, individuals who are heterozygous for an elliptocytic variant have asymptomatic elliptocytosis without anemia. Individuals who are homozygotes or compound heterozygotes for HE variants may suffer mild to severe hemolysis with moderate to marked anemia. Spontaneous elliptocytogenic mutations have been reported. Presumably, they are also inherited in an autosomal dominant fashion. In one kindred with Alport's syndrome, mental retardation, midface hypoplasia, and elliptocytosis, inheritance was X-linked and associated with a submicroscopic deletion on the X chromosome.[1325]

HE is heterogeneous with multiple genetic loci, including reports of mutations in the α-spectrin, protein 4.1, and glycophorin C genes.[1326,1327] The mutations described include deletions, point mutations, insertions, and processing defects. The incidence of one common

TABLE 15-7   Clinical Subtypes of Hereditary Elliptocytosis

Clinical Manifestations	Laboratory Features

COMMON HE
Asymptomatic
Dominant inheritance: one parent with HE
No splenomegaly
Variants:
   Some neonates with moderately severe hemolytic anemia and an HPP-like smear. Converts to typical mild HE by ≈1 year
   Some patients with mild to moderate chronic hemolysis caused by either coinheritance of the low-expression α-spectrin variant α$^{\mathrm{LELY}}$, coexistence of chronic disease producing splenomegaly, or unknown factors
	Blood smear: elliptocytes, rod forms, few or no poikilocytes
	No anemia, little or no hemolysis (reticulocytes = 1% to 3%)
	Normal osmotic fragility
	Usually a defect in α- or β-spectrin leading to decreased spectrin self-association, or a defect in protein 4.1 leading to partial deficiency or dysfunction

HOMOZYGOUS COMMON HE AND HPP
Moderate to severe hemolytic anemia
Splenomegaly
Intermittent jaundice
Aplastic crises
Recessive inheritance: typically one parent with HE and one with α$^{\mathrm{LELY}}$ or both parents with HE
Good improvement after splenectomy
	Blood smear: bizarre poikilocytes, fragments, ± spherocytes, ± elliptocytes
	Reticulocytosis
	Decreased MCV because of red cell fragmentation
	Increased osmotic fragility
	α-Spectrin defects:
	   Decreased red cell and spectrin heat stability
	   Marked defect in spectrin self-association
	In the more severe variants, partial spectrin deficiency (indicated by more spherocytes on the blood smear)

SPHEROCYTIC HE
Mild to moderate hemolytic anemia
Splenomegaly
Intermittent jaundice
Aplastic crises
Dominant inheritance pattern
Excellent response to splenectomy
	Blood smear: rounded elliptocytes, ± spherocytes. May see variable morphology within a kindred
	Reticulocytosis
	Increased osmotic fragility
	Glucose-responsive autohemolysis
	Variable molecular defects:
	   C-terminal truncations of β-spectrin
	   Protein 4.2 deficiency (some patients) leading to ovalostomatocytosis, which resembles spherocytic HE
	   Glycophorin C deficiency (rare)

SOUTHEAST ASIAN OVALOCYTOSIS Asymptomatic Dominant inheritance (homozygous lethal) Lowland aboriginal tribes, especially in Melanesia and Malaysia Very rigid red cells that resist invasion by some strains of malarial parasites	Blood smear: rounded elliptocytes, some with a transverse bar that divides the central clear space Little or no hemolysis or anemia Normal osmotic fragility Mutant band 3 that lacks anion exchange function and tends to aggregate, leading to a rigid membrane

HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; MCV, mean corpuscular volume.

elliptocytic mutation of α-spectrin, α$^{\mathrm{I/65-68}}$, approaches 1% in Central Africa. It has a worldwide distribution in people of African ancestry. Genetic haplotyping studies suggest that this mutation may have a "founder affect," originating in Central Africa similar to the Benin type of sickle hemoglobin.[1317] This observation further supports the possibility that there has been genetic selection for HE because it imparts some resistance to malaria.[1328]

Clinical Syndromes

Most of the reported patients with HE can be classified into one of four clinical categories: common HE, HPP,

spherocytic HE, and SAO (Table 15-7). With the exception of SAO, which is homogeneous in molecular genetic terms (see later), these classifications denote clinical phenotypes and not specific molecular causes, although correlations between the two exist. Numerous molecular defects in the membrane proteins of patients with HE have been identified, and HE can also be classified on the basis of these defects.

Common Hereditary Elliptocytosis

Common HE is, by far, the most prevalent form of HE, particularly in African populations.[1317,1318] The clinical characteristics of the common HE trait vary enormously,

with several clinical subtypes defined. It is important to note that different clinical patterns may be seen in members of the same family and that the clinical manifestation in single individuals may exhibit variability over time. Thus, the clinical patterns are probably more useful for illustrating the spectrum of common HE than for classifying the disease.

Silent Carrier State. This condition was identified by analyzing asymptomatic members of kindreds with HE or HPP. Affected persons have red cells with normal morphologic characteristics and no evidence of hemolysis, but detailed investigations show a subtle defect in their membrane skeletons, with decreased red cell thermal stability, decreased mechanical stability of isolated skeletons, an increased fraction of spectrin dimers in 0°C spectrin extracts, abnormal tryptic peptide maps of spectrin, or various combinations of these defects.[1320-1324,1329,1330] It is notable that some patients classified as "silent carriers" have the same molecular defect as patients with mild common HE,[1323,1324,1330,1331] thus emphasizing the variability of clinical expression.

Typical Common Hereditary Elliptocytosis (Mild Hereditary Elliptocytosis or Heterozygous Common Hereditary Elliptocytosis). This is the most common clinical form of HE.[1332-1346] Patients are asymptomatic, and HE is often diagnosed incidentally when individuals are undergoing screening for an unrelated condition. These persons are not anemic and only very rarely exhibit splenomegaly. Red cell survival may be normal,[1345] but more often there is a very mild, compensated hemolysis with a slight reticulocytosis and a decreased haptoglobin level.[1337,1339,1343,1347] In these patients, HE is hardly more than a morphologic curiosity. The peripheral blood smear shows prominent elliptocytosis with little red cell budding or fragmentation and no spherocytosis. Elliptocytes (by definition) usually exceed 30% of the red cells and, in some instances, approach 100% (see Fig. 15-49A).[1313,1330,1331,1343,1347] Very elongated elliptocytes are common (>10%). These patients are easily separated from normal individuals, who have less than 2% to 5% elliptocytes.[1339,1341,1347] Somewhat higher proportions of elliptocytes are seen in patients with anemia, particularly megaloblastic anemias, hypochromic-microcytic anemias, myelodysplastic syndromes, and myelofibrosis,[1348] but even in these individuals elliptocytes do not exceed 35%.[1341] Thus, the diagnosis of common HE is rarely difficult.

Common Hereditary Elliptocytosis with Chronic Hemolysis. More severe variants of common HE occur frequently, sometimes within members of the same kindred.[1336,1349-1352] In general, the marked compensated hemolysis is accompanied by evidence of membrane instability on the peripheral blood smear: budding red cells, fragments, and other bizarre poikilocytes. In patients with α-spectrin mutations, significant hemolysis is often due to coinheritance of a spectrin allele that leads to

decreased α-spectrin expression, such as the α^{LELY} allele, and one of the more deleterious HE alleles affecting α-spectrin (see later).[1337,1353-1358] Of the common mutations, spectrin $\alpha^{I/74}$ is more severe than spectrin $\alpha^{I/46-50a}$ and much more severe than spectrin $\alpha^{I/65-68}$. Patients with α^{LELY} in *trans* to $\alpha^{I/74}$ ($\alpha^{LELY}/\alpha^{I/74}$) have marked hemolysis and elliptopoikilocytosis when compared with their siblings with wild-type α-spectrin and $\alpha^{I/74}$ ($+/\alpha^{I/74}$), whereas patients with $\alpha^{LELY}/\alpha^{I/65-68}$ have more elliptocytes than their siblings with $+/\alpha^{I/65-68}$ but no significant hemolysis.[1356] Less often, hemolysis is caused by inheritance of a mutant spectrin that is grossly dysfunctional.[1349] This is indicated by dominant transmission of the hemolytic syndrome and by an unusually high fraction of spectrin dimers in 0° C spectrin extracts.

Common Hereditary Elliptocytosis with Sporadic Hemolysis. Uncompensated hemolysis may also develop in patients with common HE in response to stimuli that cause hyperplasia of the reticuloendothelial system, particularly if the spleen is involved. Examples include viral hepatitis, cirrhosis, infectious mononucleosis, bacterial infections, and malaria.[1344,1359-1361] Hemolysis has also been observed with thrombotic thrombocytopenic purpura and with disseminated intravascular coagulation, which suggests that elliptocytes may be especially susceptible to microangiopathic damage.[1362] For unknown reasons, pregnancy and cobalamin (vitamin B_{12}) deficiency may also transiently aggravate the disease.[863,1363]

Hereditary Elliptocytosis with Infantile Poikilocytosis. Infants with mild common HE sometimes begin life with moderately severe hemolytic anemia characterized by marked red cell budding, fragmentation, and poikilocytosis and by neonatal jaundice, which may require an exchange transfusion.[1321,1338,1347,1364-1369] Usually enough elliptocytes are present to suggest the diagnosis, but sometimes this is not so and the disorder is mistaken for sepsis, infantile pyknocytosis, or microangiopathic or oxidant-induced hemolytic anemia.[1366,1367] Neonatal HE can easily be distinguished from the latter conditions if the parents' blood smears are examined because one will show common HE. However, it is more difficult to distinguish HE with neonatal poikilocytosis from HPP (see later). Most α-spectrin variants have been associated with the neonatal poikilocytosis syndrome. Factors that determine susceptibility are unknown. With time, fragmentation and hemolysis decline, and the clinical picture of common HE emerges.[1370] This transition requires 4 months to 2 years. Subsequently, the disease is clinically indistinguishable from typical common HE. The prevalence is unknown, but in the authors' experience, it is not rare.

The fragmenting neonatal red cells are very sensitive to heat, like hereditary pyropoikilocytes (see later), but unlike pyropoikilocytes, this sensitivity lessens over time.[1369] During conversion, the poikilocytic red cells are dense and rich in hemoglobin F, whereas the smooth elliptocytes are light and enriched in hemoglobin A. This

finding suggests that the change in the disease corresponds to the change from fetal to adult erythropoiesis. No variations in the primary α-spectrin defect or its functional effects on spectrin self-association occur during conversion, so other skeletal interactions must differ in fetal and adult red cells. Mentzer and associates[1371] made the interesting suggestion that 2,3-DPG is the critical agent. Because it is not bound by hemoglobin F, the concentration of 2,3-DPG is elevated in fetal red cells. The free anion is known to weaken spectrin-actin–protein 4.1 interactions[1372-1374] and to increase the fragility of isolated ghosts at physiologic concentrations in vitro.[1363] Whether this occurs in intact red cells is unclear.[1375,1376] If it does, the underlying defect in spectrin self-association would certainly be aggravated.

Homozygous Common Hereditary Elliptocytosis. A number of patients who are homozygotes or compound heterozygotes for typical HE have been reported.[1332,1347,1377-1382] Some have had very severe, even fatal transfusion-dependent hemolytic anemia (hemoglobin levels of 2 to 6 g/dL) with marked fragmentation, poikilocytosis, spherocytosis, and elliptocytosis. Others experience hemolysis to a lesser degree (hemoglobin level of 7 to 11 g/dL). It appears that these differences reflect variations in severity of the many α-spectrin mutations that produce HE.[1347,1383] Clinically, the disease resembles HPP,[1347,1383] except for the mildest forms. Patients have an excellent response to splenectomy.

Hereditary Elliptocytosis with Dyserythropoiesis. In a small number of families with otherwise typical common HE, the sporadic occurrence of hemolysis and anemia is at least partially due to the development of dysplastic and ineffective erythropoiesis. All patients reported with this rare syndrome are from Italy and have somewhat less elongated red cells than is typical for common HE. All reported patients also show the characteristic findings of ineffective erythropoiesis, relatively low reticulocyte counts, indirect hyperbilirubinemia, and high serum iron and ferritin concentrations.[1384,1385] The erythrocytes from some patients are macrocytic. Other patients have a few spherocytes, but these are probably an artifact because OF is normal.[1384] The patient's bone marrow is hyperplastic, with decreased late erythroblasts and dysplastic features (asynchrony of nuclear-cytoplasmic maturation, binuclearity, internuclear bridges, and small numbers of ringed sideroblasts). Anemia and, presumably, erythroid dysplasia usually commence during adolescence or early adult life and advance gradually over years. Splenectomy is not curative for these patients. The data available suggest that dysplasia and elliptocytosis cosegregate because no individuals with dysplasia have been observed who did not also have elliptocytosis.[1384,1385] If so, these families must represent the occurrence of a unique subtype of typical common HE. This suggestion is supported by the fact that none of the typical HE protein defects were observed in one well-studied family.

Hereditary Pyropoikilocytosis

This uncommon disorder is manifested in infancy or early childhood as severe hemolytic anemia (hemoglobin level of 4 to 8 g/dL)[1347] characterized by extreme poikilocytosis with budding red cells, fragments, spherocytes, triangulocytes, and other bizarrely shaped cells, as well as few or no elliptocytes in some patients (see Fig. 15-49B).[1323,1386-1391] The morphology of the blood smear somewhat resembles that seen in patients who have severe thermal burns, which explains the name of the disorder. It is more similar to that observed in homozygous common HE and common HE with neonatal poikilocytosis. Most of the patients are individuals of African origin. Patients typically exhibit hyperbilirubinemia in the neonatal period or marked anemia in the first few months of life.[1390] Red cell fragmentation, erythroblastosis, and splenomegaly are also characteristic.[1390,1392] Complications of severe anemia, including growth retardation, frontal bossing, and early gallbladder disease, have been reported.[1388,1389] The red cells are very osmotically fragile, particularly after incubation.[1377,1387-1389] In the most severely affected patients, there is significant microcytosis with very low MCVs (25 to 75 fL) because of the large number of fragmented red cells.[1324,1325,1331,1347,1387,1388] Another characteristic feature of these cells is their remarkable thermal sensitivity. Hereditary pyropoikilocytes fragment at 45° C to 46° C (normal, 49° C) after short periods of heating (10 to 15 minutes).[1389] After splenectomy, hemolysis is markedly decreased, with the hemoglobin level typically ranging from 10 to 14 g/dL with 3% to 10% reticulocytes.[1347,1388,1389]

Although HPP was initially considered to be a separate disease, there is convincing evidence that it is related to HE. As noted earlier, HPP is clinically and morphologically similar to the more severe forms of hemolytic elliptocytosis. In addition, for many patients, one parent or sibling has typical common HE, and in some of these kindreds, an identical molecular defect is observed in siblings with phenotypically different diseases (i.e., HPP and common HE). In other families, all the first-degree relatives have normal phenotypes. A number of biochemical and molecular defects are shared between HE and HPP. However, only HPP red cells are typically markedly deficient in spectrin.[1347,1392-1394] The genetics of HPP suggest that each patient falls into one of three inheritance patterns.[1395] The first consists of patients who are homozygous for a structural variant of spectrin located in the region of the spectrin αβ heterodimer self-association. The second includes patients who are compound heterozygotes for structural defects of spectrin. In the third pattern, typically one parent has an α-spectrin mutation and another parent has no detectable biochemical abnormality.[1393] Studies of spectrin synthesis and mRNA levels reveal that such asymptomatic parents carry a silent "thalassemia-like" defect of spectrin synthesis. When coinherited with the elliptocytogenic spectrin mutation in the offspring with HPP, this thalas-

semia-like defect enhances expression of the mutant spectrin in the cells and leads to a superimposed spectrin deficiency. The spectrin deficiency is thought to be responsible for the large number of spherocytes and relative paucity of elliptocytes in some patients.

Spherocytic Hereditary Elliptocytosis

This dominant disorder is a phenotypic hybrid of common HE and HS. It has been reported only in white families of European descent, is not linked to the Rh gene, and appears to be a unique subtype.[1311,1344,1396-1399] The prevalence of spherocytic HE is unknown, but judging from the number of published reports, it is relatively rare and probably accounts for no more than 5% of HE in patients of European ancestry. Unlike common HE, almost all affected patients have some hemolysis. It is usually mild to moderate and is often incompletely compensated. The elliptocytes are fewer and plumper than in common HE (see Fig. 15-49C), and some spherocytes, microspherocytes, and microelliptocytes are often present. Poikilocytes and red cell fragments are uncommon, which distinguishes this disorder from common HE with hemolysis. Red cell morphology may vary, even within the same family. Some family members may have relatively prominent spherocytes and as few as 10% to 20% elliptocytes, whereas in others, elliptocytes predominate and spherocytes are rare.[1311,1396] This may cause diagnostic confusion initially, particularly if the propositus has few elliptocytes. Family studies almost always reveal some members with obvious elliptocytosis.

Spherocytic elliptocytes are osmotically fragile,[1311,1396,1398,1399] particularly after incubation. Excessive mechanical fragility and increased autohemolysis that responds to glucose are also characteristic. Gallbladder disease is common, and aplastic crises are a risk.[1396,1398] The pathologic course of spherocytic HE mimics that of HS.[1400-1402] Splenic sequestration is evident, red cells are conditioned during splenic passage, and hemolysis abates after splenectomy.[1396,1398,1401]

The molecular pathology of classic spherocytic HE is unknown. However, patients with COOH-terminal truncations of α-spectrin (see later) have many of the clinical features of spherocytic HE and probably represent an example of the disorder.[1403-1411] Patients with such truncations typically have moderate hemolysis and anemia, punctuated by recurrent, severe hemolytic crises.[1404,1405,1408] Blood smears show plump and usually smooth elliptocytes, although in a few instances poikilocytosis was prominent.[1404,1405,1407]

Patients who lack glycophorin C (see later) also have positive OF tests and rounded, smooth elliptocytes.[1412,1413] They should probably also be classified as having a recessive (and unusually mild) variant of spherocytic HE. Patients who lack protein 4.2 (another recessive condition) sometimes display features of spherocytic HE, such as ovalostomatocytosis[895,1057]; however, protein 4.2 deficiency more often resembles HS, morphologically and

pathophysiologically, and is better classified as a variant of that disorder.

Rare patients appear to be compound heterozygotes for HS and HE. One Turkish girl is a particularly good candidate.[1414] Her mother had mild HS and her father most likely had very mild common HE, whereas she suffered from moderately severe hemolytic anemia (hemoglobin level, 8.4 g/dL; reticulocyte count, 24%; bilirubin level, 1.6 mg/dL) with frontal bossing, osteoporosis, splenomegaly, and a mixture of microspherocytes and rounded elliptocytes.

Southeast Asian Ovalocytosis

SAO, which has a unique phenotype, molecular defect, and geographic distribution, is discussed later in this chapter.

Treatment

Typical common HE is mild and splenectomy is rarely required. Serial interval ultrasound examinations, beginning at approximately 6 years of age, to detect gallstones should be performed in patients with brisk hemolysis. Splenectomy to decrease hemolysis, ameliorate anemia, and avoid the formation of bilirubinate gallstones has been the cornerstone of therapy for patients with severe hemolytic HE and HPP. Most practitioners believe that the indications for splenectomy in HS should also be applied to patients with symptomatic HE and HPP. Patients with HE and HPP who have been splenectomized have experienced increased hematocrit values, decreased reticulocytosis, and improvement in clinical symptoms. The risk for thrombosis after splenectomy for HE is unclear, although cases have been reported.[1415] If hemolysis is still active after splenectomy, folic acid (1 mg) should be administered daily. Recommendations for antibiotic prophylaxis, immunization, and monitoring during intercurrent illnesses are similar to those noted for HS patients before and after splenectomy.

Neonates should be treated as any patient with hemolytic anemia. Phototherapy and exchange transfusions are warranted in neonates with severe anemia and pathologic hyperbilirubinemia. Splenectomy is never indicated in the neonatal period. Patients with extreme hemolysis should receive tranfusions until they are 2 to 3 years of age, when immunizations are effective and splenectomy can be performed safely.

Laboratory Methods to Define Abnormal Spectrin Structure in Hereditary Elliptocytosis

Thermal Sensitivity of Red Cells and Spectrin

Red cells heated to temperatures approaching 50° C for short periods become unstable and fragment spontaneously,[1416-1418] probably because of denaturation of spectrin.[1419] Normal spectrin denatures at 49° C (10-minute

exposure),[1299,1419] and normal red cells fragment at the same temperature.[1389,1420] As noted earlier, almost all patients with HPP and some patients with other forms of HE have thermally sensitive red cells. Hereditary pyropoikilocytes and red cells from infants with common HE and neonatal poikilocytosis fragment after 10 minutes at 44° C to 46° C.[1369,1389] Red cells from some but not all patients with common HE fragment at 47° C to 48° C.[1299,1389] As expected, purified spectrin from these red cells is also heat sensitive.[1299,1419] This test is limited because we do not understand, in molecular terms, why specific mutations are thermally sensitive. However, it remains one of the simplest tests available for assessing HPP in laboratories that do not specialize in membrane protein analysis.

Abnormal Spectrin Oligomerization

In many patients with HE and all patients with HPP, spectrin dimers are not properly converted to tetramers and higher oligomers in vitro or on the membrane. This important functional property is easily assessed in low-temperature spectrin extracts. At 0° C, the equilibrium between spectrin dimer and tetramer is greatly slowed. If spectrin is extracted from the membrane at 0° C and carefully protected from warming during separation of dimers, tetramers, and oligomers (usually on nondenaturing polyacrylamide gels), the proportion of each spectrin species reflects its relative proportion on the membrane.[1421] Patients with defects in spectrin self-association have abnormally high proportions of spectrin dimer in 0° C spectrin extracts (i.e., more than 10% of the total spectrin dimers and tetramers).[1351,1420,1422] The fraction of spectrin dimers is an important functional assessment in patients with α-spectrin defects. It correlates well with clinical severity and accurately predicts unusually severe mutations.[1357] Conversely, discordance between the degree of hemolysis and the fraction of spectrin dimers may alert the physician to an underlying, secondary complication (see the earlier section on common HE with chronic hemolysis).

Ektacytometry

The ektacytometer can be used to assess red cell membrane deformability and stability in patients with hemolytic disorders (see earlier).[1081-1083] Isolated red cell ghosts are subjected to high shear stress in a laser diffraction viscometer, and the "deformability index" (a measure of the average elongation of the sheared ghosts) is recorded as a function of time. Fragile ghosts fragment more quickly than normal, which causes their "deformability" to fall. The technique is a useful screening test because membrane stability is reduced in almost all membrane skeletal diseases, including HE and HPP. In addition, the ektacytometer can be modified to measure cellular deformability at different osmolalities, a technique termed osmotic gradient ektacytometry.[1084] The resulting curves depend on both membrane surface area and cell volume and are a sensitive measure of the surface loss that characterizes many skeletal defects.

Tryptic Maps of Spectrin

Limited tryptic digestion of spectrin extracted from erythrocytes, performed at 0° C, followed by SDS-PAGE or isoelectric focusing combined with SDS-PAGE (two-dimensional gels), separates the resulting trypsin-resistant domains of α- and β-spectrin.[1423,1424] In the past, these gels were used to create characteristic, reproducible maps. Among the peptides on these maps, the 80-kd αI-domain peptide, which contains the self-association site of normal α-spectrin, is the most prominent. Many of the known elliptocytogenic α-spectrin mutations affect the 80-kd domain and yield peptide maps containing one or more fragments of the domain. Historically, tryptic peptide mapping has been a useful tool to map the approximate sites of the underlying spectrin mutations; the mutations have subsequently been defined by PCR and sequencing of the corresponding region of cDNA or genomic DNA.

Genetic Analysis

Genomic DNA isolated from peripheral blood leukocytes or reverse-transcribed reticulocyte or bone marrow mRNA can be amplified by PCR with specific DNA oligonucleotide primers flanking the region suspected to contain a mutation. The amplification product is then subjected to nucleic acid sequencing or other forms of analysis. Screening techniques can be used when there are no biochemical clues to the location of the mutation. These techniques are particularly advantageous when the genes of large proteins, such as spectrin or ankyrin, are analyzed. Genomic DNA is tested in most patients because the mutant mRNA species may not accumulate in significant amounts. The single-strand conformation polymorphism (SSCP) method is a simple, sensitive, and appropriately popular example of such a screening test. Labeled, PCR-amplified DNA fragments (100 to 400 bp) are denatured, and the single strands are refolded before running on a nondenaturing gel.[1425,1426] Even a single nucleotide change usually alters the folding pattern enough to allow mutant and normal fragments to separate on the gel (70% to 90% of mutations). In some regions where common elliptocytogenic mutations have been identified, multiplex PCR techniques or simple restriction endonuclease digestion of amplified DNA can be used to rapidly screen for these mutations. Unfortunately, DNA testing for HS and HE mutations is not available commercially and very few private laboratories will do the analysis. It is hoped that commercial testing will become available as the cost of DNA sequencing comes down in the next few years.

Etiology of Common Hereditary Elliptocytosis and Related Disorders

Spectrin Defects

Abnormalities in either α- or β-spectrin are associated with many occurrences of HE and HPP. The majority

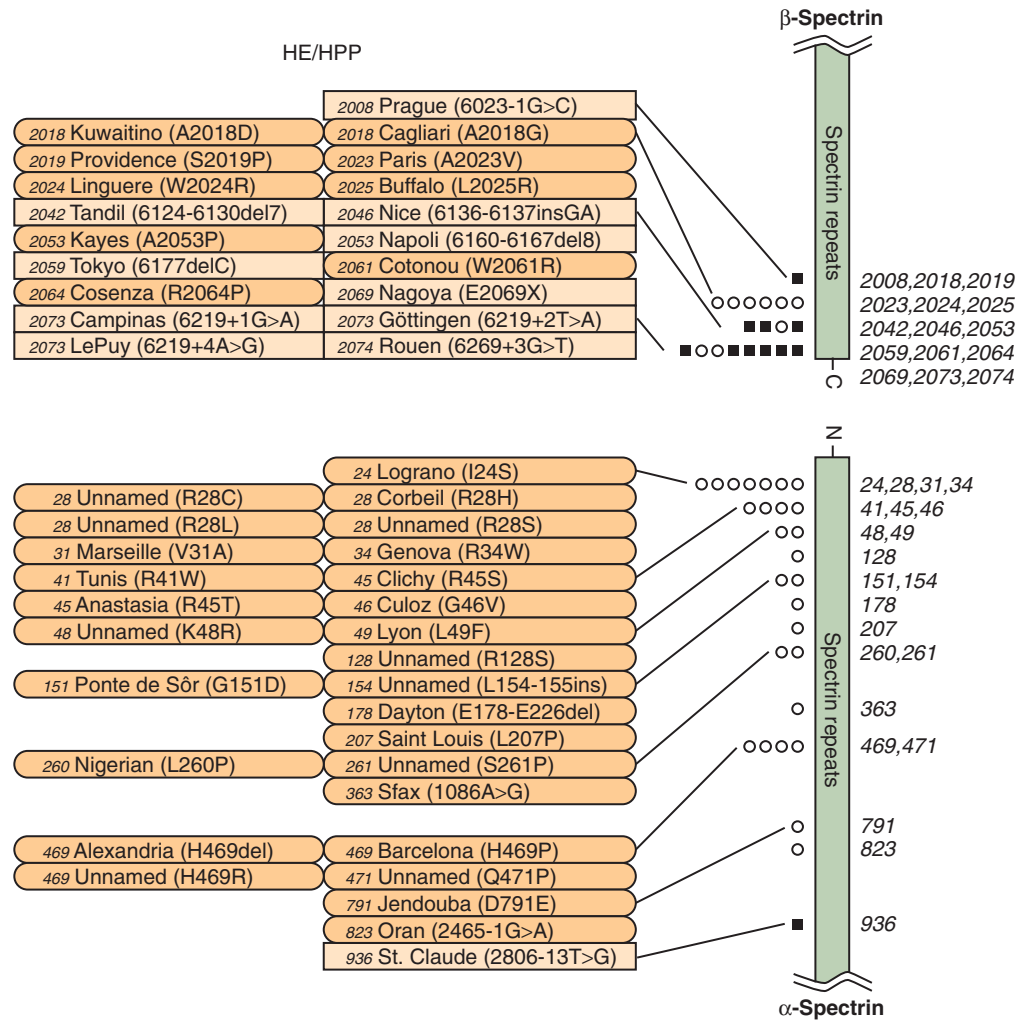
α-Spectrin

FIGURE 15-50. Spectrin mutations associated with hereditary ellliptocytosis (HE) and hereditary pyropoikilocytosis (HPP) are shown alongside a schematic representation of the N-terminals of α-spectrin and the C-terminal of β-spectrin. On the *left*, missense mutations are shown in *dark tan rounded rectangles* and *open circles*, and mutations causing truncations are shown in *light tan rectangles* and *black squares*. The nucleotide numbers of the mutations are relative to the first nucleotide of the ATG initiation codon and may differ from the numbering in some published reports. *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.)*


are due to mutations in the spectrin heterodimer self-association site (Fig. 15-50), with defective ability of spectrin dimers to form tetramers resulting in destabilization of the erythrocyte membrane skeleton. The decreased spectrin self-association is reflected by an increased proportion of spectrin dimers in 0° C, low–ionic strength extracts of spectrin and decreased conversion of spectrin dimers to tetramers in solution, in ghosts, and on inside-out vesicles. The fragile spectrin-spectrin links weaken the membrane skeleton and diminish resistance of the isolated membrane or skeleton to shear stress.[1082,1323]

The severity of the spectrin mutation in HE correlates with the degree of impairment in spectrin self-association and spectrin structural disruption, as measured by the degree of deviation of the mutant spectrin backbone from the crystal structure of the normal spectrin repeat,[1427] as well as with the amount of mutant spectrin that is produced, which is strongly influenced by the spectrin α^{LELY} polymorphism (see later).[1357,1428,1429] Of key clinical importance, mutations within or near the site of self-association produce a more profound defect in spectrin function and a more severe clinical phenotype than do point mutations in more distant spectrin repeats.

α-Spectrin Self-Association Site Defects

Most of the HE defects are in the 80-kd αI domain at the NH$_2$-terminal of the α-spectrin chain. Nine tryptic cleavage defects of the normal 80-kd αI domain peptide have been identified by tryptic mapping and are characterized by loss of the normal 80-kd peptide and appearance of one of the following: a new 78-kd peptide ($\alpha^{I/78}$), a new 74-kd peptide ($\alpha^{I/74}$), a new 65- or 68-kd peptide ($\alpha^{I/65-68}$), a new 61-kd peptide ($\alpha^{I/61}$), a new 46-kd peptide ($\alpha^{I/46}$), a new 50- or 46-kd peptide ($\alpha^{I/46-50a}$), a new 50-kd peptide with a more basic isoelectric point than $\alpha^{I/46-50a}$ ($\alpha^{I/50b}$), two new peptides of 43 and 42 kd ($\alpha^{I/43}$), or two new peptides of 36 and 33 kd ($\alpha^{I/36-33}$). Codon 28, which contains a CpG nucleotide, is a mutation "hot spot." Mutations in this codon are associated with spectrin deficiency and cause mild to severe HE.

The αβ-spectrin heterodimer self-association contact site is a combined triple-helical repeat in which two helices (A and B) are contributed by the COOH-terminal of β-spectrin and the third helix (C) is a portion of the NH$_2$-terminal of α-spectrin (Fig. 15-51; see also Fig. 15-13). These three helices pair up,[1320,1430] as they do all along the spectrin chain, and create the bond responsible for spectrin self-association. The existence and functional
FIGURE 15-51. Triple-helical model of mutations in the αβ-spectrin self-association site associated with hereditary ellliptocytosis and hereditary pyropoikilocytosis. The abnormal tryptic cleavage sites observed in α-spectrin defects are indicated. Nearly all the α-spectrin mutations are missense mutations or in-frame deletions or insertions (*red circles*). Many of the more distal mutations are in helix C near the junction between one spectrin repeat and the next and are thought to interfere with cooperative effects linking spectrin self-association to spectrin-ankyrin and ankyrin–band 3 interactions. Most β-chain defects are C-terminal trunctations (*yellow circles*) or missense mutations directly affecting spectrin self-association (*red circles*). The truncations also impair synthesis of the mutant spectrin and often lead to a spherocytic elliptocytosis phenotype. (*Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.*)

importance of this "atypical repeat" are proved by the study of human mutants, biochemical studies of wild-type and mutant recombinant peptides,[1431-1433] and molecular modeling.[1434-1437] Most α-spectrin defects, commonly attributable to missense mutations, occur in helix C of the triple-helical repeats.

Spectrin $\alpha^{I/74}$ is a heterogeneous collection of defects that result in enhanced tryptic cleavage after Arg45 or Lys48 in an extra helical segment (helix C) that juts out from the NH$_2$-terminal end of the α-spectrin chain. This is the end that participates in formation of the spectrin self-association contact site. The corresponding (COOH-terminal) end of the α chain also contains extra helices (helices A and B) in repeat 17, followed by a phosphorylated segment.

Spectrin $\alpha^{I/74}$ mutations disrupt one of the three interacting terminal helices of the contact site and markedly disrupt spectrin self-association. As a result, they are generally the most severe of the common α-spectrin mutations that cause HE and HPP. Patients who are homozygous for $\alpha^{I/74}$ defects usually have life-threatening hemolysis and an HPP-like syndrome.[1347,1357] Spectrin deficiency and the appearance of spherocytes along with elliptocytes and poikilocytes are common features of the most severe forms of HE and HPP.

In most instances, the primary defect in spectrin $\alpha^{I/74}$ variants is an amino acid substitution near the site of enhanced tryptic cleavage in the α chain.[1438,1439] Examples are Arg28Cys, Arg28Leu, Arg28Ser, Arg34Trp, Gly46Val, Lys48Arg, and Leu49Phe. Codon 28, a CpG dinucleotide, is a "hot spot" for mutation and has been associated with four different sequence variations. In addition, in an increasing number of HE and HPP kindreds with $\alpha^{I/74}$ mutations, the primary defect occurs in helices A or B of repeat 17 of β-spectrin (e.g., Ala2018Gly,

Ser2019Pro, Ala2053Pro, and Trp2016Arg). These two helices are adjacent to the $\alpha^{I/74}$ cleavage site in helix C at the NH$_2$ terminal of the α chain.

Spectrin $\alpha^{I/46-50a}$ is also heterogeneous and variable in severity. Generally, it is less severe than the disorder caused by spectrin $\alpha^{I/74}$ and more severe than that associated with spectrin $\alpha^{I/65-68}$.[1429,1440] Examples include Leu207Pro, Leu260Pro, and Ser261Pro mutations. This disorder is common in black populations, particularly the L260P defect,[1317,1441] which has an incidence of 0.5% in Benin.[1317]

Spectrin $\alpha^{I/65-68}$ is a common α-spectrin mutation (Leu154LeuLeu) that is widely distributed in blacks in West Africa, where the prevalence of HE is 0.67%,[1442] in blacks in Central Africa,[1429] and in their descendants in the West Indies and North America.[1443-1449] It is also seen in Arab populations and is the most common cause of HE in North Africa. The disorder is quite mild. It causes very mild common HE in North Africans, who sometimes have little or no elliptocytosis (i.e., are silent carriers). Even homozygotes have only mild to moderate hemolysis. Studies indicate that with one exception,[1443] all patients have an extra leucine inserted between codons 154 and 155, probably because of duplication of codon 154.[1444,1450] The high rate of occurrence of $\alpha^{I/65-68}$ and its homogeneous expression strongly suggest that it has experienced genetic selection.[1317] This has led to the hypothesis that it may provide some protection from malaria or other tropical diseases caused by blood-borne parasites. This theory has not yet been tested systematically, although there is preliminary evidence that growth of *P. falciparum* is inhibited in $\alpha^{I/65-68}$ erythrocytes.[1451]

Readers interested in descriptions of additional α-spectrin mutations that cause HE can refer to an earlier chapter by one of the authors (S.E.L.).[850]

β-Spectrin Self-Association Site Defects

Almost 20 mutations in the β-spectrin chain have been associated with HE or HPP. These mutations occur at the COOH-terminal region of β-spectrin and tend to be truncations or missense mutations that disrupt formation of the atypical triple-helix repeat, thereby weakening spectrin self-association (see Figs. 15-49 and 15-50). The molecular defects causing the truncated β-spectrin include frameshift mutations,[1405-1407,1452,1453] exon skipping,[1403,1408-1412,1454] and a nonsense mutation.[1455] Several of the missense mutations described result in excess proline residues.[1456] Because proline residues are known to disrupt α helices, this substitution emphasizes the importance of the atypical triple-helix conformation of the spectrin self-association site. Patients with β-spectrin missense mutations have common HE. However, patients with frameshift mutations leading to truncated β-spectrin have spherocytic HE. Patients who are homozygous for a β-spectrin mutation tend to have HPP and a more severe clinical course.

Spectrin Defects outside the Heterodimer Self-Association Site

Mutant spectrins outside the heterodimer self-association site, such as spectrin[St. Claude], spectrin[Oran], spectrin[Jendouba], and spectrin[Detroit], have been described in patients with HE and HPP. These mutations appear to be less severe than those that directly affect spectrin self-association in that the simple heterozygous state is asymptomatic. Patients who are homozygous for these mutations have HE or HPP.

Spectrin[St. Claude], identified in 3% of asymptomatic individuals from Benin, Africa,[1427] and in a white family of Afrikaans origin in South Africa,[1457] is caused by a splice junction mutation that leads to two variant mRNA species.[1379] One species encodes a truncated α-spectrin chain that is not assembled on the membrane. The other species encodes a protein that lacks exon 20 but is attached to the membrane[1427] and exhibits reduced spectrin-ankyrin binding.[1457] Because α-spectrin is produced in excess, heterozygous patients are asymptomatic. Spectrin[Oran] is a variant of the αII domain that is expressed at low levels.[1378] It causes no symptoms in the heterozygous state but causes severe HE in the homozygous state. The abnormal spectrin is caused by abnormal cleavage after Arg890[1378,1381] because of a mutation in the acceptor splice site upstream of exon 18 that causes exon 18 to be skipped. Spectrin[Jendouba] is a variant associated with asymptomatic HE, a mild defect in spectrin self-association,[1458] and abnormal tryptic cleavage after Lys788 as a result of an Asp→Glu mutation at codon 791. A large β-spectrin chain variant, spectrin[Detroit], with an estimated molecular mass of 330 kd has been isolated from two families.[1459,1460] Further study of one of the patients and his family members demonstrated that HE was caused by coinheritance of an α-spectrin chain variant rather than by the elongated β-spectrin chain. Family members with normal α-spectrin and heterozygous for the elongated β-chain variant had normal red cell morphology and no clinical abnormalities, but their erythrocyte membranes were more rigid and fragile than normal. The fragility is probably a consequence of both weaker spectrin dimer association and spectrin deficiency (total spectrin was about 80% of normal).

Low-Expression α-Spectrin Allele: α[LELY] Polymorphism

Some patients with HE and HPP are heterozygous for a structural variant of spectrin involving the self-association site but have a more severe phenotype than expected, including marked hemolysis and anemia that require treatment with blood transfusions or splenectomy. These patients, who also have spectrin deficiency, are usually categorized as having HE with chronic hemolysis or HPP. It has been postulated that the differences in clinical expression are at least partially due to a second defect in α-spectrin or a low-expression allele that affects spectrin production or accumulation. The parents who transmit the postulated defect are clinically and biochemically normal. The best characterized of these low-expression alleles is the α[LELY] allele (low-expression Lyon), which affects approximately 30% of the α-spectrin alleles of white Europeans, 20% of the alleles of the Japanese and Africans, and 22% of the alleles of the Chinese.[1356,1461] Therefore, approximately 42% of white Europeans are heterozygous for this allele and 9% are homozygous. The genetic advantage of the α[LELY] allele has not yet been uncovered.

The α[LELY] allele is caused by a combination of two mutations. One mutation is a C→T substitution at position −12 of intron 45, immediately upstream of exon 46, which causes the six amino acids encoded by exon 46 to be skipped 50% of the time. The second mutation is an amino acid substitution, Leu→Val at codon 1857 in exon 40, caused by a C→G substitution.[1462,1463] This mutation is found in helix B of the α-spectrin repeat and causes more rapid cleavage between the αIV and αV tryptic peptide domains, which creates an increased concentration of the 41-kd αV domain (i.e., the α[V/41] polymorphism).[1356] The effects of these two mutations are shown in Figure 15-52.

The α[LELY] allele is clinically silent by itself, even when in the homozygous state, probably because α-spectrin is normally synthesized in threefold or fourfold excess.[1464] In patients who are heterozygous for α[LELY] and an α-spectrin mutation causing HE, the limited synthesis of α[LELY] protein decreases the amount of spectrin containing α[LELY] that is incorporated into the membrane by approximately 50% and increases the relative incorporation of spectrin containing the mutant HE α chain. α[LELY] is poorly expressed as a result of the mutation in intron 45, described earlier, which causes defective spectrin nucleation because the six deleted amino acids encoded by exon 46 lie within the nucleation site that joins the α- and β-spectrin chains.[1465,1466] α Chains that lack exon
FIGURE 15-52. Nature of the low-expression α^{LELY} allele. The allele contains two linked mutations: a marker mutation, the $\alpha^{V/41}$ defect, and a splicing mutation, the α^{LELY} defect. *Left,* The $\alpha^{V/41}$ defect is caused by a G→C substitution at the beginning of exon 40, which changes a Leu1857→ Val in helix B of spectrin repeat 19. The valine impinges on the neighboring helix C of the repeat and makes it more trypsin sensitive, thereby leading to more rapid release of $\alpha^{V/41}$ peptide from the trypsin-treated spectrin derived from the α^{LELY} allele. Sodium dodecyl sulfate gels of trypsin-treated normal and α^{LELY}-containing spectrin are shown at the *bottom left.* The $\alpha^{V/41}$ peptide is marked. *Right,* The linked splicing mutation is a C→ T substitution at position −12 in the acceptor splice site of intron 45 (a second linked mutation, G→A at position −12 of intron 46, may also contribute). This causes exon 46 to be skipped in 50% of α^{LELY} spectrin molecules *(far right).* Exon 46 is very small, only six amino acids (AA), but it lies in the center of the nucleation site required for side-to-side association of the spectrin α and β chains. The half of α^{LELY} spectrin that lacks exon 46 cannot form spectrin heterodimers and is destroyed. Note that the other 50% of α^{LELY} spectrin contains exon 46 and will be functionally normal (though marked by the $\alpha^{V/41}$ tryptic peptide). *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.)*

46 fail to assemble into stable spectrin dimers and are rapidly degraded.

The effect of the α^{LELY} allele can be quite dramatic. In one family, a patient who was heterozygous for the $\alpha^{I/74}$ mutation $(+/\alpha^{I/74})$ had very mild disease and almost no morphologic abnormality, whereas a relative who had also inherited the α^{LELY} allele $(\alpha^{I/74}/\alpha^{LELY})$ had severe elliptocytosis.[1356] Similarly, in another family the α^{LELY} allele increased the proportion of spectrin $\alpha^{I/65-68}$ in heterozygotes from 45% to 65% of the total spectrin.[1356] This was associated with an increase in the proportion of elliptocytes from none or only a few to nearly 100%. Conversely, when the α^{LELY} allele is on the same chromosome as an α-spectrin mutation, it mutes the elliptocytic phenotype.[1322]

Spectrin α^{LELY} should be distinguished from the thalassemia-like defects of α-spectrin synthesis that when coinherited with some of the α-spectrin mutations, produce a phenotype of HPP. The latter defects are characterized by reduced α-spectrin mRNA levels and diminished α-spectrin synthesis.[1393,1467] In contrast, although the synthesis of α^{LELY} subunits is decreased because of poor incorporation of the peptide lacking exon 46, production of α^{LELY} mRNA is normal.

Protein 4.1 Defects

The link between protein 4.1 deficiency and elliptocytosis was first described in a consanguineous Algerian family (Fig. 15-53).[1332,1380] Partial absence of the protein is found in the 4.1(−) trait, which appears to be a common cause of elliptocytosis and accounts for 30% to 40% of occurrences in some Arab and European populations.[1339,1340,1383,1468] However, this deficiency is not observed in individuals of African ancestry.[1318]

Deficiency of cytoskeletal membrane protein band 4.1 in homozygous hereditary elliptocytosis: implications for erythrocyte membrane stability. J Clin Invest. 1981; 68:454.*)

FIGURE 15-54. Protein 4.1 mutations associated with hereditary elliptocytosis are shown alongside a schematic representation of the protein. On the *left,* four mutations abolishing the translation start site are shown in the *light tan rectangles* and *black squares.* A large deletion and a large insertion affecting the spectrin-actin binding domain are shown in the *dark tan rounded rectangles* and *open circles,* as is a missense mutation at codon 447. The nucleotide numbers of the mutations are relative to the first nucleotide of the ATG initiation codon and may differ from the numbering in some published reports. (*Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.*)

In the original Algerian kindred,[1332] protein 4.1(−) mRNA is not translated[1469] because of a 318-bp deletion that includes the downstream translation initiation site used in reticulocytes (see Fig. 15-18A).[1470] In other patients, point mutations in the downstream initiator codon (AUG→AGG[1380] and AUG→ACG[1471]) have been identified (Fig. 15-54). Interestingly, expression of protein 4.1 is relatively unimpaired in nonerythroid tissues and early erythroblasts[1472-1475] because most of the protein 4.1 isoforms in these tissues initiate translation at the alternatively spliced, upstream translation initiation site.

Protein 4.1(−) heterozygotes have clinically mild common HE with prominent elliptocytosis, often approaching 100%, and little or no hemolysis.[1476] These patients have 50% of the normal amount of protein 4.1.

Erythrocytes from patients homozygous for the protein 4.1(−) trait (i.e., complete protein 4.1 deficiency) are elliptical, fragmented, and poikilocytic (see Fig. 15-53B).[1332,1380,1477] They are very osmotically fragile and possess normal thermal stability. Membranes from homozygous protein 4.1(−) red cells fragment much more rapidly than normal at moderate sheer stress, an indication of their intrinsic instability.[1082] Membrane mechanical stability can be completely restored by reconstituting the deficient red cells with normal protein 4.1 or the spectrin-actin binding site from protein 4.1.[1330,1478]

In addition to complete protein 4.1 deficiency, erythrocytes from protein 4.1(−) homozygotes lack protein p55[1479,1480] and have only 30% of the normal content of GPC and GPD.[1380,1480-1482] This adds evidence to the hypothesis that GPC is one of the membrane attachment sites for protein 4.1.[1483] In addition, protein 4.9 is absent from isolated membrane skeletons but not from intact red cell membranes, and membrane phospholipid asymmetry is perturbed.[1332,1484] Electron microscopic studies of homozygous 4.1(−) erythrocyte membranes have revealed a markedly disrupted skeletal network with disruption of the intramembrane particles, thus suggesting that protein 4.1 plays an important role in maintenance of not only the skeletal network but also the integral proteins of the membrane structure.[1485] Homozygous patients have a severe transfusion-dependent hemolytic anemia but demonstrate a good response to splenectomy.[1332,1380,1477]

Protein 4.1 Structural Defects. Variants of protein 4.1 with abnormal molecular weights have also been described in association with HE.[1340,1486-1489] For example, a shortened protein 4.1 was discovered in an Italian family with very mild common HE and mechanically unstable red cells. The patients are heterozygous for a protein 4.1 variant that has lost the two exons encoding the spectrin/

actin binding domain (see Fig. 15-54). The mutant protein runs as a doublet of 65 and 68 kd on SDS gels and seems to be present in nearly normal amounts. It is presumed but has not been proved to be functionally inept. Another example is a high-molecular-weight variant, protein 4.1[Hurdle-Mills, 1340] which was discovered in a family of Scottish-Irish ancestry with very mild common HE. The patients are heterozygous for a duplication of three exons that include the spectrin-actin binding domain (see Fig. 15-54).[1486,1487] Membrane function appears to be preserved because red cell membranes have normal mechanical stability.[1490] It is not clear how this functionally normal variant causes HE. Other examples of variants of protein 4.1 with abnormal molecular weights have been described.[1488,1489]

Glycophorin C Defects

Elliptocytes are noted on peripheral blood smears of patients whose erythrocytes carry the rare Leach phenotype of Gerbich-negative (Ge–) cells.[1412,1413,1491-1495] These erythrocytes are devoid of GPC and GPD and, presumably secondarily, are also deficient in protein p55 and protein 4.1. It has been speculated that the protein 4.1 deficiency in Leach erythrocytes is the cause of their elliptocytic shape. Interestingly, the relative deficiency of protein 4.1 in Leach erythrocytes is less than the degree of GPC deficiency in homozygous protein 4.1(–) erythrocytes. These findings add supportive evidence to the hypothesis that GPC and protein p55 provide a binding site for protein 4.1 in the red cell.[1479]

The Leach phenotype is usually due to a deletion of 7 kb of genomic DNA that removes exons 3 and 4 from the GPC/GPD locus.[1491,1492] Patients carrying the Leach phenotype suffer from mild spherocytic HE with increased erythrocyte OF.[1412,1493-1495] In some individuals, no elliptocytes are detected on peripheral smear.[1481]

In contrast to GPC and GPD deficiency, individuals whose erythrocytes lack GPA, GPB, or both are asymptomatic and have erythrocytes of normal shape and mechanical stability.

Pathophysiology of Hereditary Elliptocytosis/Hereditary Pyropoikilocytosis

Spectrin Mutations

The principal functional consequence of the elliptocytogenic spectrin mutations is weakening or even disruption of the spectrin dimer-tetramer contact and, consequently, the two-dimensional integrity of the membrane skeleton. These "horizontal" defects are readily detected by ultrastructural examination of membrane skeletons, which reveals disruption of the normally uniform hexagonal lattice. As a result, membrane skeletons, cell membranes, and the red cells are mechanically unstable. In patients who have severely dysfunctional spectrin mutations or in subjects who are homozygous or compound heterozygous for such mutant proteins, this membrane instability

is sufficient to cause hemolytic anemia with red cell fragmentation.

The mechanism for the formation of elliptocytes is less clear. In common HE, red cell precursors are round and become progressively more elliptical as they age in vivo.[1313,1341,1496] Red cells distorted by shear stress in vitro or flowing through the microcirculation in vivo have elliptical or parachute-like shapes, respectively.[1497] Perhaps the abnormal shapes of elliptocytes and poikilocytes are permanently stabilized because the weakened skeletal interactions facilitate skeletal reorganization after prolonged or repetitive cellular deformation. Skeletal reorganization is likely to involve breakage of the unidirectionally stretched protein connections and formation of new contacts that reduce stress on the skeleton and stabilize the deformed shape.[1497] This process, first proposed in 1978, has been shown to account for permanent deformation of irreversibly sickled cells.[1498]

HPP red cells have two abnormalities: they contain a mutant spectrin that disrupts spectrin self-association, and they are partially deficient in spectrin.[1392,1393] This is either due to an elliptocytogenic α-spectrin mutation and a defect involving reduced α-spectrin synthesis or due to two elliptocytogenic spectrin alleles. In the latter situation, the spectrin deficiency might be a consequence of spectrin instability, which would reduce the amount of spectrin available for membrane assembly. In red cells carrying a lot of unassembled spectrin dimers, the fact that one ankyrin is bound per one spectrin tetramer (i.e., two spectrin heterodimers) may also contribute to the spectrin deficiency. At best, only about half of the spectrin dimers could succeed in attaching to the available ankyrin binding sites. Probably, this attachment would be less because unphosphorylated ankyrin binds spectrin dimers about 10 times less avidly than it does spectrin tetramers.[1499] The phenotype of HPP, characterized by the presence of fragments and elliptocytes, together with evidence of red cell surface area deficiency (i.e., microspherocytes), suggests that the membrane dysfunction involves both "vertical" interactions (a consequence of the spectrin deficiency) and "horizontal" interactions (a consequence of the elliptocytogenic spectrin mutations).

Protein 4.1 Variants

Hereditary elliptocytes that are deficient in protein 4.1 are similar in shape and membrane instability to elliptocytes that result from spectrin mutations.[1497] This suggests that protein 4.1 deficiency principally affects spectrin-actin contact (i.e., a horizontal interaction) rather than the skeletal attachment to GPC (a vertical interaction).

Permeability of Hereditary Elliptocytosis Red Cells

Red cells in HE consume more ATP and 2,3-DPG than normal erythrocytes do,[1500] probably because of increased

transmembrane Na^+ movement.[1501] As a result of the underlying skeletal defect, HE and HPP red cells are abnormally permeable to Na^+, K^+, and Ca^{2+} ions.[1388,1501] The excessive Ca^{2+} leak was originally thought to be the primary molecular lesion in a patient with severe microcytic hemolytic anemia and red cell thermal instability,[1388] but the patient was subsequently shown to have a spectrin mutation and, probably, HPP.[1440]

Common Hereditary Elliptocytosis and Malaria

Epidemiologic studies of the elliptocytogenic mutations of spectrin in central and western Africa suggest that their prevalence is considerably greater than would be expected for sporadic mutations. The prevalence of the spectrin $\alpha^{I/65-68}$ mutation approaches 1%,[1318] and the mutation is always associated with the same α-spectrin haplotype.[1502] Similar findings were reported for two α-spectrin mutations producing the spectrin $\alpha^{I/46-50a}$ phenotype (Leu207→Pro and Leu260→Pro). These data are of considerable interest in light of recent in vitro studies demonstrating diminished malarial parasite entry or growth in red cells that contain some of the elliptocytogenic spectrin mutants or are deficient in protein 4.1.[1451,1503,1504]

SOUTHEAST ASIAN OVALOCYTOSIS

SAO, also known as Melanesian ovalocytosis or stomatocytic elliptocytosis, is observed in the aboriginal populations of Melanesia and Malaysia and in portions of Indonesia and the Philippines.[1505-1511] The abnormality is very common in Melanesia, particularly in lowland and island tribes, in whom malaria is endemic,[1506,1511-1513] and it affects 1% to 15% of the population.[1514,1515] SAO has been detected rarely in white and African American individuals.[1516-1519] SAO is inherited in an autosomal dominant pattern.[1505-1508,1512,1520] In screening of large populations with SAO, no homozygotes have been identified,[1521,1522] thus suggesting that homozygosity leads to embryonic or fetal lethality.

Resistance to Malaria

In vivo, there is evidence that SAO provides some protection against all forms of malaria, particularly against heavy infections and cerebral malaria.[1506,1507,1512,1513,1523-1526] The prevalence of SAO increases with age in populations challenged by malaria, which suggests that individuals with SAO have a selective advantage.[1523] In vitro, SAO red cells are resistant to invasion by malarial parasites,[1527-1530] apparently because the membrane is 10 to 20 times more rigid than normal.[1531-1534] Other membrane characteristics reflect this property, including unusually high heat resistance, lack of endocytosis in response to drugs that produce dramatic endocytosis in normal cells, and strong resistance to crenation, even after several days of storage in plasma or buffered salt solutions.[1531] However, other population studies show no correlation between the SAO mutation and the prevalence of malaria,[1515,1535] which may be due to the fact that some parasite strains invade SAO red cells efficiently whereas others do not.[1536] This supports the concept that malaria parasites can use different receptors or pathways for invasion (see the earlier section on band 3 and malaria).

Etiology

The finding of tight linkage between an abnormal proteolytic digest of band 3 protein and the SAO phenotype led to detection of the underlying molecular defect.[1520] All carriers of the SAO phenotype are heterozygotes. One band 3 allele is normal and the other contains two mutations in *cis*: a deletion of nine codons encoding amino acids 400 through 408, located at the end of the cytoplasmic domain and the beginning of the first transmembrane segment of band 3, and replacement of Lys56 by Glu.[1533,1534,1537-1540] The Lys56→Glu substitution is an asymptomatic polymorphism known as band 3^{Memphis} that is in linkage disequilibrium with the 9 amino acid deletion. The mutant SAO band 3 exhibits tight binding to ankyrin,[1520] increased tyrosine phosphorylation,[1541,1542] inability to transport anions,[1543,1544] and markedly restricted lateral and rotational mobility in the membrane.[1520,1533]

Clinical Features and Morphology

Most of the cells are rounded elliptocytes, but a few are traversed by one or two transverse bars that divide the central clear space (see Fig. 15-49D).[1505,1509-1511,1520,1545] These "theta cells" or "stomatocytic elliptocytes" are not seen in any other condition. Thus, identification of multiple theta cells on a peripheral blood smear strongly suggests SAO. Some stomatocytes may also be present. The strong resistance of red cells to crenation after several days of storage[1531] provides an additional clue to the diagnosis. However, the most specific diagnostic test for SAO is amplification of the deleted region from the band 3 gene in genomic DNA or reticulocyte cDNA. This produces a single band in control red cells and a doublet in SAO cells, with the second band shorter by 27 bp.[1533,1537,1546]

Hemolysis is apparently mild or absent,[1505,1507,1509,1510] although neonatal hyperbilirubinemia and mild hemolytic anemia have been described.[1547,1548] One patient had compensated hemolysis (no anemia) with mild splenomegaly, an absolute reticulocyte count of 150 to 300 × 10^{-3} (normal, 10 to 100 × 10^{-3}), mild hyperbilirubinemia, and gallstones.[1549] This indicates that membrane rigidity is not a major determinant of red cell survival. In another well-studied patient,[1510] red cell Na^+ and K^+ permeability was increased, glucose consumption was elevated to compensate for increased cation pumping, and the cells

were osmotically resistant. Curiously, many blood group antigens are poorly expressed on the surface of SAO red cells,[1511] possibly because the rigid membrane inhibits their clustering and impedes agglutination.

SAO band 3 also is a recessive mutation for dRTA. The disease develops in patients who are compound heterozygotes for SAO and other band 3 mutations causing dRTA.[1550,1551] The reason is because sufficient heterodimers of normal and SAO band 3 reach the plasma membrane to prevent acidosis, whereas heterodimers of SAO and other dRTA band 3 molecules become trapped in the endoplasmic reticulum and lead to deficient Cl⁻ excretion.[1552]

Molecular Basis of Membrane Rigidity

SAO red cells are unique among elliptocytes in that they are rigid and hyperstable rather than unstable.[1532] The SAO band 3 mutation is the first example of a defect in an integral membrane protein leading to red cell membrane rigidity, a property that had previously been attributed to the membrane skeleton.[1553] The explanation for the rigidity is presently not clear. One hypothesis proposes that conformational changes in the cytoplasmic domain of SAO band 3 preclude lateral movement (extension) of the skeletal network during deformation.[1534,1554] A second possibility is that SAO band 3 binds abnormally tightly to ankyrin and thus to the underlying skeleton.[1513] The increased propensity of SAO band 3 to aggregate into higher oligomers may be important because the oligomers can strengthen attachment of band 3 to ankyrin.[1555] The tendency of SAO band 3 to form linear arrays would also decrease its mobility within the bilayer.[1556] Finally, SAO band 3 may adhere to the skeleton in a nonspecific manner, possibly because of denaturation of the membrane-spanning domain.[1557] Studies of the structure of the first transmembrane span of wild-type and SAO band 3 show that a bend between the cytoplasmic domain and the first transmembrane domain is absent in SAO cells; this leads to the formation of a stable helix in the region,[1558] possibly because of retraction of the polar amino acids that normally lie in the cytoplasm into the first transmembrane segment in SAO band 3.[1559] Other studies using chemical modification and proteolysis show that SAO band 3 is misfolded and affects the structure of its normal band 3 partner or partners.[1560]

The resistance of SAO red cells to malaria is presumably related to the altered properties of SAO band 3. Band 3 serves as one of the *P. falciparum* malaria receptors because invasion by the parasite in vitro is inhibited by band 3–containing liposomes.[1561] In normal red cells, parasite invasion is associated with marked membrane remodeling and redistribution of band 3–containing intramembrane particles.[1562] Intramembrane particles cluster at the site of parasite invasion and form a ring around the orifice through which the parasite enters the cell. The invaginated red cell membrane, which surrounds the invading parasite, is free of intramembrane particles. The reduced lateral mobility of band 3 protein in SAO red cells may preclude band 3 receptor clustering and thus prevent attachment or entry of the parasites.[1520,1533] Resistance to malaria has also been attributed to diminished anion exchange as a result of the inability of SAO band 3 to transport anions.[1544] In addition, SAO red cells consume ATP at a higher rate than normal cells do, and the ensuing partial depletion of ATP levels in ovalocytes has been proposed to account, at least in part, for the resistance of these cells to malaria invasion in vitro.[1531] However, diminished anion transport and ATP depletion do not appear to play a critical role in the resistance of SAO erythrocytes to malaria in vivo. This is evidenced by the fact that band 3–deficient HS red cells are considerably less resistant to malaria invasion than SAO red cells are, although both cell types have a similar decrease in anion transport, and by the fact that resistance of SAO red cells to malaria is detected in vitro even when red cell ATP levels are maintained.

HYDROPS FETALIS SYNDROMES AND DISORDERS OF THE ERYTHROCYTE MEMBRANE

Defects in the erythrocyte membrane have been well characterized in patients with severe neonatal hemolytic anemia secondary to recessive HS, homozygous HE and HPP, and hereditary xerocytosis. Several well-documented kindreds with fatal or nearly fatal anemia and hydrops fetalis associated with erythrocyte membrane defects have been described. In several patients, defects were identified in spectrin, the principal structural protein of the erythrocyte membrane.[841,1435,1442] In the other patients, homozygosity for a band 3 defect was discovered (see earlier). Membrane defects have been suspected, but not proven in numerous other patients with nonimmune hydrops fetalis with severe hemolytic anemia.

STOMATOCYTOSIS AND XEROCYTOSIS

Red cell hydration is largely determined by the intracellular concentration of monovalent cations. A net increase in Na⁺ and K⁺ ions causes water to enter and form "stomatocytes" or "hydrocytes," whereas a net loss of monovalent cations produces dehydrated red cells, or "xerocytes" (see Fig. 15-29). In the past 35 years, numerous descriptions of congenital or familial hemolytic anemias associated with abnormal cation permeability and, in some cases, disturbed red cell hydration have been reported. These cases span the range from severe stomatocytosis to severe xerocytosis. They can be divided into six provisional clinical categories based on differences in severity, morphology, cation content, lipid and protein composition, genetics, and response to splenec-

tomy: severe stomatocytosis,[1563-1579] mild stomatocytosis,[1580-1582] cryohydrocytosis,[1583-1589] stomatocytic xerocytosis,[1590] pseudohyperkalemia,[779,1591-1602] and xerocytosis (Table 15-8).[992,1591-1593,1595,1598,1603-1622] Although these divisions are useful as a method of categorization, it is likely that these categories are not unique entities, and the divisions are not clinically meaningful. Indeed, none of these apparent disorders are precisely defined in either clinical or molecular terms.

Osmotic gradient ektacytometry is a rapid and sensitive measure of red cell membrane hydration.[1084] The ektacytometer measures red cell deformability, osmotic resistance, and cell hydration. However, the equipment required is not readily available in most clinical centers. Therefore, other measures must be used in making the difficult diagnosis of a disorder of red cell membrane permeability.

Hereditary Stomatocytosis (Hydrocytosis, Overhydrated Stomatocytosis)

Hereditary stomatocytosis, the name given by Lock and co-workers[1569] to the first reported instance, is characterized by erythrocytes with a mouth-shaped (stoma) area of central pallor on peripheral blood smears (Fig. 15-55A). The clinical severity of hereditary stomatocytosis, a rare disorder, is variable; some patients experience hemolysis and anemia, whereas others are asymptomatic.

Stomatocyte membranes are remarkably permeable to Na^+ and K^+ ions, particularly Na^+ ions. Intracellular Na^+ is increased and K^+ is decreased, but the total monovalent cation content ($Na^+ + K^+$) is high, which leads to an increase in cell water and cell volume. As a conse-

quence, the "edematous cells" are sometimes called hydrocytes or overhydrated stomatocytes.

Pathophysiology

The major detectable defect in hereditary stomatocytosis is a marked asymmetric increase in passive Na^+ and K^+ permeability (the amount of Na^+ in is greater than the amount of K^+ out). Permeabilities as great as 15 to 40 times normal are observed.[1563,1573,1612] Because the influx of Na^+ exceeds the loss of K^+, stomatocytic red cells progressively gain cations and water and swell. As a result, their average density is less than normal (Fig. 15-56), and the swollen stomatocytes are osmotically fragile. Unlike normal cells, aged stomatocytes are less dense and more stomatocytic than stomatocytic reticulocytes.[1563]

In stomatocytosis, monovalent cation transporters are stimulated by the influx of Na^+, particularly the Na^+,K^+ pump and the K^+-Cl^- cotransporter,[1571] but are unable to keep up with the exaggerated cation leaks. Na^+,K^+ pump kinetics is normal,[1580] and the number of pumps is increased severalfold,[1563,1615] even after corrections for red cell age.[1623]

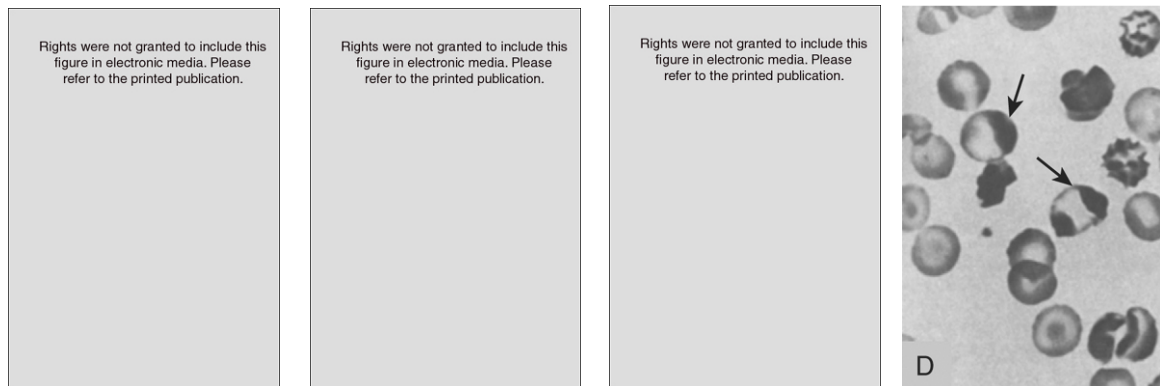
Bifunctional imidoesters, which cross-link proteins, reverse the abnormal shape and permeability of hereditary stomatocytes and normalize their survival in the circulation.[1563] The critical proteins involved have not been identified with these agents because many red cell membrane proteins are cross-linked at the concentrations required to achieve this effect. Stomatocytes are relatively rigid[1570] and expend extraordinary amounts of ATP in pumping Na^+ and K^+ in an attempt to maintain homeostasis. They are vulnerable to splenic sequestration, and predictably, splenectomy has been beneficial in some patients with severe hemolysis,[1563,1571,1572,1574,1581] but not without risk (see later).[1222]


FIGURE 15-55. Peripheral blood morphology in hereditary stomatocytosis and hereditary xerocytosis. **A,** Stomatocytosis. Many stomatocytes and occasional spherocytes are seen. **B,** Cryohydrocytosis. Some of the stomatocytes are bowl shaped, some have curvilinear slits, and some have a transverse bar dividing the central clearing. **C,** Xerocytosis (typical). Some target cells are evident, but most red cells are morphologically unremarkable. **D,** Xerocytosis (severe). Target cells, echinocytes, and dense crenated cells predominate. In occasional cells (*arrow*) the hemoglobin appears to be puddled in one portion of the cell. (*A, From Turpin F, Lortholary P, Lejeune F, Claer R. Un cas d'anémie hémolytique avec stomatocytose. The xerocytes extend to higher densities than normal red cells do. *Right,* Normal and hereditary stomatocytosis samples. Many of the stomatocytes are lighter than the control red cells. *(From Lande WM, Mentzer WC. Haemolytic anaemia associated with increased cation permeability. Clin Haematol. 1985;14:89.)*

Stomatin

The red cell membranes of all or almost all patients with the classic overhydrated form of stomatocytosis lack a 31-kd protein called stomatin or band 7.2b (Fig. 15-57).[1565,1566,1571,1575,1624,1625] Stomatin, a member of a large family of related proteins, is an integral membrane phosphoprotein whose function is not completely understood.[360,361,1575,1626-1631] The importance of stomatin is underscored by its wide tissue and species distribution. In humans, stomatin mRNA has been detected in every tissue and cell tested. Reactivity to a monoclonal antibody directed against human erythrocyte stomatin has been observed in the erythrocyte membranes of a wide variety of species, including the frog, rat, chicken, rabbit, pig, cow, and sheep.[1626] It has been hypothesized that stomatin may support, activate, or regulate an unidentified ion channel.[1575,1627,1628]

Although hereditary stomatocytosis appears to be a dominantly inherited condition and affected individuals are presumably heterozygotes, stomatin protein is almost absent, even though mRNA levels[1627] and the coding sequence of the gene[1632-1634] are normal. Immunochemistry detects some stomatin in a few red cells, particularly reticulocytes.[1576] Overall, there is about 2% to 5% of the normal amount of stomatin in red cells. Stomatin immunoreactivity in nonerythroid tissues is normal. This suggests that stomatin is made but is lost or destroyed in hereditary stomatocytes as the cells mature in the bone marrow and in the circulation. Mice with targeted disruption of stomatin are clinically and hematologically normal,[1635] which supports the idea that stomatin deficiency is secondary and not directly involved in patho-

FIGURE 15-57. Stomatin deficiency in hereditary stomatocytosis. Sodium dodecyl sulfate gels of normal and stomatocytosis red cell membranes show that the principal (31-kd) band in the band 7 region (stomatin) is missing. A similar picture is observed in most patients with severe hereditary stomatocytosis. Immunoblots confirm that stomatin is nearly absent in these cells. G3PD, glyceraldehyde-3-phosphate dehydrogenase; Hb, hemoglobin. *(Reprinted from Rix M, Bjerrum PJ, Wieth JO, Frandsen B. Congenital stomatocytosis with hemolytic anemia—with abnormal cation permeability and defective membrane proteins. Ugeskr Laeger. 1991;153:724.)*

genesis of the cation leak and hemolysis. As discussed in the first section of the chapter, stomatin resides in detergent-resistant lipid domains called lipid rafts. Recent studies show that the amount of actin and tropomodulin (TMod) associated with these rafts is markedly reduced in hereditary stomatocytes.[1578] In addition, Ca^{2+}-induced exovesiculation is enhanced in stomatocytes, and the released vesicles contain greatly increased amounts of lipid raft proteins such as annexin VII, sorcin, copine 1, and the flotillins, but decreased amounts of stomatin and annexin V.[1578] In contrast, ATP-dependent endovesiculation is reduced in stomatin-deficient hereditary stomatocytes (but not in other forms of stomatocytosis).[1579] Interestingly, cross-linking imidoesters fix this defect, as well as the monovalent cation leak.[1579] These data suggest that there may be a defect in the interaction of stomatin with the membrane skeleton in stomatocytes, although why that would cause massive monovalent cation leaks is a mystery. Unfortunately, nothing is known about interactions between the membrane skeleton and stomatin or

between TMod or actin and the lipid bilayer, so it is difficult to guess which proteins might be involved. It is also hard to guess why stomatin is deficient. Stomatin could be lost with other raft proteins in exocytic vesicles, but the vesicles are stomatin deficient not stomatin replete. In cultured erythroid cells from patients with hereditary stomatocytosis, stomatin immunoreactivity is confined to multivesicular complexes and the nucleus and is not seen on the plasma membrane.[1577] This suggests that stomatin deficiency may result from a trafficking defect, which might also affect other membrane proteins. One can imagine a defect in the trafficking mechanism itself or the loss of a chaperone, or stomatin could be abnormally modified by a post-translational process and preferentially recognized and destroyed by a protease or the proteosome.

Clinical Features

Typical Stomatin-Deficient Stomatocytosis. Diagnostic features of the classic type of hereditary stomatocytosis include the unique red cell morphology (5% to 50% stomatocytes) (see Fig. 15-55A), severe hemolysis, macrocytosis (110 to 150 fL), elevated erythrocyte Na^+ concentration of 60 to 100 mEq/L (normal range, 5 to 12 mEq/L), reduced K^+ concentration of 20 to 55 mEq/L (normal range, 90 to 103 mEq/L), and increased total $Na^+ + K^+$ content of 110 to 140 mEq/L (normal range, 95 to 110 mEq/L). The excess monovalent cations elevate cell water and thereby produce large, osmotically fragile cells with a low MCHC (24% to 30%). In many patients, hereditary stomatocytes are also moderately deficient in 2,3-DPG.[1563,1570,1615] Perhaps a portion of the 1,3-DPG normally used for 2,3-DPG synthesis is diverted through PGK to provide extra ATP for cation transport.[776] The 2,3-DPG deficiency mildly enhances oxygen affinity and causes additional water entry and cell swelling. Some patients[1568,1590] with hereditary stomatocytosis have an unexplained decrease in red cell glutathione; however, it is unlikely that this decrease is pathophysiologically significant. Stomatocytosis, like other hemolytic anemias, is often complicated by iron overload and cholelithiasis.

Hereditary Stomatocytosis Variants. Hereditary stomatocytosis is probably more heterogeneous than suggested earlier. Some patients with severe permeability defects have little or no hemolysis.[1614] In addition, studies of 44 Japanese patients with stomatocytosis show that the proportion of stomatocytes and the degree of Na^+ influx do not correlate with each other and that neither correlates with the amount of hemolysis or anemia.[1624] Furthermore, stomatin deficiency was not observed in Japanese patients with the most severe permeability defects and was present only to a mild degree in five of nine patients with more moderate Na^+ leaks. This suggests that hereditary stomatocytosis is a complex mixture of diseases or that factors other than those that regulate Na^+ leak and stomatin content are critical to demise of the stomatocyte.

Treatment: Splenectomy Is Dangerous

Splenectomy reduces the hemolytic rate in patients with severe hereditary stomatocytosis[1563,1564,1571,1572,1581] and can be beneficial; however, a high proportion of patients have experienced thrombotic complications, at times with disastrous results.[1222] Venous thrombi predominate and sometimes lead to portal hypertension or thromboembolism and pulmonary hypertension.[1222,1636,1637] Thrombotic episodes have not been reported before splenectomy. The cause of the hypercoagulable state after splenectomy in patients with hereditary stomatocytosis is uncertain. There is evidence that stomatocytes have about fourfold more PS on their surfaces than control cells do.[1638] As described earlier (see the section "Asymmetric Organization of Lipids in the Bilayer"), PS exposed on the outer surfaces of cells is highly thrombogenic.[74-76] Such cells are cleared by macrophages, which have PS receptors on their surface.[78-81] This function would presumably be impaired after splenectomy. In vitro, erythrocytes from two splenectomized individuals with hereditary stomatocytosis showed mildly increased adherence to endothelial monolayers.[1638,1639] Conceivably, this might also contribute to a hypercoagulable state.

Hereditary Xerocytosis (High-Phosphatidylcholine Hemolytic Anemia, Dehydrated Hereditary Stomatocytosis)

Hereditary xerocytosis is probably the most common of the membrane cation permeability defects. Several families with this disorder, in which red cells are markedly dehydrated, have been described,[992,1591-1593,1595,1598,1603-1622] and because the disease is often clinically mild, it is likely that many patients go undiagnosed. Physiologically, the major red cell abnormality is a change in the relative membrane permeability to potassium. Efflux of K^+ is increased twofold to fourfold and approximates Na^+ influx. There is no metabolic or hemoglobin abnormality to account for this permeability lesion, and red cell Ca^{2+} content is not increased. The nature of the permeability defect is unknown. Monovalent cation pump activity is increased appropriately for the slightly elevated Na^+ content, but the Na^+,K^+ pump cannot compensate for K^+ losses in excess of Na^+ gain. In fact, the action of the pump significantly exacerbates the rate of K^+ loss because three Na^+ ions are pumped out for every two K^+ ions returned.[1640,1641] As a consequence, xerocytes gradually become cation depleted and lose water in response to decreased intracellular osmolality. This is easily detected by centrifugation on Stractan density gradients (see Fig. 15-56).

Molecular Pathology

The gene for xerocytosis has been mapped to 16q23-q24.[1592,1642,1643] Nevertheless, little is known about the molecular pathology of the disease. When measured, the

proportion of red cell membrane PC is increased (12 to 20 fmol/cell; normal range, 10 to 12 fmol/cell).[1613] The combination of hereditary xerocytosis and high PC is sometimes given the name high-PC hemolytic anemia (HPCHA),[1598,1605,1609,1612,1613,1615] but there appears to be little reason to distinguish HPCHA from hereditary xerocytosis.[1613] Early studies suggested that the excess PC was due to diminished transfer of PC fatty acids to PE,[1609] a pathway that is normally stimulated by cellular dehydration.[1644] It is not clear why this pathway is inhibited in hereditary xerocytosis or how it relates to the underlying membrane leakiness and hemolysis.

Xerocytic red cells are also shear sensitive[1608] and are exceptionally prone to membrane fragmentation in response to metabolic stress.[992] This finding suggests a membrane skeletal defect, but none of the well-characterized membrane protein genes reside in the 16q23-q24 interval (see Table 15-2). Results of conventional analyses of red cell membrane proteins have been normal,[992] except for an increase in the proportion of membrane-associated G3PD in one family.[16456] Quantitatively, all membrane components are increased because xerocytes have 15% to 25% more surface area than normal, probably due to the increased amount of phospholipids. Xerocytes are relatively rigid cells[758] and have a dehydration-induced membrane injury.[1608] This poorly defined lesion is also found in irreversibly sickled cells[1646] and presumably is important in the pathophysiology of hemolysis. Hereditary xerocytes are unusually sensitive to oxidants.[1647,1648] Exposure of xerocytes to concentrations of H_2O_2 that do not affect normal cells causes a rapid loss of intracellular K^+, conversion of hemoglobin to methemoglobin, and cross-linking of hemoglobin to spectrin.[1648,1649] Similar sensitivity occurs in dehydrated normal red cells. Conversely, rehydrated xerocytes exhibit a normal reaction to H_2O_2. Native xerocytes have the abnormal spectrin-globin complex, and the amount correlates with the extent of dehydration in various cellular fractions and with membrane rigidity.[1650] Oxidation of normal erythrocytes with peroxide generates the spectrin-globin complex and rigid membranes.[1037] Complex formation is blocked by carbon monoxide, which prevents hemoglobin oxidation, but is not blocked by lipid antioxidants. This implies a direct role for hemoglobin in cross-linking spectrin. However, the relationship of these findings to the pathophysiology of hereditary xerocytosis is unclear.

A constellation of clinical findings, including xerocytosis, pseudohyperkalemia, perinatal ascites, and even hydrops fetalis, have been described in the fetal and newborn period.[1592,1593,1599,1618,1619] Genetic studies of patients with this constellation of disorders also show linkage to 16q23-q24.[1592] The mechanism of ascites in these patients is unclear and appears to be unrelated to anemia or hypoalbuminemia. There is one report of neonatal hepatitis in a patient,[1623] but it seems unlikely that hepatitis would have been missed in others. Although treatments such as fetal transfusion and fetal albumin infusion have been described, the efficacy of these interventions is difficult to assess because of the apparent high rate of self-resolution of symptoms in late gestation and the early neonatal period in these patients.[1619,1651,1652]

Familial Pseudohyperkalemia. Of note, Stewart and co-workers[1596,1597] reported a family with a dominantly inherited disorder characterized by loss of erythrocyte K^+ through passive K^+ leak across the red cell membrane that is exaggerated in the cold. Electrolyte analysis of plasma obtained from blood samples stored for just a few hours at room temperature or below may falsely suggest that affected individuals are hyperkalemic. Familial pseudohyperkalemia is symptomless, and affected patients do not experience hemolysis or anemia. Therefore, the key clinical importance of this disorder is that these patients are not truly hyperkalemic and have a normal electrocardiogram. These patients are at risk of mistakenly receiving hyperkalemic therapy and developing severe hypokalemia. The disorder resembles cryohydrocytosis (see later), except that K^+ loss and dehydration predominate instead of Na^+ gain and cryohemolysis. Studies of patients with hereditary stomatocytosis and particularly those with xerocytosis have shown that many of these variants also cause pseudohyperkalemia.[1591,1592,1594,1595,1653] Further evidence of overlap between these syndromes is that some forms of familial pseudohyperkalemia are linked to the xerocytosis locus at 16q23-q24.[1592,1594,1642]

Clinical and Laboratory Features

In all families with hereditary xerocytosis that have been studied, inheritance is autosomal dominant. Red cell features used for diagnosis include an increased MCHC, increased MCV, and *decreased* OF (i.e., *resistance* to osmotic lysis). The combination of an elevated MCV and MCHC is unique and suggests the diagnosis of hereditary xerocytosis. Hereditary xerocytes appear to be macrocytic despite their dehydration. This, however, is partially an artifact of cellular stiffness. In Coulter-type electronic counters, conversion of pulse height (from the resistance of a cell passing through an electric field) to cellular volume depends on cell shape. Xerocytes do not deform to the same degree as normal cells do, which causes the electronically measured MCV to be about 10% too high.[1654] This behavior also affects the hematocrit value, which is calculated from the MCV. Most patients have compensated hemolysis with little or no anemia.

Most patients also have nearly normal erythrocyte morphology, with only a few target cells and an occasional echinocyte or stomatocyte (see Fig. 15-55C). However, in the most severely affected patients,[1604] particularly after splenectomy, blood smears display contracted and spiculated red cells in which the hemoglobin appears to be aggregated in one portion of the cell (see Fig. 15-55D). The characteristic biochemical abnormalities are a reduced K^+ concentration and total monovalent cation content. In older erythrocytes, K^+ levels approach

half-normal.[1613] The clinical course is also remarkable for iron overload in the absence of transfusions,[1655] particularly in patients who are heterozygous for a hemochromatosis gene.[1622] This often requires treatment.

Red cell 2,3-DPG concentrations are moderately decreased in hereditary xerocytosis,[992,1604,1606,1607,1656] as in hereditary stomatocytosis. The reasons are unknown. Because loss of the polyvalent DPG is compensated for by an influx of monovalent chloride ions and water, patients with xerocytosis and unusually low DPG levels have fewer dehydrated red cells than expected for the degree of cation loss, and in rare cases have no dehydrated cells at all.[1657] Patients with low DPG levels also have increased whole-blood oxygen affinity and, consequently, may have little apparent anemia.[1616,1656] However, such patients have relative polycythemia and are more anemic than their hemoglobin level suggests. Autohemolysis is increased and responds to glucose, similar to the pattern seen in HS.[992,1606,1611,1615]

Treatment

Splenectomy is absolutely contraindicated for hereditary xerocytosis. The limited experience available suggests that removing the spleen does not significantly reduce hemolysis.[1604,1605] Presumably, xerocytes are so functionally compromised that they are easily detected and eliminated in other areas of the reticuloendothelial system. Moreover, splenectomy appears to dramatically increase the risk for venous thrombosis and venous thromboembolism in patients with hereditary xerocytosis.[1222,1605,1657] The cause of the hypercoaguable state after splenectomy in these patients is not known. Fortunately, most patients maintain a hemoglobin level of at least 9 g/dL, so surgical intervention is not typically considered.

Intermediate Syndromes

Hydrocytosis and xerocytosis represent the extremes of a spectrum of red cell permeability defects. A number of families with features of both conditions have been reported. The reported patients seem to fall into two groups whose red cells differ principally in morphology, OF, and sensitivity to cold.

Cryohydrocytosis

Patients with this autosomal dominant disorder[1583-1589] have a mild hemolytic anemia characterized by marked autohemolysis that is greater at 4° C than at 37° C.[1583,1585,1586,1653] The cold autohemolysis is sensitive to the method of anticoagulation. It is increased in the cold in heparin- or EDTA-anticoagulated plasma and in defibrinated plasma but not in acid citrate dextrose.[1583,1589] This may reflect unusual pH sensitivity of the abnormal red cells because cold hemolysis is accentuated at pH 8 (the pH of blood in the first three anticoagulants at 4° C) in comparison to pH 7.6 (the pH of acid citrate dextrose–anticoagulated plasma at 4° C).[1583,1589]

Blood smears show stomatocytes, some of which have an eccentric or curvilinear slit or a transverse bar bisecting the area of central pallor (see Fig. 15-55B).[1583,1653] MCV and MCHC are normal or slightly increased; however, measurements are difficult because as blood samples cool for storage, MCV rises rapidly and MCHC falls.[1585,1586] Therefore, red cell measurements in these patients must be completed before a blood sample is allowed to cool. Fresh erythrocytes are Na^+ loaded and K^+ depleted. Although the total concentration of Na^+ and K^+ is normal, measurements are complicated by the ion shifts that occur in storage of the red cells. In the cold, Na^+ and K^+ permeability is markedly increased; however, because Na^+ entry greatly predominates, the red cells rapidly swell and lyse.

The primary molecular lesion of these erythrocytes in a subset of patients was recently elucidated. In an analysis of 11 families with stomatocytic hemolytic anemia defined by marked membrane permeability at 0° C, an associated mutation was found in the intramembrane domain of the band 3 (or AE1) anion exchanger encoded by the *SLC4A1* gene.[1587] The mutations in the band 3 chloride-bicarbonate exchanger convert the anion exchanger into a leaky cation channel.

In two patients with cryohydrocytosis, stomatin was deficient when red cell membrane proteins were analyzed.[1566,1588] The stomatin-deficient red cells were found to be associated with a higher K^+ leak than were the stomatin-containing red cells in patients with cryohydrocytosis.[1588] Both of the stomatin-deficient patients also had an associated neurologic syndrome consisting of seizures, mental retardation, cataracts, and hepatosplenomegaly.[1588] Patients who have this constellation of symptoms and are deficient in stomatin are now identified as having type II hereditary cryohydrocytosis. All other cases of cryohydrocytosis described have had stomatin-containing red cells and have not had a neurologic syndrome.[1585,1586] These patients have type I hereditary cryohydrocytosis. Thrombotic complications, or hematologic improvement, has not been reported after splenectomy in the case series describing these patients, but very few patients with this disorder have been reported.

Stomatocytic Xerocytosis

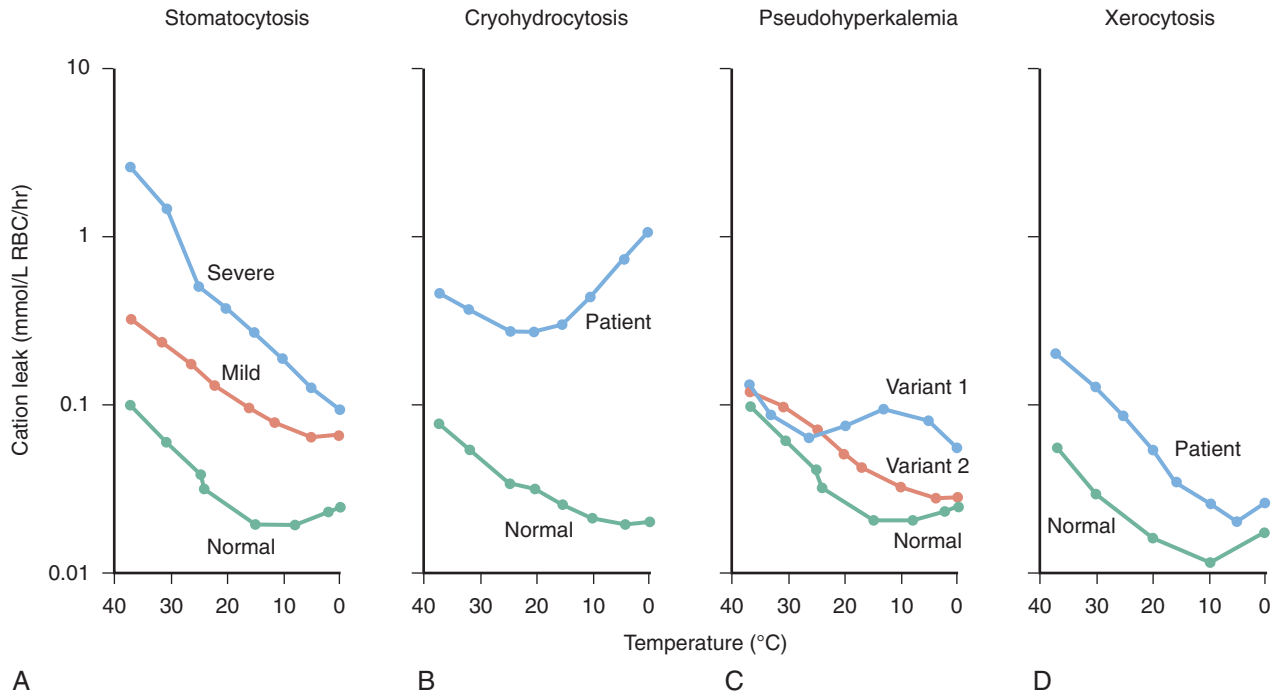
In 1971, Miller and colleagues[1590] described 54 patients with dominantly inherited stomatocytosis in a large Swiss-German family. Apparent heterozygotes (51 of 54 patients) had mild hemolysis, 1% to 25% stomatocytes on their peripheral blood smears, and no anemia. Intracellular K^+ and total monovalent cation levels were mildly decreased, and fresh red cells were osmotically resistant. Three probable homozygotes from a consanguineous mating had mild anemia, moderately severe hemolysis, marked stomatocytosis (20% to 35%), and greater cation permeability[1583,1623]; however, because net Na^+ and K^+ levels were relatively balanced, cell hydration was not seriously deranged. The molecular defect in this kindred is unknown.


FIGURE 15-58. Passive permeability of monovalent cations as a function of temperature in the hereditary stomatocytosis-xerocytosis disorders (*blue and brown circles*) in comparison to normal individuals (*green circles*). Stomatocytosis[1582,1658] (**A**), cryohydrocytosis[1586] (**B**), pseudohyperkalemia[1591,1659] (**C**), and xerocytosis[1592] (**D**) red cells are shown. Passive permeability is defined as uptake of $^{86}Rb^+$ across the red cell membrane in the presence of oubain (to inhibit the Na^+,K^+-ATPase pump) and bumetanide (to inhibit the Na^+-K^+-$2Cl^-$ cotransporter). RBC, red blood cell. *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.)*

Classification Based on the Temperature Dependence of Cation Leaks

Gordon Stewart and colleagues have classified disorders of red cell membrane cation permability based on the effects of temperature on the cation leak.[1582,1586,1592,1658] The membrane leak is measured by the residual influx of $^{86}Rb^+$ (a radioactive substitute for K^+) across the red cell membrane in the presence of ouabain (to inhibit the Na^+,K^+-ATPase pump) and bumetanide (to inhibit the Na^+-K^+-$2Cl^-$ cotransporter). This is a measure of the passive permeability of monovalent cations, although it does not exclude the contributions of the Gárdos channel and the K^+-Cl^- cotransporter. These transporters do not significantly contribute to cation permeability in normal red cells but may contribute more significantly in pathologic erythrocytes. Nevertheless, the estimate of monovalent cation leak is useful in understanding the pathophysiology of these permeability disorders and is clinically useful in the absence of genetic testing.

Normal red cells have a low leak that falls with temperature, with the minimum reached at approximately 10° C (Figs. 15-58 and 15-59).[1658] The reason for this minimum is unknown. The capacity of the Na^+,K^+ pump far exceeds the normal leak rate at physiologic temperatures, but pump activity falls sharply below room temperature and approximates the normal leak at 0° C (see Fig. 15-59). The temperature profile of the passive leak varies in each disorder (see Fig. 15-58). In classic, severe stomatin-deficient stomatocytosis, the leak rate, particularly Na^+ leak, is extremely high at body temperatures and exceeds the capacity of the Na^+,K^+ pump, which leads to cell swelling and hemolysis (see Fig. 15-58A). Stomatocytosis patients with milder leaks are better compensated by the Na^+,K^+ pump and experience less hemolysis (see Fig. 15-58A).[1582] Patients with cryohydrocytosis have a similar mild to moderate cation leak at body temperature that causes mild to moderate hemolysis. However, in cryohydrocytosis, the cation leak increases dramatically below ambient temperatures and greatly exceeds the capacity of the Na^+,K^+ pump below 10° C to 15° C, at which point it causes severe hemolysis (see Figs. 15-58B and 15-59).

Individuals with pseudohyperkalemia typically have a nearly normal cation leak at physiologic temperatures and therefore little or no hemolysis. The slope of the leak is flatter than normal and sometimes even rises at temperatures below ambient, so K^+ loss occurs during storage at room temperature (see Fig. 15-58C).

The temperature profile of the cation leak in hereditary xerocytosis parallels the normal temperature profile, but the leak is threefold to fourfold greater (see Fig. 15-58D). Although the leak is relatively small, it favors K^+, which creates a problem because the Na^+,K^+ pump extrudes three Na^+ ions for every two K^+ ions returned. Hence, the red cell cannot compensate for leaks of K^+_{out}
FIGURE 15-59. Comparison of passive monovalent cation permeability (*open circles*) and the capacity of the Na^+,K^+ pump (*solid circles*) in hereditary cryhydrocytosis (*blue circles*) and normal individuals (*green circles*). Note that the rate of cation leak greatly exceeds the pump rate in cryohydrocytosis at low temperatures, which causes the cells to swell and hemolyze. RBC, red blood cell. (*Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.*)

relative to Na^+_{in} that exceed the normal 2:3 ratio. Therefore, the pump exacerbates the loss of intracellular cations and water and probably contributes to the dehydration of xerocytes.

Other Disorders Characterized by Stomatocytosis

Acquired Stomatocytosis

In normal individuals, 3% or less of the red cells on peripheral blood smears are stomatocytic,[1659,1660] although more stomatocytic forms are evident (up to 10%) if sensitive techniques such as scanning electron microscopy are used.[1661] Because stomatocytes may occasionally occur as a drying artifact in limited areas of the smear, one must take care to examine multiple areas on several smears before diagnosing stomatocytosis. In wet preparations, stomatocytes are bowl shaped (uniconcave). Such preparations are useful in excluding artifactual stomatocytes, but the presence of bowl-shaped cells cannot be used as proof of stomatocytes because target cells are also bowl shaped in solution.[1662]

Drugs. In a prospective study of 4291 peripheral blood smears, Davidson and co-workers[1663] found increased numbers of stomatocytes in 2.3% of the preparations. Fifty-nine percent of these smears had 5% to 20% stomatocytes, 35% had 20% to 50% stomatocytes, and 6% had more than 50% stomatocytes. In this and other studies, a wide variety of drugs and diagnoses were associated with stomatocytosis.[389,1590,1663-1665] Further studies are needed to determine which associations are specific and reproducible. As discussed earlier in the chapter in the section on the bilayer couple hypothesis, amphophilic, lipid-soluble drugs can cause red cells to assume a stomatocytic shape if the drug partitions preferentially into the inner half of the lipid bilayer. The affected red cells are misshapen but are not cation loaded or hydrocytic and do not usually hemolyze. Vinca alkaloids (e.g., vincristine and vinblastine), in doses used for chemotherapy for leukemias and lymphomas, often induce hemolysis, sometimes with increased membrane Na^+ permeability and stomatocytosis.[1666] This is a particular problem in the rare instances in which these drugs must be given to patients with cancer who also have HS. We have seen two such patients, and in both cases very severe hemolysis occurred. Presumably, the explanation is that spherocytes and stomatocytes both have a decreased surface-to-volume ratio. Imposing a stomatocytic stress on HS red cells will make them even more spheroidal and hasten their demise.

Alcoholism. Acquired stomatocytosis is common in alcoholics, particularly in those with acute alcoholism, and may be associated with moderate hemolysis.[1659,1660] Red cell cation measurements have not been reported; however, severe hydrocytosis is unlikely because the results of OF tests have been normal.[1660]

Long-Distance Runners. Some marathon and long-distance runners develop mild stomatocytosis transiently after completing a race[1666,1667] (e.g., 12.8% ± 1.8% stomatocytes immediately after a race versus a baseline of 4.3% ± 1.8%).[1667]

Rh_{null} and Rh_{mod} Disease

The Rh(D) antigen and other antigens of the Rh group (cCeE) are part of two minor red cell membrane proteins encoded by two closely linked genes, one encoding the D polypeptide and the other encoding the Cc/Ee proteins. The antigenic expression of these proteins is a consequence of alternative splicing of their pre-mRNA.[389,1668] Patients who lack all Rh antigens (Rh_{null})[1669] have a moderately severe hemolytic anemia (^{51}Cr-labeled red cell half-life of 10 to 14 days)[396,1670-1672] characterized by stomatocytosis and spherocytosis. OF is only mildly increased,[396,1672] but ektacytometric analysis shows significant loss of membrane surface, particularly in denser (and presumably older) cells.[396] Red cell membrane K^+ permeability is about twice normal, which is compatible with a mild xerocytosis syndrome.[396,1673] Stomatocytosis

and hemolysis are also features of Rh$_{mod}$ disease, a related anomaly in which expression of Rh antigens is suppressed but not absent because of the influence of a suppressor gene.[1674,1675]

Tangier Disease

Tangier disease, caused by mutations in the gene encoding ATP-binding cassette 1 (ABCA1), is a rare autosomal recessive condition in which homozygotes have splenomegaly, absent or very low levels of high density lipoproteins (HDL), reduced levels of low-density lipoproteins (LDL) (typically 40% of normal), hypertriglyceridemia, mild corneal clouding, peripheral neuropathy, bone marrow foam cells (70% of patients), and characteristic orange, cholesterol ester–laden tonsils.[1676] ABCA1 is a major determinant of plasma HDL cholesterol and is critically involved in cellular trafficking of cholesterol and choline phospholipids. ABCA1 mediates the first step in reverse cholesterol transport, the transfer of cholesterol and phospholipids to lipid-poor apoproteins.[1677,1678] Cholesterol ester levels are greatly elevated in tissue macrophages in Tangier disease because of the lack of HDL, which normally return cholesterol esters to the liver. The HDL deficiency is caused by hypercatabolism of the lipoprotein. Normally, HDL binds to specific receptors on macrophages, is internalized (presumably to load up on cholesterol esters), and then recycles to the membrane surface. In Tangier disease, HDL is misrouted to macrophage lysosomes and destroyed.

Hematologic examination of one patient with Tangier disease disclosed stomatocytosis, hemolysis (hemoglobin concentration of 8.5 g/dL; reticulocyte count of 6% to 9%), and osmotically sensitive red cells.[1679] The membrane cholesterol level was low, the cholesterol-to-phospholipid ratio was decreased, and phospholipid analysis showed high phosphatidyl choline and low sphingomyelin levels. Red cell cation concentrations and permeabilities were not investigated. Because hematologic data have rarely been reported in patients with Tangier disease, it is difficult to be certain that this patient's data are not exceptional. However, previous reports of unexplained hemolysis in three patients suggest that they are not.[1680-1682]

Mediterranean Stomatocytosis

Multiple independent observations were made more than 30 years ago that stomatocytosis was common among Mediterranean individuals who migrated to Australia.[1683-1686] Clinically, these individuals had mild to moderate hemolytic anemia, normal red cell cations, and normal OF. In addition, they had macrothrombocytopenia (40,000 to 150,000 platelets 3 μm³ to 120 μm³ in size) and splenomegaly. In 1975, a study of healthy Mediterranean immigrants confirmed this finding, with 36% of individuals having more than 5% stomatocytes but no anemia.[1687] The hematologic findings of Mediterranean stomatocytosis have recently been linked to a rare inherited metabolic condition, phytosterolemia, in which

absorption of all sterols, including both cholesterol and phytosterols, is massively increased.[1688] Phytosterolemia is caused by mutations in either *ABCG5* or *ABCG8*, adjacent to chromosome 2p21.[1689,1690] The protein product of these genes normally forms a dimeric ATP-binding cassette protein in the enteric mucosa that aids in rejecting sterols into the gut. A recent study demonstrated that five pedigrees with Mediterranean stomatocytosis also had phytosterolemia with the typical mutations linked to this disease.[1688] Thus, the stomatocytosis and macrothrombocytopenia may be due to toxic effects from circulating sterols. In light of these findings, phytosterolemia should be considered in any patient found to have stomatocytic hemolysis or large platelets, or both.

Other Disorders Characterized by Xerocytosis

Adenosine Triphosphate Depletion

When red cell ATP concentrations decrease to less than 5% to 15% of normal, the cells leak cations and become rigid and echinocytic.[1691] In plasma or other Ca^{2+}-containing media, a specific K$^+$ permeability lesion (the Gárdos channel) is superimposed on the unchecked normal leak of Na$^+$ and K$^+$ and leads to cation depletion and dehydration.[1692] Coincidentally, poorly defined changes occur in the membrane skeletal structure.[1693,1694]

Presumably, these phenomena are involved in the hemolysis that occurs in inherited defects of glycolysis such as PK deficiency. Studies by Nathan and co-workers,[1695] Mentzer and Baehner,[1696] and Glader[1697] showed that PK-deficient red cells rapidly lose ATP and K$^+$ and become dehydrated, spiculated, and viscous when incubated in vitro, particularly under conditions in which residual mitochondrial production of ATP is curtailed. Contracted, crenated red cells are observed in PK deficiency,[1698,1699] as well as other disorders of red cell glycolysis. These "deflated echinocytes" are more rigid than normal[1700] and are relatively scarce in unsplenectomized patients,[1698,1699] which implies that they are premorbid cells given temporary reprieve by removal of the spleen.

Little is known about the status of membrane proteins in red cells with compromised ATP production.[1692] Small amounts of disulfide-linked spectrin complexes and marked diminution of spectrin extractability were detected in a patient with glucose phosphate isomerase deficiency,[1701] which suggests that membrane protein damage may be pathologically relevant in these disorders.

Irreversibly Sickled Cells

Irreversibly sickled cells are circulating erythrocytes from patients with sickle cell anemia that retain a sickled shape when oxygenated because of an acquired defect in the membrane skeleton.[1702] Biochemically, irreversibly sickled cells are deficient in total monovalent cations and water.[1703] The mechanism of their formation and the

nature of the acquired membrane defects responsible for their abnormal shape, cation content, and surface topography are discussed in Chapter 19.

OTHER CAUSES OF DECREASED ERYTHROCYTE MEMBRANE SURFACE AREA

Excluding hereditary spherocytosis, only a few conditions cause decreased membrane surface area leading to spherocytosis on the peripheral blood smear.

Immune Adherence

Immunohemolytic anemias are the most common cause of acquired spherocytosis in infants and children: AB(H)-related hemolysis in neonates and warm antibody–type autoimmune (or drug-related) hemolytic anemias in older children and adults. (For unknown reasons, Rh-related hemolysis in neonates rarely causes spherocytosis, whereas it does so readily later in life.) Patients who suffer from severe transfusion reactions with immunohemolysis may also have spherocytes on their peripheral blood smears. The pathophysiology of these disorders is discussed in Chapter 14.

Thermal Injury

More than 140 years ago, Schultze[1704] observed that membrane budding, fragmentation, and microspherocytosis developed in red cells heated to temperatures approaching 50° C for short periods. This phenomenon was further defined by the careful studies of Ham and co-workers and others[1416-1418] and is now believed to be due to heat denaturation of spectrin or other membrane proteins.[1419] Similar changes are observed acutely in patients with major cutaneous burns, presumably because of exposure of red cells in the skin and subcutaneous tissue to heat. During the first 24 to 48 hours after the burn, intravascular hemolysis develops, which is associated with red cell fragmentation and spherocytosis.[1705,1706] The severity of the reaction is related to the extent and degree of the burn. Generally, hemolysis is evident in patients with third-degree burns involving 15% to 20% or more of body surface area.[1705,1707] In severely burned patients, up to 30% of the red cell mass may be destroyed. This acute hemolytic process is usually complete by the third day after the burn and is followed by a persistent anemia resembling "anemia of chronic disease" seen in various disorders and described in Chapter 12.[1708,1709] An unusual variant of red cell thermal injury has been reported after the infusion of red cells that were inadvertently overheated in a blood warmer.[1710,1711]

Mechanical Injury

Hemolysis can be caused by direct physical trauma to the red cell membrane. This occurs in a variety of disorders, which are grouped under the terms microangiopathic and macroangiopathic hemolytic anemias. Membrane damage leading to intravascular hemolysis is apparently inflicted by the interaction of red cells (flowing at arterial speed) with prosthetic materials, damaged endothelial surfaces, or intravascular fibrin strands.[1712-1714] Dense microspherocytes are almost always produced by this process, but usually bizarre-shaped schizocytes and red cell fragments dominate the morphology. How such cells form is still not completely clear because simple fragmentation of red cells generates spherocytes but not schizocytes. Perhaps red cells draped over fibrin strands or attached to abnormal surfaces not only are distorted by shear but also are held in the distorted position for some time, thereby permitting rearrangement of the stressed membrane skeleton and assumption of a new, irreversibly misshapen form. This concept is strengthened by the observation that fragmentation is worsened by the presence of underlying membrane skeletal weakness.[1362]

Hypophosphatemia

Red cell glucose metabolism is compromised in patients with severe hypophosphatemia (serum phosphorus level < 0.3 mg/dL).[1715,1716] ATP and DPG levels decline and the oxygen affinity of hemoglobin increases.[1717,1718] If the red cell ATP concentration falls to very low levels (10% to 20% of normal), a severe hemolytic anemia characterized by marked microspherocytosis, spheroacanthocytosis, and red cell rigidity results.[1715,1719] The hemolysis is reversible after phosphate repletion and ATP regeneration. Severe hypophosphatemia can occur with gastrointestinal malabsorption, use of phosphate binders, starvation, diabetes mellitus, and increased urinary losses as a result of tubular dysfunction, as well as after nutritional repletion (e.g., refeeding of patients with anorexia nervosa[1720] or severe malnutrition[1721]).

Toxins and Venoms

Clostridial Sepsis

Clostridium welchii and *Clostridium perfringens* septicemias are seen in a variety of clinical situations but must particularly be considered in patients with penetrating wounds, septic abortions, peritonitis after a perforated viscus, or cholecystitis or cholangitis; in immunosuppressed patients with gastrointestinal or hematologic malignancies; and in neonates with necrotizing enterocolitis.[1722-1737] In patients with clostridial sepsis, severe, rapidly progressive intravascular hemolysis and microspherocytosis may occur.[1722,1723,1730,1736,1737] Hemolysis of the entire red cell mass has been reported.[1722,1729,1732,1738-1740] Complications include shock, acute renal failure, and death. Transfusion therapy may be ineffective. Antibiotics and hyperbaric oxygen have occasionally been used successfully to treat clostridial infections.[1726,1731,1732]

The mechanism of red cell damage is uncertain and may vary between patients. The bacteria produce several hemolytic toxins, including α-toxin, a 43-kd protein that contains an NH_2-terminal phospholipase domain and a COOH-terminal domain required for hemolysis,[1731,1741,1742] and θ-toxin, a 54-kd cholesterol-binding protein[1743-1746] that aggregates and forms membrane pores[1744,1747] leading to colloid osmotic hemolysis. α-Toxin appears to induce hemolysis through activation of sphingomyelin metabolism.[1748] *C. perfringens* also contains a neuraminidase that cleaves terminal sialic acids from red cell glycoproteins in some patients.[1749] The underlying galactose residues form the Thomsen-Friedenreich cryptoantigen (or T antigen). This antigen is easily detected because affected erythrocytes are agglutinated by peanut lectin.[1725] Because anti-T antibodies are present in almost all adult plasma, activation of T antigen can lead to significant hemolysis.[1730,1731,1733,1750] In infected infants and children who lack T antibodies, transfusion may lead to massive hemolysis and death. Rarely, T-antigen activation may precede the intravascular hemolysis and lead to early detection of clostridial sepsis and lifesaving therapeutic intervention.[1725]

In one patient with severe hemolysis, red cells showed profound proteolytic damage to membrane proteins, particularly spectrin, and no significant lipid alterations.[1751]

Venoms

The venoms of cobras and certain vipers and rattlesnakes may produce severe hemolysis and spherocytosis.[1752-1756] Spherocytic hemolytic anemia may also be seen in patients bitten by the common brown spiders (*Loxosceles reclusus* and *Loxosceles lata*) of South America and the central and southern sections of the United States[1757,1758] and in individuals with massive numbers of stings by honeybees, wasps, or yellow jackets.[1758-1761] Hemolysis in a child stung by a Portuguese man-of-war jellyfish has also been reported.[1762]

A full description of the numerous toxins in these venoms and their mechanisms of action is beyond the scope of this chapter. In general, the mechanisms of hemolysis after envenomation are not fully understood. The venoms of snakes and insects often contain phospholipases (particularly phospholipase A_2)[1763] and protein toxins that enhance their action. Examples of toxins include the mastoparans of wasp and hornet venoms[1764-1766] and melittin, a polypeptide contained in honeybee (*Apis mellifera*) venom[17678-1770] that immobilizes and clusters erythrocyte band 3 and thereby produces protein-free areas of the lipid bilayer that are susceptible to phospholipase action.[1769]

Hemolysis after brown recluse spider bites is characteristically delayed 1 to 5 days and is caused by a different mechanism.[1771] In affected patients, a transient, spherocytic, hemolytic anemia develops and produces positive Coombs test results[1772-1775] with erythrophagocytosis and deposition of IgG and C3 on the red cell surface. Venom from the brown recluse spider induces activation of an endogenous metalloproteinase that results in cleavage of glycophorin from the erythrocyte membrane, which facilitates the complement-mediated hemolysis.[1776-1778] The hemolysis usually subsides within a week, but it may be fatal.[1771,1779,1780] Complement appears to play a critical role because complement-deficient guinea pigs are resistant to the venom.[1781] The glycoprotein CD59 may play a previously unrecognized role in protection of the membrane from venom-induced injury.[1782] The venom also contains a phospholipase D that may contribute to the hemolysis.[1783]

Except for spider bites, which may be clinically deceptive initially, the potential for a hemolytic catastrophe should be obvious in patients who have been bitten or stung.[1771] An early sign of impending hemolysis may be a rapid rise in the serum K^+ level caused by prelytic leakage of this ion from the red cells. Once hemolysis is established, therapy other than transfusions is usually of little use. In patients with snake bites, localization or drainage of the venom and prompt administration of antivenom can be lifesaving.

Hypersplenism

Occasionally, transient hemolysis associated with spherocytosis and splenic sequestration of red cells develops in patients with infections associated with splenomegaly.[1784-1786] In some instances this may be attributed to latent red cell defects such as HS, but in others, no red cell abnormalities can be identified. Typically, the latter patients have subacute infections with persistent fever, splenomegaly, and numerous cells of lymphocytic or reticuloendothelial derivation (atypical lymphocytes, monocytes, histiocytes, or plasma cells) in their peripheral blood. Only a minor population of the red cells (10% to 50%) are spherical on peripheral blood smears or unincubated OF tests. Conceivably, the combination of delayed splenic passage caused by splenomegaly and pyrogenic stimulation of the reticuloendothelial system is sufficient to permit detention and conditioning of even normal red cells—a form of hypersplenism.

DISORDERS ASSOCIATED WITH INCREASED MEMBRANE SURFACE: TARGET CELLS

Red cells increase their surface area by an increase in membrane lipids. In dried smears the excess surface accumulates and bulges outward in the red cell's central clearing, thereby producing the characteristic target cell morphology. Target cells are also seen when red cell volume is diminished as a result of decreased hemoglobin synthesis (e.g., thalassemia or iron deficiency), abnormal hemoglobin charge or aggregation (e.g., hemoglobins S, C, D, and E), or decreased cell cations and water. In these instances there is a relative increase in the surface-to-volume ratio. With the exception of dehydrated red cells, an increase in membrane surface, whether relative or

absolute, has little effect on red cell deformability or life span and hence is usually innocuous.

Obstructive Liver Disease

Target cells are particularly characteristic of biliary obstruction[1662,1787] but also occur in other forms of liver disease. Like spur cells (see later), they form when red cells accumulate excess lipids from abnormal lipoproteins. However, unlike spur cells, target cells are characterized by a balanced increase in both free cholesterol and phospholipids.[1788-1790] The increase in phospholipid is confined to phosphatidyl choline (PC).[1788]

The pathogenesis of the lipid accumulation in target cells is relatively clear. The process is extracorpuscular and reversible and is due to an abnormal serum component. Normal cells acquire target cell surface area, morphologic characteristics, and osmotic resistance when transfused into patients with obstructive jaundice or incubated in the patients' serum, whereas target cells from such patients lose the patients' excess lipids and revert to biconcave discs in normal persons or their sera.[1787] Cooper and co-workers[1788] found a close relationship between the cholesterol-to-phospholipid ratios of target cells and serum lipoproteins, particularly low density lipoproteins (LDL). It is known that in obstructive jaundice a unique, abnormal lipoprotein called LP-X accumulates in the LDL density class,[1791,1792] possibly caused, at least in part, by an acquired deficiency of the hepatic enzyme LCAT. LP-X contains approximately equal amounts of free cholesterol and PC, plus a small amount of protein, cholesterol esters, triglycerides, and lithocholic acid.[1792] Normal red cells rapidly acquire excess cholesterol, PC, and surface area when incubated with LP-X in vitro,[1790] and it seems likely that this may be the source of lipids for membrane expansion and targeting in vivo.

Familial Lecithin-Cholesterol Acyltransferase Deficiency

Familial LCAT deficiency is a rare autosomal recessive disorder characterized by anemia, corneal opacities, hyperlipemia, proteinuria, chronic nephritis, and premature atherosclerosis.[1793] More extensive description of familial LCAT deficiency can be found in a recent review.[1794] LCAT deficiency is relatively asymptomatic during childhood. Proteinuria and corneal opacities are among the earliest manifestations. The latter consist of minute grayish dots that concentrate near the edge of the cornea, similar to arcus senilis. Almost all of the reported patients have had a moderate normochromic anemia (hemoglobin level of 8 to 11 g/dL) characterized by prominent target cell formation and decreased osmotic fragility.[1795-1798] Hematologic studies suggest that the anemia is due to a combination of moderate hemolysis and decreased erythropoietic compensation, but interpretation of the evidence is complicated by the coexisting renal disease. Other studies have shown that the red cells

are abnormally susceptible to peroxidative threat and have mechanically fragile membranes.[1796] There is no obvious explanation for these changes, but it is possible that they contribute to the shortened red cell life span. LCAT deficiency is caused by a variety of mutations in the LCAT gene; affected individuals are either homozygotes or compound heterozygotes for these mutations.[1799,1800] Modeling of the mutations has provided insight into the structure and function of LCAT.[1801] As expected from the absence of LCAT activity, there is a pronounced decrease in cholesteryl esters and an increase in free cholesterol and PC in plasma lipoproteins. Because LCAT is required for normal lipoprotein formation and catabolism, nascent lipoproteins and abnormal lipoprotein remnants accumulate in plasma. One of the latter is LP-X.[1802] As discussed in the previous section, this lipoprotein is believed to be responsible for target cell formation in patients with the acquired LCAT deficiency of obstructive liver disease.[1790] Free cholesterol and PC levels are markedly elevated in the red cell membranes of patients with LCAT deficiency[1793]; however, total red cell phospholipid levels are normal because the increase in PC is balanced by a decrease in PE and SM. As with liver disease, red cell targeting and lipid abnormalities can be induced by incubation of normal red cells in LCAT-deficient lipoproteins and reversed by incubation in normal serum.[1803] Other plasma membranes are also probably affected by the abnormal LCAT-deficient lipoproteins. For example, accumulations of lipid in endothelial membranes may underlie the atherosclerotic and nephritic complications seen in some patients. Phagocytosis of abnormal lipoproteins by reticuloendothelial cells leads to the appearance of foam cells and sea-blue histiocytes in the bone marrow, spleen, and other organs.[1795,1804] Serum and red cell lipids are improved in vivo when LCAT is supplied by infusion of normal plasma; however, the short half-life of this protein, 4 to 5 days, and the large amounts of plasma required make chronic replacement therapy impractical.

Fish Eye Disease

Fish eye disease is caused by partial deficiency of LCAT and is also associated with mutations in the LCAT gene.[1793,1799] It is characterized by corneal opacities (which give the disease its name), hypertriglyceridemia, and very low levels of HDLs. One report noted increased target cells and decreased OF.[1805]

Splenectomy

In the first several weeks after splenectomy, the number of target cells gradually increases,[1662,1806-1808] eventually (in otherwise normal persons) reaching levels of 2% to 10%. This change is associated with increases in osmotic resistance, membrane lipid content, and mean surface area relative to volume, indicative of expansion of the red cell membrane surface. By deduction, the spleen must

normally remove surplus membrane from such cells, a process referred to as "surface remodeling."[1809,1810] Experimental studies have clearly documented that the stress reticulocytes induced by acute blood loss or hemolysis undergo extensive surface remodeling and suggest that normal reticulocytes are remodeled to a lesser degree. In addition to membrane lipids, transferrin receptors, fibronectin receptors, and a high-molecular-weight membrane protein complex[1811] are also removed during the remodeling process. Autophagocytosis and expulsion of phagolysosomes are hypothesized to be the major mechanism of the remodeling.[751] Postsplenectomy blood smears also show increased numbers of acanthocytes, poikilocytes, and red cells burdened with useless or potentially harmful inclusions (e.g., Heinz bodies, Howell-Jolly bodies, siderotic granules, and endocytic vesicles).[1267,1268,1812,1813] The presence of these inclusions attests to the "culling" and "pitting" functions of the spleen.[1813]

SPICULATED RED CELLS: ECHINOCYTES AND ACANTHOCYTES

There are two basic types of spiculated red cells—echinocytes and acanthocytes. Echinocytes typically have a serrated outline with small, uniform projections more or less spread evenly over the circumference of the cell, whereas acanthocytes have a few spicules of varying size that project irregularly from the red cell surface. These differences are easily detected on scanning electron micrographs and can usually be discerned in wet preparations, but it is often quite difficult to make the distinction in dried smears. In general, echinocytes appear crenated in smears, that is, as cells with relatively uniform scalloped edges, whereas acanthocytes appear contracted, dense, and irregular (Fig. 15-60).

Echinocytes are readily produced in vitro by washing red cells in saline,[1814] by the interaction of red cells with glass surfaces,[1814] by amphipathic molecules that partition into and expand the outer half of the lipid bilayer,[1815] and by molecules that inhibit band 3 transport.[1815] High pH values, ATP depletion, and accumulation of Ca^{2+} also cause echinocytosis.[1816-1819] In vivo, echinocytes are most

often found in patients with advanced uremia[1819] or with defects in glycolytic metabolism,[1698] after splenectomy,[1814] and in some patients with microangiopathic hemolytic anemia. Echinocytes are also commonly seen in neonates, especially those who are premature,[1820] and in divers after decompression from pressures greater than 3 to 4 bar.[1821] They are seen transiently after transfusions with large amounts of stored blood because red cells become echinocytic after a few days of storage. Acanthocytes and echinocytes may be found in patients with neuroacanthocytosis,[1822,1823] severe hepatocellular damage,[1824] infantile pyknocytosis,[1825] anorexia nervosa,[1826,1827] In(Lu) blood groups,[1828] and hypothyroidism.[1829] Occasionally, they are the predominant morphologic feature in patients with myelodysplasia.[1830,1831]

Neuroacanthocytosis

Neuroacanthocytosis refers to a group of diseases in which neurologic changes are found in the setting of acanthocytes in the peripheral blood smear. More information about this group of disorders has recently been described and summarized.[1832] In some cases of neuroacanthocytosis, acanthocytes are not detected in the peripheral smear. However, because routine genetic testing and classic laboratory findings are not available for most of these disorders, detection of acanthocytes is one of the hallmarks of clinical diagnosis. The most sensitive and specific method for measuring acanthocytes is the use of isotonically diluted blood combined with an unfixed wet blood preparation, with the normal range of less than 6.3% acanthocytes in the total erythrocytes.[1833] The mechanism of acanthocyte formation in the neuroacanthocytoses is unknown. However, abnormalities in band 3 have been implicated and are supported by preliminary data.[1834,1835] The subsets of neuroacanthocytoses are abetalipoproteinemia, McLeod's syndrome, choreaacanthocytosis, Huntington's disease–like 2, and pantothenate kinase–associated neurodegeneration.

Abetalipoproteinemia

Abetalipoproteinemia (Bassen-Kornzweig syndrome) is the paradigm of the disorders associated with acantho-
FIGURE 15-60. Morphology of echinocytes and acanthocytes. **A,** Scanning electron micrograph of a spherical echinocyte. **B,** Peripheral blood smear of echinocytes in a splenectomized patient with pyruvate kinase deficiency. **C,** Scanning electron micrograph of an acanthocyte. **D,** Peripheral smear of acanthocytes in a patient with hepatitis and spur cell anemia.

cytosis.[1822,1837] Progressive ataxic neurologic disease, retinitis pigmentosa, fat malabsorption, and acanthocytosis are the primary manifestations of this disorder.[1837] Failure to synthesize or secrete serum apolipoprotein B–containing lipoproteins causes defective intestinal absorption of lipids and extremely low serum cholesterol and triglyceride levels. Because of deficient absorption of fat-soluble vitamin E, severe, but often reversible neurologic problems such as spinocerebellar degenerative ataxic disorder with peripheral neuropathy and retinitis pigmentosa leading to blindness develop in individuals with abetalipoproteinemia.[1838,1839] Some studies have demonstrated delay or prevention of neurologic manifestations with chronic administration of vitamin E.[1838,1839]

This rare disease is caused by various mutations in the gene encoding microsomal triglyceride transfer protein (MTP), which catalyzes the transport of triglyceride, cholesterol ester, and phospholipid from phospholipid surfaces.[1840-1842] MTP forms a heterodimer with a multifunctional protein called disulfide isomerase, which is located in the lumen of hepatic microsomes and intestinal epithelia, the sites of lipoprotein synthesis.[1842-1844] Disulfide isomerase is the only tissue-specific component, other than apolipoprotein B, required for secretion of apolipoprotein B–containing lipoproteins.[1845]

Related entities (hypobetalipoproteinemia, normotriglyceridemic abetalipoproteinemia, and chylomicron retention disease) exist and are associated with partial production of apolipoprotein B–containing lipoproteins or with secretion of lipoproteins containing truncated forms of apolipoprotein B.[1021] Patients with these diseases may also manifest acanthocytosis and neurologic disease, depending on the severity of the lipoprotein defect. The majority of patients with heterozygous hypobetalipoproteinemia do not have acanthocytosis.

Characteristically, 50% to 90% of the red cells are acanthocytes in abetalipoproteinemia.[1846] The shape defect is not evident in nucleated red cells or reticulocytes and worsens as the erythrocytes age. Membrane protein composition is normal, but membrane lipid composition is not. The PC concentration is decreased by about 20%, and the amount of SM is correspondingly increased. The cholesterol-to-phospholipid ratio is normal to mildly elevated.[1847-1849] These changes reflect abnormalities in the distribution of plasma phospholipids and a decrease in LCAT activity.[1850] The relative increases in cholesterol and SM concentration both decrease lipid fluidity,[1848] particularly in the outer half of the bilayer,[1851] and presumably contribute to the acanthocytic shape. They probably do so by expanding the outer bilayer relative to the inner bilayer because drugs that selectively intercalate into the inner bilayer convert acanthocytes to biconcave discs.[1852] However, this is almost impossible to prove because the difference in surface area of the outer bilayers of an acanthocyte and a discocyte is less than 1%.

Because of fat malabsorption and the absence of LDL, which transports vitamin E,[1853] the red cells of these patients are markedly deficient in vitamin E.[1854]

Exposure to lipid-soluble oxidants such as H_2O_2 leads to an increase in lipid peroxides, a decrease in phospholipids rich in unsaturated fatty acids such as PE and PS, damage to membrane proteins, and hemolysis. Oxidant sensitivity can be prevented by treatment with a water-soluble form of vitamin E (e.g., D-α-tocopherol polyethylene glycol succinate).[1854]

Despite increased lipid viscosity and vitamin E deficiency, the hemolysis experienced by these patients is mild.[1847] This is in striking contrast to spur cell anemia (see later), in which hemolysis of similarly shaped cells is often quite severe. It has been suggested that the difference is explained by the fact that the spleen is normal in abetalipoproteinemia whereas it is enlarged and congested by portal hypertension in spur cell anemia. It remains unclear whether this is a sufficient explanation.

Chorea-Acanthocytosis Syndrome

This syndrome was first described by Estes and co-workers.[1855,1856] Since then, this autosomal recessive disorder has been well characterized as a progressive movement disorder consisting of acanthocytosis, myopathy, and cognitive and behavior changes beginning in adolescence or adult life (8 to 62 years).[1835] The movement disorder is most typically characterized by limb chorea, but it can also be manifested as parkinsonism, orofacial dyskinesia, lip and tongue biting, involuntary vocalizations leading to mutism, seizures, and decreased or absent tendon reflexes.[1857,1858] The lingual-buccal-facial dyskinesia and oral self-mutilation are most characteristic of chorea-acanthocytosis. The myopathy causes distal muscle wasting and hypotonia, as well as increased creatine phosphokinase. The extent of mental deterioration varies but often resembles that of frontal lobe syndrome.[1859]

The mutant protein in chorea-acanthocytosis, chorein, encoded by the gene *VPS13A* on chromosome 9q21, has been identified and more than 70 different mutations have been reported to date.[1860-1863] The function of chorein is unknown, but *VPS13A* is a member of a conserved gene family involved in membrane protein trafficking.[1864] Loss of chorein may be diagnostic for this disorder because it is not seen in similar disorders such as Huntington's disease or McLeod's syndrome.[1862,1865] However, routine genetic testing is not available. Therefore, diagnosis of this disorder is made through radiologic and clinical findings, as well as evidence of muscle disease. MRI and pathologic examination show atrophy of the basal ganglia, particularly the caudate and putamen. In some patients, little or no hemolysis occurs; in others, acanthocytosis precedes the onset of neurologic symptoms.[1859] In still others, acanthocytes do not appear until late in the disease course.[1866] Splenomegaly, probably caused by the hemolysis, is noted in some patients.[1867] Elevated levels of creatine phophokinase are found in most patients.

Of note, one family has been described with a defect near the COOH-terminal end of band 3, Pro868Leu.[1868]

Hematologically, affected individuals of this kindred have 20% to 25% acanthocytes and mild anemia with reticulocytosis. However, this family's defect seems to be a distinct disorder separate from the more typically described chorea-acanthocytosis.

McLeod's Syndrome

McLeod's syndrome is a multisystemic disorder with hematologic, muscular, neurologic, and cardiac manifestations.[1869,1870] The McLeod blood group phenotype, first discovered in a dental school student named Hugh McLeod, is an X-linked anomaly of the Kell blood group system in which either red cells, white cells, or both react poorly with Kell antisera but behave normally in other blood group reactions. Affected cells lack Kx, the product of the XK gene, which is a 444–amino acid integral membrane protein precursor of the Kell antigen that has structural features suggesting a transport protein.[1869,1871-1873] As expected, Kx is defective in patients with McLeod's syndrome.[1869,1874-1878] Male hemizygotes who lack Kx on their red cells have variable acanthocytosis (8% to 85%) and mild, compensated hemolysis (3% to 7% reticulocytes).[1823,1879,1880] Some teardrop erythrocytes and bizarre poikilocytes are also present. Female heterozygotes have occasional acanthocytes (as expected by the Lyon hypothesis) and very mild hemolysis,[1823,1879] although some of these women have more severe symptoms.[1874]

Most patients with McLeod's syndrome have a subclinical myopathy associated with an elevated creatine phosphokinase level.[1876,1881,1882] The neuropathy may first be manifested as areflexia and later characterized by basal ganglia atrophy causing dystonic or choreiform movements, psychiatric symptoms, and cognitive changes.[1881-1887] These features, combined with acanthocytosis, can mimic the chorea-acanthocytosis syndrome described in the previous section. However, in contrast to chorea-acanthocytosis, cardiac symptoms such as dilated cardiomyopathy and arrhythmias also develop in most individuals with Mcleod's syndrome.[1876,1887]

The XK gene is located less than 500 kb beyond the chronic granulomatous disease locus on the short arm of the X chromosome (p21.1).[1888] Consequently, males with deletions encompassing both loci have both chronic granulomatous disease and McLeod's syndrome.[1889] It is important to recognize patients with McLeod's syndrome because if they receive transfusions, antibodies may develop that are compatible only with the McLeod syndrome red cells.[1890,1891]

Huntington's Disease–Like 2

In 2001, Margolis and colleagues described a pedigree with an autosomal dominant, Huntington-like disease attributable to CAG/CTG repeats in a novel site.[1892] Huntington's disease–like 2 has since been characterized as a hyperkinetic disorder similar to Huntington's disease that mostly or exclusively affects patients of African ancestry. This neuroacanthocytosis typically is manifested in the third decade by weight loss, dystonia, rigidity, chorea, behavioral changes, and acanthocytosis.[1893,1894] Brain imaging demonstrates marked striatal atrophy and moderate cortical atrophy, similar to Huntington's disease. The CTG/CAG trinucleotide repeat expansion has been found within a variably spliced exon on the junctophilin 3 gene (*JPH3*) on chromosome 16q24.3.[1895]

Pantothenate Kinase–Associated Neurodegeneration

This autosomal recessive progressive movement disorder is caused by a mutation in the pantothenate kinase gene, *PANK2*, on chromosome 20p13.[1896,1897] In the classic form of this neuroacanthocytosis, patients are seen within the first decade of life with a rapidly progressive motor disease leading to loss of ambulation. The atypical and intermediate forms occur later in life and progress more gradually. Pigmented retinopathy typically develops in individuals with an earlier onset of symptoms. In those with a later onset, psychiatric and speech disorders also tend to develop. The motor disease is characterized by rigidity in the lower and, later, the upper extremities. Choreic-type movements often coincide with the rigidity. Because of the effects on voluntary movement and muscular tone, difficulty chewing and swallowing also develops.[1898] Ten percent of patients have acanthocytes on the peripheral smear.[1835]

Diagnosis of this disorder is made clinically and radiologically. Pallidal abnormalities on brain MRI, described as the "'eye of the tiger" sign, consist of decreased signal intensity on T2-weighted images, compatible with iron deposits, and a small area of hyperintensity in the internal segment.[18990] All patients with this disorder have the "eye of the tiger" sign on brain MRI.[1900,1901] However, this sign is not specific to pantothenate kinase–associated neurodegeneration.[1900,1902] Historically, this disease was called Hallervorden-Spatz disease, named after Julius Hallervorden and Hugo Spatz, who originally described the disorder. In 2001, Zhou and co-authors suggested it be renamed pantothenase kinase–associated neurogeneration to avoid the objection to its eponym because Hallervorden and Spatz actively participated in the euthanasia program in Germany during World War II.[1897]

Vitamin E Deficiency

Premature infants (<36 weeks' gestation or weighing <2000 g) and children or adults with steatorrhea are susceptible to vitamin E deficiency because of decreased absorption of the vitamin.[1903-1905] Discussion of this disorder in preterm infants is now mostly of historical interest.[1906] Infants with this syndrome were fed formulas that were very low in vitamin E and very high in polyunsaturated fatty acids. As the interactions among dietary iron, polyunsaturated fatty acids, and vitamin E were defined, infant formulas were altered so that this condition has virtually disappeared in most nurseries. However, vitamin

E deficiency may cause a hemolytic anemia in infancy in patients with disorders that cause fat malabsorption, such as cystic fibrosis, abetalipoproteinemia, or chronic neonatal cholestasis.[1907-1912] Furthermore, vitamin E deficiency is also seen in individuals with mutations of the tocopherol transport protein gene involved in vitamin E metabolism.[1913,1914]

The features of severe vitamin E deficiency in infants are hemolysis, thrombocytosis, and generalized edema.[1915-1917] Infants with fat malabsorption may also have a rash or other signs of vitamin or protein malnutrition. Peripheral blood smears are often normal but sometimes show variable numbers of irregularly contracted, spiculated cells (acanthocytes or pyknocytes) and small numbers of spherocytes and fragmented red cells.[1908,1916] The mechanism of hemolysis is uncertain. Vitamin E is a lipid-soluble antioxidant, and in its absence, lipid peroxidation occurs with damage to the double bonds of unsaturated fatty acids. Phospholipids rich in unsaturated acyl chains, such as PE, are particularly susceptible.[1849,1854,1918] However, there is some evidence that damage to the sulfhydryl groups of membrane proteins may also contribute to the hemolysis.[1919] In addition, vitamin E has been shown to have a membrane-stabilizing effect against hemolysis induced by hemin.[1920]

Anorexia Nervosa

Acanthocytosis is common in many patients with severe anorexia nervosa.[1826,1827] The cause of the acanthocytosis is unknown. In individuals with anorexia, plasma lipid and low density lipoprotein (LDL) levels are typically normal or slightly decreased. However, even in patients with low levels of LDL,[1921] acanthocytosis may not be due solely to the lipoprotein deficiency because patients with much lower concentrations of LDL (e.g., those with hypobetalipoproteinemia) usually have normal red cell morphology. Severe starvation or malnutrition from causes other than anorexia nervosa can also produce acanthocytosis[1922-1924] or target cells and hypobetalipoproteinemia.[1925]

Despite the acanthocytosis, only approximately 20% to 30% of these patients experience normocytic anemia.[1926-1928] Red cell life span is normal or only slightly shortened. Leukopenia and neutropenia are common, and mild thrombocytopenia is often seen.[1826,1827,1927-1929] Based on morphology, these cytopenias are due to a hypoproliferative bone marrow,[1826] and their severity correlates with weight.[1930] The hypoplastic marrow is also deficient in fat, which is replaced by an amorphous ground substance, perhaps acid mucopolysaccharide.[1927,1931]

Spur Cell Anemia (Hepatocellular Damage)

The anemia seen in patients with liver disease has a complex etiology. Common causes include blood loss, hypersplenism, iron deficiency, folic acid deficiency, and marrow suppression from ingestion of alcohol, hepatitis
FIGURE 15-61. Peripheral blood smear from a patient with alcoholic cirrhosis and spur cell anemia.

virus infection, and other poorly understood factors.[1932,1933] In addition, in some patients, acquired abnormalities of the red cell membrane may contribute to the anemia. Two morphologic syndromes are recognized. In one, target cells predominate. In the other, a syndrome of brisk hemolysis develops in association with acanthocytes, or "spur" cells, so-called spur cell anemia (Fig. 15-61).[1824,1933-1950]

Typically, target cells are associated with obstructive liver disease, and acanthocytes are associated with hepatocellular disease. In practice, the situation is more complex. It is not uncommon for both cell morphologies to coexist, and some experimental data suggest that they are different stages of the same process. For example, when the bile duct is ligated in a rat, acanthocytes appear within 8 hours, but they convert to target cells if the obstruction persists for 7 days or longer.[1951,1952] Nevertheless, acanthocytes (spur cells) and target cells differ in many important respects, and only spur cells are considered in this section.

Spur cell anemia has most often been described in patients with alcoholic cirrhosis.[1824,1935-1937,1948,1949] However, it is also reported in those with cardiac cirrhosis,[1936] metastatic liver disease,[1940] hemochromatosis,[1939] neonatal hepatitis,[1943] cholestasis,[1933,1934] Wilson's disease, and severe acute hepatitis. The range of diseases in which spur cells are found suggests that it may occur in any disease in which damage to hepatocytes is severe.

Typically, patients have moderately severe hemolysis (hematocrit of 20% to 30%), marked indirect hyperbilirubinemia, splenomegaly, and clinical and laboratory evidence of severe hepatic dysfunction. By definition, more than 20% acanthocytes are evident in multiple areas on several peripheral blood smears. Morphologically, the acanthocytes of spur cell anemia are indistinguishable from those seen in patients with abetalipoproteinemia. In some patients, significant numbers of echinocytes and target cells may be present and spherocytes may develop, presumably as a result of vesiculation. Occasionally, this may cause some
FIGURE 15-62. Schematic illustration of the pathophysiologic course of acanthocyte (spur cell) and target cell formation in liver disease. *(Adapted with permission from Walensky LD, Narla M, Lux SE. Disorders of the red cell membrane. In Handin RI, Lux SE, Stossel TP [eds]. Blood: Principles and Practice of Hematology, 2nd ed. Philadelphia, JB Lippincott, 2003, pp 1709-1858.)*

diagnostic confusion. In our experience, however, many of these "spherocytes" have fine spicules, evident on close examination, which distinguishes them from true microspherocytes.

The red cell life span of spur cells is markedly shortened because of splenic sequestration,[1824,1936,1941,1944] and as expected, the hemolysis abates after splenectomy.[1944] Unfortunately, splenectomy is a dangerous and often fatal procedure in these very sick patients and is not generally recommended.[1944] In addition, spur cell anemia has been reported in a splenectomized patient.[1938] Some success has been reported in treating the anemia of these patients with phospholipid infusions,[1945] flunarizine,[1946] or a combination of flunarizine, pentoxifylline, and cholestyramine[1953]; however, these approaches are still experimental. Cure of the anemia has also been achieved through liver transplantation,[1954] but the disease recurs if the transplant fails.[1955]

The clinical syndrome of spur cell anemia can be produced by at least two different pathogenic mechanisms. In one group, typically consisting of patients with alcoholic cirrhosis,[1824,1937,1942] the disorder is due to an acquired abnormality of red cell lipids. The pathophysiology of spurring in these patients has been defined and reviewed by Cooper and associates[1788,1824,1944,1947,1948] and is illustrated in Figure 15-62. It occurs in two stages: cholesterol loading and splenic remodeling. In the first stage, abnormal, cholesterol-laden, apolipoprotein AII–deficient lipoproteins, produced by the patient's diseased liver, transfer their excess cholesterol to circulating erythrocytes and increase the membrane cholesterol concentration, the cholesterol-to-phospholipid ratio (Fig. 15-63), and membrane surface area.[1788,1949] This is an acquired process and can be mimicked in vitro by incubation of
FIGURE 15-63. Cholesterol and phospholipid content of target cells *(blue circles)* and spur cells *(brown circles)*. Note that target cells tend to have a balanced increase in cholesterol and phospholipid whereas spur cells are usually selectively enriched in cholesterol. *(Adapted from Cooper RA, Diloy-Puray M, Lando P, Greenverg MS. An analysis of lipoproteins, bile acids, and red cell membranes associated with target cells and spur cells in patients with liver disease. J Clin Invest. 1972;31:3182.)*

normal red cells in spur cell plasma[1824,1944] or in artificial media containing cholesterol-phospholipid dispersions with a cholesterol-to-phospholipid ratio greater than 1.0. On scanning electron micrographs, these cholesterol-laden cells are flattened and often folded, with an undulating periphery.[1948] They appear scalloped or crenated on dried smears.[1824,1944] In vivo, in the second stage, scalloped cells are converted to spur cells by a process of splenic conditioning (see Fig. 15-62) Over a period of 1 to 7 days, membrane lipids and surface area are lost, cellular rigidity increases, presumably because of the decline

in surface-to-volume ratio, and the cell assumes a typical acanthocytic form.[1824,1944] Splenectomy prevents both the formation of spur cells and their premature destruction; however, as noted earlier, it is a high-risk procedure and is seldom indicated.

The cholesterol-laden, incipient spur cell is presumably detained and remodeled by the spleen because it is less deformable than normal. The molecular explanation for this change in deformability is unknown. There is evidence that cholesterol affects the function of band 3.[1950] Cholesterol may also influence band 3 oligomerization or its interaction with other membrane proteins. In addition, it might affect the ratio of band 3 molecules with the anion channel open to the outside versus those with the channel open to the inside. Wong believes that an increase in inward-facing band 3 molecules contracts the membrane skeleton and causes echinocytosis or acanthocytosis whereas an increase in outward-facing band 3 molecules causes stomatocytosis.[1956] A slight increase in the cholesterol-to-phospholipid ratio to above normal markedly alters cholesterol organization in the membrane[1951] and increases the helical content of one or more of the major membrane proteins,[1957] conceivably including band 3. Involvement of band 3 is also suggested by the acanthocytic morphology of rare individuals carrying the band 3 HT variant.[1868]

Other studies have identified a defect in phospholipid repair.[1958] Spur cells and cholesterol-laden normal red cells exhibit decreased fatty acid acylation of phospholipids. Furthermore, red cell membrane lipid "rafts" are cholesterol-rich microdomains that contain unique proteins.[112,116] Changes in intracellular electrolytes causes shedding of these lipid "rafts."[117] It is unclear whether increasing membrane cholesterol would further increase this process. All these processses may play a role in this anemia, but further studies are needed to better understand this process.

A second group of patients with liver disease and spur cell anemia exists in which red cell membrane lipids are normal and incubation of normal red cells in the patients' plasma does not induce spurring.[1936,1940,1941] The pathophysiology of this condition is unknown and largely unstudied. It has been reported in patients with alcoholic cirrhosis[1936,1941] and metastatic liver disease.[1940] This is the form of the disease that the authors have seen in children with spur cells and severe hepatocellular dysfunction.

Infantile Pyknocytosis

In 1959, Tuffy and colleagues[1825] described a syndrome of neonatal jaundice and hemolysis associated with variable numbers of distorted, irregularly contracted, spiculated cells, which they called pyknocytes. Morphologically, these cells are very similar (and possibly identical) to acanthocytes. Normal full-term infants have 0.3% to 1.9% pyknocytes/acanthocytes on peripheral blood smears. In premature infants the normal range is 0.3% to 5.6%. Affected infants typically have jaundice and

slight hepatosplenomegaly in the first few days of life. Pyknocytosis and hemolytic anemia peak at 3 to 4 weeks of age and then decline spontaneously. Clinical severity is variable; however, some infants are severely affected (hemoglobin level of 4 to 6 g/dL, 15% to 20% reticulocytes, 25% to 50% pyknocytes), and some require exchange transfusions. Transfused erythrocytes become pyknocytic and survive poorly,[1825,1959,1960] indicative of an extracorpuscular defect. The syndrome is seen in both premature and term infants. The only consistent chemical abnormality is a mild elevation in serum aspartate transaminase (50 to 250 IU). Parents and siblings are normal.

The cause of this syndrome has not been clearly defined, and for unknown reasons, the diagnosis is seldom made today. Infants with severe G6PD deficiency,[1961] neonatal Heinz body hemolytic anemia,[1825,1962] vitamin E deficiency,[1908,1916] glycolytic enzyme deficiencies,[1698] neonatal hepatitis,[1943] severe HE,[1471] and microangiopathic hemolytic anemia may have hemolysis and pyknocytes, and infantile pyknocytosis is sometimes misdiagnosed in these infants. However, in most of the original case reports, evidence is sufficient to exclude these disorders, which suggests that infantile pyknocytosis may be a valid entity.[1963] The transient nature, mild transaminase elevation, morphologic features, and extracorpuscular etiology suggest a metabolic defect, possibly involving a circulating oxidant; however, other hypotheses are equally tenable.

Uremia

Red cell survival is reduced in patients with advanced renal failure.[1964-1966] An extracorporeal factor is involved because red cells from uremic patients survive normally when infused into normal persons whereas normal red cells survive poorly in uremic patients.[1965] The factor is nondialyzable, and some studies suggest that it is parathyroid hormone (PTH).[1967-1969] PTH levels are elevated in renal failure because of hyperphosphatemia and secondary hyperparathyroidism. PTH levels correlate closely with red cell survival and with the erythropoietin doses necessary to achieve an adequate hematocrit response in patients with chronic renal failure who are undergoing dialysis.[1969,1970] 1,25-Dihydroxycholecalciferol, a vitamin D analogue, improves the anemia in patients with renal failure and increases sensitivity to erythropoietin.[1971] In patients found to be resistant to this therapy, parathyroidectomy for secondary hyperparathyroidism with advanced renal failure often improves the hemolysis and erythropoietin sensitivity.[1971,1972] In vitro, relevant levels of PTH or its bioactive NH_2-terminal peptide augment entry of Ca^{2+} into red cells through a cAMP-independent pathway and cause the cells to develop filamentous extensions and lose membrane surface, presumably by vesiculation.[1968] These effects are largely blocked by the Ca^{2+} channel blocker verapamil. It is possible that they are responsible for the increased numbers of echinocytes observed in

some uremic patients because increased intracellular Ca^{2+} is markedly echinocytogenic.[1973] Nevertheless, the reduction in red cell survival and production of echinocytes in uremia may be due to other factors. In a randomized, controlled trial, L-carnitine supplementation in hemodialysis patients was associated with an increase in red cell survival when compared with hemodialysis patients receiving placebo therapy.[1974]

In(Lu) Gene

The major antigens of the Lutheran blood group system are Lu^a and Lu^b. They are located on two low-abundance glycoproteins of 78 kd, on which the basal cell adhesion molecule (BCAM) resides, and 85 kd, on which the Lutheran blood group resides.[1975] In addition to being expressed on the red blood cell membrane, the Lu antigens are expressed by a wide variety of tissues, including the heart, brain, lung, liver, and muscle in the adult, as well as the liver, lung, and kidney in the fetus. Furthermore, Lu glycoproteins are the red cell receptors for laminin and may be involved in the pathogenesis of sickle cell vaso-occlusive crises.[1976,1977] Recent studies have indicated that the Lu glycoproteins may also be involved in the metastasis of certain types of malignancy.[1978]

About 1 person in 5000 inherits a dominantly acting inhibitor called In(Lu)[1828,1979] that partially suppresses expression of Lu^a and Lu^b such that they are undetectable by standard agglutination tests. Such inhibition is the most common cause of the null Lutheran phenotype Lu(a–b–). The In(Lu) gene product inhibits expression of CD44, an adhesive protein; MER2, a common red cell antigen; CR1, the C3b/C4b complement receptor; AnWj, the erythroid *H. influenzae* receptor; and the glycolipid antigens P1 and i, as well as the Lu antigens.[1980] Although several of these proteins are widely expressed, the action of In(Lu) is limited solely to red cells.[1980,1981] Patients with the In(Lu) Lu(a–b–) phenotype have abnormally shaped red cells but no hemolysis.[1828] The morphology varies from normal or mild poikilocytosis to acanthocytosis. The Lu antigens directly interact with spectrin, independently of protein 4.1, which may partially explain the abnormal red cell morphology in some patients with the In(Lu) phenotype.[1982] The OF of fresh In(Lu) Lu(a–b–) red cells is normal, but during in vitro incubation, the cells lose K^+ and become osmotically resistant.

Hypothyroidism

Patients with hypothyroidism often (20% to 65%) have a small number (0.5% to 2%) of acanthocytes on peripheral blood smears.[1829,1983,1984] Given the high incidence of hypothyroidism relative to other disorders that cause acanthocytosis, it has been suggested that the presence of acanthocytes should prompt physicians to consider thyroid testing, especially in adults. This approach has led to the diagnosis of previously unsuspected hypothyroidism.[1985]

OTHER MEMBRANE DISORDERS

Oxidant Hemolysis

Oxidant damage is incurred by the red cell membrane in a variety of inherited disorders involving abnormal hemoglobins that create defects in the cells' endogenous system for detoxification of oxidants. Such disorders include sickle cell disease, thalassemias, unstable hemoglobinopathies, G6PD deficiency, and defects in glutathione metabolism. Membrane oxidant damage may also result from encounters with exogenous oxidants, such as copper. Acute copper-induced hemolysis has been reported in humans after accidental or suicidal ingestion of copper or copper-containing compounds, copper sulfate therapy for burns, copper contamination of hemodialysis units, and Wilson's disease.[1986-1992] In the first three instances, acute intoxication is characterized by flushing, chills, nausea and vomiting, diarrhea, abdominal pain, a metallic taste in the mouth, excessive salivation, headache, weakness, and acute intravascular hemolysis.[1986-1991,1993]

Wilson's Disease (Hepatolenticular Degeneration)

Wilson's disease is an autosomal recessive disorder of copper metabolism that develops between 3 and 52 years of age and is characterized by defective biliary excretion of copper, low plasma levels of ceruloplasmin, and toxic accumulation of copper in the liver, erythrocytes, kidneys, cornea, and brain.[1994,1995] The clinical consequences of toxic copper overload include cirrhosis, hemolysis, corneal Kayser-Fleischer rings, and a progressive neurologic syndrome.[1996-2009] Early diagnosis followed by effective treatment can lead to reversal of the clinical symptoms, including hemolysis.

Hemolysis is an early feature of Wilson's disease; it is seen in about 20% of patients with liver disease[1996] and may be the initial manifestation of the disorder.[1997-2004,2010-2014] Because the disease is treatable and because hemolysis may presage fulminant liver disease by days to years,[2000,2002,2003] the clinician must always consider Wilson's disease in children and young adults with Coombs-negative hemolytic anemia both with and without overt liver disease. Thrombocytopenia may also occur,[2015] and the condition has been misdiagnosed as thrombotic thrombocytopenia purpura or hemolytic-uremic syndrome. Typically, these previously well children have chemical evidence of liver disease, mild hepatosplenomegaly, a low ceruloplasmin concentration, increased erythrocyte and hepatic copper levels, and increased urinary copper excretion. The liver disease has more of a metabolic phenotype (decreased synthesis of albumin and clotting factors compared to the degree of transaminitis), but more acute, fulminant presentations are also observed. Jaundice is often seen and may be severe. The hemolysis observed in Wilson's disease is

acute, but the clinical features, though similar to those of acute copper poisoning, are usually more subtle. Hemoglobin may be detected on urinalysis, but gross hemoglobinuria is unusual. Peripheral blood smears do not usually show characteristic changes, although spur cells and target cells have been documented in patients with concurrent severe liver disease.

The Wilson's disease gene, the copper-transporting ATPase *ATP7B*, and the Wilson's disease protein, WNDP, belong to the large family of cation-transporting P-type ATPases.[2016-2020] A wide variety of mutations have been described in this gene in patients with Wilson's disease.[2021-2024] The belief is that in Wilson's disease, copper initially accumulates in hepatocytes because of absence of the copper-transporting protein, which is required for incorporation of copper into ceruloplasmin. Copper eventually reaches a toxic level in the liver and is released into the bloodstream by hepatocellular necrosis.[2002] Plasma copper is rapidly taken up by red cells.[2025] Intravascular hemolysis occurs as a consequence of oxidative damage. The oxidative effects of copper are manifold. In vitro, copper inactivates numerous red cell glycolytic and hexose monophosphate shunt enzymes; directly oxidizes reduced nicotinamide adenine dinucleotide phosphate (NADPH) and glutathione; oxidizes and denatures hemoglobin; damages membrane ATPases, fatty acid acylase, and probably other membrane enzymes; generates lipid peroxides; and cross-links membrane skeletal proteins into disulfide-bonded high-molecular-weight complexes, thereby increasing membrane permeability and rigidity.[2003,2026] However, many of these effects have not been demonstrated at concentrations of copper observed in hemolyzing erythrocytes (150 to 400 mg/dL red cells = 2.4 to 6.3×10^{-5} mol/L).[2004,2008] In vivo studies have indicated marked inhibition of hexokinase and G6PD from red blood cells in patients with untreated Wilson's disease in comparison to patients taking penicillamine and healthy children.[2027] In addition, decreased glutathione levels were found in patients with untreated Wilson's disease, as well as decreased antioxidant enzymes such as superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase. Although thus far it has not been possible to determine the exact cause of the demise of red cells, initial studies indicate that free copper (non–ceruloplasmin bound) leads to oxidative injury resulting in altered erythrocyte metabolism and antioxidant status in patients with Wilson's disease.
